Plasma for fractionation is derived from two sources, either directly by plasmapheresis, termed Source Plasma, or as a by-product of whole blood donation, termed Recovered Plasma. Source and recovered plasma differ slightly in protein and lipid content, and fractionation parameters may be adjusted slightly to accommodate those differences, but in general, either type may be used interchangeably. The plasma is usually shipped frozen as individual units from local blood or plasma collection centers to a central processing plant. At the plant, sufficient units to produce typically 2000- to 3000-L pools are thawed slowly to produce a cryoprecipitate, a cold-insoluble fraction that contains significant amounts of factor VIII, von Willebrand factor (vWF), which is usually in a complex with FVIII, fibrinogen, fibronectin, and factor XIII along with a number of other proteins present in smaller quantities.[6] The cryoprecipitate is usually removed by centrifugation. The supernatant may be treated with a chromatographic media to remove the factor IX complex and antithrombin III before it is processed by the ethanol method to obtain immunoglobulins, albumin, and other products.

Cohn's Method[7] is still the basis for most of the large-scale plasma fractionation today in the United States and much of the world. Other manufacturers use a modified ethanol precipitation method developed by Kistler and Nitschmann,[8] whereas others use newer chromatographic methods.[9,10] In the Cohn method, the ethanol concentration is increased in steps from 8% to 40% at specific combinations of pH, ionic strength, protein concentration, and cold temperature to precipitate several fractions.

The first precipitate, fraction I, contains factor VIII, fibrinogen, and other poorly soluble proteins, many of which are also removed by cryoprecipitation. Fractions II and III are precipitated together and contain the immunoglobulins that are further purified in a separate process. Because many of the fraction I proteins are removed in the cryoprecipitate, some manufacturers do not produce a separate fraction I. Instead they collect a combined fraction I+II+III. Fraction IV is often produced in two subfractions. Fraction IV-1 contains the vitamin K-dependent clotting factors, antithrombin and α_1-antitrypsin. Fraction IV-4 contains transferrin, haptoglobin, and some of the albumin, whereas fraction V is almost pure albumin.[11] The overall scheme of plasma fractionation is shown in the box.

IMMUNE GLOBULINS AND HYPERIMMUNE GLOBULINS

Since the early 1950s, immune globulin products have been prepared from Cohn fraction II + III by the method developed by Oncley.[18] Oncley's method uses additional ethanol precipitations to remove lipoproteins, IgA, IgM, and other plasma proteins, leaving fraction II, which contains purified IgG.[11] The overall ethanol method is often referred to as Cohn–Oncley fractionation. Immune Globulin is prepared from the plasma of unselected normal donors, whereas hyperimmune globulins are prepared from the plasma of donors with high

ALBUMIN AND PLASMA PROTEIN FRACTION

Albumin remains one of the major products of human plasma fractionation. During the 60 years since the initial use of human serum albumin in treating the casualties at Pearl Harbor, literally tons of albumin have been isolated and millions of units have been infused.[12] Albumin, having the highest solubility and the lowest isoelectric point of all the major plasma proteins, remains in solution until the pH is adjusted to 4.8 in the presence of 40% ethanol at –5°C when the bulk of the albumin is finally precipitated in fraction V.[13] After the removal of ethanol and salts, sodium acetyltryptophanate and sodium caprylate are added as stabilizers, and the albumin is sterile-filtered and bottled. The vials are then heated for 10 hours at 60°C to inactivate any remaining blood-borne viruses. This pasteurization method was the first significant viral inactivation process developed for a plasma product.[14]

Three albumin products are manufactured in the United States: Albumin (Human) 25% solution, Albumin (Human) 5% solution, and Plasma Protein Fraction (Human). To be designated Albumin, more than 96% of the protein content must be albumin. Plasma Protein Fraction (PPF), also usually a 5% solution, is an albumin product of lower purity obtained by coprecipitating fraction IV-4 with fraction V.[15] The total protein in PPF must be 83% or more albumin, with 17% or less globulins, and 1% or less γ-globulin. PPF is more economical to produce than albumin,[16] but the rapid infusion of PPF has been associated with hypotensive episodes.[17] Clinical indications for the use of Albumin and PPF are described in Chapter 149. Albumin (Human) is also sometimes used as a stabilizer in the formulation of other highly purified plasma and recombinant products.

antibody titers against specific antigens (eg, rho(D), hepatitis B, rabies, and tetanus). These donors may be identified during convalescent periods after infection or transfusion, or they may be specifically immunized to produce the desired antibodies. Immune Globulin products and indications are described in Chapter 149.

Intravenous Immune Globulin Concentrates

The original immune globulin concentrates, originally termed Immune Serum Globulin and currently Immune Globulin (Human), were administered by the intramuscular route, with the associated problems of limited injectable volume, poor bioavailability, and discomfort at the injection site.[19] Intravenous injection of immune globulin causes serious clinical reactions, attributed to complement-activating aggregates in these products.[20]

To overcome these limitations, Immune Globulin Intravenous (Human) (IGIV) products have been developed using a variety of methods to remove or inactivate anticomplementary aggregates. Processing and formulation techniques have been improved, and conditions have been identified, to permit these products to be prepared as either freeze-dried or liquid concentrates.[21] Today most intramuscular Immune Globulin usage is limited to hyperimmune products. Immune Globulin products tend to be self-protecting from viral transmission because of the large pools of antibodies they contain.[22] However, postinfusion viral infections have occurred. As a result, all manufacturers have incorporated viral inactivation or removal steps in the production of IGIV.[23]

The development of IGIV has permitted the administration of much higher doses, with a subsequent expansion in immunoglobulin therapy. In addition to providing passive immune protection, IGIV has been found to modulate the immune response to autoimmune diseases such as idiopathic thrombocytopenic purpura.

Subcutaneous Immune Globulin Concentrates

The first patient treated for primary immune deficiency was actually given subcutaneous injections of immunoglobulins.[24] However, as described above, intramuscular and later intravenous injections became the preferred methods. Recently one manufacturer has developed an immune globulin concentrate for subcutaneous injection, termed Immune Globulin Subcutaneous (Human).[25] It is a 16% solution administered using an infusion pump. The product is intended for patients who have problems with intravenous infusion.

COAGULATION FACTOR CONCENTRATES

The distinction between hemophilia A and B was unknown in the mid-1800s when it was first shown that the transfusion of whole blood could be used to curtail bleeding in patients with hemophilia.[26,27] By 1940, bleeding episodes were being routinely treated with plasma. However, large amounts of plasma were needed, and this method of therapy could not provide normal levels of coagulation factors without producing hypervolemia.[28] The development of more highly purified plasma-derived coagulation factor concentrates and more recently of recombinant concentrates has resulted in dramatic increases in life expectancy and quality of life for patients with hemophilia.

The major issues in the preparation and use of coagulation factor concentrates are viral safety and purity. The benefit of viral safety is obvious; with the exception of cryoprecipitate, all concentrates are now subjected to some form of treatment for the inactivation or removal of viruses that might be present in the input plasma. Purity, as it affects product efficacy and adverse reactions, is discussed below for both factor VIII and factor IX products. The purity of factor IX concentrates has definitely been shown to be important; however, the situation for factor VIII products is less clear. The development of improved coagulation factor concentrates continues to be a major focus of research.

See Chapter 151 for a detailed discussion of indications and use of coagulation factor concentrates.

FACTOR VIII CONCENTRATES

Factor VIII concentrates, generically termed Antihemophilic Factor (Human) (AHF), for the treatment of hemophilia A have evolved from cryoprecipitates to very-high-purity plasma-derived products to recombinant products. The various AHF concentrates available in the United States are shown in Table 150–1.

Cryoprecipitate

In 1959, Pool and Robinson[29] reported that when frozen plasma is thawed slowly, a residual "cryoprecipitate" results that contains most of the factor VIII activity of the original plasma. By 1965, single-donor cryoprecipitate with factor VIII concentrations 5 to 30 times that of plasma became widely available for use in the treatment of hemophilia A.[30] Single-donor cryoprecipitate is still available from many blood banks but carries a risk of viral transmission. However, large-scale cryoprecipitation is the first step in most procedures for the preparation of plasma derivatives containing high concentrations of its constituent proteins. Cryoprecipitate contains approximately one-half of the factor VIII/vWF complex and one-third of the fibrinogen and factor XIII in whole plasma.[31]

Intermediate- and High-Purity Antihemophilic Factor Concentrates

Product purity is generally measured by specific activity, the activity of the protein of interest, such as factor VIII, divided by the total

Table 150–1 Antihemophilic Factor Concentrates Marketed in the United States

Antihemophilic Factor Methods	Manufacturer	Product Name	Specific Activity†	Production Methods	Virus Inactivation/Removal
Antihemophilic Factor (Human)	Baxter	Hemofil M	2–20 2000‡	Cryoprecipitation, cold-acid precipitation, IAC, IEC	S/D (TNBP/octoxynol 9), purification steps, lyophilization
	Grifols	Alphanate	5–30§ 140‡	Cryoprecipitation, salt precipitation, PEG precipitation, AC	S/D (TNBP/polysorbate 80), dry heat (80°C, 72 hours), purification steps, lyophilization
	Talecris	Koate-DVI	9–22§ 50‡	Cryoprecipitation, $Al(OH)_3$ adsorption, PEG precipitation, glycine precipitation, SEC	S/D (TNBP/polysorbate 80), dry heat (80°C, 72 hours), purification steps
	CSL Behring	Monoclate-P	4–10 >3000‡	Cryoprecipitation, cold precipitation, $Al(OH)_3$ adsorption, IAC, AC	Pasteurization (60°C, 10 hours), purification steps
Antihemophilic Factor/von Willebrand Factor Complex (Human)	CSL Behring	Humate-P	1–2§ 40‡	Cryoprecipitation, $Al(OH)_3$ adsorption, glycine precipitation	Pasteurization (60°C, 10 hours), purification steps
Antihemophilic Factor (Recombinant)	Baxter	Recombinate	2–20 >4000‡	CHO Cell culture, IAC, IEC	Purification steps
	Baxter	Advate	4000–10,000	CHO Cell culture, IAC, IEC	S/D (TNBP/polysorbate 80, octoxynol 9)
	Bayer	Kogenate FS¶	4000‡	BHK Cell culture, IEC, IAC, IMAC	S/D (TNBP/polysorbate 80), purification steps
	Wyeth	ReFacto	9000–13,000	CHO Cell culture, IEC, IAC, HC, SEC	S/D (TNBP/octoxynol 9), purification steps

AC, affinity chromatography; BHK, baby hamster kidney cells; CHO, Chinese hamster ovary cells; HC, hydrophobic chromatography; IAC, immunoaffinity chromatography; IEC, ion-exchange chromatography; IMAC, immobilized metal affinity chromatography; PEG, polyethylene glycol; S/D, solvent/detergent; SEC, size exclusion chromatography; TNBP, tri-*n*-butyl phosphate.

*These concentrates were marketed in the United States in 2006. Data were obtained from manufacturers, distributors, and available literature.

†Factor VIII U/mg of protein.

¶Also distributed by ZLB Behring as Helixate FS.

mass of protein in the product. The activity of most plasma proteins is measured in units, where one unit is defined as the activity in one milliliter of normal human plasma. If the product is assayed against an international reference standard, the activity is expressed in International Units (IUs). There is no consensus for classification of concentrate purity. Berntorp[32] suggests intermediate purity as having specific activities of 1 to 50 IU/mg and high purity as having specific activities of 50 to 200 IU/mg. The specific activity of plasma is on the order of 0.01 IU/mg and that of cryoprecipitate is approximately 0.3 IU/mg.[33] Many of the highly purified products contain human albumin as a stabilizer, which adds additional protein and thus lowers the apparent specific activity. To describe the effective purity of such products, the specific activity is often given in the absence of the added albumin. Table 150–1 shows both values, where applicable.

After the discovery of cryoprecipitation, the development of intermediate-purity AHF concentrates was the next significant advance in the treatment of hemophilia A. Cryoprecipitate was used as the starting material, and a variety of methods were developed to remove fibrinogen, immunoglobulins, and other proteins. Fibrinogen can be removed at specific conditions of temperature and pH or by precipitation with glycine or polyethylene glycol. Aluminum hydroxide can be used to adsorb and remove the vitamin K-dependent clotting factors II, VII, IX, and X.[34] Intermediate-purity concentrates are enriched approximately 3000-fold over plasma. Until effective methods were developed for viral inactivation following the AIDS crisis of the early 1980s, patients receiving these concentrates were exposed to all of the blood-borne viruses in the donor population. It is not surprising that frequently treated patients uniformly became infected with hepatitis[35] and, later, often HIV.[36]

Intermediate-purity AHF concentrates were the mainstay of hemophilia A treatment until the development of high-purity concentrates in the late 1980s. They are still available, their chief advantage being lower cost. As described below, some intermediate-purity concentrates are also used as a source of von Willebrand factor. More recently, various ion-exchange and gel-filtration techniques were added to the precipitation methods to produce high-purity concentrates with specific activities of 50 to 200 IU/mg of protein.[37,38] However, even though these concentrates are highly purified in comparison with the intermediate-purity concentrates, significant amounts of high-molecular-weight proteins such as fibrinogen, fibronectin, and vWF tend to fractionate with factor VIII and remain in the preparations. The only high-purity concentrates currently available in the United States are the immunoaffinity-purified concentrates discussed next.

Product purity has always been an issue with AHF concentrates. The initial improvement from plasma to cryoprecipitate to intermediate-purity concentrates primarily affected infusion volume and convenience. In the early years of the AIDS crisis, some researchers wondered if the frequent exposure to the impurities in AHF concentrates depressed the immune system of hemophiliacs and made them more susceptible to adventitious diseases. As more became known about AIDS, that idea was discarded,[39] but it did provide some of the impetus for development of higher purity products. The current focus is the effect of purity on inhibitor development. Inhibitors are antibodies produced against factor VIII because the immune system sees the protein as a foreign molecule. A number of studies have been done to look at the effect of purity on inhibitor development, but the results are still controversial.[40–42]

Antihemophilic Factor Concentrates Purified by Immunoaffinity Chromatography

The next major advance in the preparation of AHF concentrates was the use of murine monoclonal antibodies (mAbs) immobilized on a

chromatographic column for the purification of factor VIII by immunoaffinity chromatography. Two different methods were developed that both start with factor VIII concentrates partially purified by conventional means.[43,44] One procedure uses an mAb that binds to the vWF portion of the factor VIII–vWF complex; the other uses an mAb that binds directly to factor VIII. In both processes, the columns are loaded with the low-purity intermediate product, washed extensively to remove unwanted proteins, and then eluted, respectively, by separation of factor VIII from the vWF–mAb complex or directly from the mAb itself. Both processes use a final chromatography step to remove the harsh elution solutions as well as any mAb that might have leached off the column. These processes produce factor VIII that is essentially pure prior to the addition of albumin as a stabilizer. Both processes include several steps that inactivate or remove viruses.

Recombinant Antihemophilic Factor Concentrates

One of the remarkable early accomplishments of molecular biology was the elucidation of the structure of factor VIII, its molecular cloning, and the successful production of recombinant human factor VIII. Because proper posttranslational processing is essential to factor VIII functionality, the products are produced in mammalian cells, either baby hamster kidney (BHK) cells or Chinese hamster ovary (CHO) cells. The CHO cells used to produce Recombinate also coexpress recombinant vWF, which helps to stabilize the FVIII and substantially increase its recovery from the culture medium. The recombinant factor VIII is purified by various combinations of immunoaffinity chromatography, ion-exchange chromatography, and gel filtration.[45] The final products contain minimal or no recombinant vWF and only trace quantities of mouse immunoglobulin, hamster protein, and cellular DNA. The second-generation product ReFacto consists of a shortened FVIII molecule with the central portion of the B-domain deleted. This produces a molecule with full activity but that is more stable during processing. The recombinant products have been shown to be safe, effective, and well-tolerated and to perform similarly to plasma-derived factor VIII in a number of clinical studies.[46]

Recombinant products have the advantage that they are nominally free from contamination with human viruses. However, some contain human or bovine components in their cell culture medium, some are purified by immunoaffinity chromatography using mAbs grown in cell culture, several are stabilized with human albumin (pasteurized) in the final product and all are produced in mammalian cells that potentially harbor unrecognized viruses in their genome. Thus there exists the theoretical possibility of virus transmission. To further minimize any possible viral risk, the three second-generation products, ReFacto, Kogenate FS, and Advate are treated with a solvent and detergent mixture that inactivates all lipid-enveloped viruses. The products are formulated without albumin or other human- or animal-derived compounds, using sugars, amino acids, and polysorbate 80 as stabilizers, with no reduction in the 2-year shelf life. ReFacto and Kogenate FS employ only human-derived compounds in their cell culture systems, and Advate employs no human- or animal-derived compounds in the cell culture systems used to produce either the product or the mAb used for purification.

FACTOR IX CONCENTRATES

Two types of plasma-derived factor IX concentrates are available today: Factor IX Complex, which contains significant amounts of the other vitamin K-dependent clotting factors, and Coagulation Factor IX (Human), a preparation substantially free of these other proteins. A recombinant product, Coagulation Factor IX (Recombinant) is also available. The factor IX concentrates available in the United States are shown in Table 150–2.

Factor IX Complex Concentrates

The vitamin K-dependent clotting factors, because of their similar structures, tend to copurify by most of the methods used to isolate them from plasma. Thus, the original factor IX products for treatment of hemophilia B were mixtures of the vitamin K-dependent

Table 150–2 Factor IX Concentrates and Related Products Marketed in the United States*

Product Type	Manufacturer/ Distributor	Product Name	Specific Activity†	Purification Methods	Virus Inactivation/ Removal Methods
Factor IX Complex	Baxter	Bebulin VH	2	IEC	Vapor heating: 60°C for 10 hours at 190 mbar, then 80°C for 1 hour at 375 mbar
	Grifols	Profilnine SD	4	IEC	S/D (TNBP/polysorbate 80), purification steps
Coagulation Factor IX (Human)	Grifols	AlphaNine SD	>150	IEC, barium citrate precipitation, AC, nanofiltration	S/D (TNBP/polysorbate 80), nanofiltration, purification steps
	CSL Behring	Mononine	>190	IEC, IAC, HIC	Sodium thiocyanate, ultrafiltration, purification steps

†Factor IX U/mg of protein.

proteins including factor II (prothrombin), factor VII, factor IX, factor X, protein C, and protein S. Because the protein in highest concentration in these products is prothrombin, they have also been identified as prothrombin complex concentrates; however, Factor IX Complex is the generic name in the United States.

The first factor IX-rich concentrate used for the treatment of hemophilia B was developed in France more than 40 years ago.[47] It was produced by the adsorption of the plasma vitamin K-dependent clotting factors with tricalcium phosphate and was successfully used to treat hemophilia B for a number of years. The original production process had a number of disadvantages and was eventually discontinued.[48] However, this method led to the development of several other processes based on tricalcium phosphate adsorption.[49] Factor IX Complex produced by these methods contains approximately equal amounts of factor II, VII, IX, and X activity units.

The next major development in the production of Factor IX Complex concentrates was the introduction of ion-exchange chromatography.[50] This represented one of the first major uses of chromatography in plasma fractionation. As shown in the box, the vitamin K-dependent clotting factors can be captured from cryoprecipitate-poor plasma by adsorption onto diethylaminoethyl (DEAE)–cellulose or DEAE–Sephadex, and the supernatant plasma can then be further fractionated by the Cohn–Oncley method for the production of immune globulins, albumin, and other products. The eluate from the DEAE resin may be further purified by additional precipitation or adsorption steps.[51] Such processes give 100-fold or more purification of factors II, IX, and X. Factor VII does not bind to DEAE under the conditions in plasma, however, and is present in only very low concentrations in concentrates prepared by these methods.

Coagulation Factor IX Concentrates

With the widespread use of Factor IX Complex, it soon became apparent that serious thromboembolic episodes and acute myocardial infarction were major complications of its infusion, especially when used in large quantities for extended periods, such as for surgical procedures or in patients with liver disease.[52,53] The cause of the thrombogenicity has not been conclusively determined. It may be due to the presence of activated clotting factors,[54,55] contaminating phospholipids,[56] or the result of an overload of factors II and X.[57,58]

On the basis of these hypotheses, methods have been developed for the preparation of second-generation factor IX concentrates that are more highly purified and essentially free of the other vitamin K-dependent clotting factors. These have been designated Coagulation Factor IX (Human). Coagulation Factor IX concentrates are manufactured from factor IX complex by additional purification steps. Of the two products available in the United States, one is prepared by immunoaffinity chromatography using an mAb to factor IX.[59] The other is purified by heparin affinity chromatography.[60] Both methods also include viral inactivation steps. These preparations have been proven to be largely nonthrombogenic in clinical use.[61,62]

Recombinant Factor IX Concentrates

A recombinant coagulation factor IX has also been developed. It is produced in cell culture by CHO cells that also coexpress a protease that enhances the ability of the cells to remove the amino-terminal propeptide. The cell culture product is purified with several chromatography steps and treated to remove viruses.[63] The product was developed with the aim of essentially eliminating any risk of viral transmission, including elimination of blood or plasma proteins from the cell culture medium and the final product formulation, avoidance of monoclonal antibodies in the purification process, and use of a nanofiltration step in the purification process to remove any viruses that might be present.[64] The final product has been shown to be structurally and functionally similar to plasma-derived factor IX.[65] However, it gives a lower recovery when infused into patients, probably because of differences in posttranslational glycosylation.[66]

OTHER COAGULATION FACTOR CONCENTRATES

As described in Chapter 151, one of the major complications in the treatment of hemophilia patients is the development of inhibitors, antibodies directed against factor VIII or factor IX. Low-titer inhibitors can usually be saturated by administering large amounts of factor VIII or factor IX. This is not an effective therapy for higher-titer inhibitors because of the large amount of factor concentrate required. However, high-titer inhibitors may be treated by immune tolerance induction therapy in which higher than usual doses of FVIII or FIX are given regularly over an extended period of time.[67] Another widely used method of treatment for patients with high-titer inhibitors is administration of either Factor IX Complex or an activated factor IX complex termed Anti-Inhibitor Coagulant Complex to "bypass" the factor VIII step in the coagulation cascade.[68]

Although the bypass mechanism is not completely understood, one hypothesis is that activated clotting factors such as factor VIIa and FXa are involved.[69,70] This has led to the development of recombinant activated factor VII (rFVIIa) for the treatment of both hemophilia A and B patients with inhibitors.[71] Recombinant factor VIIa is produced in tissue culture in BHK cells and then purified by ion-exchange and immunoaffinity chromatography.[72] The molecule is spontaneously activated during the final ion-exchange chromatography steps.[73] Factor VIIa is currently the most widely used option for inhibitor treatment,[74] especially for patients who have never been exposed to plasma-derived products. However, one issue in the use of the factor IX complexes and factor VIIa is a risk of thromboembolic complications.[75]

Another interesting approach for treating hemophilia A patients with high-titer inhibitors had been the use of a porcine factor VIII concentrate. Porcine factor VIII is efficacious in controlling hemostasis and is less readily inactivated by some human factor VIII inhibitors.[76] However, the manufacturer has discontinued the product because of the difficulty of obtaining parvovirus-free porcine plasma. They are reportedly developing a recombinant porcine FVIII concentrate to replace the discontinued plasma-derived product.[77]

von Willebrand disease (vWD), caused by missing or abnormal von Willebrand factor (vWF), is the most commonly inherited coagulation disorder.[78] There are several types of vWD, many of which can be treated with the drug desmopressin. However, a number of vWD patients do not respond to desmopressin but can be treated by replacement therapy with plasma-derived vWF. In the past, such patients were treated with plasma or, more effectively, with cryoprecipitate.[79] Cryoprecipitate has a population of vWF multimers similar to that of normal plasma; however, it is not treated for viral inactivation and therefore carries a risk of infection. More recently patients have been treated with several intermediate-purity viral-inactivated AHF concentrates that contain significant amounts of vWF.[79] Humate-P has been licensed in the United States for treatment of vWD and therefore is labeled with its vWF content.[79,80] Alphanate and Koate-DVI also contain significant amounts of vWF and have been used for treatment of vWD.[79]

A recombinant human activated protein C, generic name Drotrecogin alfa (activated), is available for treatment of severe sepsis. A protein C zymogen is produced in a human kidney cell line and purified by chromatography, including an ion-exchange step operated in a pseudo-affinity mode. The zymogen is activated with bovine thrombin. The final product has an identical amino acid sequence as plasma protein C but a slightly different glycosylation pattern.[81,82] The efficacy of activated protein C in treatment of sepsis is controversial.[83,84]

FIBRIN SEALANTS

Fibrin sealants, or fibrin glues, are topical hemostatic agents that have been used in a variety of surgical situations for their hemostatic and adhesive properties.[85] The preparations consist of two components derived from human plasma that are mixed together immediately prior to use. The first component, derived from cryoprecipitate,

Table 150–3 Additional Plasma Derivative Concentrates Marketed in the United States

Product Type	Manufacturer/Distributor	Product Name	Purification Methods	Virus Inactivation/Removal Methods
Fibrin Sealant	Baxter	Tisseel VH	Fibrinogen component: cryoprecipitation Thrombin component: IEC, calcium chloride incubation	Both components: Vapor heating (60°C for 10 hours at 190 mbar, then 80°C for 1 hour at 370 mbar), lyophilization, purification steps
	OMRIX/Johnson & Johnson	Crosseal	Fibrinogen component: cryoprecipitation, $Al(OH)_3$ adsorption, ultrafiltration Thrombin component: IEC, nanofiltration	Fibrinogen component: S/D (TNBP/octoxynol 9) Pasteurization (60°C, 10 hours) Thrombin component: S/D (TNBP/octoxynol 9), nanofiltration
$Alpha_1$-Proteinase Inhibitor (Human)	Baxter	Aralast	Cohn fractionation, PEG precipitation, $ZnCl_2$ precipitation, IEC	S/D (TNBP/polysorbate 80), nanofiltration
	Talecris	Prolastin	Cohn fractionation, PEG precipitation, IEC	Pasteurization (60°C, 10 hours) Purification steps
	ZLB Behring	Zemaira	Cohn fractionation, NA	Pasteurization (60°C, 10 hours), ultrafiltration

AC, affinity chromatography; IEC, ion-exchange chromatography; NA, not available; PEG, polyethylene glycol; S/D, solvent/detergent; TNBP, tri-*n*-butyl phosphate.
*These concentrates were marketed in the United States in 2006. Data were obtained from manufacturers, distributors, and available literature.

contains fibrinogen, along with factor XIII, and other plasma proteins.[86] Both also contain added plasmin inhibitors to delay clot lysis. Tisseel contains aprotinin, derived from bovine plasma, whereas Crosseal contains tranexamic acid.[85] The second component is human plasma-derived thrombin purified from cryo-poor plasma. Both products are treated for viral inactivation. Bovine thrombin was used for many years; however, research suggests that it may be responsible for many postsurgical hemostatic problems.[87,88] The fibrin sealant products available in the United States are shown in Table 150–3.

Because commercial fibrin sealants have only been available in the United States for a few years, a variety of methods had been used previously to prepare fibrin sealant for use in the treatment of individual patients. These "homemade" preparations are usually made with single-donor or autologous cryoprecipitate plus bovine thrombin. Some surgeons still advocate their use because of cost considerations, especially with autologous cryoprecipitate for which there is no risk of disease transmission. However, the methods are somewhat cumbersome, and the concentration of fibrinogen in the preparations, and thus their performance, is highly variable.[89,90]

PLASMA PROTEINASE INHIBITORS

The proteinase inhibitors that are present in human plasma play critical roles in the regulation of the proteolytic cascades of the coagulation, fibrinolytic, complement, and kinin systems. Most of these inhibitors have similar amino acid and structural properties and are members of a superfamily of proteins designated serpins (serine proteinase inhibitors).[91,92] Hereditary deficiencies in α_1-antitrypsin and antithrombin III can cause specific disease states, and inhibitor concentrates have been developed. The plasma proteinase inhibitor concentrates available in the United States are shown in Table 150–3.

$Alpha_1$-Proteinase Inhibitor

$Alpha_1$-Proteinase Inhibitor (Human) (API), also known as α_1-antitrypsin, was the first of the serpins to be isolated and characterized.[93] Although the protein was originally named for its antitrypsin activity, its primary physiologic function appears to be the inhibition of neutrophil elastase in the lung. Patients with hereditary deficiencies of this inhibitor develop pulmonary emphysema and liver disease.[94] In the most common form of API deficiency, mutant API protein accumulates in the liver, where it is produced, causing neonatal hepatitis, cirrhosis, and hepatocellular carcinoma.[95] This mechanism, in which mutant serpin proteins form polymers that accumulate in hepatocytes, has recently been recognized as a general characteristic of the serpins resulting in diseases called the serpinopathies.[96]

API therapy is indicated for chronic treatment of individuals with hereditary deficiency. Until recently API was an orphan drug with only one supplier and subject to chronic shortages.[97] The licensure of two more products in 2002 and 2003 has helped to ease the shortages, however, only a limited amount is ultimately available from plasma. One issue is the inefficiency of intravenous administration. It is estimated that only approximately 2% of the infused API ends up in the lung. Studies suggest that aerosol delivery of API directly into the lungs by inhalation would be efficacious and could replace intravenous administration because of its lower cost and greater convenience.[98] API is also a good candidate for recombinant production.[99]

Antithrombin III

Antithrombin III (Human) (ATIII) plays a critical role in the regulation of hemostasis as the major physiologic inhibitor of thrombin and factor Xa. Heterozygous hereditary deficiency of ATIII has been linked to an increased tendency to thrombosis. Acquired deficiencies have also been reported in women taking oral contraceptives and as a consequence of pregnancy, surgery, cirrhosis, and hepatic malignancies.[100]

The affinity of ATIII for heparin, essential for the pharmacologic effect of the drug, has also been employed as a means of purifying ATIII. Use of immobilized heparin as an affinity adsorbent for ATIII is the key step in large-scale preparation of ATIII concentrates for clinical use.[101] Thrombate III, the only product currently on the US market is purified by heparin affinity chromatography from Cohn fraction IV-1,[102] but, as shown in the box, ATIII may also be isolated from cryosupernatant or Cohn fraction I supernatant. Although heparin-based adsorbents are not specific for ATIII, other plasma proteins are bound less tightly and may be washed off with medium ionic strength buffers prior to the elution of ATIII with a high ionic strength buffer. Additional purification steps produce concentrates

that contain more than 95% ATIII.[101] ATryn, a recombinant ATIII, was recently licensed in Europe and is the first recombinant human plasma protein produced in transgenic animals to be approved anywhere.[103]

FUTURE DIRECTIONS

New Plasma-Derived Concentrates

A number of additional plasma protein concentrates that are not currently available in the United States are available in Europe and other parts of the world. These include concentrates of protein C,[104] von Willebrand factor,[105] factor VII,[106] factor XI,[107] factor XIII,[108] and C_1-esterase inhibitor.[109] There are also several other proteins in plasma that would be potentially useful as therapeutic products. These include butyrylcholinesterase for reversal of succinylcholine-induced apnea[110] and treatment of cocaine overdose.[111] Other coagulation factors and inhibitors, such as factors X[112] and XII[113] and protein S,[114] may also be candidates for use in treatment of congenital and acquired deficiencies. However, the prevalence of these disorders is small, so they would be true orphan drugs. There are also potential improvements that can be made to current plasma-derived concentrates. In addition to enhanced purification and viral clearance methods, products can be made more user-friendly. For instance, alternate delivery systems could replace intravenous administration of coagulation factors by subcutaneous injection.[115] As described above, several studies have looked at aerosol delivery of Alpha-1 Proteinase Inhibitor.[98] Fibrin Sealant products are being developed consisting of precoated resorbable bandages.[116]

Recombinant Plasma Protein Concentrates

Almost all plasma proteins licensed for human use have been cloned and expressed in a biologically active form in animal cells, and several have been developed into licensed products, as described above. The main advantages of recombinantly produced plasma proteins include freedom from human viruses and a potentially unlimited supply. Several recombinant products that are currently being developed will be produced in transgenic animals, including antithrombin III (already available in Europe)[103] and alpha-1 proteinase inhibitor.[99,117] Transgenic cows, goats, pigs, and sheep can produce large quantities of human proteins, typically 1 to 10 g/L in milk, whereas animal tissue culture systems routinely produce substantially less protein, typically 10 to 100 mg/L.[117]

Recombinant proteins can also be produced in modified forms that may give them advantageous new properties such as increased potency, longer half-life, or varied specificity.[118,119] One product already available is B-domain deleted factor VIII described above.

CHAPTER 151

TRANSFUSION THERAPY FOR COAGULATION FACTOR DEFICIENCIES

Catherine S. Manno and Peter J. Larson

This chapter covers products available to treat deficiencies of plasma coagulation proteins. The development of blood component therapy, and subsequently protein concentrates that are enriched in particular coagulation factors and other proteins, made possible the effective treatment of bleeding episodes in patients with hemophilia and other diatheses. In the 1940s, a collaborative effort funded by the US government was undertaken among protein scientists with the goal of rapidly developing a method to isolate albumin from human plasma to provide a lyophilized intravascular volume expander for use in the military. As part of this effort, Dr. Edwin Cohn developed an ethanol fractionation procedure that was amenable to large-scale manufacture.[1] Building on the foundation of the Cohn fractionation procedure (see Chapter 143), the first coagulation factor concentrates were developed in the mid-1960s and provided a safer and more effective treatment for patients with the X-linked coagulation deficiencies, hemophilia A and B. Given the limited human plasma resource as a raw material for production of all but a few coagulation protein concentrates, manufacturers of human plasma-based products attempt to derive the maximum yield from each pool of plasma. Manufacturers of plasma-derived products strive to maximize the therapeutic potential of pooled human plasma by deriving more products from these processes.

Development of recombinant products has been fueled by concerns of infectious disease transmission through the human plasma resource. Currently licensed products are produced in mammalian cell culture to optimize necessary posttranslational modifications required for biologic activity. These recombinant expression processes are complicated and expensive. Transgenic recombinant technology is currently being explored as a way to decrease or eliminate reliance on the human plasma resource and the technically rigorous production of recombinant proteins using mammalian cell culture methods.

HEMOPHILIA A AND B

The hemophilias are X-linked disorders caused by deficiencies of either factor VIII (hemophilia A, or classic hemophilia) or factor IX (hemophilia B, or Christmas disease). The genes for these coagulation factors are located in close proximity on the long arm of the X chromosome. Hemophilia A affects 1 in 10,000 males, whereas hemophilia B affects 1 in 30,000. This difference in incidence is roughly correlated with the size of the genes, and more than 30% of cases arise from spontaneous mutations.

The major morbidity of the severe hemophilias A or B is arthropathy, developing over the course of years in untreated or undertreated adults as a result of recurrent spontaneous joint bleeding. The major cause of hemorrhagic mortality is bleeding into critical closed spaces (eg, intracranial or retroperitoneal).[2] Central nervous system (CNS) bleeding occurs in 3% to 14% of patients, and mortality from CNS hemorrhage ranges from 20% to 50%[3–5] with neurologic sequelae (including seizures, motor impairment, or mental retardation) observed in 40% to 50% of survivors.[3] CNS bleeding episodes occur predominantly in patients with severe disease (<1% factor level).[3] A more detailed discussion of the hemophilias and the molecular biology of factors VIII and IX can be found in Chapters 114 through 117.

TRANSFUSION THERAPY OF HEMOPHILIA A AND B

History of Transfusion for Hemophilia

Transfusion was first proposed by Schönlein and his student Hopf in 1832 as a treatment for "bleeders" who were suffering from exsanguinating hemorrhage, and these two were likely the first to have used the term *Haemophilie* to describe the disease.[6,7] The first effective transfusion-based intervention for hemophilia is credited to Samuel Lane who, in 1840, infused 10 to 12 ounces of fresh human blood into a 12-year-old boy with postoperative hemorrhage following eye surgery for correction of a squint.[8] Subsequently, a variety of interventions employing the infusion of human and animal blood and blood derivatives were utilized in the therapy of hemorrhage in patients with congenital bleeding diatheses (Table 151–1). Citrated plasma was first employed in 1923 for the treatment of hemophilia by Feissly to overcome a major ABO incompatibility in a father-to-son transfusion.[9] Development of modern blood banking in the 1930s and expansion of transfusion during and after World War II allowed for more widespread use of whole blood and subsequently frozen plasma in the treatment of hemophilia. Because of limited availability, the use of whole blood and components of whole blood for the treatment of hemophilia and other diseases was initially confined to larger metropolitan areas. In addition, volume constraints with the infusion of whole blood and plasma made the achievement of high plasma levels of coagulation factors (>5%) difficult.[10]

The advent of modern transfusion therapy for hemophilia came with the observation that the cold-insoluble precipitate remaining following thawing of frozen plasma at 4°C contains high concentrations of factor VIII.[11] Application of this procedure to the separation of components of whole blood[12] allowed for the production of a low-volume blood product known as "cryoprecipitate." Cryoprecipitate derived from a single whole blood collection contains approximately 125 U of factor VIII and quickly replaced frozen plasma as the therapy of choice for the treatment of bleeding episodes in hemophilia A in the 1960s. The availability of cryoprecipitate made the treatment of bleeding episodes by patients in their homes, rather than at a hospital, a reality. In addition, the development of quantitative assays for factor VIII[13] and for factor IX[14] meant that the two diseases could now be distinguished and effects of transfusion therapy on circulating levels of factors could be more accurately assessed.

Prior to the discovery of plasma cryoprecipitate, significant advances had been made in the fractionation of plasma utilizing ethanol,[1] glycine,[15] polyethylene glycol,[16] a combination of glycine and polyethylene glycol,[17] and calcium or barium[18–20] to precipitate plasma proteins. These techniques, in conjunction with cold precipitation of frozen plasma, laid the groundwork that resulted in the production of the first factor VIII and factor IX concentrates for clinical use.[17,19] These concentrates could be lyophilized and stored at temperatures up to 4°C with extended stability. Infusion of factor concentrates resulted in high circulating levels of factor VIII and factor IX without the complication of volume overload and paved the way for intensive infusion therapy for serious and life-threatening bleeding complications such as intracranial, retroperitoneal, and retropharyngeal hemorrhages and major surgery. Because they were produced from large pools of single plasma donations (>1000), initial concentrates were nearly universally contaminated with viral patho-

gens such as hepatitis B and non-A non-B hepatitis (hepatitis C).[21] Initial attempts to attenuate viral transmission using pasteurization and dry heat, instituted by manufacturers in the late 1970s and early 1980s,[22,23] were found to limit the transmission of hepatitis B. Eventually these techniques were found to inactivate the human immunodeficiency virus (HIV).[24–26] Before the widespread application of these techniques, however, the majority of patients with severe hemophilia treated with concentrates between 1978 and 1985 were infected with HIV and HCV. This tragic consequence of infusion therapy helped fuel the development of modern strategies to reduce the risk of viral transmission by products derived from human plasma. These strategies include (a) careful screening of potential donors for risk factors leading to infection with transfusion-transmissible infections, (b) more vigilant surveillance of the blood donor base for the appearance of new pathogens, (c) development and implementation of testing specific for markers of infectious agents, (d) purification strategies that reduce viral load in final products, and (e) physical and chemical viral inactivation methods to treat infusible products. Finally, development and refinement in techniques of molecular biology in the 1970s and 1980s resulted in the cloning of the genes for many plasma proteins, including factor VIII and factor IX.[27–29] Within the next decade, the production and licensure of biologically active recombinant factor VIII and factor IX products had become a reality.[30–33] Concentrates of these recombinant products have been shown to be effective and have not been associated with the transmission of pathogens. Further development of recombinant products centers on the removal of all human and animal proteins in the production and formulation of products to further reduce the risk of their inadvertent contamination with emerging pathogens, such as variant prions,[34,35] and newly discovered agents, such as hepatitis G virus and TTV.[36,37] In addition, episodic supply constraints incurred in the manufacture of recombinant proteins in mammalian cell culture systems resulting in supply shortages of recombinant factor VIII[38] have led to greater interest in transgenic production of human plasma proteins compared to mammalian cell culture. With transgenic systems, raw material from which the protein of interest is purified (milk, plant tissue) can be produced in abundance.

Attenuation of Pathogens in Blood-Derived and Other Biologic Products

The development of factor VIII and factor IX concentrates in the 1960s improved the life expectancy of patients with hemophilia from approximately 11 years (prior to effective transfusion therapy) to nearly normal.[39] Experience with these first-generation concentrates, however, showed that they invariably transmitted the viral agents responsible for hepatitis B and hepatitis C,[21] which are associated with chronic hepatitis with attendant morbidity and mortality, including cirrhosis and hepatocellular carcinoma. Although efforts were being directed at methods to attenuate these known hepatitis viruses during the late 1970s and early 1980s, HIV contaminated the human blood supply. More than 70% of patients in many countries and 30% to 40% of hemophilia patients worldwide were infected with HIV.[40–43] The devastating effects of both HIV and chronic hepatitis in the hemophilia patient population provided a major impetus for the improvement in viral safety of all infusible products derived from human and, in the case of porcine factor VIII, animal blood. More recently, concern about the prion agents responsible for transmissible spongiform encephalopathies such as CJD, variant CJD, and bovine spongiform encephalopathy, as well as newly identified viral agents in the blood supply,[36,37] have reinforced the need for continued surveillance and further refinements in the production of products for the treatment of hemophilia. This attention has also been focused on recombinant products, because nearly all currently licensed products use added human or animal protein in fermentation or as stabilizers during purification or formulation. Table 151–2 lists agents that are potential contaminants of human plasma. Other viruses such as cytomegalovirus and HTLV-1 are transmissible primarily by cellular blood products.

Although ideal, the absolute removal of infectious agents in transfusable products may be unattainable and in fact may be unnecessary, because the primary goal is to make them noninfectious. Practically, this can be accomplished by reducing the levels of the contaminating agent below the level of infectivity. The most relevant agents, viruses and prions, are small and therefore difficult to separate from protein components of plasma. Some pathogens are resistant to currently employed methods of inactivation. In addition, as exemplified by HIV and prions, new agents may periodically emerge in the human population by crossing species barriers. Unless detected rapidly, newly emerging agents have the potential for global dissemination, especially if they are transmitted by transfusion of contaminated blood products. Despite these limitations, the safety of infusible products derived from human or animal sources (which includes

Data from Teitel J: Transmissible agents and the safety of coagulation factor concentrates. World Federation of Hemophilia: Facts and Figures 7:1, 1999; and Allain JP: Emerging viruses in blood transfusion. Vox Sang 78(Suppl 2):243, 2000.

cultured mammalian cells expressing recombinant protein) can be optimized by reducing the initial viral load in the source material (human plasma, culture medium, or transgenic material). With human plasma, this is accomplished by screening to limit potentially infected donors, by removal and inactivation of infectious agents, and by prospective surveillance of all products and recipients of products that potentially may become contaminated.

Current discussions in the medical, health economic, and patient communities center around achieving an appropriate balance between safety and costs given that plasma-derived products on the market today are extremely safe with regard to pathogen transmission.[44]

Infusion Regimens and Dosing for Hemophilia

The mainstay of therapy for hemophilia involves the treatment of bleeding episodes with the infusion of products capable of replacing the missing factor VIII or IX. This so-called on-demand therapy is effective in staunching hemorrhage, but not before tissue damage has occurred. Bleeding is especially destructive in the synovium, where a vicious cycle develops in which the initial bleed results in a proliferative inflammatory response and hypertrophy of synovial tissues that then become more susceptible to further trauma and bleeding. The result in the short term is repeated bleeds into the same joint, referred to as a "target joint," and eventually chronic joint destruction or hemophilic arthropathy. Chronic arthropathy often requires surgical intervention, including synovectomy, debridement, joint replacement, or even joint fusion.

With the availability of factor concentrates that allowed for the attainment of high plasma levels of factor VIII or IX, prophylactic therapy became possible. This approach was pioneered by Swedish treaters who have demonstrated that the use of prophylactic regimens,[45] wherein trough factor levels are maintained at greater than 1% of normal, reduces the incidence of arthropathy and CNS hemorrhage.[44] Greater availability of virally safe factor concentrates has allowed for the initiation of prophylactic regimens in early childhood. This "primary" form of prophylaxis has become the standard of care in developed countries. Prophylaxis is not universally practiced, however, owing to the high cost of factor concentrates, the requirement for frequent intravenous infusion, and the need for placement of central venous catheters in some patients, especially small children, to obtain intravenous access. Use of central catheters is attended by the risks of catheter-induced septic and thrombotic complications.

Dosing regimens for the treatment of bleeding episodes in hemophilia and for prophylactic regimens have evolved paralleling the availability of high-concentration pathogen-safe replacement products. Although no universal regimen for treatment has been established, certain trends prevail. In general, for non–life-threatening bleeding episodes, the goal of therapy is to achieve a plasma factor VIII or IX level of between 30% and 100%. For life-threatening bleeds or prophylaxis for surgical procedures, the goal is a level of 100% to be maintained by repeated bolus infusions or continuous infusion for a duration of 10 to 14 days or longer, depending on the severity of the bleed or surgical intervention.

The majority of prophylaxis regimens aim at achieving a trough factor level of approximately 1%. For hemophilia A, this is usually accomplished by dosing two or three times a week. Prophylactic regimens can be "primary," instituted in young children to prevent bleeding episodes, especially hemarthroses that result in chronic arthropathy, or "secondary," in which limited or prolonged periods of prophylactic therapy are instituted following a serious bleed or the development of repeated bleeding into a single joint (target joint). To prevent the development of a target joint and chronic arthropathy, many hemophilia treatment centers have recently adopted a regimen of two, three, or more infusions following a hemarthrosis. Specific dosing regimens for bleeding episodes have been developed by treaters and treatment centers. Although slight variations in indications and target plasma levels of factor VIII and factor IX between treatment centers exist, representative dosing regimens are similar and are presented in Table 151–3.[46–48]

TREATMENT OF HEMOPHILIA

Products Available for Treatment of Factor VIII Deficiency

Products available for the treatment of bleeding episodes or prophylaxis against bleeding in patients with hemophilia A include DDAVP, a vasoactive peptide that stimulates release of stored factor VIII, and infusible products containing exogenous factor VIII protein. These may be blood components, concentrates purified from blood plasma, or concentrates containing recombinant factor VIII protein.

Table 151–3 Dosing Regimens for Bleeding and Prophylaxis in Hemophilia

Site	Factor Level	Dose Hemophilia A	Dose Hemophilia B	Duration of Treatment	Comments
Joint	30%–70%	15–35 U/kg	30–70 U/kg	1–3 days	Splinting temporary splinting, no weight bearing
Life threatening (eg, intracranial, retropharyngeal, retroperitoneal)	80%–100%	40–50 U/kg	80–100 U/kg	10–14 days	Antifibrinolytic therapy with retropharyngeal bleeds
Soft tissue	30%–50%	15–25 U/kg	30–50 U/kg	2–5 days	Higher levels can be used for compartment syndrome
Surgery	80%–100%	40–50 U/kg	80–100 U/kg	10–14 (or shorter for minor procedures)	Significant blood loss can occur into large muscles of the lower extremity and the iliopsoas
Oral	20%–50%	10–25 U/kg	20–50 U/kg	1–2	Antifibrinolytic therapy
Gastrointestinal*	30%–100%	15–50 U/kg	30–100 U/kg	2–3	Should be evaluated for source
Genitourinary†	30%–50%	15–25 U/kg	30–50 U/kg	1–2	Avoid antifibrinolytic therapy
Prophylaxis‡	50%	25 U/kg	50 U/kg	qod or 3×/week	Steroids may be useful

*Depending on severity.
†Painless spontaneous hematuria often requires no treatment other than fluid intake. Persistence requires treatment and evaluation.
‡Use of a schedule of 25 U/kg qod and a dose of 40 U/kg with an interval of 2 days between the next dose may increase compliance by decreasing infusions to three per week.
Data from DiMichele,[46] Lusher,[47] and Mannucci.[48]

1-Deamino 8-D Arginine Vasopressin

The preferred product for treatment of patients with mild or moderate hemophilia A is the synthetic octapeptide DDAVP (1-deamino 8-D arginine vasopressin), a vasopressin analog. DDAVP causes a release of factor VIII (and von Willebrand factor) from endothelial cells, raising plasma factor VIII by approximately threefold (range, 2- to 12-fold) in patients with hemophilia in whom the disease is caused by decreased production or secretion of a functional protein or a protein that has decreased activity. To be effective, DDAVP relies on a partial quantitative deficiency of factor VIII; thus, patients with severe hemophilia will not benefit from its use if the causative mutation results in no synthesis, secretion, or a protein with no activity. The response to DDAVP in an individual patient is typically reproducible, and an effective response must be documented prior to its routine use or as prophylaxis for bleeding in surgical procedures. Intravenous and intranasal preparations are available. The intravenous product has been used in a subcutaneous route of administration. The intranasal preparation more easily allows a patient to administer the compound on an as-needed basis in a home therapy regimen. The phenomenon of tachyphylaxis, the decreased effectiveness of repeated doses of the compound, occurs after several, typically three, consecutive doses.

Injectable DDAVP (ZLB Behring) is available in 4 µg/mL or 15 µg/mL preparations. The recommended dose is 0.3 µg/kg, mixed in 30 mL normal saline, infused intravenously slowly over 30 minutes. This dose can be repeated after 12 to 24 hours. DDAVP nasal spray Stimate® (ZLB Behring) is available in a metered-dose pump that delivers 0.1 mL (150 µg) per activation (spray). The dose is one activation for patients less than 50 kg and two activations in separate nostrils for those more than 50 kg. Generally, only three consecutive doses of DDAVP should be used unless otherwise advised by an experienced hemophilia treater. Because DDAVP is a vasopressin analog, there is a risk of fluid retention with its use. Changes in fluid balance can result in hyponatremia and seizures, especially when

1-DEAMINO 8-D ARGININE VASOPRESSIN (DDAVP) TRIAL

1. Collect citrated plasma from the patient immediately before DDAVP infusion for testing with the postinfusion blood specimen.
2. Administer DDAVP intravenously (0.3 µg/1 kg).
3. Wait approximately 30 minutes postinfusion, carefully observing the patient for possible adverse side effects (increased blood pressure, facial flushing, rarely surgeries).
4. Collect post-DDAVP infusion specimen in sodium citrate.
5. Measure the pre- and post-DDAVP FVIII:C and VWF:Ag levels to confirm a therapeutic response.

DDAVP is used in individuals on nonfluid-restricted or salt-restricted diets (eg, the elderly or very young or surgical patients undergoing fluid replacement with solutions with concentrations <0.9% sodium). Caution is advised with the use of DDAVP in patients at risk for arterial thrombosis, as there have been reports of myocardial infarction and cerebral thrombosis with its use.[49] DDAVP is not recommended for children younger than 2 years of age.

Factor VIII Concentrates

In developed countries, the current standard of care for the treatment and prevention of bleeding episodes in patients with severe hemophilia A, and in patients with mild or moderate disease who do not respond to DDAVP, is the infusion of recombinant human factor VIII. Recovery of recombinant factor VIII ranges from 1.5 to 2.5%/IU/kg so that dosing assumes a rise in plasma factor VIII activity of 2% for every 1 IU/kg infused. Available concentrates are optimized to enhance viral clearance during purification and undergo one or

more viral inactivation steps during manufacture. Plasma-derived FVIII concentrates, treated with multiple purification and viral inactivation steps, are also available and have an excellent recent record of safety.

Intermediate- and High-Purity Plasma-Derived Concentrates

Intermediate-purity plasma-derived concentrates are prepared from cryoprecipitated plasma or fresh frozen plasma, from which factor VIII is further purified using precipitation, gel permeation, ion exchange, or affinity chromatography, often in combination. Specific factor VIII coagulant activity in these products ranges from 2 to more than 100 IU/mg of protein, and many of the methods used also copurify significant amounts of von Willebrand factor, making them useful for the treatment of some patients with von Willebrand disease (see later discussion on treatment of von Willebrand disease). More highly purified plasma-derived concentrates are produced using heparin ligand or immunoaffinity purification methods and have specific activities ranging from 140 to greater than 3000 IU/mg. To stabilize the factor VIII molecule, the majority of these products are formulated by adding human albumin prior to lyophilization.

Highly purified recombinant factor VIII concentrates have been licensed in North America, Europe, and Japan since the early 1990s. These are either full-length or B-domain deleted molecules (the B-domain is not required for activity in coagulation) that are expressed in mammalian cell culture (Chinese hamster ovary or baby hamster kidney cell lines) and are purified using immunoaffinity techniques. The development of these recombinant products was fueled primarily by concerns regarding safety of the human blood donor pool and the viral epidemics that occurred within the hemophilia population with the use of early plasma-derived products. As with highly purified plasma-derived factor VIII concentrates, the first-generation recombinant products are formulated with added albumin as a stabilizer. Newer products (Kogenate FS, Bayer, Advate, Baxter Biosciences Refacto, Wyeth) have been developed that stabilize the factor VIII molecule with nonprotein excipients.[50–52] Recombinant production methods that do not rely on the human plasma resource theoretically should provide for unlimited supply.

Plasma/Cryoprecipitate

In communities where virally inactivated factor VIII concentrates are not available, cryoprecipitate provides an effective alternative to therapy with concentrates for hemophilia A and VWD patients. Cryoprecipitate is a small-volume product (10–15 mL) enriched in factor VIII, von Willebrand factor, fibrinogen, fibronectin, and factor XIII. Dosing can be calculated assuming approximately 80 to 150 IU of factor VIII per bag of cryoprecipitate (derived from a 450-mL single whole blood donor collection unit). Thus, a typical 1750-IU dose (50% correction for a 70-kg patient) would require between 10 and 21 bags or units. The limitations of cryoprecipitate therapy are (a) lack of a viral inactivation step in manufacture of the component and (b) lack of convenience, because multiple units must be pooled into a large volume (approximately 70–100 mL) for infusion. Fresh frozen plasma and whole blood provide less desirable alternatives because adequate therapy with both of these products suffers from the limitations described for cryoprecipitate, and their use often results in intravascular volume overload. Solvent detergent (SD)-treated fresh frozen plasma product is available in some countries. ABO group-specific SD plasma is prepared by solvent detergent treatment (TNBP and Triton X100) of a pool of up to 2500 donors. Following removal of the solvent and detergent components, 200-mL aliquots are refrozen for infusion.

Products Available for Treatment of Factor IX Deficiency

Factor IX Concentrates

As with replacement therapy for factor VIII deficiency, intermediate- and high-purity products derived from plasma for the treatment of factor IX deficiency are available, as well as a single recombinant factor IX product. All of these concentrates also undergo at least one viral inactivation or exclusion step in manufacture. The volume of distribution of factor IX is approximately twice the plasma volume. This can be explained in part by the affinity of factor IX for type IV collagen present in the extracellular matrix.[53] Recovery of factor IX following infusion is therefore approximately 1%/IU/kg. The recovery observed with recombinant factor IX is approximately 20% lower than that observed with plasma-derived factor IX.[54] This is likely due to differences in posttranslational modifications between recombinant factor IX and plasma-derived factor IX.

Intermediate purity factor IX products are generally purified from plasma using anion-exchange chromatography or calcium or barium precipitate adsorption. These methods select for proteins that contain highly negatively charged epitopes. The vitamin K-dependent coagulation factors, by virtue of their gamma-carboxyglutamic acid (gla) rich domains, are such proteins; thus, these techniques copurify varying amounts of the other vitamin K-dependent coagulation factors, factor VII, factor X, and prothrombin with factor IX. Hence, the products are referred to as "prothrombin complex concentrates" (or PCCs). The levels of vitamin K proteins in these products vary and can be obtained from the manufacturer. In addition, the PCCs are contaminated with trace amounts of activated forms of vitamin K-dependent factors. The presence of these *activated* factors is the likely explanation for thromboses that have occurred with the use of these intermediate-purity products, typically in the setting of postoperative immobility or hepatic dysfunction.[55] To minimize the risk of thrombosis with the use of PCCs, it is advisable to achieve a peak factor IX level no higher than 50%.[56] Some clinicians add small amounts of heparin to infusions of these products to prevent thrombosis, and some manufacturers have formulated PCCs with heparin or antithrombin III.

High-purity factor IX products are produced from plasma using techniques of ligand affinity or immunoaffinity chromatography and typically have specific activities greater than 150 IU/mg. Two single high-purity recombinant factor IX products have been licensed in the U.S. (Alphanine, Grifols; Mononine, ZLB Behring) Thrombotic complications have not been reported with these high-purity products.

In communities where factor IX concentrates are not available, plasma may provide a means of replacing factor IX in hemophilia B patients during bleeding episodes. Each unit of fresh frozen plasma (FFP) derived from a 450-mL whole blood collection contains approximately 200 IU of factor IX. Replacement to therapeutic levels of factor IX with FFP is difficult because of the complication of volume overload. In some areas, solvent-detergent plasma provides a virally inactivated alternative to FFP.

Other Useful Adjuncts for Treatment of Bleeding in Hemophilia A and B

The antifibrinolytic agents tranexamic acid and ε-aminocaproic acid (EACA) are sometimes used in conjunction with clotting factor replacement therapy or DDAVP in the treatment of bleeding that occurs with hemophilia and other bleeding disorders. These agents interact with the lysine-binding site of plasminogen and enhance its activation. The more important effect of lysine analogs is that their occupancy of this site inhibits binding of the zymogen, plasminogen, to fibrin, which is necessary for full fibrinolytic activity. Antifibrinolytics are useful in the setting of mucosal bleeding and may substantially reduce the need for clotting factor concentrates in the setting of oral mucosal bleeding with tooth extractions. These agents are

administered preoperatively and continued postoperatively until wound healing occurs. Although tranexamic acid is more potent, it is less readily absorbed when given orally. Tranexamic acid is administered at 25 mg/kg orally or 10 mg/kg intravenously preoperatively, and therapy can be continued postoperatively using oral rinses with a 5% solution. EACA is used at a dose of 100 mg/kg preoperatively followed by 100 mg/kg every 6 hours either orally or intravenously (maximum dose 24 g/day). Dosing of EACA should be reduced in patients with renal insufficiency.

INHIBITORS OF FACTOR VIII AND FACTOR IX

A major complication in the treatment of patients with hemophilia is the development of inhibitory antibodies against the infused factors that interfere with factor activity. Rarely, antibodies may develop that do not affect activity but increase clearance of factor VIII or factor IX. The incidence of factor VIII inhibitors is approximately 30%, and inhibitors typically develop within the first 20 exposures to replacement therapy.[57,58] Well-designed prospective studies of the use of recombinant factor VIII in previously untreated patients revealed that many of these inhibitors are low titer and transient in nature.[31,32] Patients with low-titer, transient inhibitors can be managed with increased doses of factor VIII. Inhibitors to factor IX occur less frequently, with an estimated incidence of approximately 1% to 3%.[59] Patients with factor IX antibodies may have anaphylactic reactions when treated with high-purity products.[60,61]

Patients with high-titer inhibitors to either factor VIII or factor IX do not usually achieve hemostasis following factor replacement and thus present a treatment challenge. Treatment of patients who develop inhibitors involves two approaches: (a) acute treatment of bleeding episodes and (b) immune tolerance induction therapy, whereby the patient is treated frequently (often daily) with factor VIII or factor IX in an effort to suppress the production of inhibitors by the immune system (similar to allergic desensitization therapy).

Treatment of acute bleeding episodes can be accomplished by two methods. For patients with low-titer inhibitors (<5 Bethesda units [BU], a laboratory measurement of inhibitor activity), hemostasis can be accomplished with large doses of factor VIII or factor IX (eg, as high as 200 IU/kg given at frequent intervals) in an effort to neutralize or "override" the circulating inhibitor. A neutralization approach is usually ineffective for patients with high-titer inhibitors (>5–10 BU), and is also expensive because of the large amounts of factor required. These patients and patients with low-titer inhibitors who fail to respond to override therapy can be treated using products that act to "bypass" the inhibitor. The only current bypass agents include activated prothrombin complex concentrates (FEIBA, Baxter Bioscience) (aPCC), which contain factors VII, X, and prothrombin in addition to factor IX that enhance production of thrombin generation by activating the coagulation pathway at points farther down than the factor VIIIa/factor IXa step. FEIBA is used as first-line treatment of bleeding episodes in patients with inhibitors by some treaters, despite the fact that the concentrate is derived from human plasma.

Recombinant activated factor VII (rFVIIa) (NovoSeven, Novo Nordisk) product was licensed in Europe and the United States with an indication for use as a bypass agent in the treatment of inhibitors in patients with hemophilia A and hemophilia B. This product has the advantage of being the only recombinant product available for the treatment of bleeding episodes in patients with inhibitors. The dose of rFVIIa is 90 μg/kg. Recombinant factor VIIa is administered every 2 hours, compared with every 8 to 12 hours for PCCs or activated PCCs. Thrombosis has also been reported with the use of rFVIIa[62,63] and PCCs.

Despite the success achieved with immune tolerance induction regimens (80%–90%),[64] "bypass" agents will still be needed in patients undergoing tolerization, because an interval potentially as long as 2 to 3 years exists between the time that induction is initiated and the inhibitor is suppressed. Bleeding episodes that occur prior to achievement of tolerance will usually require treatment with one or other of the bypassing agents.

Treatment of Life-Threatening Bleeding Episodes in Patients With Inhibitors Against Factor VIII or Factor IX

Concentrates

1. Factor VIII containing concentrates in high doses (as high as 150–200 IU/kg) if inhibitor titer is low (<5–10 BU) or if neutralization can be demonstrated with high doses. High-dose continuous infusion of factor VIII (~10 IU/kg/hour) following a high dose bolus may be useful.
2. Recombinant factor VIIa. Dose is 90 μg/kg (or a dose up to 320 μg/kg) administered every 2 hours. Risk of thrombosis exists with this product.
3. Activated PCCs at a dose of 50 to 75 IU/kg every 8 to 12 hours. Risk of thrombosis exists with this product.

Immunomodulation

1. Antibody depletion
   a. Plasmapheresis
   b. Extracorporeal immunoadsorption of plasma (staph protein A column therapy and other methods)
2. Suppression of antibody production
   a. High-dose steroids (equivalent of prednisone 80 mg/day)
   b. Cyclophosphamide (10–15 mg/kg load and 2–3 mg/kg/day)
   c. Intravenous immunoglobulin (1 g/kg daily for 2 days)
   d. More aggressive regimens that may include vincristine, azathioprine, cyclosporine, or interferon-γ

Conservative Measures

1. Immobilization
2. Compression
3. Local application of hemostatic agents
4. Antifibrinolytics
5. Avoid venipunctures, intramuscular injections, arterial puncture, or lumbar punctures
6. Avoid use of medications that inhibit platelet function
7. DDAVP may be effective in some patients with low titer inhibitors

Treatment of life-threatening bleeds in the context of a high-titer inhibitor represents a significant challenge. The infusion of non-factor VIII concentrates, when the inhibitor titer precludes the use of factor VIII, is less effective than treatment with factor VIII concentrates and is difficult to monitor, because plasma factor VIII levels are of no value. Adjunctive therapies are frequently employed in this setting to lower the titer of the antibody to allow for treatment of the patient with factor VIII concentrates. Aggressive regimens are employed in which circulating antibodies are depleted using plasmapheresis or staphylococcal protein A immunoadsorption, and reduction of antibody production is attempted using immunomodulatory agents such as steroids, cyclophosphamide, and intravenous infusion of gamma globulin (IgG).[65–68] These strategies for acutely reducing antibody titers are also employed by some hemophilia treaters at the outset of immune tolerance induction.

VON WILLEBRAND DISEASE

Von Willebrand disease (VWD) is an autosomal dominant bleeding disorder first described by Erik von Willebrand in 1926, who named this bleeding diathesis "pseudohemophilia." Von Willebrand disease is relatively common, with a prevalence of up to 2% of the general population.[69] The penetrance and severity of the disease vary depending on the type of VWD (type 1, 2, or 3), the specific mutation, the number of affected genes, the patient's blood type, and numerous

drug, hormonal, and stress-related parameters. These factors, particularly the subtype of VWD and the patient's response to DDAVP, influence the recommended treatment for acute bleeding episodes or for prophylaxis against bleeding.

Although the disease had been described in the 1920s, and the primary defect had earlier been attributed to either platelets or the vessel wall. An understanding of the missing protein in VWD and its relationship to factor VIII was not appreciated until the 1950s. Correction of the defect with transfusion of plasma, but not with platelet concentrates alone, defined the disease as one involving a missing plasma protein factor (von Willebrand factor [VWF]) not a platelet or vessel wall defect.[70] A correlation between VWD and factor VIII activity had previously been observed, the observation that a plasma fraction from patients lacking factor VIII (hemophilia A) could correct the defect in VWD, in addition to the autosomal inheritance pattern, which helped further differentiate hemophilia A from VWD.[70] A more detailed discussion of clinical features and pathophysiology of VWD and the molecular biology of VWF can be found in Chapters 120 and 121.

TRANSFUSION THERAPY FOR VON WILLEBRAND DISEASE

The specific treatment for VWD varies with the bleeding symptoms and signs and with the subtype of VWD. Treatment is guided further by laboratory results indicating the potential success of increasing VWF with DDAVP, and the clinical experience with a particular patient and his or her natural biological family members who have VWD. When possible, attempts should be made to treat the patient without exposing him or her to plasma-derived products.

Non–Protein-Based Treatment

DDAVP is a synthetic octapeptide homolog of vasopressin that results in the release of stored VWF from Weibel Palade bodies of the endothelium (see section on treatment of hemophilia A). DDAVP is often effective for type 1 disease and may be useful in certain patients with type 2 disease. It is not appropriate for use in patients with type 3 disease in whom no stores of VWF exist. Prior to the use of DDAVP, a DDAVP trial should be conducted to document its efficacy in an individual patient. The trial is performed as described for hemophilia A. The phenomenon of tachyphylaxis is also observed when DDAVP is used to treat VWD. For bleeding that does not respond to DDAVP or in patients in whom a poor response is observed with DDAVP, other modalities (typically protein-based) must be employed.

As described for hemophilia A, the antifibrinolytic agent ε-aminocaproic acid or tranexamic acid are often administered in the setting of dental surgery to inhibit fibrinolysis. Care should be taken when these agents are administered in patients with a predisposition to thrombosis.

Estrogens upregulate VWF synthesis and may be useful especially in women. Therapy with estrogens should also help ameliorate menorrhagia in affected symptomatic patients.

Plasma-Protein-Based Therapy

Factor VIII Concentrates

Some intermediate-purity factor VIII concentrates are manufactured from plasma using methods that copurify significant amounts of VWF. Many of the products listed in Table 151–4 contain VWF, but only Humate-P (ZLB Behring) is currently licensed for the treatment of VWD. Alphanate (Grifols USA) has been studied in clinical trials to support an indication for VWD, and others, including Koate-DVI (Talecris Biotherapeutics), have been tested in vitro and in vivo for their potential use in therapy for VWD.[71–73] The multimeric pattern of VWF in these concentrates varies, and no product has the pattern of multimers that is present in normal plasma.[72] Because many of these products are effective clinically, the importance of these differences in multimer pattern remains to be determined.

Table 151–4 Other Coagulation Deficiencies

Factor	Incidence	Inheritance	Chromosome	Half-Life	Target Plasma Level	Treatment Product*
I (fibrinogen)	1–2/10^6		4	2–4 days	50–100 mg/dL	Concentrates
Afibrinogen		AR				Cryoprecipitate
Hypofibrinogen		AR or AD				
Dysfibrinogen		AR or AD				
II (prothrombin)	<1/10^6	AD	11	3 days	30%	PCCs Plasma
V	1/10^6	AR	1	36 hours	25%	Plasma
VII	2/10^6	AR	13	3–6 hours	25%	rFVIIa Concentrates PCCs Plasma
X	2/10^6	AR	13	40 hours	10%–25%	PCCs Plasma
XI		AR or AD	4	80 hours	20%–40%	Concentrates Plasma
XIII	<1/10^6	AR	1.6	9 days	5%	Concentrates Cryoprecipitate Plasma

AD, autosomal dominant; AR, autosomal recessive; PCC, prothrombin complex concentrates.
*Products are listed in order of viral safety.
Data from Cohen AJ, Kessler CM: Treatment of inherited coagulation disorders. Am J Med 99:675, 1995.

von Willebrand Factor Concentrates (Plasma-Derived and Recombinant)

Several chromatography-purified plasma-derived concentrates enriched in VWF have been studied by manufacturers in Europe.[74,75] Preliminary reports suggest that these are amenable to viral inactivation steps and may be effective both in vitro and in vivo.[72] To date, none of these have been developed as widely licensed products. Recombinant VWF has been successfully isolated from a number of expression systems and partially characterized, but a recombinant product for the treatment of patients has not yet been developed clinically.

Cryoprecipitate

Cryoprecipitate had been the mainstay of plasma-based therapy for bleeding in patients with VWD until the availability of virally inactivated intermediate-purity factor VIII concentrates with preserved functional VWF protein. These factor VIII concentrates are the products of choice for the treatment of bleeding in patients with types 1 and 2 VWD who are unresponsive to DDAVP, and for bleeding in patients with type 3 VWD. Owing to the small potential for viral contamination of cryoprecipitate, manufacture of which does not include steps to inactivate viral pathogens, cryoprecipitate is currently indicated only when virally safe concentrates containing VWF are unavailable.

ACQUIRED FACTOR VIII AND VON WILLEBRAND FACTOR DEFICIENCY

Antibodies that inhibit the activity of factor VIII can develop in previously normal patients. Most of these patients have no underlying disease; however, factor VIII antibodies can arise in the setting of autoimmune disorders or in the postpartum period. Although approximately one-third of inhibitors will disappear spontaneously, the mortality rate among affected patients is significant.

Acquired VWD is a rare autoimmune disorder that can occur in association with other autoimmune disorders or lymphoproliferative disease. Antibody may interact with the epitopes on VWF required for its normal activity or result in increased clearance of antibody–VWF complexes.

Treatment

Therapy for those patients with relatively high inhibitor titers (>5 BU) includes bypassing agents (FEIBA or rFVIIa) to stop bleeding and immunosuppression to reduce inhibitor levels. Plasmapheresis or immunoadsorption can be employed to reduce the circulating levels of inhibitors. Immunosuppressive agents and intravenous immunoglobulin (IgG) are useful adjuncts to abrogate production o the autoantibody. DDAVP can also be effective in some patients with low-titer inhibitors. Unlike inhibitors that develop with hemophilia A, exposure to factor VIII usually does not result in increased antibody titers.[76] Conservative measures to control hemorrhage should also be used in conjunction with the above, including immobilization and compression, topical or local hemostatic agents, and antifibrinolytic therapy. The use of venipunctures, intramuscular injections, and drugs with platelet inhibitory activity should be minimized or avoided.

OTHER COAGULATION PROTEIN DEFICIENCIES

Approximately 15% of inherited bleeding disorders are caused by deficiencies of coagulation factors other than factor VIII, factor IX, or VWF. Inherited deficiencies of fibrinogen and factors II, V, VII, X, XI, and XIII may result in bleeding, requiring treatment. The genes for these factors are not located on the X chromosome; thus two gene defects are typically required for symptomatic disease. Consanguinity is frequent in affected kindreds. Characteristics of these deficiencies are presented in Table 151–2. Hereditary deficiencies of factor XII, pre-kallikrein, and high-molecular-weight kininogen have not been described to result in bleeding diatheses.

The mainstays of therapy for these disorders are cryoprecipitate (for fibrinogen and factor XIII deficiencies) and plasma. In some countries, concentrates enriched in the missing protein have been available. A solvent-detergent treated pooled plasma product is also available in some regions. Pooled solvent-detergent treated plasma has the advantage over fresh frozen plasma in that it is virally inactivated but has the drawback of exposing the patient to a large number of donors (2500) with each dose.

Fibrinogen Deficiency

Bleeding disorders can result from low to absent levels of fibrinogen (hypofibrinogenemia or afibrinogenemia) or a protein with abnormal function (dysfibrinogenemia). The inheritance pattern for the former is autosomal recessive and for the latter is autosomal dominant. Dysfibrinogenemias can result in bleeding or hypercoagulability. The gene for fibrinogen is located on chromosome 4. Because fibrinogen is required for the formation of a fibrin clot, it is surprising that afibrinogenemic patients survive gestation and birth. Diagnosis is made when patients present with bleeding from the umbilical stump, intracranial hemorrhage, or mucosal bleeding. Hemarthroses can occur but are less common than observed with the hemophilias. Wound healing may be delayed. Increased incidence of fetal wastage in patients with afibrinogenemia and hypofibrinogenemia is observed, and term gestation is rarely achieved without replacement of fibrinogen.[77–79] Because the substrate for clot formation, fibrinogen, is missing or deficient, the prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin clotting time (TCT), and coagulation assays that have fibrin formation as their end points are all prolonged. Replacement of fibrinogen is accomplished with cryoprecipitate, with a goal of achieving a plasma level between 50 and 100 mg/dL and at least 60 mg/dL for maintenance of pregnancy.[79] Each bag of cryoprecipitate contains approximately 200 to 300 mg of fibrinogen. The biologic half-life of fibrinogen is between 2 and 4 days. Virally inactivated fibrinogen concentrates are available in Europe, China, and Japan (Japan Green Cross, Aventis, LFB). Adverse reactions to treatment include the development of fibrinogen antibodies, allergic reactions, and, paradoxically, thrombosis.

Prothrombin Deficiency

Congenital prothrombin deficiency is a rare autosomal recessive disorder estimated to be present at a rate of 0.5 cases per million. Disease has been described with both homozygous and heterozygous defects (including compound heterozygotes). Hemorrhagic symptoms include bruising; intracranial, mucosal, and deep tissue bleeding; and menorrhagia. Hemarthroses are rare. Correlation between bleeding and prothrombin levels is poor. No reports of a prothrombinemia appear in the literature, suggesting that complete lack of the protein is incompatible with normal development. Both the PT and the aPTT time are prolonged, and the thrombin time is normal. Treatment of prothrombin deficiency includes plasma at a dose of 15 to 20 mL/kg followed by 3 mL/kg every 12 to 24 hours to achieve levels of approximately 30%. The half-life of prothrombin is approximately 3 days. Prothrombin complex concentrates contain prothrombin and other vitamin K-dependent factors and can be used to treat prothrombin-deficient patients who are undergoing major surgery or life-threatening bleeds. Caution should be exercised, as these have been associated with thrombosis.

Factor V Deficiency

Inherited deficiency of factor V occurs in fewer than 1 per 1,000,000 people, with an autosomal recessive inheritance pattern (homozygous or compound heterozygous), resulting in factor V levels less than 20%. Symptoms include bleeding from the umbilical stump and mucous membranes, ecchymoses, menorrhagia, postpartum bleeding, and intracranial hemorrhage. Hemarthroses can occur but are less common than with severe hemophilia. No factor V-enriched plasma concentrates are available. Because factor V is in the common pathway of coagulation, both the PT and the aPTT are prolonged. Treatment of bleeding involves the infusion of plasma at 15 to 20 mL/kg with a goal of achieving levels of 20%. The half-life of factor V is approximately 36 hours. Because platelets contain stored factor V, this product has been used to treat bleeding. Platelet infusion may result in the production of platelet-specific antibodies.

Factor VII Deficiency

Factor VII deficiency occurs in approximately 1 in 500,000 people. Severe bleeding occurs with levels below 5%, and symptoms in severely affected patients are similar to those observed with severe hemophilia. Intracranial hemorrhage may occur in up to 16% of cases and in neonates following vaginal delivery. The PT is prolonged, but the aPTT and thrombin time are normal. Prothrombin complex concentrates contain factor VII and may provide a benefit over plasma because they are virally inactivated. As with the use of these products for factor VIII and factor IX inhibitors, thrombosis has been reported. Several plasma-derived factor VII concentrates have been developed and have been used to treat congenital deficiency. Recombinant activated factor VII concentrate is effective in the treatment of bleeding with factor VII deficiency.[80–83] Inhibitors to factor VIIa have developed in patients with congenital factor VII deficiency.[80]

Factor X Deficiency

Congenital deficiency of factor X is a rare condition resulting from homozygous or compound heterozygous defects in the autosomal genes for factor X located on chromosome 13. Bleeding is correlated with factor X levels, and symptoms include epistaxis, menorrhagia, hemarthrosis, intracranial hemorrhage, hematuria, and umbilical cord bleeding. Because factor X is a component of prothrombinase (the first step in the common pathway), diagnosis is suggested by both a prolonged PT and a prolonged aPTT but a normal TCT. Treatment is with plasma products (FFP or solvent-detergent treated plasma) at approximately 10 to 15 mL/kg followed by 5 mL/kg every 24 hours with a goal of plasma factor X activity levels of 20%. No factor X-specific concentrates are available, but PCCs contain variable amounts of factor X. As with the use of PCCs for other indications, the risk of thrombosis is increased.

Factor XI Deficiency

Congenital factor XI deficiency (sometimes called hemophilia C) is an autosomal disorder with a recessive pattern of inheritance and is particularly common in Ashkenazi Jews, in whom two specific mutations account for the approximately 8% prevalence of an abnormal factor XI gene.[81,82] Bleeding symptoms are variable and include postsurgical or traumatic bleeding or heavy menses in women. Spontaneous hemorrhage is not typical of the disorder, and this characteristic distinguishes the disorder from hemophilia A and B. Plasma levels of factor XI do not correlate with bleeding symptoms, as factor levels do in hemophilia A and B. The aPTT is prolonged with factor XI deficiency; PT and thrombin time are normal. Patients with factor XI deficiency are usually treated prior to surgical procedures with a goal of factor XI levels between 30 and 45 U/dL.[81] Plasma (FFP and solvent-detergent treated plasma) provides the mainstay of therapy, and dosing takes into consideration the long half-life of 60 to 80 hours. Although the half-life of factor XI in solvent-detergent plasma is comparable to that of FFP, decreased levels of factor XI in the product (approximately 30%–50%) have been reported.[83] Two virally reduced or inactivated factor XI concentrates have been developed using affinity chromatography or cation-exchange chromatography.[84] These have been demonstrated to be effective, but there have been reports of thromboembolic complications with their use, presumably because of contaminant activated factor IX. Both products are now formulated with antithrombin and heparin, but caution is advised with their use in elderly patients and in patients with preexisting cardiovascular disease. Doses should not exceed 30 U/kg and peak FXI should not exceed 100 U/dL.[85]

Because bleeding occurs in patients with factor IX deficiency more often in settings in which fibrinolysis is more active (oral mucosa, urinary tract), antifibrinolytic agents can be useful adjuncts in the treatment of such bleeding episodes or used as sole agents to prevent bleeding with dental procedures. Fibrin glue can provide a useful adjunct or be used solely in topical bleeding (dental extractions, circumcisions). DDAVP has been reported as useful for the prevention of surgical bleeding in factor XI deficiency.[86] The mode of effect of DDAVP is unclear but is likely due to the coexistence of mild VWF deficiency.

Factor XIII Deficiency

Factor XIII is a transglutaminase that catalyzes the cross-linking of γ-glutamyl and ε-lysyl groups of fibrin monomers, stabilizing the forming clot by decreasing its susceptibility to fibrinolysis. Inherited deficiency of factor XIII is autosomal recessive and results from defects in the genes for the two subunits of factor XIII located on chromosome 1 (B subunit) and chromosome 6 (A subunit). The majority of reported defects involve the A subunit. Umbilical bleeding in homozygotes may be observed at birth. Soft-tissue bleeds, hemarthroses, excessive intracranial bleeding (relative to other coagulation deficiencies), pseudotumors, and bleeding at surgery are observed in affected patients. Surgery is also complicated by poor wound healing. Affected male patients may have oligospermia and female patients may have recurrent miscarriages. Coagulation screening tests (PT, aPTT, and TCT) are normal. Solubility of clots is increased with factor XIII deficiency; thus, the diagnosis can be made by incubating clots in the presence of solubilizing agents such as 5 M urea or 1% to 2% chloroacetic acid. Factor XIII has a long half-life (9–15 days). FFP (2–3 mL/kg) or cryoprecipitate (1 bag/10–20 kg) can be administered to raise levels of factor XIII. Because of the long half-life of factor XIII, FFP and cryoprecipitate can be used on a prophylactic basis (dosing every 3–4 weeks) to prevent intracranial hemorrhage and other bleeding episodes. Two plasma-derived factor XIII concentrates have been developed and may be available in the United States on a limited basis. Dosing with factor XIII concentrate is 10 to 75 IU/kg every 4 to 6 weeks, with lower doses for prophylaxis and higher doses for the treatment of bleeding episodes. A recombinant FXIII-A_2 concentrate was found in phase I testing to be safe and potentially effective for replacement in patients with FXIII deficiency and is currently in clinical trials.[87]

OTHER PLASMA-DERIVED PROTEIN CONCENTRATES

As discussed in Chapter 143, plasma fractionation processes also allow for the isolation of plasma components other than the coagulation proteins. Immunoglobulins are isolated by a variety of techniques from the Cohn fraction II-III. α_1-Antitrypsin and antithrombin are produced from fraction IV. As with other vitamin K-dependent proteins, protein C may be isolated from Cohn fraction II.

Anticoagulant Proteins (Protein C and Antithrombin)

Brief mention should be made of plasma-derived concentrates enriched in protein C and antithrombin III. These products have been used for a variety of indications, but both are licensed for the treatment of congenital deficiencies that result in thrombosis. Protein C concentrate has also been used in the treatment of purpura fulminans with meningococcemia. Antithrombin has been used for the treatment of venoocclusive disease in patients undergoing bone marrow transplantation, heparin resistance in patients undergoing cardiopulmonary bypass, and sepsis. Recent results using a recombinant activated protein C[88] have shown efficacy in the treatment of sepsis, and its utility for other indications is not yet known.

Immunoglobulins

The use of immunoglobulins (both intravenous and hyperimmune products) for a variety of diseases is discussed elsewhere in this book.

α_1-Protease Inhibitor (Antitrypsin)

α_1-Protease inhibitor (or antitrypsin) concentrates (Prolastin, Bayer Healthcare LLC; Aralast, Baxter Biosciences; Zemaira, ZLB-Behring) are available for the prophylactic treatment of people with congenital deficiency of α_1 antitrypsin. α_1 Antitrypsin inhibits neutrophil elastase, which is thought to be responsible for the alveolar damage resulting in emphysema. These replacement products, administered intravenously, are presumed to act to delay the progression of congenital emphysema associated with this protease inhibitor deficiency.

CONCLUSION

Virally safe plasma-derived concentrates have been developed that are enriched in a variety of coagulation and other proteins. Initially, refinements in techniques of plasma fractionation formed the basis for the development of these concentrates as an improvement over the use of blood component therapy (whole blood, plasma, and cryoprecipitate). Plasma-derived protein concentrates were first developed for the treatment of the more common hemophilias A and B. Subsequent refinements were made to reduce, then eliminate, the transmission of viral and other pathogens present in the human plasma pool while increasing product purity. Techniques in molecular biology and heterologous expression of mammalian proteins have allowed for the production of some proteins, most notably factor VIII and factor IX, without reliance on the limited plasma resource. These plasma-derived and recombinant concentrates have supplanted the use of plasma or cryoprecipitate for the treatment of some congenital and acquired deficiencies of soluble plasma factors and have decreased or eliminated the attendant risks of allergic reactions, volume overload, and pathogen transmission. For patients on home infusion regimens, protein concentrates also have the benefit of increasing patient convenience, as infusion volumes are small relative to blood component therapy. Although the development of high-purity, virally safe concentrates to treat other plasma protein deficiencies that are currently treated with blood components is technically feasible, such development is limited by the very small numbers of patients with these disorders. In the future, the development of products produced in transgenic animals holds the promise of producing large quantities of recombinant proteins, thus making available more of these life-saving products for use clinically.

CHAPTER 152

HEMAPHERESIS AND CELLULAR THERAPY*

Ellen F. Lazarus and Harvey G. Klein

Bloodletting is an ancient therapy, fashionable, albeit unproved, well into the 19th century. About the time that scientific skepticism began to temper the widespread use of therapeutic phlebotomy, a new technique for blood removal, apheresis, appeared in the research laboratory.[1] The term *apheresis*, derived from a Greek verb meaning "to take away or withdraw," was coined to describe removal of one component of blood with return of the remaining components to the donor. Like phlebotomy, apheresis was used first to treat patients but later became more important for collecting blood components for transfusion. Increasingly, apheresis techniques are used to collect cell populations from the peripheral blood of healthy donors and patients for purposes of hematopoietic stem/progenitor cell (HPC) transplantation and immune cell therapies. Annually in the United States, up to 20,000 units of peripheral blood stem cells (PBSC) and therapeutic lymphocytes are collected at hospital and blood center apheresis facilities.[2]

PRINCIPLES OF APHERESIS

The principal objective of apheresis is efficient removal of some circulating blood component, either cells (cytapheresis) or some plasma solute (plasmapheresis). For most disorders, the treatment goal is to deplete the circulating cell or substance directly responsible for the disease process. Apheresis can also mobilize cells and plasma components from tissue depots. For example, lymphocytes may be mobilized from the spleen and lymph nodes of some patients with chronic lymphocytic leukemia, and low-density lipoproteins can be removed from tissue stores in patients with familial hypercholesterolemia. Apheresis also appears to mobilize $CD34^+$ cells from extravascular depots in peripheral blood stem/progenitor cell (PBSC) donors, resulting in collection of more than twice as many $CD34^+$ cells than estimated based on preapheresis peripheral blood cell counts (Fig. 152–1).[3] Apheresis may have other, less obvious effects. Lymphocyte depletion may modify immune responsiveness in some disease states, possibly by disturbing the control mechanisms of cellular immune regulation. Plasmapheresis enhances splenic clearance of immune complexes in certain autoimmune disorders.[4] When therapeutic effect is judged by clinical improvement rather than by efficiency of solute removal, apheresis is more often a helpful adjunct than a form of first-line therapy.

Several mathematic models formulated for different clinical conditions describe the kinetics of apheresis.[5–7] Removal of most blood constituents follows a logarithmic curve (Fig. 152–2). This model assumes that the substance removed is neither synthesized nor degraded substantially during the procedure, remains within the intravascular compartment, and mixes instantaneously and completely with any plasma replacement solution. When the goal of plasmapheresis is to supply a deficient substance, for example, the cleavase ADAMTS13 in the treatment of thrombotic thrombocytopenic purpura, replacement follows logarithmic kinetics similar to those developed for solute removal. From Fig. 152–2, it is evident that removal of 1.5 to 2.0 volumes will reduce an intravascular substance by approximately 80% and that processing larger volumes results in little additional gain.

Specific cell removal with centrifugal automated cell separators depends on the number of cells available, the volume of blood processed, the efficiency of the particular instrument, and the separation characteristics of the different cells. Most commercially available instruments remove platelets and lymphocytes extremely efficiently. Granulocytes and other mononuclear cells, including HPC from peripheral blood, cannot be cleanly separated from other cells by standard centrifugal apheresis equipment (Fig. 152–3). Optimal harvesting of these cells requires special techniques such as stimulating the donor with corticosteroids or cytokines and adding sedimenting agents to enhance cell separation.

TECHNOLOGY AND TECHNIQUES

The plasmapheresis technique that originated in the animal laboratory required manual resuspension of red cells and posed a substantial risk of microbial contamination of the components being reinfused. With the introduction of sterile, disposable, interconnected plastic blood bags, plasmapheresis became relatively safe and easy. However, manual apheresis proved too inefficient and labor-intensive for collecting large component volumes and raised concerns that the separated units of red blood cells might be reinfused accidentally into the wrong donor or patient. The introduction of automated on-line blood cell separators solved these problems.[8,9] Automated apheresis instruments use microprocessor technology to draw and anticoagulate blood, separate components either by centrifugation or by filtration, collect the desired component, and recombine the remaining components for return to the patient or donor.[10,11] The equipment contains disposable plastic software in the blood path and uses anticoagulants containing citrate or combinations of citrate and heparin that do not result in clinical anticoagulation of the patient or donor. Most instruments function well at blood flow rates of 30 to 80 mL/min and can operate from peripheral venous access or from a variety of multilumen central venous catheters. Newer therapeutic apheresis devices are smaller and more automated, allowing for implementation of more safety functions and improved portability.

Because the ideal method for treating disorders mediated by abnormal plasma components is to remove the offending substance selectively, a variety of on-line filtration and column adsorption techniques have been introduced or proposed. Ligands bound to a column matrix may be relatively nonspecific chemical sorbents, such as charcoal or heparin, or specific ligands, such as monoclonal antibodies and recombinant protein antigens. Two such columns are commercially available: one using staphylococcal protein A and the other using dextran sulfate cellulose beads. Staphylococcal protein A has high affinity for the Fc portion of IgG1, IgG2, and IgG4 and for immune complexes containing these IgG subtypes. This column is approved for use in therapeutic apheresis procedures for patients with chronic immune thrombocytopenia and selected adult patients with rheumatoid arthritis. The dextran sulfate cellulose columns selectively remove low-density lipoproteins and have proved effective in managing patients with homozygous hypercholesterolemia who have not responded to diet and cholesterol-lowering drug therapy (Fig. 152–4). Apheresis technology has also been adapted for extracorpo-

The number and percentage of each cell type collected can be varied by adjusting the site of collection along the interface or by changing centrifugal force, blood flow rate, or rate of cell removal.

real phototherapy of patient leukocytes (photopheresis) to treat cutaneous T-cell lymphoma and to modulate the pathologic immune response in graft-versus-host disease, solid organ transplant, and autoimmune diseases (see below).

THERAPEUTIC CYTAPHERESIS

Common indications for therapeutic cell removal are listed in Table 152–1. Most of these procedures entail simple apheresis of the patient's peripheral blood with diversion for discarding the affected red cell, white cell, or platelet fraction. Special apheresis technologies have been approved, such as photopheresis devices, which divert a cell fraction that is photochemically treated in the extracorporeal circuit and returned to the patient's circulation, and apheresis immunoabsorption columns, which selectively remove immunoglobulins in the plasma by binding to a solid matrix.

Erythrocytapheresis

Red cell exchange (erythrocytapheresis) is used most often to manage or prevent the acute vasoocclusive complications of sickle cell disease. Compared with manual exchange transfusion, mechanical cell separators offer the advantages of speed and ease and reduce the risks of rapid blood volume alteration and increased blood viscosity that may occur with simple transfusion. Automated procedures can be performed with all centrifugal instruments and programmed procedures allow accurate prediction of target hemoglobin concentration and percent hemoglobin A (HbA) at the conclusion of the procedure.

Sickle cell anemia occurs in individuals who are homozygous for a single mutation in codon 6 of the β-globin gene, resulting in substitution of a single amino acid. Although the defect appears simple, the pathophysiology of the vasoocclusive crises is complex, involving hemoglobin polymerization, change in cell shape, adhesion to endothelial cells, dysregulated nitric oxide homeostasis, and release of free

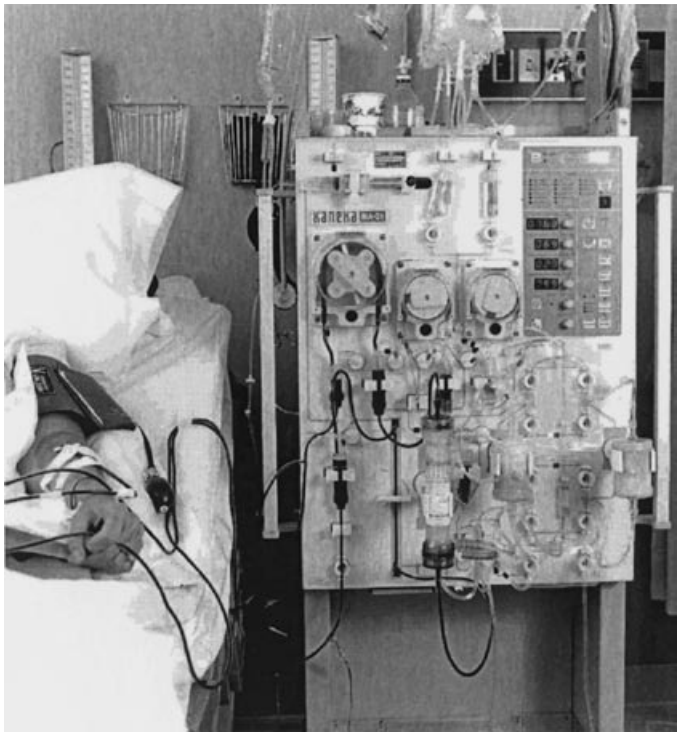

Figure 152–4 Two-stage therapeutic plasmapheresis. Plasma is separated from cells by filtration and then passed through parallel adsorption columns to remove low-density lipoproteins from a patient with homozygous familial hypercholesterolemia.

hemoglobin and inflammatory cytokines[12] Clinical manifestations vary from patient to patient. The rationale behind exchange transfusion involves improving tissue oxygenation, reducing hemolysis, and preventing microvascular sickling by diluting the patient's abnormal red cells, simultaneously correcting anemia and favorably altering whole blood viscosity and rheology. No clinical data support a single optimal level of hemoglobin A (Hb A); however, as few as 30% of transfused cells markedly decrease blood viscosity. At mixtures of 50% or greater, resistance to membrane filterability approaches normal.[13,14] In nonemergency situations, such levels can often be achieved with a simple transfusion regimen. For simple and exchange transfusions, raising the level of Hb A to between 60% and 70% while lowering the level of Hb S to 30% is generally efficacious, although even higher levels of HbA may be required to treat an ongoing crisis.

Clinical indications for exchange transfusion in patients with sickle cell anemia remain controversial, with limited controlled study data available. Simple transfusion has been shown to improve renal concentrating ability and splenic function in young sickle cell patients; exchange transfusion improves exercise tolerance and reverses the periodic oscillations in cutaneous blood flow associated with this disease.[15–17] Such observations have encouraged the use of exchange transfusion for acute complications of sickle cell disease such as acute chest syndrome, priapism, cerebrovascular accident, and hepatic and retinal infarction. Exchange transfusion for sickle cell patients has also been used for prophylaxis during pregnancy and before surgery, although prophylactic transfusion in these settings is controversial. The only randomized trial of transfusion during pregnancy has shown that prophylactic transfusion sufficient to reduce the incidence of painful crises did not reduce other maternal morbidity or perinatal mortality.[18] In a randomized study of sickle cell disease patients undergoing surgery, a conservative simple transfusion regimen (to increase the Hb level to 10 g/dL) was as effective as an aggressive regimen (to lower the Hb S level to <30%) with respect to perioperative non–transfusion-related complications. The patients in the aggressive regimen group received twice as many units of blood, had a proportionally increased red blood cell alloimmunization rate, and had more hemolytic transfusion reactions.[19] The results of this and other studies suggest that if prophylactic preoperative exchange transfusion is used, it should be limited to patients undergoing high-risk procedures in whom simple transfusion could not effectively raise the Hb A level to 70% or higher.

Transfusion prophylaxis is now clearly indicated for children at high risk for stroke. A randomized controlled study demonstrated a risk reduction of 90% in the patients who were maintained at levels of 30% or less Hb S by simple or exchange transfusion.[20] This result confirms earlier experience and indicates that in this group of children with sickle cell anemia, transfusion therapy should begin before the first event and continue indefinitely. Long-term erythrocytapheresis may be preferable for patients at high risk for stroke who have developed iron overload to levels associated with organ damage.[21]

Exchange transfusion, although relatively safe and convenient, carries all the complications of red cell transfusion. Patients are exposed to a large number of donors and are at a small but significant risk of contracting hepatitis and other blood-borne infections. As many as 33% of all patients develop alloantibodies, and life-threatening delayed hemolytic transfusion reactions have been reported.[22,23] In addition, an immunohematologic study of multiply transfused sickle cell patients shows that 85% of heavily transfused patients are alloimmunized to human leukocyte antigens (HLAs), platelet-specific antigens, or both.[24] Most centers avoid inducing nonhemolytic transfusion reactions and HLA alloimmunization by using leukocyte-depleted red cells. Extended red blood cell phenotyping at diagnosis and provision of phenotypically matched blood, when practical, can reduce the risk of red cell alloimmunization and associated hemolytic transfusion reactions. Despite the removal of red cells during exchange, patients remain in positive iron balance, although iron accumulation is slow and chelation is rarely required to prevent transfusional hemosiderosis.[21]

Other indications for red cell exchange are rare. The procedure has been used for patients with overwhelming red cell parasitic infections, such as severe and complicated malaria and babesiosis.[25,26] In these situations, red cell exchange decreases the concentration of circulating parasites and may help sustain life until conventional therapy and natural immunity take effect. Although the efficacy of this therapy has not been evaluated by controlled trials, prospective studies and review of published cases suggest the use of erythrocytapheresis for parasitemia greater than 10% to 15%, or even less in selected patients.[27] Automated red cell removal with volume replacement (isovolemic hemodilution) can be performed rapidly and safely in polycythemic subjects.[28] This maneuver should be reserved for polycythemic patients with an urgent clinical indication to lower the hematocrit (eg, evolving thrombotic stroke) for which standard single-unit manual phlebotomy might be inadvisably slow. Automated double red cell apheresis technology has more recently been used to treat individuals with hereditary hemochromatosis. This procedure removes excess iron more rapidly than manual phlebotomy,

and may be more tolerable to patients because of the lower frequency of maintenance procedures required (Fig. 152–5).[29]

Leukapheresis

Therapeutic leukapheresis has been used most successfully to help manage patients with acute leukemia and extremely high white blood cell (WBC) numbers, so-called acute hyperleukocytic leukemia (AHL). When the fractional volume of leukocytes (leukocrit) exceeds 20%, blood viscosity increases and leukocytes can interfere with pulmonary and cerebral blood flow and compete with tissue for oxygen in the microcirculation.[30] Investigations of the expression and function of adhesion receptors in leukemic cells and the role of adhesion molecules in leukocyte-induced acute lung injury in sepsis suggest that the pathophysiology of leukostasis in AHL may also be related to interactions between leukemic blasts and endothelial cells mediated by locally released adhesion molecules.[31] A single leukapheresis procedure generally reduces the WBC count by 20% to 50%, depending on the differing sedimentation characteristics of the specific blast cell population. Ordinarily, leukapheresis is initiated in a patient with acute myeloid leukemia (AML) when the blast count is higher than 100,000/mm^3 or when rapidly rising blast counts are higher than 50,000/mm^3, especially when evidence of central nervous system or pulmonary symptoms appears. The threshold for initiation of leukapheresis in patients with acute lymphocytic leukemia (ALL) is generally higher (WBC count >200,000/mm^3).[32] Other immediate measures for treatment of patients with AHL include infusion of IV fluids, administration of hydroxyurea and allopurinol, and correction of coagulopathy and thrombocytopenia.[31]

Mechanical cytoreduction for managing other leukemic processes has limited value. Although repeated leukapheresis has adequately reduced the WBC count in a series of patients with chronic myeloid leukemia, the median patient survival rate was not significantly different from that of similar patients treated with conventional chemotherapy.[33] Chronic leukapheresis can provide acceptable control of the peripheral WBC count in clinical situations such as pregnancy, when cytotoxic agents may best be avoided, but cytoreduction alone does not appear to alter the course of chronic myeloid leukemia. Some studies of patients with chronic lymphocytic leukemia suggested short-term clinical benefit, but long-term support of patients when the disease is refractory to chemotherapy does not appear to prolong life.[34,35]

Lymphocyte removal by apheresis has also been used to modify immune responsiveness in patients with autoimmune diseases, and to enhance solid organ allograft survival and reverse solid organ graft rejection, but evidence of clinical efficacy in these situations is sparse. Removal of large numbers of lymphocytes over a period of a few weeks can suppress peripheral lymphocyte counts in patients with rheumatoid arthritis for up to 1 year and can alter skin-test reactivity and lymphocyte mitogen responsiveness to a variety of stimulants.[36] Selected patients experience a modest but significant reduction in disease activity; however, the subset of patients who may derive substantial benefit from this therapy is difficult to identify.[37,38] An adsorptive type extracorporeal column of cellulose acetate beads, which selectively adsorb circulating granulocytes and monocytes/macrophages, is undergoing study in patients with inflammatory bowel disease.[39]

Photopheresis is an automated extracorporeal photochemotherapy treatment that involves leukapheresis, extracorporeal photoactivation with a light-sensitizing agent, 8-methoxypsoralen (8-MOP) and ex vivo ultraviolet A irradiation, and reinfusion of the leukocyte fraction (Fig. 152–6). The light-sensitizing agent is often delivered directly to

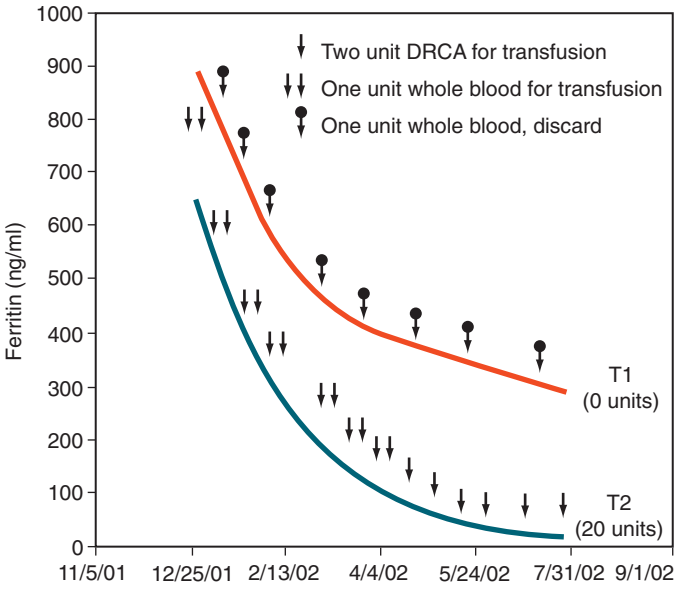

Figure 152–5 One twin was treated with manual phlebotomy (T1), and the other with double red cell apheresis (DRCA) (T2). In the same time period, ferritin levels declined more rapidly and to lower levels in the twin treated with double red cell apheresis. (*Unpublished data from Bolan CD, Leitman SF, with permission of the authors.*)

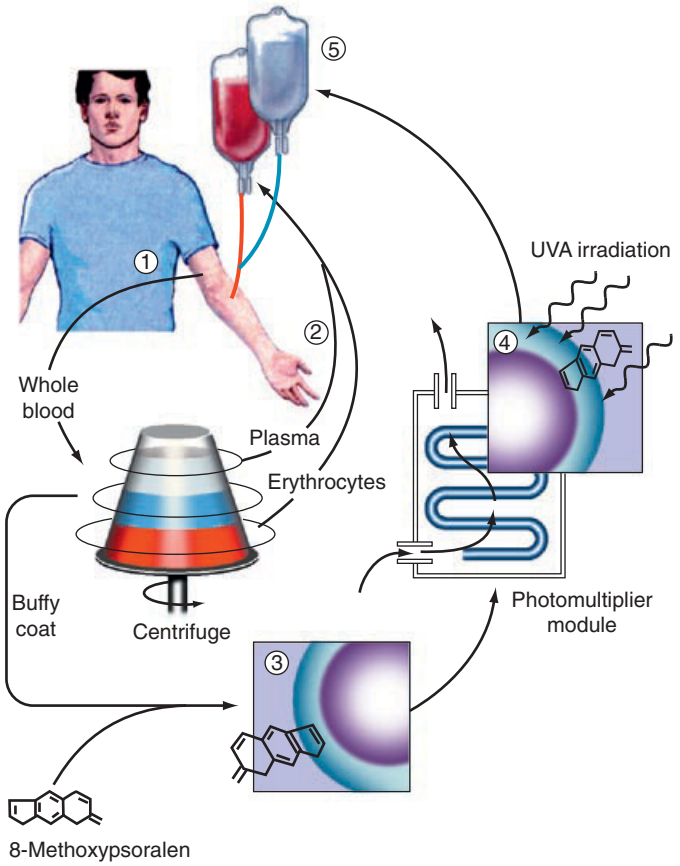

Figure 152–6 Overview of a photopheresis procedure. 1) Vascular access is achieved by placement of a peripheral intravenous line or through a temporary central venous catheter. Whole blood is withdrawn from the patient, mixed with an anticoagulant solution, and pumped to a centrifuge where it is separated into plasma, red cell, and mononuclear cell (buffy coat) fractions by elutriation. 2) Following the collection of each mononuclear cell fraction, the uncollected red cells and plasma are pumped from the plasma/return bag through a blood filter and returned to the patient. 3) The mononuclear cell fractions are mixed with 8-methoxypsoralen and then 4) pumped through a sterile cassette surrounded by UV-A bulbs, resulting in a controlled rate and amount of UV-A exposure. 5) The treated cell fraction is filtered and returned to the patient.

the extracorporeal leukocyte fraction, which may reduce the adverse effects such as nausea and vomiting associated with oral administration. The mechanism of action of photopheresis is unclear, but may involve induction of apoptosis in pathogenic T-lymphocytes and induction of a dendritic cell-mediated cytotoxic T-cell response. This therapy has minimal toxicity and is highly effective in the treatment of patients with advanced cutaneous T-cell lymphoma.[40,41] Other disorders reported to respond to photopheresis therapy include cardiac and other solid organ graft rejection,[42,43] and graft-versus-host disease (GVHD) following bone marrow transplantation in patients who do not respond to standard immunosuppressive therapy.[44,45] Acute adverse effects include skin erythema, low-grade fever, and transient hypotension. Anemia due to incomplete reinfusion of red cells may occur in patients undergoing long-term photopheresis.[41]

Plateletpheresis

Therapeutic plateletpheresis is generally reserved for patients with myeloproliferative disorders and hemorrhage or thrombosis associated with an increase in circulating platelets. Many centers consider using plateletpheresis when the patient's peripheral platelet count is greater than $10^6/mm^3$, although no consistent relation between the level of platelet elevation and the occurrence of symptoms has been found, and no generally accepted assay of platelet dysfunction predicts which patients are at risk.[46,47] A single cytapheresis procedure can lower the platelet count by 30% to 50%. Plateletpheresis can have dramatic effects for selected patients such as those with evolving digital gangrene. Attempts to maintain thrombocythemic patients at normal platelet counts by cytapheresis alone have not been successful; more practical long-term chemotherapy should be instituted concurrently. As most patients with thrombocytosis do not develop symptoms, including patients with myeloproliferative disorders, prophylactic plateletpheresis is unwarranted regardless of the platelet count.[47]

THERAPEUTIC PLASMAPHERESIS

Common clinical indications for therapeutic plasmapheresis are outlined in Table 152–2. Most procedures are performed for treatment of immunologic and hematologic disorders. A course of plasmapheresis generally consists of five to seven exchanges of 1 to 1.5 plasma volumes each, either daily or with an interval of 1 to 2 days between procedures, although the course of therapy will vary depending on the specific disease indication and rate and duration of response. Several expert committees have published practice guidelines for using plasmapheresis in a wide variety of disease states.[48–50] Some of the least controversial indications for plasmapheresis are supported by small series of uncontrolled cases that rely on some objective clinical or laboratory measurement of patient improvement.

Table 152–2 Common Indications for Therapeutic Plasmapheresis

Hematologic diseases (including blood cell–specific autoimmune diseases)
Thrombotic thrombocytopenic purpura
Idiopathic thrombocytopenic purpura (immunoabsorption)
Hyperviscosity
Posttransfusion purpura
Cold agglutinin syndrome
Coagulation factor inhibitors
ABO-mismatched marrow transplant (recipient)
Autoimmune diseases
Cryoglobulinemia
Rheumatoid arthritis (immunoadsorption, lymphoplasmapheresis)
Myasthenia gravis
Goodpasture syndrome
Guillain–Barré syndrome
Chronic inflammatory demyelinating polyneuropathy
Metabolic diseases
Homozygous familial hypercholesterolemia (selective adsorption)
Refsum disease
Other
Drug overdose and poisoning

Hematologic Indications

Two of the most common indications for plasmapheresis are treatment of thrombotic thrombocytopenic purpura (TTP) and treatment of clinical syndromes associated with paraproteinemias. Plasma exchange with fresh-frozen plasma (FFP) replacement has been estimated to improve survival rates of patients with TTP from 10% to more than 75%. Comprehensive reviews of the clinical and laboratory evaluation and treatment of patients with suspected TTP, including management with plasma exchange therapy, have been published.[51,52] Treatment usually involves daily single-volume plasma exchange with both frequency and duration of treatment guided by clinical response, increase in platelet count to 100,000/μL or more, and evidence of declining hemolysis as measured by normalization of serum L-lactate dehydrogenase (LDH) and decline in the number of schistocytes on the peripheral blood smear. Despite initial reports of improved response rates in certain patients, recent experience suggests that the use of cryoprecipitate-poor plasma may not be more effective than the use of standard FFP as a specific replacement fluid for plasma exchange in patients with TTP.[53]

The effectiveness of plasma exchange in this setting may derive from removal of antibody to and/or replacement of the von Willebrand factor-cleaving zinc metalloprotease, ADAMTS13.[54–56] However, patients with clinical features of TTP and only moderate ADAMTS13 deficiency or even normal activity may respond to plasma exchange.[57] Plasma exchange for hematopoietic progenitor cell transplant recipients with clinical features of TTP has proved far less efficacious. This syndrome likely differs in pathogenesis from classic TTP.

Small, uncontrolled studies and extensive clinical experience support the use of plasmapheresis as an adjunctive therapy for patients with paraproteinemia and hyperviscosity syndrome, and with some paraproteinemias in the absence of hyperviscosity.[58,59] Comprehensive review articles describing the rationale and treatment schedules for plasmapheresis in patients with a variety of paraproteinemias, including cryoglobulinemia and Waldenström macroglobulinemia, and other hematologic-oncologic indications, have been published.[60,61]

Low-Density Lipoprotein Apheresis and Other Metabolic Disease Indications

Evidence that cutaneous lesions and vascular lesions regress in individuals with familial hypercholesterolemia as low-density lipoprotein levels are controlled by plasmapheresis has encouraged the use of apheresis column absorption procedures in patients with homozygous disease and in poorly controlled heterozygous patients. Low-density lipoprotein apheresis is a procedure for removing apolipoprotein B-containing lipoproteins specifically from the blood by a variety of techniques, including dextran sulfate cellulose adsorption, immunoadsorption, and heparin-induced extracorporeal precipitation. Short-term safety and efficacy have been demonstrated.[62] Patients have now been treated successfully for several years; however, additional experience with this therapy will be required to prove long-term benefit for refractory hypercholesterolemia and coronary artery disease.

Simple plasma exchange may be used in patients with other inherited metabolic diseases, such as Refsum disease.[63] The frequency of

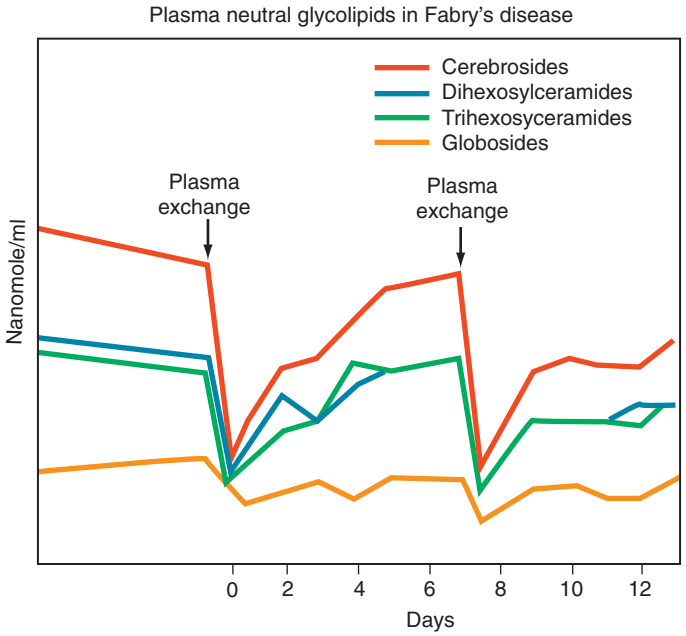

Figure 152–7 Plasma exchange to remove plasma neutral glycolipids in a patient with Fabry disease. The plasma lipid recovery curve appears to be biphasic, reflecting initial reequilibration from tissue stores and subsequent new synthesis of that glycolipid.

exchange depends primarily on total body burden, rate of synthesis, and plasma concentration of the solute to be removed (Fig. 152–7). Less evidence exists to support a role for repeated treatments in these diseases.

Immune Disease Indications and Immunoadsorption Therapies

Plasma exchange appears to have at least a temporary adjunctive role in managing some rheumatic diseases and other immune disorders characterized by circulating autoantibodies. Early success was reported in patients with Goodpasture syndrome, a disorder characterized by a specific pathogenic autoantibody directed against the renal glomerular and pulmonary alveolar basement membrane. Plasmapheresis has demonstrated similar success in myasthenia gravis, pemphigus, and Eaton-Lambert syndrome. Although nonselective plasma exchange has been used in a variety of other rheumatic diseases such as systemic lupus erythematosus and rheumatoid vasculitis, with the exception of treatment of patients with Goodpasture syndrome (in which plasma exchange is considered first-line adjuvant therapy), such use remains unproved and should be reserved for circumstances where a vital organ or life itself is endangered. In some immune disorders, such as immune thrombocytopenic purpura (ITP) and immune inhibitors to coagulation proteins, plasma exchange may be helpful during a catastrophic event, but in general, benefit of nonselective plasma exchange therapy is not established.[64]

Plasma exchange appears to be a useful therapeutic option in renal transplant patients with refractory humoral rejection and also may be used to overcome ABO and HLA incompatibilities between renal transplant patients and their only available donors. Montgomery et al have published several studies showing successful reversal of acute humoral rejection mediated by HLA-specific donor antibody using a combination of plasmapheresis and intravenous immune globulin.[65] They have also demonstrated the use of a conditioning regimen consisting of pretransplant plasmapheresis, immunosuppressive medications, and low-dose CMV immune globulin to effectively reduce donor-specific antibody and isoagglutinin titers, with and without posttransplant splenectomy and anti-CD20 treatment.[66,67] Another promising indication for plasma exchange is treatment of patients with focal segmental glomerulosclerosis (FSGS), for primary disease refractory to standard immunosuppressive therapy and for treatment of patients with recurrent disease after renal transplantation.[68]

Two immunoadsorption columns have been approved in the United States for removal of autoantibodies to factor VIII or factor IX (Immunosorba staphylococcal protein A–agarose column), and treatment of ITP and rheumatoid arthritis (Prosorba staphylococcal protein A–silica column). Several case series describe the use of immunoadsorption for patients with immune inhibitors to factor VIII or factor IX.[69–71] A phase III, multicenter, sham-controlled randomized study of staphylococcal protein A column immunoadsorption shows a significant increase in clinical response in adult patients with longstanding rheumatoid arthritis.[72] Sparse published evidence exists to support the use of immunoadsorption therapy in patients with chronic ITP refractory to standard medical management.

Plasmapheresis is also an effective first- or second-line therapy in selected patients with certain neurologic disorders. Controlled clinical trials of plasmapheresis have demonstrated efficacy in at least two of the polyradiculoneuropathies.[73,74] However, intravenous immunoglobulin alone may be equally effective in the treatment of severe Guillain–Barré syndrome.[75] A review of published studies of therapeutic plasmapheresis in multiple sclerosis (MS) concludes that plasmapheresis may be an effective therapy in acute or chronic progressive MS when conventional corticosteroid or other immunosuppressive drug therapies have failed.[76] The long-term benefit for patients with chronic progressive MS remains controversial.[77] Anecdotal reports of dramatic responses to plasma exchange in patients with primary autoimmune autonomic failure support the hypothesis that antibodies to ganglionic acetylcholine receptors are the causative agents of the severe nervous system failure characteristic of this disease.[78]

REPLACEMENT FLUIDS FOR PLASMA EXCHANGE

The success of therapeutic apheresis procedures seldom depends on the composition of the replacement solution that is used; the single exception is TTP (discussed in the previous section). With therapeutic plasmapheresis for most other disorders, the primary function of the replacement solution is to maintain intravascular volume. Additional requirements include restoration of important plasma proteins, maintenance of colloid osmotic pressure, maintenance of electrolyte balance, and preservation of trace elements lost during a prolonged course of plasmapheresis procedures. In moderately well-nourished patients, homeostatic mechanisms normally obviate the need for precise plasma replacement, and 5% albumin in normal saline or combinations of albumin and crystalloid are usually sufficient. Commonly used is 60% to 80% replacement by colloid, with the crystalloid component consisting of a combination of normal saline and an anticoagulant. Patients with clinical conditions such as hypotension, hypoalbuminemia, or preexisting coagulopathies should receive solutions prepared specifically to meet their individual requirements. Routine supplementation with calcium, potassium, or immunoglobulins is unnecessary. However, for large-volume apheresis procedures to collect PBSCs, intravenous calcium supplementation is beneficial (discussed in the following section). Because less than 500 mL is removed during most cell collection procedures and therapeutic cell depletions, no volume replacement beyond the anticoagulant and saline priming solution is required.

Problems of decreased availability and high cost of albumin have led some centers to develop protocols for alternatives to plasma-derived volume expanders, such as hydroxyethyl starch (HES), for full or partial volume replacement with plasma exchange.[79] These solutions are generally well tolerated. However, extensive replacement with HES in patients undergoing longer courses of plasmapheresis, especially those with impaired renal function, can result in diffuse tissue accumulation of the larger starch molecules (acquired lysosomal storage).[80]

COMPLICATIONS OF THERAPEUTIC APHERESIS

Automated apheresis is a minimal-risk procedure for normal healthy donors. The current generation of blood cell separators is remarkably reliable and equipped with sensitive detection and alarm systems to alert the operator to potential problems. Nevertheless, serious morbidity and rare deaths have been associated with therapeutic procedures. In most reports, deaths are related to either complications associated with the use of central venous access catheters or to cardiac and respiratory problems in patients who were critically ill before apheresis; in the latter, the contributory role of the apheresis procedure is often questionable. The most common adverse effects of therapeutic apheresis are citrate-induced hypocalcemia, allergic reactions (usually to donor plasma or other blood components), vasovagal reactions, and hypovolemia.[81] If transient paresthesia and mild vasovagal events are excluded, approximately 5% of all therapeutic apheresis procedures have medical complications.[82] The frequency of adverse reactions is influenced by the experience of the operator and the nature of the patient population under treatment.[83]

Expected and predictable effects of therapeutic apheresis include alterations in laboratory parameters due to removal and dilution by replacement fluids. A 5% to 15% decrease in hemoglobin-hematocrit, a 20% to 30% decrease in platelet count, and mild transient increase in leukocyte count are commonly observed.[84] Significantly but transiently abnormal coagulation test results are often observed (recovery generally occurs within 48 hours after a single-volume exchange procedure), as well as clinically insignificant decreased levels of other plasma proteins after serial plasma exchange procedures.[84,85]

The most common adverse effect of both donor and therapeutic apheresis procedures is symptomatic hypocalcemia caused by infusion of calcium-chelating citrate ions in the anticoagulant, and, if used as replacement fluid, anticoagulated donor plasma. It is usually manifested by mild perioral or acral paresthesia, or both, requiring no intervention other than slowing the reinfusion rate. The benefit of oral calcium supplements in this setting is questionable, although the practice is widespread. Hyperventilation may exacerbate the symptoms of hypocalcemia. More severe citrate toxicity is uncommon; signs may range from involuntary carpopedal spasm, nausea, and vomiting, to frank tetany with spasm in other muscle groups, including life-threatening laryngospasm and grand mal seizure.[86] Severe toxicity is most commonly experienced by small patients, particularly women, when the blood flow rate is rapid and the procedure is prolonged beyond a few hours. Symptoms correlate inversely with the level of ionized calcium.[87] Extremely low concentrations of ionized calcium are encountered routinely in therapeutic procedures that process more than 15 L of blood. Acute severe hypocalcemia leading to fatal cardiac arrhythmia has been reported in patients who have undergone apheresis. Controlled infusions of 10% calcium gluconate or calcium chloride are effective in the management of these complications. Because metabolism of citrate occurs predominantly in the liver and kidney, patients with conditions affecting these organs are at increased risk for severe citrate reactions. Studies of therapeutic plasma exchange procedures and of PBSC donations performed with and without calcium gluconate or calcium chloride infusion show the effectiveness of continuous calcium infusion for the prevention of mild to moderate citrate toxicity (Fig. 152–8).[87,88]

In a study of plateletpheresis donors, Bolan et al documented sustained effects of citrate infusion on bone metabolism demonstrated by changes in alkaline phosphatase, osteocalcin, parathyroid hormone, and 1,25-dihydroxyvitamin D levels, suggesting the potential for long-term effects on bone metabolism in these donors.[89] Magnesium, another divalent cation, is also bound by citrate. Despite decreases in serum ionized magnesium levels to 39% below baseline, clinical effects are not typically observed, even during large-volume leukapheresis procedures.[90]

The most severe allergic complications occur when plasma is used as the replacement solution, and this risk increases with repeated exposure.[83] Allergic reactions to ethylene oxide, an agent used in the sterilization of plastic disposable equipment, have been reported.[91] Intravenous diphenhydramine is usually effective in managing allergic reactions; premedication with steroids and precautions against anaphylaxis may be necessary for sensitized individuals. Atypical (hypotension and flushing) and anaphylactic reactions have been reported in patients receiving angiotensin-converting enzyme inhibitors undergoing different apheresis procedures, including immunoadsorption with staphylococcal protein A columns. These medications should be discontinued for at least 24 hours before apheresis.[92]

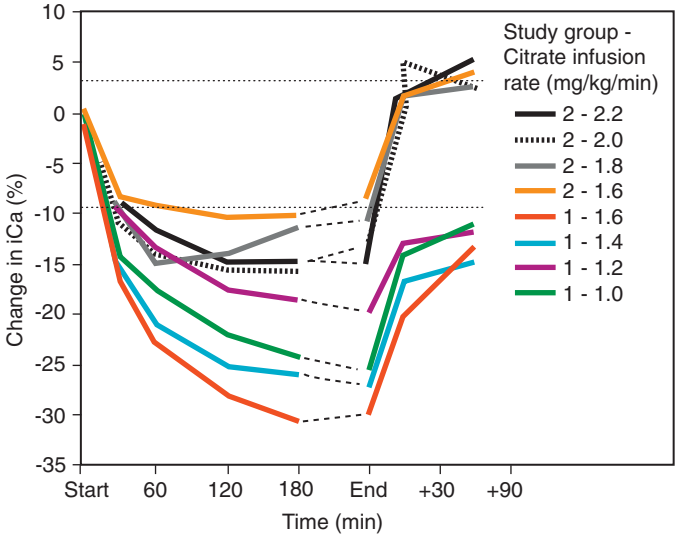

Figure 152–8 Levels of iCa are markedly lower in procedures performed without prophylactic Ca infusion and remain below the reference range 90 minutes after completion of apheresis. Dotted lines indicate upper and lower limits of the reference range. Open symbols represent procedures without prophylactic Ca; solid symbols represent those with Ca infusion. Dashed lines between 180 minutes and end-procedural values (End) reflect varying procedure duration. (*From Bolan CD, Cecco SA, Wesley RA, et al: Transfusion 2002;42:935–946, used by permission*).

Unlike donors undergoing apheresis for donation of red cells, platelets, or plasma, donors undergoing apheresis for collection of therapeutic granulocytes are stimulated with steroids and G-CSF prior to donation. The well-known association of long-term steroid treatment and posterior subcapsular cataracts has not been felt to be relevant in the context of short-term steroid stimulation for donor granulocyte mobilization. However, a small observational study showed that the frequency of posterior subcapsular cataracts was greater in granulocyte donors than in an age-matched plateletpheresis donor control group, suggesting that granulocyte donors may be at increased risk for certain types of cataract formation.[93]

Serious complications indirectly associated with therapeutic apheresis include adverse consequences of vascular access; namely, retroperitoneal or pericardial hemorrhage, pneumo- or hemothorax, thrombosis, nerve damage, and infection. A retrospective review of 381 therapeutic plasma exchange procedures at one institution reported an approximately 1% incidence of severe complications, all of them related to central venous catheters.[94]

CELLULAR THERAPY

Blood cell separators developed for hemapheresis are used increasingly to collect peripheral blood cells for novel forms of cellular therapy. The most common application of apheresis technology for cell therapy indications is the collection of HPC from peripheral blood after administration of recombinant hematopoietic growth factor or chemotherapy, or both, to "mobilize" large numbers of HPC into the circulation. The collected mononuclear cell fraction

contains a subset of progenitor cells that, on infusion, can home to and reconstitute the bone marrow in patients who receive ablative radiation or chemotherapy, or both. In the cell-processing laboratory, techniques have been developed for removing T lymphocytes, for purging tumor cells, and for selecting progenitor cells from bone marrow harvests and PBSC collection products. Donor leukocytes obtained from leukapheresis procedures are being used and studied, either with minimal further processing or in highly manipulated forms, as immunotherapy for leukemia, solid tumors, and viral complications of transplantation. Preliminary studies promise a role for autologous HPCs and other mononuclear cells that may be further manipulated in the laboratory and used as "vehicles" for experimental immune therapies in patients with cancer or infectious diseases, and for gene therapies.

Peripheral Blood Stem Cells

Pluripotent HPCs, and quite possibly primordial hematopoietic stem cells capable of reconstituting the bone marrow and the immune system, have long been known to circulate in the peripheral blood.[95] Numerous studies have confirmed the potential for rapid and durable engraftment of PBSCs mobilized into the circulation by hematopoietic growth factors, harvested by large-volume leukapheresis procedures, and subsequently administered to patients with marrow aplasia following high-dose chemotherapy. The concentration of hematopoietic stem cells in the peripheral blood can be increased by the administration of cytokines such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), and by the administration of chemotherapy. $CD34^+$ hematopoietic cell numbers in the peripheral blood generally rise 20- to 40-fold (from 1 to 3 cells/μL to 40 to 70 cells/μL) following administration of G-CSF alone, and they increase 100- to 1000-fold when chemotherapy rebound is enhanced by administration of G-CSF.[96] Efforts to define optimal collection conditions have been limited by the lack of a standardized assay; however, time and level of increase of donor peripheral blood WBC and $CD34^+$ cell counts after administration of mobilizing agents have proved to be useful indicators.[97,98] Hematopoietic colony assays have been used to characterize and quantify stem cells collected by hemapheresis. Colony assays have limited immediate utility because they require a 10- to 14-day incubation period before results are obtained. Assays that use the CD34 antigen as a marker for primitive HPCs can be used to predict the yield of PBSCs collected by leukapheresis and have the advantage of a relatively rapid turnaround time. Despite ongoing problems with interlaboratory standardization, flow cytometric analysis of cells labeled with a fluorochrome-conjugated CD34 antibody are being used increasingly for "real-time" decision making about the timing and adequacy of PBSC collections.

Several clinical scale devices for $CD34^+$ cell enrichment of leukapheresis collections by immunoabsorption or immunomagnetic techniques are available. This "positive selection" of $CD34^+$ hematopoietic cells also results in reduced numbers of cells that do not express the CD34 antigen, such as T lymphocytes. T-cell-reduced products may confer a lower risk of GVHD, and the ability to produce apheresis products enriched for $CD34^+$ cells facilitates graft manipulations for experimental cell therapies such as ex vivo expansion of $CD34^+$ cells. However, some studies suggest a higher incidence of engraftment failure and possibly delayed immune reconstitution in certain patient populations when transplants are performed with highly purified CD34-selected, T cell-depleted products.[99] As yet, no data confirm the clinical benefit of $CD34^+$ cell selection strategies. Please see Chapter 109, Graft Engineering, for a more complete discussion of ex vivo HPC enrichment and T-cell depletion.

Several problems have slowed enthusiastic universal adoption of PBSC transplants for all recipients. Concerns remain regarding the hypothetical long-term effects of exposure of healthy donors to growth factors. The possible risks of donor G-CSF administration and leukapheresis must be weighed against less evidence of benefit of PBSC compared to bone marrow (or against the rapid availability of cord blood) for pediatric recipients.[100] Also, some clinical data suggest the possibility that allogeneic PBSC transplant may result in more frequent chronic graft-versus-host disease in certain patient populations than occurs with bone marrow transplant, without obvious reciprocal benefit with regard to graft-versus-leukemia effect. [Schmitz N et al: Long-term outcome of patients given transplants of mobilized blood or bone marrow: a report from the International Bone Marrow Transplant Registry and the European Group for Blood and Marrow Transplantation. Blood 108(13): 4288, 2006].

Patient Management Issues for Therapeutic Apheresis

Important issues to consider when preparing a patient for therapeutic apheresis, for monitoring the patient during the procedure, and for managing the patient after removal from the apheresis device include:

Preparation

- Volume considerations—Calculate volume to be processed or exchanged; order replacement solutions; assess patient volume status
- Vascular access—Assess need for apheresis line placement. Note that not all large catheters are suitable for apheresis procedures.
- Medications—Evaluate impact of medications (coumadin, platelet inhibitory agents, ACE inhibitors) and indications to suspend certain medications. Albumin-bound medications may be depleted by apheresis.
- Cell counts—Patient may require transfusion for preprocedure anemia or thrombocytopenia
- Electrolytes—Assess risks for citrate toxicity; order calcium replacement solutions if indicated

Procedure

- Volume considerations—Monitor replacement fluids (saline/albumin ratio). Rapid infusion of refrigerated solutions may cause hypothermia.
- Vascular access—Observe for impaired, intermittent, or obstructed flow. Kinked tubing can result in hemolysis.
- Medications—Limitations on blood or citrate flow rate due to symptomatic citrate-induced hypocalcemia may necessitate addition of anticoagulant to the final apheresis product or inclusion of heparin in the anticoagulant regimen.
- Cell counts—Consider impact of very high or low cell counts on device settings and procedure efficiency
- Electrolytes—Continually monitor for adverse citrate effects; bolus or continuous intravenous calcium administration may be required

Postprocedure management:

- Volume considerations—Review net volume balance and consider additional infusion or administration of diuretic if needed
- Vascular access—The decision to remove the apheresis catheter should include the possibility of additional apheresis or procedures; monitor for complications associated with maintenance or removal of venous catheter
- Medications—Determine when to restart medications; consider impact of transiently reduced coagulation factor levels
- Cell counts—Patient may require transfusion for postprocedure thrombocytopenia; monitor cumulative red cell and platelet loss following repeated procedures
- Electrolytes—Assess for imbalance postprocedure, with attention to ionized calcium and magnesium, as indicated by symptoms

For allogeneic donors, the discomfort and inconvenience of multiple-day cytokine administration may be a significant deterrent. Most donors experience some degree of malaise and bone pain, and some donors require hospitalization for more serious adverse reactions to G-CSF administration. Splenic enlargement occurs commonly, and several instances of splenic rupture have been reported.[101] Citrate toxicity is a common complication of PBSC collections; although usually mild and transient, it may be severe and even life threatening in some individuals (see previous section). Venous access requires large-bore multilumen catheters, and these appear particularly susceptible to clotting, especially when patients receive recombinant cytokine stimulation. Hemorrhage, especially in thrombocytopenic patients, is another potentially severe complication of central venous catheter placement. Some patients who have received multiple prior cycles of chemotherapy and a small proportion of normal healthy donors, referred to as "poor mobilizers," fail to respond adequately to mobilization regimens.

Finally, a problem associated with all sources of HPC for transplantation is that the cells may be stored frozen in liquid nitrogen with the cryoprotectant dimethylsulfoxide (DMSO). Cryopreservation is expensive, and rapid infusion of DMSO has been associated with cardiac arrhythmias, hypertension, nausea, and vomiting. Fortunately, DMSO toxicity can be minimized by appropriate premedication, careful attention to infusion rates, and also by washing the thawed product prior to administration, although this strategy does result in measurable loss of progenitor cells. Please see Chapter 108 for a more thorough discussion of practical aspects of HPC mobilization and collection.

Adoptive Immunotherapy

The ability to mobilize and collect large numbers of mononuclear cells, along with the ability to expand these cells ex vivo and in vivo, has led to the development of therapeutic cell products for adoptive immunotherapy of some neoplastic and infectious diseases. Apheresis components collected from nonmobilized donors consist predominantly of mature blood cells, whereas those obtained from growth factor-mobilized donors contain large numbers of HPCs, mature mononuclear cells, and a variety of other cell types. Cell collections that are intended for adoptive immunotherapy may be minimally manipulated after apheresis collection, or they may be enriched for specific cell populations and/or modified ex vivo by addition of small molecules or by insertion of transgenes.

Donor Leukocytes-Lymphocytes for Infusion

Early studies of adoptive immunotherapy involved infusion of unmanipulated donor leukocytes (donor leukocyte-lymphocytes for infusion [DLI] or therapeutic cells [TC]) to chronic myeloid leukemia patients with relapse after bone marrow transplantation to induce a graft-vs-leukemia effect resulting in cytogenetic remission.[103] A retrospective analysis of DLI for relapsed hematologic malignancies after allogeneic bone marrow transplantation documents a 60% complete response rate in chronic myeloid leukemia patients overall, with an even higher response rate in patients with relapsed chronic-phase disease.[104] DLI has also effected complete or partial remission in patients with relapsed multiple myeloma after allogeneic bone marrow transplantation.[105] Newer strategies include administration of DLI after nonmyeloablative conditioning and allogeneic HPC transplant for treatment of several malignant and nonmalignant diseases.

Because small numbers of cells generally suffice, donor cells collected by leukapheresis are often aliquoted and cryopreserved for repeated treatment over a period of months. Response to DLI is often associated with the development of acute and chronic GVHD, although the severity is usually mild to moderate and controlled by immunosuppressive therapy. Another serious complication of DLI is transient or persistent marrow aplasia, which may be attributed to the destruction of residual host hematopoiesis by the infused mononuclear cells before recovery of normal donor hematopoiesis.[106]

Cytotoxic T Lymphocytes and Other Therapeutic Cell Products

Leukapheresis is also used to obtain mononuclear cells that can be manipulated ex vivo using cell selection and cell culture techniques to generate activated or cytotoxic lymphocytes to treat hematologic malignancies and solid tumors. The ability to identify and isolate human tumor antigens by advanced molecular genetic techniques has resulted in the formulation of other extensively manipulated cell products for adoptive immunotherapy of cancer. Some strategies use peptides derived from tumor antigens to sensitize antigen-presenting cells, such as dendritic cells in vitro, which can then be either directly infused as cancer vaccines, or can be used to sensitize tumor infiltrating lymphocytes or unselected peripheral blood lymphocytes ex vivo for reinfusion as specific antitumor effector cells. Techniques to translate these experimental strategies into clinically practicable therapies are under development.

In addition to treatment of neoplastic diseases, highly manipulated donor lymphocyte products are being developed as prophylaxis and therapy for serious infectious diseases, including infectious complications of bone marrow transplantation such as Epstein–Barr virus-associated lymphoproliferative disorders, adenovirus, and cytomegalovirus infection.[107] Early experience shows that adoptive immunotherapies for infection are promising, but the technology is extremely complex and prohibitively expensive at this stage of development. Please see Chapter 111 for a more complete discussion of experimental cell therapies.

Cellular Gene Therapy

Cellular gene therapy is a technique in which a functioning gene is inserted ex vivo into somatic cells to correct an inborn genetic error or to provide some new function to the cell. The gene-modified cells may be purified, concentrated, expanded, or infused without further manipulation. Successful therapy requires gene identification and isolation, efficient insertion and expression in the target cells, and sufficient circulation or engraftment of the corrected cells after infusion into the patient.

The ability to collect large numbers of lymphocytes and HPCs and to expand and manipulate their growth and differentiation in vitro makes these cells logical candidates for cellular gene therapy. Peripheral blood lymphocytes are easily collected with automated cell separation devices, can be expanded in culture systems, and can withstand cryopreservation and thawing with good recovery of viability and function. They can circulate in vivo for months and possibly years after infusion, and may persist even longer at tissue sites. Permanent correction of genetic and acquired defects might be effected by inserting the missing or defective gene into HPCs. HPCs are easily accessible in bone marrow, mobilized peripheral blood by apheresis, and umbilical cord blood. They can be concentrated to high purity using immunologic cell selection techniques, and can be cryopreserved in DMSO and subsequently thawed with good recovery of viability and engraftment potential. Pluripotent cells comprise only 1% to 2% of the total progenitor cell pool, but because of the ability of the pluripotent cells to maintain hematopoiesis for years, correction of even a small number of cells could, in theory, provide a patient with a several-log increase in gene-modified cells within each hematopoietic lineage. Unfortunately, gene transduction of long-lived progenitors has proved extremely inefficient, and risks associated with integration of the vector into the target cell DNA, including reports of ALL-like complications due to retroviral transduction of $CD34^+$ cells, must be addressed before the promise of cellular gene therapy is fulfilled. Please see Chapter 110 for a more complete discussion of gene transfer for hematologic disorders.

CHAPTER 153

TRANSFUSION REACTIONS

Yan Yun Wu, Simon Mantha, and Edward L. Snyder

A *transfusion reaction* can be defined as any untoward reaction that occurs as a consequence of infusion of blood or one of its components. Reactions are considered to be acute when they occur during transfusion or within several hours after the transfusion has been terminated (Table 153–1). Reactions also can be classified as delayed. Delayed hemolytic transfusion reactions, for example, usually occur days after the transfusion. Other types of delayed reactions occur long after the blood has been infused—months or even years—as in the case of some transfusion-transmitted diseases. From 1995 to 2004, there were 665 transfusion related fatalities reported to the FDA.[1] This chapter reviews various types of transfusion reactions.

HEMOLYTIC TRANSFUSION REACTIONS

Hemolytic transfusion reactions are caused by the immune-mediated lysis of transfused red cells. Immune-mediated hemolysis can be divided conveniently into four categories by time of reaction (acute or delayed) and by site of hemolysis (intravascular or extravascular). The four types are acute intravascular, acute extravascular, delayed intravascular, and delayed extravascular reactions (Table 153–2).

ACUTE INTRAVASCULAR HEMOLYTIC TRANSFUSION REACTIONS

Acute reactions occur when incompatible red cells are transfused into a patient who already possesses the corresponding antibody, and a reaction occurs within minutes. Because of naturally occurring ABO antibodies, infusion of ABO-incompatible blood is the most likely cause of a clinically significant acute intravascular hemolytic transfusion reaction.[2] Such a reaction could occur, for example, after transfusion of A red cells into an O recipient who has significant amounts of circulating anti-A. Although the titer and avidity of the antibody affect the extent of the hemolytic reaction, the clinical severity of an ABO-incompatible blood transfusion is greatly influenced by the degree of complement activation and cytokine stimulation. In an ABO-incompatible transfusion reaction, fixation of the C5b-9 complex occurs with release of C3a and C5a (anaphylatoxins 1 and 2, respectively). These low-molecular-weight peptides produce bronchospasm, mast cell degranulation, hypotension (C3a), and pulmonary dysfunction (C5a); the latter is secondary to migration of granulocytes to the pulmonary capillary bed, resulting in $\dot{V}/\dot{Q}$ abnormalities.[3] Fixation of the C5b-9 complement membrane attack complex produces pores in the red cell membrane, and the resultant osmotic lysis produces hemoglobinuria and hemoglobinemia.[3,4] The sine qua non of an acute intravascular hemolytic transfusion reaction is the presence of red plasma and red (dark) urine.

It is critical to distinguish, as quickly as possible, hemoglobinuria and hemoglobinemia resulting from an acute hemolytic transfusion reaction from similar signs caused by other causes. Hemoglobinuria can be confused with hematuria from bladder hemorrhage or myoglobinuria. Hemoglobinemia caused by non-immune-mediated lysis can result from mechanical hemolysis from an improperly collected blood sample. The direct antiglobulin test (DAT) usually becomes positive in an immune hemolytic reaction (if tested before all the incompatible red blood cells [RBCs] are destroyed); preparation of an antibody eluate is often necessary to identify the offending antibody. An antibody elution is the removal of antibody from the red cell by various physical or chemical techniques with concentration of the antibody in the eluting solution, which is usually albumin or saline. This antibody-containing solution, the eluate, is then treated as a serum sample and used to identify the offending blood group antibody.

The time lost in making a clinical diagnosis can turn a mild treatable reaction into one that is life-threatening. A full-blown acute intravascular hemolytic transfusion reaction is a true medical emergency. Antibody-coated red cell stroma produced during an immune hemolytic transfusion reaction induces renal vasoconstriction, resulting in acute tubular necrosis.[3,5] Another contributing cause of ischemic renal failure involves the release of free plasma hemoglobin. It has been shown that cell-free hemoglobin binds tightly to nitric oxide. Endothelium-derived relaxing factor, a powerful vasodilator, is composed in part of nitric oxide. By binding to nitric oxide, free plasma hemoglobin blocks relaxing factor and prevents renal vasodilation. This also promotes renal vasoconstriction and renal tubular ischemia, with eventual tubular necrosis.[6] The C3a and C4a generated may cause hypotension and tachycardia and may produce shock. Clinical symptoms include shortness of breath, chest pain, dizziness, and nausea. C3a can also cause bronchospasm, and C5a generation causes further pulmonary dysfunction. Many patients, curiously even anephric patients, often complain of lower back pain.[7] This is believed to be caused by ischemic muscle pain or vasospasm, rather than kidney pain from developing renal failure. In addition to complement components, cytokines and interleukins (ILs) also play a role in the clinical symptom complex associated with acute intravascular hemolytic transfusion reactions. For example, IL-1β, IL-6, and tumor necrosis factor-α (TNF-α) have pyrogenic activity; IL-8 is a neutrophil chemotactic and activating factor. These four cytokines have been generated in in vitro models of intravascular hemolysis and IgG-mediated red cell incompatibility.[8–11] The clinical variability of hemolytic transfusion reactions is likely explained by the relative balance of cytokine production in the transfusion recipient. Factors that increase the circulating levels of proinflammatory cytokines and chemokines result in more severe reactions.[12]

Therapy

Initial therapy consists of immediately stopping the transfusion, maintaining a patent intravenous line, supporting the cardiorespiratory system, and ensuring a brisk diuresis. Increasing renal blood flow is the best way to prevent acute oliguric renal failure. The usual therapeutic maneuver used to induce a diuresis is infusion of 0.9% NaCl or some other suitable crystalloid solution. Crystalloid should be given to maintain a urine output of 100 mL/hour for approximately 24 hours. Diuretics such as furosemide also can be used and are preferred by some to infusion of mannitol to increase intravascular volume.[13,14] Mannitol, if chosen, must be used with caution; if acute tubular necrosis (ATN) occurs before mannitol infusion, pulmonary edema may occur as a result of the acute increase in intravascular volume secondary to fluid expansion. Similarly, excessive

crystalloid infusion should be avoided in patients with borderline congestive heart failure. Renal damage must be minimized, however, and increasing renal blood flow helps to prevent anuric renal failure. The mechanisms responsible for the beneficial effect of increased renal blood flow likely include increased clearance of free hemoglobin, resulting in decreased binding of nitric oxide, and a return of more physiologic control of renal vasodilation. Creatinine and blood urea nitrogen (BUN) should be closely monitored; dialysis may be necessary for therapy of acute renal failure. As difficult as ATN therapy is, it is easier to treat a patient in the diuretic phase than in the oliguric phase of ATN. Support of blood pressure and respiration may require the use of vasopressors, bronchodilators, and, when necessary, intubation. High levels of dopamine cause vasoconstriction and should be avoided unless the patient's blood pressure requires high dosage. Disseminated intravascular coagulation (DIC) can occur in severe cases. The prothrombin time, partial thromboplastin time, and fibrinogen level should be closely monitored.

Laboratory Evaluation

Laboratory findings include hemoglobinuria, hemoglobinemia, and a haptoglobin level that is low to 0 mg/dL. During the hemolytic episode, the bilirubin (especially indirect bilirubin) usually increases only to 2 to 3 mg/dL if the patient has normal liver function. Elevations of bilirubin to 20 to 30 mg/dL are not seen in otherwise normal patients, even with florid hemolysis. Very elevated bilirubin levels are seen only in patients with concurrent hepatocellular disease, such as viral hepatitis or hepatic carcinoma. Because of the lysis of red cells, levels of lactate dehydrogenase (LDH) may rise markedly. If the patient shows no signs of vasomotor instability and if hemostatic and renal function is unchanged 24 to 36 hours after the incompatible transfusion, the episode can be considered to be over, with serious sequelae unlikely.

Although ABO-incompatible blood transfusions are the most common cause of an acute intravascular hemolytic transfusion reaction, other complement-fixing antigen–antibody systems, such as the Jk^a (Kidd) or Fy^a (Duffy) blood group systems, can also produce these reactions.[15]

ACUTE EXTRAVASCULAR HEMOLYTIC TRANSFUSION REACTION

In an extravascular hemolytic transfusion reaction, complement is not fixed at all or is fixed only to C3b. In either situation, because of the nature of the antigen–antibody reaction, complement activation with fixation of the C5b-9 complex does not occur. The presence of IgG on the red cell or fixation of complement to C3b results in an extravascular reaction because the antibody-coated cells are cleared by the IgG receptors in the spleen or the C3b receptors in the liver. Red cell lysis does not occur in the intravascular space. Largely as a result of the lack of generation of C3a or C5a, an extravascular hemolytic transfusion reaction does not usually present as a clinical emergency. It is characterized, as are most immune hemolytic transfusion reactions, by development of a positive DAT due to recipient

Table 153–1 Types of Acute Transfusion Reactions

Reaction Type	Presenting Signs and Symptoms
Acute intravascular hemolytic	Fever, chills, dyspnea, hypotension, tachycardia, flushing, vomiting, back pain, hemoglobinuria, hemoglobinemia, shock
Acute extravascular hemolytic	Fever, indirect hyperbilirubinemia, posttransfusion hematocrit increment lower than expected
Febrile reaction	Fever, chills
Allergic (mild)	Urticaria, pruritus, rash
Anaphylactic	Dyspnea, bronchospasm, hypotension, tachycardia, shock
Hypervolemic	Dyspnea, tachycardia, hypertension, headache, jugular venous distention
Septic	Fever, chills, hypotension, tachycardia, vomiting, shock
Transfusion-related acute lung injury	Dyspnea, decreased oxygen saturation, fever, hypotension

Workup of an Acute Intravascular Hemolytic Transfusion Reaction

If an acute transfusion reaction occurs:

1. *Stop blood component infusion immediately.*
2. Maintain intravenous access with a suitable crystalloid or colloid solution.
3. Maintain blood pressure, heart rate.
4. Maintain an adequate airway.
5. Give a diuretic or institute fluid diuresis, or both.
6. Obtain blood and urine for transfusion reaction workup.
7. Blood bank workup of suspected transfusion reaction:
   - Check paperwork to ensure correct blood component was transfused to the correct patient.
   - Observe plasma for hemoglobinemia.
   - Perform direct antiglobulin test.
   - Repeat compatibility testing (crossmatch).
   - Repeat other serologic testing as needed (ABO, Rh).
   - Analyze urine for hemoglobinuria.

   If intravascular hemolytic reaction is confirmed:
8. Monitor renal status (BUN, creatinine).
9. Monitor coagulation status (prothrombin time, partial thromboplastin time, fibrinogen).
10. Monitor for signs of hemolysis (lactate dehydrogenase, bilirubin, haptoglobin).
11. If sepsis is suspected, culture as appropriate.

Table 153–2 Hemolytic Transfusion Reactions: Serologic Presentation

Type	Antibody Detectable Initially	Primary Antibody Type	Degree of Complement Binding	Example
Acute intravascular	Yes	IgM	Full (C1–9)	ABO system
Acute extravascular	Yes	IgG	None/partial	Rh system
Delayed intravascular	No	IgG	Full (C1–9)	Kidd system
Delayed extravascular	No	IgG	None/partial	Duffy system

Adapted from Blood Transfusion Therapy: An Audiovisual Program, 2nd ed. Arlington, VA, American Association of Blood Banks, 1991.

red cell alloantibody binding to the circulating donor red cells. Moreover, an increase in indirect bilirubin, an increase in LDH, a decline in hematocrit, a decline in haptoglobin, and an increase in colorless urine urobilinogen occurs; hemoglobinuria and hemoglobinemia, however, are rarely present. The patient typically remains clinically stable; and renal failure, shock, and hemostatic abnormalities, such as DIC, are rarely seen unless the amount of incompatible blood infused is excessive. However, patients often have a low-grade fever, probably from the generation of IL-1 or other proinflammatory cytokines.[12]

The diagnostic test of choice is a DAT with an eluate. The eluate is performed to identify the antibody coating the red cells.[15] The positive DAT result reflects the patient's antibody (or antibodies) coating of the donor red cells. This is not an autoantibody (or antibodies), and the patient's own RBCs are not usually involved in the reaction.

Typically, an acute extravascular hemolytic transfusion reaction requires no special therapeutic intervention. Maintaining a good urine output and monitoring renal and hemostatic function are usually sufficient. The patient characteristically recovers in a few days as the offending donor red cells are cleared from the circulation. The pathogenic alloantibody can often be identified in the patient's serum. These acute transfusion reactions may occur if the patient's preexisting alloantibody was missed by the blood bank during the antibody screening process, if the unit of blood was labeled for the wrong patient, or if the unit was hung in error on the wrong patient.[2]

DELAYED HEMOLYTIC REACTIONS

The pathogenesis of a delayed intravascular transfusion reaction is similar to that described for an acute intravascular hemolytic reaction. However, in the delayed type, the patient develops the antigen–antibody reaction some time (3–10 days) after the transfusion. The process occurs more slowly and is less likely to present as a clinical emergency. Hemoglobinuria and hemoglobinemia can occur but often are less profound and pronounced than with an acute intravascular reaction. This probably is caused by the continual and gradual removal of antibody-coated red cells as the antibody titer rises and by the more gradual generation of C3a and C5a. The same serologic diagnostic and treatment concepts used for an acute intravascular hemolytic reaction apply here. However, the need for acute intervention is much less likely. Initiating a diuresis and monitoring renal and hemostatic function may be sufficient.

Delayed extravascular hemolytic transfusion reactions occur as well. Such antigen–antibody reactions often involve the Rh system. The clinical presentation is similar to that of an acute extravascular reaction: the patient often has no acute clinical symptoms but may present with a fever, a falling hematocrit, and the development of a new DAT. Serologic evaluation of a transfusion reaction in a patient who had a positive pretransfusion antiglobulin test result, caused by autoantibody or medication, may be confusing. Such a workup requires an expert serologist to detect the new alloantibody in the patient's serum and make a diagnosis of a hemolytic transfusion reaction.

FEBRILE NONHEMOLYTIC TRANSFUSION REACTIONS

A febrile nonhemolytic transfusion reaction (FNHTR) is suspected when a temperature rise of 1°C or more occurs during or after transfusion when no other cause can be found. In addition to fever, an FNHTR is often accompanied by shaking chills. Febrile reactions are believed to be largely mediated by cytokines. The cause of cytokine release can be related to antibody–leukocyte or antibody–platelet interactions. These could be due to cytotoxic or agglutinating antibodies in the recipient's plasma reacting against antigens present on transfused donor lymphocytes, granulocytes, or platelets.[16–19] These antibodies often have human leukocyte antigen (HLA) specificity, although they also may be neutrophil- or platelet-specific.[20,21] Conversely, the donor plasma also can contain antibody that can react with the corresponding cellular antigens in the recipient's blood.[22] The febrile reaction is mediated largely by the release of cytokines such as IL-1β, IL-6, and TNF-α from macrophages, monocytes, granulocytes, or lymphocytes.[23] IL-1 (endogenous pyrogen), through prostaglandin PGE_2 synthesis, probably stimulates the thermoregulatory center of the hypothalamus to produce fever. Other mediators such as macrophage inflammatory proteins (MIP-1) may also participate in the febrile response, but this reaction is not mediated through prostaglandin synthesis.[24] CD154 (CD40 ligand) derived from platelets may also be involved in febrile reactions by inducing cyclooxygenase-2 and PGE_2.[25]

These cytokines could be derived from three possible sources in the transfusion setting. The first is synthesis by recipient leukocytes in response to transfusion. The second is production by donor leukocytes after infusion into the recipient. The third mechanism is generation by donor leukocytes in vitro during storage before transfusion.[26] Red cells and units of platelet concentrates have sufficient potential sources of cytokines in the large number (10^7–10^8) of mononuclear leukocytes capable of cytokine synthesis. Studies have shown that generation of cytokines does occur in units of blood during storage and that such generation is directly proportional to the leukocyte count of the unit and the duration of storage.[27–29] Use of third-generation leukocyte reduction filters can lower the incidence of febrile reactions. Judging from reports of persistent febrile reactions despite use of these 3 to 4 $\log_{10}$ leukocyte reduction filters, such filtration needs to occur before storage and before the donor leukocytes begin to generate these proinflammatory cytokines in the blood storage bag. Heddle and colleagues[30] showed that febrile reactions to platelet transfusions were more likely due to proinflammatory cytokines present in the supernatant platelet-poor plasma than to the cellular elements in the platelet concentrates. Proinflammatory cytokines are not removed by bedside blood filters and enter the circulation.[31] Chemokines, such as IL-8 and RANTES, and complement components C3a and C5a are removed to various degrees by some bedside leukoreduction filters.[32,33] Prevention of cytokine generation by prestorage leukoreduction, however, is more efficient and effective than is scavenging of the biologic response modifiers by using bedside filtration technology.

The frequency of febrile reactions for a nonleukoreduced unit has been estimated to be 0.5% per unit transfused.[34,35] Reactions are most commonly seen in recipients who have been exposed to multiple white cell or platelet antigens, such as oncology patients or multiparous women. Oncology patients are at risk as a result of frequent transfusions, multiparous women from multiple exposures during childbirth. Both of these groups of patients can form multiple HLA-, granulocyte-, or platelet-specific antibodies that will react with white cells or platelets on subsequent exposure. Antigen–antibody reactions are capable of stimulating cellular activation with resultant complement fixation, cytokine generation, and activation of other biologic response modifiers.[36,37]

CLINICAL MANIFESTATIONS

Clinically, an FNHTR is characterized by fever and chills occurring shortly after the transfusion has begun.[38] The patient may have nausea and vomiting. Various factors, including rate of infusion of the blood and leukocyte content of the transfused blood (antigen load), may affect the severity of the clinical presentation of the febrile reaction. Febrile reactions also can occur several hours after the transfusion has ended.[17] Although an FNHTR often starts with the patient's complaining of feeling uneasy or "chilly," symptoms may progress from a slight tremor to true rigors. The chills or rigors are a manifestation of heat-conserving cutaneous vasoconstriction and cytokine release and result in muscular heat production.[39] These thermogenic responses, coupled with any effects due to release of IL-1β or other cytokines, may cause the patient's temperature to rise several degrees above pretransfusion levels. Although these reactions

are rarely dangerous, the severity often increases as the rate and dose of the infusion increase. Mild reactions are generally more uncomfortable and frightening than life threatening. FNHTRs are usually self-limited, with fever persisting for no more than 8 to 10 hours. Elderly patients with a tenuous cardiovascular status and critically ill patients may develop respiratory complications, hypotension, or shock. Young adults, however, are less likely to become seriously ill even with development of a high fever. As in any transfusion reaction, the onset of fever and chills requires that the transfusion be stopped, the intravenous line kept open with normal saline or a suitable crystalloid, and appropriate samples sent to the blood bank. The patient should be reassured, because anxiety may be extreme.

LABORATORY EVALUATION

The workup of a febrile reaction must be undertaken promptly. Fever may also be the first sign of an acute hemolytic reaction or infusion of a unit of red cells or platelets contaminated with bacteria. The workup consists of ruling out a hemolytic reaction by reconfirming the ABO type of the patient and the donor blood unit, repeat crossmatching to confirm patient-donor compatibility, evaluating the results of the pretransfusion and posttransfusion direct antiglobulin tests, evaluating the serum for hemolysis, and rechecking the accuracy of paperwork.[40–42] The posttransfusion DAT should yield negative findings, because an FNHTR does not involve red cell alloantibody.

As laboratory testing is being completed, the workup should extend beyond the blood bank to include bedside patient evaluation. Because fever and chills also may be caused by drugs or by diseases associated with infection or inflammation, these factors also should be evaluated. Blood cultures of the patient and the blood product, to rule out infusion of a contaminated unit of blood, is becoming more common at many medical centers. The difficulty lies in knowing when to order blood cultures: they are expensive and there is a 3% incidence of positive cultures as a result of contamination during culturing (see the Bacterial Contamination section). Most routine hospital blood banks do not have the expertise or reagents needed to identify specific HLA, platelet, or granulocyte antibodies. Accordingly, the diagnosis of a febrile hemolytic transfusion reaction is usually made without isolating an identifiable antibody. The FNHTR is often a diagnosis of exclusion arrived at after ruling out a hemolytic reaction, a septic transfusion, or other possible causes of fever.

TREATMENT AND PREVENTION

Fever from an FNHTR usually responds to antipyretics, including aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), and acetaminophen. For thrombocytopenic adult patients, acetaminophen (325–650 mg, taken orally) is the antipyretic of choice. Thrombocytopenic patients must avoid aspirin: it further compromises platelet function because of its inhibitory effect on platelet cyclooxygenase, an enzyme involved in the platelet release reaction. Nonthrombocytopenic patients may receive aspirin if its use is not contraindicated for other medical reasons. Many house officers routinely order diphenhydramine for treatment of febrile reactions. This therapy, however, should be reserved for pretreatment or treatment of possible allergic reactions. Unless the patient has a history of allergic reactions or shows signs of an allergic component to an FNHTR, such as flushing, hives, or pruritus, there is no benefit from the use of antihistamines for febrile reactions. Antihistamines produce drowsiness in some patients.

For patients with no history of febrile reactions, routine premedication is unnecessary. Adult patients with severe reactions despite premedication may require more intensive pharmacotherapy, including hydrocortisone sodium succinate (100 mg administered intravenously) given 1 to 2 hours before transfusion. Patients with severe shaking chills can be treated with meperidine (25–50 mg) intramuscularly or subcutaneously, if there are no medical contraindications. Meperidine can stop shaking chills almost immediately.[43] Febrile reactions after granulocyte transfusions and, less frequently, after platelet transfusions can be so severe that hypotension and cardiovascular collapse can occur.

Prevention of febrile reactions when pharmacologic therapy fails relies on the use of leukocyte-depleted blood components. Several leukocyte depletion techniques are available. Centrifugation can remove approximately 70% of the leukocytes in a unit of blood; cell washing or use of frozen deglycerolized red cells can remove up to 95% of contaminating white cells. Older microaggregate blood filters can reduce leukocyte content by approximately 1 to 2 logs (90%–93%).[44–51] Third-generation leukocyte-depletion red cell filters are more useful for preventing febrile reactions.[52–54] They can remove up to 4 logs (99.99%) of white cells, often lowering the level of white cells in a unit of blood from 10^9 to 10^5. They also may be useful for preventing or delaying the onset of HLA alloimmunization.[55,56] Leukocyte depletion platelet filters are also available.[57–63] The results of a multiinstitutional trial to reduce alloimmunization to platelets (TRAP Trial) have shown that reduction of leukocytes by filtration and UV-B irradiation of platelet concentrates were equally effective compared with a control group for preventing alloantibody-mediated refractoriness to platelets during chemotherapy for acute myeloid leukemia.[64]

The degree of usage of leukocyte-depleted blood components is still controversial.[65–67] Data show that a patient who has had one febrile transfusion reaction has a 1 in 8 chance of having another one.[35] Individuals with a history of recurrent severe febrile reactions should have notations made in their blood bank record to ensure future use of leukocyte-reduced components.

Although they clearly are indicated for people with multiple and recurrent febrile reactions, many physicians question whether leukodepleted blood products should be used indiscriminately for all patients.[68,69] The immunomodulatory effects of allogeneic blood transfusions on tumor growth and recurrence and susceptibility to viral infection is poorly understood, and much research has yet to be performed.[70–72] The cost of filtration is often cited as a reason to limit use of leukoreduction technology. Cost considerations, however, are often discounted when a significant threat, imagined or real, to the world's blood supply is posed. Such a threat may be associated with the risk of transmission of variant Creutzfeldt–Jakob disease (vCJD).[73] There is concern that vCJD may be transmitted by eating tissue from cows with bovine spongiform encephalopathy. In a murine model, there are some data that the agent may be present in the blood and can be associated with B cells.[74] Two reports implicate the transmission of vCJD by blood transfusion; studies are continuing. There are discussions about whether all blood should be leukodepleted in an attempt to address this potential risk to the world's blood supply.[73,75] Studies such as these[64,73–75] may begin to influence physicians to use leukoreduction technology for more patients. Such increased use, although improving the safety of the blood supply, can significantly raise the cost of medical care. However, the cost increment may be offset by reducing the potential complications.[76] After universal leukoreduction, the rate of FNHTR decreased significantly compared with nonuniversal leukoreduced blood, although this finding has not been confirmed by all studies.[77,78]

ALLERGIC TRANSFUSION REACTIONS

Allergic transfusion reactions are believed to be most commonly due to infusion of plasma proteins.[79,80] The allergic manifestations produced vary. They include skin erythema with associated mild urticaria and pruritus; a confluent rash, which is intensely pruritic; extensive urticaria; severe vasomotor instability; bronchospasm; and anaphylaxis. A patient who develops hives and a mild allergic reaction during a blood transfusion usually does not progress to a more severe anaphylactic reaction after infusion of additional blood from the same unit. The severity of allergic transfusion reactions is not necessarily dose-related.

The exact nature of the antibodies involved in the various types of allergic reactions is unclear. The mild allergic reactions are usually IgE-mediated, but other immunoglobulins may also be involved; anaphylactic reactions are most often IgE mediated.[7,81] Allergic reactions are believed to be mediated by histamine. Histamine can be released through the Ag–Ab interactions involving antibodies present in recipients against donor antigens or via antibodies passively transferred from donor against recipient antigens. Histamine can also be passively transferred from donors to recipients by transfusion of stored blood components.[82,83] Allergic transfusion reactions are quite common, occurring in approximately 1% of all transfusions.[84,85] Most of these reactions start with pruritus, followed by the development of hives. At this point, the transfusion should be stopped and the patient given 25 to 50 mg of diphenhydramine, if there are no medical contraindications and if the patient had not already been maximally premedicated. After a short interval, the transfusion can be continued, but only if the rash decreases or the hives disappear and the patient feels well and shows no signs of fever, chills, or vasomotor instability. For mild allergic transfusion reactions not associated with any cardiorespiratory problems, such as fever, bronchospasm, dyspnea, hypotension, or tachycardia, it is acceptable to continue the transfusion after the reaction has subsided, because it is not likely to recur. The risk of transfusion-transmitted disease posed by infusion of another unit of blood is greater than the risk posed by continuing a transfusion that has produced only mild urticaria. This is not true, however, if the patient shows signs of systemic toxicity from the transfusion, such as fever hypotension, bronchospasm, or tachycardia.

The treatment of mild allergic reactions involves the use of diphenhydramine or other H1 blocker.[81] Reactions are rarely serious and often do not recur with subsequent transfusions. The pathogenesis is thought to be recipient antibody directed against donor plasma proteins. Most blood banks, however, cannot identify the offending antibody; identification usually requires research laboratory techniques. Accordingly, the diagnosis of an allergic transfusion reaction is a diagnosis of exclusion. Washed red cells can be used to prevent reactions.[46,86] Leukocyte depletion or microaggregate filters are of no value because the plasma protein passes through the filter.

Most patients who have more than one mild allergic reaction should continue to receive routine bank blood and may be premedicated with diphenhydramine or similar agents. Washed cells should not be provided until a second reaction has occurred and generally should be provided only for patients with severe or recurrent reactions. The occurrence of one or two hives or mild pruritus after transfusion is not an indication for the use of washed cells or pharmacotherapy. Anaphylactic reactions, however, can be life threatening and may require intubation and pressor agents. The use of washed cells for patients experiencing these reactions is appropriate. For patients with severe or recurrent reactions, combination of H1 and H2 blockers may be more effective for treatment and premedication, and the addition of steroids may be necessary if not otherwise contraindicated.[81,87]

Although it is convenient to characterize a transfusion reaction as being purely febrile or allergic, in reality there is often a mix of the two symptoms, and the reaction is designated according to the predominant clinical sign.

BACTERIAL CONTAMINATION

Bacterial contamination of stored blood can pose grave risks to the recipient. Bacteria can enter the blood bag during venipuncture as a result of inadequate skin preparation or during component preparation.[88] Some bacteria grow best at room temperature; other (psychrophilic) organisms grow optimally at refrigerated blood bank (1°C to 6°C) temperatures. Gram-negative bacteria, including *Pseudomonas*, *Yersinia*, *Enterobacter*, and *Flavobacterium*, are organisms commonly associated with a contaminated unit of refrigerated blood.[89,90] Platelet concentrates, stored at room temperature, are also known to be subject to bacterial contamination; several reports have described fatal septic transfusion reactions due to platelets containing *Salmonella* or *Staphylococcus*.[91–93] Units of blood that are contaminated need not be obviously discolored, malodorous, or clotted; by simple visual inspection, it is extremely difficult to determine whether a unit is contaminated. However, Kim and coworkers[94] reported that visual inspection, with comparison of the blood bag segmented tubing with that of the blood bag itself, can occasionally identify units likely to be bacterially contaminated.

Individuals who receive a unit of contaminated blood may develop fever, rigors, skin flushing, abdominal cramps, myalgias, DIC, renal failure, cardiovascular collapse, and cardiac arrest. Clinically the patient presents in warm shock. These reactions may be immediate, or there may be a delay of several hours before the symptom complex becomes apparent. Reaction to infusion of a unit of contaminated blood is distinguishable from FNHTR by the former's more severe clinical presentation and is distinguishable from intravascular hemolytic transfusion reaction by the absence of the latter's characteristic hemoglobinuria and hemoglobinemia. Reactions after transfusion of infected units of blood are often attributable to endotoxin produced by gram-negative bacteria. The presence of bacteria alone, however, can also cause many of these symptoms. The symptom complex often is attributable in part to cytokines and interleukins that are generated in the contaminated, in vitro stored blood. These biologic response modifiers produce severe reactions in vivo after transfusion.[27–29,95–97] For example, nitric oxide, produced locally in smooth muscle by the synergistic action of TNF-α, IL-1, and interferon-γ, probably mediates refractory hypotension and vasoplegia associated with septic shock.[96,98]

If, during transfusion, a patient who appeared well suddenly develops rigors and shock, infusion of an infected component should be considered. If on further evaluation this diagnosis is still considered likely, the patient should be treated immediately, because delay significantly contributes to the chance of a fatal outcome. Blood pressure, pulse, respiration, and renal blood flow need to be supported. Blood infusion should be stopped the moment any transfusion reaction is suspected, and appropriate samples should be sent to the blood bank for a DAT and other studies. Cultures of the untransfused blood remaining in the blood bag should be obtained because they may be diagnostic. Broad-spectrum antibiotics should be started immediately if infusion of contaminated blood is suspected and continued until the culture results are reported. These reactions are rare[99] but can be fatal. Use of recombinant IL or cytokine inhibitors is still experimental to be useful clinically.

Because of the decrease in viral transmission by blood transfusion, septic transfusion reactions now account for a significant portion of the transfusion-related mortality in the United States.[100] Data from the BaCon (Bacterial Contamination of Blood) study showed that from 1998 to 2000, the rate of transfusion-transmitted bacteremia was 9.98 per million single-donor platelets, 10.64 per million pooled platelets, and 0.21 per million RBC units; the rate of fatal reactions was 1.94 per million single-donor platelets, 2.22 per million pooled platelets, and 0.13 per million RBC units, respectively.[100] To reduce the risk of bacterial transmission through platelet transfusion, the American Association of Blood Banks has mandated that starting in March 2004 platelet concentrates should be tested for bacterial contamination.[101] There are two bacteria detection systems approved by the US Food and Drug Administration (FDA) to be used for screening of blood components.[102,103] Since the implementation of bacterial testing of platelets, although the risks of septic transfusion reaction have been reduced, they have not been eradicated.

TRANSFUSION-RELATED ACUTE LUNG INJURY (NONCARDIOGENIC PULMONARY EDEMA)

Transfusion-related acute lung injury (TRALI), the third leading cause of transfusion-related death, was thought to be rare in the past, but it is now believed to occur in as many 1 of 5000 to 1120 transfusions.[104–108] With increasing recognition and knowledge of this

clinical syndrome, the current view of TRALI is much broader. It may range from mild dyspnea to severe noncardiogenic pulmonary edema, with symptoms including dyspnea, oxygen desaturation, respiratory failure, chills, fever, and hypotension. Most patients require oxygen support, and many may require mechanical ventilation. TRALI may develop within 1 to 6 hours of starting a transfusion, without an elevation in cardiac pressure.[22,104,105,109–113] The chest radiograph may reveal a pulmonary edema pattern (bilateral infiltrates), and there is respiratory insufficiency with a decrease in O_2 saturation, but without development of elevated left-side cardiac pressure. Copious amounts of pulmonary edema fluid are produced, as is characteristic of hypervolemia; however, the noncardiogenic reaction usually follows infusion of volumes of blood too small to produce fluid overload. The postulated pathologic mechanism includes a reaction between donor HLA (class I and II) or white blood cell antibody and recipient leukocytes. Complement and monocyte activation with aggregation of white blood cells also may occur when leukoagglutinins present in the recipient react with leukocytes contained in the infused donor blood,[22,106,107,114–117] As a result of the HLA Ag–Ab reaction, the activated leukocytes generate adhesive molecules on their surface (CD11/CD18). These proteins permit the leukocytes to attach to the cell membrane of the pulmonary endothelial cells and by diapedesis enter the interstitial space between the pulmonary capillaries and the alveolar epithelium. Once they are in the interstitial space, the neutrophils degranulate and release destructive enzymes, which produce a capillary leak, resulting in fluid filling the alveolar air sacs. Pulmonary leukostasis with pulmonary edema occurs as a result of microvascular occlusion and capillary leakage.[118,119] Complement-activated granulocytes also produce toxic oxygen radicals that damage pulmonary endothelial cells, resulting in an increase in pulmonary vascular permeability and further passage of fluid into alveolar spaces. Silliman and associates[120,121] postulated a two-step approach to the pathogenesis of TRALI. After an initial neutrophil activation step, neutrophil-priming lipids, which they believe play a key role in the process, further activate the granulocytes and produce the clinical syndrome.[113,120] Rodent model systems for TRALI have also been described.[122]

Because a definitive diagnosis of TRALI usually requires that cardiac monitoring (Swan–Ganz) catheters be in place, TRALI is difficult to diagnose outside the operating room or intensive care unit. When a patient shows signs of noncardiogenic pulmonary edema, as with all other reactions, the infusion should be stopped. These HLA/neutrophil antigen–antibody reactions may be idiosyncratic and often do not recur. Because of the difficulty in differentiating TRALI from other competing diagnoses such as circulatory overload and the patient's underline pulmonary status, efforts have been made to develop consensus guidelines to diagnose TRALI.[123,124]

To remove leukocyte antigens from units of red cells or platelets, leukocyte reduction filters may be useful; washed red cells are useful for that component as well. Treatment is symptomatic (Table 153–3). Donors who are implicated in moderate to several TRALI reactions should not be maintained as blood donors. In November 2006, the American Association of Blood Banks (AABB) made further recommendations to reduce the risks of TRALI.[125] Even though it is controversial whether multiparous women who are blood donors and blood donors who have been multiply transfused should be used as plasma donors, because their serum may contain high titers of leukoagglutinating antibodies, more and more collection facilities started to limit their use as a source for plasma components.

Table 153–3 Diagnosis of Transfusion-Related Acute Lung Injury

Onset	Within 6 hours of start of transfusion
Frequency	1:1000 to 1:4500 transfusions (probably underreported)
Signs and symptoms	Decreased O_2 saturation, fever, hypotension, tachypnea, dyspnea, diffuse pulmonary infiltrates, normal cardiac pressures (requires Swan–Ganz catheter), copious amounts of pulmonary edema fluid
Pathogenesis	HLA/granulocyte-specific antibodies (usually of donor origin) reacting with recipient leukocytes. Activates recipient neutrophils; stimulates complement activation; generates CD11/18 on the polymorphonuclear neutrophil surface, resulting in pulmonary capillary adherence and diapedesis and eventual pulmonary capillary leak syndrome. The latter is associated with generation of proteolytic enzymes and toxic O_2 metabolites, which cause endothelial cell damage.
	Neutrophil priming lipids may also play a role.
Diagnosis	Chest radiograph; blood gases; blood for HLA or antineutrophil antibodies
Differential diagnosis	Fluid overload; septic transfusion; anaphylaxis
Treatment	STOP TRANSFUSION; ventilatory support (administer O_2, intubate as needed), support blood pressure, administer steroids; diuretics of *no* value

Data from Levy GJ, Shabot MM, Hart ME, et al: Transfusion-associated noncardiogenic pulmonary edema. Report of a case and a warning regarding treatment. Transfusion 2:278, 1986.

OTHER ADVERSE EFFECTS OF TRANSFUSION

Circulatory Overload (Hypervolemia)

Hypervolemia is a form of transfusion reaction that should be considered in patients who, during a blood infusion, develop sudden severe headache, dyspnea, tachycardia, congestive heart failure, or other signs of fluid overload. Unless the patient is actively hemorrhaging, blood should never be infused rapidly, because the acute expansion of the patient's intravascular volume may exceed the capacity of the cardiovascular system to compensate. Rapidly transfusing a patient who is anemic but who is euvolemic and not actively bleeding produces no benefit and may cause harm. This caveat applies to transfusion of any blood component. Patients with compromised cardiopulmonary status may not tolerate acute blood volume expansion and may develop right- or left-sided heart failure. This is especially true for infants and the elderly. If symptoms occur, the transfusion should be stopped and some form of volume reduction, either diuretics or phlebotomy, instituted. If there is a concern that the patient may not tolerate infusion of a full unit of blood or component within the 4-hour period allotted for infusion of blood components, the blood bank can divide the product into smaller portions, which can be transfused in aliquots. As a general guide, infusions in nonbleeding adults should occur at less than 2 to 3 mL/kg/hour. The rate should be lowered to 1 mL/kg/hour for patients at risk for fluid overload. Diuretics may be given to patients with compromised cardiopulmonary status before transfusion.

The initial stages of transfusion-induced hypervolemia may be difficult to distinguish from hemolytic transfusion reaction as well as from febrile, allergic reactions or TRALI. The absence of hemoglobinuria and hemoglobinemia or the absence of a positive posttransfusion DAT result should serve to distinguish the reaction from one due to immune hemolysis, and the absence of fever, chills, or urticaria from the febrile or allergic types of reactions. The clinical use of laboratory testing such as brain natriuretic peptide (BNP) to aid in the differential diagnosis is currently under active investigation.[126] A normal BNP value suggests TRALI, whereas a high BNP suggests cardiac myocyte stretching from fluid overload.

Anaphylactic Reactions

When plasma containing IgA is transfused to patients with IgG or IgE anti-IgA antibodies, anaphylactic reactions can occur. Similarly, it may also occur in patients with deficiency of other plasma proteins such as haptoglobin.[127] Anaphylactic reactions have also been reported after transfusion of platelets administered through some types of bedside leukoreduction filters.[128] The pathogenesis of this syndrome appeared to be the activation of the contact pathway (prekallikrein converting to kallikrein) induced in plasma by the negatively charged surface of some leukoreduction filters. Kallikrein activation stimulates the conversion of high-molecular-weight kininogen to bradykinin. The bradykinin generated by the negatively charged bedside filter enters the circulation and produces a symptom complex characterized by pain, cutaneous flushing, and hypotension without fever or chills. The syndrome is often much more severe in patients already taking angiotensin-converting enzyme (ACE) inhibitors. ACE is identical to kininase II, which is responsible for degrading bradykinin. Blockage of the kininase II degradation of bradykinin by ACE inhibitors results in a prolonged bradykinin half-life and a reaction that can be very severe. Accordingly, physicians should let the blood bank know of any patients taking ACE inhibitors who require blood transfusion. Prestorage leukoreduction avoids this problem, because the half-life of bradykinin is approximately 15 seconds. Reactions have been reported with platelet as well as red cell transfusions, but most commonly with platelet transfusions administered through a bedside leukoreduction filter, with a negative surface charge. Although these reactions are rare, they can be quite serious.

Transfusion-Associated Graft-Versus-Host Disease

Transfusion-associated graft-versus-host disease (GVHD) occurs when immunologically competent lymphocytes are introduced into an immunoincompetent host who cannot destroy the donor lymphocytes. The immunocompetent donor lymphocytes engraft, recognize the host as foreign, and then attack host tissues. GVHD occurs after allogeneic bone marrow transplantation and less often after transfusion of nonirradiated cellular blood components, especially when the blood donor and recipient share some HLA antigens.[129] There is an increased danger from posttransfusion GVHD, in part because of the frequent failure of physicians to recognize the risk. Another major factor, however, is the propensity of the donor's lymphocytes to produce recipient bone marrow aplasia. In GVHD after bone marrow transplantation, the bone marrow is of donor origin, and bone marrow aplasia does not occur. In posttransfusion GVHD, however, the donor's lymphocytes attack the bone marrow of recipient/host origin, producing aplasia.

Posttransfusion GVHD is fatal in more than 90% of cases, primarily because of aplasia of the recipient's bone marrow.[130–132] It may occur 8 to 10 days after transfusion with a marked pancytopenia as well as multiorgan involvement of GVHD such as skin and liver. The signs and symptoms include nausea, vomiting, anorexia, fever, watery diarrhea, liver function abnormality, and rash. Patients often die of infection and bleeding within 3 to 4 weeks. There is no effective treatment, with the possible exception of stem cell transplantation, if posttransfusion GVHD is recognized early and if a suitable donor can be found in a short time.[133] Reports have shown that haploidentical directed donor units of blood may produce fatal posttransfusion GVHD even in immunocompetent recipients.[134,135] The use of irradiated blood (2500 cGy) is recommended in clinical situations in which posttransfusion GVHD is considered likely, such as when patients receive directed blood transfusions from their relatives. Leukocyte-reduction filters should not be used as prophylaxis against GVHD, because the exact number of leukocytes needed to produce the disease is not known with certainty. Case reports of fatal GVHD in patients who received leukoreduced but not irradiated blood have been published.[136] Several articles have addressed this subject.[137–140] Irradiation of red cells produces a membrane defect, however, which causes slow leakage of potassium and hemoglobin.[141] Accordingly, the FDA ruled that irradiated units of red cells shall have an outdate not to exceed 28 days from the time of irradiation. GVHD continues to be a rare but extremely serious complication of blood transfusion.[131,142,143] Although it is controversial, prophylactic irradiation is usually not indicated for patients with human immunodeficiency virus (HIV) infection.

Posttransfusion Purpura

Posttransfusion purpura (PTP) is a rare and self-limiting thrombocytopenia occurring 5 to 10 days posttransfusion in patients lacking a specific platelet antigen, usually PLA1 (HPA-1a).[144] They often have a history of sensitization with prior transfusions or pregnancies. After resensitization by the transfusion or additional pregnancy, patients developed potent antibodies against the platelet-specific antigen that they are lacking but are present on donor platelets. These platelet antibodies often have a high titer and can fix complement. As a result, the transfused platelets and the patient's own platelets are also destroyed through the adsorption of the antigen on their own platelets. A concurrent autoimmune process may also involve destruction of the recipient's own platelets, as shown in one case report of a positive antiantibody against the patient's own platelets.[145] The thrombocytopenia can be marked with a platelet count below 10,000/μL. The onset is sudden, although self-limited, and usually resolves in 2 weeks. Intravenous immunoglobulin (IVIG) appears to be an effective treatment, although plasma exchange, steroids, and splenectomy can also be useful. Patients with acute bleeding and needing platelet support should receive platelets without the platelet-specific antigen. If random donor platelets are given, patients can develop severe reactions, including allergic reactions. Recurrence of PTP is rare.

Microaggregate Debris and Adult Respiratory Distress Syndrome

Much has been published regarding the use of microaggregate filters for preventing adult respiratory distress syndrome after massive transfusion.[65,146–151] Microaggregate debris consists of dead platelets, granulocytes, and fibrin strands that form in blood during storage.[152–154] It was hypothesized that infusion of blood containing microaggregate debris through standard 170-μm-pore filters resulted in the passage of these 20- to 120-μm microaggregates into the pulmonary vasculature, producing occlusion of the pulmonary capillaries and pulmonary failure. Published studies have shown, however, that microaggregate filters are not required and transfused microaggregates do not appear to influence the onset of adult respiratory distress syndrome.[155,156] This syndrome is most likely, and most often, attributable to concurrent hypotension and sepsis rather than to infusion of microaggregate debris, per se. Improvements in surgical techniques, posttrauma medical care, perfusion technology, and especially treatment of shock and sepsis have contributed more to the decreased incidence of postperfusion respiratory distress syndrome than has use of microaggregate filters.[157]

LEUKOCYTE REDUCTION

There are multiple reasons to leukoreduce units of blood and components. Standards of the American Association of Blood Banks require that to be considered leukoreduced for any indication, the level of leukocytes in the final component must be less than 5×10^6.[158] This value applies to units of RBCs and single-donor apheresis platelets. For platelets prepared from whole blood, the value is less than 8.3×10^5 in all bags. Because the final pooled component also must have less than 5×10^6 leukocytes, this implies that the final pool size should not exceed 6 units. Generally accepted indications for leukocyte reduction include decreasing the incidence of HLA alloimmunization,[55,56,64] decreasing incidence of febrile transfusion

reaction, and decreasing cytomegalovirus (CMV) transmission. Other areas include decreasing the incidence of tumor recurrence and improving certain clinical outcomes.[159–161] Leukoreduction is an effective approach to reduce CMV transmission through blood transfusion, and many hospitals now use leukoreduced blood components (CMV safe) to replace CMV serologic negative blood components to prevent CMV transmission, even for allotransplantation patients.[162] As more data are published, the indications for use of leukocyte reduction filters will become clearer. Although a conservative approach to their use for well-established indications would seem most prudent, changes for the indications are always being reviewed.[69,77,163]

HYPOTHERMIA

Hypothermia can occur with rapid infusion of large quantities of refrigerated (1–6°C) blood.[164–166] Data have shown that rapid infusion of blood (1 unit every 5 minutes) may lower the temperature of the sinoatrial node to less than 30°C, at which point ventricular fibrillation may occur.[167] Most transfusions need not be given this rapidly. For routine transfusion, blood does not have to be warmed. Overwarming the blood can cause thermal injury and produce hemolysis, DIC, or shock. Use of warming techniques for some trauma patients may reduce the incidence of coagulopathies associated with major trauma.[168]

If blood is to be warmed, the temperature must be monitored and kept below a level that could cause hemolysis.[158,169] Usually, this is less than 42°C. Heating blood under running hot tap water or heating in a microwave device is unacceptable; microwave devices produce hot spots that can cause hemolysis.[170,171]

ELECTROLYTE TOXICITY

Citrate, a component of the preservative solution used in blood storage, functions as an anticoagulant by chelating calcium and interfering with the coagulation cascade. Rapid transfusion of citrated blood can be associated with a drop in ionized calcium levels.[172–174] Citrate-containing blood products, however, are routinely infused without any problem, because the citrate is rapidly metabolized to bicarbonate. In patients with normal liver function, citrate infusion is very unlikely to produce reactions. Mild to severe citrate toxicity can be seen, however, in individuals undergoing cytapheresis when large volumes of citrated plasma are reinfused.[175,176]

The effects of hypocalcemia range from mild circumoral paresthesias to frank tetany. However, severe citrate toxicity, even with massive transfusion, is very rare. More commonly, the reaction is mild and self-limiting and can be treated by merely slowing the rate of reinfusion.[177] If prolonged QT intervals or signs of tetany are seen, calcium can be administered. Infusion of calcium, however, may be associated with the development of ventricular arrhythmias and cardiac arrest.[178] Calcium should not be infused routinely, even after large-volume blood transfusions. Under no circumstances should calcium be added to a unit of blood, because it would recalcify the unit and cause clots to form in the bag.

Hypomagnesemia, presumably due to chelation of magnesium by citrate, has also been reported. Actual clinical complications of transfusion-induced hypomagnesemia, however, have not been well documented, other than in the cases of cytapheresis.[176,179,180]

Hyperkalemia due to infusion of stored blood is a rare occurrence. Although hyperkalemia is often thought to be a problem in massive transfusion, in reality development of hypokalemia is of greater concern. With storage, leakage of potassium from red cells to the extracellular fluid occurs. However, after infusion, the red cells reverse the biochemical storage lesion by restoring the Na–K ATP membrane pump, and intracellular potassium levels are restored. As the citrate is metabolized to bicarbonate, the blood becomes alkalotic, contributing to hypokalemia.[181–183] In massive transfusion, this may not uncommonly result in the need for administration of potassium. Extracellular potassium increases at the rate of approximately 1 mEq/day during the first few weeks of storage. If this presents a concern for neonates or patients with renal failure, fresher or washed blood can be requested. As there is increased potassium leakage from red cells after exposure to 25 Gy of radiation to prevent posttransfusion GVHD, a maximum 28-day shelf life from the day of irradiation is imposed on this blood component.[158] Ammonia toxicity, previously a concern with stored blood, rarely presents problems.[184]

Risk Groups for Transfusion-Associated Graft-Versus-Host Disease

Risk Well Defined
- Congenital T-cell defects (known or suspected)
- Immunologic immaturity (fetus or premature infant)
- Intrauterine transfusion
- Exchange transfusion
- Acquired T-cell defects
- Bone marrow or peripheral blood stem cell transplant recipients (allogeneic or autologous)
- Hodgkin's disease
- Haplotype sharing between donor and recipient
- Transfusions from blood relatives
- HLA-matched platelets

Risks Identified But Not Clearly Defined
- Hematologic malignancies (other than Hodgkin's disease)
- Solid tumors
- Immunologic immaturity or prematurity (in the context of small-volume transfusion)
- Certain immunosuppressive agents such as Fludarabine

Risks Not Identified
- Acquired immunodeficiency syndrome (AIDS)
- Aplastic anemia (except in setting of bone marrow transplantation or immunosuppressive therapy)

PLASTICIZERS

Plasticizers are chemicals used to make the rigid polyvinyl chloride plastic used in blood bags more malleable. The traditional plasticizer is di-2-ethylhexylphthalate (DEHP).[185] There has been some question as to whether DEHP is carcinogenic and whether its breakdown product, monoethylhexylphthalate, may cause problems because of production of peroxisomes, which may be destructive to vital organs.[186–189] Citrate-based[190,191] plasticizer and new-generation blood bags are commercially available. Ironically, DEHP plasticizers may actually serve a useful function in that they appear to stabilize the red cell membrane and also may have a beneficial effect on platelet morphology.[192–194]

HEMOSIDEROSIS

One milliliter of red blood cells contains 1 mg of iron. A unit of blood with 250 mL of red blood cells contains approximately 250 mg of iron, and 4 units of blood contain 1 g of iron, roughly the amount stored in the bone marrow. Men and nonmenstruating women lose only approximately 1 mg iron each day. Continued use of transfusion therapy in individuals with an extravascular type of hemolytic anemia, such as those with thalassemia or sickle cell anemia, in which iron is not lost from the body but is recycled, can thus result in the accumulation of excessive tissue stores of iron. Over long periods, the iron that is stored in parenchymal cells results in death of the cell and eventual organ failure.[195] Transfusion of reticulocyte-rich blood (neocytes) generally has not been found to be of value for decreasing the transfusion requirement in patients with chronic hemolytic anemias.[196]

Iron chelation therapy, such as that with deferoxamine, is now widely used and is often able to maintain patients with chronic hemolytic anemias in negative iron balance.[197,198] The recent approval of an new oral iron chelater Deferasirox provides an alternative mode of iron chelation therapy.[199]

AIR EMBOLI

With replacement of evacuated glass bottles by plastic blood bags, the risk of air embolism from phlebotomy or transfusion virtually disappeared from transfusion practice. Air, however, still may be pumped into patients by the roller pumps contained in various transfusion devices, especially apheresis and intraoperative salvage machines.[200] All such devices currently manufactured, however, contain air in-line sensors. However, any operators using this equipment must be well-trained and remain alert to the potential risk of air embolization at all times while the patient is being treated. Patients who receive air intravenously experience acute cardiopulmonary insufficiency. The air tends to lodge in the right ventricle, preventing blood from entering the pulmonary circulation. Acute cyanosis, pain, cough, shock, and arrhythmia may occur, and death may result unless immediate action is taken. The patient should be placed head down on the left side; this usually displaces the air bubble from the pulmonary valve. Use of central lines may also pose an additional risk of air embolism.

TRANSFUSION REACTIONS FROM THE INFUSION OF HEMATOPOIETIC STEM CELLS

For patients receiving hematopoietic stem cell infusions, transfusion reactions can occur similar to regular blood components. However, certain reactions are unique to the transfusion of hematopoietic stem cells. The most common are the acute reactions associated with infusion of DMSO, a cryopreservative used for freezing hematopoietic stem cells.[201,202] Signs or symptoms of DMSO toxicity range from an unpleasant taste or smell, nausea, vomiting, diarrhea, chills, and hypertension to flushing, hypotension, bronchospasm, pulmonary edema, cardiac arrhythmias, and neurologic symptoms. Antihistamines have been used to prevent and to treat DMSO-related toxicity. In addition, DMSO toxicity is dose related, and it sometimes can be prevented by washing the components before transfusion.

PATHOGEN INACTIVATION

With improvement of donor testing, especially NAT testing, the risk of transfusion-transmitted diseases has decreased dramatically, such as approximately 1:1,900,000 for the risk of HIV, 1:137,000 for HBV, and 1:1,000,000 for HCV.[203] However, the risk is never zero. Moreover, there are emerging pathogens, such as the West Nile virus,[204] that may pose risk to the blood supply. It is expensive and impossible to screen all potential pathogens to protect the blood supply. To improve blood safety, new technologies such as pathogen inactivation have been developed.[205–207] There are several platforms of pathogen inactivation technologies. The principle of most pathogen inactivation is that agents added to blood components modify DNA or RNA templates, making them inaccessible to DNA or RNA polymerase, thus inactivating pathogens, including viruses, bacteria, and parasites; and also inactivating white blood cells. Available pathogen inactivation compounds include alkylating compounds, binary ethyleneimine-like compounds, riboflavin, and methylene blue. There are available systems for pathogen inactivation of RBCs, plasma, and platelets. Preclinical studies and clinical trials including phase III have shown promising results in the efficacy and safety of pathogen inactivation agents.[208,209]

CHAPTER 154

TRANSFUSION-TRANSMITTED DISEASES

Jay E. Menitove, Eberhard W. Fiebig, and Michael P. Busch

INTRODUCTION

During the 1980s and 1990s, transfusion medicine specialists focused their attention on reducing the risks of transfusion-transmitted human immunodeficiency virus (HIV) and hepatitis C infections. Currently those risks approximate 1 per 2 million transfusions. By 2003, additional testing prevented transfusion transmission of the West Nile Virus, a viral etiology of an emerging epidemic. Further risk reduction followed introduction of bacterial testing of platelet concentrates in 2004 that reduced the risk of transfusion-associated sepsis from 1 per 5000 to approximately 1 per 100,000. By early 2007, another new test was introduced. This one seeks to lower *Trypanosoma cruzi* transmission rates in the United States from the 1 per 25,000 risk approximated prior to test implementation.

In light of the significant progress achieved to date, this chapter reviews the residual risk from the above-cited adverse infectious complications of transfusion and presents the current knowledge, pathogenesis, and risk-reduction strategies aimed at emerging pathogens threatening the blood supply.

HEPATITIS INFECTION

Hepatitis A

The hepatitis A virus (HAV), a nonenveloped RNA virus in the picornavirus family, is transmitted predominantly through the fecal–oral route. The incubation period averages 28 days (range 15–50 days) and signs or symptoms persist for less than 2 months. Approximately 10% to 15% of infected individuals develop prolonged or relapsing illness, but HAV is self-limited with no chronic carrier state. HAV is the most frequent cause of hepatitis among children under 11 years of age. Risk factors for acquiring infection include close personal contact with infected individuals and injecting drug use. Approximately 45% to 50% of those infected have no identifiable transmission source. The peak viremic period occurs 2 weeks before onset of jaundice or elevation of liver function tests. Transfusion transmission occurs infrequently and corresponds to donation by a recently infected, asymptomatic individual.[1–3] Viremia persists for a median period of 42 days (range up to 59 days) in patients with hepatitis A.[1–3] The virus resists heating at 60°C for 1 hour and is difficult to inactivate by pathogen reduction procedures developed for cellular components (eg, psoralens, and riboflavin) and fresh-frozen plasma (solvent/detergent and methylene blue). Transmission by clotting factor concentrates treated with the solvent/detergent pathogen process occurred in the 1990s and remains low-risk despite the lack of HAV infection among hemophiliac patients treated in the early 2000s.[4,16,170,268]

Hepatitis B

The hepatitis B virus (HBV) is a DNA virus in the Hepadnaviridae family. The infective virion is known as the Dane particle and has surface and core components, HBsAg and HBc antigen, respectively. In addition, within infected hepatocytes nonstructural regulatory proteins, hepatitis B e antigen, polymerase proteins, and viral progeny DNA are produced. Epitopes on the virus surface provide a basis for epidemiologic studies and consist of the HBsAg "a" d/y and w/r determinants. Recombinant vaccines target the "a" determinant of HBsAg and confer protective immunity. During active HBV infection, significant HBsAg overproduction results in the release of self-assembled 22-nm-diameter spheres and tubules in addition to Dane particles.

The average incubation period, defined as the time from infection to liver enzyme elevation and symptomatic hepatitis, is 59 days (range: 5–12 weeks) but may be as long as 6 months. Symptoms, which occur in 30% to 50% of infected persons, include anorexia, nausea, vomiting, jaundice, arthralgias, rashes, vasculitis, and glomerulonephritis. Chronicity, defined as persistent HBsAg and HBV DNA in plasma, follows acute infection in 2% to 10% of adults and 30% to 90% of young children and infants. Approximately 5% of the US population has serologic evidence of prior HBV infection (anti-HBc-reactive), and 0.4% to 0.5% (1–1.3 million) are chronically infected (HBsAg-positive). Between 1987 and 1998, reported cases of acute HBV infection in the United States declined by 76%, in great part because of expanded hepatitis B vaccination programs. Among blood donors, new HBV infections declined from 1.97 per 100,000 person-years to 1.27 between 1998 and 2001.[5]

Viral titers in blood are significantly greater than those present in the semen, vaginal fluid, and saliva. In relative terms, HBV is 100 times more infective than HIV and 10 times more infective than HCV. The predominant mode of transmission in adults and adolescents is through sexual contact. Forty percent have infected partners, 15% are males having sex with other males, injecting drug users account for 14% of cases, and one-third have no identifiable risk.

HBsAg is detectable in blood approximately 4 weeks (30–60 days) after infection. Subsequently, IgM anti-HBc antibodies appear coinciding with symptom onset. High viral titers (10^{10} genomes/mL) present at that time decline subsequently. HBsAg persists transiently in acute infections for up to 4 months (average 63 days). Antibodies against HBsAg (anti-HBs) arise subsequently and protect against reinfection. Anti-HBc identifies chronically infected low-level carriers; some anti-HBc-positive and anti-HBsAg-negative carriers contain circulating HBV DNA.[6] Although anti-HBs confers immunity, sufficient virus remains in the liver to transmit HBV following liver transplant from anti-HBs-positive donors.[7]

Most current HBV transfusion transmission cases are attributable to blood donations by asymptomatic donors during the acute infection phase prior to HBsAg appearance.[8] During this "window period" between infection and routine laboratory detection, HBV replicates relatively slowly with a doubling time of HBV viral load of approximately 2.6 days[8] (see text box below on estimating residual risk of blood screened for TTVs). Other cases are due to HBV mutants not detectable by HBsAg testing.[9] With current routine testing for HBsAg and anti-HBc, the risk for HBV transmission per unit is approximately 1 per 205,000 units.[5] Further risk reduction can be expected from recently implemented high-sensitivity serologic assays for HBsAg detecting approximately 0.1 ng/mL HBsAg compared with an average of 0.3 ng/mL with previous assays, and HBV NAT on either single donation samples or samples from multiple donors in minipools.[10,11] NAT on single donation samples has the potential to reduce the risk of transfusion-transmitted HBV by detecting newly

The Incidence Rate (IR) / Window Period (WP) Model: Estimating Residual Risk of Blood Screened for Transfusion-Transmitted Viruses

Accurate estimates of the risk of transmission of viral infections are important for monitoring and improving blood safety and for helping physicians and patients to make informed decisions about the use of blood products. As a consequence of improved protection of the blood supply from contamination with HIV and HCV, direct methods to estimate risks, such as prospective studies of transfusion recipients or testing of donor samples with sensitive research tests, have become impractical and prohibitively expensive because of the very large sample size required to conduct such studies.[13] Alternative, widely adopted and validated approaches to estimate the risk of viral transmission from blood units screened for HIV and HCV are based on mathematical modeling of the likelihood that a blood donor presents in the so-called window period of infection. The rationale is that in this period screening assays are not yet reactive but infectious virus is present in the bloodstream. The most widely used method is based on the IR/WP model, which estimates the residual risk for the virus in question by multiplying the IR (the rate of new infections in the specific blood donor population per year) by the length of the WP (in fractions of a year).[14] The model assumes that the WP risk is the single most contributing factor to residual risk (minor contributors being variant viral strains escaping detection, immunosilent carriers, and testing errors), that accurate figures for IR and WP are available, and that donors present for blood donation at the same rate during the length of the WP. These assumptions can be reasonably made, and the predictions derived from the model have been remarkably accurate over time. A major advantage of this approach is that it can be easily implemented with existing databases. The IR/WP model and its modifications have been applied worldwide to provide region-specific risk estimates. The model has also been applied to other viruses, including HBV and HTLV, although for various reasons estimates derived for the latter are less reliable.[5,8] Current US risk estimates for HIV, HCV, HBV, and HTLV shown in Table 154–1 are derived from IR/WP model calculations. Figure 154–1 shows the decline in IR, WP length, and resultant residual risk of the three major transfusion-transmitted viruses over time.

Table 154–1 Risk of Transfusion-Transmitted Diseases in the United States

Pathogenic Agent	Average Estimated Risk per Unit
Hepatitis A	unknown, presumably <1:1 million
Hepatitis B	1:205,000[a]
Hepatitis C	1:1,935,000[b]
Human Immunodeficiency Virus-1	1:2,135,000[b]
Human T-Lymphotropic Virus-I, II	1:2,993,000
Cytomegalovirus (CMV)	infrequent[c]
Parvovirus B19	unknown, presumably <1:1 million
West Nile & other Arbo Viruses	unknown, presumably <1:1 million
Malaria	1:4,000,000
Babesia	<1:1 million
Chagas disease	~1:25,000 prior to testing
Creutzfeldt–Jakob Disease (CJD), vCJD	4 vCJD cases reported
Bacterial contamination associated with symptomatic sepsis	1:500,000 per red blood cell unit 1:70,000–118,000 per apheresis platelet unit[d]

[a]Estimates for HBV reflect risk projections prior to implementation of blood donor screening with nucleic acid testing (NAT).
[b]Estimates for HIV, HCV indicate risk projections following implementation of NAT for these agents in 1999.
[c]In association with CMV risk-reduced components.

infected donors 21 to 29 days earlier than currently licensed HBsAg tests; minipool testing on the other hand offers little or no improvement over current and new investigational HBsAg assays for donor screening.[10,12] The cost and complexity of performing individual donation NAT for HBV, combined with declining HBV incidence and relatively low rate of chronic infection and clinical disease, resulted in minimal adoption of HBV NAT in the United States through 2007 despite licensure of HBV NAT assays by the FDA.[9,12] Subsequently, NAT assay revisions resulted in widespread texting.

Hepatitis C

The hepatitis C virus (HCV) is an RNA virus in the Flaviviridae family that has six genotypes. In the United States, genotypes 1, 2, and 3 cause 75%, 10%, and 10% of infections, respectively, and have similar replication and transmission rates and natural history. Genotype 1 responds less favorably to current treatment than genotypes 2 or 3.

Overall 4.1 million people (1.6% of the US population) have evidence of HCV infection and 3.2 million have ongoing chronic infections. Almost 90% of infected persons born between 1943 and 1972 reported injection drug use, high risk sexual behavior (more than 20 lifetime partners), or transfusion before 1992. Among those born before 1942, 0.9% are infected and more than 60% of those infected in this age range (approximately 240,000 persons) have a history of prior blood transfusion.[15] Sexual transmission is considered an inefficient mechanism for viral transfer. Vertical transmission occurs in 3% to 7% of infants of mothers with active infections.[15] Among blood donors, 0.07% to 0.09% have confirmed positive test results.[5]

Only 20% to 30% of newly infected persons develop symptoms during the acute infection phase. However, chronic infection develops in 75% to 85% of persons infected after 45 years of age and in 50% to 60% of those infected as children or young adults.[16] Of patients with chronic HCV infection, approximately 25% develop fibrosis that evolves into cirrhosis over an average 20-year interval. Biochemical evidence of liver inflammation occurs in 70% of those infected as adults compared to 10% of those infected as juveniles. The risk of progression to cirrhosis varies from 10% to 20% of those infected as adults to approximately 5% of those infected earlier in life.[16,17] Alcohol consumption increases the risk of progression to cirrhosis. Hepatocellular carcinoma occurs in 1% to 4% per year in those with cirrhosis.

The risk of HCV transmission by transfusion declined following introduction of surrogate markers for non-A, non-B hepatitis in the 1980s (ALT and anti-HBc) and of serologic testing for HCV antibodies in May 1990 (Fig. 154–1). The window period for the first-generation HCV antibody test extended to 6 months, but was reduced to 82 and 70 days with second- and third-generation assays, respectively.[8] Introduction of nucleic acid amplification testing for the HCV viral genome in 1999 reduced the window period to 10 to 25 days.[18] By combining NAT with serologic testing, the resultant risk per unit declined from an estimated 1 per 276,000 units to 1 per 1,935,000 units.[5,19] Of note, the residual risk estimates based on serologic testing alone have been confirmed by NAT screening in that the yield of HCV RNA-positive/HCV antibody-negative donations found among donations (1 per 263,000) was as predicted by the incidence-window period model.[20,21]

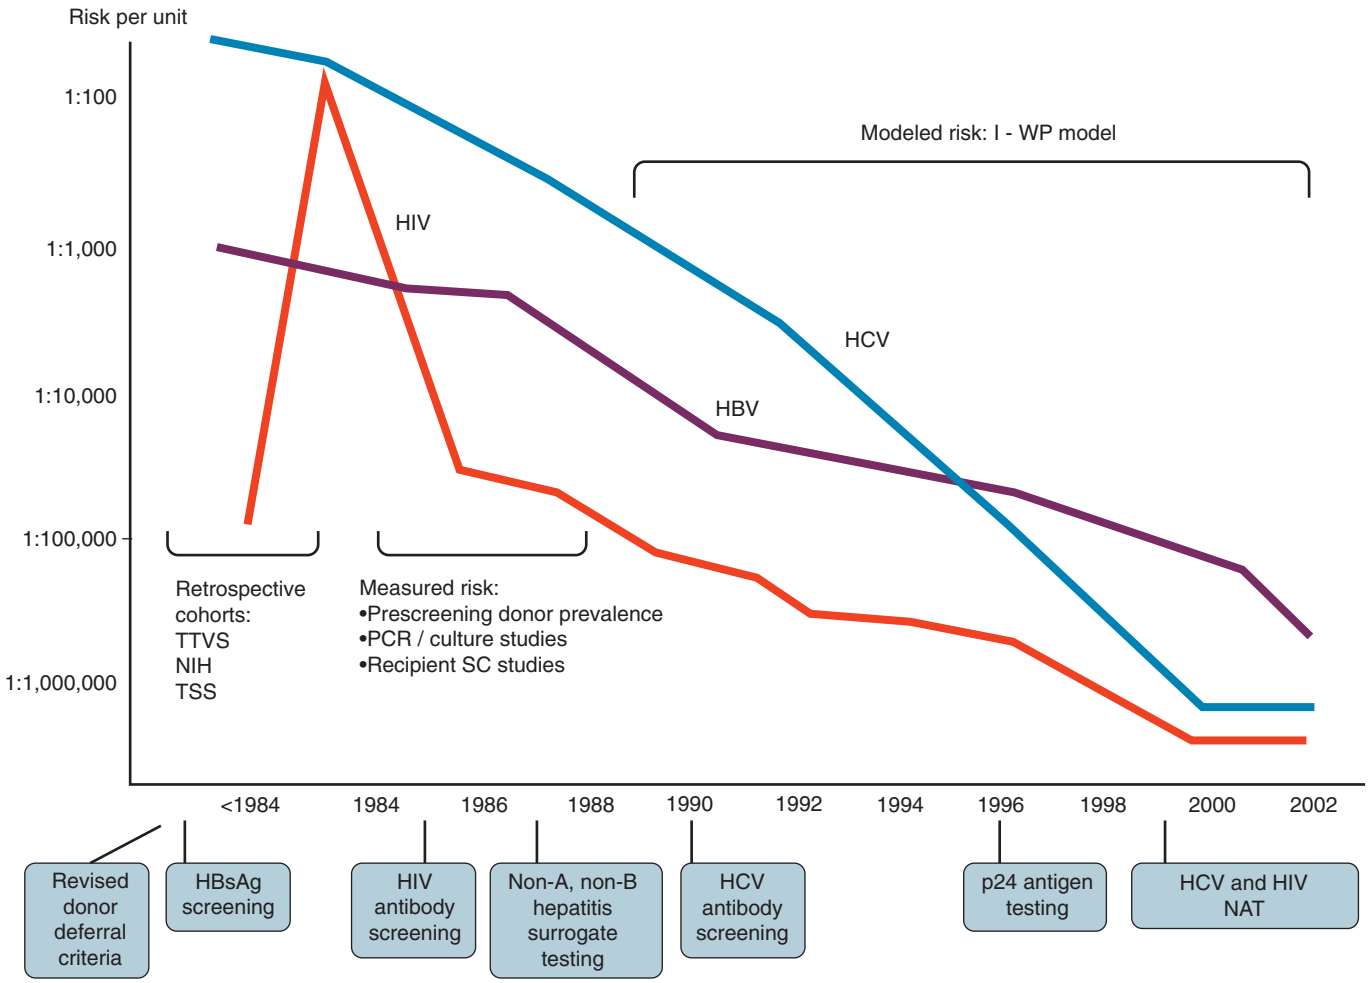

Figure 154–1 HIV, HBV, and HCV transfusion-transmission risks declined significantly during the past two decades. The boxed text below the *x*-axis indicates the major interventions contributing to risk reduction. (Data from Busch MP: Transfusion-transmitted viral infections: Building bridges to transfusion medicine to reduce risks and understand epidemiology and pathogenesis. Transfusion 46(9):1624, 2006.)

Because NAT is labor and resource intensive, HCV NAT feasibility depended on the use of so-called minipools, created by combining aliquots from 16 to 24 donations. Loss of test sensitivity due to sample pooling was tolerable given the rapid increase or burst of HCV viremia prior to antibody seroconversion (estimated doubling time of 10.8 hours in that period) and the high titer of viremia during the 40- to 50-day plateau phase preceding antibody seroconversion.[18] Consequently, NAT-positive donations that test HCV antibody negative contain 5×10^2 to 5×10^9 HCV copies per mL.[21–23] Although minipool NAT has been implemented successfully and with moderate yield in many developed countries,[21] NAT testing is expensive and the cost-effectiveness low.[24,25]

As an alternative to NAT assays, enzyme immunoassays have been developed that detect HCV core antigen in serum or plasma, either as separate tests that are run in parallel with HCV antibody screening assays or as so-called fourth-generation HCV antigen–antibody combination assays.[26,27] Although these tests significantly reduce the preseroconversion window period and are being adopted in developing countries, they have slightly less sensitivity than HCV NAT, approximately 10^5 gEq per mL,[28] and have not been introduced in the United States.

The remarkable advances in safety achieved by HCV NAT greatly reduced transfusion-associated HCV cases. Nonetheless, some newly infected individuals demonstrate fluctuations in HCV RNA, at times below NAT detection levels prior to HCV antibody seroconversion.[29] This possibly explains some of the low residual risk of transfusion-transmitted HCV infection despite the ongoing combination of HCV antibody and NAT testing.

The prolonged interval between infection and HCV clinical sequelae prompted blood bankers to conduct "Lookback" notification of previous recipients of blood donated by donors found HCV antibody positive.[30,31]

Hepatitis D

Originally called the delta agent, this is a defective RNA-containing passenger virus that requires HBV to act as a "helper" for assembly of envelope proteins. Screening for hepatitis B acts synergistically in preventing transfusion-associated hepatitis D cases by identifying donors that are coinfected with hepatitis B and D.[35]

Hepatitis E

The hepatitis E virus (HEV) is an RNA calicivirus associated with fecal-contaminated water supply that usually causes a self-limited illness. Transmission by transfusion had been postulated on the basis of cohort studies in endemic countries that showed a high prevalence of HEV among transfused patients. Recently transfusion transmission of HEV has been established in Japan, which led to the decision to screen blood donations by NAT in high-risk regions.[36] Fortunately, HEV is rare in the United States and most other developed countries and hence screening is not under active consideration.[35]

Lookback: Tracing Recipients of Earlier Blood Units from a Newly Identified Infectious Donor

The current donation from a blood donor who is found reactive on one of the routinely performed screening assays for transfusion-transmissible diseases is withheld from distribution and destroyed; previous donations from donors newly identified as infected with HIV or HCV require so-called "targeted lookback" in order to identify and notify the recipients of these potentially infectious units so they can be tested and counseled.[32,33] Targeted lookback differs from general lookback in that only recipients of "at risk donations" are identified, rather than all recipients of blood during a certain time period. The rationale for this requirement is that previous donations from newly infected donors may have been given during the window period of infection and could have been infectious despite nonreactivity on the screening assay (see box on Incidence/Window Period Model). Rules for the lookback process are complex, considering many variables and special situations. In general, lookback begins with a search by the blood collection facility for the most recent nonreactive donation from the implicated donor and all units donated during the preceding 12 months, assuming that any prior donations that could have been infectious but were not detected because of the window period phenomenon would have been contained in this time frame. The information on any identified unit(s) is forwarded to the transfusing facility, which searches its records for the recipient(s). The final step is recipient notification, preferably through the recipient's physician to allow testing and counseling as appropriate. In case of HIV, notification of relatives or legal representatives is mandatory if the recipient is deceased or judged incompetent, such notification is not required for HCV lookback. Because of longstanding implementation of sensitive screening assays and low incidence rates of HIV or HCV infection among blood donors, very few lookback investigations are triggered by confirmed reactive screening assays at present. This is in contrast with the first decade of the HIV epidemic, when it was not uncommon to perform lookback on prior donations from blood donors who were implicated because of presumed transfusion-associated HIV infection in the recipient. Large-scale targeted retrospective HCV lookback investigations were launched in many countries in the mid- to late 1990s to identify recipients of blood components who were donated by individuals before they were found to be HCV positive through blood donor screening beginning in 1990.[30,31] The efficacy of these programs have been low in general, and their value has been questioned. Recent experience in Canada further demonstrates the very limited value of targeted HCV lookback in the current setting of low disease prevalence and sensitive screening assays.[34] On the other hand it is clear that through this program some recipients could be contacted who would not have otherwise benefited from testing, counseling, adoption of a healthier lifestyle, and antiviral therapy.

Non-A–E Hepatitis

Several observations suggest hepatitis viruses other than those identified as hepatitis A-E viruses cause viral hepatitis. For example, cases of posttransfusion hepatitis occur occasionally despite screening or diagnostic testing for known hepatitis viruses. Similarly, a small but consistent percentage of community-acquired and chronic hepatitis cases test negative for known hepatitis viruses, some cirrhosis cases are classified as "cryptogenic," the etiologic agent for hepatitis-associated aplastic anemia eludes description, and the cause of some cases of acute liver failure remains undefined.[37]

Several candidate agents have been proposed as non-A–E hepatitis viruses.[38] GBV-C (initially also referred to as Hepatitis G Virus [HGV]) is a member of the Flaviviridae family and is transmitted predominantly by the parenteral route. Infection occurs frequently among those infected with HCV and HIV. Approximately 2% of blood donors and 15% to 20% of infection-drug users in the United States have detectable GBV-C RNA, and additional persons have antibodies against E2 envelope protein in the absence of GBV-C RNA, suggesting viral clearance. GBV-C has not been shown to cause liver disease, and hence there is no consideration of donor screening at this time. Of interest GBV-C infection may delay progression of disease in those coinfected with HIV, which has led to studies of the interactions of these viruses.[39]

The TT virus (TTV) is a large group of nonenveloped DNA viruses first discovered in 1997. TTVs are transmitted by transfusion, but their presence has not yet been correlated with liver disease. Although initial studies indicated a prevalence of viremia of 1% to 2% in North American blood donors, recent studies targeting more diverse TTV variants have identified viremia in the majority of healthy donors, suggesting these agents are commensal and nonpathogenic. Another entity, the SEN virus (SENV), was identified while investigating the TTV agent. SENV is a member of the Circoviridae, which are nonenveloped, curricular DNA viruses. Despite an initial report of two patients harboring SENV variants (SENV-D and SENV-H) with transfusion-associated non-A–E hepatitis, subsequent epidemiologic studies have failed to link SENV with clinical hepatitis.[37]

Thus neither GBV-C, TTV, nor SENV appear to fulfill initial indications that they represent clinically relevant hepatitis viruses. It is expected that identification of new putative viral hepatic agents will continue. The role and possible relationship of those agents to presumed non-A–E posttransfusion hepatitis awaits their discovery.

RETROVIRAL INFECTION

Human Immunodeficiency Virus-1

Initial reports of acquired immunodeficiency syndrome (AIDS) in hemophiliacs[40] and transfusion recipients[41] appeared in 1982. Subsequent studies unequivocally established transmissibility of the causative agent (HIV) by untreated coagulation factor concentrates and blood components.[42] According to the Centers for Disease Control and Prevention (CDC) 9706 AIDS cases in the United States were linked to transfusion through December 31, 2005, including 47 adults/adolescents and 3 children who were infected by blood from HIV-seronegative donors since antibody screening was implemented in early 1985.[43] In addition, since the early 1980s, 5712 hemophilic and other patients with coagulation disorders acquired HIV as a result of therapy with plasma derivatives. In hindsight the initial response to this crisis was criticized as perhaps too slow and indecisive.[44] Nevertheless, preventive measures to protect the blood supply were put in place quickly once the threat was fully recognized. Implementation of detailed blood donor history questioning with deferral of high-risk blood donors began in spring of 1983 and antibody testing for HIV in 1985. Almost all new cases after implementation of antibody screening were attributable to blood donations given during the so-called window period of infection (see text box).

Sequential introduction of improved, highly sensitive enzyme immunoassays for detection of HIV antibodies in the early 1990s, addition of testing for HIV-1 (p24) antigen in 1995, and HIV RNA testing on pooled donor samples in 1999 were instrumental in reducing the risk of HIV transmission by transfusion to its current low level (Fig. 154–1, Table 154–1). The risk for manufactured blood products, such as coagulation factor concentrates, albumin and immune globulin preparations, can be expected to be even lower because of additional viral inactivation processes, including heat (pasteurization), physicochemical processes (solvent/detergent treatment), and nanofiltration that have been implemented since the mid-1980s; indeed, no new HIV infections have been attributed to manufactured plasma derivatives since 1990.[45]

Blood centers notify donors found repeatedly reactive in HIV antibody-screening tests with appropriate counseling messages, even

if confirmatory or supplemental testing results by Western blot (WB) or immunofluorescence are negative or indeterminate. Donors with positive and persistently indeterminate WB are permanently deferred from giving blood for use in transfusion. Experimental data indicate that very few blood donors with indeterminate results by HIV supplemental tests are infected with HIV,[46] and that low-risk blood donors on occasion may have false-positive supplementary test results.[47] Recipients of prior donations from donors with confirmed positive results are traced through lookback investigations (see text box).

Human Immunodeficiency Virus-2

Human immunodeficiency virus-2, a retrovirus linked more closely to the simian immunodeficiency virus than to HIV-1, was recognized initially in West Africa in the late 1980s. Transmissibility of HIV-2 appears to be lower, the course of infection milder, and the interval between infection and AIDS and disease longer than associated with HIV-1.[48] Sixty-two cases of HIV-2 were reported in the United States as of June 30, 1995, leading to substantial concern over transfusion safety.[49] Antibody testing for HIV-1 detects 60% to 91% of HIV-2-infected persons, whereas HIV-2 antibody test kits detect more than 99%.[50] Blood donor testing for both HIV-1 and HIV-2 antibodies began in 1992. From 1992 through 1998, only three donors with HIV-2 infection were identified in the United States after screening more than 50 million donations, suggesting a very low risk for HIV-2 transmission by transfusion.[51] Almost all cases occur in Africa or have historical links to that region.[52]

HIV-1 Group M Subtype and Group O Infections

The majority of HIV-1 infections are caused by subtypes of group M (main group) viruses. In the United States and Europe almost all HIV-1 infections are caused by subtype B viruses, but worldwide other subtypes dominate locally.[52] Widely used antibody assays for detection of HIV-1 infection are based on subtype B antigens and do not perform as well with non–subtype B viral strains[53] leading to concern that infections with such strains could be missed. Fortunately, HIV-1 NAT assays appear to have good sensitivity to all group M variants, which has tempered this concern. Ongoing surveillance studies have recently been launched to monitor emergence of new HIV variants and the effectiveness of routine HIV test kits for detecting these viruses.[54]

The HIV-1 group O (outlier group) viruses were isolated from patients in Central and West Africa in 1994. These HIV-1 variants share 65% to 70% homology with HIV-1 and 56% with HIV-2. Through 1997, two HIV-1 group O-infected persons were identified in the United States and only rare cases have been reported subsequently in industrialized nations.[52,55] To safeguard against possible false-negative HIV antibody test results in blood donor screening, blood donors are deferred if they were born in, lived in, traveled to and received a blood transfusion, or had risk exposures in HIV-1 group O-endemic African countries.[56]

This deferral policy may be reversed once antibody and NAT assays with established sensitivity to group O viruses are licensed by FDA and implemented.

Human T-Lymphotropic Virus-I and -II

HTLV-I and -II are closely related retroviruses in the oncovirinae group with 60% to 70% sequence homology and shared tropism for T lymphocytes. In contrast to HIV, HTLV is rarely present in cell-free plasma and shows little active replication in infected humans. HTLV is found around the globe, with endemic foci in southern Japan, the Caribbean, certain parts of South America, Africa, the Middle East, and Melanesia.[57] An epidemic of HTLV-II infection has been observed over the past 40 to 50 years among intravenous drug users in the United States, Brazil, and Europe.[58] Transmission of both HTLV-I and -II occurs by parenteral exposures, through sexual contact, and by vertical transmission from mother to child during pregnancy and breast feeding.

Diseases associated with HTLV-I infection include adult T-cell leukemia/lymphoma (ATL), HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP), lymphocytic pneumonitis, uveitis, polymyositis, and arthritis.[59] HTLV-II does not appear to cause hematologic malignancy but has been associated with the other conditions attributed to HTLV-I infection, and also has been linked to a higher rate of common infections such as acute bronchitis, pneumonia, and urinary tract infections, suggesting a mild immunosuppressive effect of the virus.[60]

Patients with ATL have HTLV-I provirus integrated into $CD4^+$ flower-like cells.[61] ATL occurs in 2% to 4% of infected persons following a latent period that extends for many decades. The illness is characterized by leukemia, generalized peripheral lymphadenopathy, hepatomegaly, impaired liver function tests, splenomegaly, skin lesions, bone lesions, and hypercalcemia.[62,63] HAM/TSP occurs in approximately 2% of HTLV-I- and HTLV-II-infected individuals. Patients with transfusion-associated HAM/TSP develop neurologic symptoms at a median of 3.3 years after transfusion.[63] This illness is characterized by slowly progressive chronic spastic paraparesis, lower limb weakness, urinary incontinence, impotence, sensory disturbances, low back pain, hyperreflexia, and impaired vibration sense.

Risk factors for HTLV-I and -II infections in blood donors include low educational attainment, accidental needle sticks, previous blood transfusion, seven or more lifetime sex partners, and a sex partner from an HTLV endemic area. Injection drug use or having sex with a drug user associates significantly with HTLV-II but not with HTLV-I infection.[64]

Blood donor screening for HTLV-I antibodies began in 1988, and a more sensitive HTLV-I/II combination assay that detects close to 100% of HTLV-II infections was introduced in 1998.[65] The prevalence of HTLV confirmed positive infectious markers among first-time blood donors decreased approximately 10-fold during the 1990s to 0.01% in 2001 with a similar decline in incidence rates in repeat donors.[1] Consequently, risk projections based on the incidence rate / window period model were lowered to approximately 1 in 3 million blood donations in 2001.[5] Because essentially cell-free components such as plasma and cryoprecipitate do not transmit HTLV and only 30% of infected cellular components result in transmission,[66] the threat of acquiring HTLV infection from screened blood appears to be minimal at this time.

More problematic is the notification of healthy blood donors of possible HTLV infection because of a false-positive result with the screening EIA. This is more likely to occur with HTLV than with HIV or hepatitis infection because of a lack of licensed confirmatory tests for HTLV. In recognition of this deficiency, FDA approved an algorithm that accepts nonreactivity on repeat testing with a second screening EIA from a different manufacturer as evidence that infection is absent.[67] This strategy resolves nearly two-thirds of false-positive screening results but still results in a large number of false notifications and does not address the issue of providing targeted counseling for HTLV-I versus HTLV-II infection. Because blood donors who are notified of possible infection suffer considerable psychosocial stress,[68] development of supplemental tests that meet criteria for licensing is a priority.

HUMAN HERPES VIRUS INFECTIONS

Human herpes viruses (HHV) are enveloped, structurally complex double-stranded DNA viruses that cause common infectious diseases, usually associated with life-long carrier states and the possibility of recurrent reactivation infections. They are classified in 3 subfamilies, alpha-, beta- and gamma-herpesvirinae, of which the latter two contain the herpes viruses that are of greatest concern from a transfusion medicine standpoint. Members of the alpha herpes virus subfamily, herpes simplex viruses, and varicella zoster virus, rarely, if ever cause transfusion-transmitted infections.

Cytomegalovirus (HHV-5)

Cytomegalovirus (CMV), a beta herpes virus, can infect a wide range of cell types, including leukocytes of monocyte-macrophage lineage and their progenitors, of which the former represent the preeminent source of transfusion-transmitted infection.[69] Consequently, cell-depleted blood components (plasma, cryoprecipitate) do not transmit CMV. Primary CMV infection in immunocompetent individuals is usually community-acquired and often asymptomatic or associated with a mild, self-limited infectious mononucleosis syndrome. However, in virtually all cases, latent virus persists permanently in cellular reservoirs, allowing lifelong reactivation infections, or in the setting of transfusion or transplantation, viral transmission via cellular blood products, or transplanted donor organs.

In immunosuppressed patients, CMV infection leads to pneumonitis, hepatitis, gastroenteritis, retinitis, and other inflammatory conditions, often associated with considerable morbidity and mortality. Primary infection in pregnancy does not pose a threat for the woman but is associated with severe fetal malformation syndromes and congenital infections complicated by jaundice, hepatosplenomegaly, microencephaly, and thrombocytopenia. Fetal mortality rates approach 20%.[70] Premature infants (<1200 g birth weight) born to CMV-seronegative women are at particular high risk for symptomatic CMV disease, including hemolytic anemia. Morbidity varies considerably from a few percent to 50% of seronegative infants receiving unscreened, nonleukoreduced blood. CMV-seronegative marrow transplant patients are also strongly susceptible to CMV infection, with approximately 30% of those infected developing symptomatic CMV disease in the past, before institution of routine monitoring for CMV antigenemia and preemptive antiviral therapy.[71] Seronegative renal and liver transplant recipients are also susceptible to symptomatic transfusion-transmitted CMV infections, but the risk associated with receiving seropositive solid organs outweighs that attributed to blood transfusion. CMV-seronegative HIV-infected patients represent another group at risk for transfusion-transmitted primary CMV infection.[72]

On average 50% of US blood donors have antibodies against CMV, thereby indicating prior CMV exposure and potential to transmit the disease via latently infected circulating monocytes.[69] The reported risk of (usually asymptomatic) CMV infection in seronegative immunocompetent patients who receive non–leukocyte-reduced cellular blood components unscreened for presence of CMV antibodies is approximately 1%.[73,74] In contrast, the historical risk of CMV infection in immunocompromised recipients receiving CMV-unscreened, non–leukocyte-reduced blood components has been reported in various studies from 13.5% to 53.3%.[75] Selection of CMV seronegative or leukocyte-reduced blood components for susceptible patient groups have significantly reduced the risk of transfusion-transmitted CMV infection. Neither method is fail-safe in preventing transfusion-associated CMV transmission, however, and "breakthrough" infections have been reported in bone marrow transplant recipients at a rate of 1% to 2% for CMV-seronegative units and 1% to 6% for leukocyte-reduced blood components.[76,77] Whether both methods of creating "CMV-safe" or "risk-reduced" blood components are equivalent in protecting transfusion recipients continues to be a matter of debate.[78–80] At least in the allogeneic bone marrow transplant setting, a recent meta-analysis of available studies comparing both strategies found selection of CMV-seronegative components more effective than leukocyte reduction.[75] This may not translate in a difference in clinical outcomes, though, as implementation of prospective monitoring for CMV antigenemia and preemptive treatment with ganciclovir is preventing all but rare cases of CMV disease nowadays.[77]

In the absence of clear-cut scientific data and interpretation, it has been recommended that each institution review its internal policies for blood use in patients vulnerable to CMV infection.[81,82] Table 154–2 lists patient populations for whom use of CMV "risk-reduced" components, that is, CMV seronegative, leukocyte-reduced or units meeting both criteria, are thought to be beneficial. If leukocyte reduction is chosen as a means to reduce the risk of CMV transmission, components prepared by prestorage-leukocyte reduction should be selected because leukocyte removal by this method is more reliable than bedside filtration.[81,82]

Table 154–2 Patients Benefiting From CMV-Risk-Reduced Blood Components*

- Infants <1200 g with CMV-seronegative mothers
- Seronegative autologous and allogenic (CMV-seronegative donors) progenitor cell transplant recipients
- Seronegative progenitor cell transplant candidates
- Seronegative recipients of seronegative solid organ transplants
- Seronegative pregnant women
- Fetuses receiving intrauterine transfusions
- Immunosuppressed patients receiving granulocyte transfusions
- HIV-seropositive/CMV-seronegative patients

*CMV-risk reduced components include CMV-seronegative and leukocyte-reduced components. From references 69 to 82.

In the future, nucleic acid testing (NAT) for CMV genomic sequences in plasma may offer an approach for additional risk reduction by blood donor screening, as rare blood donors who present with window period infections prior to emergence of CMV antibody may be detected and their donations discarded.[83] Presently, it is not clear, however, if detection of plasma viremia by NAT equates infectivity. Current NAT assays also do not seem to be more effective than serologic screening in detecting latently infected healthy blood donors, as CMV DNA was not reproducibly detected in unequivocally seronegative samples.[84] Most promising appears to be CMV NAT screening of umbilical cord blood transplants as an adjunct to serologic screening.[85]

Another concern is CMV seropositive patients who theoretically remain at risk for second-strain infections. These have been reported in immunocompetent patients, where they appear not to be associated with added morbidity, and in recipients of solid organ transplants, where they do contribute to more severe disease than from reactivation of endogenous virus.[72,81] The source of second-strain infections in the latter setting is frequently the transplanted organ, whereas evidence linking blood transfusions as the source is not available. Furthermore, because reactivation of latent infections is a common occurrence in seropositive immunosuppressed patients, the benefit of providing reduced-risk CMV components for these patients is unproven and generally not recommended.

Ex vivo and observational clinical studies suggest a link between allogeneic leukocytes in blood transfusion and reactivation of latent CMV infection,[86] providing an argument for using leukocyte-reduced blood to decrease infections in immunosuppressed CMV-seropositive patients. Although theoretically compelling, the effectiveness of this approach has not been demonstrated in prospective studies.[87]

Epstein–Barr Virus (HHV-4)

Epstein–Barr virus (EBV), a gamma herpes virus, is the etiologic agent of heterophile antibody-positive infectious mononucleosis and is closely associated with Burkitt lymphoma, nasopharyngeal carcinoma, and posttransplant lymphoproliferative disease (PTLD).[88] Transfusion transmission of the virus is unlikely because more than 90% of the adult population has evidence of previous exposure, and infection is deterred by host virus-specific cytotoxic T lymphocytes, capable of lysing EBV-infected B lymphocytes when viral peptides are expressed on the lymphocyte surface.[89] Rare cases of transfusion-transmitted EBV presenting as infectious mononucleosis have been described in both immunocompetent recipients[90,91] and in immunosuppressed patients following solid organ transplantation.[92] Aggressive EBV-associated lymphoproliferative disorders have been observed in patients with weakened immune system following cord blood stem cell transplantation[93] but have not been documented following

transfusion. Because B lymphocytes are the likely source of transfusion-transmitted EBV infection, leukocyte reduction of cellular blood components that efficiently removes B cells is an attractive strategy to prevent infection in transfusion recipients.[94] The validity of this assumption has yet to be validated in controlled clinical trials.

Kaposi Sarcoma Virus (HHV-8)

HHV-8, a gamma herpes virus linked to Kaposi sarcoma, body cavity based lymphoma and Castleman disease has tropism to lymphocytes and monocyte-macrophages, and has been shown to be transmitted by transplantation. The possibility has been raised that transfusions given in the United States have transmitted HHV-8,[95] but definitive evidence is lacking. The seroprevalence of HHV-8 among US blood donors has been reported in regional studies as high as 20% to 25%.[96] However, a recent multicenter study in five representative US regions found a seroprevalence of only 3% to 3.5% and no evidence of viremia.[97] These findings are in agreement with epidemiologic studies that suggest sexual contact is the preferred route of HHV-8 transmission whereas blood-borne transmission appears to be an unlikely event.[98,99] On the other hand there is convincing evidence of HHV-8 transmission by transfusion in sub-Saharan Africa where seroprevalence of HHV-8 among blood donors is 40%, and fresh, nonleukoreduced transfusions are common practice.[100] Similar to what has been established for CMV infection, it can be assumed that leukocyte reduction mitigates the risk of HHV-8 transmission via transfusion, but this has not been demonstrated.

Parvovirus

Human parvovirus B19 is a 19- to 23-nm-diameter nonenveloped, single-stranded DNA virus that is included in the Parvoviridae family along with adeno-associated viruses and newly discovered viruses PARV 4, PARV 5 and bocavirus.[101] Parvovirus B19 causes fifth disease or erythema infectiosum and has been linked with transient aplastic crises in patients with sickle cell anemia, inherited hemolytic diseases, and malaria as a result of severe reticulocytopenia and anemia.[102] Acute infection impairs erythropoiesis for 7 to 10 days and causes complete cessation for 3 to 7 days, resulting in hemoglobin decreases. Arthropathy has been reported in adults and loss of joint range of motion in children with hemophilia.[103] Immunocompromised patients have been reported to suffer prolonged anemia, erythrodermia, hepatitis, myocarditis, and pancytopenia.[104] Although B19 has at least three genotypes, little is known about transmission and pathogenicity of genotypes 2 and 3.[105]

B19 infects only humans.[106] Transmission occurs through the respiratory route most commonly, through the placenta to a fetus in up to 30% of women infected during pregnancy, and through transfusion of blood, blood components, and plasma derivatives. Transmission to immunocompetent patients, and those with hemolytic hemoglobin disorders, rarely results in systemic illness. In contrast, in women infected during weeks 9 to 20 of pregnancy, fetal death occurs in approximately 11% from hydrops fetalis.[108] The overall low incidence of infection in transfused patients results from coinfusion of neutralizing antibodies or because of low viral load, less than 4×10^3 genome equivalents per mL.[105,109] B19 is highly tropic for erythroid progenitor cells gaining access to cells through the blood group P antigen, or globoside, that serves as the virus receptor.[106,107] Following acute infection, viral replication leads to extremely high viremic levels that decline in response to IgM antibody production approximately 9 days following infection.[102] B19 may persist in bone marrow, liver, tonsils, and skin of healthy persons.[101]

B19 infection is ubiquitous, with 50% of high school children demonstrating seropositivity that increases to 90% in older adults.[106,107,110] Persistent infection, including pure red cell aplasia, occurs in those not developing neutralizing antibodies to the viral capsical protein 1 (VP1). In these patients, the virus circulates at high titer, greater than 10^{12} genome copies/mL.[106,107] Patients at risk for persistent infection include those receiving chemotherapy, immunosuppressive drugs, organ transplant recipients, and those with HIV.

Blood and blood-derivative transmission involves donations during the transient 1- to 2-week high-titer viremic period. The prevalence of B19 viremia has been reported as 0.003% to 0.6% in blood and plasma donors.[109] Hence, most blood transfusion recipients are at relatively low risk of exposure whereas recipients of pooled, plasma-derived products involving thousands of donors have a significant risk. In one report, 14% of viremic plasma donors had titers between 10^4 and 10^7 genome equivalents/mL and 1 in 13,000 had titers greater than 10^7.[110] In observational studies, seroconversion occurred among recipients of plasma with high titers, $10^{7.5}$ to $10^{8.5}$ genome copies/mL treated with the solvent/detergent pathogen reduction technique suggesting the presence of anti-B19 antibodies are not protective against large viral loads. (See Pathogen Reduction/Inactivation Methods) Seroconversion did not occur among recipients of plasma with viral titers between $10^{0.5}$ and $10^{3.5}$ genome copies per mL. However, parvovirus transmission has been reported in a recipient of solvent/detergent-treated antihemophilic factor concentrate containing 1.3×10^3 genome equivalents/mL and in a recipient of a dry-heat-treated, 80°C for 72 hours, factor VIII product containing 4×10^3 genome equivalents per mL.[109,111] Solvent/detergent treatment is ineffective in preventing B19 transmission, but freeze-drying and dry-heat treatment (80°C for 72 hours) inactivates more than 4.7 logs B19, which may not be sufficient to prevent transmission.[112]

Currently, plasma derivative manufacturers use "in-process" nucleic acid testing to identify source plasma units with high-titer parvovirus B19, greater than 10^4 genome equivalents/mL. Approximately 1 per 10,000 plasma units are withheld from further processing. Because individual whole-blood donations rarely cause parvovirus infection, testing of single red cell units, platelet or plasma for parvovirus B19 is not under consideration currently. Of note, PARV4 and PARV5, but not human bocavirus, have been detected in pooled plasma derivative samples.[101]

West Nile Virus

The West Nile Virus (WNV) is a mosquito-borne lipid-enveloped RNA virus in the Japanese encephalitis flaviridae complex. Transmitted bird-to-bird by mosquito vectors, human infections occur incidentally. The first cases were identified in the West Nile district of Uganda in 1937. Subsequently, outbreaks occurred in the Middle East, South Africa, and Europe. The first North American cases appeared in New York City in 1999.[124] Starting in July 2000, WNV cases spread to the Mid-Atlantic states. In July 2001, 66 cases were reported in the eastern one-third of the United States. In 2002 the epidemic spread to the Midwest and eastern plains states. Four organ transplant recipients developed WNV infection.[125] In 2003, the epidemic intensified into in Nebraska, Colorado, North and South Dakota, and Wyoming with 9862 cases reported and more than 1000 healthy blood donors testing positive. By 2004, case reports declined in the Northeast but extended westward into Arizona and Southern California. In 2005, more than 2800 cases were reported, with approximately 25% occurring in California, relatively high activity in South Dakota, Nebraska, Louisiana, and Illinois, and low activity in the Northeast. Approximately 400 viremic blood donors were identified. In 2006, more than 4050 cases occurred with WNV activity reported in Washington for the first time and high-frequency reports in Idaho, California, Nebraska, Illinois, Louisiana, and the Dakotas.[126] More than 340 blood donors had positive test results.

WNV viremia appears 1 to 3 days following a bite from an infected mosquito. In contrast to HIV and HCV, peak WNV levels are relatively low, median 3500 copies/mL compared to 10^5 to 10^7 copies for HIV and HCV. In a cohort analysis comparing blood donors with positive WNV RNA tests to presumably uninfected donors, 61% of those with positive tests described symptoms such as headache, eye pain, new rash, or weakness within 21 days of donation

Pathogen Reduction/Inactivation Methods

Expanded blood donor screening coupled with deferral of high-risk donors have greatly reduced the risk of transfusion-transmitted diseases (TTDs) over the last two decades. These passive protective measures, however, cannot ensure complete protection from known TTDs and are of limited utility in safeguarding the blood supply from emerging and currently unknown infectious agents. Pathogen reduction and inactivation methods (PRIMs) promise to add another layer of safety by removing a broad range of pathogenic agents, reducing their capabilities to cause disease, or both.

PRIMs have long been employed in the manufacture of plasma derivatives such as albumin, gammaglobulins, and coagulation factor concentrates.[113] The relative stability of these proteins made it comparatively easy to use heat or chemical processes to inactivate infectious agents in the product without damaging the therapeutic ingredient. The principal limitation of these methods is their relative inefficiency against non-lipid-enveloped viruses such as HAV and parvoviruses. Recently, nanofiltration has become available as another effective approach to remove nonenveloped viruses in the manufacture of plasma derivatives.[114]

More challenging is treatment of blood components containing living cells or labile plasma proteins. Pathogen reduction and inactivation in acellular components poses lesser problems, and several chemical and photochemical principles have been developed.[115] Longest in use is solvent detergent-treated plasma (SDP), which has been available in Europe since the early 1990s and became available in the United States in 1998. Solvent detergent treatment is highly effective against lipid-enveloped viruses, including HIV and HCV, but is relatively ineffective against nonenveloped viruses.[116] In this context, the concern was raised that the pooling process in the manufacture of SDP that combines plasma donations from approximately 2500 individuals could lead to the inadvertent spread of viruses not affected by the treatment. Validating this concern, numerous lots of SDP were recalled in the United States following parvovirus seroconversions in recipients of SDP; rare cases of clinical disease due to parvovirus infection were also reported.[117] Unrelated to considerations regarding infectious disease transmissions, the product was withdrawn from distribution in the United States in 2002 following a series of deaths from excessive bleeding and thrombotic complications associated with use of SDP in patients with severe liver disease and liver transplants. The product is still available outside the United States, however. An alternative PRIM for treatment of plasma is photodynamic treatment in which photosensitive compounds such as methylene blue (MB), psoralens, or riboflavin (vitamin B_2) are added and activated by exposure to UV light. Pathogen inactivation occurs through oxidation (MB) or binding to DNA or RNA in case of psoralens and riboflavin. The photodynamic methods have the advantage of being suitable for single-unit treatment, avoiding the problems with pooling. Some loss of coagulation factor activity and platelets occurs, the significance of which is being studied. MB-treated plasma has been available for years in European countries, and psoralen/UV light plasma is undergoing clinical studies.[118–120] Platelets treated with psoralen/UV light are available for routine clinical practice in Europe and have successfully completed clinical studies prior to product approval in the United States[121]; a riboflavin-based method is in earlier stages of investigation. Adoption of photodynamic principles for pathogen inactivation of red blood cell components is complicated by absorption of long-wave UV light by hemoglobin. Overall pathogen reduction is seen by some transfusion medicine leaders as an important step in mitigating transfusion risk in a era of emergency pathogens.[115]

A unique problem is posed by removal or inactivation of prions, the abnormal cellular protein that has been identified as causative agent of transmissible spongiform encephalopathies, including vCJD. Existing physical or chemical methods are ineffective, and methods that work are too severe to be applied to blood products.[122] Initial hopes that leukocyte reduction would remove prions were not fulfilled, but an experimental, specially designed leukocyte reduction filter may be effective for prion removal as well.[123]

Although there is no dearth of PRIMs for blood components already available or under consideration, remaining questions of efficacy, component function, residual toxicity, and cost have to be answered before these methods will find widespread acceptance in clinical practice. It is expected, however, that newer-generation PRIMs will fulfill the stringent requirements and will provide an added layer of safety to transfusable products in the future.

compared to 20% of those not infected.[127] These findings suggest donor history information is insufficient to prevent transfusion transmission. Testing for antibodies, also, does not prevent transmission because IgM antibodies appear a median of 14 days and IgG antibodies a median of 17 days postinfection. Hence, nucleic acid testing for WNV RNA was selected as the testing strategy. Following intense collaboration among virologists, government officials test manufacturers and blood centers; WNV RNA testing was introduced at the start of the 2003 WNV season. To achieve efficiency, blood donors' samples were tested in minipools containing aliquots from 6 or 16 donors. More than 1000 donors tested positive[128–133] and six transfusion-associated WNV cases occurred during 2003. The implicated donors had low-level viremia that escaped detection in the minipool samples. Subsequently, test performance improved and blood collection agencies implemented strategies in which individual donation rather than minipool testing occurred in areas experiencing proportionally high WNV attack rates. One transfusion-associated case occurred in 2004 and one in 2006.[134] Of the 30 cases reported prior to 2006, all implicated donations tested WNV IgM-antibody negative.[135,136]

In a study involving more than 13 million blood donations between 2003 and 2005, WNV RNA testing performed on individual donation samples detected 22% of WNV-infected donors who tested negative using minipool samples.[137] Of these donations, 5.3% were antibody negative and presumably infectious. In test-positive donors, WNV RNA persisted in 42% for a median of 14 days. On the basis of multiple reports, the median viremic duration approximates 6 days but may persist for up to 104 days.[128–133,138] IgM antibodies appear 7 to 14 days postinfection and correspond to a decrease in RNA levels. IgM antibodies persist for more than 398 days in approximately two-thirds of those infected.

Up to 1% of WNV-infected patients develop neuroinvasive disease manifest by meningitis, encephalitis, or acute flaccid paralysis. Even among those with mild illness, 13 months after diagnosis, 50% WNV-infected patients report that fatigue, memory problems, and extreme weakness occurs, one-third have headaches, one-quarter suffer intention tremors, and 13% have word-finding difficulty.[138] The overall mortality rate in reported cases approximated 3.6% in 2006.

Currently, blood collection agencies conduct WNV RNA on every donation despite questions about the cost-effectiveness, $483,000 per quality-adjusted life-year for year-round minipool testing, compared to target testing based on WNV prevalence and seasonality.[139,140]

BACTERIAL CONTAMINATION

Bacterial contamination of red cell and platelet components ranked among the top three causes of transfusion-related fatalities reported to the FDA, with 85 cases (13% of all reported) in the 1995 to 2004 time period.[141] Bacteria enter blood containers as a result of inadequate skin disinfection at the phlebotomy site, transient asymptomatic bacteremia at the time of blood donation, a break in technique

during pooling or sealing, or through disruption of container integrity. Bacterial proliferation occurs more rapidly in platelet concentrates stored for up to 5 days at room temperature than in red cells stored for up to 42 days at refrigerated temperatures.[142,143] Importantly, bacterial contamination represents a well established risk associated with autologous transfusion, because of more permissible acceptance standards of autologous donors and usually long storage times of donated blood units which favors bacterial growth.[144]

The frequency of bacterial contamination in red blood cell units has not been well established but can be expected in the order of at least 1 in 30,000 transfusions, with a prevalence of significant clinical outcomes of 1 in 500,000 transfusions and fatalities at a rate of 1 in 10,000,000. Prior to universal screening of platelet products for bacterial contamination in the US which occurred in March of 2004, the rate of bacterial contamination in allogeneic platelets was estimated at 1 in 1,000 to 3,000 units, the rate of life-threatening septic reactions at least at 1 in 100,000 recipients, and the rate of fatalities at 1 in 500,000.[145,146] Large-scale culturing of platelet component samples since implementation of screening for bacterial contamination demonstrated a lower contamination rates of approximately 1 in 5,000,[147,148] but the previously observed rates for sepsis and fatalities are probably low estimates, related to underreporting.[149] It can be expected that because of interception of screening-positive platelets, current transfusion reaction and fatality rates have improved, although it is clear that contaminated platelets may escape detection with available methods, and breakthrough cases of transfusion-associated sepsis continue to occur.[147,150]

Septic transfusion reactions should be suspected if the following occur within 1 to 4 hours of transfusion: fever greater than 1°C to 2°C from pretransfusion levels, chills and rigors, tachycardia more than 120 beats per minute or an increase of 40 beats per minute, or an increase or fall in systolic blood pressure of greater than 30 mm Hg. Additional signs and symptoms include nausea, vomiting, diarrhea, bleeding, oliguria, or septic shock.[142,145] Septic transfusion reactions may be confused with febrile, nonhemolytic transfusion reactions or may be masked by concurrent antibiotic administration.

Microorganisms isolated from contaminated red cell units include *Serratia liquefaciens*, *Pseudomonas* species, the plant pathogen *Enterobacter agglomerans*, and most important, *Yersinia enterocolitica*. The latter, a gram-negative endotoxin-producing organism is remarkable for its preference to grow at colder temperature in iron-enriched environments. Gram-positive skin saprophytes account for most of the organisms contaminating platelet concentrates, with the remaining attributed to gram-negative organisms associated with occult bacteremia. Most fatal reactions are due to endotoxin reactions associated with gram-negative bacteria. Platelet concentrates contaminated with *Bacillus* species, *Escherichia coli*, *Klebsiella* species, *Staphylococcus aureus* and *S epidermidis*, *Serratia marcescens*, and *Streptococcus* species account for 85% of fatal reactions.[151] The bacterial dose in platelet concentrates leading to morbidity or mortality is not known precisely. Bacterial concentration of 10^8 CFU per mL resulted in fatalities.[152]

Immediate recognition of a septic reaction, followed by prompt discontinuation of the transfusion, and antibiotic administration form the mainstay of therapy. Prevention relies on careful donor selection, and scrupulous adherence to aseptic techniques and precautions from component collection, processing, transport and storage to transfusion at the bedside. Better prevention of bacterial contamination may be achieved by newly introduced skin disinfection solutions and diversion and discard of the first 15–30 mL of collected blood. These methods alone or in combination may reduce the bacterial load in skin fragments trapped in the phlebotomy needle that subsequently enter blood storage containers.[153,154]

In addition to precautionary measures to minimize bacterial contamination of blood products, screening for and interdiction of affected units is now in place for whole blood derived and apheresis platelets. Both culture-based methods and alternative approaches, such as microscopic examination of stained platelet smears, detection of decrease in pH and glucose associated with bacterial growth, and visual assessment for loss of "swirling," which describes the normal shimmering light reflection of platelets bags when viewed against a light source, have been applied to screening. Culture-based methods are more sensitive and reliable than surrogate tests but require time for bacterial growth to occur. Depending on the system used, contamination rates from 1 to 500 bacterial CFU/mL are generally detected 24 hours after inoculation of the culture media.[153] It should be noted, however, that bacteria grow at variable rates.[151] *Staphylococcus epidermidis* grows slowly and *Propionibacterium acnes* requires, on average, 69 hours for detection. Despite excellent sensitivity some slow-growing bacteria, which nevertheless can cause significant reactions, will be missed with the usual approach of platelet release after the first 12 to 24 hours of incubation, if the cultured sample shows no growth. As culturing generally continues until the expiration date of the platelet unit or detection of growth, there is further opportunity to intercept released platelets that have not been transfused or alert physicians about the potential risk of bacterial contamination in cases where the units were already administered.

Non-culture methods for detecting bacteria in platelet units allow rapid testing just before transfusion, that is, at a time point when assessment for bacterial contamination is most relevant and has the greatest chance to identify a significant bacterial concentration. Current tests defect 10^{4-6} CFU/mL, and are used as an adjunct point of care test for platelets tested by bacterial culture. Visual inspection for discoloration or loss of swirling is subjective and performs poorly. Gram staining and multireagent strip testing generally require bacterial contamination levels of at least 10^6 CFU/mL, a threshold that may not reliably detect all platelet units that have the potential to cause septic reactions.[153] In addition, the latter test can be expected to have a 1% false-positive rate, which translates into substantial product wasting. Future nucleic acid-based nonculture methods currently under development promise to be more sensitive and specific, which would make them a more suitable alternative to culture methods.

Prior to the mid-1980s, platelet concentrates were stored for 7 days. Following reports of septic reactions, the shelf-life was reduced to 5 days to decrease the interval during which bacteria could proliferate. Methods for detecting and interdicting contaminated platelets may permit return to a 7-day storage interval, with the benefits of decreasing outdating and increasing availability of this component with limited shelf-life. In the United States, blood suppliers briefly distributed platelets with a 7-day shelf life following enrollment in an FDA-mandated postmarket surveillance (PASSPORT) study that included testing for bacterial contamination by a sensitive culture method.[155] Initial experience suggested that extended platelet storage coupled with bacterial testing substantially decreased platelet loss from outdating, but some platelet products with negative bacterial cultures obtained 24 hours postcollection had bacterial growth when tested 7 days later, leading to discontinuation of 7 day storage.

SPIROCHETE INFECTIONS

Syphilis

No cases of transfusion-associated syphilis (*Treponema pallidum*) infections have been reported in the United States in the past 4 decades. Donor selection changes, uniform serologic testing, lack of spirochete viability in blood stored at refrigerated temperatures, decreases in the rate of primary syphilis, and widespread antibiotic usage either alone or in combination contributed to this successful outcome.[156–159] Currently, most blood collection agencies use an automated test for detecting treponemal antibodies. Approximately 50% of donors with confirmed positive test results, have evidence of a treated syphilis infection.[157] Persistent false-positive reactions occur in patients with hepatitis, mononucleosis, viral pneumonia, chicken pox, measles, immunizations, or pregnancy. Donations with reactive syphilis tests are discarded unless nonreactive in a confirmatory test. Blood centers defer donors with positive confirmatory tests for 1 year and then restore donor eligibility provided the donor underwent adequate syphilis treatment and has a negative non-treponemal serologic test result.[158]

Lyme Disease

The *Borrelia burgdorferi* spirochete causes Lyme disease, the most frequently occurring tick-borne infection in North America and Europe.[160] *Ixodes scapularis*, the black-legged tick, transmits *B burgdorferi* in the northwestern and north-central parts of the United States, and *I pacificus*, the western black-legged tick, transmits the infection along the Pacific coast. The ticks feed predominantly in late spring and early summer during the nymphal stage whose bites are associated predominately with transmission to humans. Deer are not infected; rather they transport and maintain the ticks.

B burgdorferi spirochetemia occurs in 44% of patients with Lyme disease and peaks 7 to 10 days post–tick bite. The spirochete survives routine red cell and frozen plasma storage for up to 45 days and in platelets for 6 days. Transfusion transmission of *B burgdorferi* has been demonstrated in a murine model.[161–164] Despite these observations, no human transfusion-associated cases have been reported. This may reflect the relatively short spirochetemia phase and deferral of donors with fever, headache, malaise, myalgia, arthralgia, Bell Palsy or rash that occurs 3 to 30 days after exposure. Individuals with a history of Lyme disease are accepted as blood donors 12 months following treatment and resolution of symptoms.

Other Tick-Borne Pathogens

The rickettsial agents, human monocytic ehrlichiosis (HME) and human granulocytic anaplasmosis (HGA), formerly human granulocytic ehrlichiosis, are intracellular organisms that survive in stored blood. *Ehrlichia chaffeensis* causes HME and is transmitted to humans through Lone Star tick bites (*Amblyomma americanum*).[161,165] Most cases occur in the south-central and southeastern United States. *Anaplasma phagocytophilum* causes HGA and occurs predominately in the northeastern, upper Midwestern areas of the United States. *I scapularis* or *I pacificus* ticks transmit the organism. Coinfection with the agents of Lyme disease, babesiosis, HGA have occurred. In a murine study, coinfection with *A phagocytophilum* and *B burgdorferi* result in decreased antibody response to the former but not the latter.[166] Symptoms include fever, chills, and headache often associated with thrombocytopenia, leukopenia, and increased liver enzymes.[160] Intracellular aggregates appear in monocytes in the HME and inclusions appear in granulocytes in HGA. Seroprevalence studies in blood donors in Wisconsin and Connecticut report 0.5% to 3.5% seropositivity for *A phagocytophilum* antibodies.[165]

One case of transfusion-associated HE occurred 9 days after an RBC transfusion donated by an asymptomatic donor exposed to deer ticks 2 months previously. The RBCs had been stored for 30 days prior to transfusion.[167] Leukocyte reduction does not completely remove *E chaffeensis*.[168]

In a study involving military recruits in Arkansas who had been exposed to tick bites and unknowingly infected with *E chaffeensis* and *Rickettsia rickettsii*, the agent of Rocky Mountain Spotted Fever (RMSP), no clinical illness occurred in recipients. One possible RMSP seroconversion was reported.[169] A case report of transfusion-associated RMSP involved a donor developing symptoms 3 days postdonation. The recipient developed symptoms 6 days posttransfusion.

Other tick-borne agents implicated in transfusion include Colorado tick fever virus and tick-borne encephalitis virus.

PARASITIC INFECTIONS

Malaria

Four plasmodium species (*P falciparum*, *P vivax*, *P ovale*, and *P malariae*) cause the protozoan disease, malaria. Up to 150 million cases occur worldwide annually, with most occurring in sub-Saharan Africa. Other endemic areas include parts of Asia and Central and South America. Local, mosquito-borne transmission occurred in the United States in 2003 in Palm Beach County, Florida in which seven persons were infected.[170] Of 1,066 imported cases in civilian travelers in 2003, 561 traveled to Africa, 109 to Asia/Western Pacific, 59 to Central America/Caribbean, 21 to South America, and only 6 from Mexico.[171] Transmission occurs through the bite of an infected female Anopheles mosquito and, rarely, transfusion or congenitally. Anopheles mosquitoes generally feed between dawn and dusk thereby limiting the risk to travelers who usually visit malaria areas during daylight hours.

In nonendemic countries, transfusion-associated malaria risk arises from semiimmune blood donors. Such persons are asymptomatic despite high titer antimalaria antibodies and low-level malaria parasitemia. Those donors without malarial immunity who travel to endemic areas and became infected, generally, are symptomatic when they are parasitemic and would not be accepted as blood donors.

Between 1979 and 1986 most malaria cases in the United States occurred among foreign civilians rather than US civilians. Currently, most cases occur in US civilians, reflecting increased travel and reduced immigration. Transfusion-associated malaria cases occur infrequently, approximately once per 4 million transfusions.[172] Through 2003, 95 transfusion-associated malaria episodes or 2.5 per year were reported. *P falciparum* accounted for 36% of the cases, *P malariae* for 28%, *P vivax* for 27%, *P ovale* for 5% with the remainder unknown or mixed species. *P falciparum* cases increased in frequency between 1990 and 2003, accounting for 73% of the cases compared to 24% of the cases between 1970 and 1989.

The incubation period for transfusion-associated malaria ranges between 8 and 90 days. *P falciparum* has the shortest time, mean 17 days (range 8 to 36 days) and *P malariae* the longest, mean 51 days (range 8 to 90 days).[172] Among the cases reported, 94% were associated with RBC or whole blood and 6% with platelets. Foreign-born donors accounted for 60% (64% from Africa). Transmission from fresh frozen plasma has not been reported.

The current strategies for reducing the low risk of transfusion transmission in the United States involve deferral of donors who have traveled to malarious endemic regions during the previous 12 months; who have a history of malaria within the previous 3 years, and who emigrated from a malarial area or revisited that area within the previous 3 years. Some residual risk remains because transfusion transmission of *P falciparum*, *P vivax*, and *P ovale* has been reported 5, 2.5, and 7 years, respectively, after departing malarious areas.[172] In contrast, under the current policy, approximately 1% of US blood donors are deferred because of travel to malarious areas, of which nearly 40% traveled to Mexico, where only 6 of the more than 1000 imported cases originated.

To create a more approximate balance between geographic deferral and actual risk of malaria infection, various strategies are under discussion. These include antibody testing (which identifies the 1.5% to 3% of infected travelers), malaria antigen detection, and nucleic acid testing. The sensitivity of the latter may be insufficient, 0.004 parasites per μL (or 200 parasites per mL whole blood) because a dose of 100 parasites transmits infection.[173]

Babesia

Babesia microti, a piroplasm protozoan, causes the rodent-borne zoonosis babesiosis. The deer or black-legged tick *I scapularis* transmits this organism following 48 hours or more of feeding. In addition, these ticks transmit *B burgdorferi* and ehrlichiosis agents. *Peromyscus leucopus*, or the white footed mouse, serves as the natural reservoir. *B. microti* is the agent most frequently associated with babesiosis, but MO-1, WA-1, CA-1 and B. divergens also cause clinical disease. Infections often go unrecognized.

Parasitemia persists for an average 82 days in asymptomatic patients but chronic carrier states have been identified.[174,175] *Babesia* has been found by polymerase chain reaction in approximately one-half of seropositive blood donors.[176,177] In asplenic patients,

intraerythrocyte parasitemic levels can approach 85% resulting in severe, life-threatening anemia.

Endemic areas include coastal and island areas of New England and New York as well as parts of California, Washington, Missouri, Wisconsin, and Minnesota.[165,176,178–180] Seroprevalence in blood donors varies and recently was found in 1.4% of blood donors in endemic areas of Connecticut.[177] At least 70 cases of transfusion-associated Babesia infections have been reported in the endemic and nonendemic regions of the United States. The parasite retains infectivity in red cell components at refrigerated or frozen temperatures and in residual RBCs contained in platelet concentrates stored at room temperature. The intraerythrocytic location of *B microti* favors transfusion transmission of this agent over *B burgdorferi*.[178] Transfusion-acquired cases occur 1 to 9 weeks following transfusion.[181] Based on studies in an endemic region where more than 1% of blood donors are seropositive for *B microti* infection the risk of acquiring *B microti* infection from an RBC transfusion was 1 in 1800 and for platelets 0 in 371.[181] The diagnosis is made by examining blood smears for intraerythrocytic ring forms, maltese cross-like tetrads, antibabesial antidotes and PCR assays for babesial DNA.[175,182] Treatment includes clindamycin or guinine or other antimicrobials. In severe cases, clinicians perform exchange transfusions especially in splenectomized patients.[181]

Currently, no specific strategies exist to prevent transfusion-associated babesia cases. Hence, clinical awareness and prompt antibiotic therapy serve as the primary treatment modalities. Questioning donors about tick exposure or tick bite has a low predictive value[165] and serologic or PCR testing await availability. All prospective blood donors are asked about prior Babesia infections and those answering affirmatively are deferred.

Leishmaniasis

Phlebotomine sand fly bites transmit Leishmania infections to humans. In addition, transplacental, sexual, and transfusion transmission occurs. The promastigote form of the parasite resides in the gastrointestinal tract of sand flies and is injected into humans through a skin bite. In humans, promastigotes are phagocytosed by monocytes and transformed into amastigotes. The latter then reproduce and reside in macrophages and the reticuloendothelial system. Organisms present within monocytes and free amastigotes that are released during refrigerated storage temperatures that transform into promastigotes and remain extracellularly are involved in transfusion transmission. *L tropica* survives also in monocytes contained in frozen red cell preparations and in platelet concentrates stored at room temperature. However, *L tropica* has not been found in cell-free plasma.[183]

At least 10 cases of transfusion-associated leishmaniasis attributed to *L donovani* have been reported in endemic areas, mostly in young children or neonates. A probable case of platelet transfusion-transmitted *L donovani* was reported in India. Several animal model studies demonstrate transmission by blood transfusion.[184,185]

Following reports of *L. tropica*-related viscerotropic leishmaniasis in veterans of the Persian Gulf Operation Desert Storm conflict between August 1990 and December 1992, those serving in this theater of operations were deferred from blood donation for 1 year. The deferral period reflected the development of fever, malaise, abdominal pain, and intermittent diarrhea that occurred up to 7 months following return to the United States. *L tropica* was found in the bone marrow of 7 patients and in the lymph node in one. Intracellular amastigotes were seen in the peripheral blood of the one patient in whom this was studied.[186] Following reports of cutaneous and visceral leishmaniasis in troops involved in the Afghanistan and Iraq wars, a similar 1-year deferral following departure from Iraq was instituted in October 2003.[187] Those with skin infections are deferred permanently. Questions have been raised about extending the deferral period.[188] Desert Storm occurred during a season when sand flies are inactive compared to the much longer exposure time for troops stationed in Afghanistan and Iraq where infections with *L tropica* and *L major* predominate, but where *L donovani* is also present. Asymptomatic infections occur frequently in healthy donors and organisms may circulate in peripheral blood more than 1 year following exposure. Foxhounds infected with Leishmania species have been found in 18 states and 2 Canadian provinces. Transmission occurred only among dogs.[189] The possibility of transmission to humans and the increased number of military personnel returning from Iraq raise concerns of future transfusion transmission.

To date, there are no cases of transfusion-transmitted Leishmaniasis in the United States. The widespread use of leukocyte-reduction filters, may have a beneficial role because these filters reduce both intracellular and extracellular parasite contaminations by 3 to 4 logs.[183,190] Awareness of potential transfusion transmission and surveillance remain important mechanisms for determining the transfusion risk.

Toxoplasmosis

Toxoplasmosis is caused by the intracellular protozoal parasite *Toxoplasma gondii*, whose usual host is the domestic cat. The parasite is transmitted by infected cats or soiled cat litter and by eating raw or undercooked pork, goat, lamb, beef, or wild game. Approximately 20% to 25% of the US population has evidence of infection. Transfusion-associated disease has been described in immunocompromised patients.[191–193]

Chagas Disease

American trypanosomiasis, or Chagas disease, consists of an acute phase that varies from no symptoms to manifestations that may include fever, skin rash, conjunctivitis with palpebral edema, lymphadenopathy, and hepatosplenomegaly. The acute phase usually resolves in 4 to 8 weeks unless severe myocarditis or meningoencephalitis intervenes. The latter is associated with fatal outcomes. Following a latent stage of undetermined duration, the chronic phase occurs in up to 30% to 40% of infected patients, manifesting as cardiac disease, megacolon, or achalasia.[194–197]

The flagellate protozoal parasite *T cruzi* causes Chagas disease. The disorder is widespread in Latin America. Humans become infected when bitten by *T cruzi*-infected insects of the Reduviidae family.[198,199] Once infection occurs, low-level parasitemia usually persists for life; treatment is effective in eradicating the parasite only when rendered during the initial acute stage.[194–201] Vector transmission is unlikely in the United States, but 50,000 to 100,000 infected Latin American immigrants reside in the United States.[194] The organisms remain viable in whole blood stored at refrigerator temperatures for 18 days, for longer than 8 months in citrated blood samples stored at room temperature, and following freezing and thawing. In South America, approximately 13% to 49% of recipients of parasitemic blood become infected. There is concern that additional transfusion-associated Chagas disease cases will occur as immigration increases to the United States from Central and South America.[194–199,202,203]

Risk factors for *T cruzi* infection include birth or residence in endemic regions such as Central America, South America, or Southeastern Mexico; living in dwellings with palm leaf-thatched roofs or mud walls, where vector insects reside; oral intake of contaminated foodstuff; and a history of receiving a blood transfusion in Latin America.[194–198,201,204] Among donors who lived in poor housing or received a blood transfusion in endemic areas, 3% to 4% had *T cruzi* antibodies.[205] One study, conducted in California, found that 1/340 donors had a risk factor for Chagas disease.[206] A large survey conducted from 1994 to 1998 in Los Angeles and Miami among immigrant blood donors from endemic areas observed *T cruzi* seroprevalence rates of 1/7500 and 1/9000, respectively.[202] The risk of transmission of *T cruzi* infection from these donors remains unclear, however, as none of the 18 recipients in the survey who received blood from a seropositive donor, and who were available for testing, had evidence of infection.

Some studies have estimated the transmission rate per infected blood unit to be approximately 18%. A recently reported lookback study involving blood donations in Mexico made prior to determining the donors were *T cruzi* seropositive found four of nine recipients of subsequently determined seropositive whole blood or platelets to be seropositive.[208] Lifelong low-grade parasitemia persist in approximately 50% of those infected and 13% to 63% of those seropositive have been found parasitemic.[196,207]

Since 1987, seven cases of transfusion-associated Chagas disease have been reported in the United States and Canada and symptoms developed 2 to 3 months' posttransfusion.[209–214] In at least six cases, platelets were the implicated component; the unit in the seventh case was not identified. *T cruzi* may separate with platelets or room-temperature storage may favor parasite survival, although *T cruzi* survives 18 to 21 days in refrigerated RBCs.[197] In each of the 6 cases, the implicated donor emigrated from a *T cruzi* endemic region (Bolivia, Mexico, Paraguay, Chile) between 16 to 33 years before the implicated donation. In addition, acute Chagas' disease has been reported in organ transplant recipients.[215,216]

The increasing prevalence of *T cruzi*-infected blood donors, the reports of transfusion-associated cases in the United States, and some autochthonous cases,[217] have triggered efforts to mitigate the risk of transfusion transmitted Chagas disease. Questioning donors about geographic location of birth or extended stay or transfusion in Chagas endemic areas interdicts 75% of donors. However, implementing this approach without a testing protocol has a high degree of nonspecificity causing unnecessary donor deferrals.[197,206,208,218] Leukocyte reduction by filtration decreases *T cruzi* transmission in a mouse model by 50% to 70%.[219]

Serologic testing, under development for many years achieved FDA licensure as a blood donor screening test in December 2006. The approved assay uses a *T cruzi* epimastigote lysate.[220] Another assay based on chimeric recombinant antigens is undergoing clinical trials.[221] These sensitive and specific assays were predicted to remove approximate 600 potentially *T cruzi*-infected blood components annually in the United States. Initial testing results show this 1 per 30,000 donors test positive, but none of more than 50 lookback cases showed serologic evidence of infection. Long-term serologic testing strategies remain under consideration. For example, testing each donor once or twice, recording the results, and retesting only if potential risk exposure occurs. Plasma used for derivative manufacturing undergoes pathogen inactivation procedures that have demonstrated activity against *T cruzi*. Methylene blue and visible illumination reduce *T cruzi* viability in plasma intended for direct transfusion.[222,223]

CLASSIC AND VARIANT CREUTZFELDT–JAKOB DISEASE

Classical Creutzfeldt–Jakob disease (CJD) is a rare, fatal, degenerative neurologic disease with a long asymptomatic latent period that was first described in 1920. The etiologic agent of CJD is thought by most experts to be a prion protein (PrPsc), an abnormal conformation of a normal cellular protein (PrPc) that can induce conformational transformation (recruitment) of additional PrPc to PrPsc, resulting in deposition of insoluble precipitates in neural tissue and progressive dementia.[224,225] CJD is one of a variety of prion diseases of humans that occur spontaneously at a rate of approximately 1 per million throughout the world, or can be transmitted vertically in familial conditions such as Gerstmann Straussler Scheinker syndrome or horizontally through ritualistic cannibalism (Kuru).

There are no reported cases of transmission of classical CJD by blood transfusion. Nevertheless, as a result of the long incubation phase of the disease (as demonstrated from growth hormone transmissions), concern arose in the mid-1990s that CJD transmission could occur from asymptomatic donors to blood transfusion recipients.[226] This theoretical risk led to the establishment of enhanced donor deferral policies (based on iatrogenic exposure or family history of the disease) for potential CJD carriers. Several recent epidemiologic studies have confirmed earlier studies in failing to establish a link between transfusion and transmission of CJD.[227,228] Although still regarded as a theoretical risk, there is an emerging consensus that classical CJD is not transmitted by transfusion.

Like classical CJD, variant (vCJD) is a fatal, degenerative neurologic disease, although it occurs in younger persons and has distinctive clinical, histopathologic, and biochemical features. In contrast to classical CJD, vCJD disease is new, with the first reports from the United Kingdom (UK) occurring in 1996.[229] The etiologic agent of vCJD, a prion, is the same agent that causes bovine spongiform encephalopathy (BSE). The outbreak of vCJD in the United Kingdom followed a massive epidemic of BSE in the 1980s and 90s that was traced to the recycling and processing of material (offal) from dead sheep and cattle into food meal for cattle. After this practice was banned in 1988, the outbreak eventually subsided after reaching a peak in the early 1990s. Transmission of the BSE prions to humans occurred by oral consumption of beef and other cattle products containing reticular endothelial or neural tissue. The number of new vCJD diagnoses in the United Kingdom rose steadily in the first few years after 1995 from 3 to 28 cases annually in 2000 but has decreased since then to 5 cases in 2005 and 3 in 2006. At the end of December 2006, 162 definite or probable cases of vCJD have been reported in the United Kingdom.[230] An additional 36 cases originated elsewhere, mostly in France and several other European countries, but a few cases were identified outside Europe, including 3 cases in the United States and 1 each in Canada, Japan, and Saudi Arabia. Several but not all of the patients in the latter category had spent more than 6 months in the United Kingdom between 1980 and 1996, that is, during the BSE epidemic in Britain. Although it appears that the vCJD outbreak is resolving and has been much smaller than initially feared, concern persists that there could be a second larger wave of the epidemic because of delayed onset of the disease in an affected population that is currently asymptomatic but harbors abnormal prion proteins. This is based in part on observing abnormal prion protein accumulation in random surgical tissue samples in the United Kingdom, which may represent preclinical vCJD disease. In one retrospective study, 3 of 12,674 (approximately 1 in 3500) appendectomy and tonsillectomy specimens from persons aged 20 to 29 showed this finding.[231] Furthermore, a critical polymorphism at codon 129 of the normal prion protein coding for methionine or valine leads to significant variation in the susceptibility to, and incubation period of, human prion diseases.[232] As only 37% of the general British population is homozygous for methionine, and therefore most susceptible, a larger population (52%) of heterozygotes may still be in the latent stage of the disease.

On the basis of findings in animal models which suggested that blood and its components could be infectious via transfusion,[233–235] and the observation that initially all known cases of vCJD could be traced to time spent in the United Kingdom, a policy was adopted in 1999 of indefinite deferral of persons who spent more than 6 months in the United Kingdom from 1980 to 1996.[236] The prediction was that this would reduce the number of donors potentially infected with vCJD by approximately 70% and would result in the deferral of approximately 2.5% of otherwise eligible donors. Following discovery of vCJD cases in continental Europe, the deferral policy was later revised to include donors if they had spent more than 3 months in the United Kingdom or 5 years in Europe since 1980.[236]

As of 2006, four probable cases of transfusion-transmitted vCJD have been reported in the United Kingdom, meaning that they could have developed vCJD independent of transfusion, but this possibility is regarded highly unlikely based on epidemiologic considerations.[228] Three of the four cases were diagnosed 6.5, 7.8, and 9 years after receiving non–leukocyte-reduced red blood cells or a blood component from two different donors who developed clinical symptoms of vCJD 40 and 21 months after donating. In the other case, the recipient of non–leukocyte-reduced red cells had no clinical symptoms of vCJD but showed abnormal prion proteins in lymphoid (but not neural) tissues postmortem and was therefore considered to be in a preclinical stage of the disease. Five years before his death from unrelated causes he had received non–leukocyte-reduced red blood cells

from a donor who showed clinical symptoms of vCJD infection 18 months after donating. These four cases represent 6% of the total population of 66 UK recipients who received blood components from 18 different donors subsequently diagnosed with vCJD. No further cases of probable transfusion-transmitted vCJD have been identified in this cohort or anywhere else so far (as of January 2007, 23 of the 66 UK recipients were alive and could still develop clinical disease later on). It is not possible to derive general predictions on vCJD risk associated with blood transfusion from the UK experience but prion transmissibility by transfusion leading to clinical disease cannot be regarded a mere theoretical consideration anymore. As there are no blood donor screening tests for vCJD, development of suitable pathogen reduction or inactivation methods (PRIMs), in case of prevention of prion transmission most likely a filtration-based approach,[123] holds the greatest promise for protection from transfusion-transmitted prion diseases (see box on PRIMs).

POTENTIAL EMERGING INFECTIONS

Simian Foamy Virus and Other Non-Human Primate Retroviruses

The pandemic human retroviruses, HIV-1/2 and HTLV-I/II, were each the result of multiple independent introductions of viruses from nonhuman primates (NHPs). A series of recent findings focused on populations exposed to NHPs has demonstrated that transmission of retroviruses from NHPs to humans is a regular and ongoing phenomenon.[237–246] These results show that three new retroviruses previously undocumented in humans, including the simian foamy viruses (SFVs), HTLV-3, and HTLV-4, have all been identified in persons exposed to NHPs,[240–246] which has raised concern over risks to the safety of the blood supply.

SFVs are of particular concern because these are widespread retroviruses among Old and New World monkeys, apes, and prosimians.[247] SFV infects more than 70% of captive adult NHPs, but does not appear to be associated with disease in any host species.[240,243,246] SFV is genetically diverse and has persisted in primates for more than 30 million years.[248] Humans are susceptible to infection with a variety of SFV subtypes from both monkey and ape species. Persistent cell-associated viremia has been found in infected persons.[240,243] SFV sequences can be consistently amplified from peripheral blood mononuclear cells (PBMNCs), and virus can be readily isolated from these cells.[240,243] SFVs have been found among humans exposed to NHPs in natural settings in Cameroon through hunting, butchering, and keeping wild NHP pets, suggesting that SFV may likely be prevalent among West and Central African populations who frequently hunt, butcher, and consume bushmeat.[241] SFV also has been found in persons occupationally exposed to captive NHPs in primate research facilities and zoos in North America and Europe.[240,243,244] A study of workers exposed to Asian macaques around religious temples in Indonesia reported one infected worker.[245] No disease has been seen in 14 infected primate workers in the United States.[240,243] The limited number of cases and potential selection biases inherent in studying a healthy worker cohort, however, limit the ability to identify potential disease associations in these studies.[240,243]

It is noteworthy that many of the SFV-infected primate workers have donated blood in the United States, and several were retrospectively confirmed to be SFV-infected at the time of their donation.[240,243] A retrospective study of recipients from an SFV-infected blood donor failed to identify evidence of infection in three recipients of red cells (one of whom received leukoreduced units, the other two did not) and one recipient of platelets.[249] Several recent reports by Khan and Kumar[250] and Brooks et al[251] provided direct evidence of SFV transmission by transfusion of whole blood into rhesus monkeys. Evidence of transfusion-transmitted infection included seroconversion, identification of SFV sequences in monkey PBMNCs, and isolation of infectious virus from PBMNCs.

In assessing the potential impact of an emerging infection like SFVs, one must examine person-to-person transmissibility, survival in blood products, measurable frequency in the population, availability of a blood screening test, and evidence of disease in infected individuals. For SVF, lack of documented disease associations and of sensitive and specific serologic assays, has led the US FDA to postpone consideration of deferral or screening of potential donors exposed to NHPs. In contrast, in Canada health authorities have recently recommended deferral from blood transfusion and cell, organ and tissue donation for those individuals who work directly with NHP in institutions such as zoos, public or private biomedical research institutions, and animal sanctuaries. This approach provides additional protection against unrecognized simian viruses other than SFV that may also be infecting these donors.[242,246,252]

Influenza Viruses

Influenza remains a major cause of morbidity and mortality in the United States and worldwide, particularly in the elderly and immunosuppressed populations. In years of high influenza activity, influenza incidence in pediatric populations range from 5% to 9.5% and weekly mortality incidence due to pneumonia and influenza can peak at over 10% of all cause mortality in the United States. The threat of pandemic influenza A has recently gained prominent attention with human cases of highly pathogenic avian influenza A (H5N1) detected in China, Southeast Asia, and more recently in Turkey and Africa.[253]

The threat that influenza poses to the blood supply remains largely unexplored. It has been assumed to be negligible based on the premise that asymptomatic donors will not be viremic and potential donors with symptomatic influenza infection (with or without viremia) will be deferred from donation. However, murine models suggest that viremia is transient and only present early in the disease course,[254] raising the possibility that significant numbers of blood donors harbor influenza viremia during a presymptomatic or asymptomatic phase. A human study of nasal challenge of volunteers with Asian influenza demonstrated viremia within 24 hours of challenge in 4 of 11 subjects, and 4 of 4 subjects tested with the most sensitive assay available at the time.[255] Viremia was cleared prior to the development of symptoms or nasal shedding of virus. During epidemic spread of influenza, a pre-symptomatic viremic phase could result in significant numbers of transmission events. Viremia during the symptomatic phase of influenza is rare,[256–258] and the frequency of viremia during presymptomatic or asymptomatic infection is unknown.

Quantifying the potential threat to the blood supply is particularly crucial in preparation for a predicted global influenza pandemic. A more virulent strain of influenza could result in higher blood viral loads and cause increased morbidity and mortality compared to circulating influenza A and B strains. This is even more relevant when one considers that highly pathogenic avian influenza H5N1 is a systemic disease.[259,260] A recent report suggests that infection with avian influenza among human populations exposed to sick birds may not be uncommon,[261] further underlining the need to study whether influenza A infection is associated with viremia.

If influenza infection resulted in a viremic phase prior to the onset of symptoms, it would have implications for blood safety. Because of their underlying health problems, blood product recipients would be expected to suffer increased morbidity and mortality secondary to influenza A infection compared to healthy donors. If influenza was transmissible by transfusion, testing of the blood supply could become particularly important during pandemic outbreak of highly pathogenic influenza A. Additional product discards (as a result of a positive test) would further endanger blood donation availability and such additional stress on the system would need to be taken into consideration when modeling the effect of a potential pandemic on the blood supply.

Detection of influenza in the blood presents a challenge owing to the lower viral loads found in blood compared to nasopharyngeal secretions. Red blood cell fractions may contain more influenza than plasma or white blood cell fractions because of the hemagglutinin moiety of influenza.[262] Both NAT-based and rapid antigen or neur-

aminidase detection tests have been developed to detect influenza A and B in recent years. Although NAT tests appear to have higher sensitivity than antigen or neuraminidase activity assays for nasopharyngeal samples, the relative abundance of viral RNA to influenza antigen or neuraminidase in the bloodstream of infected individuals has not been determined. Studies are now in progress to validate NAT and antigen assays for detection of influenza A in blood and to quantify the proportion of blood donors with detectable viremia and antigenemia during periods of high influenza activity.

Dengue

Dengue viruses, transmitted by Aedes mosquitoes, infected at least 96 US travelers in 2005, almost as many as occurred in the previous 5 years. Illness associated with infection ranges from no symptoms to fever, minor or major bleeding, thrombocytopenia, and increased vascular permeability manifest by hemoconcentration and pleural or abdominal effusions. The incubation period varies between 3 and 14 days. The travel destination of those infected included Mexico (44% of cases), Central America (26%), Caribbean (22%), and Asia (8%). No transfusion-associated cases occurred. However, the increased number of cases and reports of transmission by bone marrow transplantation and needle-stick injuries involving symptomatic patients raises the possibility of transfusion transmission by asymptomatic travelers returning from endemic areas.[263–267]

Severe Acute Respiratory Syndrome

A novel enveloped RNA coronavirus infected more than 1800 patients in 17 countries between February and March 2003 causing the Severe Acute Respiratory Syndrome. A two week asymptomatic incubation period fostered virus spread through close person-to-person contact and raised the possibility of blood-borne infection. For this reason blood collection agencies deferred anyone from donating blood for at least 14 days after possible exposure to SARS and those with illness for at least 28 days after recovery.[268,269] The epidemic subsided within months and no transfusion-associated SARS cases occurred.

Lymphocytic Choriomeningitis

Organ transplantation-associated lymphocytic choriomeningitis virus (LCMV) infection occurred in two clusters involving two donors and eight transplant recipients. Seven of the eight recipients died. Transmission of LCMV, a rodent-borne arena-virus occurs through contact with pet rodents, mice, and hamsters. The transplant-related cases represent the first person-to-person transmission other than vertical transmission during pregnancy. Serologic surveys indicate that up to 5% of US adults have evidence of LCMV infection. Viremia has been documented in mice and humans. In light of other pathogen transmission by both organ transplantation and transfusion, for example, West Nile Virus, *T cruzi*, rabies, the future possibility of LCMV transmission by blood transfusion remains a possibility.[270,271]

Rabies

The Rabies virus is not transmitted hematologically. Contact with blood, urine, or feces is not considered an exposure risk. However, an organ donor infected via a bat bite transmitted rabies to the liver and the two kidney recipients.[272] The transmission occurred presumably through exposure to infected neuronal tissue.

CONCLUSION

Progress in testing technologies continues to decrease the residual risk of transmitting known pathogens through transfusion. Additional efforts, such as pathogen reduction and improved donor screening for pathogens, should provide further benefit. The emergence of newly discovered pathogens and wider geographic spread of known pathogens through emigration and commercial globalization, however, will create pressure for additional interventions. Unfortunately, all of these approaches increase costs and conflict with the simultaneous, ongoing interest in controlling medical care costs.

As such, global surveillance and public health measures, not priority issues previously, take on greater significance not only for public health in general but also for reducing the risk of transfusion-transmitted infections.

CHAPTER 155

TRANSFUSION MEDICINE IN HEMATOPOIETIC STEM CELL AND SOLID ORGAN TRANSPLANTATION

Richard M. Kaufman and Jerome Ritz

HEMATOPOIETIC STEM CELL TRANSPLANTATION

The array of hematopoietic stem cell transplantation (HSCT) approaches used to treat patients with malignant or nonmalignant diseases has continued to grow in complexity. In concert, the scope of transfusion medicine has expanded to support the development of novel hematopoietic stem cell therapies. Currently, hematopoietic stem cells are obtained from three sources: bone marrow (BM), mobilized peripheral blood stem cells (PBSCs), and umbilical cord blood (UCB). After harvesting, and before infusion into the patient, stem cell products undergo a variety of manipulations in the laboratory, ranging from simple processing (eg, red blood cell depletion, freezing) to sophisticated graft engineering (eg, T-cell depletion, retroviral transduction). Like conventional blood components, hematopoietic stem cell products are prepared in rigorously controlled environments using good manufacturing practices. Specific details of hematopoietic stem cell mobilization, collection, and processing are discussed elsewhere (see Chapter 146).

The focus of this section is on the unique issues involved with providing optimal transfusion support to the HSCT patient. After myeloablative conditioning and stem cell transplantation, there is a 1- to 4-week period of pancytopenia when patients require multiple RBC and platelet transfusions.[1–3] In general, the criteria for transfusion after HSCT mirror those of other clinical settings, but the magnitude of support required may be great. Frequent platelet transfusions are given to prevent bleeding, and as a result, alloimmunization and platelet refractoriness are important concerns. Switching of ABO blood groups occurs commonly in the allogeneic HSCT patient population, posing unique problems to the blood bank and transfusion service. Because HSCT patients are typically highly immunocompromised, strategies are needed to prevent transfusion-transmitted cytomegalovirus (CMV) disease and transfusion-associated graft-versus-host disease (TA-GVHD).

ENGRAFTMENT AND BLOOD COMPONENT SUPPORT AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

The level of transfusion support required by a particular patient after HSCT is dictated largely by the kinetics of engraftment and subsequent hematopoietic reconstitution. A key parameter affecting the engraftment rate is the source of stem cells used (Fig. 155–1). In the 1990s, several randomized trials demonstrated the superiority of PBSC over BM-derived stem cells in terms of faster platelet and neutrophil recovery for patients undergoing autologous HSCT.[4–6] More rapid recovery using PBSC rather than BM was later documented in the allogeneic HSCT setting as well. On average, neutrophil recovery (neutrophil count $>0.5 \times 10^9$/L) occurs 2 to 6 days earlier when PBSC versus BM is used as the source of stem cells. Similarly, platelet recovery (platelet count $>20 \times 10^9$/L) occurs 5 to 8 days earlier after PBSC transplantation than after BMT.[7–11] One reason for the faster engraftment of PBSC products is that the cellular composition of PBSC and BM is very different. PBSC products contain approximately threefold more $CD34^+$ cells and 10-fold more mature T cells than BM products.[7]

There is a strong relationship between the $CD34^+$ cell dose administered and the speed of hematopoietic recovery.[12–17] Faster engraftment rates have translated into decreased blood component usage.[13,14] For example, Haas and colleagues[14] reported that autologous PBSC transplant patients given more than 2.5×10^6 $CD34^+$ cells/kg received significantly fewer platelet transfusions than patients receiving less than 2.5×10^6 $CD34^+$ cells/kg (median of 4 vs 13 platelet units). In addition to the higher numbers of $CD34^+$ cells in PBSC products, there are multiple qualitative factors that differ between PBSC- and BM-derived stem cells, including cell surface molecule expression, metabolic activity, clonogenicity, and cell cycle status.[18,19] What impact these factors have on engraftment remains incompletely understood.

Several clinical factors may affect the rate of hematopoietic recovery and transfusion requirements after HSCT. Accelerated platelet recovery has been associated with a higher pretransplantation platelet count and receiving a graft from a human leukocyte antigen (HLA)-identical sibling donor. Factors associated with delayed platelet recovery include prior radiation therapy, the presence of fever, hepatic venoocclusive disease, GVHD, and the use of posttransplantation granulocyte colony-stimulating factor (G-CSF) or granulocyte–macrophage colony-stimulating factor (GM-CSF).[24] The use of recombinant human erythropoietin (rHuEPO) has been shown to accelerate RBC recovery and decrease RBC transfusion requirements among allogeneic HSCT patients.[25–28] The particular conditioning regimen that is used also affects hematopoietic recovery. In particular, nonmyeloablative transplantation protocols predictably result in decreased transfusion requirements.[29]

Although PBSC products are the most commonly transplanted source of stem cells currently, the use of UCB transplants for both pediatric and adult recipients has continued to grow at a rapid pace.[20] One reason is that only approximately 30% of patients requiring HSCT have an HLA-matched related donor.[21] Precise HLA matching has been demonstrated to be significantly less important for UCB products versus BM or PBSC. Also, UCB transplants are associated with a lower rate of graft-versus-host disease (GVHD). A primary disadvantage of UCB is the lower $CD34^+$ cell content of these products. The currently accepted minimum cell dose for UCB transplant is 1.7×10^5 $CD34^+$ cells/kg or 2.5×10^7 nucleated cells/kg, about one order of magnitude lower than the threshold for PBSC or BM transplant.[20] The lower cell content of UCB has been linked to a higher rate of graft failure as well as slower hematopoietic recovery.[22,23] For this reason, UCB transplants using two (or sometimes more) grafts simultaneously are often performed, particularly in adult patients.

The growth in UCB banking has created the (potential) advantage of rapidly available grafts to patients requiring transplantation. The University of Minnesota, for example, has reported that the search for a UCB unit typically takes approximately 1 day, compared with 3 to 4 months for a PBSC or BMT donor.[20] It is possible that the ability to provide UCB grafts quickly will translate into better patient outcomes, but this has not been proven to date. UCB transplantation is a fairly new field, yet considerable efforts have already been made to standardize UCB banking practices. The FDA has driven the concept that all human cellular or tissue-derived therapies, regardless of source, need to fit into an established regulatory framework and must meet the same essential requirements for donor screening and

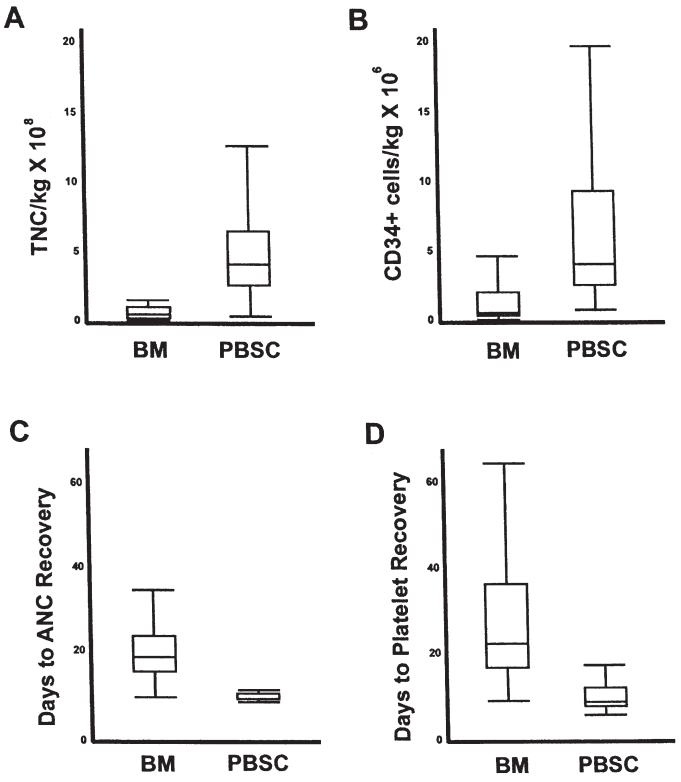

Figure 155–1 Comparison of peripheral blood stem cell (PBSC) products with bone marrow (BM). BM (n = 187) and PBSCs (n = 104) were collected from autologous donors at the Dana-Farber Cancer Institute and Brigham and Women's Hospital from 2000 through 2002. **A,** The total nucleated cell content (TNC/kg recipient weight) was significantly higher in PBSC products (median, 4.2×10^8 nucleated cells/kg) than in BM products (0.5×10^8 nucleated cells/kg). **B,** The $CD34^+$ cell content of PBSC products was also significantly higher compared with BM (median, 4.3×10^6 $CD34^+$ cells/kg versus 0.5×10^6 $CD34^+$ cells/kg). **C,** Reconstitution of neutrophils (absolute neutrophil count $>0.5 \times 10^9$/L) occurred more rapidly in recipients of PBSCs (median, 10 days) compared with BM (median, 18 days). **D,** Similarly, platelet recovery (platelet count $>20 \times 10^9$/L) was more rapid in PBSC recipients (median, 11 days versus 27 days for BM recipients). *(Courtesy of G. Kao, Dana-Farber Cancer Institute, Boston, MA.)*

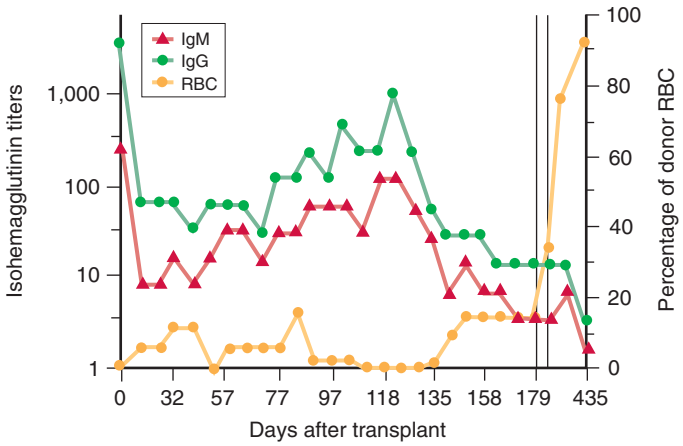

Figure 155–2 Delayed red blood cell (RBC) reconstitution in the recipient of a major ABO-incompatible stem cell transplant. The appearance of mature RBCs corresponded to declining anti-donor isoagglutinin titers. This patient remained RBC transfusion dependent for 12 months after transplantation. *(From Maciej Zaucha J, Mielcarek M, Takatu A, et al: Engraftment of early erythroid progenitors is not delayed after non-myeloablative major ABO-incompatible hematopoietic stem cell transplantation. Br J Haematol 119:740–750, 2002.)*

good tissue practices.[23a] Two US accrediting agencies, the AABB and the Foundation for Accreditation of Cellular Therapy (FACT), have developed standards for collecting, testing, processing, and storing UCB samples, with the intent of ensuring the quality of UCB products provided.[23b]

ABO-INCOMPATIBLE HEMATOPOIETIC STEM CELL TRANSPLANTATION

In approximately 20% of allogeneic HSCT, ABO incompatibility exists between the donor and recipient.[30] ABO incompatibility is classified as major (the recipient has ABO antibody directed against donor RBCs), minor (the donor has ABO antibody directed against recipient RBCs), or both (major–minor). In most cases, the clinical impact of donor–recipient ABO incompatibility on HSCT is minimal. ABO incompatibility does not appear to affect overall patient survival, graft rejection, or GVHD.[31–33] Nevertheless, clinically significant hemolytic complications resulting from ABO incompatibility occasionally do occur.

In major ABO-incompatible HSCT (eg, group A donor → group O recipient), two types of hemolytic complications may be seen. Immediately on infusion, mature donor RBCs contained within the stem cell product may be destroyed by preformed ABO antibody in the recipient. The usual practice is to reduce the volume of RBCs contaminating major ABO incompatible stem cell products to less than 10 mL. This manipulation effectively eliminates most immediate hemolytic reactions.

The second potential hemolytic complication of major ABO-incompatible HSCT is that recovery of the recipient's RBC counts may be delayed, in some cases dramatically (Fig. 155–2). This condition is a form of pure red cell aplasia (PRCA).[34] PRCA is characterized by peripheral blood reticulocytopenia and the absence of histologically detectable erythroid precursors in the bone marrow of the recipient. Peripheral-blood ABO antibody titers are characteristically elevated. Red cell transfusion dependence may last for several months after the recovery of platelets and granulocytes. Although red cell *reconstitution* is delayed in these cases, red cell *engraftment* is not. Using in vitro colony assays, the presence of early erythroid progenitors can be demonstrated in the bone marrow at the same time after transplantation as myeloid progenitors.[35] Early erythroid progenitors do not express ABO antigens and appear to survive normally in the bone marrow. On undergoing differentiation, the erythroid precursors begin expressing ABO antigens and are targeted by host ABO antibodies. It has been proposed that PRCA associated with major ABO-mismatched HSCT may be more likely to occur in the setting of nonmyeloablative SCT, because host hematopoiesis may be relatively preserved.[36] A higher PRCA rate in nonmyeloablative SCT has not been observed consistently,[35,37] perhaps because of differences in treatment regimens. The optimal therapy for PRCA after major ABO-incompatible HSCT has not been defined. Various treatment modalities used with variable success have included plasma exchange,[30,34] corticosteroids,[38] rHuEPO,[39,40] antithymocyte globulin,[41] donor lymphocyte infusion (DLI),[42] rituximab,[43] and discontinuation of cyclosporine.[36]

Minor ABO-incompatible HSCT (eg, group O donor → group A recipient) has been associated with immediate hemolysis from passively transfused donor ABO antibody and with delayed hemolysis caused by ABO antibodies produced by mature donor lymphocytes contained in the graft. Minor ABO incompatibility does not affect overall rates of graft rejection, GVHD, or patient survival.[31,33] Depletion of donor plasma in the graft generally eliminates the problem of immediate hemolysis caused by passively transfused ABO antibody. The more serious potential problem is the passenger lymphocyte

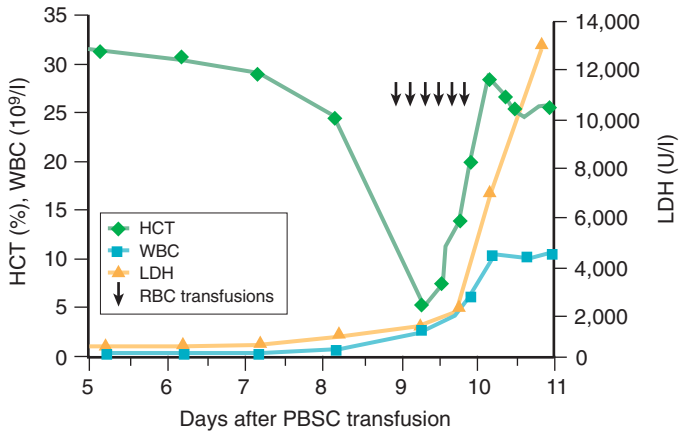

Figure 155–3 Severe hemolysis in the recipient of a minor ABO-incompatible stem cell transplant. Serologic testing revealed that donor-type anti-A isoagglutinins caused the hemolysis. *(From Bolan CD, Childs RW, Procter JL, et al: Massive immune haemolysis after allogeneic peripheral blood stem cell transplantation with minor ABO incompatibility. Br J Haematol 112:787, 2001.)*

Table 155–1 Examples of Transfusion Restrictions After ABO-Incompatible Hematopoietic Stem Cell Transplantation

ABO Type			Transfusion Restriction	
	Donor	Type of Mismatch	Red Blood Cell	Plasma
A	A	None	A or O	A or AB
A	O	Minor	O	A or AB
A	AB	Major	A or O	AB
A	B	Major/minor	O	AB

syndrome, whereby mature donor lymphocytes engraft in the host and produce anti-A or anti-B antibodies that bind to and cause the destruction of circulating host RBCs (Fig. 155–3). This complication typically occurs 1 to 3 weeks after transplantation and is heralded by a positive direct antiglobulin test (DAT) and a fall in hematocrit level. Rarely, hemolysis may be massive.[44] Standard practice is to transfuse group O or donor group RBCs to dilute the recipient red cells and to monitor patients closely for clinical and laboratory evidence of hemolysis. Exchange transfusion has been performed in this setting but is usually unnecessary.

Less is known about ABO incompatibility with respect to UCB transplantation versus PBSC transplantation or BMT. Recent case series, however, suggest that PRCA and other isoagglutinin-mediated potential adverse consequences of ABO-incompatible stem cell transplantation are far less likely to occur with UCB than with the other stem cell sources. Tomonari and colleagues, for example, reported zero cases of PRCA among 21 major and 18 major–minor ABO-mismatched UCB recipients. Zero of 29 recipients of minor ABO-incompatible UCB transplants developed immune hemolysis in their series.[44a] Similarly, Snell and colleagues[44b] reported that 0/14 minor ABO-incompatible UCB recipients developed immune hemolysis, compared with 14/25 contemporaneous patients who developed immune hemolysis after receiving a minor ABO-incompatible PBSC transplant.

The blood bank places specific RBC and plasma restrictions on patients undergoing ABO-incompatible HSCT (Table 155–1). RBCs are selected to be compatible with donor and recipient plasma, and plasma products are selected to be compatible with donor and recipient RBCs. These practices are begun on day 0 of HSCT or earlier if feasible. ABO antigens are widely expressed on endothelial tissues; HSCT recipients therefore may be considered ABO chimeras even after full RBC recovery.

PROPHYLACTIC PLATELET TRANSFUSIONS

Most platelet transfusions administered to cancer patients are given prophylactically rather than to control active bleeding. In the past, a platelet count of 20,000/mm^3 was generally used as a transfusion "trigger."[45,46] Later studies have supported the concept that prophylactic platelet transfusions can safely be provided using even lower platelet thresholds, with associated inventory and cost savings. In an observational study of acute leukemia patients, Gmur and colleagues[47] demonstrated that the platelet transfusion threshold could be set safely at 5,000/mm^3 for patients without fever or bleeding, and at 10,000/mm^3 for patients with such signs. Platelet transfusion triggers of 10,000/mm^3 versus 20,000/mm^3 were compared directly in two randomized, prospective studies of patients with acute leukemia.[48,49] Both of these studies and a third nonrandomized, prospective study[50] demonstrated no increased risk of bleeding when a trigger of 10,000/mm^3 was used. All of these trials included provisions for transfusing thrombocytopenic patients at higher platelet counts if associated risk factors for bleeding (eg, fever) were present. Relatively few studies have directly examined prophylactic platelet transfusion specifically in the setting of HSCT. Nevertheless, the 10,000/mm^3 trigger has been widely applied to the HSCT patient population, and it appears to be safe for patients lacking associated clinical factors (eg, infection, GVHD).[51,52] Frequently, these clinical factors are more important determinants of bleeding risk than the platelet count alone. Approximately two-thirds of bleeding events after HSCT occur in patients with platelet counts above 20,000/mm^3.[24,53]

The widespread use of a 10,000/mm^3 transfusion trigger is believed to have helped conserve the overall platelet supply. A complementary approach that is being studied currently is one of optimizing the dose of prophylactic platelets transfused. Most platelets undergo senescence after circulating for 8 to 10 days. But there is thought to be a second platelet clearance route: a small fixed daily loss of platelets that occurs independent of platelet age. Platelets leaving the circulation via this route (approximately 7.1×10^9 platelets/L/day) are hypothesized to help maintain vascular integrity.[55] In theory, a low dose of prophylactic platelets could meet this daily requirement, and using a low dose (eg, transfusing pools of 3 whole-blood derived platelet concentrates rather than the current 6) might yield considerable component savings over time.[56] A randomized controlled trial designed to empirically determine the optimal prophylactic platelet dose is being performed by the US Transfusion Medicine/Hemostasis Clinical Trials Network.[57] In this study, termed "PLADO" (PLAtelet DOsing), thrombocytopenic patients are randomized to receive either medium- (standard) (2.2×10^{11} platelets/m^2), low- (1.1×10^{11} platelets/m^2), or high-dose prophylactic platelets (4.4×10^{11} platelets/m^2). The primary end point is the percentage of patients with Grade 2 or higher bleeding in each arm. An interesting alternative approach, using therapeutic rather than prophylactic platelet transfusions, is being studied by Wandt and colleagues in Germany.[58]

ALLOIMMUNIZATION AND PLATELET REFRACTORINESS

Because HSCT patients typically receive large numbers of transfusions with cellular blood products, they are at risk to become alloimmunized to HLA antigens. Although graft failure associated with histocompatibility differences between donor and recipient is usually attributed to rejection by host T lymphocytes, host antibodies may also mediate graft failure by complement-mediated cytotoxicity or by antibody-dependent cell-mediated cytotoxicity.[59] To prevent graft failure and platelet refractoriness, it is important to prevent HLA alloimmunization in patients who are possible candidates for HSCT. In particular, blood transfusions from the potential stem cell donor

Table 155–2 Causes of Platelet Refractoriness

Patient Factor	Clinical Effects	Blood Bank
Alloimmunization	Fever	ABO match
Bone marrow transplantation	Sepsis	Platelet storage time
Gender	Splenomegaly	Platelet cross-match
Circulating IVIG	Clinical bleeding	HLA match
Transfusion number	RBC use DIC Neutropenia	

DIC, disseminated intravascular coagulation; HLA, human leukocyte antigen; IVIG, intravenous immunoglobulin G; RBC, red blood cell.

Table 155–3 Degree of HLA Matching for HLA-Matched Platelets

Match Grade	Description	Examples of a Donor Phenotype for Recipient Who Is A1,3;B8,27
A	Four antigen match	A1,3;B8,27
B	No mismatch present	A1,-;B8,27
B1U	One antigen blank or unknown	A1,3;B8,27
B1X	One cross-reactive group	A1,3;B8,7
B2UX	One antigen blank and one cross-reactive	A1,-;B8,7
C	One mismatched antigen	A1,3;B8,35
D	Two or more antigen mismatched	A1,32;B8,35

Data from Vengelen-Tyler V: Technical Manual, 12th ed. Bethesda, American Association of Blood Banks Press, 1996.

should be avoided because of the risk of sensitizing the patient to HLA and non-HLA antigens.

Platelet refractoriness may be defined as the failure to achieve an adequate platelet increment after two or more platelet transfusions (Table 155–2). A number of nonimmune factors have been linked to platelet refractoriness, including fever, sepsis, disseminated intravascular coagulation (DIC), drugs (eg, amphotericin), bleeding, splenomegaly, hepatic venoocclusive disease, and GVHD. In a subset of cases, platelet refractoriness is caused by alloimmunization. Platelets express HLA class I antigens, relatively low levels of ABO antigens, and several platelet-specific antigens. All of these molecules are potential targets of an immune response. Antibodies directed against HLA molecules are responsible for most cases of immune-mediated platelet refractoriness. Notably, less than half of all platelet-refractory patients have demonstrable antiplatelet or anti-HLA antibodies.[60,61] Platelet counts obtained at 10 minutes to 1 hour posttransfusion that repeatedly fail to demonstrate an adequate corrected count increment (CCI) usually indicate an immune mechanism of platelet destruction.[62] If the 10-minute to 1-hour posttransfusion platelet count shows a reasonable increment, but the platelet count falls back to baseline by 18 to 24 hours, a nonimmune mechanism of refractoriness may be presumed. HLA antibody screening of patients provides a second important line of evidence. A panel reactive antibody (PRA) level of 70% is often used as a threshold for diagnosing alloimmunization.[63]

Although platelets express class I HLA antigens, platelets themselves are poor immunogens. Preclinical studies in mice[64] and rats[65] suggested that white blood cells (WBCs) contaminating platelet products are the cells primarily responsible for stimulating an anti-HLA immune response in platelet transfusion recipients. It was hypothesized that removing WBCs from platelet products could prevent alloimmunization and platelet refractoriness. This was subsequently shown to be true in human studies.[66–69] The definitive study was the multicenter prospective Trial to Reduce Alloimmunization to Platelets (TRAP study),[69] which compared alloimmunization rates in 530 newly diagnosed AML patients randomized to receive unmodified, pooled platelet concentrates (control); filtered, pooled platelet concentrates (F-PC); filtered single-donor apheresis platelets (F-AP); or UV-B-irradiated pooled platelet concentrates (UVB-PC). Anti-HLA antibodies were detected in 45% of controls, compared with 17% to 21% of patients receiving modified platelets. Thirteen percent of control group patients became platelet-refractory, compared with only 3% in the F-PC group, 4% in the F-AP group, and 5% in the UVB-PC group.

Current filtration and apheresis technology can yield blood products with less than 10^6 residual leukocytes. It is standard practice to provide patients requiring long-term blood component support with leukoreduced products. Leukoreduction provides the additional benefit of reducing CMV risk in susceptible patients and of reducing the rates of febrile nonhemolytic transfusion reactions. The benefits in the HSCT patient population are clear; whether prestorage leukoreduced products need to be provided to all patients is controversial.[70–73] Blood suppliers in many European countries and Canada have moved to providing exclusively prestorage leukoreduced products. Suppliers in the United States have made efforts to do the same, although universal prestorage leukoreduction is currently not mandated by the regulatory agencies (eg, US Food and Drug Administration, American Association of Blood Banks) overseeing blood transfusion practices.

Once platelet refractoriness has been demonstrated, several strategies may help in obtaining therapeutic platelet increments in vivo. If refractoriness is nonimmune in nature (eg, sepsis), the underlying cause must be treated. A trial of ABO-matched, fresh (1 to 2 days old) platelets may be helpful.[74] In cases of immune-mediated refractoriness, a trial of HLA-matched platelets or crossmatched platelets may be indicated. Owing to the polymorphism of the HLA loci, it is often not possible to find perfect HLA-A and -B locus matches, leading to the use of platelets mismatched at one or more loci (Table 155–3). Grade A (4 antigens matched) or BU (3 antigens matched/one antigen unknown) matched platelets provide the highest probability of a successful response.

CYTOMEGALOVIRUS INFECTION

CMV is a human herpesvirus (HHV-5) capable of infecting a variety of cell types, including mature WBCs and their progenitors. CMV causes significant morbidity and mortality in immunocompromised patients, including seronegative HSCT recipients. Allogeneic HSCT patients in particular are at risk to develop serious manifestations of CMV disease, which include pneumonitis, gastroenteritis, hepatitis, encephalitis, and retinitis. CMV disease is considerably less common in the autologous transplant setting.[75] When a patient who is CMV-seropositive at baseline undergoes HSCT, CMV disease occurs primarily as a result of reactivation of latent virus.[76] In those cases where the HSCT donor is seropositive and the recipient is seronegative, CMV transmission may occur by means of the stem cell product. When both donor and recipient are seronegative, CMV infection results primarily from the transfusion of infectious blood components.[78,79]

Serologic screening of blood products is currently the most effective means of reducing the risk of transfusion-transmitted CMV. In

a randomized study by Miller and coworkers,[77] only 18% of seronegative allogeneic BM recipients who received seronegative blood components developed CMV infection, versus 38% of patients receiving unscreened blood products. No benefit of serologic screening was observed in cases where the donor or recipient was seropositive. As the use of CMV seronegative blood components for seronegative HSCT recipients became adopted widely, CMV infection rates dropped from approximately 23%–37%[77–79] to 1%–4%.[80] The infrequent CMV infections still seen in part represent limitations of the serologic testing methodologies, such as donations made in the preseroconversion window period.[81] A number of sensitive PCR-based methods have been explored to measure CMV viral load in blood donors.[82] The clinical utility of DNA-based screening for CMV is unclear.

Because the seroprevalence of CMV in various communities ranges from 40% to 80%, it is logistically difficult for blood banks to maintain an inventory of CMV seronegative components.[83] As an alternative to serologic screening, leukoreduction of blood components using filtration or other means has been used to render blood products "CMV safe." The AABB defines leukoreduced products as containing less than 5×10^6 WBCs.[81] Using current apheresis and filtration technologies, residual WBC counts of less than 1×10^6 are readily obtainable. In 1977, a study of seronegative heart surgery patients showed that whole blood leukoreduced by centrifugation (58% reduction of leukocytes) resulted in a seroconversion rate of 12.5%, compared with 67% in recipients of nonleukoreduced blood.[84] Since then, a number of studies have demonstrated lower seroconversion rates, with blood products leukoreduced by saline washing, freeze-deglycerolization, and filtration. Filtration of red cells was shown to decrease transfusion-acquired CMV infection in infants,[85] and the use of filtered blood components was shown to decrease CMV seroconversion in patients undergoing treatment for acute leukemia.[81,82] Leukocyte depletion was further reported to be effective for preventing CMV disease in the autologous[86] and allogeneic[87] HSCT settings.

In 1995, Bowden and colleagues[80] reported a large prospective study of 502 seronegative marrow transplant patients randomized to receive seronegative or filtered blood products to test the hypothesis that these methods are equivalent in preventing CMV transmission. In the primary statistical analysis, there were no significant differences in the rates of CMV infection (1.3% vs 2.4%) or CMV disease (0% vs 2.4%) between the seronegative and filtered arms, respectively. The primary analysis excluded patients who seroconverted within the first 21 days of HSCT, based on the premise that they most likely would have been infected with CMV before transplantation. Complicating the interpretation of this study is that a secondary analysis of all patients seroconverting between days 0 and 100 showed a significantly worse outcome for patients in the filtered arm: 2.4% of patients in the filtered arm developed CMV disease, compared with 0% in the seronegative arm. Moreover, five of the six patients in the filtered arm who developed CMV disease progressed to fatal pneumonia. There were no deaths in the seronegative arm. Another confounding factor is that bedside filtration was used, which was subsequently shown to suffer from a relatively high rate of failure.[88] Later methods would be expected to provide better and more consistent leukoreduction. Nevertheless, patients receiving leukoreduced blood showed a low level (2.4%) of CMV infection, which is in keeping with the historical figures of 1% to 4% CMV seroconversion with the use of CMV-seronegative components. The investigators conclude by stating: "We believe that the results of this study justify abandoning the maintenance of dual inventories of seronegative and unscreened blood products. The need to perform serologic screening of blood products of CMV could be eliminated altogether."[80]

Given the previous considerations and the data associating filtered RBC units with an increased risk for CMV infection in HSCT patients,[89] it remains unclear whether leukoreduced products are equivalent to seronegative products for the prevention of CMV transmission. It is certain that leukoreduction is extremely effective in decreasing CMV transmission, and the use of leukoreduced CMV-safe products as a substitute for seronegative products has become an accepted practice standard.[81] Overall, although transfusion-transmitted CMV remains a problem in the HSCT population, the rates seen using seronegative or leukoreduced products are far lower than they have been in the past, in large part because of improvements in surveillance and preemptive therapy.[90]

TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

TA-GVHD is a devastating complication of blood transfusion primarily affecting immunocompromised patients, including patients undergoing allogeneic or autologous HSCT. The basic mechanism underlying TA-GVHD is that viable, immunocompetent lymphocytes in a blood product engraft and proliferate in the transfusion recipient. The donor lymphocytes attack host tissues, including skin, liver, intestine, and marrow. Signs and symptoms generally appear 7 to 10 days after transfusion. Patients typically present with fever, rash, elevated liver function test results, and nausea, vomiting, and diarrhea. Severe, refractory pancytopenia often develops as well, in most cases leading to the patient's death. The pancytopenia seen differentiates TA-GVHD from classic GVHD after HSCT. Whereas TA-GVHD involves immune rejection of host marrow cells, the marrow is spared in classic GVHD, because donor and recipient BM are selected to be HLA-compatible. In most cases, TA-GVHD is fatal within 3 to 4 weeks of transfusion, with most patients dying from complications of marrow failure (i.e., bleeding or infection).

TA-GVHD occasionally occurs in completely immunocompetent patients. In these cases, the mechanism is a "one-way" HLA match, in which the transfusion recipient shares an HLA haplotype with a donor who is homozygous for that haplotype. The transfused lymphocytes are recognized as self by the host immune system and are not rejected. The recipient's cells, however, are seen as foreign by the infused lymphocytes, leading to a GVH response. Shared HLA haplotypes are more likely to occur among first-degree family members and in population groups with limited HLA heterogeneity. In the United States, the risk of transfusion of blood from HLA-homozygous donors to unrelated HLA-heterozygous patients is estimated to be approximately 1 in 7174. In Japan, a more genetically homogeneous population, the risk is much greater (1 in 874).[91] The incidence of TA-GVHD in the United States is clearly much lower than would be expected based on HLA considerations alone.[92] Although underreporting may play a role, it is likely that other factors, including the use of blood that is stored for up to 6 weeks (with decreased leukocyte viability) and the rejection of HLA-homozygous cells based on minor transplantation antigens, also are factors.

There is no effective therapy for TA-GVHD. Fortunately, TA-GVHD is effectively prevented by gamma irradiation of blood products before transfusion. One case of TA-GVHD has been documented after irradiation with 1500 rad,[93] and previous studies suggest that irradiation to 2000 rad is required to reduce mitogen-responsive lymphocytes by 5 to 6 logs compared with unirradiated controls.[94] Based on these observations, irradiated blood products are required to receive 2500 rad (25 Gy) to the central part of the container, with 1500 rad (15 Gy) as the minimum dose to any other point.[95] Cellular blood products are required to be irradiated for the following situations: recipients identified to be at risk for TA-GVHD, donations made by blood relatives of the recipient, and donors selected to be HLA-matched with the recipient.[96] At this time, it is recommended that only cellular blood products and fresh plasma be irradiated. TA-GVHD has not been reported to be caused by transfusion of plasma or cryoprecipitate that has been frozen and thawed.

SOLID ORGAN TRANSPLANTATION

Transfusion medicine is integral to the success of any solid organ transplantation program. The role of the transfusion medicine specialist and hematologist focuses on blood group compatibility,

histocompatibility, transfusion and coagulation support, and adjunctive treatment of humoral rejection. Improved surgical technique and advances in prevention of allograft rejection have led to tremendous growth in solid organ transplantation during the past decade. During 2002, for example, 25,700 solid organ transplantations were performed, including more than 14,000 kidney, 5000 liver, 2000 heart, and 1000 lung transplantations in the United States. The Annual Report of the United Network for Organ Sharing (UNOS) is available on the Internet (www.optn.org/data/annualReport.asp). The availability of multiple drugs to prevent organ rejection, including prednisone, cyclosporine (Sandimmune, Neoral, SangCya), tacrolimus (Prograf, FK506), mycophenolate mofetil (CellCept), daclizumab (Zenapax), antithymocyte globulins (Atgam, Thymoglobulin, Orthoclone), and rapamycin (Rapamune), has extended graft and patient survival. Designed to suppress T-cell activation and cytokine release, these drugs are not cytotoxic agents and lack direct marrow toxicity.

IMMUNOHEMATOLOGY AND SOLID ORGAN TRANSPLANTATION

Renal Transplantation

Pretransplantation Blood Transfusion

After the initial investigations by Opelz and colleagues,[89] numerous studies documented that pretransplantation blood transfusions promoted prolonged renal allograft survival. As a result, deliberate use of random donor transfusions before cadaver donor renal transplantation and donor-specific transfusions (DSTs) before living-related donor transplants became widespread. A proportion of deliberately transfused patients became HLA alloimmunized, however, and the resulting HLA incompatibility eliminated them as candidates for transplantation. The introduction of cyclosporine in the 1980s led to improved graft survival and the benefit of pretransplantation transfusions became more difficult to document.[90] As a result, the practice of pretransplant transfusion was abandoned.

ABO Compatibility

ABO compatibility between donor antigens and recipient antibodies is critical for successful renal transplantation.[100] ABH antigens are richly expressed on vascular endothelial cells[101] and renal cells[102] and are excreted in the urine.[103] As a result, ABO incompatible grafts are at high risk for humoral rejection, and transplantation against ABO barriers has traditionally been contraindicated.[104,105] Because group O recipients are restricted to group O donors, several experimental protocols have investigated the use of group A_2 donors (who express group A antigens at approximately one-fourth the strength of group A_1 individuals) for group O or group B recipients with low-titer anti-A antibodies.[106,107] Protocols aimed at allowing renal transplantation across the ABO barrier typically involve pretransplant plasmapheresis or immunoadsorption to remove anti-ABO antibodies, in combination with immunosuppressive agents and careful monitoring of antibody titers.[108] Short-term results with such protocols have in some cases been encouraging.[109,110] In some cases, high titers of anti-ABO antibody can continue to circulate in the recipient—but without corresponding damage to the antigen-positive transplanted organ. This phenomenon, termed *accommodation*, is not well understood.[111]

HLA Compatibility

The importance of serologic HLA compatibility between donor antigens and recipient antibodies is well established for renal transplantation. Recipients who express warm-reactive antibodies to HLA class I antigens of the donor are at risk for hyperacute rejection characterized by complement activation, intravascular coagulation in the graft, organ ischemia, and necrosis that may occur within minutes of establishing blood flow to the graft. Several techniques are used for HLA crossmatching, and there is controversy regarding which method has the highest predictive value. Standards of the American Society for Histocompatibility and Immunogenetics (www.ashi-hla.org/) require that the final crossmatch employ a technique with greater sensitivity than the basic microlymphocytotoxicity test. Such techniques may use longer incubation times, more wash steps, an antiglobulin reagent, B-cell targets, dithiothreitol, or flow cytometry.[112,113]

Recognition of the importance of HLA-serologic compatibility led to the practice of monthly HLA antibody screening of serum from HLA-sensitized patients awaiting kidney transplants. Antibody specificities that are identified are recorded and the corresponding antigens avoided when allocating suitable kidney allografts. Some programs also consider compatibility results using archived sera when allocating allografts to recipients who are known to be HLA sensitized. Analysis of recipient HLA specificities has revealed that identification of antibodies directed against common "public antigens" may be more clinically meaningful than antibodies to private HLA antigens.[114–116] Understanding the exact value of HLA matching for long-term graft acceptance is complicated by the power of immunosuppressive medications, the polymorphism of the HLA system, variable response to different loci within the major histocompatibility complex, and the confounding effects from minor histocompatibility antigens. Studies of the precise value of matching have yielded conflicting results; nevertheless, consideration of the extent of match remains a high priority in organ allocation. DNA-based HLA typing continues to advance understanding of the role for HLA matching in renal transplantation.

Routine practice does not require HLA matching of donor and recipient when allocating cadaver kidneys. However, retrospective studies of graft survival have suggested that certain HLA mismatches are associated with a higher incidence of rejection,[117] and large retrospective analyses have provided evidence that greater degrees of HLA matching between the donor and recipient result in longer graft survival.[118,119] For example, Takemoto reported that allograft half-life was 12.5 years among more than 7,600 cadaver-donor transplants without HLA-mismatches compared with 8.6 years among 81,000 HLA-mismatched cadaver-donor transplants.[120] Studies have shown that matching for HLA-DR antigens may be more important than HLA-A,B,C.[96] Although not all have agreed that matching improves outcomes,[121] the potential benefits have prompted organ banks to allocate cadaver organs based on the degree of HLA match rather than simply on the results of HLA compatibility testing. However, matching cadaver organs to distant recipients may carry the disadvantage of prolonged cold-ischemia time. As a result, allocation based on HLA matching combined with limitation of cold-ischemia time is used. Despite the beneficial effects of HLA matching, matched *cadaver* transplants do not survive as well as matched *living-related* transplants. The difference may reflect not only injury to the graft during preservation but also the influence of histocompatibility mismatches not recognized by existing HLA-typing techniques.

Liver Transplantation

ABO Compatibility

Ordinarily, the donor liver must be ABO compatible with the recipient. Transplantation of ABO incompatible livers has occurred by error or under urgent circumstances, with limited success.[122–124] ABO-incompatible liver transplants may occur more frequently in pediatric cases when a compatible donor organ is unavailable and recipient blood group alloantibodies are poorly developed.[125] Data from the UNOS Scientific registry found that ABO mismatch was among the strongest independent predictors of adverse outcome after emergency liver transplantation.[126] In another series, survival of emergently transplanted ABO-incompatible grafts was 30% compared

with 76% for emergently transplanted ABO compatible grafts.[127] The immune response to ABO-incompatible grafts is consistent with a pattern of hyperacute rejection.[128] No standards exist regarding transfusion support for ABO-incompatible grafts, but the use of RBCs and FFP compatible with both donor and recipient would seem desirable.

Hemolytic Antibodies of Donor Origin

Passenger lymphocytes that accompany a graft may continue to secrete antibodies directed against blood group antigens during the early postoperative period. If the recipient's native red cells or transfused red cells express the matching antigen, a Coombs-positive hemolytic anemia may appear approximately 1 week after transplant.[129] Although the direct antiglobulin test may only be weakly reactive, rather brisk hemolysis typical of complement fixing ABO antibodies can occur. Acute renal failure from intravascular hemolysis in this setting is rare but has been reported.[130]

Approximately 30% of patients transplanted with ABO-compatible but nonidentical livers have been reported to develop postoperative hemolysis mediated by anti-ABO antibodies produced by passenger lymphocytes.[131] Hemolysis has also been reported to result from non-ABO blood group antigens[128] but is most commonly seen when the donor is group O and the recipient is group A_1. Posttransplant hemolysis has been reported after all types of major solid organ transplants, including liver,[130] kidney,[132] heart–lung,[133] spleen,[134] and pancreas.[135] It is most common after liver transplantation, probably by virtue of the greater number of passenger lymphocytes that accompany this large organ. This phenomenon is uncommon after kidney transplantation because of UNOS policies that reserve group O donors for group O recipients. The diagnosis is confirmed by testing an eluate made from the patient's red cells against non–group O target cells—a test not routinely done by the blood bank in the evaluation of a positive direct antiglobulin test. Treatment consists of transfusion with cells compatible with donor and recipient antibodies. Red cell exchange is usually not required and the condition is generally self-limited because donor lymphocytes are deleted posttransplant.

Alloantibodies to Red Cell Antigens

Patients with clinically significant alloantibodies directed against red cell antigens outside the ABO system pose a unique problem in the setting of the massive transfusion requirements that unpredictably accompany liver transplantation.[136] Depending on the availability of antigen-negative donor units, one strategy is to begin surgery with antigen-negative compatible red cells and then allow transfusion to "wash out" recipient alloantibody before switching to antigen-positive red cells. Approximately 1 blood volume of antigen-negative units can be reserved for the end of the case to reconstitute the patient with compatible blood for the postoperative period. Antibody washout can be roughly predicted from the presurgical antibody titer as measured by twofold serial dilution. Each blood volume of transfusion reduces the titer by one dilution. For example, an antibody that reacts at 1:16 titer requires roughly 4 blood volumes of transfusion to wash out.

Heart and Lung Transplantation

Cardiac transplantation has become an established therapy for life-threatening cardiac dysfunction, including coronary disease, cardiomyopathy, and congenital cardiac defects. One-year patient survival rates of approximately 85% and 5-year survival rates of 70% have been achieved through the use of effective immunosuppressive regimens, improved recipient selection criteria, the use of heart-assist devices to bridge the waiting time between diagnosis and transplantation, the development of percutaneous endomyocardial biopsy for improved detection of early rejection episodes, and more effective management of postoperative infectious complications. As a result of these improvements, research has shifted from short-term problems such as acute rejection to those factors influencing long-term morbidity-free survival.

Cadaver lung transplants and living-related partial lung transplants have been used in the treatment of a variety of end-stage pulmonary diseases, including cystic fibrosis, emphysema, and α_1-antitrypsin deficiency. A variety of techniques have been developed to prevent rejection of the bronchial anastomosis between donor and recipient. Combined heart–lung transplants are infrequent and are used in the treatment of congenital heart disease with Eisenmenger syndrome or primary pulmonary hypertension.

ABO Compatibility

Because ABO antigens are present on cardiac endothelial tissue, ABO compatibility of donor and recipient is a prerequisite for heart transplantation. ABO is a major determinant of waiting time for heart and lung transplant recipients, with group O recipients consistently requiring longer waiting times. As with other solid organ transplants, ABO-compatible but -nonidentical allografts are used. However, ABO-identical transplants may have a better overall survival than ABO-compatible but -nonidentical grafts. ABO-incompatible heart transplants are absolutely contraindicated in adults because of the risk of hyperacute rejection. However, many successful ABO-incompatible heart transplants have been performed in infants.[137] The infant immune system does not produce T cell-independent antibodies, and early ABO-incompatible heart transplantation produces tolerance in the recipient to donor blood group A or B antigens. The primary mechanism underlying this tolerance appears to be specific elimination of donor-reactive B lymphocytes.[138] Thus, a type O infant who receives a type A heart transplant will typically have normal levels of circulating anti-B antibody, but not the usually expected anti-A antibody later in life.

HLA Compatibility

The clinical significance of HLA antibody testing in cardiac and lung transplantation remains controversial and surveyed practices show a lack of consensus.[139,146,147] Recipients with HLA antibodies to donor antigens do not experience hyperacute rejection and some studies have reported no adverse outcomes despite incompatible crossmatches at the time of transplantation.[140] However, most studies have found that patients with HLA antibodies, detected by a pretransplantation HLA crossmatch or by a highly panel-reactive antibody (PRA), have a higher frequency of rejection episodes in the first months after transplantation. Whether this reflects a direct effect of HLA antibodies or represents a marker of recipient cellular immune responsiveness is not resolved. For example, in a review of 500 cardiac transplants at the Cleveland Clinic, sensitized patients (PRA > 10%) had a 1-year graft survival of 76% compared with 89% for nonsensitized patients ($P = 0.02$).[141] As with renal transplants, some studies have suggested that antibodies to class I HLA antigens[142] or antigens specific to the donor[143,144] are more important predictors for early rejection episodes. Other studies have not found HLA antibodies to play a critical role in graft rejection.[145]

Xeno-antibodies

Naturally occurring xeno-antibodies in humans represent a major immunologic barrier to xenotransplants. Similar to ABO antibodies, xeno-antibodies are directed against sugar epitopes, including α-galactose found on the cells of all mammals other than humans and Old World monkeys. Antibodies to α-galactose fix complement avidly and produce a potent hyperacute rejection.[148] As a result, strategies to overcome this immune barrier have been directed against

the level of antibody[149] and against prevention of complement activation.[150,151]

TRANSFUSION MEDICINE SUPPORT FOR SOLID ORGAN TRANSPLANTATION

Specialized Blood Components

Cytomegalovirus-Reduced Risk Blood

The implications of CMV infection are different in solid organ transplant recipients compared with bone marrow transplant recipients. After solid organ transplantation, the recipient's immune system is not chimeric, and immunosuppression is less extensive than that required for allogeneic marrow transplantation. As a result, solid organ recipients appear to have better immunity against infections such as CMV, which cause less postoperative morbidity.

Most serious CMV infections result from primary transmission from the donor allograft rather than from blood transfusion.[152,153] CMV-seronegative recipients of CMV-seropositive allografts are therefore at greatest risk for posttransplantation infection regardless of blood transfusion therapies. For example, in a study of liver transplant recipients, it was found that symptomatic CMV disease, CMV hepatitis, invasive fungal disease, and death were each more likely to occur in patients who acquired CMV from the donor organ rather than from transfusion.[154] When the recipient is CMV-seropositive, reactivation infection is more common than transfusion-transmitted disease. Second-strain infection can occur from the allograft, but has not been reported as a result of transfusion. This may result from the fact that the allograft is retained whereas blood donor leukocytes are largely apoptotic and cleared shortly after transfusion. When the organ donor or the recipient is CMV positive, the use of CMV-negative blood components should be considered investigational.

However, when both donor and recipient are CMV-negative, CMV-reduced-risk blood is indicated for lung transplantation.[155] CMV-reduced risk blood is defined as blood from CMV-seronegative donors or leukoreduced blood—either of which can effectively prevent CMV transmission by transfusion. CMV-reduced risk blood is not generally used for adult liver transplant cases because of the large number of products required. CMV-reduced risk blood products are not a strict requirement among most solid organ recipients. For example, Preiksaitis reported the incidence of postoperative CMV among CMV-seronegative recipients who were supported with CMV-untested and nonleukoreduced blood components.[153] Although postoperative CMV was very common (131 [85%] of 154) when the organ allograft was CMV-seropositive, CMV syndromes were at near background levels (3 [2.4%] of 127) when organ donor and recipient were CMV seronegative despite the use of blood components that were not CMV-reduced risk. Among the different categories of transplantation, the incidence of postoperative transfusion-associated CMV was 0 of 57 (0%, renal), 0 of 29 (0%, heart), 2 of 20 (10%, liver), and 1 of 6 (16.7 %, lung).[153] Current interest has centered on the use of PCR for the early detection of CMV infection as a guide to the preemptive use of ganciclovir.[156,157]

γ-Irradiated Blood Components

Patients undergoing solid organ transplantation are not known to be at increased risk for TA-GVHD.[158] As a result, γ-irradiated cellular blood components are not currently required for solid organ transplant recipients preoperatively or postoperatively. Because γ-irradiation results in dramatic elevation of plasma potassium levels in stored red cells, irradiated and stored red cells may increase the risk of hyperkalemic cardiac arrest at the time of massive transfusion.

Massive Transfusion during Liver Transplantation

OLT has become the treatment of choice for life-threatening end-stage hepatic failure.[159] Successful OLT requires a close working relationship between the surgical team, anesthesia services, and blood services because the operation sometimes requires spectacular quantities of blood support. Improved surgical technique, use of venovenous bypass for those cases in which the vena cava is interrupted, argon laser-directed electrocoagulation, and better preservative solutions for storing the donor liver ex vivo have contributed to decreased transfusion requirements during surgery.[160,161] One-year and 5-year patient survival rates are approximately 85% and 75% respectively.

Causes of Bleeding

Intraoperative transfusion requirements for OLT cannot be predicted on the basis of preoperative coagulation screening.[162] Rather, the presence of severe portal hypertension, previous right upper quadrant surgery, vascular abnormalities of the portal vein, poor left ventricular function, pulmonary hypertension, poor nutritional state, or comorbid diseases are the most important predictors of massive transfusion and decreased survival. Prior transjugular intrahepatic portosystemic stent-shunt (TIPSS) does not appear to adversely affect surgical outcomes during OLT.[163]

OLT requires a difficult right upper quadrant dissection of the recipient hepatic bed, which can be complicated by severe portal hypertension, friable collateral vessels, adhesions from prior procedures, or inflammation from the patient's underlying disease. Removal of the liver requires isolating the blood supply of the organ and clamping and cutting the portal vein, hepatic artery, common bile duct, and the hepatic vein or the inferior vena cava above and below the liver. The period after the recipient hepatectomy and before reestablishing blood flow to the new graft is referred to as the anhepatic phase of surgery and is the period of greatest risk.

Patients who require OLT usually have multiple hemostatic abnormalities associated with acute or chronic liver failure. Decreased coagulation factors, splenomegaly with thrombocytopenia, dysfibrinogenemia, and chronic fibrinolysis with elevated fibrin split products may all be present in varying combinations. Some patients develop a profound intraoperative fibrinolysis. Tissue plasminogen activator (tPA)—presumably released from recipient blood vessels or from the vessels of the graft in response to shock, acidosis, pharmacologic pressors, ischemia, or preservation injury—circulates in high concentration. Normally cleared by the liver, tPA released during and immediately after the anhepatic phase of surgery is not cleared from the bloodstream. As a result, tPA activity can reach 10 to 100 times normal levels and a pathologic systemic lytic state ensues.[164,165] A sudden decrease in all coagulation factors occurs with particularly marked declines in fibrinogen and factor VIII.[166] Proteolysis of von Willebrand factor may also occur.[167] Less severe cases may not demonstrate systemic lysis but may lyse clot at sites of previous hemostasis. As the liver allograft begins to function, tPA is rapidly cleared and fibrinolysis decreases.

Transfusion Support During Liver Transplantation Surgery

A rapid transfusion device designed to deliver large volumes of blood components in a rapid fashion is essential for OLT. These devices consist of a sterile holding reservoir, high-capacity blood filter, roller pump, in-line blood warmer and air detection device. Blood is pumped through large-bore catheters placed in the antecubital or central veins. Intraoperative blood recovery devices are a useful adjunct to blood support during OLT, particularly in cases requiring massive transfusion.[168,169] Blood suctioned from the operative field is anticoagulated with citrate and collected in a sterile holding reservoir. The shed blood is then centrifuged, the supernatant discarded, and

the residual packed red cells washed with saline. The saline-suspended packed red cells may then be pumped to the rapid transfusion device or transferred to a plastic blood collection bag for later reinfusion.

OLT demands careful but aggressive component therapy guided by the clinical course and the results of intraoperative coagulation monitoring.[170] Serial intraoperative hematocrit and coagulation monitoring using a limited number of tests with rapid turnaround time provides valuable information for rational blood component management. Some OLT centers monitor coagulation using thromboelastography—a method that measures whole blood coagulation by impedance to an oscillating cylinder.[171,172] Other programs use traditional measurements such as the prothrombin time, fibrinogen, and platelet count. Either method of monitoring is valuable, provided that testing is done serially, results are reported rapidly, changes are correlated in the operating room with the clinical picture, and abnormalities are interpreted by someone with experience in the coagulopathy of OLT.

Red cell support must be given in consideration of the competing needs of other patients. Probably as a consequence of postoperative immunosuppression, Rh-negative individuals transfused with Rh-positive blood at the time of transplantation are not likely to make anti-D.[173] Nevertheless, Rh-negative women of childbearing age without anti-D are initially supported in many programs with a reasonable number of D-negative units and then switched to D-positive cells should more blood be needed. In some programs, Rh-negative males and females who are not of childbearing potential are treated from the outset with Rh-positive blood. Because many OLT patients are massively transfused, delayed hemolytic transfusion reactions in the postoperative period if directed against high-frequency antigens can result in dramatic hemolysis.

The use of fresh frozen plasma (FFP), platelet concentrates, and cryoprecipitate is guided by the clinical course and by the results of intraoperative monitoring.[174] Although care must be given to prevent dilutional coagulopathy, it is not necessary to mix equal ratios of red cells and FFP or platelet concentrates. Reasonable goals of component therapy in the absence of fibrinolysis or other complications include an international normalized ratio (INR) of less than 2 or 2.5, a platelet count higher than 50,000 to 100,000/μL, and a fibrinogen concentration more than 100 mg/dL. Antifibrinolytic agents are indicated during or shortly after the anhepatic phase of surgery in those patients who demonstrate a systemic lytic state.[175] A loading dose and continuous infusion of ε-aminocaproic acid,[176] tranexamic acid, or aprotinin[177] has been used with success. Hourly bolus doses have also been used. Tranexamic acid[178,179] or aprotinin[180,181] each reduced operative blood loss during liver transplantation when studied in randomized, prospective, placebo-controlled trials. Because the routine use of antifibrinolytics may result in thrombotic complications in some patients, our program uses antifibrinolytics for those patients who show evidence of fibrinolysis. Recombinant activated factor VII has been used to promote hemostasis during liver transplantation. Although a small pilot study suggested decreased transfusion requirements compared with historical controls,[182] a subsequent controlled trial failed to demonstrate a favorable effect on blood loss. For all patients, local hemostasis provided by meticulous and advanced surgical skill remains critically important.

Metabolic Complications of Massive Transfusion During Liver Transplantation Surgery

Patients undergoing massive transfusion during OLT are susceptible to all the major complications of massive transfusion, including hypothermia, dilutional coagulopathy, electrolyte imbalance, pulmonary dysfunction, and transfusion-transmitted infections. OLT patients are uniquely at risk for life-threatening hypocalcemia as a result of citrate toxicity.[183] Magnesium is also chelated by citrate, and low magnesium concentrations may accompany massive transfusion during OLT surgery.[184] Because the liver is the main organ for citrate metabolism and because OLT patients can receive very rapid infusions of large volumes of FFP that is rich in Na_3-citrate, the quantity of citrate infused per kilogram body weight per minute can quickly exceed the rate of citrate removal.[185] Citrate toxicity is more pronounced if concomitant renal failure is present because the kidney is the major site of citrate excretion. The principal effects of citrate toxicity are cardiovascular. An initial blunted response of cardiac output to left-ventricular volume loading is followed by hypotension resulting from poor cardiac output and decreased systemic vascular resistance. If misinterpreted as hypotension due to hypovolemia, a more rapid transfusion of citrate-rich blood components will worsen cardiac output. Citrate toxicity is aggravated by hypothermia and hyperkalemia. Because a widened QTc interval on the electrocardiogram has low specificity and poor predictive value, intraoperative monitoring of the ionized calcium level is essential during OLT. Untreated severe depression of the ionized calcium or magnesium results in bizarre electrocardiographic disturbances and fatal arrhythmias.

Plasmapheresis and Photopheresis

The indications for plasmapheresis in transplantation patients remain poorly defined and not established by controlled clinical trials. Preoperative plasmapheresis or blood exchange is able to lower titers of ABO antibodies, especially those of the IgM class.[124,149] Plasmapheresis is less effective at reducing titers of HLA antibodies, which are largely IgG in nature. Plasmapheresis has been reported to successfully treat some patients with postoperative HLA-mediated humoral rejection of renal allografts.[187] Photopheresis refers to a treatment in which blood passes along an extracorporeal circuit and is exposed to a photoactive chemical (psoralen) plus ultraviolet light. Used initially in the treatment of Sézary syndrome, photopheresis has been applied to the treatment of solid organ transplant rejection unresponsive to standard therapy. Uncontrolled studies have reported success in cardiac, renal, lung, and liver transplants.[188]

CHAPTER 156

HEMATOLOGIC MANIFESTATIONS OF SYSTEMIC DISEASE: LIVER AND RENAL DISEASE

Peter W. Marks and Rachel Rosovsky

Disorders of the liver and kidney can be associated with very significant hematologic effects. With hepatic dysfunction, effects on red blood cell morphology and coagulation predominate, whereas with renal disease, effects on red blood cell production and platelet function predominate. Understanding the pathogenesis of such disorders facilitates accurate diagnosis and management.

HEMATOLOGIC MANIFESTATIONS OF LIVER DISEASE

Progressive liver disease can eventually result in cirrhosis and is associated with portal hypertension and splenomegaly. Portal hypertension is associated with variceal and gastrointestinal bleeding and resultant anemia. Splenomegaly is associated with any combination of leukopenia, anemia, or thrombocytopenia.[1] Because the liver is integrally involved in the metabolism of lipids, which are major constituents of the red blood cell membrane, abnormalities in erythrocyte size and shape may arise with hepatic dysfunction.[2] The liver is also a vital organ contributing to the blood coagulation process. It is a major site of synthesis for virtually all of the proteins involved in the soluble hemostatic system and is involved in the clearance of products of proteolysis. These features facilitate the delicate balance of the coagulation system. Patients with liver disease, therefore, are at increased risk for developing a variety of hemostatic defects.

This section will discuss several of the hematologic problems commonly encountered in patients with liver disease: red blood cell abnormalities, vitamin K deficiency, bleeding due to hepatic failure, and complications in liver transplantation. It will also touch upon the effects of alcohol on the hematologic system.

RED BLOOD CELL ABNORMALITIES

Morphologic Abnormalities

Abnormalities in lipid metabolism that occur in liver disease can lead to changes in red blood cell size and shape. Macrocytosis may be an initial finding, followed by the development of target cells and acanthocytes (spur cells) (Fig. 156–1A). These changes are associated with abnormal cholesterol loading of the red blood cell membrane. Cholesterol loading of the lipid bilayer acts to restrict the mobility of integral membrane proteins. The erythrocytes are therefore unable to undergo normal deformation as they transit the vasculature.[3] When cholesterol loading is sufficiently severe, passage of such red blood cells through the microcirculation of the spleen leads to cytoskeletal damage and the irreversible deformation of the red blood cell noted morphologically as spur cells.[4]

Spur Cell Anemia

A hemolytic anemia associated with few other hereditary or acquired conditions, spur cell anemia is most commonly observed in chronic or severe liver disease.[5] In contrast to its mild manifestations in individuals with alpha beta-lipoproteinemia (see Chapter 46), in liver disease spur cell anemia may be quite severe and can cause life-threatening declines in hemoglobin concentration. Treatment options for this disorder have been disappointing. Therefore the development of spur cell anemia in a patient with hepatic failure generally is indicative of a very poor prognosis. Depending on the cause, patients may also suffer from disseminated intravascular coagulation, gastrointestinal bleeding, and/or liver failure. There have been a few case reports of clinical improvement using a combination of therapeutic agents such as flunarizine, pentoxifylline, and cholestyramine,[6,7] but for the most part, the only effective treatment has been liver transplantation.[8]

Coagulation Defects and Liver Disease

The clinical manifestations of coagulopathy based on hepatic dysfunction range from asymptomatic laboratory abnormalities to life-threatening hemorrhage. These manifestations of liver disease are the result of a variety of derangements in hemostasis. There is decreased synthesis of clotting factor proteins, which are produced primarily in the liver. In addition, defective forms of fibrinogen may be synthesized in liver disease due to abnormal posttranslational modification of this protein. The defective fibrinogen produced has an inability to polymerize normally into fibrin strands. This defect is manifest in the laboratory with abnormal thrombin and reptilase times (measures of fibrinogen cleavage and polymerization into fibrin), often in the setting of normal immunologic amounts of fibrinogen. Because fibrin is a polymer of many subunits, even small numbers of abnormal fibrin molecules can poison the multimerization process and result in a bleeding diathesis.[9]

Although many assays are available in the coagulation laboratory to elucidate the more precise nature of the factors affected, a carefully performed history and physical examination, in combination with an appropriate initial laboratory evaluation, will often reveal the cause and facilitate the treatment of most hemostatic abnormalities in patients with liver disease.

VITAMIN K DEFICIENCY

Deficiency in vitamin K may occur in a variety of medical and surgical settings. Poor oral intake, broad-spectrum antibiotics, and age are all risk factors for vitamin K deficiency. The uptake of the vitamin is intimately linked to the liver, as biliary salts are required for intestinal absorption.[10] Vitamin K deficiency can therefore be caused by anything that impairs the metabolism of bile acids. This includes intra- or extrahepatic cholestasis, biliary system fistulae or obstruction, primary biliary cirrhosis, or treatment with bile acid binders (ie, cholestyramine).[11] There are also nonhepatic causes of vitamin K deficiency, such as malnutrition or the administration of broad-spectrum antibiotics.[12,13] Finally, the most commonly used oral anticoagulants, coumarin derivatives such as warfarin, act by disrupting the vitamin K cycle.

Vitamin K is fat soluble and is an essential component in the production of several of the coagulation proteins (see Chapter 130).[14] It was initially named "Koagulationsvitamin" in reference to its connection with the coagulation system.[15] Investigation of the underlying cause of the hemorrhagic disease that cattle developed in the early

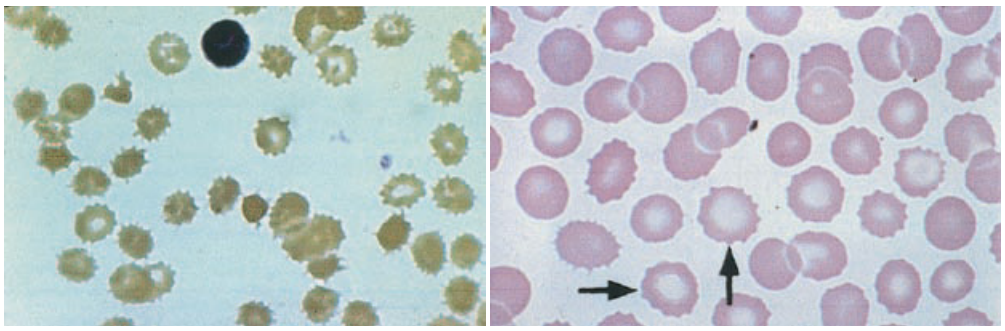

Figure 156–1 Morphology of acanthocytes and echinocytes. **A,** Acanthocytes, or spur cells, are most commonly observed in significant numbers on the peripheral blood smear in cases of liver disease, although they may also be prominent in certain rare disorders (eg, alpha beta-lipoproteinemia). Their characteristic features are spines that seemingly project from the surface of the cell. Such morphologic change represents the result of irreversible cytoskeletal damage due to passage of abnormally stiff cells through the reticuloendothelial system. **B,** Echinocytes, or burr cells, are the hallmark of uremia, although they may be observed as an artifact on less than optimally prepared smears. An undulating or bumpy red blood cell surface characterizes this morphologic change, the cause of which is unknown.

part of the 20th century (eventually found to be due to the ingestion of spoiled sweet clover containing coumarols) helped to elucidate the role and importance of this factor.[16,17] Vitamin K serves as a coenzyme in the posttranslational carboxylation of factors II, VII, IX, and X.[18] This modification creates sites on these proteins for calcium ion coordination and thereby renders them functional.[19,20]

An alteration in the synthesis of vitamin K-dependent coagulation factors is usually reflected by changes in specific laboratory parameters. Initially, there is a prolongation of the prothrombin time (PT) because factor VII, a critical component of the coagulation cascade synthesized in the liver, has a half-life of only 4 to 7 hours. An increase in the activated partial thromboplastin time (PTT) may occur as well when there is a substantial decline in factors II, IX, and X, which have longer half-lives.

Replacement of vitamin K may be warranted when the PT is prolonged by more than 3 seconds or to an International Normalized Ratio (INR) of greater than 1.5. When there is no evidence of active bleeding and the INR is moderately prolonged, vitamin K can be administered orally, subcutaneously, intramuscularly, or intravenously, although the intramuscular route is less preferable in the setting of coagulopathy. Dosing regimens commonly utilized include 5 mg orally or 10 mg subcutaneously once a day for 3 to 5 consecutive days.[21] If there is no improvement in the PT after three doses, however, additional replacement usually provides no further benefit.[22,23] Additionally, in patients with severe liver disease, vitamin K supplementation often has only a modest effect in correcting the prolonged PT.[24] In this setting, inadequate hepatic protein synthetic function is the primary issue.

When the INR is greatly prolonged in the absence of bleeding (INR >9), administration of intravenous vitamin K, either alone or in combination with other agents, may be indicated. In cases of simple vitamin K deficiency, such as that due to dietary deficiency or due to warfarin administration, intravenous administration of doses of between 1 and 2 mg can lead to complete correction of the INR within 4 to 6 hours. In this regard, many clinicians have avoided this route of administration because of reports of fatal allergic reactions in the literature.[25] More recently, the risk of anaphylaxis and the administration of vitamin K has been more thoroughly reviewed. Reports of adverse drug reactions in association with vitamin K were collected and categorized by route of administration, dose, and type of reaction. Although there were more anaphylactic reactions documented with intravenous administration of the drug than any other route of administration, the actual number of reports was relatively small given its widespread use.[26] That being said, it might seem most prudent to administer vitamin K intravenously slowly and only in circumstances when patients are at high risk for hemorrhage or are actively bleeding.

BLEEDING IN FULMINANT COAGULOPATHY

The bleeding patient with liver disease poses many challenges, the most immediate of which is to locate the source of the bleed and then attempt to correct it. Patients with hepatic dysfunction may bleed from varices, ulcers, or disseminated intravascular coagulation, to name a few entities. Such patients generally require some type of plasma component replacement therapy in addition to correction of the underlying anatomic defect.[21,27–30] Patients who are undergoing invasive procedures or who are in imminent danger of bleeding will also need treatment for the purpose of prophylaxis. Each source of therapy must have its particular advantages weighed against its potential detrimental side effects.

Fresh frozen plasma (FFP) has been used as a first-line treatment because it contains all the components of the clotting and fibrinolytic system present in circulating blood, except for platelets. It is currently recommended as an adjunctive hemostatic agent in any patient actively bleeding or for prophylaxis before invasive procedure in patients with coagulopathy due to liver disease.[31–35] Although the recommended dose is weight based (1 mL/kg body weight generally increases clotting factors 1% to 2%), in most clinical situations calculations are not performed. Instead, patients receive on average 4 to 8 units of FFP. Because factor VII has such a short half-life, additional infusions are often required every 6 to 12 hours to maintain a hemostatic effect. This practice of transfusion translates into a fairly large volume load. In some patients with liver disease, who already have an expanded intravascular plasma volume, this therapy is not well tolerated.

Allergic reactions are observed in 1% to 3% of patients treated with FFP and are usually confined to urticaria. Anaphylaxis is rare and can occur in the setting of IgA deficiency. Hemolysis can take place if there is ABO blood group incompatibility, and antibodies against granulocytes present in the donor plasma can cause the very rare complication of transfusion-related acute lung injury.[36] Other potential adverse effects of FFP include the risk of viral transmission. The risk of transmitting human immunodeficiency virus, hepatitis B, or hepatitis C is similar to that of whole blood.[37] Use of solvent/detergent-treated plasma has been explored as a method to lessen the risk of these potential infections.[38] Unfortunately, there appear to be potential hepatic side effects of solvent/detergent-treated plasma in certain populations of patients, and additional development of such products is required.

In severe bleeding episodes, replacement solely with FFP is sometimes insufficient. If the patient is actively bleeding, red blood cell transfusions are required to maintain an adequate hematocrit level and prevent shock. In patients with a platelet count below 50×10^9/L or suspected platelet dysfunction, platelet transfusions may also be

Management of Coagulopathy in Liver Disease

Appropriate management of the patient with liver disease and coagulopathy can prevent complications or minimize bleeding. Because patients with liver disease often have a combination of defects, such as thrombocytopenia from hypersplenism, decreased circulating levels of coagulation factors, and abnormal fibrinogen due to impaired hepatic synthesis, bleeding may be particularly severe and require the administration of multiple different blood products.

A trial of administration of vitamin K 5 to 10 mg a day for 3 to 5 days by the oral (preferred) or subcutaneous route is reasonable in patients with mild to moderately elevated clotting times who are not actively bleeding. In more severe cases of liver disease, the maneuver generally has little or only temporary effect.

In patients who are actively bleeding, fresh frozen plasma (FFP) provides a ready source of all of the coagulation factors. Administration of 15 to 20 mL/kg (equivalent to about 1000 to 1500 mL or four to six bags of FFP) is generally reasonable as a start. Two common mistakes are often made, both related to the relatively short half-life (several hours) of several clotting factors: (a) the units of FFP are given too slowly over a number of hours or (b) after initial administration of FFP and correction of clotting times, additional units are not administered in a timely manner. The solution to the former error is to administer the units over the course of no more than 1 to 2 hours; the solution to the latter is to monitor coagulation parameters and/or empirically give 2 to 4 additional units of FFP approximately every 6 hours.

Dysfibrinogenemia should be suspected when coagulation times fail to correct despite apparently adequate and timely administration of FFP. In this setting, it can be quite difficult to overwhelm the inhibitory effects of abnormal fibrin monomers present in the patient. Administration of cryoprecipitate, 10 to 20 units, in addition to FFP may help in overcoming this barrier. In addition, administration of cryoprecipitate should be considered for rapid replacement of fibrinogen in bleeding patients with fibrinogen levels below 50 to 100 mg/dL.

Moderate to severe thrombocytopenia should also be corrected. In the bleeding patient, platelet transfusion is reasonable if the count falls below 50,000/μL, and certainly if it falls below 20,000/μL. Unfortunately, because of hypersplenism, platelet recovery is often poor. Nonetheless, there is likely some residual hemostatic benefit in the bleeding patient. Additionally, in the rush to transfuse other blood products, an adequate hemoglobin concentration should also be maintained by transfusion of packed red blood cells as necessary.

Recombinant factor VIIa (Novoseven) has been used off-label in the setting of liver disease to try to achieve hemostasis. Doses leading to correction of the prothrombin time in the setting of liver disease are generally only about one-half to one-quarter (25–50 μg/kg) of the doses required for the treatment of hemophilia with inhibitors. The duration of the correction obtained is generally 4 to 8 hours. It should be noted, however, that correction of the prothrombin time does not necessarily correlate with prevention of bleeding. Because of its short half-life, use of recombinant factor VIIa may be most appropriate in certain circumstances, such as when emergency procedures are necessary, or to temporize until more durable measures can be taken. Even in such cases, care should be taken to maintain an adequate fibrinogen level and/or consider the possibility of a dysfibrinogenemia, as much of the action of the clotting cascade ultimately rests on the successful production of fibrin polymers.

helpful.[39] Alternatively, exchange transfusions in combination with platelets and plasma can be effective in controlling bleeding, especially in patients with liver disease who cannot tolerate the volume load associated with FFP.[40]

In cases of advanced liver disease, disseminated intravascular coagulation may be present. Alternatively, in the setting of massive transfusions, hypofibrinogenemia may exist. The use of cryoprecipitate is indicated if the fibrinogen level falls below 100 mg/dL. For every 10 kg of body weight, one unit of cryoprecipitate, which contains factors VIII, XIII, von Willebrand factor, fibronectin, and fibrinogen, will increase the fibrinogen level by approximately 50 mg/dL.

Cryoprecipitate does not contain significant amounts of any of the vitamin K-dependent coagulation factors and therefore, in the setting of vitamin K antagonists or deficiency, prothrombin complex concentrates (PCCs) are sometimes useful. Concomitant administration of antithrombin concentrates or heparin is often given prior to the PCC to decrease the risk of thromboembolic complications, which can occur when using these agents.[41] Two rarer problems associated with the use of PCCs are acute anaphylactic reactions secondary to the presence of foreign proteins and the development of inhibitors. Thus, given the potential hazards of PCCs, they should be used only in emergency situations, such as in the setting of critical bleeding and volume overload in patients with advanced liver disease. When these agents are utilized, laboratory monitoring for disseminated intravascular coagulation is mandatory.[42]

Recombinant factor VIIa (rFVIIa) has shown promising results in the management of patients with coagulopathy due to liver disease.[43,44] It was first approved as an antihemophilic agent, and, since then, it has shown favorable results when used off-label in managing patients with coagulopathies caused by liver disease.[45–47] In nonbleeding cirrhotic patients, for example, rFVIIa transiently reverses prolonged prothrombin times. The duration of this normalization is dose dependent. Transient correction of the PT by rFVIIa was also observed in patients undergoing liver biopsy and in patients experiencing variceal bleeds.[48–50] Finally, as described below, rFVIIa has been used in patients undergoing orthotopic liver transplantation and has possibly resulted in improved hemostasis, less blood loss, reduced blood product requirements, and, in one study, even a slight improvement in survival.[51]

As compared with FFP, rFVIIa has no risk of viral transmission and has the advantage of being administered in a small volume. The observed efficacy with rFVIIa in transiently correcting major laboratory parameters has potentially allowed for safer invasive procedures and decreased use of blood products in patients with liver disease. The optimal dosing schedule and a more complete safety profile of rFVIIa still needs to be determined, however, in large randomized controlled trials. In addition, whether the observed effects translate into improved survival in cirrhotic patients with coagulopathy remains to be seen.

SPECIAL CONSIDERATIONS IN LIVER TRANSPLANTATION

Patients undergoing orthotopic liver transplantation often experience severe hemostatic alterations, of which the most significant is bleeding. The different stages of transplantation, which include the preoperative, anhepatic, reperfusion, and convalescent phases, confer different hemostatic risks.[52] In the preoperative phase, for example, the underlying liver disorder and its subsequent amount of liver parenchymal cell damage is associated with preexisting compromise of the hemostatic system. During the anhepatic phase, a decrease in the hepatic clearance of activated coagulation factors and an absence of clotting factor production causes an increase in tissue plasminogen activator and a decrease in plasminogen activator inhibitor 1, respectively.[53–56] This state of hyperfibrinolysis continues during and after the graft reperfusion phase, where it has been postulated that endothelial cell injury further releases thromboplastic substances,

including tissue plasminogen activator.[57] Additional challenges in liver transplantation include the extent of the surgery and the possibility that the transplanted liver may be rejected.

The intense fibrinolytic activity and resultant bleeding problems associated with orthotopic liver transplantation have been controlled in the past with multiple transfusions of packed red blood cells, FFP, and platelet concentrates. In an attempt to reduce the amount of blood loss and resulting transfusion requirement, the use of antifibrinolytic agents has been explored in this setting. Two randomized controlled studies showed that prophylactic therapy with aprotinin significantly decreased hemorrhagic blood loss.[58,59] An additional randomized study compared the antifibrinolytic agent tranexamic acid to aprotinin and found similar safety and efficacy between the two agents.[60] However, there is controversy regarding the overall safety and efficacy of these agents.[61] In any case, reasonable caution should be taken when using antifibrinolytic agents such as aprotinin. The drugs have the potential to disrupt the balance of the coagulation system, and, in the randomized trials, patients at increased risk of thromboembolic complications (ie, with malignancies) were excluded. There have been a few case reports of fatal thromboembolism associated with its use, although it is unclear whether aprotinin was the only cause implicated in these instances.[62] Additionally, allergic reactions and renal dysfunction have occurred.[63–65]

Recombinant factor VIIa (rFVIIa) is another hemostatic agent whose use has been, and continues to be, investigated in the setting of orthotopic liver transplantation. Initial small studies suggested a potential benefit of rFVIIa with a reduction in the number of red blood cell transfusions required.[66,67] However two subsequently conducted randomized controlled trials did not confirm such a benefit.[68,69] Other trials have suggested that use of rFVIIa might be most effective in patients at the highest risk for bleeding.[70] In summary, routine use of rFVIIa in the setting of liver transplantation remains controversial, although there is some evidence to suggest that there may be high-risk situations in which its use is warranted.

EFFECTS OF ALCOHOL

Even in the absence of significant liver disease, chronic alcohol intake frequently leads to a mild to moderate macrocytosis, generally in the 100 to 110 fL range.[71] In addition, the intake of alcohol may be associated with other phenomena such as poor dietary intake and gastrointestinal bleeding, which are associated in turn with megaloblastic anemia due to folate deficiency and with iron deficiency, respectively. If folate and iron deficiencies are simultaneously present, the mean corpuscular volume may actually be normal, but the red blood cell distribution width will be elevated.

Other manifestations of heavy alcohol intake include direct toxic effects on the bone marrow, with reversible suppression of hematopoiesis. Although all lineages can be affected, anemia and thrombocytopenia are most common. Particularly when folate deficiency is present a sideroblastic anemia can occur in which there is defective iron utilization for hemoglobin synthesis.[72] Alcohol also impairs platelet production and function.[73] This is in addition to thrombocytopenia resulting from portal hypertension and splenomegaly. Recovery from significant thrombocytopenia generally occurs rapidly within approximately 1 week of cessation of alcohol intake. The hematologic effects of alcohol are particularly pronounced in patients with hepatic cirrhosis who continue to consume alcohol. These individuals may present with bleeding with moderate to severe pancytopenia and may require significant blood product support.

HEMATOLOGIC MANIFESTATIONS OF RENAL DISEASE

Because the kidney is the locus for the production of the primary driver of red blood cell production, erythropoietin, it should follow that renal injury would be associated with anemia, and this is borne out by fact. Although end-stage renal disease is associated with severe anemia (see later), even modest renal damage, such as that seen in diabetic patients with very modestly elevated serum creatinine levels, can be associated with impaired erythropoietin production.

Renal disease can be associated with subsequent defects in red blood cells, platelets, leukocytes, and coagulation factors. In addition, acquired disorders, such as hemolytic-uremic syndrome, can manifest simultaneously as hematologic and renal disturbances.

Abnormal red blood cell morphology due to uremia is manifest with the presence of echinocytes (burr cells) on the peripheral blood smear (see Fig. 156–1B). The pathogenesis underlying this morphologic change is unknown. Uremic toxins also significantly impair platelet function, leading to an acquired aspirin-like platelet release defect. This finding, in combination with a decreased quantity and/or function of certain clotting proteins, including von Willebrand factor, can lead to significant bleeding complications. Cellular and humoral immunity mediated via lymphocytes are also adversely affected in renal disease, and a wide variety of leukocyte defects have been reported in this setting.[74] In clinical practice, however, hypoproliferative anemia, bleeding complications, and hemolytic-uremic syndrome are the most frequent clinically relevant entities encountered, so they are covered in greater detail here.

MANAGEMENT OF HYPOPROLIFERATIVE ANEMIA

End-stage renal disease is a major health problem in the United States, with incidence increasing every year. The associated anemia is a cause of significant morbidity and mortality. Although the cause of the anemia is multifactorial, reduced erythropoietin production is primarily responsible. Erythropoietin is a glycoprotein hormone synthesized primarily in the kidney.[75,76] This crucial component in the regulation of hematopoiesis is essential for the proliferation, maturation, and differentiation of erythroid precursors (see Chapter 25).[77]

Previously, the great majority of patients on dialysis required chronic blood transfusions. This situation has changed dramatically with the introduction of recombinant human erythropoietin (rHuEPO) into clinical practice. In addition to accelerating erythropoiesis and reducing allogeneic blood transfusions, rHuEPO has been shown to increase exercise capacity and improve quality of life, sleep, cognitive function, and sexual function in anemic patients with chronic renal failure.[78–82] A small number of prospective and retrospective clinical studies have also shown that treatment with rHuEPO decreases the rise in creatinine, slows the decline of glomerular filtration rate, and delays initiation of dialysis in patients with chronic renal failure. The results from these few exploratory clinical trials support the hypothesis that using rHuEPO and correcting anemia may slow the rate of progression of renal failure.[83–85]

Treatment of anemia may also have significant cardiovascular benefits in this population. A few recent studies have shown that left ventricular hypertrophy is directly related to the level of anemia in chronic renal failure patients.[80–82] In addition, left ventricular mass has been shown to be an independent determinant in the survival of patients on dialysis.[86] Thus, treatment with rHuEPO may have benefits in terms of cardiac function, and subsequently, survival for these patients.[87] However, data also suggest that excessive correction of the hemoglobin level to values greater than approximately 12 g/dL may be associated with an increased incidence of cardiovascular and thromboembolic events. Therefore, the use of erythropoiesis-stimulating agents to increase hemoglobin values to greater than 12 g/dL is not routinely recommended.

Although rHuEPO can be administered intravenously or subcutaneously, the subcutaneous route appears to be advantageous. It is easier to administer and can be given less frequently. Hypertension and, to a much lesser degree, thrombosis have been reported in patients on dialysis.[85,88] In addition, a short-lived influenza-like syndrome has been described.[89] Rare side effects include allergic reactions, seizures, hyperkalemia, and thrombocytosis. Pure red blood cell aplasia, thought to be due to the development of antierythropoietin antibodies, is also a rare but serious complication that has primarily been reported with certain preparations of rHuEPO.[86,87,90]

Management of the Anemia of Renal Disease

Recombinant human erythropoietin (rHuEPO) and the longer-acting modified erythropoietin, darbepoetin, have revolutionized treatment of the anemia of renal disease. However, owing to their potential for adverse events, the potential inconvenience of their administration by the parenteral route, and their expense, they should be used thoughtfully and judiciously.

Regardless of the extent of renal insufficiency, patients who are candidates for erythropoietin replacement should have an assessment of their iron stores. Analysis of serum parameters, such as ferritin, iron, and transferrin generally suffice for this purpose. If there is any hint that iron deficiency may be present, it should be addressed prior to, or at least concomitantly with, the administration of rHuEPO. Although oral replacement may be reasonable in a patient with borderline iron stores and renal insufficiency, intravenous replacement with iron dextran, iron gluconate, or iron sucrose should be considered in patients with more severe iron deficiency or renal failure.

In the setting of mild to moderate renal insufficiency, such as that often seen in diabetic patients, it is not unreasonable to initiate therapy on a weekly basis if using rHuEPO or every other week when using darbepoetin when the hemoglobin is less than 9 g/dL. After the hemoglobin concentration increases to greater than 10 g/dL, the frequency of administration or dose can be tapered to maintain a level between 10 and 12 g/dL. In some exceptional circumstances, such as in patients with significant congestive heart failure or pulmonary disease, maintenance of hemoglobin at a higher level may be determined to be beneficial.

If there is no response to erythropoietin after 4 to 8 weeks of weekly therapy with rHuEPO or biweekly therapy with darbepoetin, iron stores should be reevaluated. If adequate, dose escalation of rHuEPO or darbepoetin by 50% and an additional trial for 4 to 8 weeks is reasonable. After that time, however, the drug should be discontinued and consideration be given to the cause for the lack of response, which is otherwise rare in the setting of anemia purely due to renal insufficiency. Usually, a dose of 40,000 U of rHuEPO every 1 to 2 weeks or 200 µg of darbepoetin every 2 to 4 weeks often suffices to maintain a hemoglobin level greater than 10 g/dL.

An increase in the hemoglobin to greater than 10 g/dL after a 4-week course of therapy is frequently the target goal when administering rHuEPO. Some patients may fail to respond or may be resistant to the effects of rHuEPO. The most common cause for a failure in response is iron deficiency anemia.[91] Other contributing factors that may affect the response are cobalamin or folate deficiency, infection, chronic inflammation, secondary hyperparathyroidism, malnutrition, hemoglobinopathies, aluminum toxicity, or bone marrow fibrosis. [89,92–94]

Iron deficiency is almost universal in the dialyzed patient. Gastrointestinal bleeding, blood draws, and hemodialysis all contribute to this iron-deficient state.[95] In addition, by accelerating erythropoiesis, rHuEPO actually can cause functional iron deficiency.[91,92] As a result, iron supplementation in chronic renal failure patients is usually essential. Even with the most rigorous protocols, oral iron preparations have not been as effective as intravenous ones, largely because of poor absorption resulting in failure to maintain adequate hematologic parameters (hemoglobin >11–12 g/dL, transferrin saturation >20%, plasma ferritin concentration >100 ng/mL). Thus, intravenous iron is often administered.[96,97] There are now multiple formulations of intravenous iron available for administration, including iron dextran (InFeD), sodium ferric gluconate complex (Ferrlecit), and iron sucrose (Venofer). The latter two preparations often utilized because they would appear to have more favorable safety profiles.[94,98–100] In particular, anaphylactic reactions appear to be somewhat less common.[101]

A hyperglycosylated rHuEPO, darbepoetin (Aranesp), is available.[102] It has the same mechanism of action as rHuEPO with the advantage of having a two- to threefold longer half-life.[103,104] Consequently, it can be dosed less frequently, allowing for fewer injections.[105,106] Darbepoetin appears to be equivalent to rHuEPO in terms of its clinical outcomes in patients with chronic renal failure, specifically in reaching a target hemoglobin, the time it takes to reach that target, and the percentage of patients who reach that goal.[107,108] It is also a well-tolerated medication and has a safety profile that is similar to that of rHuEPO.[109,110] There have been no antibodies to native or recombinant erythropoietin detected to date in patients treated with darbepoetin.

HEMOSTATIC AGENTS FOR USE IN UREMIA

Bleeding from uremia is one of the major causes of morbidity in patients with end-stage renal disease.[104,105] There are multiple factors contributing to the pathogenesis of this bleeding risk, but recent focus has centered on platelet dysfunction,[107,108,111] abnormal platelet–vessel wall interactions,[109] retention of uremic toxins,[110] presence of anemia, and increased levels of nitrous oxide.[112–114]

The hemorrhagic manifestations commonly seen with uremia include epistaxis, gastrointestinal and genitourinary bleeding, subdural hematomas, hemorrhagic pericarditis, ecchymoses, and prolonged bleeding from skin puncture sites. A number of therapeutic options exist for the treatment of the hemorrhagic diathesis caused by uremia, and these should be considered in any patient who is actively bleeding or about to undergo a surgical procedure.

Correction of anemia with either red blood cell transfusions or recombinant human erythropoietin contributes significantly to reducing the bleeding tendency. Raising the hematocrit to 27% or greater has been shown to decrease the bleeding time and improve platelet function.[115–117] Similarly, hemodialysis has been shown to partially correct the bleeding time and potentially decrease the risk of bleeding.[118]

Perhaps the most convenient and safest treatment for bleeding in the setting of uremia, regardless of whether a patient is being dialyzed, is the use of desmopressin (ddAVP). Possibly through release of von Willebrand factor from endothelial stores and through improved platelet signal transduction, it frequently improves hemostasis. In a randomized placebo-controlled trial, administration of 0.3 µg/kg of ddAVP resulted in a decrease in the bleeding time 1 hour after the infusion. However, the duration of action was relatively short and the improvement lasted only 6 to 12 hours.[119] If a longer duration of action is needed, administration of conjugated estrogens can be considered.[114,120] An intravenous dose of 0.6 mg/kg is given daily for 5 days. Although estrogens are slower in their onset of action, and perhaps somewhat less reproducible in terms of response, their effect can last 7 to 10 days. The mechanism of action of estrogens is not well understood but may be related to their effects on nitrous oxide. Finally, cryoprecipitate, rich in von Willebrand factor and fibrinogen, can also sometimes temporarily correct the bleeding time. It appears to act as quickly and last as long as ddAVP. A commonly used dose is 10 units every 12 to 24 hours.[121]

MANAGEMENT OF HEMOLYTIC-UREMIC SYNDROME AND THROMBOTIC THROMBOCYTOPENIC PURPURA

Hematologic and renal abnormalities can manifest nearly simultaneously and suddenly in two disorders: hemolytic-uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP)(see Chapter 139). Distinguishing between these two entities can be difficult.[122,123] They are both characterized by thrombocytopenia, microangiopathic hemolytic anemia, and platelet aggregation ultimately leading to end organ dysfunction.[124] In HUS, the microvascular thrombi tend to occur within the renal microcirculation, causing acute renal failure. In TTP, the microvascular ischemia occurs in

many organs and may affect the cerebral circulation, causing neurologic abnormalities.

Although not infrequently idiopathic, both HUS and TTP have been associated with the administration of various medications such as cyclosporine (HUS) and clopidogrel (TTP). In addition, the occurrence of HUS has been associated with Shiga toxin-producing bacteria (*Escherichia coli* 0157:H7).[119] Interestingly, the clinical course of HUS appears to depend on cause. Children who suffer from postdiarrheal HUS generally improved on their own with supportive care, and they only occasionally require short-term dialysis.[125] Patients with medication-related HUS tend to have poorer prognoses.

Deficiencies in factors of the alternative complement pathway have been associated with HUS, and ADAMTS-13 deficiency has been found in some patients with TTP.[121,126,127] However, rapid determination of the level of these proteins is not yet routinely available, so the distinction between HUS and TTP, when made, generally relies on associated clinical findings.

In adults, HUS and TTP are often managed similarly by clinicians. Plasma-based therapies have been demonstrated to significantly decrease the mortality rates associated with HUS-TTP, and studies have documented the value of plasma exchange over simple plasma infusion.[128,129] The efficacy of plasma exchange possibly comes from its ability to remove the toxic factors implicated in the initiation of these disorders as well as replace a depleted, missing, or inhibited factor such as the ADAMTS-13 protease.[130,131] Some clinicians advocate that plasma exchange should begin promptly in any individual suspected of having HUS or TTP, regardless of whether the former or the latter is more strongly suspected.[132] Daily therapy with total plasma exchange is recommended until remission is evident, as determined by resolution of any renal and/or neurologic failure, normalization of platelet count and lactate dehydrogenase level, and a stable hematocrit level reflecting absence of ongoing hemolysis, or until it is clear that no further clinical benefit is being derived. Further research will hopefully better elucidate the pathogenesis of HUS and TTP and thereby facilitate the development of tailored therapies for each of these entities.

SUMMARY

There are numerous hematologic manifestations of liver and renal disease ranging from morphologic changes of red blood cells to coagulation abnormalities affecting hemostasis. Optimal patient care is facilitated by an understanding of these associated complications and their appropriate management.

CHAPTER 157

HEMATOLOGIC MANIFESTATIONS OF SYSTEMIC DISEASE: INFECTION, CHRONIC INFLAMMATION, AND CANCER

Peter W. Marks and David S. Rosenthal

Various infections, chronic inflammatory conditions, and malignancies share potential hematologic manifestations. Depending on the nature of the particular condition, such effects may be observed as abnormalities in one or more of the hematopoietic cell lineages or in the function of the blood coagulation cascade. Because hematologic manifestations often are early indicators of systemic disease, familiarity with the disease entities associated with such changes is important knowledge for the practicing clinician.

INFECTIOUS DISEASES

Bacterial, fungal, protozoan, and viral infections may have major hematologic manifestations.[1] In certain cases, such as that of infection with malarial parasites, there is a characteristic finding, such as hemolytic anemia. In other cases, the effects may be more diverse, or an infectious agent may cause different disease manifestations in different individuals. Such is the case for tuberculosis, which can lead to pancytopenia in some individuals and a leukemoid reaction in others. Past medical history may also have an effect on the hematologic manifestation of disease. For example, infection with *Babesia* is often subclinical, yet in the case of individuals who have undergone splenectomy, fulminant manifestations are not uncommon. This section will focus on the etiologic agents and manifestations associated with bacterial, fungal, protozoan, and viral infections, with the exception of human immunodeficiency virus (HIV) infection and infectious mononucleosis associated with Epstein–Barr virus (EBV) infection, which are described in detail in Chapters 158 and 54, respectively.

PANCYTOPENIA

Bacterial, fungal, protozoan, and viral infectious agents are sometimes associated with pancytopenia, which may range from a mild depression in blood counts to severe trilineage aplasia. Pancytopenia may be caused by direct toxic effects leading to bone marrow necrosis, bone marrow replacement (myelophthisis), inhibitory effects of inflammatory mediators, or activation of the reticuloendothelial system leading to hemophagocytic syndrome.[2] Alternatively, it may be the result of persistent congestive splenomegaly resulting from infections such as salmonellosis, tularemia, syphilis, toxoplasmosis, schistosomiasis, malaria, infectious mononucleosis, or hepatitis.[3,4]

Particularly in patients with poor nutritional status, immunocompromise, or previous treatment with chemotherapy, pancytopenia can result from gram-positive, gram-negative, or fungal infections, such as with *Brucella*, *Salmonella typhi*, *Aspergillus*, or *Mucor*. Mycobacterial infections leading to granuloma formation are also associated with pancytopenia,. This feature may be the first symptom of these infections, which tend to manifest less acutely.

Viral infections associated with pancytopenia include those with arboviruses, such as dengue, which cause transient effects, and suspected agents, such as a non-A to -G hepatitis that appears to be associated with more durable aplastic anemia.[5] The latter association with viral infection is suspected, rather than proven, as particularly in young adult males pancytopenia may be preceded clinically by hepatitis. In general, immunosuppressive therapy or allogeneic bone marrow transplantation is the treatment of choice in such cases.

ANEMIA

Infectious agents can cause anemia by a variety of different mechanisms. These broadly fall into the categories of decreased production, increased destruction, or blood loss (Table 157–1). Although the effect of increased destruction by infectious agents is generally confined to the red cell lineage, decreased production is often, but not invariably, associated with general myelosuppression and effects on other cell lineages.

Anemia Caused by Decreased Production

Anemia due to inflammatory changes, frequently described in adults as the anemia of chronic disease or the anemia of chronic inflammation, is one of the most common manifestations of infection. In the pediatric age group, similar, more transient changes are often described as the anemia of acute infection.[6,7]

The anemia of chronic disease can be characterized as a normocytic, normochromic, or mildly microcytic, hypochromic anemia with a low reticulocyte count. Serum iron and transferrin levels are often low in patients with normal to increased body iron stores. The pathophysiology of the anemia of chronic disease has become increasingly defined.[8] The anemia of chronic disease appears to result from a combination of increased levels of hepcidin in combination with the release of several cytokines. In this setting several events occur: (a) Iron becomes trapped in the reticuloendothelial system, (b) erythropoietin levels decrease, and (c) cytokines directly suppress the hematopoiesis in the bone marrow. The iron-regulatory protein hepcidin plays a key role in this process through its eventual effects on diverse aspects of iron metabolism (Fig. 157–1).[9]

Though confined to specific anatomic spaces, several localized infections with bacterial, fungal, or protozoal agents are often associated with the anemia of chronic disease. These include abscesses, cavitary pulmonary disease, chronic infectious arthritis, chronic osteomyelitis, and endocarditis. For example, hypoproliferative anemia may manifest in patients with tuberculosis. In most clinical cases, the degree of anemia tends to correlate with the duration and extent of infection.

Viral infections can also be associated with hypoproliferative anemia. Parvovirus B19 infection is the classic example.[10] This agent infects red blood cell precursors via receptor-mediated entry through the blood group P receptor. It can then replicate in erythroid progenitor cells. Although the transient red aplasia that generally results from parvovirus B19 infection is most often apparent clinically in patients with underlying hematologic conditions, including hemoglobinopathies and in immunodeficiency syndromes, it occasionally manifests in otherwise healthy individuals.[11] A specific example of the manifestation of parvovirus B19 infection in patients with hematologic disorders is the occurrence of aplastic crises in patients with sickle cell disease.[12] Additionally, lack of clearance of the virus in immunocompromised individuals can lead to prolonged periods of anemia. In such cases, treatment with immunoglobulin may prove beneficial.[13]

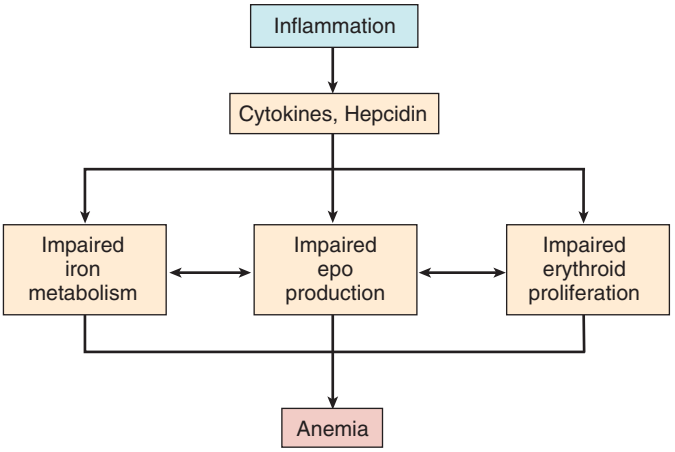

Figure 157–1 Pathophysiology of the anemia of chronic disease. The same potential mechanisms are involved in the hypoproliferative anemia that is frequently seen in infectious diseases, rheumatologic conditions, and malignancy. An inflammatory condition (infection, systemic inflammatory disease, or malignancy) leads to the production of hepcidin and cytokines, which subsequently prevent iron from being released from the reticuloendothelial system, leading to decreased erythropoietin (epo) release and inhibited hematopoiesis.

Table 157–1 Mechanisms of Anemia in Infectious Diseases

Decreased production of red blood cells
Anemia of chronic disease
Anemia of acute infection (pediatrics)
Aplasia
Increased destruction of red blood cells
Parasitization of the erythrocyte
Hemolytic uremic syndrome
Disseminated intravascular coagulation
Effects of enzyme deficiency (G6PD)
Immune-mediated hemolysis
Blood loss
Gastrointestinal (helminthic infections)
Genitourinary (schistosomiasis)
Pulmonary (tuberculosis)

Table 157–2 Causes of Infection-Related Hemolytic Anemia

Erythrocytic parasitization
Malaria
Babesiosis
Bartonellosis
Toxin production
Clostridium perfringens
Immune hemolysis
Cold agglutinin disease
Mycoplasma pneumoniae
EBV
Paroxysmal cold hemoglobinuria (Donath-Landsteiner antibodies)
Secondary and congenital syphilis
Measles
Measles vaccination
Antigen-antibody complex ("innocent bystander")
Haemophilus influenzae
Polyagglutination
Enteric bacteria
Oxidative effects of infection or treatments for infection
G6PD deficiency
Mechanical destruction
DIC
HUS
Endocarditis

DIC, disseminated intravascular coagulation; EBV, Epstein-Barr virus; G6PD, glucose-6-phosphate dehydrogenase; HUS, hemolytic uremic syndrome.

Anemia Caused by Increased Destruction

Hemolytic anemia in the setting of infection can result from various mechanisms, including those related to direct invasion of red blood cells with pathogens, toxin production, resultant immune reactions, inherent increased susceptibility of red cells to hemolysis, and mechanical effects (Table 157–2). Diagnosis of these entities relies on a carefully performed history and physical examination, which in the setting of a heightened index of suspicion should be followed by an appropriate diagnostic evaluation. In some cases, specialized testing, such as serology, molecular diagnostics, or enzymatic assays, is critical to an accurate diagnosis. In other cases, examination of the peripheral blood, through review of thin or thick smears or of special stains, provides the definitive diagnosis. This is the case for infection with intraerythrocytic parasites as in babesiosis or malaria.

Although malaria is perhaps the best-known parasitic infection causing hemolysis, several other agents are capable of producing this effect. Infection may be caused by adherence of agents to the red cell membrane followed by its disruption, or by infestation of the erythrocyte by the parasite, often as an obligatory step in the life cycle of the pathogen. Infection caused by *Bartonella bacilliformis* is an example of the former, whereas infection with tick-borne *Babesia microti* is an example of the latter.[14,15] Bartonellosis (Oroya fever) is like malaria in that it is a vector-borne illness. It is transmitted to humans by the bite of a sand fly found in the high Andes. The disease manifests with fever, chills, and hemolysis within 2 to 3 weeks of infection. Resultant hemolysis can be particularly severe or even fatal if untreated with appropriate antibiotics (eg, tetracycline or chloramphenicol). In the case of malaria, the pathogenesis of erythrocytic infection has been elucidated.[16] In the case of *Plasmodium falciparum*, merozoites, which are abundantly present in the bloodstream, adhere to glycophorin molecules on the surface of red cells. The merozoites are then able to transiently disrupt the membrane and underlying cytoskeletal structure of the erythrocyte in order to gain entry, without causing lysis of the cell. The organisms subsequently feed on hemoglobin, produce various proteins, and eventually undergo destruction in the spleen. Hemolysis can be particularly severe in some cases (Blackwater fever) when acute intravascular hemolysis results from an autoimmune reaction. In this case, the direct antiglobulin (Coombs) test is positive.

The effect of bacterial hemolytic toxins is rarely observed in humans, except in the case of infection by *Clostridium perfringens*.[17] Although clostridial sepsis is rare, it is sometimes seen in the setting of septic abortion, biliary tract disease, traumatic wound infection, or in the setting of severe pancytopenia, such as in individuals undergoing intensive induction or consolidation chemotherapy for hematologic malignancies. The organism produces a lecithinase (α-toxin), which reacts with red cell membrane lipoproteins to release lysolecithin, which is then lytic to the cells.[18] Although the underlying organism is sensitive to antibiotics (eg, metronidazole), fulminant infection in the presence of underlying disease and decreased oxygen-carrying capacity frequently lead to mortality.

Immune mechanisms are ultimately responsible for the hemolytic conditions that result from infection with a variety of pathogens.[19] These can broadly be divided into autoimmune, antigen–antibody complex ("innocent bystander"), and polyagglutination reactions. Certain infectious agents can stimulate antibody production with affinity for red cell surface proteins, thereby causing autoimmune hemolytic anemia. Intravascular and extravascular mechanisms have

been defined: the former are generally secondary to immunoglobulin M (IgM) or "cold" antibodies, whereas the latter are generally secondary to IgG or "warm" antibodies. The two most common infections causing cold autoimmune hemolytic anemia are those due to *Mycoplasma pneumoniae* and EBV associated with infectious mononucleosis.[20] Each of these infections results in the production of IgM antibodies to the I system of red cell membrane antigens (I and i are carbohydrate surface antigens). In the case of *M pneumoniae* the target antigen is the I antigen, and in the case of EBV it is the i antigen. These antibodies bind to red cells at temperatures lower than 37°C and fix complement, eventually leading to hemolysis. The incidence of cold autoimmune hemolytic anemia from these infections is relatively low. When it occurs, the mainstay of treatment is supportive care and maintenance of warm body temperature, as low external temperatures can significantly exacerbate hemolysis. Immunosuppressive therapy is not generally indicated. Other bacterial and viral infections such as those with *Legionella*, mumps, rubella, and cytomegalovirus (CMV), as well as vaccination against measles, have also been occasionally associated with cold autoimmune hemolytic anemia. IgG antibodies that react with red cells in the cold cause a rare form of cold autoimmune hemolytic anemia. These Donath–Landsteiner antibodies are responsible for paroxysmal cold hemoglobinuria.[21] Although they may also be idiopathic, in the setting of infection they are associated with syphilis in adults and viral infections, such as varicella, mumps, or measles, in children. Warm autoimmune hemolytic anemia in response to infection is very rare.

Antigen–antibody complexes are a rare cause of hemolysis due to infection through an "innocent bystander" effect. In this case, the infectious agent, or an antibiotic administered for its eradication, leads to antibody formation. These antibody–antigen complexes then attach to the red cell surface and lead to hemolysis. *Haemophilus influenzae* type b meningitis has been associated with this mechanism of hemolysis in children.[22] Polyagglutination is a rare type of hemolysis that results from the exposure of hidden erythrocyte antigens and subsequent reaction with antibodies that would not normally react with intact antigens.[23] For example, neuraminidase, produced by enteric bacteria, can effect such a change, ultimately leading to hemolysis.

An inherent increased susceptibility of red cells to infection occurs in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.[24] Although this trait, prevalent in African and Mediterranean populations, is relatively protective against malarial infection, it also makes these individuals susceptible to oxidant stress. G6PD is chiefly responsible for the production of antioxidants in the red cell (reduced glutathione). Decreased production of antioxidants in G6PD deficiency leads to the production of oxidized hemoglobin and oxidized lipids within the red cell. This eventually results in hemolysis within the spleen. Oxidized aggregates of hemoglobin are visible as Heinz bodies on supravital staining of blood smears with methyl or crystal violet (Fig. 157–2). The resultant removal of these Heinz bodies in the process of RBC destruction leads to the characteristic bite cells seen on a peripheral blood smear. Hemolysis in G6PD deficiency may result from infections and from therapeutics used in their management (Table 157–3). Bacterial and viral infections have been implicated, as well as a number of antibiotic and antimalarial agents.

Finally, hemolysis may result from infectious agents. For example, disseminated intravascular coagulation (DIC) caused by bacterial or fungal infection or hemolytic uremic syndrome caused by *Escherichia coli* 0157:H7 infection causes shearing of the erythrocyte within the vasculature, leading to the characteristic microangiopathic changes on the peripheral blood smear. Such mechanical hemolysis may also be seen in severe cases of endocarditis due to turbulent flow through abnormal cardiac valves.

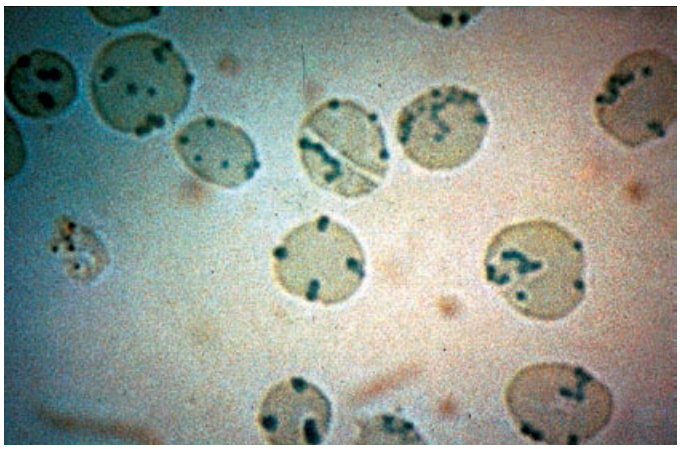

Figure 157–2 Heinz body preparation revealing aggregates of precipitated hemoglobin, such as those that might be present in a G6PD-deficient patient with infection or undergoing treatment with oxidant medications. G6PD, glucose-6-phosphate dehydrogenase.

Anemia Caused by Blood Loss

Several infectious agents are associated with disruption of the integrity of the mucosa of the gastrointestinal or genitourinary tracts, and therefore lead to blood loss anemia. Infection with *Helicobacter pylori*, a major causative agent in peptic ulcer disease, is a significant cause of blood loss anemia in developed nations.[25] Worldwide, helminthic infections, such as that of the hookworm, are a major cause of iron deficiency anemia as a result of chronic blood loss through the gastrointestinal tract. Eradication of these infectious agents and iron replacement, if appropriate, lead to resolution of the anemia.

WHITE BLOOD CELL CHANGES

Changes in leukocyte parameters are often one of the hallmarks of infection. These include changes in number and in cellular morphology. However, the changes encountered may vary significantly, depending on the type of infection and the host affected. For example, certain infections are commonly associated with leukocytosis, whereas others are associated with leukopenia. In addition, the same infectious agent might cause leukocytosis in one individual but leukopenia in another.

Morphologic Abnormalities

Review of the peripheral blood smear can provide significant insight into the possible presence of infection. Early changes in infection may

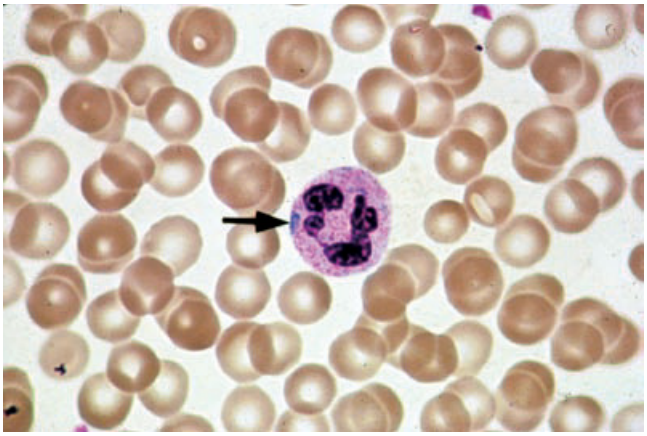

Figure 157–3 Döhle bodies seen on a Wright–Giemsa-stained smear. These *sky blue inclusions* in the cytoplasm of neutrophilic leukocytes represent collapsed stacks of Golgi apparatus. When they are observed, the differential diagnosis is relatively short. When present in the setting of toxic granulations or vacuolization, or both, the likely cause is an infection or significant marrow stimulation, such as that seen with myeloid growth factor administration. When present in nearly all neutrophilic leukocytes, and in the setting of giant platelets, Döhle bodies are indicative of May-Hegglin anomaly, an inherited autosomal dominant disorder.

include an increase in the number of bands, even before the development of overt leukocytosis. A greater shift to immaturity (left shift) may occur when infection is severe, with metamyelocytes or even earlier forms present on the peripheral blood smear. Particularly revealing are the presence of toxic granulations, cytoplasmic vacuolization, and Döhle bodies (Fig. 157–3); their appearance should trigger an assessment for the possibility of infection. Indeed, occasionally, these changes may precede the development of other infectious symptoms and signs. Rarely, in cases of severe systemic infection, organisms may be seen within leukocytes on peripheral blood smear. On Wright–Giemsa-stained smears, both gram-negative and gram-positive organisms stain purple, in contrast to their appearance on traditional gram stains.

Morphologic changes in white blood cells may also be observed on a peripheral blood smear that may underlie a predisposition to infection. For example, pseudo-Pelger–Huët anomaly and hypogranulation of polymorphonuclear leukocytes may indicate an underlying myelodysplastic syndrome.

Leukocytosis

The extent of increase in the white blood cell count may vary depending on the etiologic agent, severity of infection, and host factors. Most limited bacterial infections are associated with a white blood cell count of 12 to 14 $\times$ 10^9/L, whereas systemic infections will have a white blood cell count of 15 to 30 $\times$ 10^9/L. Massive infections, particularly with certain agents, may produce leukemoid reactions with elevations in the white blood cell count to 150 to 200 $\times$ 10^9/L.[26] Such severe elevations in white blood cells often trigger significant concern among clinicians for the possibility of underlying hematologic malignancies. Particularly in the presence of anemia or thrombocytopenia, or both, such elevations in white blood cell can present diagnostic challenges that require resolution through bone marrow examination or other specialized diagnostic testing. Leukemoid reactions are defined as a white blood cell count of greater than 50 $\times$ 10^9/L, with or without the presence of immature cells, in the absence of evidence of leukemia.

Various hematologic malignancies may be mimicked by the response to infectious agents (Table 157–4). Among these, a picture that appears like chronic myelogenous leukemia (CML) is probably the most common. A high white blood cell count with few immature cells may accompany infection when underlying disorders are present, such as malignancy, rheumatologic disease, or glomerulonephritis. A variety of bacterial infections, in the absence of underlying disorders, can also manifest with a similar picture. For example, disseminated tuberculosis may manifest with white blood cell counts of up to 200 $\times$ 10^9/L and a moderate left shift.[27] Although bone marrow examination is sometimes necessary to distinguish such conditions, the wide availability of molecular diagnostic testing for the BCR–ABL translocation can help exclude CML from consideration based on a peripheral blood sample.

Laboratory findings suggesting hematologic malignancies other than CML may also be seen. A rebound phenomenon resembling acute myelogenous leukemia (AML) may accompany recovery from antibiotic-induced agranulocytosis and after marrow suppression from severe bacterial and protozoan infections. A mature lymphocytosis, such as that seen in chronic lymphocytic leukemia (CLL), is less likely to be mimicked by infection; although before the introduction of antibiotics, cases of potentially fatal cases of pertussis were reported in the setting of a hematologic picture similar to CLL.[28] More commonly among hematologic conditions mimicked by infection, the presence of immature lymphoid cells resembling lymphoblasts in young adults with infectious mononucleosis occasionally leads to an inappropriate diagnosis of acute lymphocytic leukemia (ALL). Review of a combination of laboratory parameters including heterogeneity of atypical lymphocytes, liver function tests, and serology helps to exclude ALL. Changes indicative of myelodysplasia may also occur with viral infections, and can be difficult to distinguish from an underlying marrow disorder. In addition, certain conditions may be associated with the appearance of nucleated red blood cells in addition to immature myeloid cells (leukoerythroblastic response).[29] These include septicemia, miliary tuberculosis, and histoplasmosis. When concern exists for a potential underlying hematologic disorder in the setting of infection, careful monitoring in the recovery phase from infection is indicated.

Table 157–4 Hematologic Conditions Mimicked by Infections

Neutropenia and Neutrophilia

Although white blood cell counts of less than 1.5×10^9/L can occur paradoxically in almost any infection, they are most commonly encountered in patients with compromised bone marrow as a result of chronic debilitation, nutritional deficiency, or chemotherapy. In addition, certain infections characteristically present with neutropenia. These include a few bacterial pathogens, protozoan, and viral infections (Table 157–5). Viral pathogens are notable in this regard, and include infectious hepatitis, influenza, and HIV infection. Neutropenia may also occur late in the course, during the bacteremic phase, of typhoid, paratyphoid, and tularemia. Agranulocytosis, however, is a rare complication of infection. If it occurs after initiation of antibiotic therapy, it is suggestive of an adverse drug reaction. Alternatively, it suggests an underlying primary bone marrow disorder or immunodeficiency syndrome. For example, an aplastic picture may occur in immunosuppressed patients infected with a viral infection such as parvovirus B19.[30]

Neutrophilia usually accompanies the leukocytosis and left shift that occur in infections. More than two-thirds of cases of infection-related neutrophilia are secondary to bacteria.[31] However, neutrophilia is sometimes present in infection in the absence of an increased total white blood cell count. This change may be seen early in the response to infection, as neutrophilic leukocytes are released from the marginated pool in response to inflammatory mediators and catecholamines.

Lymphocytopenia and Lymphocytosis

Lymphocyte counts of less than 1×10^9/L are common in acute bacterial, fungal, viral, and protozoan infections, in addition to being quite common in hospitalized patients.[32] Chronic infections with tuberculosis, histoplasmosis, and brucellosis are also associated with lymphocytopenia. Alterations in the numbers of B and T cells may also occur with infection, and changes in T-cell subsets can occur in bacterial, fungal, and viral diseases, in addition to HIV, with which they are classically associated.[33] For example, early in the course of acute bacterial infection, the total number of T cells can decline, whereas the number of B cells increases.

Lymphocytosis is a rare finding in bacterial infections, with the exception of that from *Bordetella pertussis* (Table 157–6). In this case, it is suspected that the toxin produced by the organism inhibits lymphocyte migration out of the bloodstream into tissues. However, rickettsial and viral infections are associated with lymphocytosis (Table 157–6). Acute infectious lymphocytosis, a disorder of unclear etiology suspected to be related to viral infection with an adenovirus or coxsackievirus A, can sometimes be associated with a significant lymphocytosis of 30 to 100×10^9/L.

Morphologic abnormalities in lymphocytes, particularly in viral infections such as infectious mononucleosis, can occasionally appear to mimic those of patients with ALL. Although variation in the atypical nature of such lymphocytes is a helpful diagnostic clue on examination of the peripheral blood smear, flow cytometric analysis can help eliminate leukemia from consideration without the need for a bone marrow biopsy.[34]

Other Changes in White Blood Cells

Eosinopenia is generally a correlate of the severity of infection, and its presence may suggest a poor prognosis. Eosinophilia, defined as an absolute count greater than 0.25×10^9/L, although rare in typical bacterial, fungal, and viral infections, is common in invasive parasitic disease.[35] Protozoan infection with trichinosis, schistosomiasis, filariasis, and echinococcal disease are frequently accompanied by eosinophilia. Unless invasive, helminthic intestinal infections tend not to cause a change in the eosinophil count. Significant eosinophilia may also be seen in bronchopulmonary aspergillosis, coccidioidomycosis, and *Chlamydia pneumonitis* of infancy. In contrast to eosinophilia, basophilia is rarely seen in response to infection. Its presence suggests an underlying myeloproliferative disorder.

Monocytosis, defined as an absolute count greater than 0.95×10^9/L, may be seen in subacute or chronic infections. It may also develop during the recovery phase of any infection. Infections associated with monocytosis include tuberculosis, syphilis, subacute bacterial endocarditis, brucellosis, and many rickettsial and protozoan infections including malaria, trypanosomiasis, and kala-azar. Infection with varicella-zoster can also cause a significant monocytosis. In the case of tuberculosis, the monocyte-to-lymphocyte ratio may reflect the activity of disease. Normally this ratio is about 0.3, and when it exceeds 1 it is associated with active exudates and a poor prognosis.[36] With improvement of disease, this ratio returns toward normal.

PLATELETS AND ABNORMALITIES OF COAGULATION

Thrombocytopenia

Thrombocytopenia in the absence of disseminated intravascular coagulation may be seen in septicemia associated with bacterial, fungal, or viral infections, and can occasionally be quite severe.[37] More than 65% of cases of bacteremia are associated with thrombocytopenia, and about one-third of cases are associated with decreases in platelet counts to below 50×10^9/L. The mechanism underlying thrombocytopenia in the absence of DIC may be related to suppression of platelet production, increased platelet utilization, and immune phenomena.

Bacterial and viral infections may also be associated with the development of immune thrombocytopenia. Hepatitis C infection in particular is associated with this complication.[38] Certain antibiotics, such as vancomycin, are also occasionally associated with the development of immune thrombocytopenia.

Thrombocytosis

Infection is one of the more common causes of mild to moderate thrombocytosis to the range of 500 to 700×10^9/L, although platelet counts of up to 1000×10^9/L may be seen.[39] This is particularly true in chronic infections such as tuberculosis, osteomyelitis, and subacute bacterial endocarditis, as well as during the recovery from infection. In general, elevated platelet counts in the presence of infection are best managed by observation, and there is no role for antiplatelet agents.

Coagulation Abnormalities

Many cases of DIC are associated with an infectious etiology. Possible underlying causes include endothelial surface damage and tissue necrosis. Bacterial, fungal, viral, and protozoan infections have all been implicated (Table 157–7). While treating the underlying infection, supportive care with the transfusion of appropriate blood products is indicated.

Thrombotic complications (aside from DIC) are uncommonly caused by infection, but do occur. These include suppurative thrombophlebitis at intravenous sites in the arms or legs, septic thrombophlebitis of the pelvic veins, and thrombosis caused by aspergillus infection.[40] In such cases, coordinated management is necessary, and may require the administration of antibiotic or antifungal agents along with anticoagulants.

CHRONIC INFLAMMATORY DISORDERS

Rheumatoid arthritis is well associated with the anemia of chronic disease. In addition, anemia and other hematologic manifestations may occur in other chronic inflammatory disorders, including systemic lupus erythematosus (SLE), polymyalgia rheumatica, scleroderma, mixed connective tissue disease, and Sjögren syndrome, among others. On some occasions, the hematologic complications may be the dominant symptoms of these conditions.

ANEMIA

Anemia Caused by Decreased Production

The anemia of chronic disease is one of the most common hematologic disorders in chronic inflammatory conditions. The mechanism of pathogenesis is similar to that described for the anemia due to infection (see Fig. 157–1).[41] A combination of inflammatory cytokines, increased hepcidin production leading to the sequestration of iron in the reticuloendothelial system, and decreased erythropoietin production leads to decreased red cell production. Though erythropoietin deficiency does not appear to be the primary event leading to the development of anemia, its therapeutic administration to patients can in many cases overcome other barriers to red cell production, leading to improvement in anemia.[42] In particular, the beneficial effect of erythropoietin has been documented in the management of anemia in rheumatoid arthritis.[43] Recombinant human erythropoietin (rHuEPO) and darbepoetin, a modified erythropoietin with a longer half-life, are available for the treatment of such patients. When using these agents, it is particularly important to assess whether there are adequate iron stores. Iron-deficient individuals will not respond

Treatment of the Anemia of Chronic Disease with Erythropoietin

When administered appropriately, erythropoietin (EPO) can significantly improve the quality of life of patients with anemia of chronic disease. Therapy with either recombinant human erythropoietin (rHuEPO) or with darbepoetin is best considered only for patients with hemoglobin values of less than 10 g/dL, unless specific comorbidities such as significant cardiac or pulmonary disease exist. Though not specifically approved for this indication, a starting dose of 40,000 U rHuEPO weekly or 200 µg darbepoetin every other week is often sufficient to produce a 1 to 2 g/dL improvement in hemoglobin in patients with replete iron stores. After several weeks it may be necessary to decrease the frequency or dose of administration, based on response. If a response is not observed after 4 to 8 weeks of therapy and the patient is iron replete, the dose may be escalated by 50%. Thereafter, a lack of response after 4 to 8 more weeks of therapy should lead to its discontinuation and a search for other potential causes of the anemia. In some cases, bone marrow examination to search for underlying disorders such as myelodysplasia may be indicated.

The single most common reason for a lack of response to erythropoietin in patients with chronic inflammatory disorders, and rheumatoid arthritis in particular, is the concomitant presence of iron deficiency anemia. Given the inconvenience of subcutaneous injections and the cost of erythropoietin, iron stores should routinely be assessed before erythropoietin therapy is initiated. When severe iron deficiency is present, consideration may be given to the administration of intravenous iron. Preparations such as iron dextran, iron sucrose, and iron gluconate are now available for this use. Use of these agents must be tempered somewhat against their side effects, which include a small risk of allergic reactions.

to erythropoietin, and frank iron deficiency may be provoked by the stimulation of erythropoiesis in patients with borderline iron stores.[44]

Chronic inflammatory conditions have also been associated with other causes of hypoproliferative anemia. Acquired pure red cell aplasia has occasionally been associated with both rheumatoid arthritis and SLE.[45,46] The diagnostic distinction between the anemia of chronic disease and acquired pure red cell aplasia is based on the degree of anemia, as well as the finding on bone marrow examination of severe hypoplasia in the setting of relative preservation of other lineages in the latter entity. Unlike the anemia of chronic disease, acquired pure red cell aplasia does not respond to therapy with erythropoietin. Toxic effects of medications should be excluded. Although spontaneous remission sometimes occurs after several weeks, treatment with immunosuppressive or cytotoxic agents is often necessary.[47]

Myelodysplastic syndromes have also been associated with rheumatologic manifestations. Cases have been reported in which arthritis preceded the development of myelodysplasia, as well as cases in which rheumatologic manifestations such as vasculitis occurred subsequent to the diagnosis.[48] Optimal therapy for such patients has yet to be defined, though experimental approaches, such as the administration of antitumor necrosis factor (TNF) therapy, have been investigated.[49]

Anemia Caused by Increased Destruction

Autoimmune hemolytic anemia is associated with several rheumatologic disorders. In particular, in SLE it has also been associated with immune thrombocytopenia (Evans syndrome) and/or with leukopenia. Most typically this is a direct antiglobulin test (Coombs)-positive anemia found in the setting of other indicators of warm autoimmune hemolytic anemia (spherocytes on a peripheral blood smear, increased reticulocyte count, and elevated lactate dehydrogenase [LDH]).

If the anemia is mild and patients are asymptomatic, no specific therapy for autoimmune hemolytic anemia need be administered. Patients with more severe anemia who are symptomatic may be treated for warm autoimmune hemolytic anemia with corticosteroids (prednisone 60–100 mg/day followed by a slow taper). Those who do not respond, or who cannot be weaned off of corticosteroids, are candidates for splenectomy. Therapies used for patients unable to undergo splenectomy or who are refractory to splenectomy include other immunosuppressant and cytotoxic agents, as well as danazol.[50] In addition, responses to anti-CD20 monoclonal antibody have been reported.[51]

Anemia Caused by Blood Loss

Iron deficiency anemia is common in chronic inflammatory disorders, and particularly in patients with rheumatoid arthritis treated with aspirin or other nonsteroidal drugs, which often lead to gastrointestinal blood loss. However, its diagnosis can be particularly challenging, as hallmarks of iron deficiency anemia commonly used in clinical practice may be absent. Surrogate measures of iron stores are affected by the inflammatory response (eg, serum ferritin may be elevated as an acute phase reactant), and patients may be taking medications (eg, methotrexate) that lead to overall elevations in the mean corpuscular volume. The diagnosis is clear when the serum ferritin value is less than 10 μg/L and is highly suggested when the value is less than 30 μg/L, yet iron deficiency may still be present along with much higher ferritin levels.[52] Use of a combination of mean cell volume, transferrin saturation, and ferritin and use of soluble transferrin receptor have been proposed as better noninvasive measures.[53,54] However, the diagnosis of iron deficiency must sometimes rely on bone marrow examination. In such cases, iron staining of a bone marrow aspirate may be preferable to that of a bone marrow biopsy as certain fixatives may leach out iron from the biopsy.

Therapy to remediate iron deficiency in patients with rheumatoid arthritis and other chronic inflammatory conditions may depend on the extent of anemia and on the administration of concomitant medications. In particular, the administration of strong antacid medications, such as proton pump inhibitors, may decrease oral iron absorption. In some cases where administration of such medications is necessary, and the degree of anemia is moderately severe, consideration may be given to the administration of intravenous iron. Rapid repletion of iron by the intravenous route is highly effective, but is occasionally associated with side effects that include allergic reactions.

WHITE BLOOD CELL CHANGES

Two rheumatologic disorders are associated with changes in white blood cell parameters: SLE is often associated with neutropenia, and rheumatoid arthritis is occasionally associated with neutropenia and splenomegaly (Felty syndrome).[55] In SLE, neutropenia is often mild to moderate, is not associated with a significant increased risk for infection, and does not require specific therapy.

Felty syndrome is a more problematic issue in patients with a history of rheumatoid arthritis. It tends to manifest years after the initial diagnosis of rheumatoid arthritis, often when the arthritis is not very active.[56] Various pathophysiologic mechanisms have been proposed, including antineutrophil antibodies and T cell-mediated suppression of neutrophil production.[57] Because hairy cell leukemia and T-γ lymphoproliferative disorder may manifest similarly, they must be considered in the differential diagnosis.

The neutropenia in Felty syndrome may be severe and can be associated with recurrent infections, as well as with leg ulceration. Particularly in infection requiring treatment, use of hematopoietic growth factors, such as granulocyte colony-stimulating factor (G-CSF) or granulocyte–macrophage colony-stimulating factor (GM-CSF), may be beneficial, and prolonged hematologic responses are sometimes observed. However, complications with the use of G-CSF may occasionally include the reactivation of arthritis and the development of vasculitis; these may be minimized by using the lowest possible dose of G-CSF necessary to maintain a white blood cell count higher than 1000 μL.[58] Alternatively, treatment with corticosteroids or cytotoxic agents can lead to improvement of the neutropenia, although no single therapy has a high response rate. The role of splenectomy remains controversial.

An increased incidence of lymphoproliferative disorders, such as lymphoma, has been noted in patients with rheumatologic disorders. This appears to be particularly true for Sjögren syndrome, in which the incidence of non-Hodgkin lymphoma is significantly higher than that of the general population.[59]

PLATELETS AND ABNORMALITIES OF COAGULATION

Thrombocytopenia and Thrombocytosis

Immune-mediated thrombocytopenia is not uncommon in patients with SLE and other rheumatologic disorders; however, in rheumatoid arthritis, this finding is rare. The signs and symptoms, as well as diagnosis and management, are largely similar to that of idiopathic cases of immune-mediated thrombocytopenia.[60] An area of some controversy is the use of splenectomy for patients who have failed first-line therapy with corticosteroids. Although it has been suggested in the past that splenectomy was relatively ineffective treatment for patients with SLE, more recent literature suggests that it may be beneficial.[61,62] Aside from splenectomy, other therapies may be considered. Administration of immunoglobulin may serve as a temporizing measure, whereas other drugs that take longer to act, such as immunosuppressants, cytotoxic agents, or danazol, are tried. The anti-CD20 monoclonal antibody rituximab has been used effectively, without formal regulatory approval, for the management of immune-mediated thrombocytopenia and may be considered as a therapeutic

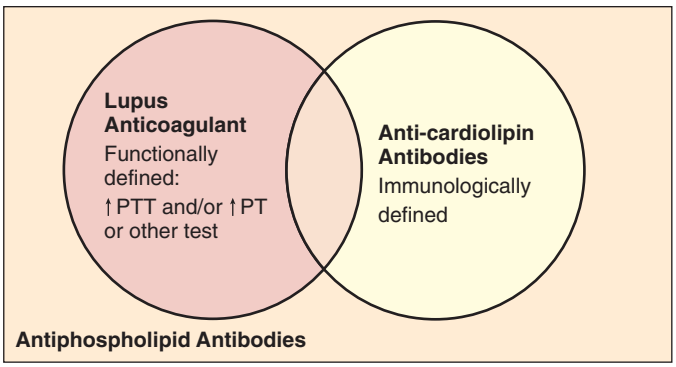

Figure 157–4 Overlap between the detection of lupus anticoagulants and anticardiolipin antibodies. Lupus anticoagulants are defined by their effects on coagulation-based assays, whereas anticardiolipin antibodies are immunologically detected. PTT, partial prothrombin time; PT, prothrombin time.

option.[63] No single therapy has a particularly high response rate, and sometimes it is necessary to move from trials of one therapeutic agent to another.

As opposed to thrombocytopenia, thrombocytosis is relatively common in rheumatoid arthritis as an acute phase reactant. Generally, the platelet count is moderately elevated, although platelet counts of up to 1,000,000/μL may occasionally be seen. Thrombocytosis correlates with elevation in the sedimentation rate and may serve as a marker of disease activity.[64] Complications from such elevated platelet counts, such as thrombosis, are rare. Rebound thrombocytosis may be seen in SLE and other rheumatologic disorders after splenectomy or withdrawal of offending cytotoxic agents. No therapy is generally indicated.

Abnormalities of Coagulation

Lupus anticoagulants and anticardiolipin antibodies are common in patients with SLE and other rheumatologic disorders.[65] Other antibodies potentially affecting coagulation, such as those to β_2-GPI, may also be present.[66] Particularly when present in high titer, anticardiolipin antibodies may be associated with lupus anticoagulant activity and with thrombosis (Fig. 157–4). Despite their name, however, lupus anticoagulants are not specifically associated with lupus and are anticoagulants in vivo only occasionally. In the absence of complications, treatment is not indicated.

Of note, in contrast to many other causes of thromboembolic disease, lupus anticoagulants are associated with both arterial and venous disease. *Antiphospholipid antibody syndrome* is the term that has been used to describe the presence of thromboembolic disease, recurrent fetal loss, and thrombocytopenia in the setting of the presence of a persistent lupus anticoagulant.[67] Once a diagnosis of antiphospholipid antibody syndrome has been made in the setting of thromboembolic disease, long-term anticoagulation is indicated, because of the high risk of recurrent events. Although it was previously thought that increased intensity anticoagulation with warfarin (to an international normalized ratio [INR] of 2.5 to 3.0) was appropriate, standard intensity anticoagulation (to an INR of 2.0 to 2.5) is now considered sufficient.[68,69] However, for specific patients with recurrent events while on warfarin, consideration needs to be given to higher-intensity anticoagulation with warfarin or in some cases to anticoagulation with agents such as low-molecular-weight heparin.

CANCER

Hematologic abnormalities are common in patients with cancer, both as a result of the underlying disease and as a consequence of therapy.[70] In addition, patients with certain hematologic malignancies may be predisposed to infection, which can lead to complications such as DIC.

ANEMIA

Anemia is the most common hematologic abnormality in patients with cancer.[71] It may be observed in about 50% of patients at some time during their course of presentation or treatment. Although there is significant overlap with infection and chronic inflammation in the underlying mechanisms leading to anemia, certain unique causes exist in patients with malignancy, particularly those related to the side effects of therapy (Table 157–8).

Anemia Caused by Decreased Production

Anemia occurs frequently in patients with hematologic or nonhematologic malignancies. Independent of bone marrow invasion, the anemia of chronic disease is common in nonhematologic cancers and may represent the initial finding. The extent of anemia is often, but not invariably, proportional to the stage of disease. The underlying pathophysiology of the anemia of chronic disease is similar to that observed in infection and chronic inflammation (see Fig. 157–1).[72] In addition, this anemia is often responsive to the administration of erythropoietin, and the same caveats hold (see box on Treatment of the Anemia of Chronic Disease with Erythropoietin). Patients will not respond to therapy if they are iron deficient.

Replacement of the marrow space with leukemia may lead to anemia, often in the setting of pancytopenia. Solid tumors can also invade the marrow space causing myelophthisis, manifesting with anemia or pancytopenia if involvement is more extensive. In such cases, a leukoerythroblastic peripheral blood smear may be seen with teardrop forms of erythrocytes, nucleated red cells, and immature white blood cells. The solid tumors most commonly associated with marrow invasion include breast cancer, prostate cancer, small-cell lung cancer, and lymphoma. Treatment of the underlying malignancy is the therapy of choice, although administration of erythropoietin sometimes leads to improvement of the anemia.[73]

Aside from treatment-related anemia, other causes of anemia are less common that those previously noted. Nutritional deficiencies sometimes are found, such as folate deficiency in anorexic patients and vitamin B_{12} deficiency in patients who have undergone gastric or

colonic resection (vitamin B_{12} deficiency taking several years to manifest itself). Pure red cell aplasia has a significant association with thymoma; 10% to 15% of patients may present with this complication.[74] Pure red cell aplasia has also been reported in non-Hodgkin lymphomas, non–small-cell lung cancer, breast cancer, and gastric cancer. The mechanism underlying the development of pure red cell aplasia may involve a combination of humoral and cellular events leading to a suppression of erythropoiesis.[75] Although treatment of the underlying disease sometimes leads to improvement in pure red cell aplasia, therapy is frequently required. Corticosteroids, antithymocyte globulin, danazol, and cytotoxic agents have been used.

Anemia has increasingly been recognized as a complication of cancer chemotherapy. Various cytotoxic agents are associated with bone marrow suppression. Although associated effects of the myeloid and megakaryocytic lineages tend to resolve within 1 to 2 weeks with most agents, anemia tends to be long lasting. Cumulative effects of multiple cycles of chemotherapy lead to more pronounced decreases in the number of RBCs. Administration of rHuEPO has been demonstrated in several clinical trials to improve anemia and quality of life in patients receiving cancer chemotherapy.[76,77] Both rHuEPO and darbepoetin have been approved for the treatment of anemia related to cancer chemotherapy, and guidelines for their use in appropriate patient populations are available.[78]

Anemia Caused by Increased Destruction

Several mechanisms may lead to red cell destruction in cancer. These include autoimmune hemolytic anemia and microangiopathic hemolytic anemia, either related to DIC or to drug-induced hemolytic uremic syndrome. Autoimmune hemolytic anemia is most commonly associated with lymphoproliferative disorders. Warm autoimmune hemolytic anemia affects about 25% of patients with CLL. It also occurs in roughly 50% of patients with angioimmunoblastic lymphadenopathy, although it is less frequent in other lymphomas (non-Hodgkin and Hodgkin) and myeloma.[79] Autoimmune hemolytic anemia is a well-described complication of the treatment of CLL with fludarabine, possibly related to induction of immune dysregulation.[80] Use of this agent should be avoided in patients with preexisting autoimmune hemolytic anemia. Warm autoimmune hemolytic anemia is also occasionally associated with solid tumors, including adenocarcinomas and squamous cell carcinomas. Although treatment of the underlying malignancy may lead to resolution of autoimmune hemolytic anemia, therapy directed at management of the anemia is often required. Similar therapies, including immunosuppressants, cytotoxic agents, or splenectomy may be required.

Cold autoimmune hemolytic anemia is also observed in association with lymphoproliferative disorders. Although it is less common than warm autoimmune hemolytic anemia, it is estimated that about 50% of patients who present with apparently idiopathic cold autoimmune hemolytic anemia (unrelated to bacterial or viral infection) have an underlying hematologic malignancy. Keeping patients warm is a mainstay of therapy for patients with cold autoimmune hemolytic anemia. Corticosteroids and splenectomy are generally ineffective. More recently, several case reports have appeared of effective therapy using anti-CD20 monoclonal antibody for patients with cold autoimmune hemolytic anemia. In some instances therapy with this agent addresses both the underlying disorder and the anemia.[81]

Anemia may be seen as one component of microangiopathic change. Moderate- to high-grade DIC is a common complication of certain hematologic malignancies (M3 and M5 AML) and certain advanced solid tumors, particularly mucin-secreting metastatic adenocarcinomas. In such cases, laboratory parameters often reflect a classic DIC pattern, and fragmented erythrocytes are observed on peripheral blood smear. Low-grade DIC leading to anemia and occasional schistocytes on smears of less pronounced or atypical coagulation abnormalities may also be observed, sometimes in patients with metastatic prostate cancer. Therapy with blood products is a temporizing measure. Resolution of the anemia relies on effective treatment of the underlying malignancy.

Hemolytic anemia may also follow the administration of cancer chemotherapy. Microangiopathic change may occur as a component of therapy-induced hemolytic uremic syndrome. Mitomycin C is an agent well known to cause this complication; however, others may do so as well.[82] For example, gemcitabine has also been associated with hemolytic uremic syndrome.[83] Discontinuation of the potentially offending agent is indicated.

Another cause of chemotherapy-induced hemolysis is the administration of doxorubicin, a strong oxidant, to patients with G6PD deficiency. Although hemolysis may be self-limited in patients with the A– genotype, it may be more pronounced in those with the Mediterranean genotype, and require cessation of doxorubicin therapy.

Hemolysis may be seen in conjunction with hemophagocytic syndrome, which may be observed in association with malignancies, as well as with infectious diseases.[84] In particular, hemophagocytic syndrome has been reported is association with non-Hodgkin lymphomas and leukemias. Although therapy for the underlying malignancy may sometimes lead to amelioration of disease, this syndrome often has a fatal outcome.

Anemia Caused by Blood Loss

Iron deficiency anemia often manifests in malignancies of the gastrointestinal tract, particularly colorectal cancers. Genitourinary cancers, such as renal cell carcinoma and bladder cancer, can also lead to iron deficiency, but this occurrence is less common. Although therapy with iron preparations can lead to improvement in anemia, absent a clear understanding of the source of blood loss, the empiric administration of iron should be reserved for those who are too infirm to undergo a diagnostic evaluation. Failure to undertake such an evaluation can lead to serious consequences, such as missing the early detection of a localized colon cancer that later goes on to manifest in metastatic disease.

WHITE BLOOD CELL CHANGES

Leukocytosis

Leukemia often, though not invariably, manifests with an elevated white blood cell count. In addition, several solid tumors are associated with leukocytosis or even leukemoid reactions.[85] The latter may occur in response to a high degree of necrosis with the tumor mass. Malignancies associated with leukocytosis include non–small-cell lung cancer (bronchogenic type), renal cell carcinoma, and gastric carcinoma. Therapy is such cases should be directed at the underlying disease.

Neutropenia

Neutropenia may be the sign of a hematologic malignancy. It also may reflect significant marrow invasion by solid tumors, leading to myelophthisis and a leukoerythroblastic peripheral blood smear.

With solid tumors, neutropenia is most commonly seen as a side effect of chemotherapy. Many cytotoxic chemotherapy agents cause significant myelosuppression, with nadirs in the WBC count that occur days to a few weeks after administration, depending on the specific agent. In certain circumstances when the likelihood of prolonged neutropenia is high, such as with high-dose-intensity chemotherapy for solid tumors, administration of G-CSF or GM-CSF may be indicated. Guidelines have been developed to help clinicians determine when use of such agents is indicated.[86]

Lymphopenias

Treatment with several chemotherapeutic agents can produce deficits in total lymphocyte count or in lymphocyte subsets. Fludarabine and

cladribine (2-chlorodeoxyadenosine) are two examples. The deficit in T-cell function following a single 5- to 7-day course of cladribine can last for numerous months, leading to an increased risk for opportunistic infections, such as *Pneumocystis carinii* pneumonia.[87] Strong consideration should be given to the administration of *Pneumocystis carinii* pneumonia prophylaxis, and potentially to antifungal prophylaxis in individuals treated with these agents.

PLATELETS AND ABNORMALITIES OF COAGULATION

Thrombocytopenia and Thrombocytosis

Several hematologic malignancies may manifest with prominent thrombocytopenia. Although this often reflects underlying marrow replacement, in certain instances, such as lymphoproliferative disorders, it may be reflective of an autoimmune disorder. For example, immune-mediated thrombocytopenia may represent an early finding in CLL.

Marrow replacement with solid tumors may also lead to thrombocytopenia. However, the most common circumstance in which thrombocytopenia is encountered in cancer patients is after chemotherapy with cytotoxic agents. Different agents are associated with transient thrombocytopenia, although several drugs, such as mitomycin C and carboplatin, are associated with longer-lasting effects, particularly after several cycles of chemotherapy are administered.

Thrombocytosis may be a prominent presenting feature of the myeloproliferative disorders, as well as myelodysplastic syndrome with the 5q– chromosomal abnormality.[88] A mild to moderate reactive thrombocytosis also frequently occurs in the setting of solid tumors. Whether this contributes to the hypercoagulable state of malignancy is unclear.

Abnormalities of Coagulation

Coagulation abnormalities are frequent in patients with cancer. Bleeding complications resulting from DIC represent one end of the spectrum, and thromboembolic complications resulting from a confluence of factors represent the other end.

DIC has been associated with AML, particularly the M3 and M5 subtypes. It also has been reported in association with other malignancies, particularly mucin-secreting adenocarcinomas such as gastric cancer. In such cases, blood product support is a temporizing measure while therapy for the underlying disease is administered. Chronic low-grade DIC has been associated with metastatic prostate cancer and can manifest atypically. Thrombocytopenia and low fibrinogen levels may be the primary manifestations, rather than abnormalities in coagulation times. Low-dose heparin may be beneficial for some patients, although it must be used cautiously.[89]

A few chemotherapy agents have clinically significant effects on coagulation aside from causing thrombocytopenia. The most notable of these is L-asparaginase, which is associated with the production of abnormal fibrinogen, which can lead to hemorrhagic or thrombotic complications.[90]

Although Trousseau syndrome was long ago identified as a potential complication of malignancy, thromboembolic complications have increasingly been identified as a cause of morbidity and mortality in cancer patients.[91] A variety of factors place patients at increased risk for thrombosis (Table 157–9). In some cases, such as in patients with malignant brain tumors, the risk for thrombosis during the course of illness exceeds 25%. The use of anticoagulants for the prevention of thrombosis in patients with malignancies must be tempered against the potential bleeding complications and the poten-

Table 157–9 Risk Factors for Thrombosis in Cancer

Procoagulants produced by tumors
Tissue factor
Cysteine protease activity
Vascular invasion
(Often observed in renal, gastric, germ cell, lung, adrenocortical tumors)
Host response to tumors
Elevated levels of factors V, VIII, IX, and XI
Decreased levels of protein C, antithrombin
Physical Inactivity
Surgical procedures
Decreased performance status
Depression
Limb immobility
Pathologic fractures
Paresis
Inherited or acquired thrombotic tendencies
Factor V Leiden, prothrombin gene mutation
Lupus anticoagulants
Indwelling venous devices
Central venous catheters
Other intravascular devices (filters, stents)
Chemotherapy-induced changes

Management of Thrombotic Complications in Cancer Patients

Tumor-related effects, host response, and therapeutic interventions combined lead to the high rate of venous thromboembolic disease that is observed in cancer patients. Though the risks of anticoagulation for a given patient should always be carefully considered, the potential benefit of prophylactic or therapeutic anticoagulation should not be underestimated for cancer patients in particular.

Use of low-dose prophylactic anticoagulation for patients with indwelling central venous catheters does not appear to be supported by well-controlled randomized trials.[92,93] Given these data, it would seem most appropriate to initiate therapy with full-intensity anticoagulation with either warfarin or low-molecular-weight heparin whenever a patient is judged to be at sufficiently high risk for catheter-related thrombosis, so long as this risk is felt to outweigh the potential for bleeding complications.

Using warfarin in particular to treat cancer patients with thrombotic complications can be challenging, especially in individuals with poor oral intake or diarrhea. With these individuals, unfractionated heparin or low-molecular-weight heparin may be administered at therapeutic doses. This is preferable to the insertion of mechanical devices. Except in circumstances such as that of recent intracranial surgery, use of vena-caval filters should be avoided because as clots form around the devices, they can impede blood flow and exacerbate swelling of the lower extremities.

If a patient experiences recurrent thrombotic events while receiving standard-dose anticoagulation therapy with warfarin, the intensity of anticoagulation may be increased to a higher target INR. However, it may be preferable to switch to therapeutic doses of low-molecular-weight heparin rather than to increase the intensity of anticoagulation, as in clinical practice this appears to have similar or greater efficacy and is simpler from the standpoint of patient monitoring and compliance. Care should be taken, however, when using low-molecular-weight heparin in patients with evidence of renal impairment, as low-molecular-weight heparin is cleared via a renal mechanism.

Regardless of whether warfarin or low-molecular-weight heparin is used for treatment, long-term anticoagulation should be administered to cancer patients who have experienced a thrombotic event so long as the malignancy is active. In patients with metastatic disease, this often translates into lifetime anticoagulation.

tial difficulty in using anticoagulants with patients receiving chemotherapy.

The high incidence of thrombotic complications in patients with malignancy has led to trials of prophylactic administration of anticoagulants, particularly in the setting of long-term indwelling central venous catheters. Although the use of very low dose anticoagulation (1 mg warfarin daily) or prophylactic dose low-molecular-weight heparin (enoxaparin 40 mg daily) does not appear to be effective in preventing thrombotic complications, the safety and efficacy of prophylaxis with standard treatment doses of anticoagulants remains open.[92,93]

Thromboembolic events in patients with metastatic cancer may best be managed with long-term anticoagulation, if the risk-to-benefit ratio is acceptable (see box on Management of Thrombotic Complications in Cancer Patients). Although use of warfarin is often reasonable as an initial therapy, regulation of the international normalized ratio can be difficult in cancer patients. There is also a significant failure rate. This has led to trials of low-molecular-weight heparin in this setting, as their administration is somewhat easier to regulate. Low-molecular-weight heparin is effective in the treatment and prophylaxis of thromboembolic events in cancer patients.[94]

SUMMARY

Infection, chronic inflammation, and cancer all share in common the potential ability to have profound effects on the blood. In some cases, such as for the anemia of chronic disease, the likely pathogenesis is also shared. Knowledge of the hematologic manifestations of these disorders facilitates their accurate diagnosis and management.

CHAPTER 158

HEMATOLOGIC MANIFESTATIONS OF AIDS

Alexandra M. Levine

DEFINITION OF AIDS

The definition of acquired immunodeficiency syndrome (AIDS) was initially based exclusively upon clinical symptoms and signs.[1] As knowledge of the viral etiology evolved, the case definition of AIDS underwent multiple revisions by the Centers for Disease Control and Prevention (CDC). Inclusion of specific clinical illnesses in a patient with serologic evidence of infection with the human immunodeficiency virus (HIV) was classified as clinical AIDS, whereas an HIV-infected patient with a CD4 count of less than 200 cells/mL (0.2×10^9/L) was considered to have immunologic AIDS.[2–4] The specific AIDS-defining clinical illnesses employed in the United States are depicted in Table 158–1.

Although this expanded definition is employed in industrialized nations, the World Health Organization (WHO) adopted alternative case-definition systems for the diagnosis of AIDS in resource-poor countries where serologic and immunologic testing are not readily available.[5]

Two major subtypes of HIV have been associated with AIDS.[6] In most areas of the world, HIV-1 is the predominant type, associated with immunodeficiency and clinical AIDS. However, a second type, termed HIV-2, has been isolated from AIDS patients from West Africa, where this retrovirus is endemic.[7] Infection with HIV-2 leads to a more prolonged asymptomatic duration of disease, with less immunodeficiency and a decreased risk of developing full-blown clinical AIDS over time.[7]

EPIDEMIOLOGY OF AIDS

Origin of Human Immunodeficiency Virus-1

HIV-1 is a member of the primate Lentivirinae subfamily of retroviruses,[6,8] RNA viruses that induce a chronic cellular infection by converting their RNA genome into a DNA provirus that is integrated into the genome of the infected cell. Infection by these lentiviruses is characterized by long periods of clinical latency followed by a gradual onset of disease-related symptoms.[6,9–11]

At approximately the same time that AIDS was first recognized in 1981, reports of a similar immunodeficiency syndrome, characterized by wasting and opportunistic infections, was described in several colonies of macaques housed at primate centers in the United States.[10,12,13] The illness, known as simian immunodeficiency syndrome, was associated with infection by a retrovirus, termed simian immunodeficiency virus (SIV).[14] Subsequent testing revealed that over 20% of all symptomatic African green monkeys or African mangabeys tested from the wild had serologic evidence of SIV infection.[15–17] The SIV viral strain infecting these monkeys was subsequently found to be related to HIV-2, a less virulent strain of human immunodeficiency virus, found primarily in West Africa.[7,18] An immunodeficiency virus related to HIV-1 and infecting African chimpanzees was also identified.[19] Recent evidence suggests that the subspecies of chimpanzee *Pan troglodytes* may have been the original reservoir of HIV-1, whereas the Sooty mangabey may have been the original reservoir for HIV-2.[17,20,21] Thus, human AIDS is actually a zoonotic infection, presumably first acquired in hunters who were exposed to the infected blood of their simian prey.

Factors Leading to Current Pandemic of HIV

Although initial transmission of HIV-1 from chimp to man is thought to have occurred several hundred years ago, social circumstances at that time did not promulgate widespread transmission to others. However, by the mid- to late 1960s, political and societal circumstances were beginning to change dramatically in ways that were conducive to the rapid spread of this infection in humans. The movement of previously isolated African peoples from rural villages to large urban centers; a change in sexual habits, resulting in widespread exposure to increasing numbers of sexual partners; the worldwide epidemic of illicit parenteral drug abuse; and the advent of commercial air travel all contributed to the current pandemic of HIV infection.

The WHO has recently estimated that more than 40 million people had been infected by HIV worldwide by 2003,[5] with approximately 28 million of these living in sub-Saharan Africa. The cumulative number of deaths due to HIV/AIDS has surpassed 25 million, with 75% in Africa. Approximately 15,000 new infections occur each day, and HIV/AIDS has now become the fourth most common cause of death, worldwide.

Methods of HIV-1 Transmission

HIV may be transmitted by sexual contact with an infected partner, by parenteral drug use with a contaminated needle, by exposure to infected blood or blood products, and by perinatal exposure from an infected mother to her infant.

Sexual Transmission

HIV-1 has been isolated from the semen of HIV-infected men as well as from cell-free seminal fluid and may be detected during the first 2 to 4 weeks after primary infection.[22,23] Factors associated with increased viral burden in semen include more advanced, clinically symptomatic HIV disease, higher levels of HIV-RNA in blood, CD4 cell counts of less than 200/mL, and presence of seminal fluid leukocytosis. HIV infection has been reported after exposure to infected semen during artificial insemination.[22–24]

HIV has been recovered from cervical and vaginal secretions of HIV-infected women,[25,26] and HIV-infected endothelial cells and macrophages have been detected in cervical biopsies.[27] Factors that influence the levels of HIV-1 in female genital tract secretions include the stage of HIV disease, menstruation status, hormonal parameters, concomitant vaginal infection, age, HIV-1 RNA level in plasma, and antiviral therapy.[28] Although female-to-female transmission of HIV has been reported,[29,30] this appears to be relatively unusual.

HIV transmission may be facilitated by the presence of other ulcerative or nonulcerative sexually transmitted diseases,[31] and HIV has been isolated directly from genital ulcers.[32] Prevention or treat-

ment of sexually transmitted disease has been associated with a decrease in HIV-1 transmission.[33]

Transmission Through Injection Drug Use

Sharing needles and syringes is an important mode of transmission among injection drug users.[34] The use of cocaine or other such non-injection drugs has also been associated with an increased risk of HIV infection,[35] by providing the opportunity for engagement in high-risk sexual behaviors.

Transmission Through Infected Blood Products

The risk of infection with HIV after receiving a single unit of infected blood is approximately 90%.[36] Transfusion of blood products derived from multiple units of pooled blood can also transmit HIV and clearly accounted for the initially high prevalence of HIV infection among patients with hemophilia. Screening of all donated blood for HIV-1 in the United States began in March 1985, and, together with the subsequent routine heat or solvent detergent treatment of clotting factor concentrates, has resulted in a marked decrease in new transfusion-associated HIV infections. Guidelines for proper inactivation of HIV in clotting factor concentrates have been developed.[37,38] Currently, the risk of acquiring HIV through receipt of a unit of blood that tests negative for antibodies to HIV-1 is approximately 1 in 493,000.[39]

Mother-to-Child Transmission

The risk of infection from mother to infant differs in various parts of the world, ranging from approximately 15% in Europe to 15% to 30% in the United States and 40% to 50% in Africa.[40–42] HIV-1 may be transmitted in utero,[43,44] at the time of delivery (intrapartum)[45,46]; or postpartum, through breast-feeding of HIV-1 infected mother's milk.[47,48] Several factors have been shown to predict an increased risk of perinatal transmission. In terms of the mother, more advanced HIV disease,[49,50] higher HIV-1 viral load in the plasma,[51,52] cigarette smoking,[53] and active injection drug use[54] have all been associated with increased risk of transmission. In terms of the details of delivery, premature rupture of the amniotic membranes (>4 hours),[55,56] presence of chorioamnionitis,[54] and vaginal delivery, as opposed to elective cesarean section,[56,57] have each been associated with increased rates of vertical transmission. In terms of the infant, breast-feeding, prematurity, and low gestational age are reported as risk factors for HIV transmission.[55–58] The CDC has made formal recommendations regarding the optimal care for HIV-1-infected pregnant women.[59] These recommendations differ for resource-rich and resource-poor settings. In the United States, the use of antiretroviral agents in pregnancy and delivery, with subsequent administration to the infant for the first 6 weeks of life, has resulted in a dramatic reduction in the rate of transmission, from approximately 25% to 8% with use of zidovudine alone, and even lower with use of combination antiretroviral therapy, termed *highly active antiretroviral therapy* (HAART).[60] With the further use of elective cesarean section and avoidance of breast-feeding, transmission rates have dropped to approximately 2% or less.[56–59] The efficacy of shorter courses of zidovudine or nevirapine (a nonnucleoside reverse transcriptase inhibitor) have been demonstrated and may be more practically feasible in resource-poor regions of the world, although significant hepatic toxicity and development of drug resistance have been reported after use of single-dose nevirapine in this setting.[61–64] The long-term toxicities of in utero exposure to antiretroviral agents are unknown. To date, however, with the exception of efavirenz,[65] there have been no clinical data to indicate any excess in congenital birth defects after use of these antiretroviral agents,[66] nor has there been evidence of an increase in malignant disease among those children exposed in utero.[67] Furthermore, the use of antiretroviral agents during pregnancy has resulted in a 43% decrease in the number of children with perinatally acquired HIV infection in the United States when comparing data from 1992 and 1996.[68]

Transmission to Health Care Workers

HIV may be transmitted from infected patients to health care workers, primarily through accidental needle stick exposures. Risk factors for greater likelihood of infection include presence of more advanced HIV disease in the source patient, occurrence of a deep needle stick injury, presence of visible blood on the needle or device, and prior insertion of the needle directly into a vein or artery.[69] The risk of such iatrogenic infection, from a source patient with full-blown clinical AIDS is approximately 0.3% per exposure. Iatrogenic infection after mucocutaneous exposure to infected fluids is approximately 0.1%, whereas transmission through intact skin, though reported, is exceedingly rare.[69,70] The use of short-course antiretroviral therapy (postexposure prophylaxis) has been associated with significant decreases in the risk of infection, and guidelines have been recommended for use of such prophylaxis.[69,70] Briefly, antiretroviral therapy should be initiated as quickly as possible after exposure, and certainly within 72 hours. Therapy is continued for 4 weeks. The specific regimen to be employed is based on the infection status of the source person, and the degree of risk posed by the exposure.[69]

PATHOGENESIS OF HIV/AIDS

HIV-1 Structure and Gene Products

HIV-1 has three structural genes necessary for replication: *gag*, *pol*, and *env*.[6] These viral genes encode proteins that are required for binding to the host cell, intracellular synthesis of provirus by reverse transcription, proviral integration into the host-cell genome, and viral assembly and release. The 9-kb genome of HIV-1 also contains at least six additional genes involved in the regulation of viral gene expression and cellular latency: *vif*, *vpu*, *vpr*, *tat*, *rev*, and *nef* (Fig. 158–1).[6,71]

env

HIV-1 is an icosahedral virion with a protein-rich envelope in a membrane derived from the host cell (see Fig. 158–2).[72] The surface of the virus particle contains a 120-Da glycoprotein (gp120) that is linked noncovalently to a 41-kd transmembrane protein (gp41). Both proteins are derived from a 160-kd precursor protein that is encoded by the *env* gene. The intracellular processing of gp160 involves the assembly of oligomeric trimer complexes, which are glycosylated and subsequently cleaved into the respective gp120 and gp41 components in the Golgi apparatus of the host cell.[73] HIV gp120 serves as a virion receptor for noninfected cells,[74] with virus

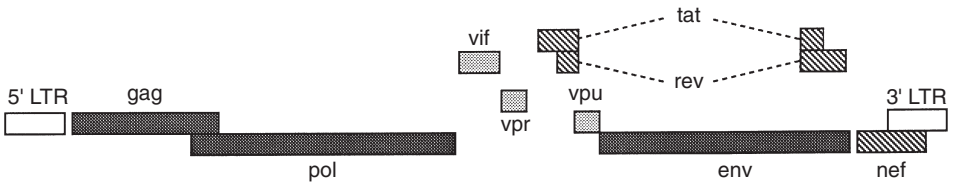

Figure 158–1 Genetic organization of HIV-1. The nine genes of HIV-1 are shown. Structural proteins of the virion and enzymes required for replication are encoded by *gag*, *pol*, and *env* (*darkly shaded regions*); regulatory proteins (*crosshatched areas*) are encoded by *tat* and *rev*, arising from doubly spliced messages, and *nef*. The *vif*, *vpr*, and *vpu* genes perform specialized functions relevant to cellular interactions. Two identical long terminal repeats (LTRs) are present at the 5′ and 3′ end of the genome and contain sequences critical for viral transcription and activation by cellular and viral factors.

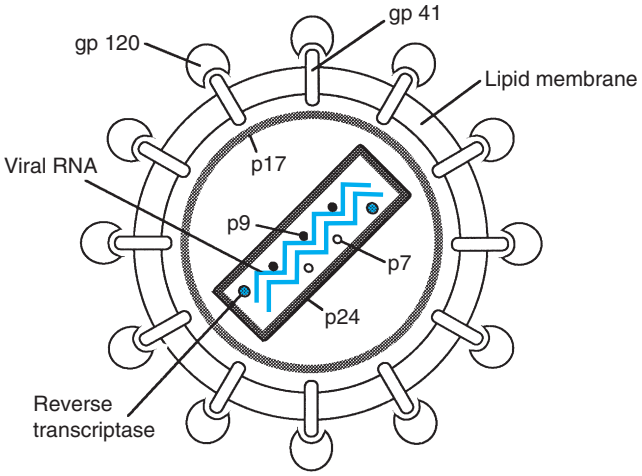

Figure 158–2 Structure of the HIV virion. Two coding strands of genomic RNA are packaged in a nucleoid core with the p7, p9, and p24 proteins and reverse transcriptase. The core is surrounded by the p17 matrix protein lining the inner surface of the envelope. The envelope consists of a lipid bilayer derived from the infected cell and glycoprotein spikes that consist of the outer gp120 molecule, which contains the binding site for CD4, and gp41, which anchors the glycoprotein complex to the envelope and mediates fusion of the viral membrane with the cell membrane during viral penetration.

initially binding to the CD4 antigen on uninfected cells, and then to one of two chemokine coreceptors, CCR5 or CXCR4.[75–77] The CD4-binding domain of gp120 is located on the carboxyl terminal region of the molecule.[78] Within the CD4-binding site of gp120 are a number of regions that display significant genetic variation between different viral isolates without compromising viral binding.[78,79] The binding of CD4 results in a conformational transition in the V3 variable loop of gp120, exposing the chemokine receptor-binding site of the viral particle and increasing the affinity of gp120 binding to CCR5 by 10- to 100-fold.[73,80] The complexing of gp120 with CD4, with subsequent conformational change, also exposes the HIV-1 transmembrane-anchoring protein, gp41, which is necessary for fusion of the viral membrane with the membrane of the newly infected cell.[80] These viral proteins are immunogenic. Consequently, antibodies against both gp120 and gp41 can be detected in the serum of all individuals infected with HIV-1.[81] However, antibodies capable of neutralizing HIV and preventing cellular infection appear to develop only after infection is well established. Furthermore, these antibodies are not capable of efficiently controlling ongoing infection.[73] The envelope genes of HIV-1 demonstrate the greatest genomic diversity when compared to all other genetic components of the virus.[82]

gag

The *gag* gene encodes a 54-kd precursor protein that is cleaved by a viral protease to form four viral core proteins: p24, p17, p9, and p7 (see Fig. 158–2).[6,83] The 24-kd protein (p24) forms the shell of the nucleocapsid. The 17-kd myristoylated matrix protein (p17) is located between the viral envelope and the nucleocapsid and functions to stabilize the virion and, as part of the p54 *gag*-precursor protein, to assist in targeting viral assembly at the cell surface. The 7-kd protein (p7) and the 9-kd protein (p9) are tightly associated with the viral RNA, stabilizing it in the viral ribonucleoprotein core.[83]

pol

The *pol* gene encodes three critical viral proteins. The first, reverse transcriptase, is a 66-kd protein that generates a complementary copy of DNA (cDNA) from the viral RNA genome. The cDNA is then used as a template, generating a double-stranded DNA provirus, which then integrates into the host cellular genome.[84] The *pol* gene also encodes a 31-kd integrase protein that is required for stable integration of proviral double-stranded DNA into host cellular DNA.[85] Additionally, the 5′ region of the *pol* gene encodes a viral protease that cleaves the p54 *gag* precursor protein.[86,87] A defective protease leads to the production of noninfectious virions.[86]

Regulatory and Accessory Genes

After integration of proviral DNA into the host genome, HIV-1 proviral transcription leads to the expression of regulatory proteins designated *tat*, *rev*, and *nef*.[88] *Tat* is a small nuclear protein that is essential for HIV replication and, in conjunction with other cellular proteins, TAK (Tat-associated kinase) and CycT (cyclin T), assists in viral RNA elongation, resulting in a 1000-fold increase in HIV-1 expression by the infected cells.[89–91]

Rev results in the production of a viral protein that regulates nuclear export of unspliced viral RNA.[92] Like *tat*, *rev* is essential for viral replication and must bind to a *rev*-responsive element located in the *env* gene.

The *nef* gene product has a role in the modulation and downregulation of the cellular receptor, CD4, as well as HLA class I molecules on the cell surface, and may also play a role in increasing viral infectivity, as well as facilitating the recruitment of uninfected $CD4^+$ lymphocytes.[88,93–96]

The product of the *vpu* accessory gene appears necessary for viral maturation and budding from the host cell, assisting in the membrane transport of *env* gene products,[97] whereas viral infectivity appears to require the protein product of the *vif* gene.[98] Of interest, *vif* also interacts with a cellular RNA editing enzyme, APOBEC3G, which, in the absence of *vif*, induces hypermutation and frequent inactivation of viral proteins.[99] The *vpr* gene product is incorporated into the nascent viral particle, where it helps in the targeting of viral RNA and DNA complexes to the nucleus, and induces cell cycle arrest in infected cells.[88,100]

Life Cycle of HIV-1

After initial infection, HIV-1 gp120 binds to the CD4 surface membrane protein on susceptible target cells, resulting in a further high-

affinity binding to the chemokine CCR5 or CXCR4 receptor.[73,101] Human helper-inducer (CD4) T-lymphocytes, monocytes-macrophages, epithelial Langerhans cells,[102,103] follicular dendritic cells, megakaryocytes, and thymic cells express both CD4 and chemokine receptor molecules and are susceptible to infection by HIV-1. The structural diversity of the gp120 viral receptor has resulted in viral strains with selective or restricted patterns of infection, such as those that readily infect monocytes, whereas others are tropic for CD4 lymphocytes.[79,82,104] Macrophage-tropic (M-tropic) strains of HIV use the CCR5 chemokine receptor to infect both macrophages and memory $CD4^+$ lymphocytes, whereas T-tropic strains primarily use the CXC4 chemokine receptor, but may also use CCR5.[101] Additional chemokine receptors CCR2 and CCR3 have also been implicated as coreceptors for HIV infection of certain cell types.[101] In general, upon initial establishment of HIV infection, CCR5 coreceptors are used, allowing infection of macrophages and memory $CD4^+$ T lymphocytes.[105] Over time, HIV variants usually evolve to use the CXCR4 receptor, a change that is associated with more rapid $CD4^+$ cell decline, and clinical progression to AIDS.[106] The importance of chemokine coreceptors in the transmission of HIV has been demonstrated by various experiments in nature; individuals who are homozygous for a deletion allele (32 deletion) of CCR5 are apparently resistant to acquiring HIV-1 infection if exposed, whereas heterozygous, though infectable, do relatively well and are likely to become long-term nonprogressors.[107,108] Aside from the importance of chemokine coreceptors, viral transmission is also markedly enhanced by the presence of dendritic cells which express DC-SIGN, a C-type lectin. These dendritic cells bind to gp 120 and facilitate transfer of cell-associated virus to $CD4^+$ T cells; they are thought to be operative in the transmission of HIV across mucosal barriers.[109,110]

After binding to the CD4 and chemokine receptors on the host cell, the virus envelope fuses with the host cell membrane (Fig. 158–3).[104] This fusion is mediated by a hydrophobic domain on the amino terminal portion of gp41.[80] The internalized nucleocapsid is then destabilized, and it dissociates after binding to the cellular protein cyclophilin A,[111] exposing the viral RNA genome associated with reverse transcriptase. Reverse transcription then proceeds by the synthesis of a single cDNA strand, followed by degradation of the viral RNA by the ribonuclease H activity of viral p66.[112,113] Subsequently, reverse transcriptase then acts as a DNA polymerase, forming a second DNA strand. This synthesis of the double-stranded DNA provirus must proceed rapidly to prevent the degradation of viral RNA by intracellular enzymes.[114] The estimated rate of base substitution errors for HIV reverse transcriptase may be as high as 1 in 1700 to 1 in 2000.[82,113] This results in 5 to 10 nucleoside mutations per virus for each replication cycle and explains the high degree of genomic diversity observed between viral isolates of HIV.[82]

The integration of the proviral material is now necessary for stable infection of the cell. In this regard, viral integrase is capable of both cleaving host DNA and integrating a linear form of the provirus into transcriptionally active regions of host chromosomes.[85,115] Kinetic studies of HIV-1 infection have detected viral DNA present in the cytoplasm within 2 to 3 hours of infection, whereas nuclear viral DNA has been detected by 24 hours.[116]

After successful integration of the viral genome, the HIV-1-infected cell may then develop either a latent or a persistent form of infection. Subsequent HIV-1 transcription and replication can be upregulated via multiple factors, including activation of the infected cell, because HIV-1 does not replicate efficiently in resting lymphocytes or macrophages.[117,118] Cytokines, transactivating factors of other viruses, or cellular transactivating proteins, such as NF-κB, may also enhance HIV proviral transcription.[118,119]

After appropriate activating signals, transcription of the provirus occurs via cellular RNA polymerase, leading to the production of genomic RNA, which is then transported to the cytoplasm. Structural proteins of the *gag*, *pol*, and *env* genes are then synthesized; these are expressed as precursor proteins, which are then cleaved by viral protease to yield mature viral proteins. Proteolysis of proteins by the viral protease is essential for viral maturation and infectivity.[86] The products of the *env* gene, gp120 and gp41, are then transported to the cell membrane. The ribonucleoprotein core assembles in the cytoplasm of the host cell and subsequently moves to the membrane surface for budding. The efficient packaging of the viral RNA with viral proteins is dependent upon packaging signals present in the *Gag* region of the viral RNA, whereas the budding of virus from the cell surface appears to be dependent upon the product of the *vpu* gene, which assists in membrane transport of *env* gene products.[97,120]

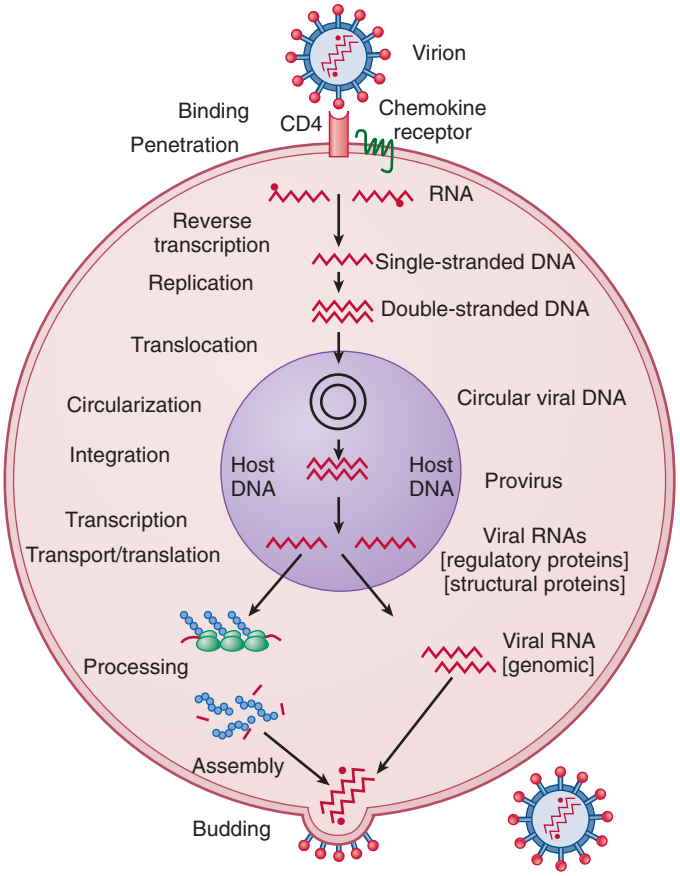

Figure 158–3 HIV life cycle. Binding of the virion to the cell surface is mediated by a specific interaction of the gp120 envelope glycoprotein with the cellular CD4 molecule and members of the chemokine receptor family of proteins (usually CCR5 or CXCR4). Penetration occurs as the viral membrane fuses with the cellular membrane in a process that requires the gp41 envelope molecule. The viral capsid is uncoated and viral genomic RNA is reverse transcribed and duplicated by the viral reverse transcriptase to produce a double-stranded copy of viral DNA. The DNA duplex is transported to the nucleus, where it integrates into host chromosomes. After appropriate activating signals, the provirus is transcribed by cellular RNA polymerase and transported to the cytoplasm. Proteins are translated and processed through biochemical steps that depending on the protein, involve glycosylation (envelope), cleavage (envelope, Gag, Pol), myristoylation (p17), and phosphorylation (Rev, Nef). Packaging of genomic RNA with viral proteins occurs as envelope glycoproteins are inserted into the cell membrane, and a new virion subsequently buds outward from the plasma membrane.

An interesting aspect of HIV-1 is its ability to replicate in an ongoing manner, over years, at an exceptionally rapid pace. Thus, approximately 10^9 to 10^{10} new virions are produced every day.[121] With this rapid rate of production and exceptionally high rate of base substitution errors for the HIV reverse transcriptase,[112–114] a high degree of genomic diversity results,[82] with the potential for rapid emergence of new, resistant isolates after exposure to antiretroviral agents.

Although most virally infected, activated $CD4^+$ cells are rapidly destroyed (see below), other cell populations, such as memory $CD4^+$ cells, macrophages, and dendritic cells live for prolonged periods and

serve as a reservoir for long-term infection.[122] The latent, proviral infection of long-lived memory CD4+ cells serves as a source for potential reactivation of viral replication throughout the lifetime of the infected individual, despite the use of effective antiretroviral therapy.[121,123]

Mechanisms of Immune Dysfunction

HIV infection results in both aberrant immune regulation as well as immunodeficiency. The numerous defects in cellular immune response observed with HIV infection include decreased lymphocyte proliferation to soluble antigens, decreased helper response in immunoglobulin (Ig) synthesis,[124] impaired delayed hypersensitivity,[1,2] decreased interferon-γ production,[125] and decreased T cell-mediated cytotoxicity of virally infected cells.[126] Defects in B-lymphoid function[127–129] as well as in innate immune function have also been described.[130]

CD4+ Lymphocyte Depletion

Infection with HIV-1 results in a progressive loss of CD4-positive (CD4+) T lymphocytes, resulting from the direct cytopathic effect of HIV on these cells.[131,132] Additionally, the formation of syncytial multinucleated giant cells by a mechanism involving fusion of infected cells expressing viral gp120 with noninfected CD4+ T lymphocytes is another mechanism of CD4 depletion.[133] The propensity of certain viral stains to form syncytia appears to be associated with an aggressive clinical course.[133,134] More recent experimental data suggest that an HIV-1 phenotypic switch from an M-tropic (nonsyncytial) to a T-tropic (syncytial) virus may be the central event in the development of HIV-induced immunodepletion.[134]

The host immunologic response against HIV-infected lymphocytes may also contribute to the progressive loss of CD4+ lymphocytes by antibody-mediated and cytotoxic T cell-mediated mechanisms.[135] Noninfected lymphocytes may also become "innocent bystander" targets for immunologic destruction by binding free gp120 to their surface CD4 protein, which may also lead to apoptosis of these uninfected cells.[136,137] Additionally, the high production of TNF-related apoptosis-inducing ligand (TRAIL) by monocytes in HIV-infected individuals may also contribute to the death of CD4+ T lymphocytes.[138]

Defective production of immunostimulatory cytokines, such as interleukin-2 (IL-2),[139–141] or exaggerated expression of inhibitors of T-lymphocyte proliferation, such as transforming growth factor-β (TGF-β),[142] can contribute to the progressive decline in CD4 lymphocytes. HIV-1 tat protein has also been shown to downregulate IL-7 receptor expression on CD8 T cells; because optimal proliferation and function of these cells requires IL-7 signaling, it is possible that the loss of effective cytotoxic CD8+ cell function may also be involved in HIV-related immune dysfunction.[143] High-level replication and budding of virus, resulting in membrane injury, has also been proposed as a mechanism for lymphocyte cytotoxicity as well. Lastly, thymic dysfunction due to HIV may lead to defective maturation and release of CD4+ lymphocytes into the periphery.[144]

Of interest, although significant CD4+ depletion occurs over time with resultant clinical deterioration, immune defects are present even prior to such profound cellular loss. These defects may relate to the fact that initially HIV-1 selectively infects memory, as opposed to naive CD4+ cells,[145,146] which preferentially express the CCR5 chemokine receptor, more likely to be utilized in the early stages of infection by HIV.[147,148] Furthermore, specific depletion of CD4+ helper cells that specifically stimulate the Th1 immune responses involved in cell-mediated immunity has also been demonstrated in the early phases of HIV infection, again leading to immune defects prior to actual CD4+ depletion in later stages of infection.[149,150]

Recent advances in combination antiretroviral therapy have resulted in marked suppression of viral replication, with resulting reductions of blood and tissue viral reservoirs.[151,152] Efficient viral suppression has resulted in significant and prolonged immunologic reconstitution characterized by increased CD4+ lymphocyte numbers, reduced opportunistic infections, and prolonged survival.[153,154] However, significant deficits in the immunologic repertoire persist, and complete immunologic reconstitution has not yet been attained.[155,156]

Defects in B-Cell Immunity

A number of defects in humoral immunity have been associated with HIV infection. Pronounced polyclonal activation of B lymphocytes is common, resulting in polyclonal hypergammaglobulinemia.[127,128] Spontaneous proliferation of B cells is observed in patients with advanced HIV infection.[128,129] In contrast, antigen-specific B-cell proliferation and antibody production are decreased in patients with AIDS, which may also result from the loss of helper T-lymphocyte activity.[157,158]

The aberrant B-lymphocyte regulation in HIV infection is associated with a pronounced increase in autoimmune phenomena.[159] In addition to an increased frequency of positive antiglobulin test results, antibodies against neutrophils,[160,161] lymphocytes,[162] and platelets[161,163] have also been reported.

Aberrant B lymphoid regulation and function are also operative in the development of aggressive, B-cell lymphomas in HIV-infected patients; in this regard, lymphoma became an AIDS-defining illness in 1992.[4] Of note, the B lymphoma cells are not infected by HIV, but result from the chronic B-cell stimulation and proliferation induced by HIV, with eventual development of genetic errors leading to clonal selection and malignancy.[164] Approximately half of these lymphomas are also associated with Epstein–Barr infection (EBV), which has been shown to be monoclonal, and present within the nucleus of the lymphoma cells.[165,166] These aggressive B-cell lymphomas are most likely to occur during the later stages of HIV infection, with significant CD4+ cell depletion; their incidence has significantly decreased with the widespread use of highly active antiretroviral therapy (HAART).[167] Hodgkin lymphoma (HL), another B lymphocytic malignancy, is also statistically increased in the setting of HIV.[168] Of interest, however, the incidence of HL appears to be increasing in the era of HAART, perhaps reflecting the importance of the cellular milieu of the Reed–Sternberg (RS) cell, which is rich in CD4+ lymphocytes, with paucity of infiltrating CD8+ or natural killer cells.[169–171] As CD4 cells rise with effective use of antiretroviral therapy, the cellular milieu within nodal tissue may become more supportive of further growth and inhibition of apoptosis of the malignant RS cells. Further discussion of these B-cell lymphomas associated with HIV may be found in Chapter 86.

Defects in Immune Accessory Cells and Natural Killer Cells

Monocytes, macrophages, and follicular dendritic cells of the lymph nodes express CD4 antigen and can be infected by HIV.[172,173] Monocytes and macrophages are resistant to HIV-induced cytotoxicity and serve as a chronic reservoir of HIV expression.[172,173] Although functional defects in the chemotaxis of HIV-infected monocytes have been reported,[174] most studies have failed to demonstrate consistent defects.[175,176] Nonetheless, HIV nef protein interferes with the macrophage colony-stimulating factor (M-CSF) receptor signaling pathway, inhibiting the functions of M-CSF in monocytes and macrophages, which suggests that modulation of monocytes and macrophages may be involved in HIV-1 disease progression.[177] The follicular dendritic cells appear to play an important role in HIV clearance in early asymptomatic HIV disease. However, a progressive depletion of these cells is observed over time, resulting in increasing plasma viremia. The loss of follicular dendritic cells results in defective antigen processing in patients with advanced HIV disease.

Natural killer (NK) cell activity is decreased in the blood of HIV-infected individuals.[178,179] In combination with $CD4^+$ helper lymphocyte depletion, decreased NK activity results in defective clearance of virally infected cells. Although the number of NK cells is reported to be normal,[178,179] the defect in NK activity appears to result from a deficiency in the signals for cell activation. These aberrations in innate immunity have been shown to correlate with development of various opportunistic infections in HIV-infected persons.[130] The addition of exogenous IL-2 can improve NK lymphocyte function.[180]

DIAGNOSIS OF HIV INFECTION

The primary diagnostic screening tool for HIV infection is detection of antibody via the enzyme-linked immunoassay (ELISA). However, because a positive ELISA result may not be specific for HIV-1 infection, all positive ELISA screening test results should be verified by immunoblot, using HIV-1-specific antigens.

Employing recent ELISA and immunoblot techniques, the median time from initial infection to first detection of HIV antibody has been estimated to be approximately 2 to 4 weeks, whereas 95% of cases are expected to seroconvert within 5.8 months.[181] Presence of HIV infection for longer than 6 months without detectable antibody is extremely uncommon.[182–184]

The presence of the p24 antigen or HIV RNA in serum or plasma may precede seroconversion by several weeks.[185] This initial rise in p24 antigen correlates with the burst of viremia that occurs shortly after primary HIV infection.[186] Despite these observations, p24 antigen screening of donated units of blood appears to provide no benefit over conventional ELISA and immunoblot techniques.[187]

Testing by polymerase chain reaction (PCR) may detect presence of HIV within days or a week of initial infection. However, PCR is not used as a screening tool, as false-positive results have been detected in as many as 9% of individuals.[184]

MONITORING THE COURSE OF HIV INFECTION OVER TIME

HIV infection results in a progressive process characterized by gradual depletion of immune function and eventual development of rather nonspecific symptoms, followed by specific infections and/or neoplastic disease. Patients who develop full-blown AIDS generally experience relentless deterioration in physical health, ultimately succumbing to one or more complications secondary to acquired immunodeficiency, organ dysfunction, and/or malignancy associated with HIV infection.

The course of HIV infection can be monitored by serial determination of $CD4^+$ cell counts, as well as serial assessment of the quantity of HIV-1 RNA in the plasma; these studies have allowed a more rational basis on which to predict the course of disease in individual patients. In a pivotal study performed by the Multicenter AIDS Cohort (MACS), a longitudinal cohort study of HIV disease in homosexual and bisexual men, the earliest, baseline level of HIV RNA in plasma was found to correlate significantly with prognosis over time.[188] In a subsequent study, use of both viral load and $CD4^+$ cells was found to more accurately predict the prognosis of HIV-infected men.[189] Current guidelines from the US Public Health Department suggest institution of HAART in all patients with symptomatic HIV or AIDS, and in asymptomatic HIV-infected individuals when the CD4 count falls below 350 cells/mL (0.35×10^9/L) or when the HIV viral load reaches 100,000 copies/cc or more, in patients with CD4 cells >350/mL.[190]

HIGHLY ACTIVE ANTIRETROVIRAL THERAPY

In addition to the use of viral load monitoring, the development of potent new antiretroviral agents, including the protease inhibitors,[153] has recently led to a remarkable improvement in the natural history of HIV infection.[154] The use of HAART usually consists of three or four different antiretroviral medications, typically from two or three classes of agents, including the nucleoside (or nucleotide) reverse transcriptase inhibitors (NRTIs), nonnucleoside RT inhibitors (NNRTIs), protease inhibitors (PIs), and fusion inhibitors (Table 158–2).[190] Although a detailed discussion of these agents is outside the scope of this chapter, use of HAART has resulted in stunning clinical improvements, associated with a 73% decrease in the incidence of new opportunistic infections and a 49% decrease in death due to AIDS when data from 1994 were compared to data from 1997–1998.[154] Remarkable decreases in the incidence of cytomegalovirus disease, atypical *Mycobacterium intracellularis* infections, and other serious opportunistic infections have occurred as a consequence of HAART therapy,[191] and improvement in immune function has also been documented.[192] It may now be possible to discontinue the routine use of prophylaxis against *Pneumocystis carinii* or other opportunistic infections in patients who have been successfully treated with HAART.[193] These remarkable improvements in disease outcome have been maintained over time.[194]

Table 158–2 Antiretroviral Therapy

	Trade Name
Reverse transcriptase inhibitors (nucleosides)	
• Zidovudine (ZDV; AZT)	• Retrovir
• Didanosine (ddI)	• Videx
• Zalcitabine (ddC)	• HIVid
• Lamivudine (3TC)	• Epivir
• Abacavir (ABC)	• Ziagen
• Emtricitabine (FTC)	• Emtriva
Reverse transcriptase inhibitors (nonnucleosides)	
• Efavirenz	• Sustiva
• Nevirapine	• Viramune
• Delavirdine	• Rescriptor
RT inhibitors (nucleotides)	
• Tenofovir	• Viread
Protease inhibitors	
• Saquinavir	• Invirase
• Saquinavir	• Fortovase
• Indinavir	• Crixivan
• Nelfinavir	• Viracept
• Ritonavir	• Norvir
• Amprenavir	• Agenerase
• Lopinavir + Ritonavir	• Kaletra
• Atazanavir	• Reyataz
• Fosamprenavir	• Lexiva
• Tipranavir	• Aptivus
• Darunavir	• Prezista
Fusion inhibitor	
• Pentafuside (T20)	• Fuseon
Integrase inhibitor	
• Raltegravir	• Isentress
CCR5 antagonists	
• Maraviroc	• Selzentry
Fixed dose combinations	
• AZT + 3TC	• Combivir
• AZT + 3TC + ABC	• Trizivir
• 3TC + ABC	• Epzicom
• Tenofovir + Emtriva	• Truvada
• Tenofovir + Emtriva + efavirenz	• Atripla

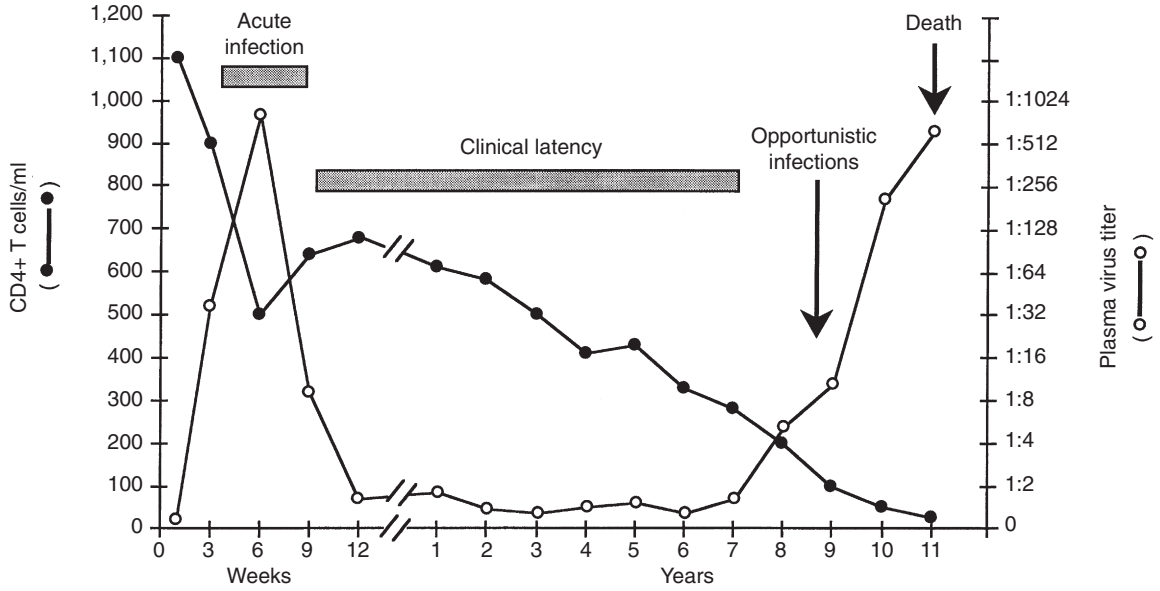

Figure 158–4 Natural history of HIV infection in an infected individual. A typical course of HIV infection is shown. During primary infection, there is active viral replication with viremia and widespread dissemination of virus to lymphoid tissues, during which time a sharp decline in the number of $CD4^+$ lymphocytes occurs. This is followed by a prolonged period of clinical latency, characterized by a slow but progressive decline in $CD4^+$ lymphocytes. When the $CD4^+$ cell number falls to less than 200/μL, the clinical course is generally complicated by opportunistic infections. A quantitative increase in viremia occurs during this time, reflecting increased viral replication.

CLINICAL STAGES OF HIV INFECTION

Acute Retroviral Syndrome

An acute clinical illness is often associated with initial HIV infection, occurring in approximately 50% to 90% of individuals.[186,195,196] This syndrome begins approximately 1 to 3 weeks (range 5 days to 3 months) after primary infection and usually lasts for 1 to 2 weeks. Prominent symptoms include significant fatigue and malaise; fever, which may be as high as 40°C (104°F); headache; photophobia; myalgias; and a morbilliform rash, seen in approximately 40% to 50% of patients. Generalized lymphadenopathy may occur toward the end of the acute illness. The symptoms are quite nonspecific and may be similar to those of other viral illnesses, such as infectious mononucleosis. All symptoms of this acute retroviral syndrome subside within several weeks, coincident with the initial host immune response to HIV, as shown in Fig. 158–4. However, headache may persist as an intermittent complaint, as may generalized lymphadenopathy, termed persistent, generalized lymphadenopathy (PGL), which occurs in approximately 75% of patients.[186,196] Initial attempts to employ HAART therapy in patients with the acute retroviral syndrome, in the hope of preventing or delaying the progression of HIV disease have not yet shown success.

Asymptomatic HIV disease (CDC Category A)

After resolution of the acute retroviral syndrome, the patient usually returns to a state of normal vigor and well-being. During this period, the patient harbors HIV in blood and in genital secretions and may transmit the virus to others. This phase of asymptomatic infection persists for approximately a decade in the absence of therapy and appears similar in all racial and ethnic groups, all geographic areas, both genders, and all risk groups for HIV infection.[197–199] Certain genetic polymorphisms have been described in the chemokine receptor genes that serve as coreceptors for HIV (eg, 32 deletion of CCR5), which predict for better prognosis and longer periods of AIDS-free survival.[107,108]

Symptomatic HIV Disease (CDC Category B)

With time, more significant manifestations of disease occur, with development of fatigue, fevers, weight loss, and/or night sweats. Unusual infections can occur, such as oral candidiasis, herpes zoster, and/or molluscum contagiosus, which, although not serious enough to be considered AIDS-defining, do serve to alert the clinician that underlying immune deficiency may be present.[200] Recurrent episodes of vaginal candidiasis or other gynecologic infections may be the first symptom of Category B disease in women. Immune thrombocytopenic purpura (ITP) may also occur during the course of symptomatic HIV infection. Presence of symptomatic, Category B disease would be an indication for initiation of antiretroviral therapy, even in the absence of surrogate markers of disease progression, such as CD4 cell depletion or elevated HIV-1 viral load in plasma.

AIDS (CDC Category C)

Over time, progression of HIV-induced immunodeficiency is expected, especially in the absence of effective antiretroviral therapy, leading to the development of opportunistic infections, specific neurologic symptoms, wasting syndrome, or malignant disease (Kaposi sarcoma, B-cell lymphoma, invasive cervical cancer).[200] These clinical illnesses are indicative of full-blown clinical AIDS, as depicted in Table 158–1.

The term *immunologic AIDS* is employed in individuals who have not yet developed an AIDS-defining clinical illness but in whom significant $CD4^+$ depletion has occurred, defined as a CD4 cell count lower than 200/μL, or less than 14% $CD4^+$ cells.[4] These individuals are at high risk for rapid development of clinical AIDS, and should clearly be treated with HAART, in an attempt to prevent these illnesses and their resultant morbidity and mortality.

LABORATORY CORRELATES OF DISEASE PROGRESSION

With progression from the initial acute retroviral syndrome to more advanced disease, various laboratory parameters may be used to

predict outcome in individual patients.[188,189,201] Quantitation of plasma HIV RNA (viral load) and $CD4^+$ lymphocyte count are the most useful parameters. The $CD4^+$ lymphocyte count falls during the acute retroviral infection and then stabilizes during early asymptomatic infection and may appear relatively normal, as shown in Figure 158–4. The $CD4^+$ count then decreases by approximately 40 to 80 mL/year in the absence of antiretroviral medications,[202] although there is significant variability among patients.[203]

An initial measurement of plasma viral load by RT-PCR or branched-DNA (bDNA) methods provides important prognostic information that can be useful in determining when to start antiretroviral medications.[188,189] The serial assessment of plasma HIV viral load also allows for rapid assessment of efficacy of antiretroviral medications. Changes in viral load usually precede significant alterations in $CD4^+$ lymphocyte counts.[153,189]

Several nonspecific markers of disease progression have also been defined, including β_2-microglobulin[204] and neopterin,[205] each of which has independent predictive value in estimating the probability of progression to AIDS. However, each of these surrogate markers has been largely replaced by the more specific molecular assays to quantify plasma HIV viral load.

ABNORMALITIES OF HEMATOPOIESIS INDUCED BY HIV

Hematopoietic Progenitor Cells (CFU-GEMM)

Early in the AIDS epidemic, the potential for direct infection of the $CD34^+$ hematopoietic progenitor cell was considered, as these cells have been shown to express both the CD4 receptor and the CXCR4 coreceptor necessary for HIV-1 viral entry.[206,207] Furthermore, early experiments indicated that these progenitors were, indeed, infectable by HIV-1.[208,209] However, more recent evidence has indicated that the hematopoietic progenitor cell is not infected by HIV-1.[210–213]

Abnormalities in More Committed Myeloid Progenitors and Marrow Stroma

Although the $CD34^+CFU^-GEMM$ is not infected by HIV per se, the more committed myeloid progenitor cells can be infected and are clearly functionally abnormal, with markedly decreased colony growth.[214] Thus, as a result of cell surface interactions with HIV gp 120/160, decreased colony growth of BFU-E; CFU-GM, CFU-G and CFU-M have all been reported.[214] Likewise, the microenvironment of the marrow, necessary for normal blood cell growth and development, is also abnormal. The multiple cells, such as T cells and macrophages, that comprise this microenvironment (stroma) are infectable by HIV, resulting in decreased production of various hematopoietic growth factors, and further abnormalities of progenitor cell growth.[215–217] Additionally, cytokine dysregulation may lead to decreased growth of hematopoietic colonies, because of excessive production of TNF-α and interferon-γ by HIV-infected stromal cells in the marrow.[214,218,219] All of these factors, along with numerous additional abnormalities, eventually lead to the frequent development of cytopenias, including anemia, neutropenia, and/or thrombocytopenia.

MORPHOLOGIC CHANGES OF HEMATOPOIETIC CELLS IN HIV-1 INFECTION

Peripheral Blood Smears

The peripheral blood smear may be quite variable in patients with underlying HIV infection, dependent on other underlying conditions or infections (see Fig. 158–5A,B).[220] Numerous morphologic changes in red cells, white cells, and platelets have been described. In terms of the red blood cell, morphologic changes will vary in patients with anemia, dependent on the specific etiology of the anemic process. Neutrophils may reveal dysplastic changes, such as hyposegmentation, or PelgerHuët forms.[220,221] Prominent granulation has been described, as well as increased size of the neutrophils.[220,221] Large, vacuolated monocytes and atypical lymphocytes have been described as well. In terms of the platelet, large platelets may be seen in those individuals with HIV-related ITP.

Bone Marrow Findings

The appearance of the marrow in HIV-infected persons can be quite varied (see Fig. 158–5C–H). The marrow is hypercellular in more than 50% of patients, despite peripheral cytopenias.[221–226] This strongly suggests the possibility of ineffective hematopoiesis as a common mechanism for HIV cytopenias. Varying degrees of dysplasia may also be seen, with dysplasia appearing more frequently in patients with advanced HIV disease and a hypocellular marrow.[221,226,227] Moderate plasmacytosis is often observed, particularly in patients with hypergammaglobulinemia. An increase in marrow reticulin has been seen.[226,227] Other changes include presence of "soft" granulomas,

Thrombocytopenia in the HIV-Infected Patient

Thrombocytopenia is relatively common among HIV-infected persons, and may be caused by various medications, by malignant disease within the marrow, or most commonly by immune mechanisms. Immune thrombocytopenic purpura (ITP) is thought to be secondary to molecular mimicry between gp IIb/IIIa on the platelet surface and the outer membrane gp 120/160 of HIV. In addition to immune destruction of antibody-coated platelets through the Fc receptor on macrophages in the spleen, complement-mediated platelet destruction has also been described. The rate and level of platelet production in HIV-infected persons may also be perturbed, due to the direct infection of megakaryocytes. Patients with HIV-related ITP usually do have excessive bleeding, which has been reported in less than 10%. Nonetheless, bleeding may occur and therapy may also be indicated prior to the performance of invasive procedures. The initial therapy of choice for patients with HIV-ITP is effective antiretroviral therapy (HAART). Although many regimens have been shown effective in this regard, zidovudine appears particularly useful, with response rates in the range of approximately 70%. Responses to HAART are relatively rapid, occurring within 1 or 2 weeks, and may be durable. In the patient who does not respond to HAART, or in those with clinical bleeding or requirement for an invasive procedure, high dose intravenous gammaglobulin (IVIg) at a dose of 1000 to 2000 mg/kg may be used effectively, as in HIV-negative patients. Nonetheless, only 25% of patients will sustain prolonged elevation of platelet counts after IVIg. Use of anti-Rh (D) antibody is associated with increase of platelet counts to more than 50,000/dL in approximately 60% of patients, when given intravenously at a dose of 25 μg/kg. Higher doses (75 μg/kg) may also be used, as in patients with HIV-negative ITP. Anti-Rh (D) therapy may only be useful in those Rh-D-positive patients who have a spleen and whose hemoglobin level is high enough to allow the predicted hemolysis, occurring as a consequence of the Anti-Rh (D) therapy; a loss of 1 to 2 g of hemoglobin is expected. Corticosteroids may also be effective in HIV-infected patients with ITP, although this drug may be more problematic in the setting of HIV-induced immunosuppression. Splenectomy may be efficacious, and is not associated with progression of the underlying HIV disease. In patients with platelet counts greater than 20,000/dL, who do not respond to these various therapies, consideration can be given to simply watching without specific further treatment for the ITP.

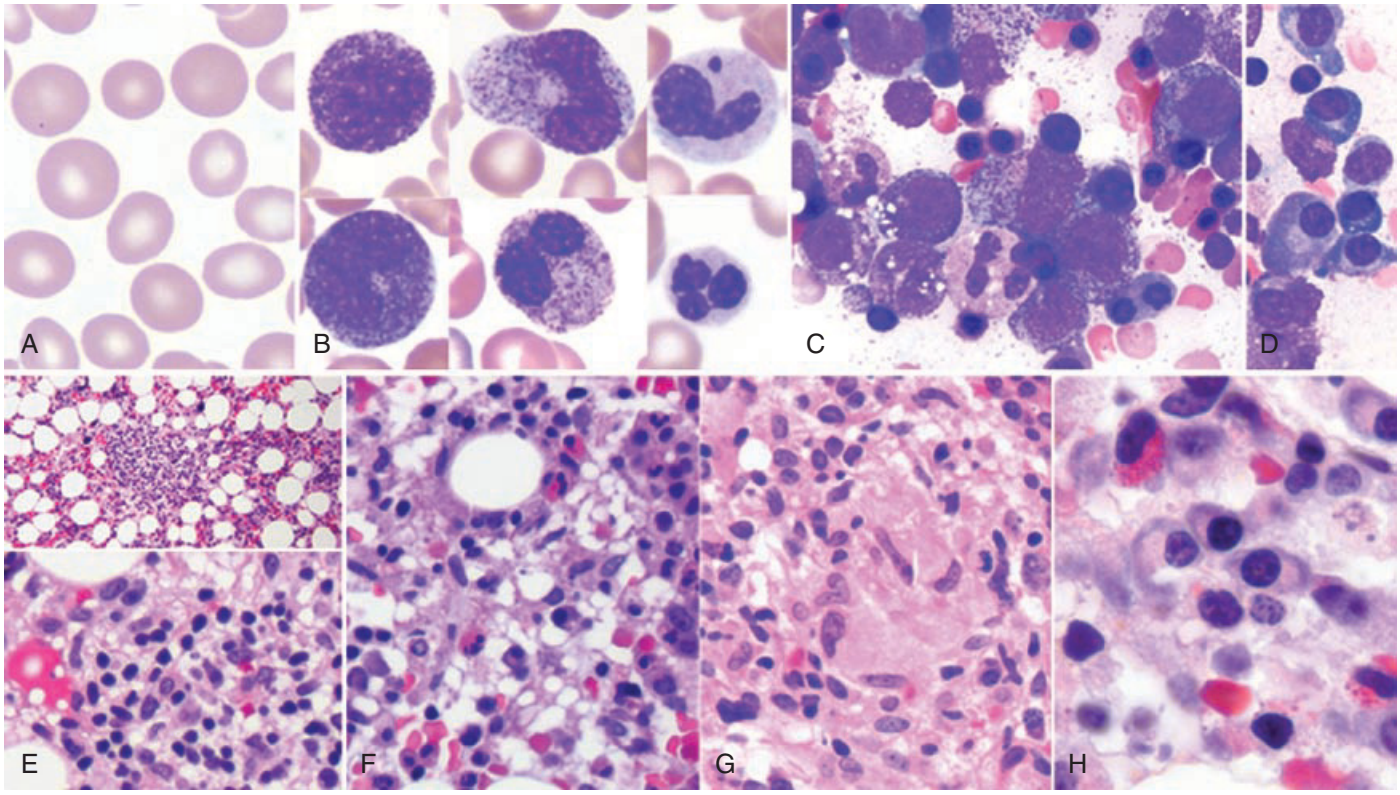

Figure 158–5 Typical peripheral blood and bone marrow findings in HIV (**A**–**H**). The peripheral smear not uncommonly shows anemia, which is sometimes macrocytic (**A**). There frequently is a neutrophilia with left shift, toxic granulation, and some mild dysplastic change is present in the granulocytes (**B**). In some patients, particularly those with severe disease, some of the segmented neutrophils show cytoplasmic inclusions similar to the Howell–Jolly bodies seen in red cells (**B**, *top, right cell*). These are nuclear in origin and are not microorganisms. The bone marrow is normo- or hypercellular and frequently shows granulocytic hyperplasia with left shift, and megaloblastoid change in the myeloid and erythroid cells lines (**C**). Typically there is also a reactive plasmacytosis (**D**). The biopsy commonly shows atypical reactive lymphoid infiltrates (**E**), poorly formed (**F**) or well-formed granuloma (**G**), and increased plasma cells (**H**).

even in the absence of specific infection other than HIV-1. Additionally, the pathologist should be alert to the possibility of marrow infiltration by lymphoma, Kaposi sarcoma, Hodgkin lymphoma, and/or various fungal and acid-fast organisms. In this regard, bone marrow examination is often requested for the purpose of obtaining a diagnosis in HIV-infected patients with fever of unknown origin. The diagnostic yield from the procedure is rather low, at approximately 20%, with infection due to mycobacterial or fungal infections seen most commonly.[228]

ANEMIA IN HIV INFECTION

Incidence and Risk Factors for Anemia

Anemia is very common in HIV-infected individuals, diagnosed in approximately 10% to 20% at initial presentation and developing in approximately 70% to 80% of patients over the course of disease.[226,227,229] In an attempt to ascertain the precise incidence of anemia in the setting of HIV infection, Sullivan and colleagues evaluated data derived from the case records of 32,867 HIV-infected persons followed from 1990 through 1996.[229] This cohort, termed the Multistate Adult and Adolescent Spectrum of HIV Disease Surveillance Project, is composed of individuals who receive HIV care in hospitals and HIV clinics in nine US cities. Using a hemoglobin level of less than 10 g/dL to define anemia, the 1-year incidence of anemia was 37% among patients with clinical AIDS; 12% among patients with immunologic AIDS; and 3% among HIV-infected individuals with neither clinical nor immunologic AIDS. Using a hemoglobin cutoff value of 12 g/dL as criteria for anemia in a large group of participants from the Women's Interagency HIV Study (WIHS), Levine and colleagues found a higher prevalence of anemia in HIV-infected women compared to HIV-uninfected controls.[230] Thus, 37% of the 2056 HIV infected women were anemic at baseline, compared to 17% of the 569 HIV-negative controls ($P < 0.001$). In the HAART era, an observational cohort study of 6725 HIV-infected patients from across Europe also documented a high prevalence of anemia,[231] with 58% diagnosed with mild anemia, defined as hemoglobin level of 8 to 14 g/dL in males or 8 to 12 g/dL in females, whereas 1.4% had severe anemia, defined as a hemoglobin level of <8 g/dL.[231] These data thus confirm the high incidence of anemia among HIV-infected patients in both the pre-HAART and HAART eras. Further, the frequency and severity of anemia in HIV-infected patients appear to correlate with HIV-related factors, such as CD4 cell counts less than 200 cells/mL (0.2×10^9/L), higher plasma HIV-1 RNA levels and a history of having been diagnosed with a clinical AIDS-defining condition.[229–231]

Etiology of Anemia

The etiology of anemia in the setting of HIV infection is often multifactorial, with numerous different causes having been described, as depicted in Table 158–3.

Anemia Due To Decreased Production of Red Blood Cells

A decrease in production of red blood cells may result from factors suppressing the $CD34^+$ CFU-GEMM progenitor cell, such as inflammatory cytokines or the HIV virus itself.[226] In addition, a blunted production of erythropoietin has been documented in anemic HIV-infected patients, similar to the suppression seen in other states of chronic infection or inflammation. In this regard, a specific defect in the posttranscriptional synthesis of erythropoietin has been described.[232]

Infiltration of the marrow by tumor, such as non-Hodgkin lymphoma, may be associated with anemia.[233] Furthermore, although rather uncommon in the general population, in patients with underlying HIV infection, Hodgkin lymphoma involves bone marrow in 50% to 60%, and often presents with pancytopenia, commonly in association with systemic B symptoms, such as fever, drenching night sweats, and/or weight loss.[234,235]

Involvement of marrow by infection, such as *Mycobacterium avium* complex (MAC), may also lead to the decreased production of red cells (see Fig. 158–6). In addition, MAC may also be associated with cytokine-induced marrow suppression. Other opportunistic infections that may involve the bone marrow and lead to anemia include *M Tuberculosis*, cytomegalovirus, herpes simplex virus, as well as multiple fungal organisms, including histoplasmosis, coccidioidomycosis, and Cryptococcus.[228,236] Aside from inducing hypoproliferative anemia due to involvement of the marrow, these infections may also involve the gastrointestinal (GI) tract, leading to chronic blood loss and eventual iron deficiency anemia.

Infection of the marrow by parvovirus B19 is another cause of hypoproliferative anemia in HIV-infected patients, resulting in specific infection of the pronormoblast (see Fig. 158–7).[237,238] Thus, although marrow failure affecting all three lines has been described in association with parvovirus B19 infection, a pure red cell aplasia is the usual consequence. Parvovirus infection is usually acquired during childhood, leading to "fifth disease," one of the common childhood exanthems. Exposure to the virus leads to an antibody response, with subsequent resistance to further infection. Approximately 85% of adults have serologic evidence of prior parvovirus infection. However, the seroprevalence of such antibodies among HIV-infected patients is only 64%. This would suggest that these individuals may have an ineffective immune response against newly acquired infection, or may have lost prior seropositivity. The diagnosis of parvovirus B19 can be made on marrow examination, revealing giant pronormoblasts with clumped basophilic chromatin and clear cytoplasmic vacuoles; diagnosis can be confirmed by in situ hybridization using sequence-specific DNA probes for parvovirus B19.[239] Therapy for parvovirus-induced red cell aplasia consists of infusions of intravenous (IV) gamma globulin that contain antibodies from plasma donors, most of whom have previously been exposed to parvovirus. Doses of 400 mg/kg/day for 5 to 10 days or 1 g/kg/day for 3 days have been used successfully.[240] Relapse of parvovirus B19-induced red cell aplasia may occur, necessitating retreatment in these individuals.[238]

Hypoproliferative anemia in HIV-infected patients may also commonly occur as a consequence of the use of multiple medications, many of which may cause marrow and/or red cell suppression. Zid-

Table 158–3 Causes and Mechanisms of Anemia in HIV Infection

Mechanisms of Anemia	Cause of Anemia
Decreased red cell production	Neoplasm infiltrating the marrow Lymphoma Kaposi sarcoma Others Infection Atypical tuberculosis (*Mycobacterium avium intracellularis* or *Mycobacterium avium complex*) *Mycobacterium tuberculosis* Cytomegalovirus B19 parvovirus Fungal infection Medications HIV infection • Abnormal growth of burst-forming units–erythroid • Anemia of chronic disease • Blunted erythropoietin production and response Iron deficiency anemia secondary to chronic blood loss
Ineffective production	Folic acid deficiency Dietary Jejunal pathology: malabsorption B_{12} Deficiency Malabsorption in ileum Gastric pathology
Increased red cell destruction	Coombs-positive hemolytic anemia Hemophagocytic syndrome Thrombotic thrombocytopenic purpura Disseminated intravascular coagulation Medications Sulfonamides, dapsone Oxidant drugs in glucose-6-phosphate dehydrogenase deficiency

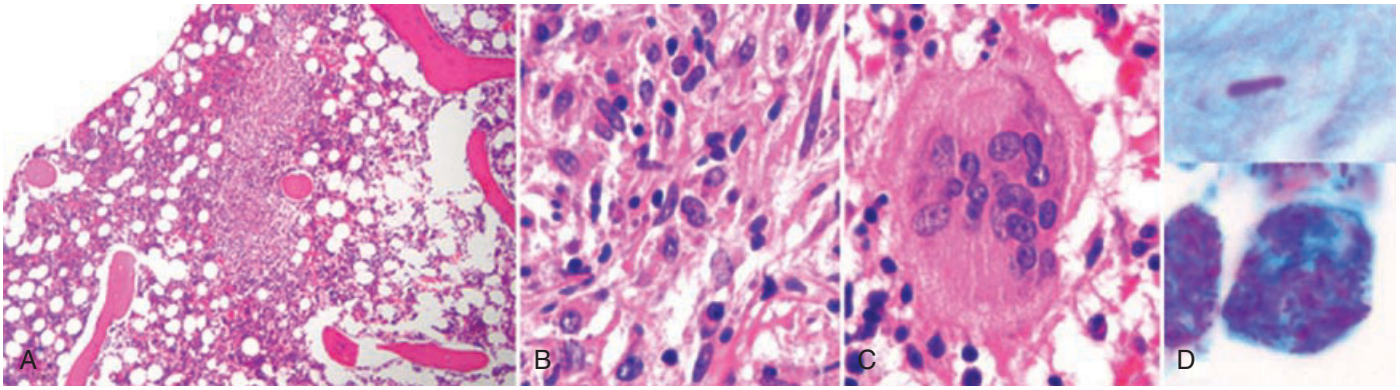

Figure 158–6 Acid-fast organisms in granuloma (**A–D**). Large poorly formed granuloma in the bone marrow (**A**) is composed of loosely aggregated histiocytes, lymphocytes, and plasma cells (**B**), with occasional giant cells (**C**). The acid-fast stain shows rare elongated slightly beaded organisms, typical of *Mycobacterium tuberculosis* (**D**, *top*). In *Mycobacterium avium* complex, the organisms frequently stuff histiocytes (**D**, *bottom*).

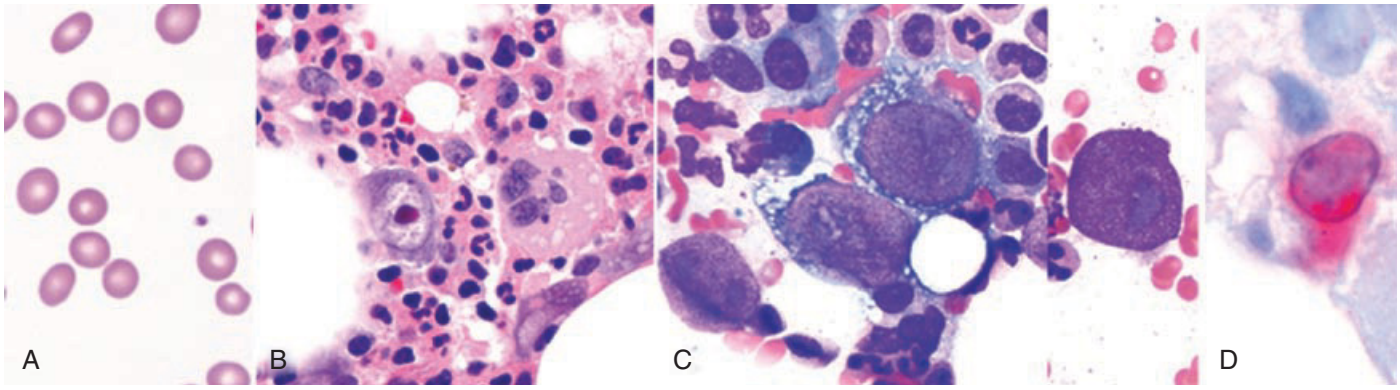

Figure 158–7 Human Parvovirus infection in HIV (**A**-**D**). The peripheral blood smear shows anemia with no polychromasia (**A**). The marrow biopsy shows mostly granulocytic and megakaryocytic elements with a lack of erythroid forms (**B**), except for rare large pronormoblasts with nuclear inclusions (**B**, *center*). On the aspirate, the large degenerating pronormoblasts have nuclear inclusions that resemble large nucleoli (**C**). These are viral inclusions. Sometimes the pronormoblasts are totally degenerated, and present as only bare nuclei, with the viral inclusion still obvious (**C**, *right*). An immunostain for parvovirus in a degenerated pronormoblasts is illustrated (**D**).

ovudine (AZT), the first licensed antiretroviral agent, is uniformly associated with macrocytosis [mean cell volume (MCV >100 fm)], which can be used as an objective indication that the patient has been compliant with this medication.[241] It is noteworthy that transfusion-dependent anemia (hemoglobin <8.5 g/dL) has been reported in approximately 30% of patients with full-blown AIDS, receiving zidovudine at doses of 600 mg/day. However, the incidence of severe anemia is only 1% when the same dose of zidovudine is used in patients with asymptomatic HIV disease.[242] Azidothymidine has also been associated with bone marrow failure, and should not be used together with myelosuppressive chemotherapy in HIV-infected patients with malignancy.[243] Although other reverse-transcriptase inhibitors, such as lamivudine, didanosine, or stavudine may cause anemia, this outcome is rather unusual. Other commonly used medications that can cause anemia in HIV-infected patients include trimethoprim-sulfamethoxazole, ganciclovir, sulfadiazine, pentamidine, rifabutin, flucytosine, amphotericin, foscarnet, and cidofovir.

Anemia Due To Increased Red Cell Destruction

Increased red cell destruction may be seen in HIV-infected patients with G-6-PD deficiency who are exposed to oxidant drugs, such as dapsone or sulfa-containing therapy, frequently employed for therapy or prophylaxis of *Pneumocystis carinii* infection.[244] Hemolytic anemia may also occur in HIV-infected patients with disseminated intravascular coagulation (DIC) or thrombotic thrombocytopenic purpura (TTP)[245]; presence of fragmented red cells and thrombocytopenia on blood smear will be seen in the latter two conditions, and Heinz bodies will be seen in association with G-6-PD deficiency. Hemophagocytic syndrome (hemophagocytic lymphohistiocytosis), with abnormal activation and proliferation of mature macrophages/histiocytes with increased phagocytic activity has also been described in association with HIV, and may occur as a consequence of acute HIV infection.[246–249] This disorder has recently been shown to result from severe imbalance of IL-18 and IL-18 binding protein, resulting in activation of Th-1 lymphocytes and macrophages, which then escape control by NK-cell cytotoxicity.[250]

An additional cause of red cell destruction in HIV-infected patients is the development of autoantibodies, with resultant positive Coombs test and shortened red cell survival. It is interesting to note that a positive direct Coombs test result has been reported in as many as 18% to 77% of HIV-infected patients, although the incidence of actual hemolysis is quite low.[251] When present, anti-I antibody and antibody against auto-U antigens have been described, occurring in 64% and 32% of HIV-infected patients, respectively.[252–254] A high incidence of positive direct Coombs test results has also been detected in patients with other hypergammaglobulinemic states, indicating that the positive Coombs test seen in HIV-infected patients may simply be secondary to the polyclonal hypergammaglobulinemia that is known to occur in the setting of HIV infection.[254]

Anemia Due To Ineffective Production of Red Cells (B_{12} or Folic Acid Deficiency)

Folic acid is absorbed in the jejunum and is responsible for the one-carbon transfer required in the synthesis of DNA. A deficiency of folic acid leads to a megaloblastic anemia, with large ovalocytes in the blood, hypersegmented neutrophils, and a decrease in all three lines, with resultant anemia, neutropenia, and thrombocytopenia. Because tissue stores of folate are relatively small, a deficiency of folate in the diet lasting as little as 3 to 6 months may lead to anemia. It is thus apparent that HIV-infected patients who are ill and not eating properly, as well as those with underlying disease of the jejunum, may be unable to absorb sufficient folic acid. The classic changes of megaloblastic anemia will be detected upon examination of the bone marrow, whereas serum and red cell folate levels will be low.

Ineffective production of red cells, with peripheral pancytopenia, elevated indirect bilirubin level, and low reticulocyte count may also be seen in vitamin B_{12} deficiency. The absorption of B_{12} requires initial production of intrinsic factor by parietal cells in the stomach, with subsequent absorption of the complex of B_{12} and intrinsic factor within the ileum. Thus, malabsorption of B_{12} can occur in various disorders of the stomach, by production of antibodies to the H^+/K^+ ATP pump or to intrinsic factor (pernicious anemia), or by various disorders of the small bowel and ileum (infection or Crohn disease). Although B_{12} deficiency is unlikely on a dietary basis alone, patients with HIV infection appear to be prone to B_{12} malabsorption, presumably because of the myriad of infections and other disorders that may occur in the small intestine. Negative vitamin B_{12} balance has been documented in approximately one-third of patients with AIDS, the majority demonstrating defective absorption of the vitamin.[255] Diagnosis of B_{12} deficiency can be made by documenting low serum B_{12} levels, along with elevated levels of folic acid, homocysteine, and methylmalonic acid in the serum , whereas the earliest indication of negative B_{12} balance is the finding of low B_{12} levels in blood in patients taking transcobalamin II.[256] Monthly administration of parenteral B_{12} will correct the deficiency and the resultant anemia and pancytopenia in the peripheral blood. Because B_{12} deficiency may also cause neurologic dysfunction (subacute combined degeneration of the cord), with motor, sensory, and higher cortical dysfunction, the possibility of vitamin B_{12} deficiency should also be considered in HIV-infected patients with these neurologic symptoms and signs.

Anemia in the HIV-Infected Patient

Anemia is an independent risk factor for death in HIV-infected individuals, regardless of the actual etiology of the low red cell count. The actual mechanisms or cause of this association are not well understood. There are multiple reasons for an HIV-infected person to become anemic, including decreased red cell production, ineffective production, or hemolysis. In terms of decreased red cell production, HIV itself may be operative, associated with blunted erythropoietin production and response as well as abnormal growth of BFU-E. Anemia due to HIV per se may be treated with highly active antiretroviral therapy (HAART). Erythropoietin may also be effective, and such therapy has been associated with improvements in both hemoglobin levels and in quality-of-life parameters. Multiple medications may cause hypoproliferative anemia, with low reticulocyte count and normal indirect bilirubin levels in the setting of HIV, including zidovudine (AZT), the first of the antiretroviral drugs to be licensed in the United States, as well as lamivudine, didanosine, and stavudine. Prophylactic antiinfective agents such as sulfonamides, trimethoprim, and pyrimethamine and pentamidine may cause anemia and should be considered in the evaluation of these individuals. Other antiinfectives, including antiviral agents such as ganciclovir, foscarnet and cidofovir; and antifungal agents such as flucytosine or amphotericin are relatively common causes of anemia in the HIV-infected patient. In addition, various infections may themselves cause hypoproliferative anemia, as described with atypical TB (MAI/MAC), *Mycobacterium tuberculosis*, cytomegalovirus, B19 parvovirus, and various fungal infections. Development of malignancy, with marrow involvement, may also cause a hypoproliferative anemia, occurring predominantly in patients with Hodgkin Disease and/or non-Hodgkin lymphoma. Furthermore, more "usual" causes of hypoproliferative anemia, such as iron deficiency due to chronic blood loss, should also be considered in HIV-infected patients with low reticulocyte counts, normal indirect bilirubin levels, and hypochromic, microcytic anemia. Multiple causes of ineffective red cell production have also been described in HIV-infected patients, who present with anemia, low reticulocyte levels, and elevation of indirect bilirubin. These include folic acid deficiency, due to inadequate diet or to jejunal pathology; or B_{12} deficiency due to malabsorption in the ileum, or gastric pathology with decreased production or production of antibody to intrinsic factor. Lastly, numerous causes of hemolytic anemia have been described in HIV-infected patients. These individuals present with an elevated reticulocyte count, and elevated indirect bilirubin levels. Coombs positive hemolytic anemia has been described, and is relatively common in patients with HIV-related Castleman disease. Hemophagocytic syndrome has been described, as has thrombotic thrombocytopenic purpura (TTP). Multiple drugs may also be associated with hemolysis in this setting, including sulfonamides, dapsone, and oxidant drugs in the patient with underlying G6PD deficiency.

Consequences of Anemia in HIV Infection

Decreased Survival

Several large cohort studies have shown that anemia is an independent risk factor for shorter survival in HIV-infected patients.[229,231,257,258] In the Multistate Adult and Adolescent Spectrum of HIV Disease Surveillance Project, anemia, defined as a hemoglobin level lower than 10 g/dL or a physician's diagnosis of anemia, was found to be associated with an increased risk of death for all CD4 ranges in this cohort.[229] However, the greatest risk of death was noted in patients with baseline CD4 cell counts greater than 200 cells/mL (0.2×10^9/L), with a relative risk of death 150% higher than for individuals in the same CD4 cell count strata without anemia (RR 2.3, $P < 0.001$). In comparison, the risk of death was increased by approximately 60% for anemic patients with baseline CD4 cell counts lower than 200 cells/mL (0.2×10^9/L). Importantly, recovery from anemia was shown to be independently associated with improved survival. Thus, among anemic patients with baseline CD4 counts lower than 50 cells/mL (0.05×10^9/L), those who remained anemic (hemoglobin level remained <10 g/dL) had a 160% higher risk of death than patients who recovered from anemia following treatment. In another series of 2348 HIV-infected patients from Baltimore, development of any grade of anemia was found to be independently associated with decreased survival, with the risk of death approximately threefold increased in those with a hemoglobin level of 7 to 8 g/dL and fourfold increased in those with a hemoglobin level below 6.5 g/dL.[257] Of significance, use of erythropoietin was associated with a decreased risk of death, as was use of antiretroviral therapy. Similarly, an additional study performed among 6725 European HIV-infected patients demonstrated that hemoglobin level at baseline, together with CD4 count and viral load, were independent prognostic factors for survival.[194,231] For each 1-g/dL decrease in hemoglobin level, the relative hazard of death was 1.39 (95% CI, 1.34–1.43; $P < 0.0001$). Finally, in the large multicenter prospective study of 2056 HIV-infected women, Levine and colleagues confirmed the independent association between anemia and decreased survival.[258] Anemia has also been confirmed as an independent predictor of mortality among HIV-infected persons in resource-poor regions of the world[259] and use of total lymphocyte count and hemoglobin concentration has been suggested as a more cost-effective way to monitor HIV progression in these settings.[260] Further work is required to elucidate the precise mechanisms underlying this strong prognostic association, and it is conceivable that anemia may simply serve as a surrogate marker for more advanced systemic illness.

Disease Progression

Anemia has also been shown to be independently associated with more rapid clinical progression of HIV infection. In one large European study aimed at identifying predictive factors for disease progression among HIV-infected patients receiving HAART, the most recent measured hemoglobin level, CD4 cell count, and HIV-1 viral load, as well as a history of clinical AIDS before initiation of HAART were all independently related to the risk of disease progression.[261] Thus, with mild anemia (hemoglobin of 8–14 g/dL for men and 8–12 g/dL for women), the relative hazard of disease progression or death was 2.2 (95% CI 1.6–2.9, $P < 0.0001$), whereas for severe anemia (hemoglobin <8 g/dL), the relative hazard was 7.1 (95% CI 2.5–20.1, $P = 0.0002$).

Effects on Quality of Life

Presence of anemia has consistently been associated with decreases in quality of life, as measured by the Linear Analogue Scale (LASA), and other such instruments.[262,263]

Effect of Highly Active Antiretroviral Therapy on Anemia

Recent studies have confirmed the ability of HAART to correct or improve the anemia of HIV infection. In a study of 6725 HIV-infected patients from across Europe,[231] use of HAART was statistically associated with improvement in hemoglobin levels. In addition, prolonged HAART use was associated with a greater likelihood of correcting anemia. Thus, 65.5% of the cohort was anemic before the use of HAART, 53% were anemic after 6 months of HAART, and 46% were anemic after 12 months of HAART. In a study of

905 HIV-infected patients from Baltimore, use of HAART was associated with an increase in hemoglobin levels after 1 year of follow-up.[264] Among the patients with a baseline hemoglobin level less than 14 g/dL, 21% of patients receiving HAART recovered from anemia (hemoglobin >14 g/dL) compared to only 8% in those not receiving HAART ($P = 0.0006$).[264] In multivariate analysis, use of HAART was strongly associated with freedom from anemia, after adjusting for CD4 cell count, HIV-1 RNA level, sex, race, history of injection-drug use, and use of various therapies for anemia. More recently, data from the Women's Interagency HIV Study (WIHS) demonstrated that use of HAART for as little as 6 months was independently associated with a higher likelihood of resolution of anemia, and longer use was associated with more profound improvements.[258] In addition, use of HAART for at least 12 months was significantly associated with a reduced risk of developing anemia.[258]

The mechanisms whereby HAART may protect against development of anemia or correct preexisting anemia are not yet fully understood. Nonetheless, because HIV infection directly contributes to the development of anemia, it is conceivable that HAART may protect against or correct anemia simply by decreasing the level of HIV-1 viral burden and/or by overcoming the factors responsible for the anemia of chronic disease. Additionally, use of HAART has been associated with an increase in hematopoietic progenitor cell growth,[265] whereas ritonavir, a protease inhibitor, has also been shown to directly stimulate progenitor cell growth and to inhibit apoptosis of hematopoietic progenitors in vitro.[266]

Use of Erythropoietin in HIV-Infected Patients With Anemia

A blunted response to erythropoietin is extremely common in the setting of HIV infection.[232] The mechanism of this decreased production is likely a posttranscriptional defect, as levels of messenger RNA for erythropoietin are normal although erythropoietin protein levels are decreased.[232] In addition, development of autoantibodies to erythropoietin has been described in HIV-infected patients.[267] Multiple studies have now confirmed the beneficial effect of erythropoietin in HIV-infected patients with anemia, in whom marrow function has been suppressed as a result of HIV or other chronic infectious or inflammatory diseases.[268,269] Erythropoietin is also effective in treating the anemia due to zidovudine or other medications, including cancer chemotherapy, that suppress the marrow.[260,270]

The baseline level of endogenous serum erythropoietin can predict which patients are likely to respond to the therapeutic use of erythropoietin. Thus, patients with a baseline endogenous erythropoietin level of 500 IU/L or less are expected to respond to such therapy, whereas those with endogenous levels greater than 500 IU/L are not. Erythropoietin is administered subcutaneously at a dose of 100 to 200 U/kg body weight, three times weekly until normalization of the red blood cell and then given approximately once every week or every other week to maintain a hemoglobin concentration of approximately 12 g/dL. Recent trials have demonstrated the equivalent efficacy of 40,000 units of erythropoietin given weekly as compared with the original thrice-weekly schedule in anemic HIV-infected patients.[263]

Data from recent studies have indicated that correction of anemia by erythropoietin is associated with improvement in quality of life (QOL) measures,[262,263,271] with the mean Linear Analogue Scale (LASA) QOL score increasing by 41% and the Medical Outcomes Study–HIV (MOS-HIV) overall QOL score increasing by as much as 37% in one study.[262]

Toxicity of erythropoietin is uncommon, consisting primarily of local pain at the site of injection, mild fever, or rash. However, the prevalence of these side effects has been similar to those seen with placebo-treated patients. Development of pure red cell aplasia has been described in HIV-negative patients receiving the Eprex product (epoetin alfa) from Europe, although this complication is uncommon and has not been reported in the setting of HIV.[272]

Currently, several prospective trials have also evaluated the efficacy and toxicity of darbepoetin alfa, a novel erythropoiesis-stimulating protein (NESP), in anemic HIV-infected patients. Compared with conventional erythropoietin, darbepoetin alfa has a longer terminal half-life, owing to the presence of additional sialic acid residues, and thus offers the advantage of a less frequent dosing schedule.[273,274] Preliminary data from one recent study suggested that darbepoetin-alfa given at a dose of 3.0 mg/kg once every 2 weeks is effective in improving the hemoglobin level in the majority of HIV-infected patients as well as in maintaining hemoglobin levels and improving quality-of-life measures.[275]

NEUTROPENIA

Incidence and Etiology of Neutropenia in HIV

Neutropenia is reported in approximately 5% to 10% of patients with early, asymptomatic HIV infection and in more than 50% of those individuals with more advanced HIV-related immunodeficiency.[226,269] In a study of 1729 HIV-infected women, evaluated as part of the Women's Interagency HIV Study, the prevalence of neutropenia (<2000/μL) at baseline was 44%, whereas 7% had less than 1000 neutrophils/μL. Over 7.5 years of follow-up, neutrophil counts lower than 2000/μL occurred on at least one occasion in 79%, whereas absolute neutrophil count (ANC) lower than 1000/μL was documented in 31%.[276] Factors associated with more severe underlying HIV disease, such as lower $CD4^+$ cell counts and higher HIV-1 RNA levels correlated statistically with development of neutropenia on multivariate analysis in this study, whereas prevention of neutropenia was seen in those patients receiving combination antiretroviral therapy without inclusion of zidovudine.[276]

As with other peripheral blood cytopenias in the setting of HIV infection, multiple etiologies may be present, either singly or in combination (Table 158–3).[277] Thus, decreased colony growth of the progenitor cell CFU-GM[278,279] may lead to decreased production of both granulocytes and monocytes. Soluble inhibitory substances produced by HIV-infected cells have been noted to suppress neutrophil production in vitro, suggesting that autoimmunity may play a part in the development of neutropenia in HIV infection.[160,280] However, more recent studies have now shown that the presence of neutrophil-bound immunoglobulin (Ig) correlates best with stage of disease rather than with neutropenia per se.[281] Decreased serum levels of G-CSF have been described in HIV-seropositive subjects with afebrile neutropenia (<1000 neutrophils/mL), indicating that a relative deficiency of this specific hematopoietic growth factor may also contribute to persistent neutropenia.[282] Suppression of myelopoiesis may also occur as a consequence of the inflammatory cytokines induced by HIV infection, such as transforming growth factor-β and tumor necrosis factor-α.[283,284] In a more direct manner, certain HIV-1 proteins, such as tat protein and protein 24 (p24) have also been implicated in suppression of myelopoiesis.[284,285] Other causes of neutropenia in HIV infection include the presence of opportunistic infections, and/or malignancies involving the bone marrow. Finally, myelosuppression and neutropenia may also result from any one of several medications that are commonly prescribed for HIV-infected patients. In a recent study of 87 consecutive HIV-infected patients with ANC levels lower than 2000/μL, only 3 individuals were not receiving drugs associated with neutropenia, and 66% were receiving three or more potentially myelosuppressive medications.[286] The medications most frequently associated with neutropenia in this setting include trimethoprim-sulfamethoxazole, pentamidine, pyrimethamine-sulfadiazine, flucytosine, amphotericin, foscarnet, cidofovir, and ganciclovir, used to treat or prevent various opportunistic infections. In addition, certain antiretroviral agents, such as zidovudine, lamivudine, didanosine, stavudine, abacavir, and indinavir have also been associated with neutropenia.[243,287–289] Chemotherapeutic agents are also commonly associated with neutropenia, as is interferon-alpha.

Abnormalities of Granulocyte and Monocyte Function in HIV

Aside from absolute neutropenia, patients with HIV infection may also experience decreased function of granulocytes and monocytes. Thus, impaired chemotaxis and reduced expression of adhesion molecules on neutrophils has been described. Additionally, abnormal Fc processing by macrophages has been documented, whereas decreased opsonization, decreased production of superoxide with diminished intracellular killing of bacterial or fungal organisms by granulocytes has also been noted.[290–293]

Risk Factors for Infection in Neutropenic HIV-Infected Patients

In patients with cancer who receive chemotherapy, multiple studies have shown that the risk of bacterial infection rises when the ANC falls below 1000 cells/mL and increases further when the ANC falls below 500 cells/mL.[294] Several studies have confirmed the same relationship in patients with HIV infection. Thus, Moore and colleagues found that the risk of bacterial infection increased 2.3-fold for HIV-infected individuals with ANC less than 1000 cells/mL and rose by 7.9-fold in those with ANC levels less than 500 cells/mL.[295] Lower ANC counts have been associated with increased risk of hospitalization for serious infection, as shown in a review of 2047 HIV-positive patients.[296] On multivariate analysis, the severity and duration of neutropenia were found to be significant predictors of the incidence of hospitalization for serious bacterial infections.[296]

In a recent study of 62 HIV-infected patients with ANCs of 1000 cells/mL or less, 24% developed infectious complications, most commonly within 24 hours after the onset of neutropenia.[297] On multivariate analysis, the three factors independently associated with infectious complications included presence of a central venous catheter, neutropenia in the previous 3 months, and a lower nadir of granulocyte count (250 cells/mL in those with infections vs 622 cells/mL in those without). Among patients with medication-associated neutropenia, the most common cause was zidovudine, followed by trimethoprim-sulfamethoxazole, and ganciclovir; neutropenia was less likely to be associated with infection in these patients than in individuals who were neutropenic owing to the use of cancer chemotherapy.[297]

Another more recent study, however, has suggested that the risk of serious infectious complications in neutropenic HIV-infected patients is quite low.[286] In this prospective study of neutropenia (defined as an ANC of 1000 cells/mL or less) in 87 consecutive HIV-infected patients, all except three episodes of neutropenia were associated with known myelosuppressive medications. The majority of patients had received cotrimoxazole (62%), lamivudine (56%), and/or zidovudine (40%).[286] The mean ANC of these individuals was 660 cells/mL (range 100–900 cells/mL) and the median duration of neutropenia was 13 days. Severe neutropenia was, however, uncommon; only three patients had ANC nadirs lower than 200 cells/mL. Of importance, serious neutropenia-related sepsis in this setting was uncommon, with culture-proven infection occurring in only 8% and presumed infection in a further 8% of patients. No patient died of infection. As expected, patients with infections had significantly lower ANC nadirs (mean, 460 vs 710 cells/mL) and significantly lower CD4 cell counts (mean, 64 vs 126/mL), but did not have a longer duration of neutropenia than those patients who did not develop infection.

The state of underlying HIV-1 infection may also influence the risk of febrile neutropenia in HIV-infected patients. Thus, a recent prospective observational cohort study indicated that low $CD4^+$ lymphocyte counts were associated with an increased risk of bacterial infection in HIV-infected neutropenic patients.[286] A similar relationship has also been reported in HIV-negative patients undergoing chemotherapy; in this setting a low pretreatment CD4 count ($<450/mm^3$) was an independent risk factor for febrile neutropenia and early death.[298]

Of interest, the occurrence of neutropenia (ANC $<2000/\mu L$) per se was not associated with decreased survival among a group of 1729 HIV-infected women.[276]

Impact of Highly Active Antiretroviral Therapy on Neutropenia

Recent evidence indicates that use of HAART may be associated with an improvement in leukopenia and neutropenia in treated patients.[266] Thus, in a group of 66 HIV-infected patients treated with HAART, significant increases in total leukocyte counts and absolute granulocyte counts were seen after 6 months of treatment.[266] Of interest, Sloan and colleagues have recently demonstrated a direct stimulatory effect of protease inhibitors on human hematopoiesis.[299] In a prospective study of 1729 HIV-infected women, Levine and colleagues demonstrated that combination antiretroviral or HAART therapy, without zidovudine, were associated with protection against development of neutropenia over time, whereas this protection was lost when zidovudine was part of the antiretroviral regimen.[276] Furthermore, HAART therapy, even when zidovudine was included, was statistically associated with resolution of preexisting neutropenia among these women. These data would indicate that mild to moderate levels of neutropenia may be managed by use of HAART alone, although several months of therapy are required to achieve the desired effect.[276]

Use of Granulocyte–Macrophage Colony-Stimulating Factor or Granulocyte Colony-Stimulating Factor in Neutropenic, HIV-Infected Patients

Granulocyte–Macrophage Colony Stimulatory Factor

When administered subcutaneously to HIV-infected patients with neutropenia, GM-CSF results in dose-dependent increases in granulocytes, monocytes, and eosinophils.[300,301] Therapy with GM-CSF may also improve neutrophil function by enhancing phagocytosis, degranulation, leukotriene B_4 synthesis, release of arachidonic acid, superoxide anion generation, and antibody-dependent cellular cytotoxicity.[302,303] Although there were initial concerns that GM-CSF may increase HIV replication,[304] subsequent in vitro studies have indicated that GM-CSF, in fact, inhibits HIV-1 replication in monocytes and macrophages.[305]

In one study comparing 123 HIV-positive leukopenic patients (defined as a white blood cell count $<3 \times 10^9/L$) treated with subcutaneous GM-CSF versus 121 nontreated leukopenic HIV-positive controls, administration of GM-CSF for 12 weeks was found to significantly increase the total leukocyte count of treated patients.[306] In patients receiving GM-SCF, the total leukocyte count increased by 22% at week 1 and by 65% at week 12, when compared to baseline values ($P < 0.001$), whereas the circulating monocyte levels increased by two- to threefold at week 12 ($P < 0.001$). In contrast, the total leukocyte count decreased by 24% below baseline values at week 12 ($P < 0.001$) in the control group. Of importance, no statistically significant change occurred in HIV p24 antigen levels in patients treated with GM-CSF, even among those who were not receiving antiretroviral therapy.[306]

The safety and efficacy of GM-CSF in HIV-infected patients receiving antiretroviral therapy has also been confirmed in another randomized placebo-controlled trial involving a group of 105 HIV-infected patients.[307] GM-CSF was given at a dose of 125 $\mu g/m^2$ twice weekly for 6 months. Patients randomized to antiretroviral therapy plus GM-CSF achieved a greater reduction in plasma viral load, they were more likely to achieve HIV-1 RNA levels below the limit of detection, and they also demonstrated a lower frequency of zidovu-

dine resistance mutations than those who received antiretroviral agents plus placebo. Side effects of GM-CSF include primarily an influenza-like syndrome, with fever, bone pain, myalgia, fatigue, malaise, and headache.

Granulocyte Colony-Stimulating Factor

G-CSF has also been shown to be effective at preventing severe neutropenia and reducing the incidence of bacterial infections and the number of days of hospitalization in neutropenic HIV-infected patients.[308] Kuritzkes and colleagues randomized 258 such patients with CD4 counts below 200 cells/mm^3 and moderate neutropenia (defined as an ANC of 750–1000/mL) to receive G-CSF (1 μg/kg/day or 300 μg three times per week) versus no treatment for 24 weeks.[308] Patients in the control group who developed severe neutropenia (ANC less than 500/mL) were rerandomized to receive G-CSF according to one of the two treatment groups. Treatment with G-CSF was effective at preventing the development of severe neutropenia and in reducing the incidence of bacterial infections, independent of CD4 count, number of prior opportunistic infections, or baseline use of zidovudine. Thus, in an intention-to-treat analysis, the incidence of severe neutropenia was 1.7% in the treated group versus 22% in the control group, whereas the incidence of bacterial infections was 31% lower in the treated group (2.93 vs 4.25/1000 patient days). Furthermore, patients treated with G-CSF had 54% fewer severe bacterial infections and 45% fewer hospital days for bacterial infections. Of importance, there was no difference between the groups in terms of toxicity or HIV RNA levels in plasma. The most frequently reported adverse events were fever, diarrhea, fatigue, nausea, headache, anemia, abdominal pain, vomiting, and myalgia. Thus, it would appear that administration of G-CSF when patients are mildly neutropenic may be superior to waiting for patients to become severely neutropenic. However, as discussed, effective use of HAART may also be equally efficacious in resolving mild to moderate neutropenia.

The early recommendations for dosing of G-CSF included use of 5 mg/kg/day given subcutaneously. Recent evidence suggests, however, that much lower doses of G-CSF may be effective in HIV-infected persons. Thus, an initial dose of 1 mg/kg/day is often initiated and used until the neutrophil count rises to acceptable levels (>1000 cells/mL). This is followed by a titration of dosing, often requiring therapy only once or twice per week, as necessary to maintain the desired response.[309,310]

Thus, use of G-CSF or GM-CSF to improve neutropenia in HIV-infected patients has been shown to be both safe and effective. Although patient survival has not increased as a consequence of G-CSF or GM-CSF,[311] these drugs will allow safer administration of other necessary medications, and will also potentially reduce both the incidence of bacterial infections and number of hospital days.[301,308,311]

THROMBOCYTOPENIA

Thrombocytopenia is relatively common during the course of HIV infection, occurring in approximately 40% of patients and serving as the first symptom or sign of HIV infection in approximately 10%.[312,313] Sullivan and colleagues[313] evaluated the 1-year incidence of thrombocytopenia (<50,000/mL) in a group of 30,214 HIV-infected patients as part of the retrospective Adult and Adolescent Spectrum of Disease Project. The incidence of thrombocytopenia over 1 year was 8.7% in patients with clinical AIDS, 3.1% in patients with immunologic AIDS (CD4 <200 cells/mL), and 1.7% in patients with neither. Development of thrombocytopenia was associated with history of clinical or immunologic AIDS, injection drug use, history of anemia or lymphoma, and African American race. After controlling for multiple factors (AIDS, CD4 count, anemia, neutropenia, antiviral therapy, and receipt of prophylaxis against *P carinii*), thrombocytopenia was significantly associated with shorter survival (risk ratio = 1.7, 95% confidence interval = 1.6–1.8).[313]

More recently, Pearce and colleagues evaluated the incidence of thrombocytopenia, defined as a platelet count lower than 150,000/mL, among 1990 HIV-infected and 553 HIV-negative women who were part of the Women's Interagency HIV Study. At baseline, 15% of HIV-positive women were thrombocytopenic, compared to 1.6% of HIV-negative women ($P < 0.001$).[314] Factors associated with increased risk of thrombocytopenia included HIV infection, low CD4 levels, increasing viral load, smoking, and Caucasian race/ethnicity. Of importance, the study also found thrombocytopenia to be a significant predictor of both all-cause and AIDS-related mortality among women infected with HIV. Thus, HIV-infected women with a platelet count lower than 50,000/mL had a fivefold increased risk of death from any cause compared to women with normal platelet counts (HR = 5.10, 95% confidence interval = 2.71–9.58) and an approximate threefold increased risk of death from AIDS (HR = 3.36, 95% confidence interval = 1.44–7.83). The statistically significant increase in mortality due to thrombocytopenia was maintained even after exclusion of those patients who died of bleeding events.

Mechanisms of Thrombocytopenia in HIV-Related Immune Thrombocytopenic Purpura

Increased Platelet Destruction

As in "de novo" immune thrombocytopenic purpura (ITP), HIV-infected patients with ITP also demonstrate increased platelet destruction via Fcγ-mediated phagocytosis by macrophages in the spleen.[315] In HIV-related ITP, however, multiple mechanisms for development of platelet-associated antibody have been described, often occurring simultaneously in a given patient. Thus, presence of platelet-specific antibodies, immunochemically characterized as antiglycoprotein (GP)IIb and/or GPIIIa, have been detected in HIV-infected patients with ITP, indicating a mechanism similar to that described in de novo disease.[316] However, cross-reactive antibody between HIV gp160/120 and platelet GPIIb/IIIa has also been demonstrated.[317] Thus, Bettaieb and colleagues found that serum antibodies against HIV gp160/120 could be eluted from platelets of patients with HIV-related ITP and that these HIV-specific antibodies shared a common epitope with antibodies against platelet GPIIb/IIIa on the platelet surface. The specific immunodominant epitope against which the antibody is directed in HIV-ITP is the β_3 GPIIIa integrin, GPIIIa49–66, which shares a known epitope region with HIV-1 protein nef.[318–320] Of interest, purified anti-GP IIIa49–66 antibody from patients with HIV-ITP can induce platelet fragmentation by catalyzing hydrogen peroxide generation in a complement-independent manner, serving as yet another mechanism of platelet destruction in this setting.[321] A binding partner of β_3 GPIIIa integrin is talin-H, a cytoskeletal platelet protein that plays a key role in the regulation of integrin activation and can be cleaved during platelet activation and also by HIV-1 protease.[322,323] Following platelet fragmentation by complement independent generation of hydrogen peroxide, talin-H may be exposed, leading to antibody production. In this regard, the talin head has been shown to serve as yet another immunodominant epitope of the antibody response in patients with HIV-ITP.[324] It is thus apparent that molecular mimicry between various HIV-associated and platelet-associated proteins may be operative in the immune destruction of platelets in some cases of HIV-related ITP. A further mechanism of antibody-induced destruction of platelets arises from the nonspecific absorption of immune complexes against HIV onto the platelet Fc receptor, thus providing a "free" Fc portion for subsequent macrophage binding and phagocytosis.[316]

Decreased Platelet Production

Kinetic studies of platelet production and destruction have been performed in patients with HIV-related ITP, with results compared

to a group of normal control subjects and to a group of patients with de novo ITP.[315] Mean platelet survival was found to be significantly decreased in patients with HIV-ITP, occurring to the same extent in patients receiving zidovudine and in those who were untreated. It is interesting to note that the mean platelet survival was also significantly decreased in HIV-infected patients with normal platelet counts. In addition to this increased destruction of platelets, mean platelet production was also found to be significantly decreased in patients with untreated HIV-ITP, although those patients receiving zidovudine demonstrated a subsequent increase in platelet production, occurring even in zidovudine-treated HIV-infected individuals without thrombocytopenia. Kinetic studies performed by Cole and colleagues confirmed the decrease in platelet production seen in patients with HIV-ITP, despite a sixfold elevation in thrombopoietin levels and a threefold expansion of megakaryocyte mass when compared to normal controls.[325] This finding suggested the possibility of HIV-induced apoptosis of megakaryocytes.[326] Thus, it is apparent that patients with HIV-ITP, though experiencing a moderate increase in platelet destruction, are also faced with significant decreases in platelet production, which occur even in those individuals with normal platelet counts.[315]

Infection of the Megakaryocyte by HIV

The cause for the reduced production of platelets in the setting of HIV infection may be direct infection of the megakaryocyte by HIV. Thus, Kouri and colleagues first demonstrated that human megakaryocytes bear a $CD4^+$ receptor capable of binding HIV-1,[327] whereas Zucker-Franklin et al showed that HIV-1 could be internalized by human megakaryocytes.[328] The presence of the HIV-1 coreceptor, CXCR4, on megakaryocytic progenitors, megakaryocytes, and platelets was subsequently demonstrated as well.[329] Furthermore, employing in situ hybridization techniques and a ^{35}S HIV riboprobe (antisense to an HIV *env* sequence), HIV transcripts have been detected in megakaryocytes of 5 of 10 patients with HIV-ITP, indicating that the megakaryocyte had been infected by HIV in these cases.[330] Expression of viral RNA was also detected in all 10 patients, using in situ hybridization techniques. Specific ultrastructural damage in the HIV-infected megakaryocytes has been noted, consisting of blebbing and vacuolization of the surface membrane.[331] The documentation of significant increases in platelet production after receipt of zidovudine[332] would be consistent with the hypothesis that a major mechanism of this disorder is the direct infection of the megakaryocyte by HIV.

Recently, Harker and colleagues described three chimpanzees infected with HIV-1 who developed ITP associated with elevated levels of antibody against platelet GPIIIa. Use of recombinant pegylated human megakaryocyte growth and development factor (MGDF) was associated with a decline in antiplatelet antibodies in serum, an increase in peripheral blood platelet counts, and an increase in the number of megakaryocytes and megakaryocyte progenitors in the marrow.[333] These changes would imply that the mechanism of ITP in HIV-infected chimps includes insufficient compensatory increases in platelet production, similar to that decreased in humans.

Therapy for HIV-Related Immune Thrombocytopenic Purpura

The Need for Therapy

HIV-ITP may undergo spontaneous remission in approximately 18% of patients.[163] Furthermore, most patients with HIV-ITP do not experience bleeding, with hemorrhagic events described in only 8% of such individuals.[334] Nonetheless, treatment is indicated when bleeding occurs, in preparation for an invasive procedure, in patients with platelet counts lower than 30,000/μL, or lower than 50,000//μL in those with underlying coagulopathies. As detailed below, antiretroviral therapy is quite effective in patients with HIV-ITP and may serve as the initial reason for starting such antiviral treatment.

Zidovudine

The Swiss Group for HIV Studies was the first to demonstrate the efficacy of zidovudine therapy in patients with HIV-ITP.[332] Ten seropositive patients, with platelet counts ranging from 20,000 to 100,000/mL, received zidovudine at a dose of 2 g/day for 2 weeks, followed by 1 g/day for 6 weeks. This was followed by 8 weeks of placebo. All 10 patients experienced an increase in platelet counts while on zidovudine, with a mean increase of 54,600/mL range (53,200–107,800/mL). In contrast, no patient experienced an increase in platelet count while on placebo. The time to onset of response was approximately 8 days, with full response achieved by day 30. These results were subsequently confirmed by others.[335]

The optimal dose of zidovudine in HIV-ITP was studied by Landonio et al, who compared a dose of 500 mg/day in 35 patients with 1000 mg/day in another group of 36 individuals.[336] The majority of patients in both groups were injection drug users, with similar mean platelet counts (approximately 23,000/mL) and mean $CD4^+$ counts (approximately 400 cells/mL). A response rate of 57% was achieved in the low-dose group, with 11% experiencing complete response. In contrast, a response rate of 72% was achieved in those receiving 1000 mg zidovudine per day, with complete response in 39%. At month 6, a significant difference remained between the groups, with a mean platelet count of 56,000/mL in the low-dose group versus 98,200/mL in those receiving high-dose zidovudine. It is apparent from this study that high-dose zidovudine is advantageous in patients with HIV-ITP.[336]

Highly Active Antiretroviral Therapy in Immune Thrombocytopenic Purpura

Recently, HAART has been shown to be effective in the treatment of HIV-related ITP. In a report of 37 such patients, use of HAART was associated with a significant increase in platelet count, documented after 3 months of treatment, independent of baseline platelet count or the concomitant use of zidovudine.[337] Similarly, in a retrospective study involving 15 patients with HIV-related ITP treated with HAART, 11 (73%) had an increase in platelet count to values of 50,000/mL whereas eight (53%) had an increase in platelet count to values of 100,000/mL after 6 months of HAART therapy.[338] Consistent with these findings, data from the Women Interagency HIV Study demonstrated a strong association between the use of HAART and resolution of thrombocytopenia (defined as a platelet count >150,000/mL).[314] Thus, compared to thrombocytopenic women not receiving antiretroviral therapy, women in a non–AZT-containing HAART regimen were nearly 2 times more likely to improve their thrombocytopenia (OR = 1.84, 95% confidence interval = 1.31–2.59, $P < 0.001$), whereas women in an AZT-containing HAART regimen were even more likely to resolve their thrombocytopenia (OR = 2.85, 95% confidence interval = 1.96–4.15, $P < 0.0001$).[314] Thus, HAART is an important treatment modality in patients with HIV-related ITP and should be the initial treatment of choice in these patients. It is likely that effective use of HAART significantly decreases HIV viral load, and in so doing ameliorates many of the effects of HIV on megakaryocytes and on platelet production as well as platelet destruction.

Interferon-Alpha

A prospective, randomized, double-blind, placebo-controlled trial of Interferon (IFN)-α at a dose of 3 million units thrice weekly given subcutaneously was conducted in 15 patients with HIV-related

ITP.[339] A platelet response was documented in 66%, with a mean increase of 60,000/mL. The average time to response was 3 weeks. When interferon therapy was discontinued, platelet counts returned to baseline values within 3 months, indicating the necessity to maintain IFN-α therapy over time. In an attempt to ascertain the mechanisms by which IFN-α exerts its effects, Vianelli et al demonstrated a prolongation in platelet survival, whereas no significant increase in platelet production was noted.[340]

High-Dose Intravenous Gamma Globulin

Intravenous gamma globulin (IVIG), at a dose of 1000 to 2000 mg/kg, has been used effectively in pediatric and adult patients with de novo ITP, resulting in a significant rise in platelet counts within 24 to 72 hours in the majority of individuals.[341] Bussel and Haimi treated 22 patients with HIV-related ITP employing 1 to 2 g/kg during a 2- to 5-day period, depending upon the platelet response.[342] The average platelet count prior to therapy was 22,000/mL, rising to a mean of 182,000/mL (range 10,000–404,000/mL) within 2 to 5 days. Only two patients did not respond, whereas 77% experienced an increase to more than 100,000/mL, and 86% had an increase to more than 50,000/mL. However, when IVIG was discontinued, only 25% of patients maintained the increased platelet count, whereas the remainder required repeat infusions approximately every 21 days. The major problem with IVIG appears to be cost, which is quite significant. For this reason, IVIG is often reserved for use in patients who are acutely bleeding or require an immediate increase in platelet count, for example, prior to an invasive procedure.

Anti-Rh Immunoglobulin

The use of anti-Rh Ig in nonsplenectomized Rh-positive patients with HIV-related ITP represents another potential mode of therapy.[203] Requirements for effective therapy with anti-Rh (D) include a baseline hemoglobin level adequate to permit a 1- to 2-g decrease due to therapy-related hemolysis, presence of Rh positivity in the patient, and presence of a spleen, the site at which red cells would preferentially be phagocytized. Oksenhendler et al treated 14 Rh-positive patients with HIV-ITP employing 12 to 25 μg/kg of anti-Rh Ig given intravenously over 30 min on two consecutive days.[343] Nine (64%) Rh-positive patients responded with a platelet count above 50,000/mL, with response first noted at a median of 4 days (range 3–12 days), and median response duration of 13 days (range 0–37 days). Maintenance therapy was administered at a dose of 13 to 25 μg/kg IV every 2 to 4 weeks, resulting in a long-term response (>6 months) in five of six such patients. Subclinical hemolysis occurred in all, with a drop of hemoglobin of 0.4 to 2.2 g. Gringeri et al subsequently confirmed these results and also studied the use of intramuscular (IM) anti-D Ig for maintenance treatment after successful induction therapy by the intravenous route.[344] Patients self-administered the IM anti-Rh at a dose of 6 to 13 μg/kg/week. After induction, 83% of patients had achieved a platelet count above 50,000/mL, a response that was maintained in 85% over time. It is thus apparent that anti-Rh Ig may be used safely and effectively in patients with HIV-related ITP, providing an alternative that in some institutions may be as little as one-half the cost of high-dose IVIG.[343,344] Although not yet published in HIV-infected patients, higher dosing schedules of anti-D Ig, using 75 μg/kg/day have been associated with more rapid and durable increases in platelet count when studied in HIV-negative individuals with ITP.[345]

Splenectomy

Splenectomy has been used effectively in patients with de novo ITP who are refractory to corticosteroids, resulting in return to a normal platelet count in approximately two-thirds.[346] At the onset of the AIDS epidemic, several anecdotal case reports described a rapid progression to AIDS postsplenectomy, and the procedure was largely abandoned. More recently, Oksenhendler et al reported long-term experience in a cohort of 185 patients with HIV-ITP.[347] Splenectomy was eventually performed in 68 of these patients, at an average of 13 months from initial diagnosis of HIV-ITP. The mean platelet count presplenectomy was 18,000/mL, rising to 223,000/mL postoperatively. A response was seen in 92% of patients, with complete response (platelet count >100,000/mL) in 85%. Maintenance of the elevated platelet count for longer than 6 months was documented in 82%. In comparing the survival or rate of progression to AIDS in the 68 splenectomized patients versus the 117 who did not undergo the procedure, no difference was found, indicating that splenectomy was not associated with more rapid progression of HIV disease. Similar conclusions were made by Kemeny et al.[348] It is important to note, however, that 5.8% of patients undergoing splenectomy in Oksenhendler series experienced fulminant infection, consisting of *Streptococcus pneumoniae* meningitis in two and *Haemophilus influenzae* sepsis in one. It is thus apparent that patients should undergo prophylactic vaccination prior to splenectomy and that such surgery may ultimately be safer in those HIV-infected patients who can still achieve an appropriate antibody response to vaccination against *S pneumoniae* or *H influenzae*.

Corticosteroids

Corticosteroids remain the initial therapy of choice in patients with de novo ITP and at a dose of 1 mg/kg/day are associated with an 80% to 90% response rate.[349] Similar results have been documented in patients with HIV-related disease.[350] However, the immunosuppressive effects of high-dose corticosteroids have made such therapy far from optimal in HIV-infected patients. Furthermore, because corticosteroids are associated with increased growth of Kaposi sarcoma (KS),[351] the potential development of fulminant KS in HIV-infected patients who are coinfected by Human Herpes Virus 8 (HHV-8) has further dampened the enthusiasm for this therapeutic modality.

Other Causes of Thrombocytopenia in HIV-Infected Patients

Although HIV-ITP is the most common cause of low platelet counts in the setting of HIV, other etiologies may also occur, such as infiltration of bone marrow by malignancy or opportunistic infection. Thrombotic microangiopathy due to TTP or HUS may also occur in the setting of HIV, resulting in characteristic thrombocytopenia. Additionally, multiple drugs used commonly in HIV may also be associated with thrombocytopenia.

THROMBOTIC MICROANGIOPATHY

Prior to the availability of HAART, TMA was well described in HIV-infected patients, seen in approximately 1% to 2%.[244,352–355] Both hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) have been described,[352,354,356,357] with the former more likely to be diagnosed in later stages of HIV infection. HIV-infected patients with TTP tend to present similarly to those without underlying HIV infection, with fragmented schistocytes and thrombocytopenia on peripheral blood smears, as well as fever, subtle abnormalities of renal function, and a variety of neurologic abnormalities, including altered mental status, seizures, transient focal neurologic deficits.[244,352–355]

The actual mechanism of TMA in patients with HIV is unclear, and may involve endothelial cell damage or perturbation, perhaps by HIV, or by CMV, inflammatory cytokines, or toxins produced by *Shigella dysenteriae* and *Escherichia coli* 0157:H7.[358] Nonetheless, similar to de novo TTP,[359] persistence of high-molecular-weight von Willebrand factor (vWF) multimers, with complete deficiency of the

vWF-cleaving protease, ADAMTS-13, has been described,[360,361] with demonstration of an IgG1 antibody to ADAMTS-13 in one case.[360]

In terms of therapy for HIV-TTP, several case reports have noted a response to antiretroviral therapy.[361,362] In general, however, treatment is similar to that used for de novo TTP, consisting of plasma exchange, in which plasmapheresis is performed, removing unusually large vWF multimers and antibodies against ADAMTS-13, along with infusion of fresh-frozen plasma or cryosupernatant.[359] Response to such therapy as been reported in more than 50% of HIV infected cases.[244,353–355,357]

VENOUS THROMBOTIC DISEASE

Although numerous case reports of venous thrombosis occurring in HIV-infected patients have been published, an increased incidence of venous thromboembolic disease has only recently been described in the setting of underlying HIV infection.[363–370] In the Multistate Adult and Adolescent Spectrum of HIV Disease Surveillance Project sponsored by the CDC, the incidence of thrombosis among 42,935 HIV-infected individuals was found to be 2.6 per 1000 person-years.[212] The incidence was lower for individuals with immunologic AIDS (1.8 per 1000 person-years) or asymptomatic HIV infection (1.3 per 1000 person-years) than for persons with clinical AIDS (6.2 per 1000 person-years). Factors significantly associated with the risk of thrombosis included an age of 45 years or more, CMV retinitis, other AIDS-defining opportunistic infections, hospitalization, use of megestrol acetate, and use of indinavir.[369] Use of other antiretroviral agents, sex, race, and a history of injection drug use were not associated with an increased risk for thrombosis.

However, in another study that directly compared the risk of venous thromboembolism in HIV-infected patients and HIV-negative controls, no statistically significant difference in the rate of thrombotic disease was reported between the groups, when studied overall (HIV-infected, 2.8%, vs HIV-negative controls, 1.8%).[368] Nonetheless, when considering only those patients under the age of 50 years, the frequencies were significantly different (HIV-infected, 3.31% vs HIV-negative controls, 0.53%, $P < 0.0001$).

In an attempt to determine the incidence of venous thrombosis in HIV-infected patients compared to individuals without HIV infection, and to determine whether the introduction of combination antiretroviral therapy altered the rates of thrombotic disease, Fultz and colleagues retrospectively reviewed the medical charts of 37,535 HIV-infected veterans and 37,535 age-, race-, and site-matched controls.[370] Compared to HIV-negative controls, HIV infection was associated with a 39% increased incidence of thromboembolism in the pre-HAART era (standardized incidence ratio [SIR] = 1.39; 95% confidence interval = 1.26–1.52) and a 33% increased incidence in the post-1996 era (SIR = 1.33; 95% confidence interval = 1.24–1.43). This increased risk of thrombosis was independent of a diagnosis of malignancy, HIV-related opportunistic infection, or use of central venous catheters. Furthermore, thrombosis was significantly associated with increased mortality in all groups. It is thus apparent that venous thrombotic disease is increased in the setting of HIV infection, independent of many of the more commonly known risk factors.

HIV infection is known to result in increased levels of proinflammatory cytokines, such as TNF-α, IL-1, and IL-6, which can contribute to the development of a procoagulant state by upregulation of factor VIII and downregulation of protein S.[371–373] These same cytokines have also been shown to downregulate the expression of numerous proteins necessary for fibrinolysis.[374] Elevated factor VIII levels per se are a component of the inflammatory state,[375] and elevated factor VIII activity has been independently associated with an increased prevalence of deep vein thrombosis in HIV-negative individuals.[376]

Several studies have suggested that progressive HIV infection may be associated with the development of a hypercoagulable state. In one recent study comparing 94 HIV-infected women and 50 HIV-negative controls, Levine and colleagues documented a clear relationship between progressive stages of HIV disease and stepwise increases in factor VIII activity along with decreases in levels of functional protein S, both of which have been associated with increased risk of thromboembolism in HIV-infected individuals.[377] Thus, functional protein S activity progressively decreased from 76% in HIV-negative women, to 67% in those with asymptomatic HIV, 62% in those with immunologic AIDS, and 46% in those with clinical AIDS ($P < 0.0001$), whereas factor VIII activity statistically increased in a stepwise manner, from 116% in HIV negatives, to 149% in asymptomatic HIV, 196% in immunologic AIDS and 211% in patients with clinical AIDS ($P < 0.0001$). Of interest, no patient demonstrated presence of a lupus anticoagulant.[377] Other studies have also reported abnormalities of coagulation proteins in HIV-infected patients, such as acquired deficiencies in protein S,[378–383] protein C,[383,384] and heparin cofactor II.[385] Thus, although the precise mechanisms leading to thromboembolism in HIV are not yet elucidated, it is possible that the progressive proinflammatory milieu of HIV infection may be operative.

The presence of anticardiolipin antibodies has been described in as many as 80% of HIV-infected patients, and their prevalence may be higher in patients with clinical AIDS.[386–388] Patients with antiphospholipid syndrome are at risk for clinical thrombosis, in addition to persistent laboratory abnormalities, including presence of lupus anticoagulant (LA), ACAs, or other antiphospholipid antibodies. Although ACAs may be associated with a hypercoagulable state,[389] most studies have found no correlation between high levels of ACAs and clinical thrombosis in the setting of HIV infection[386–388]; nevertheless, isolated case reports of patients with ACAs and unusual sites of venous thrombosis have been described.[390–392] Furthermore, LA is a stronger predictor of thrombosis than ACAs in patients with antiphospholipid syndrome.[393] Of interest, no case of LA was found among the 92 HIV-infected patients studied by Levine and colleagues.[377]

Although the incidence of venous thrombotic events (VTE) is clearly not as common as the other hematologic disorders described in HIV, an increase in VTE is clearly expected in the setting of HIV infection, possibly as a consequence of cytokine activation in an underlying inflammatory state, or other factors. Clinicians should be alert to the possibility of VTE, and to development of VTE in unusual sites, in the setting of underlying HIV infection.

CHAPTER 159

HEMATOLOGIC ASPECTS OF PARASITIC DISEASES

David J. Roberts

INTRODUCTION

Parasitic diseases are not common in medical, let alone hematologic, practice in North America or Europe. However, much of the world's population are infected and become symptomatic from a plethora of parasites, and many of these infections represent global public health problems.

Although some significant parasitic diseases are transmitted in temperate climates, the majority of parasites of significance to human health are endemic in the tropical world. This reflects not only socioeconomic circumstances but also the origin of our species in tropical Africa, where the human host, parasites, and also vectors have established complex relationships over evolutionary timescales.[1] Notwithstanding such geographical variation in the incidence of parasitic disease, both travelers and recent migrants now present to hematology clinics and laboratories all over the world with increasing frequency. Even here, there are marked variations in practice in North America and Europe; where the United Kingdom reports more cases of imported malaria than the United States of America and indeed has a 10-fold greater incidence of malaria per capita, reflecting the increased frequency of travel to and from endemic areas compared to North American populations.

Malaria, leishmaniasis, malaria, trypanosomiasis, and babesiosis may present directly or indirectly to hematologists. This account will concentrate on the biological, clinical, and hematologic features of these infections and the hematologic aspects or complications of their treatment. Comprehensive accounts of the general medical aspects of these diseases are provided in many recent textbooks.[2–4]

MALARIA

Malaria is a major public health problem in tropical areas, and it is estimated that it is responsible for 1 to 3 million deaths annually and 300 to 500 million infections.[5] The vast majority of morbidity and mortality from malaria is caused by infection with *Plasmodium falciparum*, although *P vivax*, *P ovale*, and *P malariae* also are responsible for human infections. In endemic areas, a significant proportion of the mortality and morbidity is due to anemia. In Europe and North America, malaria is not infrequently a clinical problem in travelers or recent arrivals from malaria-endemic areas and hematologists may be involved in the diagnosis and management of the disease. Moreover, in nonendemic areas, malaria may cause a fatal transfusion-transmitted infections and detection of blood donors who may be carrying the disease represents a major challenge for blood services.

Epidemiology

Approximately 1000 million people live in areas of endemic or epidemic malaria. The global mortality and morbidity have been recently revised to 350 million cases and 1 million deaths per year following an evaluation of the prevalence of infection in Southeast Asia (Fig. 159–1). There is increasing anecdotal evidence that the incidence of severe disease is now falling, sometimes spectacularly, in many parts of Africa following the widespread introduction of artemisinin combination treatment, impregnated bednets, and residual spraying under the local campaigns.[6] Evidence of more general effectiveness of WHO's "Roll Back Malaria" is yet to appear (rbm.who.int/).

The distribution of malaria is determined by features of host, vector, and parasite. In summary, the global distribution of autochthonous or endogenous malaria is limited by the lower temperature limits for development of the parasite in the mosquito (sporogony) of 20°C for *P falciparum* and 15°C for other human malarias. Within these limits transmission does not occur above 1500 m in arid regions or in the Central and South Pacific (due to the absence of suitable vectors). In addition, *P vivax* malaria is rare in Africa where the population frequency of the blood group Duffy negative ($Fya^{-}Fyb^{-}$) is high. *P ovale* requires a lengthy period of sporogony and is confined to areas of Africa and Southeast Asia with a high density of susceptible *Anopheles* spp.

In some malarious areas the seasonal pattern of clinical malaria is determined by the increase in vector density after rainfall, leading to an increase in new infections as transmission increases. In naïve individuals, parasites can cause chronic infection lasting many months.

The intensity of transmission determines the distribution of clinical symptoms in different age groups. In general, in areas of high transmission younger children suffer from severe disease. Where transmission is less intense, older children suffer from severe disease. Finally, if the rate of transmission is very low, few cases of malaria are seen in any age group and such populations would have little natural immunity. In such areas, a sudden increase in vectorial capacity (through the accidental introduction of efficient vectors or higher density, biting, or survival of the resident vectors), more rapid parasite sporogony, or migration of infected or nonimmune populations can result in epidemics where large numbers fall ill in all age groups. The transition from high to low transmission has been classified by holo-, hyper-, meso-, and hypoendemicity. These categories can be related epidemiologically to age-specific rates of parasite prevalence or splenomegaly and theoretically to the reproductive ratio of malarial infection.[7,8]

Malaria exerts a substantial selection for human traits that protect from infection. Sickle cell trait and thalassemia traits protect from infection and are truly polymorphic characteristics in many parts of the world. Understanding the genetic epidemiology has provided the foundation of population genetics and has provided classic examples of principle of genetic selection in vivo—for example, balancing selection for sickle cell trait and negative epistasis for sickle cell trait and alpha thalassemia. The homozygous forms of these characteristics cause significant clinical disease, for example, sickle cell disease, beta-thalassemia, and G6PDH deficiency. In endemic areas, these genetic diseases represent major public health problems. For a review, see references 9 and 10.

Parasitology

In *P falciparum* (see later for a discussion of the other human parasites) the infective sporozoite forms are inoculated into the bloodstream from the salivary glands of a female *Anopheles* mosquito (Fig. 159–2). These thin, needle-shaped cells, 10 to 12 μm in length circulate briefly with a half-life of approximately 30 minutes, before traversing macrophages and several hepatocytes before residing in a

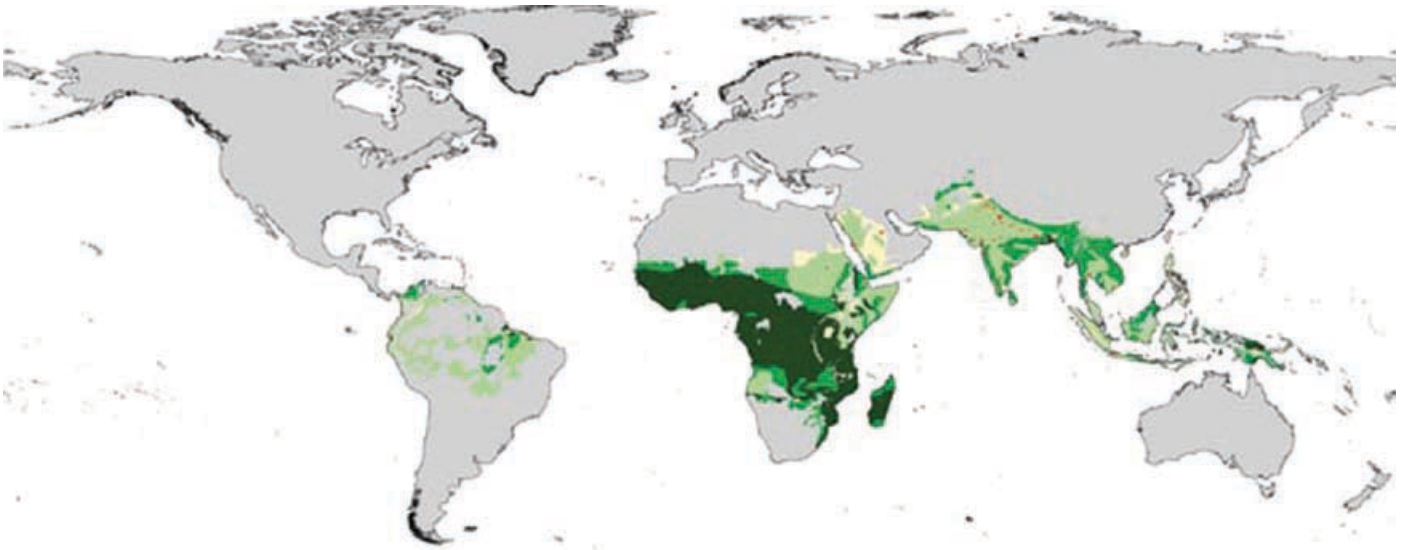

Figure 159–1 Global malaria endemicity. Areas are coloured according to malaria endemicity (prevalence): *light green*, hypoendemic (areas in which childhood infection prevalence is less than 10%); *medium green*, mesoendemic (areas with infection prevalence between 11% and 50%); *dark green*, hyperendemic and holoendemic (areas with an infection prevalence of 50% or more); unclassified areas (*yellow*) represent only 6% of the global population at risk and are due to discrepancies in recent data. Grey areas are a combined mask of areas outside of the transmission limits and areas of population density less than 1 person/km^2 *(Data from Snow RW, Guerra CA, Noor AM, Myint HY, Hay SI. The global distribution of clinical episodes of* Plasmodium falciparum *malaria. Nature 434:214, 2005.)*

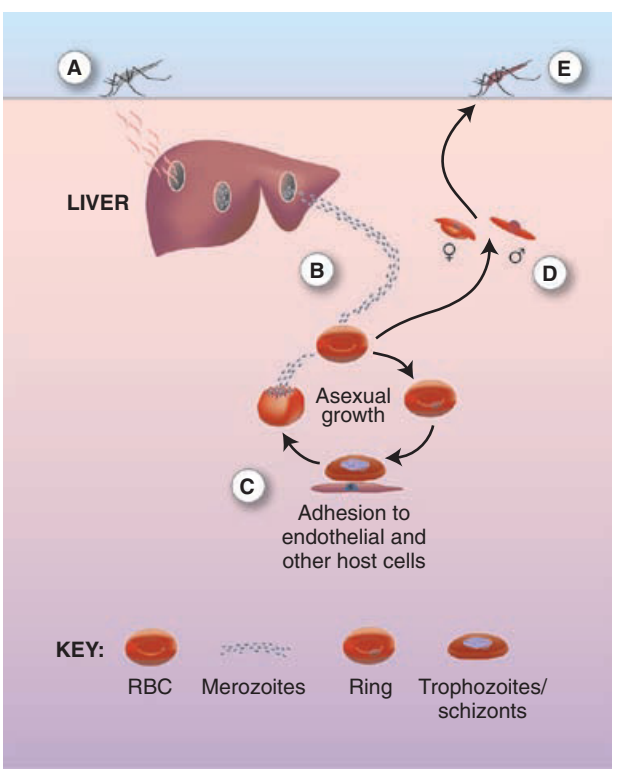

Figure 159–2 *Plasmodia* life cycle. **A,** The asexual life cycle begins when sporozoites from a female mosquito taking a blood meal enter the circulation and invade hepatocytes. **B,** Up to 10, 000 merozoites are formed. Following rupture of the hepatocyte, infective merozoites are released and invade erythrocytes (RBC). **C,** Within RBC, the parasite develops through the stages of rings, trophozoites, and schizonts. Mature schizonts burst to release erythrocytic merozoites that invade new RBC. **D,** A small proportion of merozoites in RBC transform into male and female gametocytes that are ingested by the mosquito. **E,** The male and female gametes fuse and transform into an oocyst, which divides asexually into many sporozoites that migrate to the salivary gland from where they are released during the next blood meal.

single hepatocyte.[11,12] Here rapid multiplication takes place over 5 to 8 days to produce a liver schizont, 80 µm in diameter and containing 30,000 ± 10,000 merozoites that are released into the bloodstream, where they infect erythrocytes.[13] When ready to leave hepatocytes, the parasite induces cell death in the hepatocytes and causes the release of merozoites in membrane-enclosed structures or merosomes that are extruded from the infected cell, so avoiding host cell defense mechanisms.[14]

The merozoites bind and then invade red blood cells (for review of red cell and merozoite interactions see reference 15). The host plasma membrane is invaginated to form the parasitophorous vacuole. For the first 10 hours, the developing parasites appear as fine "ring forms." Between 10 and 15 hours, the cytoplasm thickens and 16 hours after invasion granules of the black pigment hematin, the end-product of hemoglobin digestion, begin to appear. Ligands are expressed at the surface of the infected red blood cell that mediate adhesion to host receptors on venular endothelium. These trophozoites no longer circulate throughout the body but are sequestered in the peripheral circulation. Nuclear division begins, at approximately 30 hours, to form schizonts, containing up to 32 merozoites. At 48 hours, the red blood cell is ruptured to release the merozoites into the circulation to continue further cycles of asexual multiplication.

The erythrocytic cycle of schizogony may achieve a 10-fold increase in parasitemia in vivo and a patent or microscopically detectable infection 6 days after the liver stage is completed. After two or more cycles, the infection becomes clinically apparent by the paroxysms of fever that accompany the release of merozoites. Cycles of schizogony continue until the rate of parasite multiplication is reduced by chemotherapy, specific or nonspecific defense mechanisms, or occasionally, the demise of the host.

Some merozoites do not multiply but become committed during the previous erythrocytic cycle to form male or female gametocytes.[16] Gametocytes are distinguished by dispersed pigment in a single nucleus, in a fully grown parasite, and are sequestered for the first 5 days of their development in the peripheral circulation. Thus 8 to 10 days after the start of clinical infection, mature, crescent-shaped gametocytes appear in the blood.

The sexual phase (or sporogony) of the parasite life cycle begins after a male and female gametocyte are ingested by a feeding female *Anopheles* mosquito. In the midgut of the mosquito the gametocytes shed the red blood cell membrane. This change is apparently precipi-

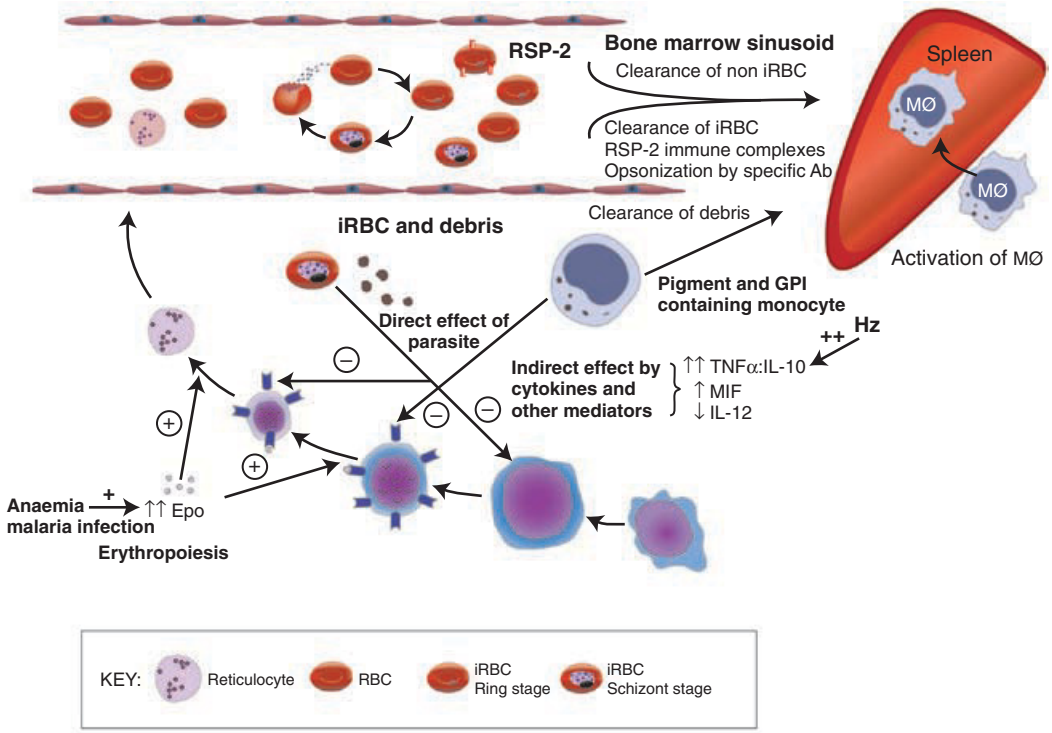

Figure 159–3 Pathogenesis of malarial anemia. Severe malarial anemia is characterized by destruction of infected red blood cell (iRBC) following schizogony and clearance of both iRBC and uninfected RBC. During malarial infection, changes in membrane protein composition occur and the resultant immune complexes of RBC, Ag, and immunoglobulin (Ig) (eg, RBC–RSP2–Ig) are cleared by macrophages to the spleen where they become activated. Pigment-containing macrophages may release inflammatory cytokines and other biologically active mediators such as 4-hydroxy-nonenal (HNE). Macrophage inhibitory factor may be released by macrophages or a *Plasmodial* homolog may suppress erythropoiesis. Malarial pigment or other parasite products may have a direct inhibitory effect on erythropoiesis. Inhibition of erythropoiesis may be at one or more sites in the growth and differentiation of hematopoietic progenitors. Both indirect and direct effects may cause suppression of the bone marrow and spleen resulting in inadequate reticulocyte counts for the degree of anemia. Hz, hemozoin; GPI, glycophosphatidylinositol anchors of merozoite proteins; Epo, erythropoietin; MΦ, macrophage; RSP-2, ring surface protein-2; Ig, immunoglobulin.

tated by the drop in temperature. A female gametocyte forms a single macrogamete, but male gametocytes undergo several rounds of nuclear division to produce flagellated microgametes. These microgametes are motile and migrate to fertilize a macrogamete. The resulting zygote enlarges to form a mobile oökinete and migrates through the epithelial wall of the mosquito midgut to rest finally on the external surface. The oöcyst divides repeatedly to form up to 10,000 sporozoites, which travel up through the hematocelomic fluid to enter the acinar cells of the salivary glands. Once here they are infective when injected into the host.

Major differences exist in the life cycles of other human *Plasmodium* spp. First, in *P vivax* and *P ovale* infections, some sporozoites entering the liver form dormant hypnozoites that only begin to divide after a variable period of some months to cause further blood-stage infections or relapses. Second, the cycle of erythrocytic development in *P malariae* takes 72 hours and thus causes quartan fever (ie, on days 1 and 4).

The Pathophysiology of Malarial Anemia

Malaria gives ample reasons for both increased red cell destruction and reduced red cell production (see Fig. 159–3 for overview).

Loss of Infected Erythrocytes

Destruction of red blood cells is inevitable as parasites complete their 48-hour growth cycle and lyse their temporary host cell. Some parasites may be removed from erythrocytes as immature ring forms by phagocytized cells, leaving the red blood cells with residual parasite antigens to continue to circulate, albeit with reduced survival.[17] Infected erythrocytes may also be phagocytosed by macrophages following opsonization by immunoglobulins and/or complement components.[18,19] Other signals for recognition of infected erythrocytes by macrophages include abnormally rigid membranes and exposure of phosphatidylserine and other altered host antigens.[20–23]

Loss of Uninfected Erythrocytes

The activity and the number of macrophages are increased in malarial infection, and increased removal of uninfected cells may occur. Moreover, the signals for recognition of uninfected erythrocytes for removal by macrophages are enhanced. Uninfected erythrocytes bind increased amounts of immunoglobulin and/or complement as detected in the direct antiglobulin test (DAT or Coombs Test).[24–26] These antibodies do not have a particular specificity but are more likely to represent immune complexes absorbed onto the surface of red blood cells. However, an association between a positive DAT and severe anemia has not been established. More recent studies have shown that red cells from malaria patients were not only more susceptible to phagocytosis but also showed increased surface IgG and deficiencies in CR1 and CD55 compared with controls.[22,23]

Role of the Spleen

Some degree of splenomegaly is a normal feature of malarial infection, and the prevalence of splenomegaly in regions of malarial trans-

mission is used as a major indicator of the level of malarial endemicity. The importance of the spleen in host defence against malaria has been demonstrated in experimental systems, and individuals whose spleens have been surgically removed are thought to be more susceptible to severe infection. Indeed, the phenomenon of parasitic sequestration is thought to have evolved primarily as an immune evasion strategy so the mature parasite can avoid passing through the spleen.[27]

Active erythrophagocytosis is a conspicuous feature within the bone marrow during *P vivax* and *P falciparum* malaria,[28,29] and it is highly probable that this also occurs within the spleen. Cytokines may be responsible for activating macrophages during malaria infection. Children with acute *P falciparum* malaria have high circulating levels of interferon-γ and TNF-α,[30] a synergistic combination of cytokines that activate macrophages.

Several studies have attempted to define the pathophysiologic changes in the spleen during acute malaria. In animal models, malaria is accompanied by increased intravascular clearance of infected or rigid, heat-treated cells by the spleen,[31] alterations in the splenic microcirculation,[32] and myelomonocytic recruitment to the spleen and liver.[33] In studies of human malaria it has been found that increased splenic clearance of heated red cells occurs during acute attacks.[34]

Changes to the uninfected red blood cells during infection also contribute to their own enhanced clearance by phagocytes. Uninfected red cells in children and adults with severe disease are less deformable and this is a significant predictor of the severity of anemia and indeed outcome, consistent with the notion that these cells are being removed by the spleen.[20] It has also been found that immunoglobulin (Ig) G-sensitized red cells are rapidly removed from the circulation by the spleen and that unusually rapid clearance persists well into the convalescent phase.[35]

Thus, all the available evidence points to increased reticuloendothelial clearance in *P falciparum* malaria, persisting long after recovery. These changes are presumably a host defence mechanism, maximizing the clearance of parasitized erythrocytes.

The Role of Ineffective Erythropoiesis in Severe Malarial Anemia

Reticulocytopenia has been confirmed in numerous clinical studies of malarial anemia.[36,37,38] The histopathologic study of the bone marrow of children with malarial anemia shows erythroid hyperplasia with increased numbers of erythroid precursors (Fig. 159–4). However, the maturation is abnormal by light and electron microscopy. Abdalla and Weatherall described the hallmark characteristics of such abnormal maturation, namely cytoplasmic and nuclear bridging and irregular nuclear outline.[39,40] They later confirmed that the distribution of the erythroid progenitors through the cell cycle is abnormal in malarial anemia, with an increased proportion of cells in the G2 phase compared with normal controls.[41] Horstmann and colleagues confirmed these findings using the same criteria as Abdalla, they studied six patients with falciparum malaria before and after treatment.[38]

Ineffective erythropoiesis also contributes to anemia in animal models of malaria. A recent study has shown that vaccinated *Aotus* monkeys, after a challenge infection, may develop moderate to severe anemia following rapid clearance of uninfected erythrocytes but with low reticulocyte counts, indicating bone marrow dysfunction.[42] Erythropoiesis is disrupted in mice during malaria infection. Mice infected with *P berghei* show reduced bone marrow cellularity, erythroblasts, BFU-E, and CFU-E as early as 24 hours postinfection.[43] The cellularity and CFU-S content of the femoral marrow of BALB/c mice infected with *P chabaudi adami* decreases as the parasitemia increases.[44]

Schofield and colleagues have outlined the transcriptional profile of genes in the brain and spleen of mice infected with *P berghei* ANKA. In murine splenocytes, enzymes of the glycolytic pathway and interferon-inducible genes were upregulated whereas genes associated with erythropoiesis were suppressed.[45]

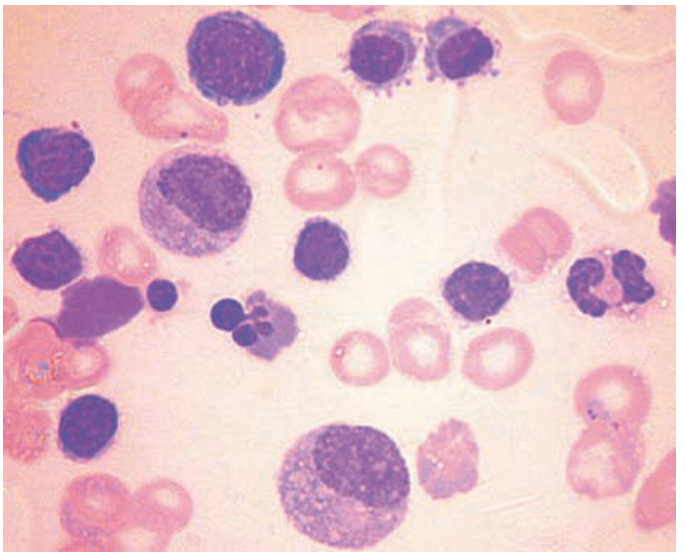

Figure 159–4 Bone marrow aspirate in malaria. Although erythropoiesis is usually normoblastic in individuals with acute or chronic malaria, the examination of bone marrow frequently shows changes reflecting dyserythropoiesis, such as the irregular nuclei and cytoplasmic bridges in erythroblasts seen in this figure. Two young rings of *Plasmodium falciparum* can be seen in an erythrocyte. (*Giemsa stain × 900*). *(Courtesy of Dr Saad H. Abdalla.)*

Modulation of Erythropoiesis by Cytokines

Given the importance of erythropoietin (Epo) to erythropoiesis, attention has been focused on the levels of this crucial cytokine in malarial infection. Serum Epo was appropriately raised in a single study of African children suffering from malarial anemia.[46,47] However, other studies in adults from Thailand and Sudan have suggested that the Epo concentration, although raised, was inappropriate for the degree of anemia.[48,49] The most recent studies of the level of Epo in African children have shown a supraphysiologic rise in Epo levels compared to age-matched community controls with nonmalarial anemia.[50] These data would support a hypothesis that high levels of Epo in malaria anemia may exert a cytoprotective effect and improve the outcome in severe malaria.

The prime candidates for the host factors mediating dyserythropoiesis are imbalances of the tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), and interleukin-10 (IL-10). The concentrations of TNF-α and IFN-γ have been correlated with the severity of the disease.[51–53] Whereas low concentrations of TNF-α (<1 ng/mL) stimulate erythropoiesis, higher levels of TNF-α have been shown to suppress erythropoiesis.[53] Furthermore, it is possible that high levels of these inflammatory cytokines may contribute to reduced and abnormal production of erythrocytes, and also to increased erythrophagocytosis.

Recent evidence has suggested that the release of macrophage inhibitory factor (MIF) inhibits the growth of early erythroid and myeloid progenitors during murine malaria infection[54] and $MIF^{-/-}$ mice are protected from anemia during experimental malaria infection.[55] However, the role of MIF in human malaria infection has not been established.

High levels of the Th2-type cytokine, IL-10, might prevent the development of severe malarial anemia. Low levels of IL-10 have been described in African children with severe malarial anemia.[51] Similarly, defective IL-12 production has been shown experimentally to be associated with increased severity of malaria in a rodent model and

low IL-12 levels have been associated with severe malaria in African children.[56–59]

Modulation of Erythropoiesis by Infected Erythrocytes

There is also substantial evidence that lysate of infected erythrocytes may directly modulate the function of host cells. During its blood stage, the malaria parasite proteolyses host hemoglobin in an acidic vacuole to obtain amino acids, releasing heme as a by-product, which is autooxidized to potentially toxic hematin (aquaferriprotoporphyrin IX, H_2O–Fe(III)PPIX). β-Hematin forms as a crystalline cyclic dimer of Fe(III)PPIX and is complexed with protein and lipid products as malarial pigment or hemozoin. Arese and colleagues showed that the function of monocytes and of monocyte-derived macrophages is severely inhibited after ingestion of malaria pigment or hemozoin. These cells were unable to repeat phagocytosis and to generate oxidative burst when appropriately stimulated.[60–62] Furthermore, after phagocytosis of hemozoin human and murine myeloid cells were unable to kill ingested fungi, bacteria, and tumor cells[63] and to respond to IFN-γ stimulation, but instead responded by increased release of interleukin-1β (IL-1β) and TNF-α,[64] macrophage inflammatory protein-1α (MIP-1α) and MIP-1β.[65]

The hemozoin polymer of heme moieties may be complexed with biologically active compounds. The oxidation of membrane lipids catalyzed by the ferric heme produces the lipoperoxides.[62,66] There is accumulating evidence that HNE and other lipoperoxides including 15-hydroxy-arachidonic acid (15-(*R*,*S*)-HETE) may play a role in the pathophysiology of malaria. Arese and colleagues showed that HNE and HETE are generated in parasitized erythrocytes and that the toxicity of hemozoin was reduced after removal of lipids. HNE also inhibits the upregulation of surface expression of ICAM-1, VCAM-1, and E-selectin following TNF-stimulation.[67] Moreover, endoperoxides produced in pigment-containing monocytes or macrophages may impair erythroid growth.[68] Hemozoin may also directly inhibit erythroid development in vitro and increased levels of plasma hemozoin and pigment in monocytes have been associated with anemia.[50]

Modulation of Erythropoiesis by Infection

In children presenting with acute malaria, bacteremia is associated not only with anemia but also with excess mortality.[69] Parvovirus B19 may cause a transient reticulocytopenia and thus severe and sudden anemia in those suffering from a hemolytic anemia or fetal anemia and intrauterine death.[70] Most children in Africa have serologic evidence of infection early in life. However, acute infection with this virus is uncommon in those presenting with severe malarial anemia.[47,71]

Prevalence and Etiology of Anemia in the Developing World

In endemic areas the etiology of anemia is complex. Acute or chronic malaria infection is a major precipitating factor in children with severe anemia causing admission to hospital.[47]

Longitudinal studies from the Gambia have shown that whereas the mean hemoglobin levels in children varies significantly through the year, anemia is much more common in the rainy season when malaria transmission is its highest.[72] However, the rains are also associated with an increase in water-borne diarrheal disease and poor food supplies. So the seasonal increase in anemia in malaria endemic areas arises on a background of low or frankly deficient stores of hematinics and/or other micronutrients. Iron deficiency, which affects at least 20% of the world's population, is a major factor in the seasonal surge of anemia in the tropical rainy season. Low iron stores at birth and dietary iron deficiency may be exacerbated by hookworm or schistosomal infection. Folate deficiencies and/or increased requirements may occur in many populations, although frank folate deficiency is uncommon. Recent studies have shown that a low baseline hemoglobin level at the start of the season for malaria transmission is a major risk factor for developing severe malarial anemia.[73]

Quantifying the contribution of these individual factors to anemia reliably requires intervention studies. In Tanzania, Menendez and Alonso and their colleagues have shown that iron supplementation and antimalarial prophylaxis prevented 30% and 60%, respectively, of all cases of moderate anemia presenting during the malaria transmission season.[74] The same group preformed another trial, giving sulphadoxine-pyrimethamine or placebo at the same time as routine vaccinations delivered through the WHO Expanded Program on Immunisation (EPI). All children received iron supplementation between 2 and 6 months of age. This simple intervention reduced severe anemia by 50% compared to the placebo group, whereas serologic responses to EPI vaccines were not affected by the intervention.[75]

There is now widespread interest in repeating these trials elsewhere to define strategies to prevent anemia in children living in areas with different patterns of malaria endemicity.[76]

Features of Malarial Anemia

The Spectrum of Disease Caused by Malarial Infection

The signs and symptoms of malarial infection in humans are caused by the asexual blood stage of the parasite. Infection with blood-stage parasites may result in a wide range of outcomes and pathologies. Indeed, the spectrum of severity ranges from asymptomatic infection to rapidly progressive, fatal illness. The clinical presentation of malarial infection is also wide and influenced by age, immune status, and pregnancy and by the species, genotype, and perhaps the geographic origin of the parasite. In endemic areas, many infections present as an uncomplicated febrile illness. In more severe forms of the disease, children may present with prostration or inability to take oral fluids or in younger children and inability to suckle. Alternatively, they may exhibit a number of syndrome(s) of severe disease, including anemia, coma, respiratory distress, and hypoglycemia and may also have a high rate of bacteremia.[69,77]

In most age groups, anemia is frequently accompanied by more than one syndrome of severe disease, and the already substantial case fatality rate of 15% to 20% for severe malaria in African children rises significantly when multiple syndromes of severe disease are present.[77]

The age distribution of anemia and other syndromes of severe disease are a consistent but puzzling feature of the epidemiology of clinical malaria. Children born in endemic areas are protected from severe malaria in the first 6 months of life by the passive transfer of maternal immunoglobulins and by fetal hemoglobin. Beyond infancy, the most common form of presentation of severe disease changes from anemia in children aged 1 to 3 years old, in areas of high transmission, to cerebral malaria in older children, in areas of lower transmission.[78] As transmission intensity declines further, severe malaria is most frequently found in older age groups.

The Clinical Features of Malarial Anemia

The blood stage of falciparum malaria may cause life-threatening anemia; a hemoglobin level of less than 5 g/dL is considered to represent severe disease. Children with anemia may present with malaise, fatigue, and dyspnea or respiratory distress, which usually represents metabolic acidosis, but in an ill child acute respiratory infection must be carefully excluded.[77,79,80]

Acidosis is largely due to excessive lactic acid and other anions. Salicylate toxicity and dehydration may also play a role. However,

the majority of children presenting with respiratory distress are severely anemic, have a metabolic acidosis secondary to reduced oxygen-carrying capacity and respond to rapid transfusion of fresh blood (for a review, see reference 81). A minority of those with respiratory distress do not respond to appropriate resuscitation. They probably represent a heterogeneous clinical group and may have renal failure, systemic bacterial infection, or a more profound syndrome of systemic disturbance due to malarial parasites.

Hemolytic Syndromes Including Blackwater Fever

The sudden appearance of hemoglobin in the urine indicating severe intravascular hemolysis leading to hemoglobinemia and hemoglobinuria or blackwater fever received particular attention in early studies of anemia in expatriates living in endemic areas.[82] There was an association between blackwater fever and the irregular use of quinine for chemoprophylaxis. This drug can act as a hapten and stimulate production of a drug-dependent complement-fixing antibody. Recent studies of sudden intravascular hemolysis have shown it is rare in Africa, but more common in Southeast Asia and Papua New Guinea, where some cases are associated with G6PD deficiency and treatment with variety of drugs including quinine, mefloquine, and artesunate.[83] However, in the majority of cases, the cause of sudden hemolysis cannot be accounted for and it seems likely unidentified hemolytic mechanism(s) may operate.

The Hematologic Features of Malarial Infection

The anemia of falciparum malaria is typically normocytic and normochromic, with a notable absence of reticulocytes, although microcytosis and hypochromia may be present because of the very high frequency of alpha and beta thalassaemia traits and/or iron deficiency in many endemic areas.[47,71]

The anemia of malaria may be accompanied by changes in the white cell and platelet counts and in clotting parameters, but these changes are neither in themselves diagnostic nor guide management. Malaria is accompanied by a modest leucocytosis, although leucopenia may also occur. Occasionally, leukemoid reactions have been observed. Leucocytosis has been associated with severe disease.[84,85] A high neutrophil count may also suggest intercurrent bacterial infection. Monocytosis and increased numbers of circulating lymphocytes are also seen in acute infection although the significance of these changes is not established.[86] However, malarial pigment is often seen in neutrophils and in monocytes and has been associated with severe disease and unfavorable outcome.[87,88]

Thrombocytopenia is almost invariable in malaria and so may be helpful as a sensitive, but nonspecific marker, of active infection. However, severe thrombocytopenia ($<50 \times 10^9$/L is rare. Increased removal of platelets may follow absorption of immune complexes, but there is no evidence for platelet-specific alloantibodies.[89] By analogy with erythropoiesis, there may be a defect in thrombopoiesis but this has not been established. Thrombocytopenia is not associated with disease severity, although somewhat paradoxically platelets have been shown to contribute to disease pathology in animal and in human malaria.[90,91] Moreover, in human infections, platelets may form clumps with infected erythrocytes.[92] One explanation of this paradox could be that low levels of platelets might not only be a marker of parasite burden but also be protective from severe disease and/or be associated with antiinflammatory cytokine responses.[93]

Disordered coagulation and clinical evidence of bleeding are not infrequent in nonimmune adults contracting malaria and presenting with severe disease. Patients may present with bleeding at injection sites, gums, or epistaxis. Abnormalities of laboratory tests of hemostasis, suggesting activation of the coagulation cascades, occur in acute infection. However, histologic evidence of intravascular fibrin deposition is notably absent in those dying from severe malaria in adults.[94] Factor XIII, normally responsible for cross-linking fibrin, is inactivated during malaria infection, and these data may explain low levels of fibrin deposition in the face of increased procoagulant activity.[95]

The bone marrow is typically hypercellular. The most striking findings are of grossly abnormal development of erythroid precursors or dyserythropoiesis. The developing erythroid cells typically demonstrate cytoplasmic and nuclear bridging and irregular nuclear outline.[39,40] These changes are probably central to the pathophysiology of malarial anemia and are discussed in detail below. The proportion of abnormal erythroid precursors and the degree of dyserythropoiesis are markedly greater in chronic compared to acute infection, suggesting that the inhibition and abnormal maturation of erythroid precursors may have somewhat differing etiologies in acute and chronic infection.[39]

The role of hematinic deficiency in children presenting with malaria and anemia may be difficult to assess. The relative importance of absolute and functional iron deficiency have not been defined. Nevertheless, many hospitals give a course of iron supplementation after an episode of acute malaria, although no general guidelines have been established. Chronic hemolysis may increase folate requirements, but frank deficiency is uncommon in children presenting with acute malaria, at least in East Africa.[47] Folate deficiency may be more common in West Africa and protocols for folate supplementation after malaria must reflect local experience.

Malarial Anemia in Pregnancy

Pregnancy is accompanied by a series of physiological changes that predispose not only to anemia but also to malaria. Hemodilution causes a physiological decrease in hemoglobin. Moreover, the demand for both iron and folate increases as the fetus grows and often precipitates frank folate or iron deficiency, particularly in multigravid women.

Occult malaria infection, often without fever, may cause anemia and placental dysfunction. This effect is greatest in primigravidae and has been attributed to the adhesion of parasitized erythrocytes to chondroitin sulfate A and hyaluronic acid in the placenta (for reviews, see references 98 and 99).[96,97] Fetal growth is impaired and babies born to women with placental malaria are on average 100 g lighter than controls born to women without malaria. The subsequent contribution of malaria to infant mortality is substantial.[100] Furthermore, the increase in hematopoiesis demanded by hemolysis during malaria infection may precipitate frank folate deficiency. Finally, women who are not immune to malaria are more likely to develop hypoglycemia and pulmonary edema during pregnancy.

The increase in maternal and fetal morbidity and mortality secondary to malaria may be prevented by routine hematinic supplementation and by intermittent treatment with antimalarials during the second and third trimesters with sulphadoxine-pyrimethamine (Fansidar).[101]

Hyperreactive Malarial Splenomegaly

Although splenomegaly, secondary to malarial infection, usually regresses as immunity is acquired, some people living in endemic areas develop progressive, massive splenomegaly.[102] The pathophysiology of such hyperreactive malarial splenomegaly (HMS) is poorly understood but certainly results in B-cell hyperplasia with high levels of polyclonal IgM, reaching a level greater than 2 SD above the local reference mean. The specific antimalarial antibody titer is high, although only a small proportion of the polyclonal IgM response is directed at malarial antigens. B-cell hyperplasia may provoke proliferation of both T cells and macrophages and IgM levels may cause cryoglobinemia and stimulate erythrophagocytosis.

Patients may present typically between 20 and 40 years old, with massive splenomegaly without lymphadenopathy, anemia that may be severe, neutropenia, and thrombocytopenia. The anemia may cause life-threatening hemolytic crises and/or neutropenia associated

with severe bacterial infection. Thrombocytopenia is rarely symptomatic. The bone marrow shows hypercellularity, with a lymphocytosis in marrow and peripheral blood. The high IgM levels distinguish HMS from CLL or other lymphoproliferative disorders. However, the polyclonal proliferation of B cells may transform to a true clonal lymphoproliferative disorder. This appears to be derived from a naïve B cell, although the exact classification of such lymphoproliferative disorders is poorly defined,[103] although there is a single report of a high incidence of B prolymphocytic leukemia in one population.[104]

Treatment for HMS is life-long antimalarial prophylaxis. Regression of signs and symptoms returns over 1 to 2 years but may relapse if antimalarial therapy ceases. Splenectomy is contraindicated as it is technically difficult, with considerable interoperative mortality and may predispose to severe infection.

Anemia and *P vivax*, *P ovale*, and *P malariae* Infection

In *P vivax* and *P ovale* malaria, high parasitemias are rare as invasion of erythrocytes is limited to reticulocytes. The parasites do not appear to sequester in the peripheral circulation or to cause organ-specific syndromes. Mortality is limited to occasional deaths from splenic rupture and from intercurrent illnesses in already weakened individuals.

Nevertheless, *P vivax* malaria has been clearly associated with anemia during pregnancy and with low birth weight of children of affected mothers. Here cytokines or other inflammatory mediators appear to cause placental dysfunction.[105] *P malariae* infection is also rarely fatal but is distinguished by the persistence of blood-stage parasites for up to 40 years. It can however cause a progressive and fatal nephrotic syndrome.[106]

Malaria Diagnosis

The diagnosis of malaria is based on the identification of circulating blood-stage parasites. The standard methods of preparing thick and thin films are straightforward and allow a simple method to diagnose infection (Table 159–1).[107–109] However, malaria diagnosis poses particular problems for inexperienced staff. The main biological problem is that the level of circulating parasites is only weakly associated with the overall parasite burden as falciparum-infected erythrocytes are sequestered in capillary venules; thus the parasitemia is not a reliable guide to the severity of disease. Second, missing or delaying the diagnosis of falciparum malaria may result in serious morbidity and mortality. Finally, the most sensitive methods for diagnosis of infection, namely microscopy, require both skill and time.

Table 159–1 Malaria Diagnosis

Thick and thin films should be prepared for cases of suspected malaria.
Immunochromographic tests lack sensitivity to detect low levels of parasites that may be highly clinically significant.
Routine Giemsa or May–Grünwald–Giemsa stains are unlikely to give satisfactory results as the pH is too low.
Films can be stained with Giemsa or Leishman stain (thin films) or Field stain (thick films). (For details see *Guideline: The Clinical Diagnosis of Malaria*, www.bcshguidelines.org).
200 high-power fields (×100 objectives) should be examined in a thick film.
Asexual parasitemia should be reported after counting 1000 RBCs in a thin film. A graticule or grid may help counting.
If parasitemia is less than 1 : 1000 RBCs, parasitemia may be counted in a thick film in relation to the number of WBCs.
During active infection, daily parasite count should be obtained.
Counting and speciation of malaria parasites should be verified by a second observer.
Reports on negative films despite a strong clinical suspicion of malaria should be qualified that negative films do not exclude a diagnosis of malaria. Repeat films should be requested if clinically appropriate. Thrombocytopenia may heighten suspicion of malaria.

In endemic areas, laboratory staff are skilled at the examination of thick films and routinely are able to detect 1 parasite in 100 HPFs of a thick film, which corresponds to a sensitivity of approximately 5 to 50 parasites/μL.[107,110] Thin films are used for speciating parasites and the circulating asexual forms of the four main malaria species can be readily identified, whereas the sexual forms (gametocytes) of the species require some skill and regular practice (Figs. 159–5 and 159–6).

Nevertheless, diagnosis of malaria by microscopy in nonendemic countries has proven problematic. Routine laboratories may only achieve sensitivities of the order of 500 parasites/μL using thick films.[110,111] Quality assurance schemes show that performance of routine hematology laboratories in the recognition of and speciation of malaria parasites is poor.[109,111]

There has therefore been a strong drive to use nonmicroscopy methods for malaria diagnosis. It is now apparent that these methods are not sufficiently sensitive for clinical diagnosis, although they may have a role in detecting parasites of more than 500 parasites/μL when experienced staff are not available and/or as part of an out-of-hours service. However, it must be emphasized that these tests are no substitute for careful microscopy. Operationally this means that hematology labs need to make the diagnosis of malaria and must maintain the skills needed for reliable examination of thick films.

A number of methods based on the fluorescent staining of parasite DNA and/or RNA and the concentration of parasites have been devised.[112–114] However attractive these methods may appear, their sensitivity is limited by background staining of cellular debris and the limit of their sensitivity is approximately 100 parasites/μL. The time taken in preparing samples and the specialized equipment and skills needed to use these methods limits their effectiveness in routine practice.

Detection of circulating malarial antigens is another potentially attractive, but ultimately limited, alternative to the laborious method of screening blood films. The widely available tests detect Plasmodium histidine rich protein-2 (Binax test, Launch Diagnostics Ltd), and Plasmodium-specific lactate dehydrogenase (OptiMal-IT test, TCS Biologicals, UK) by immunochromatography.[115] The formulation of the tests using dipstick antigens allows rapid testing to be performed by laboratory staff. However, the sensitivity is 100 to 1000 parasites/μL and this is comparable to the sensitivity achieved by inexperienced but not experienced microscopists. The current recommendations for malaria diagnosis in the United Kingdom emphasize clearly that these tests only have a place when experienced staff are not available.

Amplification of circulating parasite DNA using the repeated rRNA genes is an extremely sensitive method of malaria diagnosis.[116] The sensitivity may be as low as 0.005 parasites/μL or 5 parasites/mL.[117,118] Undoubtedly, this is a useful tool for reference laboratories but is not yet in routine diagnostic use.

Treatment

Malaria requires urgent effective chemotherapy to prevent progression of disease and may be the most crucial public health intervention to reduce global mortality from malaria. The drug treatment of malaria must take account of the expected pattern of drug resistance in the area where infection was contracted, the severity of clinical disease, and the species of parasite. The spread of drug-resistant parasites and the optimal use of affordable, effective drugs are of continual concern and these have recently been reviewed (Table 159–2).[119–121] Artemisinin-based combination treatments have been the mainstay of treatment for falciparum malaria in Southeast Asia for more than

Text continued on p. 2353.

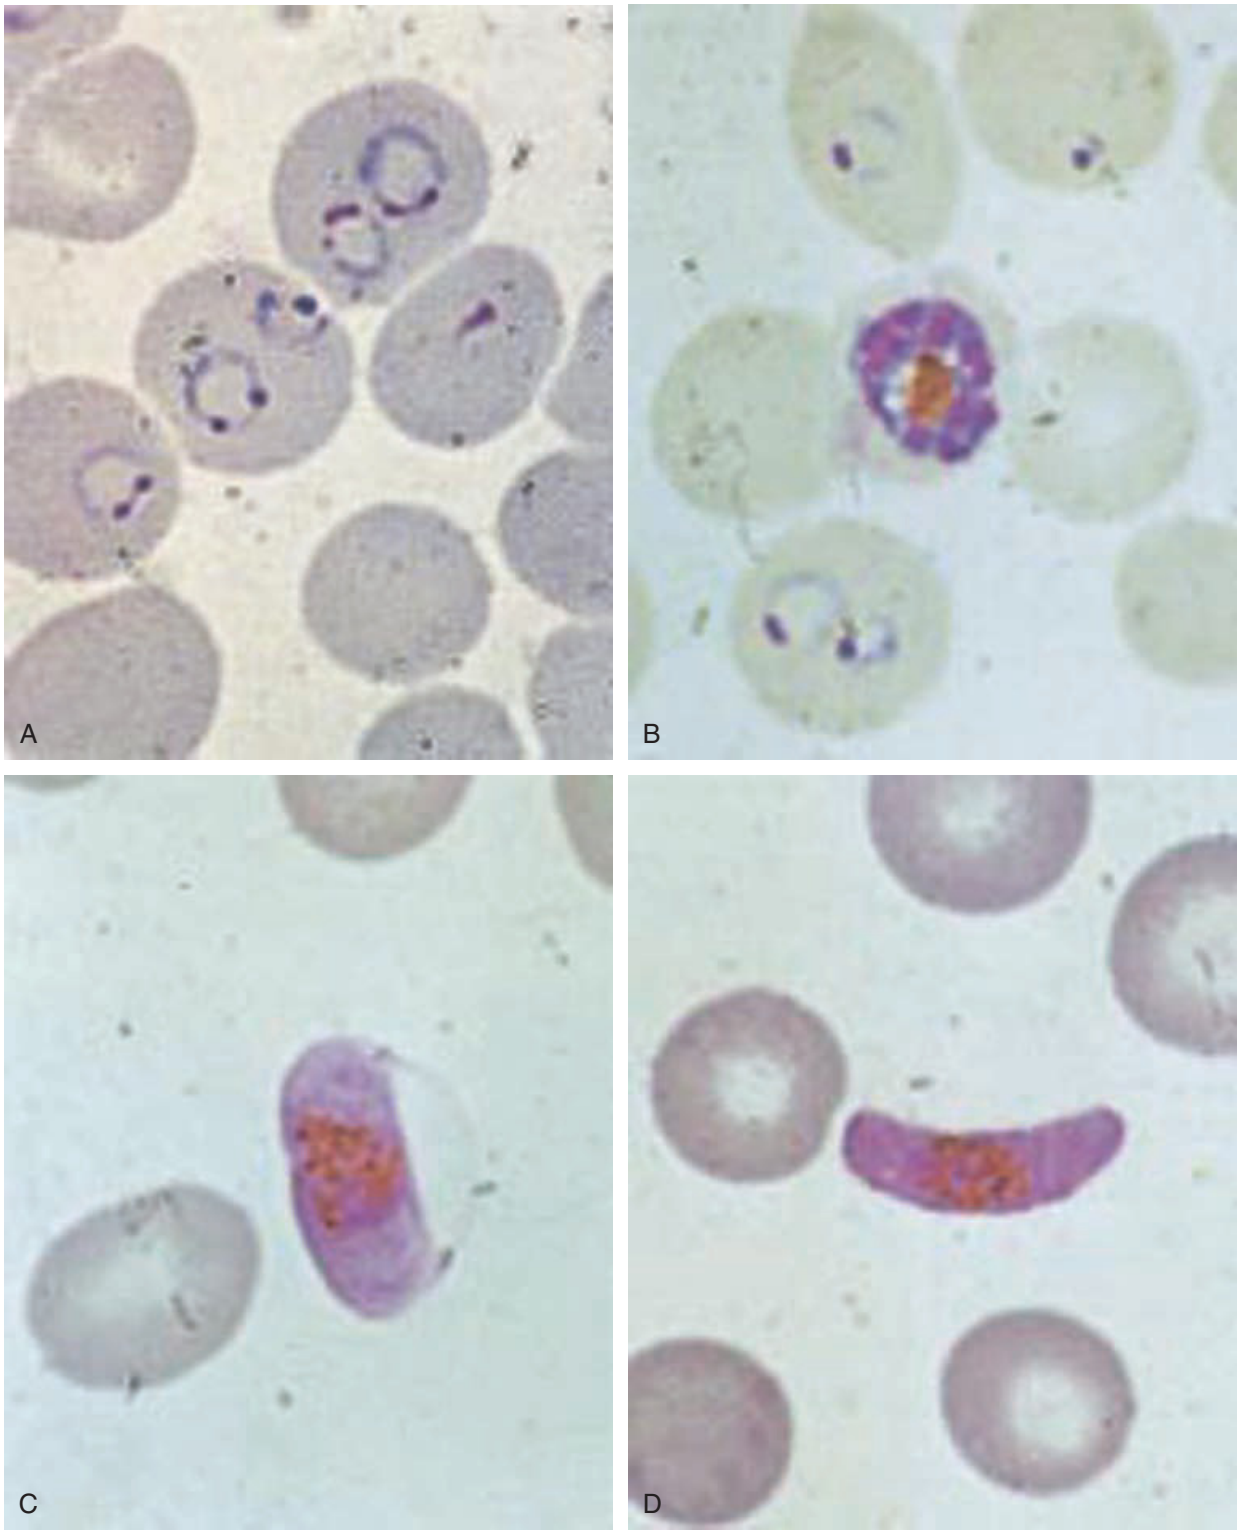

Figure 159–5 Blood stage malaria (thin blood films). *Plasmodium falciparum*: Fine rings (**a**) predominate, with mature trophozoites and schizonts (**b**) appearing uncommonly in the peripheral circulation because infected cells adhere to postcapillary venules. Host cells are not enlarged. Basophilic clefts and spots of irregular shape and size (Maurer clefts and dots) may be seen in erythrocytes containing more mature parasites. They are thought to be aggregates of parasite proteins that are being exported from the parasite to the surface of the red cell. Crescent-shaped male (**c**) and female gametocytes (**d**) are diagnostic. (*Giemsa* × *1500*). *Plasmodium vivax*: All stages of asexual parasites—from young trophozoites

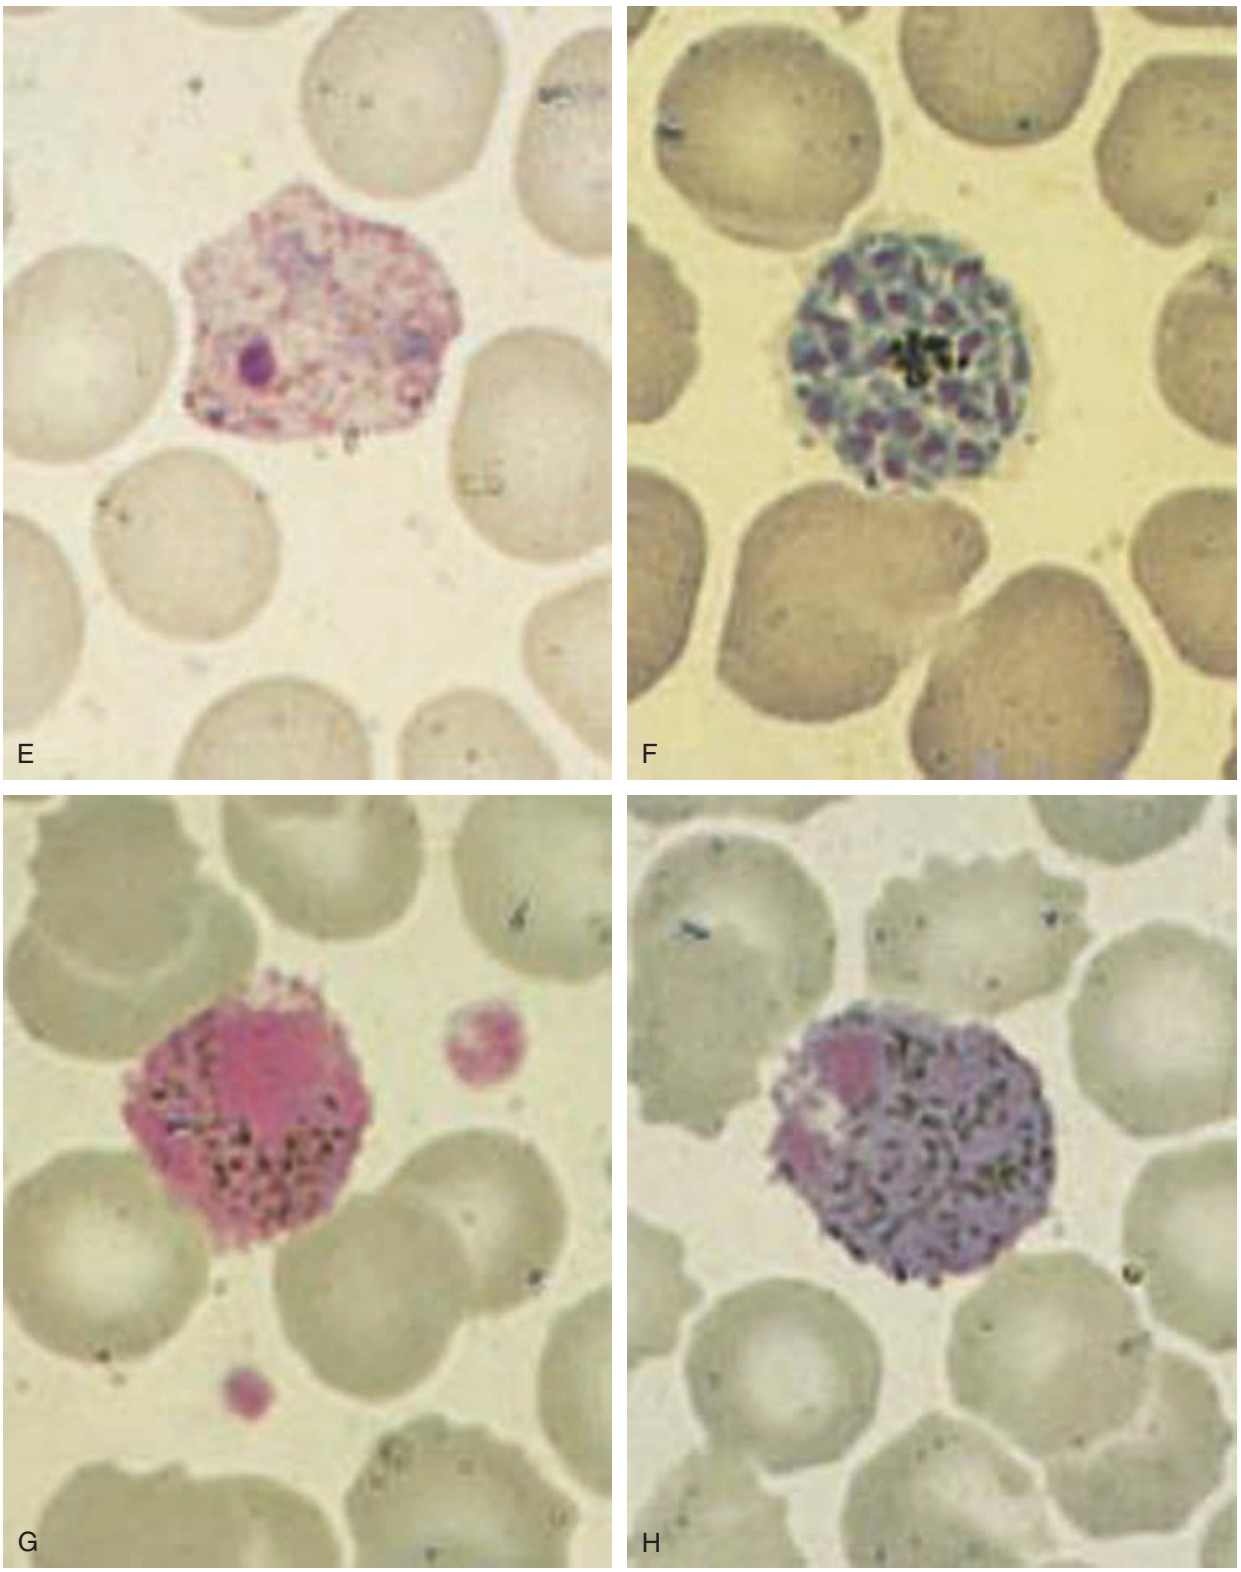

Figure 159–5, cont'd (**e**) to schizonts—appear in the peripheral circulation in vivax malaria together with gametocytes. The parasites are large and ameboid, and produce schizonts with approximately 16 daughter cells (merozoites) (**f**). Pigment is well developed. Host red cells are enlarged and uniformly covered with fine eosinophilic stippling (Schüffner dots). Gametocytes are round, with the male (microgametocytes; (**g**) being approximately 7 μm, and the female (macrogametocytes; (**h**) being 10 μm or more in diameter. (*Giemsa × 1500*). *Plasmodium ovale*: Intraerythrocytic ring forms

(Continued)

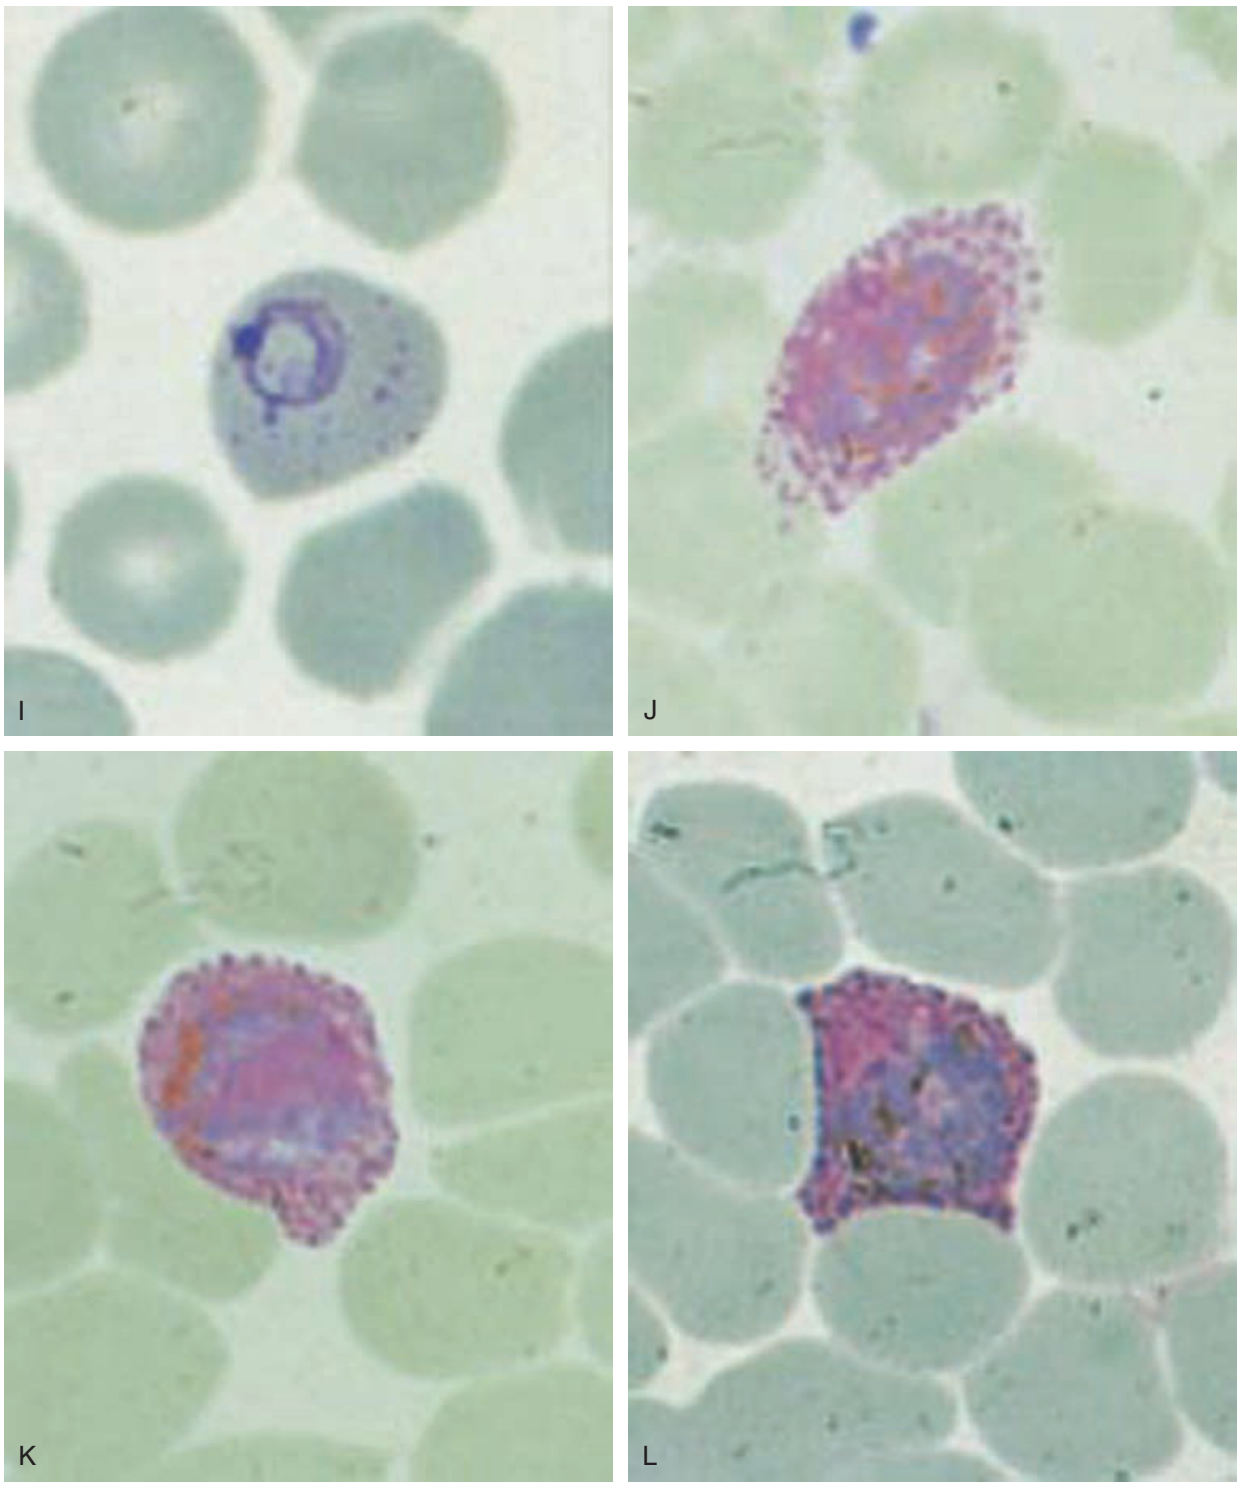

Figure 159–5, cont'd (**i**) have a prominent nucleus. The older parasites (**j**) differ from *P vivax* in being more compact and producing about eight merozoites at schizogony. Like *P vivax*, the host red cells contain Schüffner dots and tend to be ovoid and fimbriated. Male (micro-) and female (macro-) gametocytes (**k** and **l**) are smaller than those of *P vivax*. (*Leishman × 1500*). *P malariae*: All intraerythrocytic stages may appear in the peripheral circulation, from young trophozoites

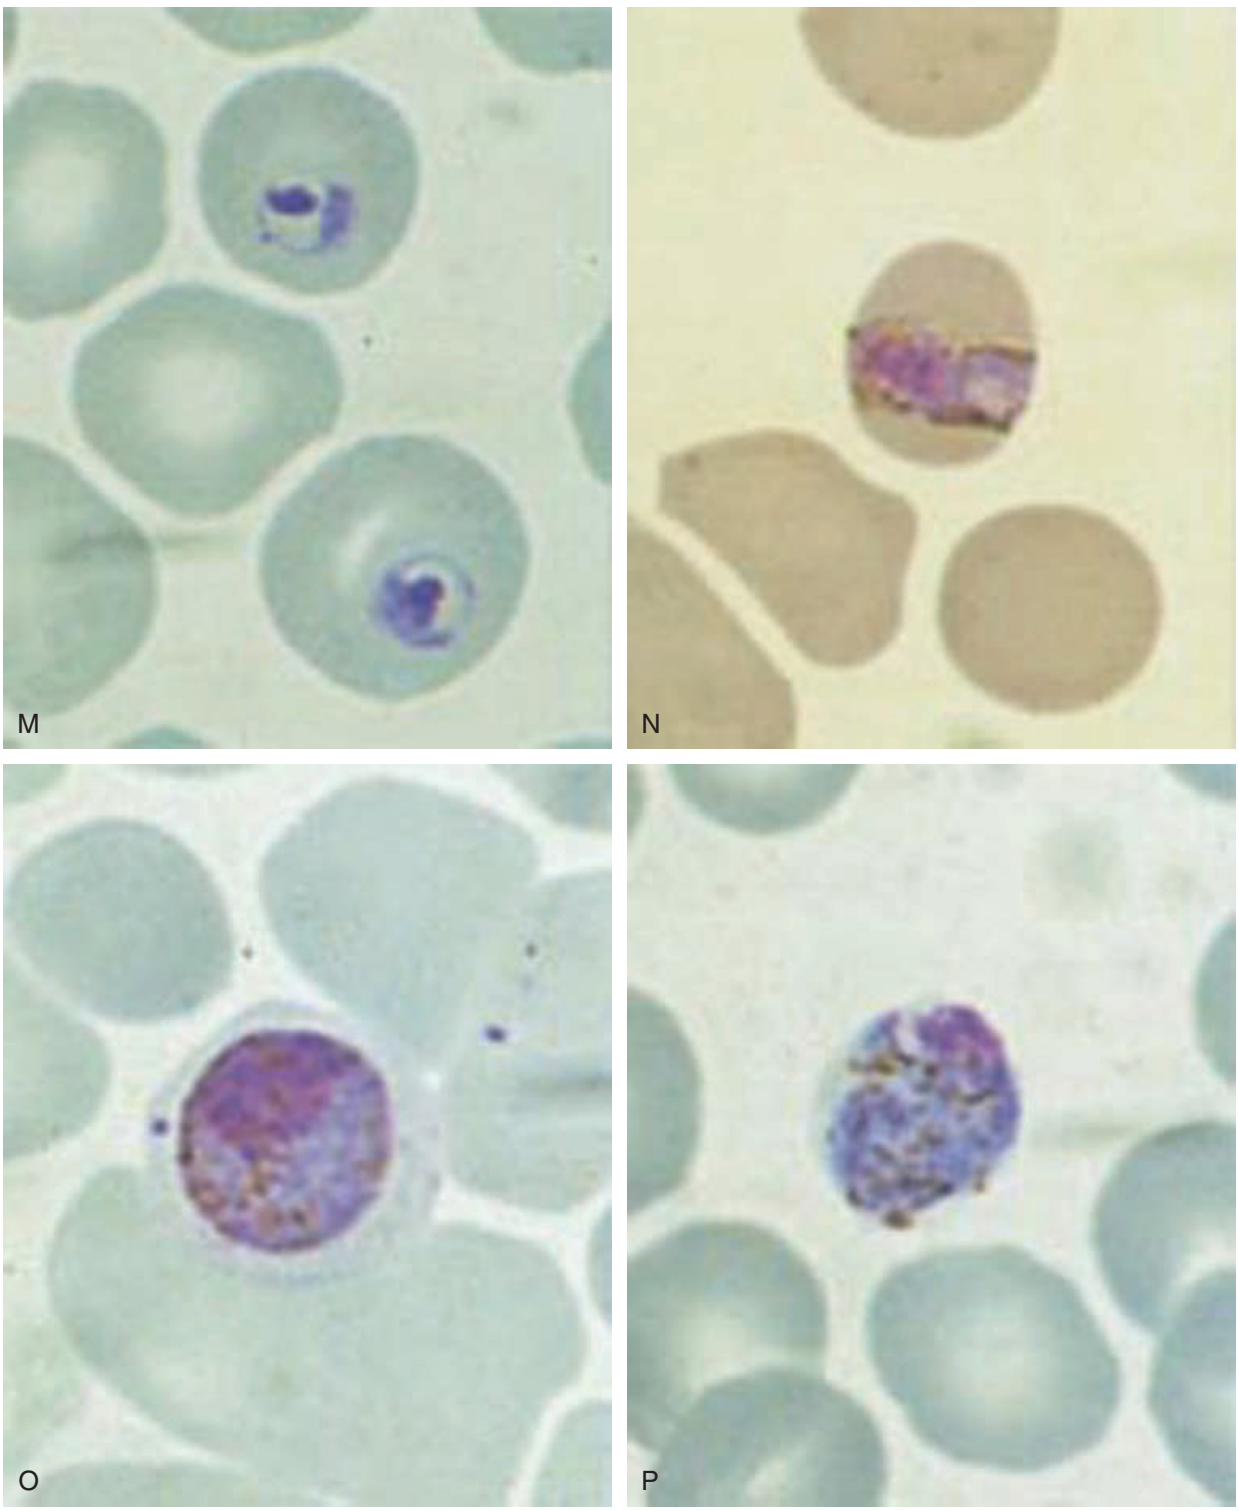

Figure 159–5, cont'd (**m**) to compact schizonts with eight merozoites. Band forms (**n**) stretching across the red cell are common. With special staining, a very fine stippling (Ziemann dots) is sometimes seen. Host red cells are not enlarged. Gametocytes, no larger than their host cells, are round and compact with distinct blackish pigment, being finer in the males (**o**), in which the nucleus is more diffuse and the cytoplasm somewhat mauvish, whereas the granules are fewer and larger in the female (**p**), which stains a bluer color. (*Leishman × 1500*)

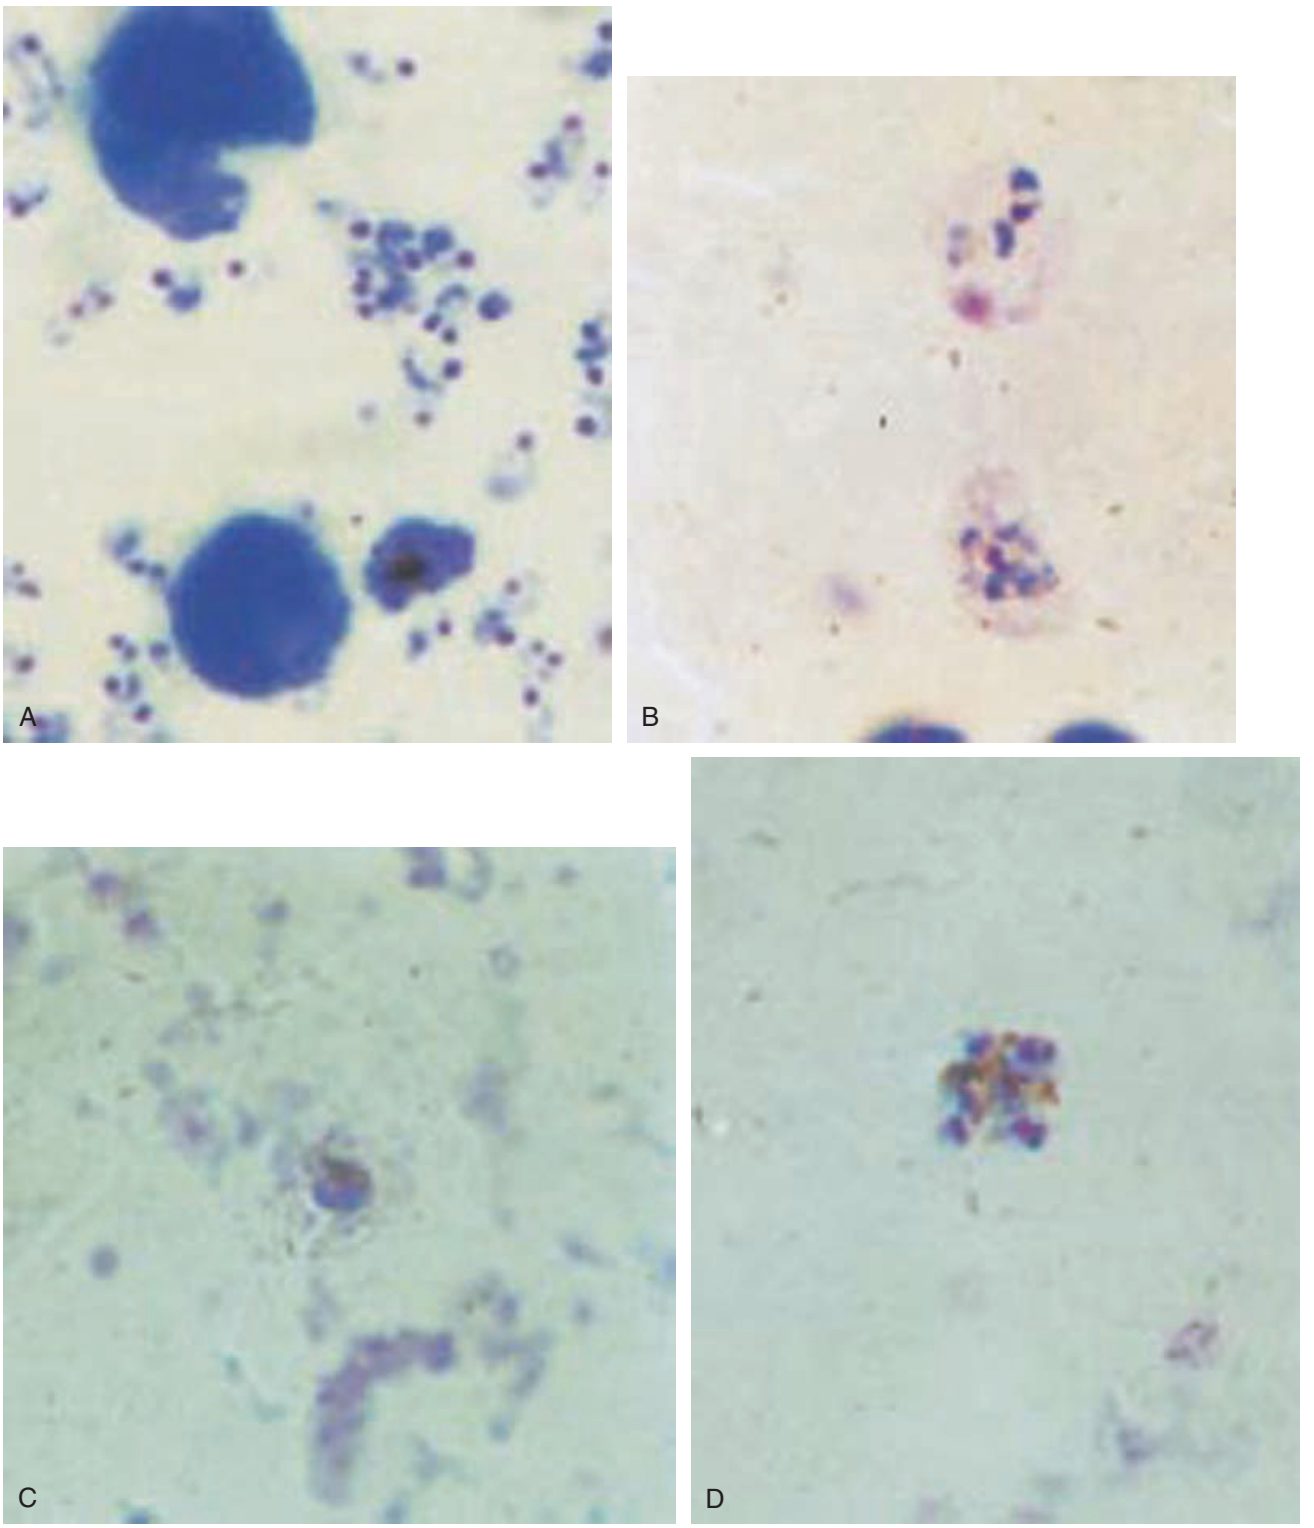

Figure 159–6 Blood-stage malaria (thick blood films). *Plasmodium falciparum*: Usually only young rings (**a**) are seen in acute infections, although sometimes in very large numbers. *Plasmodium vivax*: All stages may be present; here two young trophozoites are seen (**b**), with Schüffner dots seen as "ghost cells" in the thinner parts of the film where the host cell has been hemolyzed. *Plasmodium ovale*: The Schüffner dots of *P ovale* also may show up in a thick film as a ghost cell, but the parasite can be distinguished from *P vivax* by the solid appearance and heavy pigment even of young trophozoites (**c**). *Plasmodium malariae*: Younger parasites can be recognized by their heavy pigment, but this may be so heavy that it obscures the other inner structures. Schizonts containing up to eight merozoites with a central mass of pigment (**d**) are characteristic. *P malariae* is difficult to differentiate from *P ovale* in thick films, in which the parasites are easily confused. However, unlike *P malariae*, *P ovale* may be seen in ghost cells (**c**). (*Field* × *1500*)

Table 159–2 Commonly Used Antimalarial Drugs and Their Side Effects

	Oral Dose	Parenteral Dose	Side Effects
Sulphadoxine-Pyrimethamine	Sulphadoxine 25 mg/kg Pyrimethamine 1.25 mg/kg as a single dose (max 1500 mg Sulphadoxine and 75 mg pyrimethamine)	For IM injection, doses as for oral	Use with caution in first trimester Causes kernicterus in neonates Skin rashes, fatal Stevens–Johnson syndrome
Amodiaquine	10 mg/kg for 3 days	Not used	Hepatitis Fatal agranulocytosis when used for prophylaxis
Artemether	3.2 mg/kg day 1 1.6 mg/kg days 2–7	3.2 mg/kg IM day 1, then 1.6 mg/kg for 3 days, then oral	Reticuolcytopenia
Artesunate	4 mg/kg OD for 7 days	2.4 mg/kg IM day 1, then 1.2 mg/kg for 3 days, then oral	Reticulocytopenia
Artemether/lumofantrine	Fixed dose combination: artemether (20 mg) with lumofantrine (120 mg), twice daily for 3 days if <15 kg then 1 tablet, 15–25 kg 2 tablets, 25–35 kg 3 tablets, >45 kg 4 tablets		
Quinine	10 mg/kg of salt (max 600 mg) 8 hourly for 7 days	20 mg/kg in 10 mL/kg isotonic fluid over 4 hours, then 10 mg/kg over 2 hours given 12 hourly in children and 8 hourly in adults	Thrombocytopenia, intravascular hemolysis (Blackwater fever) when used prophylactically, nausea, tinnitus, deafness
Mefloquine	15 mg/kg base day 1, 10 mg/kg base day 2	Not given	Psychosis, fits
Halofantrine	6 mg/kg base 6 hourly for 3 doses and repeat after 1 week.	Not given	Delay in AV conduction so prolonged QT interval

10 years and are now increasingly recommended as first-line treatment throughout the rest of the world.[122] The hematologic side effects of antimalarial drugs in use today are few. Amodiaquine is associated with neutropenia and agranulocytosis. Artemisinin-based treatments may cause reticulocytopenia but this is not clinically significant.

In severely ill patients, good nursing care is vital. Monitoring and treatment of fits and hypoglycemia is essential and antipyretics should be given.[123]

Certainly, blood transfusion is in principle a straightforward solution to the treatment of severe malarial anemia, although controversy exists over the trigger for transfusion and the rate of administration of blood. The standard regimes of cautious and slow delivery of blood have been challenged by the demonstration that rapid initial flow rates may correct lactic acidosis and hypovolemia. However, in nonimmunes and in pregnant women, blood transfusion must be accompanied by careful hemodynamic monitoring to avoid precipitating or exacerbating pulmonary edema.

No formal controlled trials for the transfusion of patients with malaria have been performed. Whatever clinical guidelines emerge, in reality blood transfusion in the heartland of malaria-endemic areas is beset by many practical and theoretical problems. First, the absence of well-characterized donor panels (and thus systematic blood collection) frequently jeopardizes the supply of blood. Second, even when standard screening for HIV is in place, the residual risk of HIV transmission in the serologic window of infectivity remains at 1 in 2000.[124] At a practical level, positive indirect antiglobulin tests in acute infection may make the exclusion of alloantibodies difficult. Depending on the clinical urgency and transfusion history, the least serologically incompatible blood may have to be given.

One therapeutic option available in North America and in Europe for the urgent treatment of nonimmune patients with severe disease would be an exchange blood transfusion. This procedure removes nonsequestered, infected erythrocytes and possibly circulating toxins. In the absence of evidence from trials for the use of exchange transfusion in malaria, some have suggested that this treatment could be given for hyperparasitemia (>20%) in severely ill nonimmune patients.[125,126]

The salient features that make this clinical problem a major public health concern are the very large numbers of children affected and the difficulty of satisfactory treatment by blood transfusion outside specialist centers.

Malaria as a Transfusion-Transmitted Infection

Malaria is undoubtedly the most common transfusion-transmitted infection in the world. In endemic areas a large proportion of adult donors will be parasitemic, perhaps 20% to 80% depending on the rate of transmission. Here the donor deferral is impractical and treatment of recipients with a course of effective antimalarials is the most practical alternative.

In nonendemic areas, transmission of malaria is an occasional but potentially devastating complication of blood transfusion, and considerable thought and resources are required to combat the problem effectively.

The first case of transfusion-transmitted malaria (TTM) was in 1911.[127,128] Between 1911 and the mid-1970s the incidence of TTM rose to more than 140 cases per year, with *P vivax* the most common species causing infection, although the proportion of cases due to *P falciparum* has steadily increased, perhaps reflecting the speed and destination of international travel. It is striking that the background problem, namely in malaria in returned travelers, is much more common in the United Kingdom than the United States, with the per capita incidence differing by nearly a factor of 10 and a higher proportion of cases due to *P falciparum* in Europe and the United Kingdom compared with the United States.[129]

Recent experience in the United Kingdom and United States has emphasized the seriousness of transfusion-transmitted malaria. Two of the last five cases of malaria due to blood transfusion in the United

Table 159–3 UK Donor Selection Guidelines for Donors "At-Risk" of Transmitting Malaria

Donor "Risk" Category	Guidelines
Resident	Defined as having lived in Sub-Saharan Africa (except South Africa) or Papua New Guinea for a continuous period of 6 months at any time of life. Permanent deferral unless malaria antibody negative at least 6 months after returning from a malarious area. Any subsequent visits to any malarious area each require a 6-month deferral period and a negative antibody test prior to reinstatement.
History of malaria	Permanent deferral unless malaria antibody negative at least 3 years after cessation of treatment or last negative
Undiagnosed febrile illness	While abroad or within 4 weeks of return Deferral for 12 months or 6 months if malarial antibody negative
All other risks	Deferral for 12 months or 6 months if malarial antibody negative

Kingdom were fatal.[130–132] Whereas in the United States, 14 cases of transfusion-transmitted malaria were reported between 1990 and 1999, but only 2 cases between 2000 and 2005.[133]

Detecting these cases after transfusion is frequently delayed as malaria infection acquired in nonendemic countries rarely figures in immediate differential diagnosis and requires careful examination of the blood film.

The mainstay of preventing TTM in the United Kingdom is donor deferral backed up by detection of circulating antibodies to malaria antigens. The guidelines for donor deferral were carefully revised after analysis of circumstances of recent TTM (Table 159–3).[134] These criteria recognize that malaria in the nonimmune is likely to present within 6 months of return from an endemic area and that significant immunity to falciparum malaria may be acquired by residence after 6 months in a malarious area.

The criteria also required that residents, those having had malaria or an undiagnosed febrile illness, may be reinstated if antimalarial antibodies cannot be detected. The importance of antimalarial antibody testing rests on the fact that it is a very sensitive method to detect chronic infection whereas the identification of circulating malarial antigens or nucleic acids or microscopy would fail to detect a level of 1 parasite/mL, which would still give a highly infectious dose in a unit of blood.

The assays for antimalarial antibodies previously used indirect immunofluorescence antibody tests (IFAT) to detect reactivity to a crude parasite lysate as a target antigen. However, an enzyme-linked immunosorbent serologic assay (ELISA) using recombinant malarial antigens have proved to be a more practical if slightly less sensitive alternative to IFAT.[131,134,135] These tests detect antimalarial antibodies in less than 2% of donors who have visited endemic areas. It has been calculated that the return of 90% of malarial antibody-positive visitors to the donor pool releases an extra 50,000 units a year in the United Kingdom, and this is a highly cost-effective process to reduce the attrition of eligible blood donors.

Donor deferral is based on the potential of a donor to carry malaria and is therefore based on the area of travel, length of stay of residence, elapsed time since leaving the endemic area and history of malaria. It has been repeatedly shown that application of even the most thorough donor questionnaires allows some of those carrying malaria to give blood as guidelines are frequently incorrectly applied or questions answered inaccurately in routine practice.[133,136]

In Canada donors reporting diagnosis or treatment of malaria defer permanently[12] and in the United States donors are deferred 3 years after treatment.[133] The criteria will inevitably cause unnecessary deferral of those who never actually had malaria but also permits some individuals with low-level chronic infection to donate as malaria not infrequently presents more than 3 years after returning from endemic areas.[133,132] The last case of malaria transmitted in the United Kingdom was by someone who left a malarious area 8 years previously and the longest recorded case of recrudescence of malaria infection is 44 years for *P malariae*.

In conclusion, permanent deferral of all those visiting malaria-endemic areas is unlikely to be a viable strategy to prevent TTM as donor bases are declining. Preventing malaria transmission through blood transfusion requires comprehensive, regularly reviewed and effectively implemented guidelines for donor deferral and laboratory testing. Even the best strategy is a compromise and medical laboratory staff should be aware of the rarely, but potentially serious, possibility of fever after transfusion that could be caused by malaria.

VISCERAL LEISHMANIASIS

Leishmaniasis is a generic term of infection by 30 or so species of the obligate intracellular parasites from the genus *Leishmania*. Visceral leishmaniasis or Kala-azar presents with a wide spectrum of systemic and hematologic features.

Epidemiology

Visceral leishmaniasis (VL) occurs in all countries bordering the Mediterranean and across the Middle East, including Saudi Arabia and Yemen. Indian VL occurs in the eastern regions (particularly Assam, Bengal, Bihar, Uttar Pradesh, Madras, and Sikkim) and in Nepal and Bangladesh. African Kala-azar is endemic in Kenya, Ethiopia, and the Sudan and sporadic elsewhere in tropical Africa. In the Americas, VL occurs in foci across Mexico, Central America, Colombia, Venezuela, Guyana, Brazil, Bolivia, and northern Argentina (Fig. 159–7).

The total burden of disease is difficult to estimate but significant. Leishmaniasis burden is endemic in 88 countries, with 500,000 new cases of VL per year, with the vast majority occurring in India, Bangladesh, Nepal, Northern Sudan, and northeastern Brazil.[137] VL is associated with poverty and undernutrition in endemic areas, particularly in the hyperendemic foci of southern Sudan and the Ganges river basin. In the Mediterranean area, it is increasingly seen in association with HIV infection, where infection rates in HIV-infected people may be as high as 10%.

Visceral Leishmaniasis (VL) is caused by a number of species of the *Leishmania donovani* complex.[138,139] In the Mediterranean and areas in the Middle East and Central Asia through to China, *Leishmania infantum* predominates whereas *L donovani* is more prevalent in India and Africa. *Leishmania tropica* is a less common cause of VL in these areas. Throughout their range in the Old World, parasites are transmitted by the female sandfly of the *Phlebotomus* genera.

Leishmaniasis is caused by different parasites and vectors in the New World, where *L chagasi* and *L amazonensis* are transmitted by the *Lutzomyia* genera of sandfly.

Leishmania organisms are present in blood and so the disease can be transmitted by blood transfusion, as a sexually transmitted disease, as a congenital infection, by needle sharing for intravenous drug abuse, or within a laboratory by intradermal inoculation of *L donovani* promastigotes.[140,141] Very few cases of *Leishmania* have occurred as transfusion-transmitted infections in Europe or North America, with under 10 cases in infants or immunocompromised patients over the last fifty years. In endemic areas, this problem represents a much greater but unquantified risk.

Parasitology

Leishmania amastigotes live and multiply within macrophages by binary fission. They are round or ovoid bodies, approximately 2 to

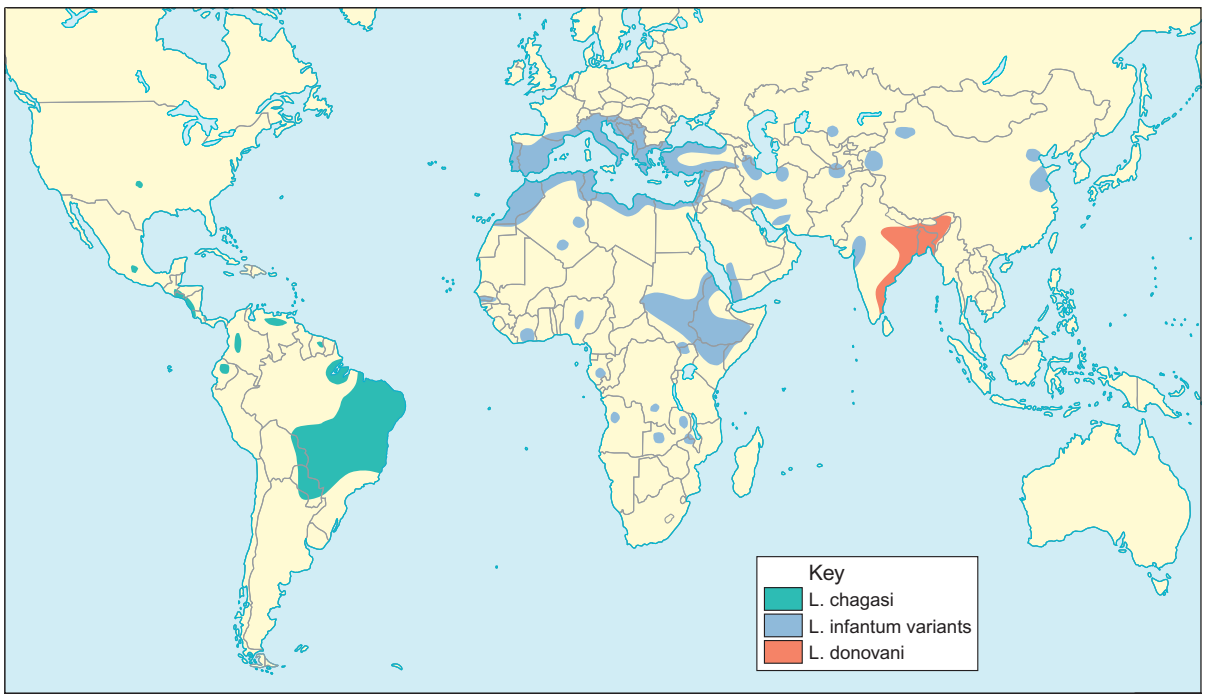

Figure 159–7 Epidemiology of visceral leishmaniasis (VL). VL caused by parasites of the *Leishmania donovani–Leishmania infantum* complex occurs in the Mediterranean littorals, the Middle East, and adjacent parts of the former Soviet Union, the Sudan, east Africa, the Indian subcontinent and China, and South America (*Leishmania chagasi*). An arid, warm environment provides ideal ecologic conditions for the breeding of many species of sandfly. Zoonotic kala-azar due to *L infantum* and *L chagasi* is commonly associated with dry, rocky, hill country where cases are typically scattered. In India, *L donovani* is essentially an anthroponosis. This type of kala-azar may occur in severe epidemic fashion, as can kala-azar in the Sudan.

3 μm in diameter. Occasional rupture of cells allows invasion of uninfected monocytes and macrophages by free forms. Sandflices ingest amastigotes within macrophages from blood or skin. In the insect's stomach, free amastigotes multiply and divide asexually, becoming elongated and developing flagella as metacyclic promastigotes. Within 2 weeks, such infective forms migrate through the lining of the stomach and enter the proboscis of the sandfly, allowing them to be inoculated in the human host while the sandfly takes a blood meal. Promastigotes are taken up by macrophages, where they become amastigotes by simple fission.

The large elongated fusiform promastigote measures 15 to 20 μm in length and 0.5 to 3.5 μm in width. Cultured promastigotes may also demonstrate rounded forms 4 to 5 μm in diameter. In Giemsa or other Romanovsky stains, a large nucleus and smaller distinct rod-like kinetoplast are obvious. The organisms must be distinguished from *Histoplasma capsulatum*.

Pathology

Parasites spread within macrophages to local lymph nodes and then to the liver, spleen, and bone marrow. They are also present more widely, in particular in the gastrointestinal tract and epidermis. In the subclinical cases, a cellular mediated immune response causes a granulomatous lesion and resolution of the infection. However, in clinical VL little if any inflammatory response to the rapidly extensive and expanding parasite-laden parasite macrophages is seen. Where it shows, a granuloma develops at the site of the initial inoculation but may not be apparent at the time of presentation.

Clinical Features of Visceral Leishmaniasis

The spectrum of clinical disease is wide, from asymptomatic infection to acute or chronic illness. Perhaps only 1% to 3% of all infections are symptomatic, with an incubation period of 10 days to 10 years, but it is typically between 3 and 6 months.

The high number of seropositive individuals in relation to clinical cases suggests that spontaneous cure without symptoms or with mild systemic symptoms and hepatosplenomegaly occur in the majority of individuals. In endemic areas, a significant number of seropositive children, who do not develop classical VL, suffer a subclinical form of disease with malaise, fever, poor weight gain, intermittent cough, diarrhea, hepatomegaly, and variable splenomegaly. In these cases, Leishmania were neither cultured nor seen in bone marrow aspirates.[142] There are also reports of VL presenting as mild nonspecific illness with fever, fatigue, cough, and abdominal pain in returning army personnel from the Middle East. In these cases, *L tropica* was isolated from bone marrow or lymph nodes.[143]

Patients with typical, chronic VL often present with malaise and considerable fatigue and the slow onset of low grade fever, anorexia, and weight loss. They usually have anemia, progressive and occasionally massive splenomegaly, hepatomegaly, lymphadenopathy, and hypergammaglobulinemia, with increasing skin pigmentation (hence the name kala-azar from the Hindi for black sickness). Patients may have jaundice, petechia, or purpura, heart murmurs, and edema. The size of the spleen is related to the length of infection and severity of the pancytopenia. In Africa, patients may have diffuse polymorphic papular lesions at presentation. Oral, nasal, nasopharyngeal, and laryngeal ulcers may occur during active disease or after treatment. The large spleen, often extending to the right iliac fossa, may be painful. Other features of acute disease include cough, epistaxis, and in some severe cases concurrent infection of the respiratory or gastrointestinal tracts and/or tuberculosis.

The typical features of VL may be preceded by bacteremia, bacterial infection, acute hepatitis or Guillain–Barré syndrome. VL may be associated with hepatic necrosis, cholecystitis, or neuropathy. Occasionally, lymphadenopathy may occur without systemic features of the disease. Here, histology shows noncaseating granulomas and amastigotes within macrophages.

A more acute presentation in recent migrants and visitors to endemic areas may include a high periodic fever, similar to classical malaria, with malnutrition, bleeding, hepatitis, and/or acute renal failure.

Immunocompromised Hosts

Coinfection of HIV and VL is now a well-recognized clinical entity in the Mediterranean and undoubtedly occurs more widely (for reviews, see references 148 and 149).[144–147] VL occurs in the setting of late-stage AIDS with $CD4^+$ lymphocyte counts of less than 200×10^6/L. Patients present with fever, splenomegaly, and pancytopenia with frequent and sometimes atypical involvement of the gastrointestinal and respiratory systems and skin. The typical hematologic features of VL are sometimes absent and serologic tests are often negative, although antibodies to 14- and 16-kd Leishmania antigens may be detected by Western Blot.[150] However, organisms are plentiful in bone marrow and even in buffy coat preparations. Some patients may have few symptoms and the diagnosis of VL in immunocompromised patients requires a high index of suspicion. Treatment is difficult, with poor responses to pentavalent antimony. Liposomal amphotericin is the drug of choice. However, relapses are usual and maintenance treatment is required.

VL may also occur after transplantation, after immunosuppressive treatments, including chemotherapy or other immunodeficiency states.[151,152] Although patients present with a typical combination of fever, pancytopenia, and splenomegaly, the diagnosis may be missed if not considered.

Hematologic Features

VL causes a moderate normocytic, normochromic anemia.[153] The pathogenesis of anemia is multifactorial and includes hemodilution, shortened red cell survival, and reduced erythropoiesis.[154] The plasma is low, with plentiful stored iron typical of the anemia of chronic disease.[155] One report has suggested that that Epo levels are reduced compared to what would be expected for the degree of anemia.[156] Occasionally, folate deficiency secondary to malabsorption and/or increased cell turnover or coexistent iron deficiency are associated with macrocytic or microcytic anemia, respectively.[157]

The direct Coombs test is usually positive for C3 components and IgG and anti-I agglutinins may be present, but the presence and strength of the test is not correlated with the severity of the anemia. The positive DCT appears to be due to absorbed immune complexes onto erythrocytes.[158] The neutrophil survival is reduced and the differential white count shows neutropenia, relative lymphocytosis, and low eosinophil levels, with a white cell count typically in the range 2 to 4×10^9 L.

Neutrophil function may be impaired.[159] Pancytopenia is more severe in those with concurrent HIV infection. A leukemoid reaction to infection has been reported.

Typically the platelet count is reduced to 50 to 200 10^9 L as platelet survival is reduced. Mucosal bleeding may occur but extensive purpura is uncommon.

The prothrombin time is usually mildly prolonged to 2 to 4 seconds longer than control, secondary to impaired liver function. Fibrinolytic activity is increased and in advanced cases fibrinogen levels may be reduced. Disseminated intravascular coagulation or vasculitis may occur.[153,160] Full coagulation screening is advisable if a splenic aspirate or bone marrow biopsy is planned.

The bone marrow is usually hypercellular, with increased erythroid, myeloid, and platelet precursors. Lymphocytes may be increased and macrophages contain Leishman–Donovan bodies (Fig. 159–8). If weight loss and malabsorption are extensive, the marrow may undergo gelatinous transformation.[161]

The mechanism of leucopenia and thrombocytopenia is multifactorial. There is evidence for reduced bone marrow production of granulocytes and platelets and also for their autoimmune destruction and/or increased splenic clearance.

After treatment, hematologic recovery is slow and full recovery may take many months.[155]

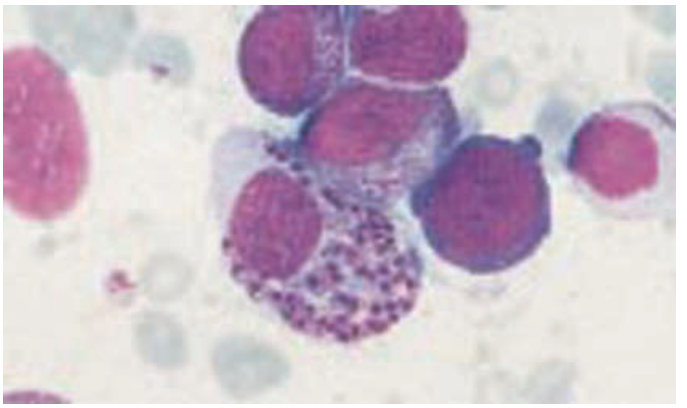

Figure 159–8 *Leishmania infantum* in macrophage from bone marrow. Although typically found in macrophages as shown here, isolated extracellular amastigotes from disrupted host cells are commonly seen in such preparations. (*Giemsa × 810*)

Laboratory Features

The epidemiologic context and clinical features can suggest a diagnosis of Leishmaniasis. Hematologic and biochemical tests are nonspecific; biochemical tests may show mild elevation of bilirubin and transaminases and more commonly raised alkaline phosphatase. Previously, the nonspecific formol gel test was used to indicate hypergammaglobulinemia. Diagnosis is confirmed by direct examination of parasites by microscopy, culture, or polymerase chain reaction (PCR) (for a detailed review, see reference 162).

Morphology

The pathognomic amastigotes of *Leishmania* spp. can be found in a variety of sources. The diagnosis is often made by splenic puncture or by bone marrow aspiration where large numbers of amastigotes may be seen within macrophages. Amastigotes are stained using Giemsa or other Romanovsky stains and demonstrate a purple nucleus and the large anterior kinetoplast (Fig. 159–8).

In nonimmunocompromised patients, splenic aspirates are positive in more than 95% and bone marrow aspirates positive in more than 85%, buffy coat macrophages positive in more than 70%, and lymph nodes positive in more than 60% of patients with VL. In practice, samples are taken from the least invasive sites first, although lymphadenopathy is not invariable.

Where coinfection of HIV and Leishmania occurs, amastigotes are more reliably found in bone marrow than in peripheral blood and may also be demonstrated in biopsies from a wide variety of sites. Biopsy material can be stained with polyclonal anti-Leishmania serum and indirect immunofluorescence. However, direct demonstration of parasites is less sensitive than culture or PCR.

Splenic Aspiration

Splenic aspiration is rarely performed in North America and Europe but is a common diagnostic procedure in endemic areas. Aspiration is contraindicated in the presence of a bleeding tendency, portal hypertension, or a splenic hydatid cyst. Splenic aspirates are obtained from the middle of the long axis of the spleen. After cleaning the skin, a 21-gauge needle attached to a 5-mL syringe is inserted sub-

cutaneously in line with the long axis of the spleen. The needle should be swiftly inserted to a depth of approximately 2 or 3 cm at an angle of roughly 45° to the skin, applying negative pressure. The needle should be withdrawn immediately while maintaining negative pressure and only taking a few seconds for the entire procedure. The splenic tissue may be expelled from the needle using a small amount of air and by fixing the stain using standard procedures.

Culture

Amastigotes may be grown as motile promastigotes from aspirates on the classical Novy, MacNeal, and Nicolle medium (NNN) or other suitable media, at 22 to 24 °C and populations double only every 2 to 3 days.[163,164] Inoculation of material into the susceptible golden hamster is no longer used to grow parasites.

Molecular Methods

The PCR may detect low levels of infection, and has been used for diagnosis and monitoring of treatment and to genotype the parasites.[165–167] Blood from filter paper can be used to prepare DNA, but as for direct morphology, PCR from bone marrow samples is a more sensitive method to demonstrate parasites.[168] It may be particularly useful for monitoring treatment and relapse in HIV- and *Leishmania*-infected patients.[169]

Serologic Tests

Serologic tests have to be interpreted in the light of the clinical findings. The tests are useful to screen suspected cases or populations for VL. However, they are unreliable in immunocompromised patients, who frequently are seronegative in spite of patient inflection. Conversely, those harboring a subclinical infection may be seropositive but samples may fail to yield evidence of parasites. Finally, serology is positive many years after treatment or self-cure.

An indirect IFAT or ELISA using freeze-dried Leishmania antigen have sensitivity and specificity greater than 95%. A direct agglutination test (DAT) is also available with purified freeze-dried antigen and is a highly sensitive and specific test.[170] The freeze-dried antigen is very stable even when stored in extreme conditions.

The ELISA and immunochromatographic tests using recombinant Leishmania K39 antigen are 100% sensitive and more than 98% specific in Asia.[171,172] The sensitivity and specificity of the DAT and K39 ICT are broadly similar, although the K39 test was less sensitive in the Sudan than in Asia.[173]

Treatment in patients without HIV coinfection may be monitored using urine antigen tests using detection of the K39 and K26 Leishmania antigens. These tests become negative 3 weeks after commencing treatment.

Management

General supportive care is important and includes correction of nutritional and hematinic deficiencies, blood transfusion in severe anemia, and antibiotics for secondary infections.

Specific chemotherapy for VL uses a number of potentially toxic drugs. Intercurrent infections must be identified and treated, and general measures include improvement of nutritional status (for review of treatment, see references 174 and 175). Use of pentavalent antimonials including sodium stibogluconate (Pentostam) and meglutamine antimonate (Glucantime) are now limited, especially in South Asia, by increasing drug resistance.

Amphotericin B is effective against Leishmania and is used in endemic areas where high levels of resistance to pentavalent antimonials are present. It may be given as a slow intravenous infusion in 5% dextrose over 4 to 6 hours, beginning at 0.1 mg/kg a day, increasing to 1 mg/kg until a total dose of 20 mg/kg has been given. Side effects include anaphylaxis, anemia, fever, bone chills, bone pain, and thrombophlebitis. Hypokalemia and hypomagnesemia are significant problems, and potassium loss and supplementation may be reduced by the concurrent use of amiloride to prevent renal tubular potassium leakage.[176]

Reduced toxicity from amphotericin is achieved using liposomal amphotericin preparations (AmiBisome). It is an effective and safe treatment and is used when affordable. The recommended dose is 3 mg/kg/day on days 1 to 5, 14, and 21. Studies have shown a short course of treatment of the single infusion at 5 mg/kg or 5 daily infusions of 1 mg/kg have cure rates of over 90%. In patients with HIV, a dose of liposomal amphotericin at 4 mg/kg/day on days 1 to 5 followed by 4 mg/kg/day on days 10, 17, 24, 31, and 38. The relapse rate is high and close monitoring of patients is required.

Miltefosine is a new drug and effective orally against visceral leishmaniasis in India and Africa.[177,178] The current regimes are 100 mg/day or 2 mg/kg/day in children for 4 weeks. Higher than 95% cure rates have been achieved. Gastrointestinal upset occurs frequently. Miltefosine is teratogenic and may reduce fertility. It has a long half-life and has a low therapeutic index, which may contribute to the development of resistance and so combination chemotherapy is being investigated to combat development of resistance.

Intramuscular paromomycin has been used at a dose of 15 mg/kg/day for 21 days. It has recently been shown to be equivalent to amphotericin B for the treatment of visceral leishmaniasis in India.[179] Moreover, patients treated for VL in Africa with sodium stibogluconate and paromomycin have an improved outcome compared with therapy with sodium stibogluconate alone.[180]

Post-kala-azar dermal Leishmaniasis may occur in up to 10% of patients after treatment for VL. It occurs mainly in India and is common in Africa. It occurs after treatment of visceral Leishmaniasis and may occur up to 10 years after treatment. It presents as a maculopapular rash spreading around the mouth, trunk, and limbs. These nodules and papules contain amastigotes. Prolonged treatment may be required to eliminate infection.

Leishmaniasis as a Transfusion-Transmitted Infection

Leishmaniasis poses problem as a potential transfusion-transmitted infection in endemic areas. The disease can be transmitted by blood and platelet concentrates, although leukodepletion by filtration reduces organisms by many orders of magnitude and so probably also the risk of transmission. In Europe, given the low absolute risk of transmission, donor deferral is used to reduce the risk of donation by anyone who is parasitemic.[181] It is has been noted that service personnel returning from the Middle East represent a group of potential donors who may have been exposed to infection.[182]

AFRICAN TRYPANOSOMIASIS

African Trypanosomiasis is caused by the flagellate protozoa *Trypanosoma brucei* spp, named after David Bruce, a Scottish parasitologist who first demonstrated the parasite in the blood of cattle affected by "nagana." In man, Aldo Castellani demonstrated Trypanosomes in the cerebrospinal fluid of patients with sleeping sickness. Bruce was able to show the protozoa in blood and showed that they were transmitted from antelopes to cattle by the tsetse fly and blood of patients suffering from sleeping sickness.

Epidemiology

Trypanosomes are transmitted by some species of the large and distinctive tsetse flies (*Glossina* spp.) in a sporadic distribution south of the Sahara and north of the Zambezi river. Of the three species, *Trypanosoma brucei brucei* infects animals whereas *T brucei gambiense* causes infection and sleeping sickness in Central and West Africa and

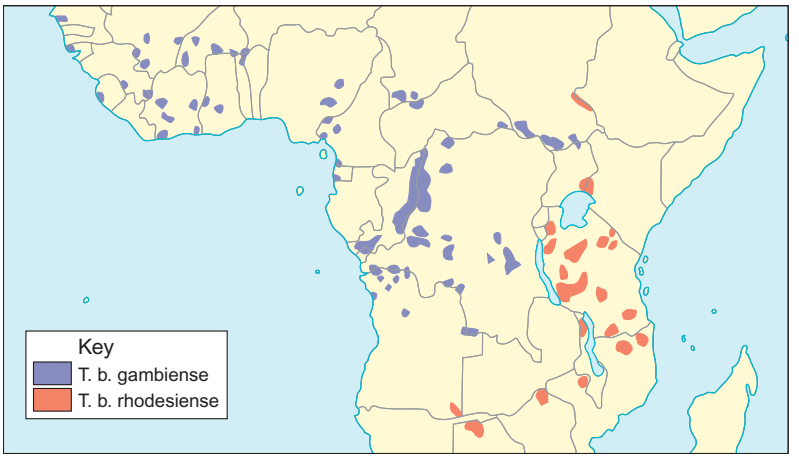

Figure 159–9 Distribution of *Trypanosoma brucei* infection in humans. African trypanosomiasis is confined to equatorial Africa, with a patchy distribution depending on detailed topographical conditions. It is caused by two subspecies of *T brucei*: *T b gambiense* infection is widespread in West and Central Africa, mainly by riverine species of tsetse fly (*Glossina*), but *T b rhodesiense*, transmitted mostly by savannah species, is restricted to the east and east-central areas, with some overlaps between the two. Although domestic pigs form an important reservoir for *T b gambiense* infection, various wild ruminants are the major sources for *T b rhodesiense*. The epidemic reemergence of African trypanosomiasis in recent years is exemplified by the death of at least 96 people in Angola in 2003, when 3,115 cases were confirmed among a suspected 270,000 new cases in that country. In the same year it was estimated that some 500,000 people across Africa were suffering from trypanosomiasis, which was likely to have a mortality rate of approximately 80%. Recent reports indicate a spread of transmission from the northern towards the southern parts of Angola. *(Adapted from WHO Map No. 98005)*

T brucei rhodesiense causes disease in East and Central Africa. *T b gambiense* is transmitted mainly between humans by the *G palpalis* group in foci along watercourses in West and Central Africa. *T b rhodesiense* is transmitted by the *G morsitans* groups widely distributed in the East African Savannah. Here, the disease is clearly a zoonosis, with antelopes and domestic cattle as reservoir hosts and afflicting mainly hunters, guides, and game wardens and may occasionally occur in tourists on safari in the game parks of East Africa (Fig. 159–9).

Historically, the disease has caused major epidemics, causing hundreds of thousands of deaths and has prevented human settlement in large areas of Africa. Over 50 million people are now at risk of trypanosomiasis and it has been estimated that the disease causes over 50,000 deaths each year. Most cases are reported in Zaire and northwestern Uganda, with a few hundred or fewer each year in neighboring East African countries.

Case finding and control measures have substantially reduced the risk of epidemics. Epidemics of disease have been associated with a breakdown in health services, for example, in villages in the areas of Lake Victoria in Uganda and more recently in Zaire, Angola, and southern Sudan.

Parasitology

The small mobile trypomastigotes circulate and may be seen in peripheral blood. These flattened, fusiform organisms are pleomorphic, but typically of a similar size to a red blood cell, approximately 20 μm long and have an undulating membrane, attached to the protruding flagellum, extending from the anterior pole of the elongated body (Fig. 159–10).

Parasites multiply by binary fission and may cause chronic parasitemia and evade humoral immune responses by clonal antigenic variations of the major surface glycoprotein.[183]

When trypomastigotes are taken up in a blood meal, by the tsetse fly, they multiply in the mid gut by simple fission. Later, they penetrate the wall of the gut and migrate to the salivary glands. There, as morphologically distinct epimastigotes, they become infective (or metacyclic) trypomastigotes 15 to 30 days after first infecting the fly. In endemic areas, up to 1% to 5% of flies may be infected. Flies remain infective until they die, several months later.

Figure 159–10 Original illustration of *Trypanosoma* (*Trypanozoon*) *brucei gambiense* in human blood by J. Everett Dutton. Polymorphic trypanosomes were first discovered a century ago, in 1895, by Bruce in the blood of domestic cattle suffering from the wasting disease nagana in South Africa. The first observation of these protozoa in humans was by R. M. Forde, who noted, in 1902, "small worm-like, extremely active bodies" in the blood of a sick European seaman in the Gambia. The parasites seen here in a Romanowsky-stained, thin blood film, which were described and named by Dutton in the same year, are responsible for sleeping sickness in west Africa. *(Reproduced by kind permission of the Director, Liverpool School of Tropical Medicine.)*

Pathology

The lymphatic, cardiac, and central nervous systems are involved by the disease. Initially, proliferation of trypanosomes within lymph nodes and the spleen is accompanied by expansion of the lymphocytes, macrophages, and erythrophagocytosis. Polyclonal activation of lymphocytes results in high production of IgM and rheumatoid factor, and anti-DNA antibodies may appear. Later fibrosis and endarteritis supervenes with proliferation of endothelial cells and perivascular infiltration of plasma cells and lymphocytes. The liver shows infiltration of the portal tracts and fatty degeneration.

In *T b rhodesiense*, cardiac involvement may be extensive, with endocarditis, myocarditis, and pericarditis leading to extensive damage and death.

In the second stage of the disease, trypanosomes multiply within the CNS and cause a chronic meningoencephalitis. Edema, hemorrhages, granulomatous lesions, and thrombosis contribute to cerebral degeneration. Lymphocytosis and plasma cells with large eosinophilic inclusions (Mott cells) may be found in the CNS.

Intriguingly, nonpathogenic species of African trypanosomes may be killed by the human high-density lipoprotein (HDL) particles. Haptoglobin-related protein (Hpr), apolipoprotein L-I (apoL-I), and apolipoprotein A-I (apoA-I) act to kill parasites and appear to require assembly for significant biological activity.[184,185] *T brucei rhodesiense* is resistant to killing by human sera as it appears HDL complexes, although internalized, are not targeted to the lysosomes.[186]

Clinical Features

T brucei gambiense

Local inflammation at the site of inoculation causes a distinctive chancre or painful, indurated ulcer appearing 2 to 3 days after an infective bite and lasting for up to a month.

Trypanosomes multiply in the lymphatic system for 6 to 14 days before causing patent infection in the blood, characterized by waves of parasitemia and fever. Later, invasion of the central nervous system may occur by transit of organisms through the choroid plexus and/or endothelial cells.

In the blood stage of infection, fever, headache, and arthralgia are prominent. Lymphadenopathy is common, particularly in the posterior triangle of the neck (Winterbottom sign). There may be intermittent rashes (often circinate erythema), pruritus, or edema. Moderate splenomegaly occurs in 10% to 20% of patients. A few infected patients are asymptomatic.

This early stage of infection may last for up to 2 years or more before CNS involvement, although rapidly progressive disease may occur. The CNS phase of disease is marked by the progressive onset of headache, disinhibited behavioral changes, mood, thought, and sleep disturbance. Wasting is prominent. Signs of diffuse CNS damage in the last phases of the disease include dementia, extrapyramidal and cerebellar dysfunction, and hyperesthesia. Tendon reflexes are increased and signs of UMN lesions widespread. Death usually occurs by intercurrent infection.

T brucei rhodesiense

T brucei rhodesiense is more virulent, causing a more serious acute disease, with systemic features including serous effusions, hepatocellular jaundice, and a mild normocytic, normochromic anemia. Hepatosplenomegaly and lymphadenopathy are common but involvement of cervical lymph nodes is less typical. Myocarditis is rare but may cause death before CNS involvement. Here CNS disease occurs sooner and is more rapidly progressive than *T brucei gambiense* infection and is fatal within 1 to 3 months.

Infection with *T brucei gambiense* may resolve in the vast majority of cases. Where infection persists there is typically a long asymptomatic phase. Numerous lymph nodes are enlarged to 1 to 2 cm in diameter and are soft, mobile, and painless.

The differential diagnosis of trypanosomiasis includes malaria, typhoid, fever, and viral hepatitis in the acute phase, whereas lymphadenopathy may suggest infectious mononucleosis or TB. In the cerebral phase of the disease, syphilis, TB, HIV-associated cryptococcal meningitis, or chronic viral encephalitis must be considered.

Children

Those affected in utero may be born with CNS abnormalities. In children, the disease is more rapidly progressive, and epileptic seizures and psychomotor retardation are the principal features of the disease.

HIV

The frequency of HIV seropositivity has been reported to show no significant differences between those presenting with trypanosomiasis and age-matched controls.[187,188] These results do not exclude that coinfections may modulate the course of the disease or the effectiveness of treatment.

Hematologic and Laboratory Features

The main hematologic features are a normocytic, normochromic anemia and moderate thrombocytopenia.[189] The anemia of trypanosomiasis is multifactorial. Hemodilution, hemolysis, and dyserythropoiesis or ineffective erythropoiesis all contribute to the pathogenesis. Hemolysis may be caused directly by lytic factors released by trypanosomes or indirectly by deposition of immune complexes and subsequent clearance of coated erythrocytes. In vitro studies have suggested that the variant surface glycoprotein from trypanosomes may be shed and taken up onto the erythrocyte membrane, where antibody and complement deposition could contribute to hemolysis. Bone marrow response is inadequate and although the nature of the defect is unclear, there is failure in incorporation of iron into erythroid precursors as is seen in many forms of the anemia of chronic disease. In mice infected with human trypanosomiasis, TNF-α contributes to bone marrow suppression, but detailed studies of the pathogenesis of anemia in human infections have not been reported. Serum IgM levels may be elevated to 4 times normal and with raised IgG levels cause an increased erythrocyte sedimentation rate.

The white cell count may be elevated with monocytosis, lymphocytosis, and circulating plasma cells, but eosinophilia is absent. Plasma cells with eosinophilic inclusion or Mott morular cells may occasionally be seen.

Petechia and purpura may be secondary to vascular injury, thrombocytopenia, and a complex but poorly defined coagulopathy. Abnormal liver function may cause prolonged clotting times. Functionally, both thrombosis and fibrinolysis are increased, and fibrin degradation products (D-dimers) have been are raised in acute disease and in *T b rhodesiense* a frank disseminated intravascular coagulation may become evident.[190]

Examination of the bone marrow shows hypercellularity. Gelatinous degeneration may be seen in wasted patients.

Mononuclear cells are present late in the disease and the cell count corresponds to the degree of neurologic involvement and may reach more than 300/μL in severely ill patients. The CSF protein levels are elevated (0.4 to 1.0 g/L).

As disease progresses, the circulating parasites become scarce. However, anemia and endocrine dysfunction, including amenorrhea, reduced libido, and impotence become apparent.

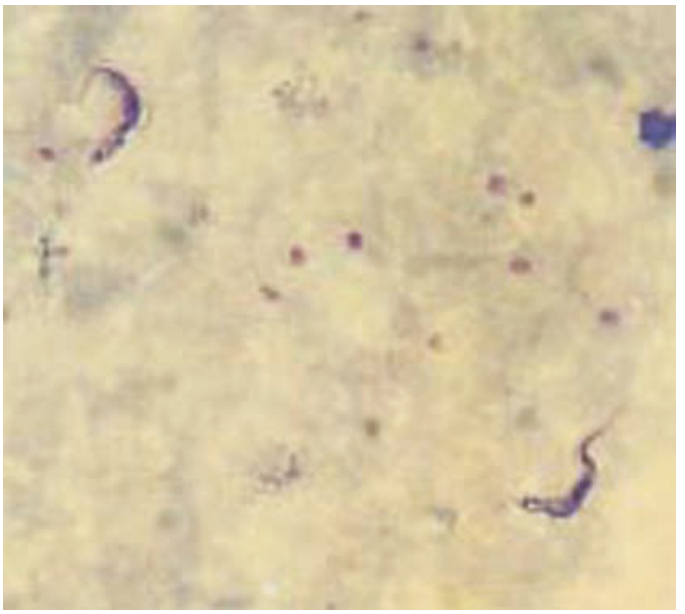

Figure 159–11 *Trypanosoma brucei rhodesiense* in human blood. *T b brucei* parasitizes wild and domestic animals but does not infect humans. The different subspecies can be distinguished with certainty only by biochemical techniques, such as electrophoretic typing of their isoenzymes or by the use of DNA probes. *T b gambiense* and *T b rhodesiense* (and *T b brucei* of animals) are virtually indistinguishable in blood films. Note the small kinetoplast and free flagellum. Both subspecies from humans will infect guinea pigs, but only *T b rhodesiense* is infective to rats, in which the parasites are polymorphic, that is, long, thin, intermediate and short, stumpy forms of trypomastigotes may coincide. (*Giemsa* × *900*)

Parasitologic Assays

Direct detection of the parasite is particularly important in the light of the toxicity of the treatment.

Trypanosomes may be detected in lymph node aspirates and in wet and thick blood smears (Fig. 159–11). An aspirate may be taken from enlarged nodes. Aspirated fluid can be examined under a coverslip and motile trypanosomes are typically seen at the edges of the coverslip.

Trypanosomes can be seen in wet smears, where a drop of blood is placed on a slide and examined under a coverslip. Alternatively, thick or thin Giemsa-stained blood films are made as for malaria diagnosis. The sensitivity may be increased by microcentrifugation.[191]

More recent methods to detect the low levels of parasitemia seen in *T b gambiense* include quantitative examination of the buffy coat using acridine orange[192] and small-scale ion-anion exchange chromatography.[193] Here, erythrocytes are retained in the column whereas trypanosomes are eluted and are visible after concentration by centrifugation. The sensitivity of detection with these methods ranges from 10^4 mL for wet smears to 10^2 mL for ion-exchange columns and centrifugation.

In *T b rhodesiense*, examination of the blood is more likely to yield a positive result than aspiration of lymph nodes.

Inoculation of the aspirate or samples into susceptible animals or in vitro culture has been used to detect low level parasitemia. Mice and rats were used to detect *T b rhodesiense*, whereas the multimammate rat (*Mastomys natalensis*) and guinea pigs were used for *T b gambiense.*

Cerebrospinal Fluid

Trypanosomes may be found in the CSF as disease progresses, although a double centrifugation technique may be required to demonstrate organisms. Here, 5 to 10 mL of CSF are centrifuged and the sediment taken up into a capillary tube and recentrifuged before examining the capillary tube under a coverslip (Fig. 159–12).[194]

Figure 159–12 Trypomastigote of *Trypanosoma brucei brucei* in cerebrospinal fluid. A single organism is seen in this sample taken from cerebrospinal fluid filtered in a "minicolumn." (*Giemsa* × *1200*)

Serology

Serologic tests are use for passive population screening in control programs (for a review, see reference 195). A Card Agglutination Test for Trypanosomiasis (CATT) is robust and can be used without extensive laboratory facilities.[196,197] The test contains freeze-dried trypanosomes with the LiTat 1.3 variant antigens. And can be obtained from the Institute of Tropical Medicine, Antwerp (www.itg.be/itg/). It is quite sensitive (>95%) but lacks specificity due to cross-reactivities with animal *Trypanosoma* spp. Although useful as a patient screening test in hospital for suspected cases of Trypanosomiasis, the predictive value for a positive test falls when screening populations for active cases. It has nevertheless been reported to double the number of active cases found. Some patients may be false-negative using this test if they are infected by parasites that do not express this variant antigen. Further versions of this assay have been developed to use dried blood on filter paper, namely the micro-CATT and macro-CATT, but these are less sensitive than the whole blood assay.

In *T brucei gambiense* serologic tests are not widely available and direct examination of blood and CSF for parasites is the first line of investigation.

The card indirect agglutination trypanosomiasis test (TrypTect CIATT) can detect circulating antigens in *T b gambiense* and *T b rhodesiense* infection by latex agglutination. The sensitivity of the test is 95.8% for *T b gambiense* and 97.7% for *T b rhodesiense* and so significantly higher than that of lymph node puncture, microhematocrit centrifugation, and CSF examination after single and double centrifugation.[198]

A rapid latex agglutination test (LATEX/*T b gambiense*) contains a mixture of three variable surface antigens of the bloodstream form of trypanosomes and has been used to detect antibodies in patients infected with *T b gambiense*. At 1 : 16 serum dilution, test specificity was 99%, whereas sensitivity ranged from 83.8% to 100% depending on the geographic origin of the samples. The test sensitivity falls to 66% for 66 CSF samples from second-stage patients.[199] A rapid latex agglutination test, LATEX/IgM, for the semiquantitative detection of IgM in CSF is available.[200]

Finally, immunofluorescence assays and ELISA tests for antibodies using whole parasites are highly sensitive and specific, although less practical for mass screening.[201]

Treatment

Treatment of Trypanosomiasis depends on the subspecies of trypanosome present. The drugs may be difficult to source and are toxic, so treatment requires expert help.

Early stage *T b gambiense* may be treated with pentamidine for 7 days (IV or more usually IM; 4 mg/kg/day). Hematologic side effects include neutropenia and more general side effects include hypotension, hypercalcemia, hyperkalemia, renal failure, and hyperglycemia. Pentamidine will not cure CNS disease and so examination of the CSF is required after initial treatment of the blood-stage diseases.

Eflornithine (α-difluoromethylornithine) for 14 days (IV; 100 mg/kg, 6-hourly) is effective for CNS treatment for *T b gambiense*.[202] It is a toxic drug suppressing DNA replication by inhibition of ornithine decarboxylase and thus polyamine synthesis and DNA replication. It causes dose-dependent bone marrow suppression with anemia, neutropenia, and thrombocytopenia in the majority of patients. The effects are reversible and are rarely dose-limiting. It is effective neither in children nor in coinfection with HIV, where metarsoprol is required.

Metarsoprol is a trivalent organic arsenical compound and is more toxic but cheaper than eflornithine. It is used in Africa for the treatment of late-stage CNS trypanosomiasis. It is given as three daily IV injections, at a dose of 3.6 mg/kg up to 180 mg, on two occasions a week apart. If the CNS leukocyte count is greater than 20/mm^3, a further three injections are given a week later.

Metarsoprol causes a secondary encephalopathy in 5% to 10% of treated cases and is fatal in half of these.[203] The incidence and severity of encephalopathy may be reduced by concurrent administration of prednisolone (1 mg/kg/day up to 40 mg) started 1 to 2 days before metarsoprol treatment.[204] When steroids are used is necessary to give patients antimalarial and antihelminthic therapy, especially if *Strongyloides stercoralis* is present.

Prior treatment of blood-stage disease with pentamidine may reduce antigen levels and possibly adverse events. Promethazine, anticonvulsants, and antiemetics are important adjunctive treatments prior to commencing CNS therapy.

Polyneuropathy occurs in 10% of cases treated with metarsoprol and may be severe, causing quadriplegia. If neuropathy is suspected, metarsoprol should be stopped immediately and thiamine (100 mg, three times a day) given until symptoms subside.

Patients require prolonged specialist follow-up over 2 years, including blood and CSF examination for parasites. A rising CSF leukocyte count is a good guide to CSF relapse even in the absence of a demonstration of parasites.[205]

In treatment for early-stage *T b rhodesiense*, suramin is given as five IV injections (20 mg/kg, up to 1.5 g) on days 1, 3, 6, 14, and 21. Adverse effects include fever, proteinuria, paresthesia, pruritus, and urticaria. Hemolytic anemia, agranulocytosis, and thrombocytopenia have been reported as side effects.

Combination therapy of antitrypanosomal drugs has now been used to increase the efficacy of treatment and to overcome increasing drug resistance.

It may be possible to use the antitrypanolytic factors in serum to kill pathogenic parasites. The major trypanocidal factor in human serum is apolipoprotein L-1 (apoL-1)[206]; apoL-1 is taken up in the parasite but neutralized in the lysosome by serum resistance-associated protein (SRA), which binds to a specific apoL-1 domain. Truncated apoL-1, which lacks this SRA-binding domain, may kill pathogenic trypanosomes and represents a new avenue for therapy that can be applied to human disease.[207]

Trypanosomiasis as a Transfusion-Transmitted Infection

Trypanosomiasis is a transfusion-transmitted infection. Asymptomatic or early-stage patients with trypanosomiasis are clearly a threat to the blood supply. Patients are excluded in the United Kingdom, Europe, and North America by the general donor queries relating to fever and constitutional symptoms.

In endemic areas, exclusion of infected donors is particularly with early-stage *T b gambiense* is clearly a more complex problem as patients may be asymptomatic for long periods of time if the degree of risk is unknown and no specific screening procedures are in place.

In summary, hematologic involvement in trypanosomiasis is peripheral to the main two features of the disease, but examination of lymph node aspirates, blood, and CSF is essential for diagnosis and management of the disease. Occasional patients may become severely ill and have complex hematologic abnormalities. In endemic areas, trypanosomiasis may pose a risk to the blood supply.

AMERICAN TRYPANOSOMIASIS

American trypanosomiasis (or Chagas disease, named after the Brazilian parasitologist Carlos Chagas), is caused by infection with *T cruzi*. This flagellated protozoon is transmitted by the triatomine insects, the reduviid bugs. The acute phase of infection is characterized by fever and high parasitemia, followed by a chronic phase with positive serology and low parasitemia but with end-organ damage to the heart, peripheral nervous system, and gastrointestinal tract, causing a chronic cardiomyopathy, neuropathy, and megaesophagus and megacolon.

Epidemiology

Chagas disease may occur in the Americas from the southern United States to Chile, but the highest prevalence is in Bolivia and Brazil (Fig. 159–13). There are 10 to 20 million seropositive people in Latin America, although the incidence of new infection is falling rapidly.[208] Infections are found not only in rural areas but also in recent migrants to urban areas in North and South America. It is estimated that approximately 100,000 seropositive individuals are living in the United States. True, endogenous (autochthonous) infection in the United States is vanishingly rare. Visitors to endemic areas are only rarely infected, with only a handful of cases being recorded in intrepid travelers spending time in traditional housing in rural areas. The range of reservoir hosts and species of triatomine bugs transmitting infection is wide.

Parasites may be also transmitted by blood transfusion (see below), vertically from mother to child by breast feeding, organ transplantation, and rarely by sexual transmission. Several outbreaks in Brazil have been reported after contamination of food by triatomine bugs and their feces. Laboratory infection by accidental ingestion or inoculation of parasites is well recorded.

Parasitology

T cruzi parasites are from the order Kinetoplastids and family Trypanosomidae, existing as infective trypomastigotes in the bloodstream of vertebrate hosts. These organisms are fusiform cells, 10 to 20 μm in length, with a distinctive large posterior kinetoplast, containing mitochondrial DNA. They can enter phagocytes, muscle and nerve cells, and a wide variety of other cell types and here transform to oval amastigotes 2 to 5 μm in diameter. They multiply by fission, and amastigotes develop into mature trypomastigotes released on rupture of the cell to begin a new cycle of invasion and multiplication.

Slender, highly motile and broader, less motile trypomastigotes have been distinguished, which may be relatively more infective for host cells and insects, respectively.

The species of triatomine bugs that commonly transmit disease are able to cause extensive infestation of simple mud-and-wattle thatched houses in rural Latin America.[209] Here, Chagas disease is a disease of poverty associated with poor housing. These bugs are infected by circulating trypomastigotes after taking a blood meal on

Figure 159–13 Distribution of Chagas disease. Human infection is endemic in parts of Central and South America from the Andes to the Atlantic coast and as far south as the latitude of the River Plate (Río de la Plata) shown here in green. Two major intergovernmental programmes were started in 1991 to eliminate domestic vectors by a combination of spraying residual insecticides in houses, the use of insecticidal paints, and the deployment of fumigant canisters. The countries covered in the two initiatives, the second of which started in 1997, are shown in the figure. The latter program instituted universal blood screening to avoid transmission from infected blood donors. In less than a decade, remarkable progress has been made. Transmission (by the major vector, *T infestans*) was eliminated in Uruguay by 1997 and in Chile by 1999. Major reductions in transmission have also been reported from other endemic countries but, to date, not complete control. *(Southern Cone Initiative; Andean and American Initiative areas.)*

sleeping victims. In the mid gut, trypomastigotes transform into epimastigotes and multiply by fission, before migrating to the hind gut where they develop into metacyclic trypomastigotes, adherent to the epithelium of the rectum. These infective forms are excreted into the feces and people are infected by rubbing this infected material from the bug into the skin or conjunctival membranes. In the human host, multiplication into macrophages is followed by rapid dissemination of trypomastigotes into the blood and hence to tissues.

The genome sequence of *T cruzi* has stimulated a plethora of comparative and genomic approaches to the study of the parasite.[210,211]

Trypanosoma rangeli Infections

The nonpathogenic trypanosomes can be transmitted directly to people by the bite of the triatomine bugs and they exist only as circulating trypomastigotes. No tissue amastigotes exist. Circulating organisms are sparse, but sometimes diagnosis can be made by careful microscopic examination of the distinctive morphology of these organisms in blood smears. The anterior position of the nucleus and small kinetoplast distinguish it from *T cruzi* (Fig. 159–14). The

Figure 159–14 *Trypanosoma rangeli. T rangeli* is a long, slender trypanosome also transmitted by reduviid bugs from wild animals to humans. It is readily distinguished by its shape from *T cruzi* in blood films, and appears to be nonpathogenic to humans. (*Giemsa × 1200*)

antibodies produced to *T rangeli* cross-react with those from *T cruzi* and hence cause false-positive serologic tests for *T cruzi*. However, the species may be differentiated by xenodiagnosis or molecular genetics in specialized laboratories.[212] The importance of recognizing this nonpathogenic infection is to avoid unnecessary treatment for *T cruzi*.

Pathology

There is a wide variation in the pathogenicity of isolates and some regional variation in the clinical spectrum of acute and chronic illness. Molecular typing has demonstrated considerable heterogeneity of *T cruzi* isolates, although the association between strains of parasite and the outcome of infection are unclear. Clearly, the organism must have many mechanisms of the immune evasion to cause chronic infections in a high proportion of individuals. Some of these have been elegantly defined, including resistance to activation of the alternate pathway of complement, specific mechanisms of entering the host cells and evasion of intracellular killing by the oxidative burst and lysozymes. Both $CD4^+$ and $CD8^+$ T cells are important for killing *T cruzi*-infected cells, and interferon-γ has shown to be important to control disease, whereas TGF-β and IL-10 enhance parasite replication.

End-organ damage occurs after tissues have been infected by *T cruzi* amastigotes, but the mechanisms leading to extensive cell damage are not clear. After multiplication, tissue amastigotes form pseudocysts in the heart with little or no inflammatory reaction, although occasionally acute myocarditis with focal hemorrhage and inflammation may lead to heart failure. As the disease progresses, the inflammatory response is increased and is associated with increased tissue damage. There may be an autoimmune component to this inflammatory response but the precise pathogenesis is poorly understood.[213] In the heart, chronic myocarditis leads to a decline in cardiac function. In late-stage disease, amastigotes can be found in almost all organs. Acute myocarditis with focal hemorrhage and inflammation may also lead to heart failure. Involvement of the brain, meninges, liver, lymph nodes, and spleen are common. Damage to the muscle walls and intramural nerve plexus in the esophagus and colon leads to dilation of these structures in the later phases of the disease.

Clinical Features

In about half the patients, a granuloma (or chagoma) occurs where parasites have been inoculated. The tender erythematous papule becomes keratotic and later heals, forming a hyperpigmented scar. When the conjunctiva are inoculated, the extensive unilateral periorbital edema may be prolonged (Romana's sign).

The severity of the acute illness is variable and ranges from asymptomatic infection or a mild febrile illness to a severe, potentially fatal illness with cardiac failure and meningoencephalitis in a minority of cases. Myalgia, generalized lymphadenopathy, hepatosplenomegaly, headaches, facial or generalized edema, vomiting, diarrhea, and anorexia are common features of the acute disease. The disease may be worse in children. The acute illness typically resolves in 4 to 8 weeks.

Chagas disease must be distinguished from typhoid fever, visceral leishmaniasis, brucellosis, toxoplasmosis, and malaria in cases of chronic, febrile illness in endemic areas.

Chronic Disease

The acute phase of *T cruzi* infection is followed by a variable latent or indeterminate phase with no clinical symptoms. Indeed, patients may never present with signs of end-organ damage. However, up to a third of clinically infected patients may develop cardiac involvement and show right-bundle branch block, AV conduction abnormalities, and/or abnormal T and Q waves. The patient may experience palpitations, chest pain, edema, and dizziness or syncope or dyspnea. The heart is enlarged and intramural thrombus may cause sudden death.

In a further minority of chronically infected patients, the gastrointestinal tract is infected with abnormal motility of the esophagus and colon, leading to dysphagia and/or severe constipation. Occasionally other hollow organ systems may be affected.

Pregnancy and Congenital Infection

In pregnant women, Chagas disease can cause spontaneous abortion, premature birth, intrauterine growth retardation, and stillbirth. Congenital infection occurs in 1% to 2% of women with chronic infection. Prompt diagnosis of circulating parasites in neonates at risk of congenital Chagas disease is essential to begin early treatment. It is recognized that infection can also be transmitted by breast feeding. Most children are asymptomatic but 10% to 20% of children have a mild systemic illness with hepatosplenomegaly. More severely affected newborn children have pneumonitis, meningoencephalitis, and diffuse dermal granulomas. Petechiae, purpura, and a generalized bleeding tendency may occur.[214]

Immunocompromised Patients

The disease may recrudesce after chemotherapy for malignant disease, immunosuppressive therapy, or after organ transplantation. The clinical disease may be fulminating with obvious parasitemia. Irregular erythematous indurated lesions have been described during *T cruzi* recrudescence after solid organ transplantation. Here, tissue amastigotes can be demonstrated by fine-needle aspiration.

HIV

Coinfection with *T cruzi* and HIV has been reported from urban centers in Brazil. *T cruzi* develops in end-stage disease with $CD4^+$ T-cell counts of less than 400/μL. Patients may be severely ill, the majority with meningoencephalitis and often with a space-occupying lesion. Typically, the CSF shows a mild lymphocytosis (<100 cells/μL). Parasites may be seen in the blood and occasionally the CSF. Cardiac involvement and heart failure is common.

Hematologic and Laboratory Features

A mild normocytic, normochromic anemia is typical of acute illness. The pathogenesis of the anemia and contributions of hemolysis and bone marrow depression has not been studied in humans, but in experimental infections in mice, uncontrolled infection and TNF-α can be shown to contribute to depressed hematopoiesis. A modest lymphocytosis and increases in liver and muscle enzymes may be present. Nonspecific ECG changes, first-degree heart block, and cardiomegaly suggest early myocardial involvement.

Hematologic abnormalities are not usually found in the late stage of disease where cardiomyopathy with cardiac failure, rhythm disturbance, and angina and systemic emboli from intramural thrombus may occur. Trials of systemic anticoagulation have not been conducted.

Diagnosis

Microscopy

During the acute phase of the disease, motile trypanosomes can be identified in wet preparations or buffy coat preparations using concentration methods and detailed morphology, including Giemsa-stained gently prepared thick and thin films to avoid damage to parasites (Fig. 159–15). Trypanosomes can be aspirated from the chagoma in the acute phase of disease and visualized in a wet preparation of needle aspirates. Parasites may occasionally be found in lachrymal fluid.

Sensitivity is increased by the concentration methods described for *T brucei* above. Organisms may also be sought in centrifuged serum after blood has clotted or by centrifugation after lysis of red blood cells with 0.8% ammonium chloride. Trypomastigotes can also be detected in other specimens including CSF, bone marrow, pericardiac fluid and tissue biopsies. Organisms must be distinguished from the morphologically similar nonpathogenic *T rangeli* (Fig. 159–14 and see above).

After the acute phase, circulating parasites are not visible although inoculation of blood into the susceptible animals (xenodiagnosis), in vitro culture, or molecular methods may demonstrate patent infection. Parasitemia may be obvious in immunocompromised patients in the chronic phase of disease.

Xenodiagnosis

Infection of laboratory triatomine bugs by a seropositive patient is more sensitive than morphology in chronically infected patients. It

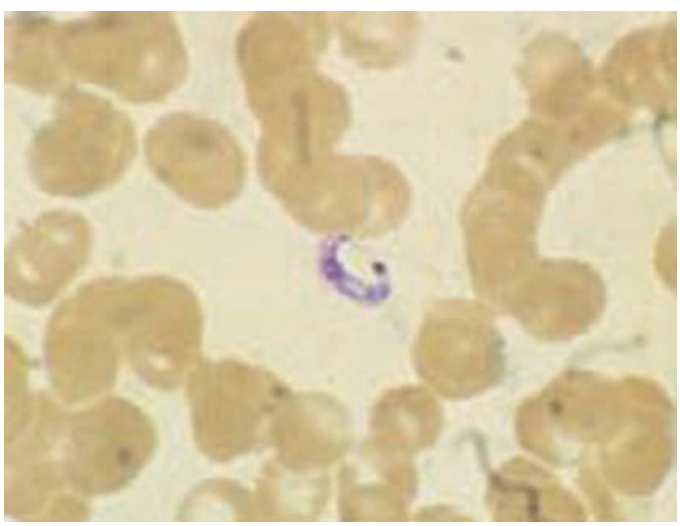

Figure 159–15 *T cruzi* in human blood film. The causative agent occurs in blood films characteristically as short C-shaped or S-shaped trypomastigotes with a prominent kinetoplast. It is otherwise monomorphic. (*Giemsa × 950*)

is also possible to infect susceptible laboratory animals. However, these techniques are only available in specialized centers in Latin America.

In Vitro Culture

Epimastigotes can be cultured using blood agar (Novy Nichol MacNeal [NNN]) medium or other media such Schiender insect medium. After 4 weeks' or more culture at 26°C, epimastigotes may be detected.[215,216]

Serology

Serology is a sensitive method of detecting infection after the acute phase. In Latin America, a number of commercial assays are available using crude epimastigote lysates in a variety of different formats. Serologic tests have used IFAT and ELISA using crude antigen prepared from in vitro cultures of epimastigotes. These tests must be carefully controlled with appropriate positive or negative sera. Chronically infected patients usually give a positive test if titers are greater than 1:80.[217] These have a sensitivity and specificity of more than 95%. These antibodies may cross-react with antibodies to malaria, leishmaniasis, syphilis, and some autoimmune conditions. ELISAs should be used in conjunction with a confirmatory test such as Western blotting.

In South and North America, a number of companies market ELISA-based assays using recombinant antigens, synthetic peptides, or a concentrated extract of excretory-secretory antigens from either Brazil or Tulahuen strain *T cruzi* trypomastigotes (total trypomastigote excretory-secretory antigens [TESAs]). These assays may provide more rapidly available and cheaper tests without loss of sensitivity and specificity (see section Chagas Disease as a Transfusion-Transmitted Infection below for further discussion).

Serologic testing may be useful in the evaluation of people who may have been exposed to Chagas disease, pregnant women, patients about to undergo immunosuppressive treatment or to receive chemotherapy or who have been diagnosed with HIV or other immunosuppressive illness. Children born to seropositive women will have maternally derived IgG anti–*T cruzi* antibodies, but demonstrate IgM anti–*T cruzi* antibodies if congenitally infected.

Molecular Diagnosis

Amplification of *T cruzi*–specific sequences by PCR is potentially the most widely applicable, sensitive, and specific method for detecting parasites. A number of assays have been developed, based on the application of repetitive sequences in kinetoplast DNA.[218] Studies have suggested that PCR is the most sensitive technique available for direct detection of *T cruzi* in chagasic patients and that it can be a very useful instrument for follow-up of patients after specific treatment[218] and the detection of congenital infection.[219]

Treatment

The detailed treatment of Chagas disease is beyond the scope of this chapter. Treatment of the acute, intermediate, and chronic phases requires expert supervision as parasitologic cure is only achieved in half the cases and monitoring progress requires specialist testing and evaluation and where necessary treatment of end-organ damage. The current and potential future chemotherapy[220,221] have recently been reviewed.

Nifurtimox is a synthetic nitrofuran that inhibits pyruvic acid synthesis by inhibition of lactic dehydrogenase**.** It is given for 30 to 120 days at 3 to 5 mg/kg three times a day. The most serious side effects are peripheral neuropathy, mental disturbance (including psychosis) and hemolytic anemia associated with glucose-6-phosphate dehydrogenase deficiency.

Benznidazole is widely available in Latin America and is given at 2.5 to 5 mg/kg twice a day for 30 to 60 days. Severe hematologic complications are common and bone marrow depression is a serious side effect. Thrombocytopenia may be severe and neutropenia may progress to agranulocytosis. Other serious complications include photosensitivity, neuropathy, and weight loss.[222]

Supportive therapy is required for heart failure and acute meningoencephalitis. Surgery may be required for alleviation of esophageal and chronic dysfunction. In the absence of effective or simple therapy, control of triatomine bugs and an improvement in the housing stock are essential to prevent and control disease.

Trypanosomiasis as a Transfusion-Transmitted Infection

Chagas disease may occur as a TTI and represents a real threat to the safety of the blood supply in endemic areas. It is estimated that 1.5% to 50% of contaminated units cause infection in recipients, a wide range that may reflect the stage of infection in the donor, the type and processing of the component, and the immune status of the recipient.[223]

In endemic areas, seropositivity is high, reaching 50% in some areas of Bolivia and 1% to 2% in major areas in Brazil. Control of blood transfusion–transmitted infection is part of the WHO strategy for control of Chagas disease.[224–226] Serologic screening, tests using synthetic peptide antigens, or a mixture of recombinant antigens to detect anti–*T cruzi* antibodies in chronically infected blood donors, are more than 95% sensitive[227,228] and these serologic tests, replacing those based on crude antigens, have allowed improved coverage of screening of blood donors throughout Latin America.[229]

It is also possible to treat blood with gentian violet (0.25 g/L for 24 hours at 4°C) or with methylene blue to kill circulating organisms. It has also been shown that amotosalen plus UVA photochemical inactivation technology is effective in inactivating *T cruzi*, in platelet concentrates and plasma.[230] In addition, prophylactic benznidazole can be given to immunosuppressed patients receiving blood products in endemic areas.

Outside Latin America, Chagas disease is an occasional cause of TTI, mainly in immunosuppressed patients. It is possible that minor infections are not recognized in healthy individuals. Clearly the high rates of seropositivity in individuals from endemic areas suggest that recent migrants may easily transmit the disease.

In the United Sates, the overall seropositive rate among blood donors is 1:250,000, with local incidence rates reaching 1:7500 or greater in Los Angeles and Miami.[223] These rates are probably underestimates as migration from endemic areas has recently increased. *T cruzi* can be detected by PCR in about half the seropositive donors and remain viable for at least 20 days surviving cryopreservation and thawing.[223] *T cruzi* has been reported to be transmitted after organ transplantation[231,232] and after blood transfusion in seven patients who were immunosuppressed.[233–237]

Donors can be excluded a medical questionnaire eliciting obvious symptoms of acute or chronic disease. Prospective studies have shown these questionnaires would miss many infected donors,[238,239] including those infected congenitally.[240]

In the United States, new tests have been requested by the Food and Drug Administration to combat this threat. A radioimmune precipitation assay (RIPA) is the most sensitive method to detect anti–*T cruzi* antibodies,[241] although RIPA cross-reactivity has been reported in patients with visceral leishmaniasis.[242] It is, however, unsuitable for mass screening. An ELISA based in a concentrated extract of excretory-secretory antigens from either Brazil or Tulahuen strain *T cruzi* trypomastigotes (TESAs)[243,244] had an overall sensitivity of 100% and specificity of more than 94%, and a prototype *T cruzi* lysate-based ELISA has been developed and appears to be 97.7% sensitive and 100% specific.[241]

It is only to be hoped that sensitive screening tests are consistently applied to reduce transmission of Chagas disease by blood products in endemic and nonendemic countries. On a more general note, it is encouraging that the initiatives to control *T cruzi* infection across Latin America are showing real evidence of success.[208,245]

BABESIOSIS

Babesiosis is an intraerythrocytic infection caused by parasites from the order Piroplasmida and the genera Babesiidae. The infection is zoonosis transmitted by hard-bodied ticks and causes fever and hemolytic anemia.[246] Several distinct *Babesia* spp. cause disease in different geographical areas.[247,248]

There are two well-defined *Babesia* species that cause human infection. *Babesia microti* is a parasite of small rodents in northeastern United States and is spread by nymphs, larvae, and adult forms of the hard-bodied ixodid ticks (*Ixodes dammini*). Infection of the white-tailed deer by ticks allows multiplication and spread of the infected ticks. Infections can be transferred to humans by all forms of the tick after prolonged feeding. The infection is therefore most common in people holidaying or working in forested areas of northeastern United States. The offshore islands of Nantucket, Martha's Vineyard, Block Island, and Shelter Island are foci of disease, but it also occurs inland in Connecticut and New York State. Hundreds of cases have been recorded since the first identified case in 1969. Visitors and workers in endemic areas should avoid tick bites using appropriate clothing and repellents.

In Europe, *B divergens* and the morphologically indistinguishable parasite *B bovis* are transmitted to humans by ticks (*Ixodes ricinus*) from cattle. Less than 50 cases have been recorded. European cases of *B microti* and *B canis* infection have also been reported.[247]

A handful of cases of infections with poorly defined *Babesia* spp. have been reported from the western United States. These organisms are morphologically indistinguishable from *B microti* but are distinguished by molecular methods. The MO1-type piroplasm has caused illness in an index case in Missouri in 1992 and the WA1-type and CA1–4 piroplasms caused disease in five cases reported from Washington State and California respectively in 1994.[249,250] A further *B microti*–like organism has been isolated from an asymptomatic woman in Taiwan.[251]

B microti and the WA1-type piroplasms have been transmitted by blood and platelet transfusions. Transplacental infection by *B microti* has been reported.

Parasitology

Parasites appear to be introduced into the bloodstream, where they invade erythrocytes. There they multiply by asexual fission to produce 2 to 4 merozoites. These infective forms are released after lysis of the erythrocyte and begin another cycle of invasion multiplication. Parasites are cleared by macrophages. The contribution of antibodies and cell-mediated immune response has not been defined, although *Babesia bovis* expresses clonally variant antigens on the surface of infected erythrocytes.[27]

Clinical Features

The North American *B microti* infections have an incubation period of several weeks and after infection by blood transfusion clinical symptoms have taken from 17 days to many months to become manifest.[252–255]

The spectrum of clinical disease is wide. *B microti* may cause asymptomatic infection or present with a mild flu-like illness in most cases in people with normal immune and splenic function.[256] The cardinal manifestations are fever and hemolytic anemia. Splenectomy, old age, and immunosuppression, including HIV, may increase the risk of more severe clinical disease.[257–259] The disease may progress to ARDS, disseminated intravascular coagulation, or renal failure.[252] Patients who have had a splenectomy should avoid exposure to ticks in forested areas where the disease is transmitted.

B divergens in Europe predominantly causes symptomatic infection in people who have had a splenectomy.[260,261] Here, the case fatality rate is of the order of 50%.

Patients present with high fever, often with chills and sweats, jaundice, fatigue, malaise, headache, arthralgia, and myalgia. Gastrointestinal disturbances are common and people may complain of dark urine secondary to hemoglobinuria. In some cases, the disease progresses with respiratory failure secondary to ARDS, disseminated in intravascular coagulation and renal failure requiring the appropriate supportive care.[262] Such severe cases resemble severe malaria in nonimmunes and it has been suggested that the pathophysiology-like malaria includes adhesion and sequestration of infected erythrocytes and the release of proinflammatory cytokines. These diseases may be confused with *falciparum* malaria, leptospirosis, or viral hepatitis.

Hematologic and Laboratory Features

The hematologic features of the disease are dominated by substantial intravascular hemolysis.[262,263] Physical examination shows pallor, jaundice, and mild hepatosplenomegaly.

The laboratory findings are those of a compensated intravascular hemolytic anemia and thus feature low hemoglobin and haptoglobin and increased reticulocyte count, serum lactate dehydrogenase, and hemoglobinuria and proteinuria. Moderate thrombocytopenia is common.[255,264] Electron microscopy suggests uninfected erythrocytes are damaged during infection and so likely to be cleared more rapidly than normally.[265] The white cell count is usually decreased with atypical lymphocytosis and occasional evidence of hemophagocytosis. However, leucocytosis may occur, particularly in *B divergens* infections.

The Direct Coombs test is frequently positive for both C3 components and IgG. Polyclonal hypergammaglobulinemia is seen and levels of C3 and C4 are reduced in acute infection.[266] Liver function tests show raised indirect bilirubin and mildly raised transaminase levels.

Diagnosis

The blood films stained with Giemsa or Romanovsky stains show ring-like intraerythrocytic parasites. Morphology is variable and ring, rod, and ameboid forms of babesia parasites may be seen (Fig. 159–16).[246] Occasionally, multiple intraerythrocytic forms can be seen, linked to form a tetrad or colloquially "Maltese Cross." However, at low parasitemia, babesia parasites may easily be mistaken for ring-stage forms of *P falciparum*. Moreover, false-positive sightings *of Babesia* spp. may be due to platelets, nonspecific stain deposit overlying erythrocytes, or indeed other intraerythrocytic inclusions.

Parasitemias are variable and in *B microti* infections may be low or transient.[256] In symptomatic infection, parasitemias typically range from less than 1% to 10% and rarely much higher, more than 70%, in severe infections.

Low-level parasitemias may be detected by inoculation of the blood into susceptible animals, including the golden hamster (*Mesocricetus auratus*), but is not routinely available.

An indirect fluorescent antibody test using crude antigen is available in the United States through the Division of Parasitic Diseases at CDC.[267] Titers greater than 1:64 are regarded as positive and has been reported to be 88% to 96% sensitive and 90% to 100% specific.

PCR analysis is the most useful method of detecting or confirming low levels of parasitemia, when serologic tests are positive and can also be used to monitor treatment.[268] Species-specific PCR primers are available to provide precise identification of infected parasites. Nevertheless, some rare forms of piroplasma parasites cannot be classified.

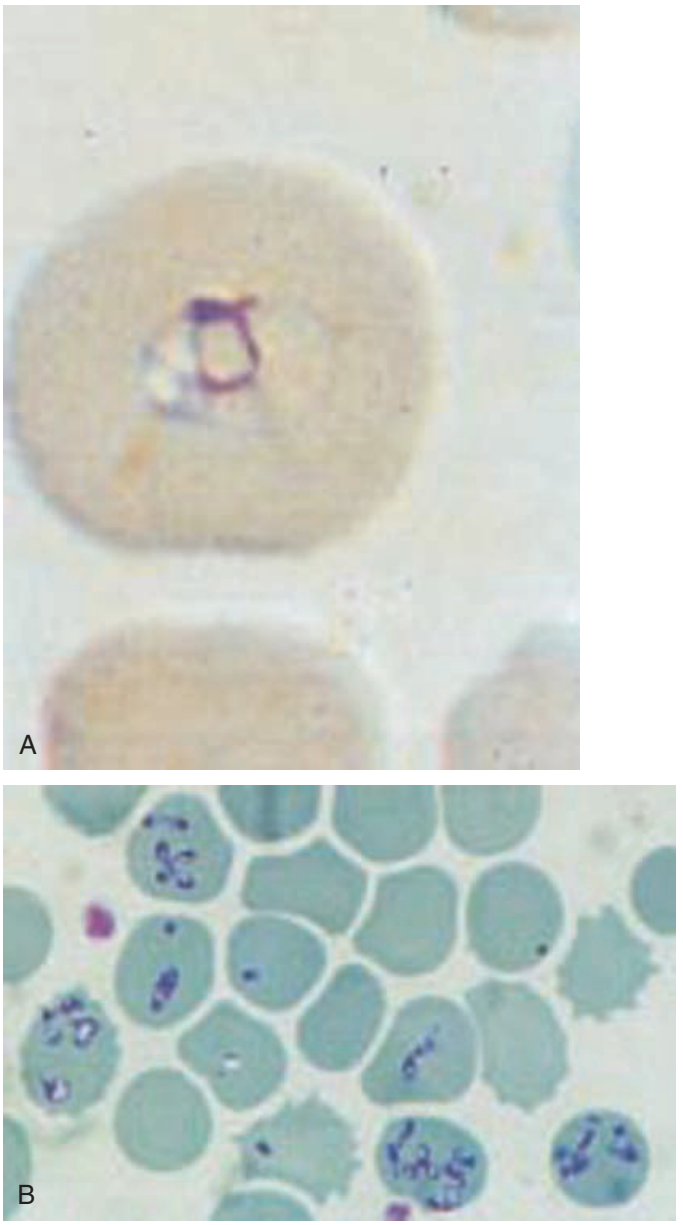

Figure 159–16 Babesia parasites. Human infection with species of piroplasm transmitted by the bite of the tick *Ixodes ricinus* infected from cattle is a rare occurrence. Infection in normal people with this piroplasm may give rise to a self-limiting fever and parasitemia, as in the case of infection with the rodent parasite *Babesia microti* on the northeastern seaboard of the United States via the tick *Ixodes scapularis* (**a**). Heavy red-cell infection may develop, however, in splenectomized patients, leading to fatal hemolytic anemia. This patient died from an infection acquired from the cattle parasite *B divergens* in Scotland (**b**). Other species of *Babesia* that occasionally infect humans, for example, the WA1, CA1, and MO1 isolates from the United States are distinguished by molecular means. (*Giemsa × 700*)

Treatment

Many *B microti* infections are self-limiting, and therapy is used for moderate or severe disease.[269,270] The usual treatment is a 7- to 10-day course of clindamycin (up to 1.2 g twice a day; children 20 to 40 mg/kg/day) and quinine (650 mg three times a day; children 25 mg/kg/day). These two drugs may be given parentally in severe disease.

B divergens infections are often fatal in splenectomized patients and therapy is based on somewhat limited experience. Pentamidine with co-trimoxazole has been used successfully, whereas individual patients treated with pentamidine and co-trimoxazole or quinine, chloroquine, and pyrimethamine have been unsuccessful. Three cases have been treated successfully with large volume exchange transfusions (2–3 blood volumes) and intravenous clindamycin and oral quinine.[271] This regime of clindamycin and intravenous and oral quinine gives the best chance of success in the absence of randomized control RCT evidence.

Atovaquone and azithromycin have also been used successfully and may represent alternative regimes to clindamycin and quinine.

Exchange transfusion has been suggested as a useful adjunctive treatment if the parasitemia rises to greater than 10% and/or in severely ill patients. *B divergens* infections can run a rapidly progressive course and early exchange transfusion should be considered.

The parasite and hemoglobin levels should be regularly monitored during treatment.

Serology and PCR testing of seropositive cases may be helpful in making a diagnosis. An indirect IFAT is available for *B divergens* and *B microti*. The IFAT titer is usually greater than 1:64 in acute infection. The reported sensitivity of the *B microti* IFAT is 88% to 96% and specificity 90% to 100%.[23] Antimalarial antibodies may cross-react in this test.

Babesia and Transfusion-Transmitted Infection

Prevention of babesia as a transfusion-transmitted infection in the United States requires screening donors about a previous history of babesiosis and excluding patients with fever and a low hematocrit level. In the United Kingdom, a conservative approach has been taken and all donors who have visited northeastern United States between May and October are excluded, in addition to the standard criteria of screening out febrile and/or anemic donors.

EOSINOPHILIA

Eosinophilia may be caused by a wide variety of systemic diseases and parasitic infections. The association with parasitic disease is through part of the Th2 T-cell response stimulated by helminths (worms), filaria, and cestodes. In general, protozoan infections, such as malaria, amebiasis, giardiasis, are not associated with eosinophilia. However, case reports do exist suggesting isosporosis, toxoplasmosis, and infection with *Dientamoeba fragilis* can cause eosinophilia.

The rise in absolute eosinophil count depends on the degree of tissue invasion and is therefore modest with tapeworms and adult roundworms resident in the bowel but much higher where invasion occurs, for example, *Toxocara canis* or filaria. Some parasites have migratory larval stages, for example, ascariasis (roundworms) and clonorchiasis.

The differential diagnosis of eosinophilia in those who have lived in tropical areas is therefore wide. Evaluating the patients must begin by establishing the degree of eosinophilia (minimal, $<1 \times 10^9$/L; moderate, 1 to 3×10^9/L; high $>3 \times 10^9$/L), the relation to travel (where necessary), and the presence of symptoms. A wide range of systemic diseases are associated with eosinophilia, and the eosinophil count may be high in drug allergy, pulmonary infiltrate with eosinophilia, and vasculitides.

Eosinophilia in Travelers

Evaluating the cause of eosinophilia in travelers to tropical areas where many parasitic diseases are endemic requires a systematic approach to narrow down likely possibilities by considering existing systemic diseases that may cause eosinophilia (particularly allergy, drug ingestion and autoimmune disease, vasculitis, or arthritis), the areas visited, duration of stay and history of exposure to soil-transmitted nematodes, freshwater potentially infected with schistosomiasis,

and rural areas where loiasis, onchocerciasis, and hydatid disease may be contracted.

Physical examination may show subcutaneous swellings associated with filaria or hepatosplenomegaly consistent with schistosomiasis, hydatid disease, or toxocara.

Laboratory examination requires a stepwise approach given the breadth of the differential diagnosis (Table 159–4). The details of specific parasitologic tests are beyond the scope of this chapter, and detailed investigation would certainly require consultation with colleagues in infectious diseases.

Some parasitic causes of eosinophilia may not be diagnosed during the incubation period as larval stages of nematode worms may cause eosinophilic drug migration, but eggs will not be excreted in stools for many months. Moreover, filarial infections do not produce detectable parasites in blood or skin for many months after exposure.

In immunocompromised patients or those about to receive diagnosis, eosinophilia may be crucial, given the risks of giving immunosuppressive therapy such as chemotherapy or hematopoietic stem cell or solid organ transplantation to a patient with a chronic parasitologic infection. Patients with undiagnosed eosinophilia and possible exposure to *Strongyloides* should be given empirical course of treatment.

Table 159–4 Approach to Investigation of Eosinophilia in a Returning Traveler

History	Allergy Drugs and vitamins (L-tryptophan) Regions, localities, and duration of exposure
Physical examination	Skin, subcutaneous tissues Liver/spleen Signs of other systemic disease
Initial investigations	Full blood count and differential white blood cell count Stool examination for ova and parasites (×3) Urine analysis Examination of midday urine for ova and parasites (×3) (in those who have traveled to Africa or the Middle East)
Further investigations as suggested by travel and exposure from history	As suggested by travel and exposure from history *Strongyloides* culture and serology Duodenal aspirate (strongyloidiasis, hookworm) Serology (schistosomiasis, filariasis) Day/night blood films (filariasis)
Further studies if suggested by history and physical examination	Skin snips (onchocerciasis) Chest x-ray (hydatid cyst, tropical pulmonary eosinophilia, paragonimiasis) Soft tissue x-ray (cysticercosis) Sputum examination for ova and parasites (paragonimiasis) Abdominal ultrasound (hydatid cyst) Cystoscopy with or without biopsy (schistosomiasis) Rectal snips (schistosomiasis)

OTHER PARASITIC DISEASES

Many parasitic diseases cause some minor hematologic disturbance. A few may present with distinct hematologic features or indeed syndromes.

Filariasis

Lymphatic filariasis is caused by *Wuchereria bancrofti* and *Brugia malayi*. Infection with *W bancrofti* occurs throughout the tropics but by far the majority of cases are in Asia. The distribution of *B malayi* is more restricted to China, Southeast Asia, and southern India. The male and female adult worms live in the lymphatics and the female worm releases vast number of microfilariae, each 250 to 300 μm in length. Microfilariae develop but do not appear to multiply in the mosquito.

Infection may present with lymphangitis; often recurrent and unlike bacterial infections, the inflammatory features may spread distally. Over time, lymphatic obstruction may cause hydrocele, lymphedema (if severe elephantiasis), chyluria, and tropical pulmonary eosinophilia. *B malayi* causes neither hydrocele nor chyluria.

Filariasis is most easily diagnosed by finding microfilariae in peripheral blood in a wet preparation. Motile microfilariae can be seen under low power and may be concentrated by centrifugation or filtration using a 3-μm filter. They are speciated in thin or thick films by their nuclear distribution and sheath characteristics (Fig. 159–17) and the two pathogenic species must be distinguished from the nonpathogenic species *Mansonella perstans* and *M ozzardi*, which do not have sheaths. Circulating *W bancrofti* antigens can also be detected in the circulation by ELISA or immunochromatographic methods. Adult worms can sometimes be imaged by ultrasound. Filarial DNA from all species can be detected by PCR. Serology is unhelpful as many people become exposed without developing clinical symptoms.

The worms cause marked or severe eosinophilia (see below) with counts greater than 10^9/L. Migration of worms through the lungs may exacerbate the eosinophil count and cause minor respiratory symptoms and fluctuating radiologic signs. Other causes of tropical pulmonary eosinophilia are the worms (helminths) Ascaris, Strongyloides, Schistosoma, and Toxocara. Of these organisms causing pulmonary symptoms and signs, filariasis alone is responsive to diethyl carbamazine. Albendazole and ivermectin may also be used against filarial infection.

Toxoplasmosis

Toxoplasmosis may cause a mild illness or a more prolonged course with constitutional symptoms, atypical lymphocytes and thrombocytopenia. Congenital toxoplasmosis as a result of infection acquired during pregnancy is a cause of neonatal thrombocytopenia, where it may be accompanied by cerebral calcification, hepatitis, and pneumonitis. In immunocompromised patients, new or reactivated toxoplasmosis may cause severe disease, including encephalitis, pneumonitis, and hepatitis. Thrombocytopenia is frequently accompanied by anemia and leucopenia.

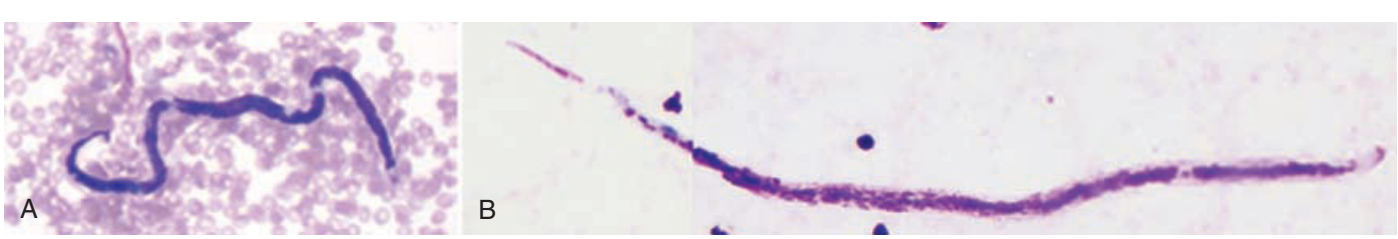

Figure 159–17 Microfilaria (*Brugia malayi*) on thick (**A**) and thin prep (**B**). Speciation is determined by the nuclear distribution and sheath characteristics.

Amebiasis

Amebiasis causes hypochromic, microcytic anemia both as a result of chronic blood loss and as an anemia of chronic disease where disease progresses to formation of a liver abscess. Neutrophilia accompanies severe tissue damage caused by perforation of the bowel or a liver abscess or may be present in a secondary bacterial infection. Sometimes a leukemoid reaction with high white cell count and extreme left-shifted myeloid cells can be seen. Prolonged and/or extensive liver damage may cause prolongation of the prothrombin time.

Giardiasis

Acute giardiasis causes folate deficiency through malabsorption of folate in the small intestine. Chronic infection can cause vitamin B_{12} deficiency as ileal absorption of the vitamin is impaired.

Hookworm Infection

Adult hookworms attach themselves to the lining of the small bowel and take blood meals. The accumulated blood loss may be extensive as worms consume 2.0 mL (*Neomercator americanus*) or 0.5 mL of blood (*Ancylostoma duodenale*) each day. These infections are a common contributing factor to iron deficiency anemia in children where infection is acquired by eating or walking barefoot on larva-infected soil. The disease is usually diagnosed by finding excreted eggs in stool samples, and treatment is with albendazole.

Tapeworm Infection

The fish tapeworm (*Diphyllobothrium latum*) is a rare cause of vitamin B_{12} deficiency. This tapeworm is transmitted in the Far East by eating raw or partially cooked fish. Infection has to be extensive and causes vitamin B_{12} deficiency; however, such cases are rare, even in endemic areas.

Schistosomiasis

Schistosoma hematobium causes blood loss in urine. Infection is acquired by swimming in fresh water, where cercariae from the infected snail host enter the skin and migrate to the blood vessels of the bladder. Chronic blood loss is a cause of iron deficiency anemia in children in endemic areas, but infection is likely to be diagnosed at an early stage in travelers because of the striking symptoms of painless hematuria. Treatment is with praziquantel.

SUMMARY

Parasitic diseases present many problems for global heath. They cause a wide spectrum of hematologic abnormalities, and in endemic areas, a broad knowledge of the parasitic disease is vital for everyday practice. In nonendemic areas, there are a few situations where the diagnosis or management of these diseases may fall within the remit of hematologists and hematology laboratories, particularly malaria and the diagnosis of anemia, cytopenias, eosinophilia, and hepatosplenomegaly. Here, a high index of suspicion is often needed for the diagnosis to be made. A good travel history is crucial to establish exposure to parasitic disease and to prompt the search for the appropriate organisms. Several parasitic diseases pose a threat for the safe supply of blood, and the problems of screening of these infections are far from solved. Beyond everyday practice the pathophysiology and prevention of these diseases pose major challenges for biomedical research and public health.

CHAPTER 160

HEMATOLOGIC PROBLEMS IN THE SURGICAL PATIENT: BLEEDING AND THROMBOSIS

Mark T. Reding and Nigel S. Key

INTRODUCTION

Surgical patients often present unique challenges to the consulting hematologist. They may develop hemostatic disorders ranging from unexpected bleeding to pathologic thrombosis, both of which can be potentially life-threatening. Consultation may be sought to assess preoperative bleeding risk and/or to recommend strategies to prevent postoperative thrombosis. The hematologist may be called upon to assist in the management of patients with a previous history of bleeding or thrombosis, and in those with unexplained bleeding or thrombosis in the postoperative period. This chapter will review the preoperative evaluation of bleeding risk, the management of patients with hemostatic abnormalities, perioperative management of patients on long-term oral anticoagulation, and strategies to prevent surgery-induced venous thromboembolism (VTE).

PREOPERATIVE EVALUATION OF HEMOSTATIC RISK

Preoperative evaluation of hemostatic risk begins with a carefully taken history. Particular attention should be directed at specific bleeding symptoms, and any history of bleeding associated with surgical procedures, including circumcision, tonsillectomy, and dental extractions. A detailed family history and record of medication use, including nonprescription medications, should be obtained. In adults, an interview to assess for the presence or absence of bleeding symptoms has a high discriminating power when used in a screening situation, where no bleeding disorder is suspected, but may be less discriminatory for those referred for specialty evaluation.[1] In the pediatric population, the medical history may be less reliable as a screening method because of fewer previous hemostatic challenges.[2]

Obtaining an adequate bleeding history may be complicated by the fact that many hemostatically normal people consider their bleeding to be excessive. Surveys of healthy individuals frequently report excessive nosebleeds (5%–39%), gingival bleeding (7%–51%), easy bruising (12%–24%), menorrhagia (23%–44%), postpartum bleeding (6%–23%), and bleeding following dental extraction (up to 13%) and tonsillectomy (up to 11%).[1,3–5] Thus, a thorough search for objective confirmation of reported symptoms is essential. Also, a constellation of bleeding symptoms, rather than any single symptom, is most helpful in suggesting the presence and etiology of an underlying bleeding disorder.

The need for routine preoperative laboratory testing is controversial. Those in favor of testing point to the asymptomatic nature of some hemostatic abnormalities that may cause surgical bleeding and the occasional failure to obtain a detailed history.[6–8] A prospective study of preoperative screening in children before tonsillectomy found both history and laboratory screening to have high specificity but a low positive predictive value for perioperative bleeding.[7] Another study found that perioperative blood loss in adult cardiothoracic surgery patients could be predicted with a model, which included the bleeding time, prothrombin time (PT), and platelet count.[9] Given the variety of potential hemostatic defects, however, no simple screening system will identify all patients at increased risk of bleeding. Those against routine laboratory testing[10] point to retrospective studies indicating that they rarely detect unexpected bleeding disorders,[11,12] and also emphasize the problems in evaluating false-positive abnormalities. A recent literature review found insufficient evidence to conclude that an abnormal prothrombin time/international normalized ratio (PT/INR) predicts bleeding during invasive procedures.[13] A retrospective review[14] of the value of preoperative platelet count, PT, and activated partial thromboplastin time (aPTT) in 828 patients undergoing major noncardiac surgery found that only 2% had abnormal results, and most were expected on the basis of history and physical examination. Furthermore, no relation between abnormal laboratory tests and intraoperative blood loss or postoperative bleeding complications was found.[14] This is not surprising, given the lack of studies using an evidence-based approach to determine the degree of abnormality in the PT/INR or aPTT at which an invasive procedure may be unsafe.[15] A number of prospective studies have also concluded that routine screening laboratory tests in asymptomatic patients are not predictive of peri- or postoperative bleeding.[16–20] Thus, for an unselected population, in the absence of historical risk factors or physical examination findings suggestive of an underlying bleeding tendency, the likelihood of an unsuspected, clinically significant congenital or acquired coagulopathy is low enough that routine laboratory screening is not warranted,[21] particularly for those undergoing low risk procedures. However, it has been suggested that Ashkenazi Jews should receive special consideration, because of the relatively high prevalence of factor XI deficiency. In this population, screening aPTT might be reasonable to consider.[21]

The bleeding time has long been used to assess primary hemostasis and to predict the risk of hemorrhage associated with invasive procedures. However, there is now general consensus that in the absence of a history of a bleeding disorder, the bleeding time is not useful in this setting.[22] More recently, a platelet function analyzer (PFA-100) has been developed for rapid, quantitative, in vitro global testing of platelet function.[23–27] The clinical sensitivity (94%–95%) and specificity (88%–89%) of this instrument are virtually identical to platelet aggregometery,[27] and it is clearly superior to the bleeding time.[24,28] It has been suggested that the PFA-100 could be used in screening for primary hemostatic defects in routine clinical practice,[29] but such testing has limitations. The PFA-100 has high sensitivity for moderate to severe von Willebrand Disease and severe platelet defects, such as Glanzmann thrombasthenia and Bernard–Soulier syndrome, but it has poor sensitivity for milder intrinsic platelet disorders like storage pool disease, Hermansky–Pudlak syndrome, and primary secretion defects.[28] Although the PFA-100 is most useful when a hemostatic defect is clinically likely, in such cases additional testing is usually necessary to establish a specific diagnosis.[28,30,31] If clinical suspicion is high, further testing is indicated even with normal PFA-100 results.[28] Thus, the PFA-100 should not be used for general unselected screening[31] and adequately designed clinical trials are needed to clarify the role of this device in predicting surgical bleeding risk.[30]

Notwithstanding the ongoing controversy regarding the value of preoperative laboratory screening, it seems reasonable to adopt an approach that it is a compromise, in which the level of hemostatic risk for the proposed surgery or invasive procedure (Table 160–1) forms the basis for an approach to preoperative evaluation (Table 160–2). A hemostatic history should be obtained in all patients, and in those about to undergo a low-risk procedure no laboratory tests are required. For moderate-to-high risk procedures, additional screen-

Table 160–1 Risk of Bleeding With Surgical or Invasive Procedures

Risk	Type of Procedure	Examples
Low	Nonvital organs involved, exposed surgical site, limited dissection	Lymph node biopsy, dental extraction, cataract extraction, most cutaneous surgery, laparoscopic procedures, coronary angiography
Moderate	Vital organs involved, deep or extensive dissection	Laparotomy, thoracotomy, mastectomy, major orthopedic surgery, pacemaker insertion
High	Bleeding likely to compromise surgical result, bleeding complications frequent	Neurosurgery, ophthalmic surgery, cardiopulmonary bypass, prostatectomy or bladder surgery, major vascular surgery, renal biopsy, bowel polypectomy

Table 160–2 Preoperative Hemostatic Evaluation

Routine Screening	
Surgical Risk	**Approach**
Low	History only
Moderate or high	History, PT, aPTT, platelet count
Consultation History	**Approach**
Negative or minimal for bleeding	PT, aPTT, platelet count, biochemical profile, complete blood count with differential, review of peripheral smear
Suggestive of bleeding disorder	Add to above as indicated: platelet function tests, von Willebrand antigen, ristocetin cofactor, factor VIII, factor IX, factor XI, factor XIII assays

ing could include a PT/INR, aPTT, and assessment of the platelet count.

In practice, a hematologist is rarely consulted for routine screening because surgeons have adopted approaches based on their own training and local practice patterns. Rather, consultation is sought because of a history suggesting a bleeding disorder or an abnormal test that is found on screening. The approach of the consultant cannot be one of "routine screening" because the judgment of the referring physician that a bleeding disorder may be present indicates an increased probability of finding an abnormality. If a referral is obtained as a result of an abnormal screening test result, this finding must be pursued and the abnormality fully explained. However, for all referrals the history is still of central importance and must include a thorough review of any bleeding episodes, including hospital records and results of prior hemostatic testing, as well as careful attention to the family history. The physical examination should focus on evidence of bleeding and on identifying systemic disorders such as hepatic or renal disease. If the history of bleeding is negative or minimal, appropriate laboratory testing would include a PT/INR, aPTT and a biochemical profile to evaluate hepatic and renal function. A complete blood count and examination of the peripheral blood smear are useful to identify myeloproliferative disorders, gray platelet syndrome, or thrombocytopenia. If the history is suggestive of a hemostatic abnormality, a full evaluation is indicated and additional specific testing is usually required because von Willebrand disease, mild deficiencies of factors VIII, IX, and XI, severe factor XIII deficiency, platelet function defects, and fibrinolytic abnormalities may not be identified by global screening tests (Table 160–2).

HEMOSTATIC AGENTS

A variety of hemostatic agents are available and may be useful for the prevention or treatment of bleeding in the surgical patient. These agents work through a variety of mechanisms to facilitate hemostasis, including enhancement of primary hemostasis, stimulation of thrombin generation and fibrin formation, and inhibition of fibrinolysis.[32] However, it is important to note that there are a paucity of safety data involving hemostatic agents, as most trials have been designed to assess therapeutic efficacy rather than potential complications including thrombosis.[32,33] The use of desmopressin, fibrin sealants, topical thrombin, antifibrinolytics, and recombinant factor VIIa will be discussed here. Blood products (platelets, fresh frozen plasma, cryoprecipitate) and clotting factor VIII and IX concentrates are discussed elsewhere (Chapters 125 and 151).

Desmopressin

Desmopressin (1-deamino-8-D-arginine vasopressin, or DDAVP) is a synthetic analog of the antidiuretic hormone arginine vasopressin. Intravenous, subcutaneous, or intranasal administration of DDAVP results in transient increases in plasma concentrations of factor VIII and von Willebrand factor as a result of their release from vascular endothelium.[34] Peak levels (typically 2–4 times basal) are achieved 30 to 60 minutes after intravenous and 60 to 90 minutes after subcutaneous or intranasal administration.[35] Doses may be repeated at intervals of 12 to 24 hours, but tachyphylaxis may occur after 3 or 4 doses,[36] limiting further usefulness of DDAVP. Expression of GPIb and GPIIb/IIIa on platelet membranes is also enhanced following administration of DDAVP.[37]

DDAVP is the treatment of choice for patients with mild hemophilia A or type I von Willebrand disease who require low-risk surgical procedures. Moderate- or high-risk procedures usually require administration of clotting factor concentrates.[35] DDAVP may also be useful for patients with congenital or acquired platelet function disorders.[35,37,38] Although initially felt to be promising,[39] the efficacy of DDAVP in reducing blood loss and transfusion requirements associated with cardiopulmonary bypass has not been supported by subsequent clinical trials,[40–43] an impression that has been confirmed by large meta-analyses.[44,45] Worrisome also is the fact that meta-analysis has shown a 2.4-fold increase in perioperative myocardial infarction in cardiac surgery patients treated with DDAVP.[45] Thus, the routine use of DDAVP in cardiac, orthopedic, or other elective surgical procedures is not recommended,[33,46] although certain subgroups of patients, such as those with platelet dysfunction, may benefit.[33,37,46–48] Because of the small but important risk of myocardial infarction,[49] DDAVP should be used with caution in any surgical patient with a history of, or risk factors for, coronary artery disease.[37,46]

Fibrin Sealants

Fibrin sealants (also referred to as "fibrin glue" or "fibrin tissue adhesive") are hemostatic agents composed of purified, virally inactivated human fibrinogen, human thrombin, and sometimes added components such as human factor XIII and bovine aprotinin.[50] These agents reproduce the final steps of the coagulation cascade, resulting in formation of a stable fibrin clot.[51] Commercially available in Europe and Japan for more than 25 years, concern about viral transmission halted development and limited the use of fibrin sealants in the United States until 1998, when licensing was approved by the Food and Drug Administration. Fibrin sealants may be a useful adjunct in achieving surgical hemostasis, reducing the need for postoperative transfusion, and possibly decreasing postoperative wound complications. A relative disadvantage of these agents is that to be effective, they need to be applied to a tissue surface that is dry (and therefore not actively bleeding).

Fibrin sealants are used in cardiovascular surgery to seal suture lines and anastomoses, and are helpful in reducing air leakage in

thoracic surgery.[50,52] They may also be used in plastic and reconstructive surgery, hepatic surgery, orthopedic surgery, dental surgery, in the treatment of upper gastrointestinal hemorrhage, to prevent and treat CSF leakage in neurosurgery, and in urologic procedures.[50,52,53] Fibrin sealants may be particularly useful in laparoscopic and bariatric surgery.[52] The use of fibrin sealants has been shown to reduce perioperative blood loss in patients with a variety of congenital bleeding disorders.[54]

In spite of their increasing use across a wide range of surgical specialties over the last several years, recent studies continue to paint a conflicting picture regarding the benefits of fibrin sealants. In a study of 85 patients and 80 controls undergoing unilateral total knee arthroplasty, the use of fibrin sealant (along with autologous platelet gel) resulted in significantly higher postoperative hemoglobin levels, decreased transfusion requirements, and lower incidences of wound leakage and poor healing.[55] In contrast, a meta-analysis of 11 trials investigating the use of fibrin sealant in breast cancer surgery found no benefit in reducing postoperative wound drainage or seroma formation.[56] Some argue that discrepant results between studies may be due to differences in the fibrin sealant preparations used, application techniques, and outcome measures.[52] Regardless, there are few randomized controlled trials in the literature to guide clinical practice, and the methodological quality of the available studies has been criticized.[33,57]

Topical Thrombin

Thrombin derived from bovine plasma has been used for more than 30 years as a topical hemostatic agent in surgical patients. However, plasma-derived bovine thrombin has been associated with the development of antibodies that may cross-react with human blood proteins, leading to hemorrhagic complications.[58–60] Recombinant human thrombin is now being developed as an alternative agent.[61–63] A phase III clinical trial was completed in the fall of 2006 but has not yet been published.

Antifibrinolytics

Antifibrinolytic agents include the synthetic lysine analogs 6-aminohexanoic acid (aminocaproic acid) and 4-(aminomethyl)cyclohexane carboxylic acid (tranexamic acid), and the serine protease inhibitor aprotinin. Although both types of antifibrinolytic agents are used in managing surgical bleeding, the fact that the lysine analogs are orally available facilitates their use in other clinical situations as well.

Aminocaproic acid and tranexamic acid

Both aminocaproic acid and tranexamic acid bind reversibly to the lysine binding site on plasminogen, thereby interfering with fibrin binding, which is required for activation by plasminogen activators.[35] Although tranexamic acid is approximately 10 times more potent than aminocaproic acid and has a longer half-life, both drugs have similar hemostatic effects even in the absence of laboratory signs of excessive fibrinolysis.[64] Extravascular tissue accumulation with inhibition of tissue fibrinolysis and subsequent clot stabilization is thought to explain the efficacy of these drugs.[35]

Because the oral form of tranexamic acid is no longer commercially available in the United States, aminocaproic acid has become the lysine derivative of choice. It is commonly used to treat mucosal hemorrhage (menorrhagia, epistaxis, dental bleeding) in patients with congenital coagulopathies, and is also effective for prevention of oral bleeding in those who require dental work while receiving long-term oral anticoagulant therapy. Although aminocaproic acid is sometimes used to treat bleeding in patients with thrombocytopenia, there is a lack of randomized controlled trials in the literature to guide clinical practice.[38] The use of antifibrinolytic drugs in patients with gastrointestinal bleeding would seem rational given the high concentration of fibrinolytic enzymes in the digestive tract, and a meta-analysis of more than 1200 such patients found reductions in recurrent bleeding, need for surgery, and mortality.[65] However, improvements in the efficacy of other medical and endoscopic treatments have limited the use of these drugs in this setting, although they are still useful for some patients with underlying bleeding disorders.[35] The urinary tract is also rich in plasminogen activators and some clinical trials comparing tranexamic acid or aminocaproic acid with placebo in patients undergoing prostatectomy have shown reduced blood loss, but not a reduced need for transfusion or decreased mortality.[35] Additional data from appropriately designed clinical trials are needed before the routine use of antifibrinolytic agents in urologic surgery can be recommended.[47]

The largest experience with the use of aminocaproic acid in surgical patients exists in those undergoing cardiac surgery. Older meta-analyses have consistently shown that prophylactic treatment of cardiac surgery patients with aminocaproic acid results in a 30% to 40% reduction in postoperative bleeding, without an increase in thromboembolic complications.[45,66–68] Similar results have been shown with tranexamic acid.[37] Other meta-analyses have shown that aminocaproic acid and tranexamic acid are effective in reducing surgical blood loss, but have yielded inconsistent results in reducing transfusion requirements.[46,69] A wide variety of dosing schedules may partly explain these heterogeneous results.[46] A recent meta-analysis showed that both agents were effective in reducing blood loss and transfusion requirements in those undergoing cardiac surgery.[70]

Two randomized controlled trials[71,72] have shown that high-dose tranexamic acid significantly reduces surgical blood loss and transfusion requirements in liver transplant recipients. A recent meta-analysis identified 23 studies with a total of 1407 liver transplant patients who received aminocaproic acid, tranexamic acid, or aprotinin compared with each other or with controls/placebo. This review found that tranexamic acid and aprotinin reduced transfusion requirements without any increased risk for hepatic artery thrombosis, VTE, or perioperative mortality.[73] Additional studies comparing the efficacy of tranexamic acid with aminocaproic acid and/or aprotinin are needed.[37]

A number of studies have demonstrated that antifibrinolytic agents reduce blood loss in orthopedic surgery. A recent meta-analysis[74] identified 43 randomized controlled trials in total hip and knee arthroplasty, spine fusion, musculoskeletal infection, or tumor surgery. Aprotinin and tranexamic acid significantly reduced the number of patients requiring transfusion, with a dose–effect relationship suggested for tranexamic acid. Aminocaproic acid was not found to be effective, although the data were sparse. Similarly, data were too limited to make any definitive conclusions about the safety of these agents in orthopedic surgery patients.

There are case reports of thrombosis associated with both aminocaproic acid and tranexamic acid. However, no significant increase in thrombotic complications has been observed when these drugs have been used in patients undergoing cardiac, liver transplant, or orthopedic surgery, although those studies were not specifically powered to evaluate for thrombotic complications.[35,37,70,73]

Aprotinin

Aprotinin is a polypeptide extracted from bovine lung that inhibits the action of serine proteases including plasmin and kallikrein.[35] In addition to its antifibrinolytic activity, aprotinin is also thought to preserve platelet function and have antiinflammatory effects, both of which may be mediated by inhibition of protease-activated receptors expressed on platelets, vascular endothelium, and neutrophils.[75] The pharmacokinetics of aprotinin are complex and there is wide interindividual patient variability.[46] Renal failure results in reduced clearance and prolonged half-life of this drug. As neither the optimal dose nor the appropriate therapeutic concentration required for effective hemostasis has been definitively established, many different dosing regimens have been used.[46]

A large number of clinical trials have consistently shown that prophylactic administration of aprotinin can improve hemostasis and

reduce requirements for transfusion of red blood cells, platelets, and fresh frozen plasma in a majority of patients undergoing cardiopulmonary bypass.[33,37,46] A large meta-analysis of randomized controlled trials using aprotinin in cardiac surgery has also demonstrated decreased mortality and a reduced incidence of repeat thoracotomy, without any increased risk of perioperative myocardial infarction.[45] Furthermore, another meta-analysis of randomized controlled trials showed a lower incidence of stroke in cardiac surgery patients treated with high-dose aprotinin.[76]

Although there is abundant solid evidence that aprotinin effectively reduces blood loss and transfusion requirements in cardiac surgery patients, recent literature highlights the risk of serious adverse events associated with this drug and has fueled much debate. A nonrandomized observational study involving 4374 patients who received elective coronary revascularization compared aprotinin, aminocaproic acid, and tranexamic acid with no treatment.[77] This study found that use of aprotinin was associated with a doubling of the risk of renal failure requiring dialysis, a 55% increase in the risk of myocardial infarction or heart failure, and a nearly doubled increase in the risk of stroke or encephalopathy. Aminocaproic acid and tranexamic acid reduced blood loss to a similar degree, but without any increased risk of adverse renal, cardiac, or cerebrovascular events. The same investigators also recently reported that aprotinin use is associated with an increased risk of long-term (5 years) mortality following coronary artery bypass graft surgery.[78] Another recent cohort evaluation of 3348 patients who underwent cardiothoracic surgery in a single center that reserves aprotinin use for complex surgeries and for those patients whose religious beliefs forbid blood transfusion confirmed an increased risk of postoperative renal dysfunction, but found no increased risk of myocardial or cerebrovascular events.[79] Although aminocaproic acid and tranexamic acid appear to be relatively safe, it is important to note that the numbers of trials and study participants are much smaller for these drugs than for aprotinin. Moreover, trials comparing aprotinin with aminocaproic acid and tranexamic acid have been too few and too small.[33] The Blood Conservation Using Antifibrinolytics: A Randomized Trial in a Cardiac Surgery Population (BART) study plans to enroll 2970 patients undergoing high-risk cardiac surgery to determine whether aprotinin is superior to aminocaproic acid or tranexamic acid in reducing the risk of postoperative bleeding, adverse cardiovascular events, renal failure, and mortality. Although the safety debate remains, and until the results of the BART study are available, aprotinin is still the hemostatic agent of choice but should be limited to use in complex cardiac surgeries or in situations when excessive blood loss is anticipated, such as when antiplatelet agents have already been used.[33]

Although the use of aprotinin in orthotopic liver transplantation was first reported more than 15 years ago, its routine use in this setting has long been debated. Two randomized controlled trials have shown a 30% to 40% reduction in transfusion requirements in liver transplant recipients.[80,81] Aprotinin may also have favorable hemodynamic effects following graft reperfusion,[82] possibly because of inhibition of the release of bradykinin and other vasodilating substances. Prophylactic administration of aprotinin has also been shown to significantly reduce perioperative bleeding in patients undergoing noncardiac thoracic surgery and orthopedic surgery, although the extent of the clinical trial data is more limited.[37]

Because of its bovine origin, aprotinin may cause hypersensitivity reactions. The incidence is less than 1%, increasing to approximately 3% upon reexposure to the drug. Thus, retreatment within 6 months is not recommended.[48,83] In addition to the recent safety concerns noted above, the similar beneficial effects, yet significantly greater cost, of aprotinin compared with aminocaproic acid or tranexamic acid have led some to question the routine use of aprotinin in surgical patients.[48]

Recombinant Factor VIIa

Recombinant factor VIIa (rfVIIa) is a hemostatic agent that is currently licensed in the United States only for the management of bleeding in hemophilia patients with factor VIII or factor IX inhibitors and in those with congenital fVII deficiency. This drug is believed to induce hemostasis at local sites of tissue injury through enhancement of thrombin generation on the surface of thrombin-activated platelets.[84] Recombinant fVIIa also activates thrombin activatable fibrinolysis inhibitor (TAFI), which in turn stabilizes the clot by inhibiting fibrinolysis.[85] The use of rfVIIa in the management of hemophilia and factor VII deficiency is reviewed in Chapters 126 and 127. Accumulating anecdotal experience and case series have generated interest in the use of rfVIIa in other settings, and it is increasingly being used for off-license indications, such as to control refractory bleeding after surgery or major trauma, and to prevent bleeding in surgeries where blood loss is expected to be excessive.

Difficult to control "coagulopathic" hemorrhage commonly occurs without preexisting coagulation deficits in those who suffer major trauma and roughly half of all early trauma deaths are due to hemorrhage. Such bleeding is typically multifactorial, with contributions from the dilution of platelets and clotting factors secondary to large-volume transfusions, excessive transfusion of citrate anticoagulant, hyperfibrinolysis, hypothermia with subsequent slowing of the enzymatic coagulation reactions, and acidosis. In 1999, a report of the successful treatment of a bleeding soldier with rfVIIa[86] generated widespread interest in the use of rfVIIa outside of hemophilia. A number of case reports and series followed, describing favorable results with the use of rfVIIa in trauma patients. A randomized, controlled trial published in 2005[87] that included 143 blunt and 134 penetrating trauma patients currently provides the best evidence regarding the efficacy of rfVIIa in this setting. In a post hoc analysis of the group with blunt trauma, three successive doses of rfVIIa significantly decreased red blood cell transfusion (mean reduction of 2.6 units) and decreased by approximately half the number of patients requiring massive transfusion (more than 20 units of red blood cells). Similar trends were observed in the patients with penetrating trauma but were not statistically significant. Although this study supports the use of rfVIIa in blunt trauma, particularly in coagulopathic patients,[88] many issues require further investigation, including dosing and timing of administration.[89]

Significant hemostatic alterations may result from cardiopulmonary bypass, leading to excessive postoperative bleeding. Hypothermia, hemodilution, and activation of the coagulation, fibrinolytic, and inflammatory pathways all contribute to the complex hemostatic defect associated with cardiopulmonary bypass. In addition, use of newer anticoagulant drugs including direct thrombin inhibitors, low-molecular-weight heparins, pentasaccharides, and platelet inhibitors may also contribute to hemorrhagic risk in cardiac surgery patients.[90] Perioperative bleeding is a major cause of morbidity and mortality and thus the current widespread interest and increasing off-label use of rfVIIa in this patient population.[89] A number of case reports and uncontrolled case series in both adult and pediatric populations have suggested that rfVIIa is effective in decreasing blood loss and transfusion requirements in many patients with intractable bleeding following cardiopulmonary bypass. Although well-designed, randomized, placebo-controlled trials are lacking, considering the current published experience and the pathophysiology of perioperative bleeding in this setting, there appears to be a role for rfVIIa in the treatment of life-threatening, refractory hemorrhage associated with cardiac surgery. There is little evidence to justify the prophylactic use of rfVIIa in these patients. Additional study is urgently needed to address questions regarding optimal dosing, safety, and cost-effectiveness.[89–91]

Elective surgical procedures may potentially be amenable to the possible blood-sparing effects of rfVIIa. A randomized double-blind placebo-controlled trial of 36 patients undergoing retropubic prostatectomy demonstrated greater than 50% reduction in surgical blood loss in patients treated with a single intraoperative dose of rfVIIa.[92] Conversely, however, in a similarly designed trial in 204 noncirrhotic patients undergoing partial hepatectomy, treatment with rfVIIa resulted in a much less dramatic reduction in blood loss.[93] In addition, because the amount of bleeding reported in the control group of the former study has been perceived as excessively high, rfVIIa is not routinely or commonly recommended for elective prostate or other urologic surgery.[89] The published experience in orthopedic,

vascular, and obstetric/gynecologic surgery is still too limited and subject to publication bias to draw meaningful conclusions.[89]

Neurosurgical patients are distinct from other groups in that rather than treating massive hemorrhages, the goal is to treat relatively small bleeds within a closed space where even mild or modest benefit may result in significantly better clinical outcomes.[89] A recent, randomized, placebo-controlled study of intracerebral hemorrhage showed that treatment with rfVIIa within 4 hours after the onset of symptoms limits growth of the hematoma, reduces mortality, and improves functional outcomes at 90 days, albeit with a small increase in the frequency of thromboembolic events.[94] Solid evidence supporting the use of rfVIIa for other neurosurgical indications is still limited, but this study has had a major impact on the management of hemorrhagic stroke in North America, and has promoted the implementation of additional ongoing clinical trials.[89]

The primary safety concern with the use of rfVIIa is thrombosis. Most of the initially reported thrombotic events were associated with other risk factors such as preexisting atherosclerotic vascular disease or advanced age.[95] In hemophilia, the risk of thrombosis is estimated to be less than 1%.[96,97] However, with the increasing use of rfVIIa in patients without hemophilia, concerns about the thrombogenic potential of this drug remain. Much of the published literature describing off-label use of rfVIIa reports a very low incidence of thrombotic complications, but it is important to recognize that most of these studies involved patients with already impaired coagulation and were not specifically designed to assess for thrombotic risk. A review based on the FDA MedWatch database[98] has heightened awareness about the thrombogenic potential of rfVIIa. Both arterial and venous thromboembolic events have been reported, and the vast majority have occurred with off-label use of rfVIIa. The thromboembolic event was felt to be the probable cause of death in 72% of the reported fatalities. Half of the thromboembolic events occurred within 24 hours of the last dose of rfVIIa, and many occurred within 2 hours.[98] Similar concerns have been raised by a recent report describing a 9.4% incidence of thromboembolic complications after administration of rfVIIa to trauma patients, with 10 of 14 deaths attributed at least in part to the thromboembolic event.[99] Further studies are clearly needed to better define the efficacy and safety of rfVIIa in surgical and trauma patients.

MANAGEMENT OF PATIENTS WITH HEMOSTATIC ABNORMALITIES

Patients with known hemostatic abnormalities are often referred prior to surgery for assessment of bleeding risk and recommendations regarding perioperative management. The approach to these patients should be according to the following considerations: (a) the risk of bleeding associated with the specific surgery or procedure must be evaluated (Table 160–1); (b) the need for surgery and its urgency must be carefully considered; greater risks are more warranted for correction of life-threatening conditions than for purely elective procedures; (c) the nature and severity of the patient's hemostatic abnormality and the ability to correct it must be recognized; and (d) consideration must also be given to the duration of replacement that will be required, with appreciation of potential bleeding that may be associated with events in the postoperative period such as removal of sutures and deep drains and the need for physical therapy, especially after orthopedic surgery. The following sections discuss perioperative management of some common coagulation abnormalities; the management of congenital factor deficiencies and von Willebrand disease are discussed elsewhere in this text (Chapters 125, 127 and 129).

Thrombocytopenia

Thrombocytopenia is one of the most common acquired hemostatic abnormalities, and the availability of platelet transfusion makes consideration of both emergency and elective surgery reasonable even in severely thrombocytopenic patients. The best index of bleeding risk in thrombocytopenic patients is the platelet count. In nonsurgical patients a threshold platelet count of 10,000/μL is widely used for prophylactic transfusions, yet there is inadequate scientific evidence to determine the platelet count below which the risk of surgical bleeding is increased.[100,101] The American Society of Anesthesiologists Task Force on Blood Component Therapy concluded that prophylactic platelet transfusion in surgical patients is usually indicated when the count is below 50,000/μL and is rarely indicated when the count is above 100,000/μL.[100] Clinical trials addressing this issue are still lacking.[102,103] For low-risk surgery, a single transfusion to increase the platelet count to more than 50,000/μL followed by close observation may suffice, whereas transfusion to maintain the platelet count at greater than 50,000/μL for moderate-risk surgery and greater than 100,000/μL for high-risk surgery is usually appropriate. The optimal duration of postoperative platelet support has not been carefully studied, but even for moderate- or high-risk surgery, platelets may be needed for less than 1 week as they are principally required for primary hemostasis. The platelet count should be monitored closely during the postoperative period, with the expectation that platelet survival will be shortened by infection, fever, or bleeding. In addition, platelet transfusion may be indicated for surgical patients despite an apparently adequate count in the presence of known or suspected platelet dysfunction and microvascular bleeding.

When thrombocytopenia is due to increased platelet destruction (eg, immune thrombocytopenic purpura), prophylactic platelet transfusion is largely ineffective and is indicated only for active, serious bleeding. In preparation for surgery, therapy with steroids and/or intravenous gamma-globulin often will increase the platelet count to a satisfactory level so that transfusion is not needed. Rh_o(D) immune globulin (WinRho) may also be useful in this setting.

Platelet Dysfunction

Patients with platelet dysfunction represent a large group in whom preoperative consultation is sought, typically because of an abnormal bleeding history or the discovery of a prolonged bleeding time or other laboratory assessment of platelet function with a normal platelet count. Drugs are the most common cause of acquired platelet dysfunction. Many commonly used types of medications including aspirin and other nonsteroidal antiinflammatory drugs, antibiotics, antidepressants (SSRIs), cardiovascular drugs, and newer antiplatelet agents, including ADP receptor and GPIIb/IIIa antagonists, can cause platelet dysfunction. Ethanol as well as certain foods and herbal supplements can also inhibit platelets: a careful history is therefore essential. Any drugs that interfere with platelet function should be discontinued before surgery and avoided in the perioperative period if possible.

A number of medical conditions can also cause acquired platelet dysfunction. The etiology may be fairly obvious in cases of renal or liver disease, myeloproliferative disorders, leukemias, myelodysplastic syndromes, or dysproteinemias, but consideration of undiagnosed intrinsic platelet defects (storage pool disease or platelet release defects) or von Willebrand disease may be necessary. Treatment of the underlying disease is the most effective approach, if possible. If not, platelet transfusion may be indicated, but the dose required to achieve hemostasis is difficult to predict and depends in part on the severity of the underlying platelet abnormality. As discussed above, treatment with DDAVP may be appropriate in selected patients. The exact mechanism of action of DDAVP in acquired platelet dysfunction is not well understood, but one study suggests that DDAVP interacts directly with platelets and exerts a priming effect on platelet aggregation stimulated by ADP or collagen.[104] Expression of GPIb and GPIIb/IIIa on platelet membranes is also enhanced following administration of DDAVP.[37]

Renal Disease

Impaired hemostasis has long been recognized in patients with chronic renal failure and is discussed in greater detail in Chapter 156.

The pathogenesis is multifactorial, but is due in large part to alterations in platelet function.[105] Anemia also contributes to platelet dysfunction in chronic renal failure. Red blood cells release ADP, which in turn inactivates vascular prostacyclin (PGI_2), an inhibitor of platelet function.[106] Correction of anemia, now routinely accomplished through the use of recombinant erythropoietin, also improves the rheologic factors that facilitate platelet interaction with the vessel wall. Increase in hematocrit, whether by the use of erythropoietin or transfusions, is accompanied by significant shortening of the bleeding time and improvement of platelet adhesion.[107] In addition to platelet dysfunction and altered balance between mediators of normal endothelial function, the pathophysiology of uremic bleeding is complicated by the comorbidities in this patient population, such as vascular disease and hypertension, and the medical treatment of those conditions.[108]

Owing to the success of erythropoietin, other hemostatic agents now play a smaller, yet still important, role in the management of bleeding in patients with renal insufficiency, particularly those with acute or subacute renal failure. DDAVP was shown in a randomized placebo-controlled trail to normalize bleeding times within 1 hour in uremic patients.[109] DDAVP may be useful for treating acute bleeding, and for prophylaxis prior to biopsy or urgent surgery. Conjugated estrogens also improve bleeding times and reduce or stop bleeding in uremic patients through unknown mechanisms.[110,111] Unlike DDAVP, the clinical effect of conjugated estrogens is delayed for several hours, but they have a much longer duration of action (10–15 days).[35] Thus, conjugated estrogens are more useful for management of chronic recurrent bleeding and perhaps prior to elective surgery. DDAVP and conjugated estrogens may be given concurrently, thereby taking advantage of the different timing of their hemostatic effects.[35] Conjugated estrogens may be given orally or intravenously, usually as five to seven daily doses, and are usually well tolerated, with negligible side effects. Cryoprecipitate can also shorten the bleeding time in patients with renal failure, but concerns about viral transmission and the effectiveness of other hemostatic agents have limited its routine use in this setting.

Liver Disease

Hemostatic alterations in patients with acute or chronic liver disease (Chapter 156) are complex and involve both procoagulant and anticoagulant pathways.[112,113] Although patients with liver disease are typically felt to have deficient hemostasis, this concept has been challenged in recent literature.[113] In fact, patients with liver disease may develop portal vein or hepatic artery thrombosis, which are partly due to a hypercoagulable state.[113]

The coagulopathy of liver disease is usually the result of a combination of several deficits,[114,115] including (a) reduced synthesis of pro- and anticoagulant clotting factors, which is proportional to the extent of hepatocyte damage.[114] Slight prolongation of the PT/INR occurs in mild to moderate liver disease, primarily because of decreased factor VII synthesis. More advanced liver disease is accompanied by additional clotting factor decrements, including factors II, IX, and X, followed by fibrinogen and factor V. Factor VIII levels are typically preserved (and often elevated) even in severe liver disease. (b) Vitamin K deficiency due to impaired enterohepatic recirculation of bile salts and subsequent malabsorption may compound the reduction in clotting factor synthesis. (c) Dysfibrinogenemia due to synthesis of abnormally glycosylated fibrinogen occurs in 60% to 70% of patients with liver disease.[116] This results in a disproportionate prolongation of the thrombin time relative to a mildly prolonged PT/INR and aPTT. (d) Thrombocytopenia is common in advanced chronic liver disease, and occurs in up to 65% of those with cirrhosis.[117,118] Platelet counts rarely drop below 30,000–40,000/μL and spontaneous bleeding on this basis alone is uncommon. Thrombocytopenia results from both hypersplenism and reduced hepatic synthesis of thrombopoietin.[119] Direct ethanol toxicity and folate deficiency may also impair megakaryocyte production. (e) Platelet dysfunction through a variety of mechanisms is also seen in liver disease,[115] although this may be offset by elevated von Willebrand factor levels.[120] (f) Hyperfibrinolysis due to impaired hepatic clearance of plasminogen activators and/or reduced synthesis of endogenous inhibitors of fibrinolysis (α_2-antiplasmin, TAFI) is also common with advanced liver disease.[114,115]

Patients with severe decompensated liver disease and markedly abnormal coagulation tests are at increased risk of bleeding, and surgery should be avoided except as a lifesaving measure. In evaluating hemostasis in patients with less severe disease, the PT/INR and aPTT may be good indicators of decreased synthesis of clotting factors and vitamin K deficiency, but they are poor predictors of bleeding risk. Several published studies have shown the failure of the PT/INR and aPTT to predict bleeding following liver biopsy.[13,121–125] Similarly, preoperative hemostatic testing has generally not been shown to be clinically useful in predicting bleeding during liver transplantation.[126] A study in patients with liver disease found that INRs in the range of 1.3 to 2.0 generally correspond to levels of factors II, V, and VII that are adequate for hemostasis.[127] A preoperative platelet count is needed to identify thrombocytopenia and some assessment of platelet function may be useful to determine whether platelet function is abnormal in the setting of a normal or near-normal platelet count. A thrombin time should also be performed, to evaluate for dysfibrinogenemia. Tests for fibrinogen/fibrin degradation products, D dimer, and euglobulin clot lysis time may be useful in evaluating disseminated intravascular coagulation or accelerated fibrinolysis.

In patients with mild liver disease and mild-moderate PT/INR prolongation (<2.0), serious surgical bleeding is unlikely in the absence of other hemostatic abnormalities, and prophylactic intervention is not necessary for low- or moderate-risk surgery. For high-risk surgery or greater degrees of hemostatic abnormality, transfusion of fresh frozen plasma is the most commonly used approach for correcting the coagulation abnormality, although there are no good prospective studies to guide the use of fresh frozen plasma in this situation. It should be noted that the PT of fresh frozen plasma is approximately 15 seconds, so complete correction of the patient's PT/INR cannot usually be achieved.[128] Administration of platelets should be considered for more severe degrees of thrombocytopenia, although recovery will be decreased in the presence of splenomegaly. Administration of DDAVP may be useful in correcting abnormal platelet function in some cases.[129] Administration of 5 to 10 mg vitamin K will usually shorten the PT/INR if vitamin K deficiency is a contributory factor. As discussed above, antifibrinolytic agents may also be useful in the reduction of perioperative hemorrhage in patients with liver disease.

INTRAOPERATIVE AND POSTOPERATIVE BLEEDING

Excessive bleeding during or after surgery is a serious and potentially life-threatening complication that requires immediate evaluation and a rapid approach to diagnosis and institution of treatment. The first consideration should be to differentiate between "surgical" and "coagulopathic" causes of bleeding. Failure to surgically control bleeding vessels at the operative site is the most frequent cause of postoperative bleeding, and is suggested by evidence of hemorrhage only at the operative site and seen as expanding hematoma, excessive blood in surgical drains, or saturated wound dressings. Conversely, coagulopathic bleeding is suggested by slower "oozing" at the operative site in addition to evidence of bleeding outside the operative field that may be seen as petechiae, purpura, or bleeding at sites of venipuncture, urinary or vascular catheters, or nasogastric and endotracheal tubes.[130] In addition to careful physical examination, laboratory tests including PT/INR, aPTT, and platelet count are an essential part of the evaluation. Other useful tests may include fibrinogen activity, a test for fibrin degradation products or D dimer, and euglobulin lysis time to search for evidence of DIC or fibrinolysis. The peripheral blood smear should also be reviewed to examine platelet morphology and number and to identify possible red blood cell fragmentation that may occur in DIC. The possibility of a preexisting hemostatic abnormality that may have been undetected

before surgery should also be considered. Revisiting the patient's family and past medical history, along with a thorough review of preoperative medication use may yield important diagnostic clues.

When evaluating hemostatic tests in surgical patients, changes that normally occur in response to surgery must be considered. These vary depending on the extent of tissue dissection and duration of the procedure. Consumption as well as hemodilution from crystalloid and blood product infusion both lead to acute reductions of coagulation factors and platelets during surgery and in the initial postoperative period. This is typically followed by changes resulting from the acute phase response, including increases in fibrinogen, platelet count, factor VIII, and plasminogen activator inhibitor-1 during the first postoperative week.[131]

Alterations in coagulation factor levels that occur during surgery and in the initial postoperative period can limit the reliability of the PT/INR and aPTT in evaluating the bleeding surgical patient. Clinical practice guidelines have consistently recommended transfusion of fresh frozen plasma when PT/INR and aPTT results exceed the mean reference range by 1.5 times.[100,132–137] However, a prospective study of 16 patients with bleeding caused by dilutional coagulopathy following spinal surgery found significant variability in the PT/INR and aPTT, and suggested that depending on which test system was used, clinical decisions regarding coagulation factor replacement therapy might differ.[138] Conversely, another and larger retrospective study in a similar patient population found that the PT/INR and aPTT had sufficient sensitivity and specificity to be helpful in guiding transfusion therapy,[139] and some consensus panel guidelines do recommend that transfusion of fresh frozen plasma and cryoprecipitate in the bleeding surgical patient be guided by coagulation studies.[140] Additional prospective studies of patients undergoing other types of surgery are needed to more clearly define the role of coagulation testing in the management of surgical bleeding.

Coagulopathy Associated With Massive Blood Loss/Transfusion

Massive bleeding (loss of one or more blood volumes in a 24-hour period) may occur in the setting of severe trauma or major surgery, and requires aggressive transfusion of blood products and other fluids. In addition to a dilutional coagulopathy, other complications including consumptive coagulopathy, hypothermia, electrolyte abnormalities (due to citrate intoxication) and acid–base disturbances may also develop.[141] In patients without a preexisting coagulopathy, replacement of approximately 1.5 blood volumes is the threshold for the development of dilutional coagulopathy.[142] At that point, PT/INR, aPTT, fibrinogen level, and platelet count should be determined. If the PT/INR or aPTT is prolonged greater than 1.5 times control, the fibrinogen level is below 100 mg/dL, or the platelet count is reduced to 50,000 to 70,000/μL, clinical coagulopathy is suspected and appropriate blood product administration is indicated, particularly if additional blood loss is expected. The same coagulation parameters should be measured again with the replacement of each additional half blood volume (ie, 5–6 units of red blood cells).[143] With prolonged hypotension, acidosis, or extensive tissue trauma and ischemia, tissue factor and tissue plasminogen activator may be released into the bloodstream, initiating DIC. Obstetric catastrophes also commonly result in DIC. Consumptive coagulopathy results in hemostatic failure at lower volumes of blood loss or replacement and simple administration of blood components may not correct the coagulopathy. In these circumstances, restoration of systemic and hepatic perfusion (the liver is an important site of clearance of fibrin degradation products and activated coagulation factors) is essential for regaining control of hemostasis.

Cardiopulmonary Bypass

Cardiopulmonary bypass is associated with unique hemostatic changes. Perfusion through the extracorporeal membrane oxygenator has profound effects on platelets and clotting factors: platelet count, hematocrit, and levels of coagulation and fibrinolytic factors are reduced to approximately 50% of baseline after starting bypass, and remain reduced throughout the procedure, with the exception of factor V, which may be further reduced to less than 20%.[144–147] These changes may be caused in part by exposure to artificial surfaces and also by a tissue factor-dependent pathway related to surgical trauma.[148] Cardiopulmonary bypass results in significant platelet dysfunction reflected by release of α-granule contents, the generation of platelet microparticles, abnormal in vitro aggregation tests, and a prolonged bleeding time that usually corrects within 1 hour postoperatively.[144–149] In addition to quantitative and qualitative defects, cardiopulmonary bypass also results in platelet activation, which may contribute to thrombotic and inflammatory complications.[150] Patients with acute ischemic coronary syndromes—who may be candidates for urgent cardiac surgery—are routinely treated with drugs such as GPIIb/IIIa inhibitors that further impair platelet function, which may already be associated with cardiopulmonary bypass. If surgery cannot be delayed, consideration of prophylactic platelet transfusions may be required.[151] Inadequate neutralization of heparin by protamine sulfate given after completion of cardiopulmonary bypass may result in a prolonged aPTT and thrombin time with a normal reptilase time and is an indication for additional protamine sulfate. The use of DDAVP, antifibrinolytic drugs, and rfVIIa to reduce the hemorrhagic complications of cardiac surgery is discussed above.

Orthotopic Liver Transplantation

In addition to the complex coagulopathy of end-stage liver disease, orthotopic liver transplantation is accompanied by major alterations in hemostasis. The surgical procedure itself can be divided into three stages, each with its own profile of coagulation abnormalities.[152] Bleeding during the preanhepatic stage, while the host liver is surgically isolated, is due primarily to the patient's preexisting coagulopathy and is determined by the severity of the underlying liver disease. Excessive fibrinolysis may be encountered during this stage in 10% to 20% of those with cirrhosis. The anhepatic stage begins with surgical removal of the liver. Bleeding during this stage is primarily hemostatic because of DIC and excessive fibrinolysis.[152,153] As the donor liver is reperfused, the postanhepatic stage begins, and serious bleeding is often encountered as a result of a combination of hyperfibrinolysis, metabolic acidosis, hypothermia, electrolyte abnormalities, and sometimes impaired cardiac function.[152,154] The multifactorial nature of the coagulopathy associated with orthotopic liver transplantation requires a combination of therapeutic interventions. In addition to transfusion of blood products, other hemostatic agents such as DDAVP and antifibrinolytics may be useful and are discussed above. There has also been much interest in the use of rfVIIa, and two large randomized, placebo-controlled trials have recently been completed. In one study, a single dose of rfVIIa prior to surgery failed to reduce the number of red blood cell transfusions required.[155] The other study used repeated doses of rfVIIa during surgery, which also failed to reduce the number of red blood cell units transfused or intraoperative blood loss. However, a small but significant increase in the number of patients who avoided red blood cell transfusion entirely was observed in the treatment group.[156] As for other types of surgery, questions about optimal dosing, cost-effectiveness, and safety remain to be answered, and it is still questionable whether rfVIIa should be used as prophylaxis in liver transplant patients outside of a prospective clinical trial.[157]

Perioperative Anticoagulation Management

Hematologists are frequently consulted for advice on the perioperative management of patients on long-term oral anticoagulation. Important considerations to be taken into account include (a) the underlying indication for anticoagulant therapy; (b) in the case of secondary antithrombotic prophylaxis, the remoteness of the most

Table 160–3 Perioperative Management Strategies for Patients on Chronic Oral Anticoagulant Therapy

Clinical Situation	Suggested Anticoagulation Management
Low bleeding risk surgery (dental, cataract, skin)	Reduce dose of OAT to achieve INR ≈ 2
Low thrombotic risk	
Aortic valve prosthesis without	Stop OAT 4 nights before surgery
Other thrombotic risk factors*	Safe to operate when INR ≤ 1.4
or	Restart OAT on evening of surgery
AF with low stroke risk	Use prophylactic perioperative UFH/ LMWH if indicated (depends on type of surgery)
or	
VTE > 3 months previously	
Moderate thrombotic risk	
Mitral or multiple prostheses	Stop OAT 4 days prior to surgery
or	Begin IV UFH† when INR < 2.0 (target APTT = 2–3 × control)
Aortic prosthesis with risk factors for thrombosis	Stop heparin 5 hours presurgery
or	Begin UFH prophylaxis and OAT as soon as possible postoperatively; continue heparin until INR has been therapeutic for >48 hours
AF at high stroke risk	
or	
VTE within past 3 months	

AF, atrial fibrillation; OAT, oral anticoagulant therapy; UFH, unfractionated heparin; VTE, venous thromboembolism.

*Risk factors include caged-ball or single tilting disc valve, AF, history of stroke/TIA/other embolic event, left ventricular failure, underlying hypercoagulable state, including cancer.

†LMWH at full-treatment doses may also be used for bridging, although an FDA warning about their use in patients with mechanical valve prostheses was issued in 2002 (discussed in text).

Adapted from Dorman BH et al: Identification of patients at risk for excessive blood loss during coronary artery bypass surgery: Thromboelastography versus coagulation screen. Anesth Analg 76(4):694, 1993.

recent thrombotic event; (c) other comorbid conditions that may increase the risk of thrombosis, and/or the potential consequences of thrombosis, while oral anticoagulation is temporarily interrupted; and (d) the risk of bleeding, and/or the potential consequences of bleeding, associated with the procedure. Suggested management strategies are summarized in Table 160–3.

Traditionally, patients on chronic oral anticoagulation were admitted to hospital several days prior to surgery for "bridging" anticoagulation, at which time warfarin was discontinued, and dose-adjusted unfractionated heparin (UFH) was administered by continuous infusion. The short half-life of UFH allows it to be safely discontinued approximately 4 to 6 hours ahead of the procedure. In recent years, there has been a trend toward the use of low-molecular-weight heparins (LMWH) in place of UFH.[158–160] LMWHs have the advantage that in most patients with normal renal function, no monitoring is required, so that therapy can be administered in the outpatient setting. In addition, the risk of heparin-induced thrombocytopenia is less with LMWHs.[161] However, the longer half-life (generally in the range of 4–6 hours) necessitates withdrawal of these agents 12 hours or more preoperatively, although even then, significant circulating anticoagulant activity may remain in the plasma.[162] Bridging with UFH may still be appropriate for some patients, for example those with an estimated creatinine clearance less than 30 mL/min in whom the half-life of LMWHs may be prolonged, in some patients with mechanical prosthetic heart valves (see below), or in those at increased risk of bleeding if treated on an outpatient basis. To date, there are no published randomized control trials data on which to base decisions regarding the relative efficacy and bleeding risks of perioperative anticoagulation management; thus, all recommendations are at best grade 1C+. One concern with the lack of randomized studies is the fact that it has been assumed that heparins are equally efficacious as warfarin in reducing the risk of arterial thromboembolism in patients with atrial fibrillation or mechanical heart valves, whereas in fact there are few data to support this assumption.[163]

In general, as long as it is known to be in the therapeutic range, oral anticoagulation therapy can be continued without any significant increased risk of bleeding in patients undergoing single or multiple dental extractions (see section on management of anticoagulation in patients undergoing dental surgery), joint and soft tissue injections and arthrodesis, cataract surgery, dermal surgery, and upper or lower endoscopy or colonoscopy with or without biopsy.[164,165] For other surgeries, temporary interruption of oral anticoagulation is usually required. Even with a normal diet, 4 to 5 days should be allowed for full or near full reversal of oral anticoagulation targeted to an INR of 2.0 to 3.0. A more rapid reversal over 24 to 36 hours can be achieved if necessary by administration of a small oral dose of vitamin K_1 (1.0–2.5 mg).[166] Large doses of vitamin K_1 (>10 mg) are generally unnecessary for this purpose, and will lead to prolonged refractoriness to warfarin after it is reinitiated. Although frequently used, subcutaneous administration of vitamin K_1 is associated with highly variable absorption, and should be avoided. Intravenous vitamin K_1 has the advantage of more rapid INR reversal compared to the oral route,[167] but it should be administered slowly to avoid anaphylactoid reactions. Urgent reversal of oral anticoagulation prior to surgery may call for the administration of fresh frozen plasma, although large volumes are usually required to reverse the INR, and indeed, complete normalization cannot usually be achieved. Furthermore, the effect is relatively short-lived because of the short half-life (approximately 6 hours) of transfused factor VII. Therefore, concomitant vitamin K_1 administration is also always required to ensure maintenance of adequate hemostasis. Prothrombin complex concentrates (PCCs; 25–50 U/kg) may be used to control hemorrhage in the orally anticoagulated patient who is actively bleeding,[168] and they have been used to expeditiously reverse warfarin therapy prior to emergency surgery.[169] These concentrates are manufactured by fractionation of pooled plasma, and contain all the vitamin K-dependent procoagulant factors (II, VII, IX, and X), with a varying content of heparin and antithrombin, and the vitamin K-dependent anticoagulant proteins C and/or S. They are then subjected to one or more virucidal processes. Concern has been raised that PCCs may be associated with an increased risk of thrombosis.[170] However, the reports of thrombosis with these agents generally preceded the availability of modern day nonactivated concentrates, and occurred in patients with hemophilia who had received >200 U/kg/day for several days. Nonetheless, because the thrombotic risk might be accentuated in the perioperative period, the risk–benefit of these agents to reverse anticoagulation prior to surgery needs to be carefully weighed. Recently, the use of recombinant factor VIIa to reverse anticoagulation prior to emergency surgery has also been reported,[171] but further experience is needed before this approach can be recommended. In either case, the hemostatic agent needs to be supplemented by oral vitamin K_1 therapy to provide sustained correction of the coagulopathy.

Depending on the estimated risk of thrombosis when warfarin is discontinued, bridging with LMWH (or UFH) may be required while the INR is in the subtherapeutic range.[165,172] In this regard, a number of specific issues, which are considered in the next paragraph, surround each of the three most common indications for long-term oral anticoagulation therapy, namely VTE, atrial fibrillation (AF), and mechanical cardiac valve prostheses.[173] Although no LMWH yet has FDA approval for this purpose, large case series support the safety of this approach.[160,174,175] Regardless of whether bridging anticoagulation with UFH or LMWH is employed, the INR should be checked preoperatively to ensure that the pharmacologic effect of warfarin has been adequately reversed. Most surgeries can be safely carried out when the INR is less than 1.5.

Venous Thromboembolism

Patients are generally anticoagulated with warfarin to a target INR of 2.0 to 3.0 for several months to years after an acute episode of

VTE (here defined as deep vein thrombosis ± pulmonary embolism) (see Chapter 135). Before deciding on a perioperative anticoagulation management strategy in these patients, it is helpful to assess separately the risks of bleeding and recurrent VTE in the pre- and postoperative periods.[158] Although somewhat dependent on the type and magnitude of the intervention and method and duration of anesthesia, the risk of thrombosis is magnified up to 100-fold during the postoperative period.[176] In some individuals, for example those with a critically reduced cardiopulmonary reserve, even a minimal risk of pulmonary embolism may be unacceptable. Conversely, the potential consequences of even a modest amount of bleeding may be unacceptable in certain situations, for example, bleeding into an enclosed space such as the central nervous system in a patient undergoing neurosurgery.

It has been estimated that the risk of recurrent VTE after an acute VTE event without anticoagulant therapy is approximately 40% at 1 month and 10% at 2 months.[158] Even in patients appropriately treated with anticoagulants, the cumulative risk of recurrent VTE at 3 months is in the order of 6% to 8%, with approximately three quarters of events occurring within the first 3 to 4 weeks.[176–178] The risk gradually recedes thereafter, such that it is essentially back to baseline by approximately 3 months. However, the baseline risk may itself vary considerably. For example, in the case of an individual with a history of idiopathic VTE (ie, not associated with surgery or trauma), it may be as high as 10% to 15% per annum, at least during the first 2 to 3 years.[179,180] Especially high rates of recurrence may also be seen with underlying cancer, chronic cardiorespiratory disease, or antiphospholipid syndrome.[177,179,180] Therefore, wherever possible, it is usually preferable to delay elective surgery for a minimum of 2 to 3 months after an acute episode of VTE. In the extreme situation where surgery is unavoidable within the first month after an acute VTE, the risk–benefit ratio usually favors bridging with full-dose UFH or LMWH prior to and resuming again as soon as possible after surgery.[160,165,172] Generally speaking, a delay of 12 hours is sufficient to ensure adequate hemostasis after surgery, before heparin is reinitiated, although of course this will also depend on the type of surgery and its customary bleeding risks. When UFH is used, no bolus dose should be administered to avoid over-anticoagulation and the attendant increased risk of bleeding. In the second or third months after an acute VTE, the heightened risk of VTE after surgery still favors full-intensity heparin therapy initiated as soon as possible in the postoperative period. However, the preoperative risk of recurrence has receded to the point where prophylactic doses of subcutaneous heparin or LMWH are probably sufficient.[158] One of these agents should be initiated when the INR is less than 2.0 and continued until approximately 12 hours preoperatively. In most patients who are 3 or more months remote from their most recent episode of VTE, preoperative bridging anticoagulation is usually unnecessary. Standard postoperative prophylaxis with LMWH/UFH is then administered with simultaneous reinitiation of warfarin.

Atrial Fibrillation

Several large prospective studies have established the major risk factors for and rates of embolic stroke and bleeding for patients with nonvalvular atrial fibillation.[181,182] Low thrombotic risk patients include those who are relatively young (<65 years) with "lone" atrial fibrillation and no additional risk factors for stroke, such as a previous history of stroke or transient ischemic attack (TIA), hypertension, diabetes, or left ventricular dysfunction. Their risk of stroke without anticoagulant therapy is estimated to be less than 1% per annum, although there are limited clinical trials data on this topic.[183] At the opposite end of the spectrum, the estimated risk of stroke may approach 15% per annum in elderly patients (>75 years) with a previous history of stroke and one or more of the above risk factors.

A reasonable approach to perioperative anticoagulation management in patients with AF is to discontinue oral anticoagulation 4 to 5 days ahead of the planned surgery, with no bridging therapy except for those at high risk (stroke or TIA within previous month, rheumatic mitral valvular disease, nonvalvular AF with two or more risk factors). A large single-center series using a standardized LMWH bridging algorithm in patients at risk for arterial thromboembolism reported a thromboembolism rate of 0.4%, and a 0.7% incidence of major bleeding.[184]

Mechanical Prosthetic Heart Valves

The major thrombotic risks associated with mechanical prosthetic heart valves are systemic embolization, and valve thrombosis, which usually presents as acute congestive heart failure. These risks are dependent on the location of the valve (higher in the mitral position than the aortic position), number of valves, and type of valve.[185] The earlier model ball-and-cage valves (eg, Starr-Edwards) are considered to be more thrombogenic than the single leaflet tilting disc models (eg, Bjork-Shiley, Medtronic), which in turn are more thrombogenic than the bileaflet tilting disc models (eg St. Jude). The annual risk of thrombosis in patients with mechanical valves not receiving oral anticoagulation will therefore vary with (a) the type and location of the valve(s) and (b) certain comorbidities that increase the thrombotic risk, such as atrial fibrillation, congestive heart failure, enlarged left atrium, left ventricular aneurysm, and intracardiac thrombus. Estimates of the risk of thrombosis without anticoagulation are generally in the range of 8% to 15% per annum, but these figures may be exaggerated owing to the overrepresentation of older-model valves in these series.[186]

It is generally agreed that bridging with UFH or LMWH is unnecessary for the patient with an isolated prosthetic valve in the aortic position without any other major risk factors who is to undergo elective surgery. Warfarin therapy is merely discontinued 4 to 5 days ahead of the procedure, and is reinitiated as soon as possible after surgery with prophylactic doses of UFH or LMWH.[174,187,188] On the other hand, bridging may be indicated for patients with an aortic valve prosthesis and other risk factors for thrombosis, for mitral valve prosthesis, and for multiple valvular prostheses. In this situation, intravenously administered UFH with a target APTT of at least twice the control level is an accepted option. A growing experience with outpatient LMWH bridging (given at full therapeutic doses) suggests that it may be as effective and safe as UFH, at a lower overall cost. However, in 2002, the manufacturers of Enoxaparin issued a drug label "Warning" indicating that the use of Enoxaparin was not recommended for thromboprophylaxis for patients with prosthetic heart valves.[189] This action was prompted by the deaths of two pregnant patients with prosthetic valves from thrombotic complications while taking Enoxaparin. The warning was subsequently reworded to acknowledge that the standard approach—infusional dose-adjusted UFH—has also been associated with adverse thrombotic outcomes in pregnant women with prosthetic heart valves, and that this topic has not been studied adequately.[187,190,191] It is therefore likely that pregnancy represents a very different situation with respect to the failure rate of all heparins in bridging. The accompanying hypercoagulable state and increased plasma volume and glomerular filtration rate (which can affect the volume of distribution of the drug) contribute to the uniqueness of the pregnant patient with a prosthetic valve.[192,193] In the absence of data from randomized controlled trials, consensus is moving toward recommending the use of LMWH without routine monitoring for bridging anticoagulation in nonpregnant patients, based on an absence of evidence of any lesser efficacy or safety.[184,188,191] LMWH is probably also a reasonable option for longer-term prophylaxis in the pregnant patient who cannot take warfarin, although in this situation, routine periodic monitoring of anti-Xa activity is recommended with appropriate dose adjustments to target a peak anti-Xa activity (4–6 hours postdosing) of 0.7 to 1.2 U/mL.[187,191] The relatively low enrollment of subjects with mechanical heart valves receiving LMWH in registries of bridging anticoagulation suggests that there remains some reluctance to use this approach.[160,194,195] Indeed, recent recommendations from the American College of Cardiology and American Heart Association continue to recommend UFH given by continuous infusion rather

than LMWHs for bridging in patients at high risk of thrombosis.[187] This category would include all patients with mitral or tricuspid valve replacements and those with an aortic valve replacement and additional risk factors (atrial fibrillation, previous thromboembolism, a "hypercoagulable condition," older-generation mechanical valves, >1 mechanical valve, or a left ventricular ejection fraction < 0.3). It is clear that there is clinical equipoise in the optimal choice of bridging for higher risk patients, and data from prospective randomized clinical trials are urgently required to resolve the issue.

Management of Anticoagulation in Patients Undergoing Dental Surgery

A common reason for hematologic consultation is to provide recommendations for the patient on long-term oral anticoagulation therapy in whom dental surgery, including dental extraction(s), is scheduled. In a randomized clinical trial, a nonsignificant increase in bleeding complications occurred in patients continued on oral anticoagulation without adjustment (other than ensuring the INR was <4.0), compared to an intervention group in which anticoagulation was discontinued for 2 days to achieve an INR less than 2.0.[196] It is likely that the concurrent use of an antifibrinolytic agent mouthwash—which has independently been shown to reduce blood loss in this situation[197,198]—would further diminish the bleeding risk.

Management of Anticoagulation in Patients Undergoing Gastrointestinal Endoscopic Procedures

In deciding on the most appropriate periprocedural management of oral anticoagulant therapy in patients undergoing GI endoscopy, a working knowledge of the bleeding risk associated with the various interventional procedures is required (Table 160–4). Although simple diagnostic colonoscopy is associated with a very low bleeding risk (approximately 0.1%), colonic polyps will be identified in approximately one-third of patients undergoing routine screening. Endoscopic polypectomy may be associated with a significant bleeding risk. Risk factors for hemorrhage include hypertension, polyp size, sessile morphology, and location in the ascending colon. Bleeding is frequently delayed, with a median onset at approximately 5 days, although it may encountered up to 14 days postprocedure.[199] A consensus statement from the American Society for Gastrointestinal Endoscopy recommends continuing warfarin in the therapeutic range in patients who have a low risk of bleeding (eg, upper- or lower-GI endoscopy ± biopsy). On the other hand, interruption of anticoagulation (either temporary cessation or halving the dose for several days preoperatively in all but the highest thrombotic risk patients[200]) is recommended in those undergoing high-risk procedures (Table 160–4). In those patients with the highest risk of thromboembolism (eg, atrial fibrillation with valvular disease and/or prior history of stroke), bridging anticoagulation with heparin is recommended before and after high-risk procedures.[201]

Management of Anticoagulation in Patients Receiving Neuraxial Anesthesia

A special situation concerns the management of perioperative anticoagulation, particularly LMWHs, in patients receiving neuraxial (spinal and epidural) anesthesia or analgesia for surgery. The advantages of these forms of regional anesthesia compared to systemic anesthesia (superior analgesia, decreased transfusion requirements, and lower incidence of thrombotic complications) must be weighed against the risk of spinal hematoma. This rare but potentially disastrous complication is a result of needle- or catheter-induced vascular trauma during placement into the subarachnoid or epidural space. Bleeding usually occurs into the epidural space, probably because of the prominent epidural venous plexus. It presents more frequently as a delayed but progressive sensory or motor deficit, or bladder or bowel dysfunction, rather than radicular back pain. Attention was drawn to this problem in the mid-1990s when multiple cases of spinal hematoma associated with the use of the LMWH Enoxaparin were reported to the US Food and Drug Administration. Significant risk factors that have been identified include the timing of both needle or catheter placement and removal in relation to the last dose of LMWH, the concurrent use of antiplatelet agents, and trauma during the regional anesthetic procedure.[202] Spinal hematomas have been reported with both single-dose and continuous neuraxial anesthesia, although the risk is considered to be much lower with the former procedure. Recommendations designed to minimize the risk of spinal hematoma include (a) placement of the needle at least 10 to 12 hours after the last prophylactic dose, or longer (eg, 20–24 hours) after the last full therapeutic dose of LMWH; (b) similarly, removal of an indwelling catheter should be delayed for at least 10 to 12 hours after a dose of LMWH, most of which have a half-life in the range of 4 to 6 hours.[202] Once-daily prophylactic LMWH regimens are associated with lower trough anticoagulant levels than twice-daily regimens, and they may be a safer choice in patients in whom indwelling catheters are employed,[203] with removal of the catheter scheduled for 20 or more hours after the last dose of drug. It is generally considered safe to administer the next dose of LMWH 2 hours after catheter removal. The synthetic pentasaccharide, Fondaparinux (Arixtra), also carries a black box warning from the FDA, although in fact very little is known about the associated risk of spinal hematoma formation. The long plasma half-life of the agent (21 hours) should be borne in mind when making treatment decisions about its use when regional anesthesia is being concurrently employed.[202] Avoidance of the simultaneous use of antiplatelet agents, including aspirin and nonsteroidal antiinflammatory agents, is advisable in the case of all these anticoagulants. For further information about this topic, the reader is referred to the American Society of Regional Anesthesia and Pain Medicine (ASRA)

Table 160–4 Risk of Bleeding Associated With Various Endoscopic Procedures

Low-Risk Procedures	High-Risk Procedures (Approximate Bleeding Risk (%))
Diagnostic esophagogastroduodenoscopy	Colonoscopic polypectomy (1%–2.5%)
Flexible sigmoidoscopy and colonoscopy ± biopsy	Gastric polypectomy (4%)
Diagnostic endoscopic retrograde cholangiopancreatography	Laser ablation and coagulation (<6%)
Biliary stent insertion without endoscopic sphincterotomy	Endoscopic sphincterotomy (2.5%–5%)
Endosonography	Dilatation of benign or malignant strictures
Push enteroscopy	Percutaneous endoscopic gastrostomy

EGD, esophagogastroduodenoscopy; ERCP, endoscopic retrograde cholangiopancreatography; EUS, endosonography.

Second Consensus Conference on Neuraxial Anesthesia and Anticoagulation.[202]

Prophylaxis for Venous Thromboembolism After Surgery and Trauma

Epidemiology and Natural History

The overall incidence rate of VTE in the community is approximately 1 in 1000 per annum. It has been estimated that hospitalization for surgery accounts for about one-quarter of cases of VTE, and is associated with an almost 22-fold increased risk. Trauma accounts for about half as many additional cases, with a 13-fold increased risk.[176] Additional identified risk factors (which may coexist in these individuals) include malignancy, central vein catheterization, a history of superficial venous thrombosis, and neurologic disease with extremity paresis. Older age is also a strong independent risk factor, whereas hormonal therapies (oral contraceptives, hormone replacement therapy, tamoxifen, and raloxifene) compound the risk in women.[177] In hospitalized patients, DVT is often clinically silent, and pulmonary embolism may be rapidly fatal. It has been estimated that more than 12 million hospitalized patients per annum are at risk of VTE.[204] Because screening for asymptomatic DVT by ultrasonography is expensive yet relatively insensitive,[205] widespread use of prophylaxis is widely acknowledged to be the most effective strategy to minimize the burden of venous thromboembolic disease. This strategy has also been shown to be a cost-effective approach.

Although patients on the surgical and trauma services represent a significant proportion of VTE disease burden, they also provide an important opportunity for prevention through the appropriate design and utilization of validated VTE prophylaxis regimens. A comprehensive treatise detailing the proceedings of the Seventh ACCP (American College of Chest Physicians) Consensus Conference on Antithrombotic Therapy was published in 2004, and is generally accepted as the reference standard for evidence-based VTE prophylaxis in surgical patients.[206] The reader is referred to these guidelines for details of recommended regimens, including dose, frequency, and duration of therapy. Some general principles from this document will be discussed here, with a focus on more recent developments and ongoing controversies in the field.

Using sensitive techniques such as ascending venography, much has been learned about the frequency and natural history of DVT formation after surgical procedures. In many studies, venography was performed at 7 to 14 days postoperatively, to coincide with the termination of pharmacologic prophylaxis. Recently however, it has become clear that DVT formation may continue for up to several weeks after surgery, and the trend in the last several years in certain situations, such as after hip replacement or abdominal/pelvic cancer surgery, has been toward longer duration of therapy, up to 28 to 35 days (discussed further below). Venographic studies have also shown that many DVTs are asymptomatic, that the process is dynamic—with a minority of thrombi extending whereas most resolve spontaneously, and that distal (infrapopliteal) DVTs are much less important from a clinical standpoint, because they are associated with a much lower risk of embolization. These studies have defined the absolute risks of VTE according to these end points, and allowed a given individual's risk of VTE to be assessed preoperatively (Table 160–5). Low-risk individuals are defined as those aged less than 40 years undergoing minor surgery lasting less than 30 minutes, with no additional risk factors. At the other end of the spectrum, very high-risk individuals are those aged more than 40 undergoing major orthopedic lower extremity or spinal surgery, or who have suffered major trauma. A history of prior VTE, or presence of a thrombophilic disorder or cancer further heighten the risk in this group.[206]

Nonpharmacologic Methods of Venous Thromboembolism Prophylaxis

Early ambulation should be a routine component of postoperative care whenever possible. It has been shown to be associated with a lower risk of postoperative VTE, for example after hip replacement surgery.[207] Properly fitted elastic stockings (ie, those not leading to venous compression above the knee) are a useful adjunct in VTE prophylaxis, but are generally insufficient as the sole prophylactic modality. On the other hand, intermittent pneumatic compression devices, both those that provide intermittent calf ± thigh compression or foot pumping action, may be used as the primary modality in all but the highest risk group of patients undergoing high-risk general surgery, or hip or knee surgery, and some forms of neurosurgery. These devices presumably reduce the risk of VTE by preventing venostasis in the immobilized limb(s). Although it has been postulated that they also enhance fibrinolysis by stimulating endothelial release of plasminogen activators, recent data have failed to support this hypothesis.[208,209] Compliance is a constant concern with these

Table 160–5 Recommendations for Prophylaxis of Deep Vein Thrombosis

Approximate Risk Category*	Patients	Calf DVT	DVT	PE	Recommendation
Low	Surgical patients under 40, surgery lasting <30 minutes, no additional risk factors	1%–2%	0.5%–1%	0%–0.1%	Ambulation, leg exercises
Moderate	Surgical patients older than 40, having abdominal or thoracic surgery lasting >30 minutes	20%–30%	2%–10%	1%–3%	Low-dose heparin
	Neurosurgery or other patients with high bleeding risk				Pneumatic compression
High	Hip fracture Hip replacement Knee replacement Open prostatectomy Gynecologic malignancy	40%–80%	20%–40%	5%–10%	Warfarin,† LMWH Warfarin,† adjusted-dose heparin, LMWH LMWH, external pneumatic compression Pneumatic compression Pneumatic compression

DVT, deep vein thrombosis; LMWH, low-molecular-weight heparin; PE, pulmonary embolism.
*Without prophylaxis.
†Given in low-dose regime.

devices, as is the possibility of reduced efficacy in significantly overweight individuals. Intermittent pneumatic compression is often used as an adjunct to pharmacologic prophylaxis in high-risk individuals.[210]

Inferior vena cava filters are occasionally used to prevent pulmonary embolization in patients with extensive trauma in whom the bleeding risks are (sometimes incorrectly) perceived to be too high for the use of pharmacologic prophylaxis [211–213] There are very few prospective randomized trials to support the use of IVC filters,[214] and in one of the few such trials, filter placement was associated with a significantly greater risk of late-onset DVT.[215] Filter deployment may still be a reasonable approach in a patient with a very recent VTE who requires urgent surgery in whom aggressive anticoagulant prophylaxis is not considered feasible. Recently, temporary (retrievable) IVC filters, which generally require removal within 2 to 3 months, are being increasingly used in this type of situation, despite an absence of data from randomized clinical trials.[216–218] However, accumulating experience generally appears to be favorable; for example, in a large retrospective series of almost 450 trauma victims in whom retrievable IVC filters were placed (76% for prophylactic indications), only 3 cases of migration, 2 breakthrough pulmonary emboli, and 6 symptomatic IVC occlusions were recorded.[219]

Table 160–6 Suggested Dosing Regimens for Prophylactic Low-Molecular-Weight Heparins and Pentasaccharide for Orthopedic or General Surgery

Drug	Orthopaedic Surgery	General Surgery
Enoxaparin	30 mg (3000 IU) every 12 hours Begin 12–24 hours after surgery Continue for 7–10 days Consider extended prophylaxis After THA (40 mg once daily Until 28–35 days postsurgery)	40 mg (4000 IU) once daily Begin 1–2 hours presurgery
Dalteparin	5000 IU once daily	2500 IU once daily Begin 1–2 hours presurgery
Tinzaparin	75 IU/kg once daily Begin 1–2 hours preoperatively	
Fondaparinux	2.5 mg once daily Begin 6 hours postsurgery	

IU, international units

Pharmacologic Methods of Prophylaxis

Although the efficacy of aspirin as a primary and secondary intervention in arterial vascular occlusive disorders is now well established, it is not generally recommended for prophylaxis of perioperative VTE, and certainly not as a sole agent. In reality, the true efficacy of aspirin in this situation is probably an understudied area. Intriguingly, in the very large Pulmonary Embolization Prevention (PEP) trial, 160 mg a day of aspirin initiated preoperatively as an adjunctive therapy to conventional prophylaxis was associated with a reduction in symptomatic pulmonary embolism from 1.2% with placebo to 0.7% ($P < 0.001$), although there was an increased rate of bleeding requiring transfusion.[220]

Several agents form the mainstay for VTE prophylaxis in surgery in the 7th ACCP Conference recommendations (Table 160–6). These are UFH (given subcutaneously, either 5000 Units 2 to 3 times daily without monitoring, or every 8 hours with dose adjustment to maintain a high normal midinterval APTT), LMWH (enoxaparin, tinzaparin, or dalteparin) given subcutaneously once or twice daily (depending on the agent), and warfarin (given postoperatively and adjusted to a target INR of 2.0–3.0). Fondaparinux, a synthetic pentasaccharide that selectively inhibits factor Xa in an antithrombin-dependent manner, is also licensed for VTE prophylaxis in total hip and knee arthroplasty surgery, and hip fracture surgery.[221] Additional antithrombotic agents are currently under development in phase II or III trials, including orally available factor Xa and thrombin inhibitors,[222,223] and inhibitors of the tissue factor–factor VIIa complex, such as recombinant nematode anticoagulant protein (rNAP-c2).[224] Potential drawbacks of these newer agents include the lack of specific antidotes in the event of bleeding,[225] and the fact that many of these drugs are excreted via the kidney, necessitating caution in patients with renal impairment. An advantage of LMWHs and other structurally unrelated molecules over UFH is (respectively) the reduced risk of heparin-induced thrombocytopenia. For example, clinically apparent HIT was present in 2.7% of patients receiving prophylactic doses of UFH after hip surgery, compared to 0% in this cohort who received LMWH ($P = 0.0018$).[226] However, HIT may occur as a rare complication of LMWHs such as Enoxaparin, Tinzaparin, or Dalteparin.[161] On the other hand, although the anti-PF4–heparin antibodies responsible for HIT may be stimulated during Fondaparinux therapy, they do not react against the PF4–Fondaparinux complex,[227] and the clinical syndrome (thrombocytopenia and thrombosis) has not been described with this agent.

In general, all these forms of thromboprophylaxis are associated with roughly a 70% risk reduction in perioperative VTE, but there are some important differences in efficacy that have been demonstrated in specific types of surgery,[206] which are briefly outlined below. Conversely, the bleeding risks are principally related to dose and host risk factors, and to a lesser extent the choice of agent and timing of administration in relation to surgery. In general surgery, it is usually recommended that either UFH or LMWH be given 1 to 2 hours in advance of surgery.[163] In orthopedic surgery in the United States, LMWH is traditionally initiated 12 hours postoperatively, which may in fact be suboptimal when compared to regimens in which these agents are initiated in close proximity to surgery (between 2 hours preoperatively and 6–8 hours postoperatively).[228] Details of suggested dosing schedules are shown in Table 160–6.

Orthopedic Surgery

Major orthopedic surgery (total hip and knee arthroplasty, hip fracture, and spinal surgery) is among the highest risk forms of surgery, with venographically detected DVT occurring in 40% to 70% of patients not receiving prophylaxis.[229] The corresponding rates of death due to PE is 0.1% to 0.4% of patients undergoing total hip replacement, 0.2% to 0.7% undergoing total knee replacement, and 3.6% to 12.9% following hip fracture surgery.[206] Meta-analysis has demonstrated that the protection against proximal DVT afforded by low-dose UFH may be inferior to LMWH. An acceptable alternative to LMWH is warfarin, which is preferred by many orthopedic surgeons. Most commonly, warfarin is initiated the evening of surgery, although in some protocols it is begun on the evening prior to surgery, without any apparent difference in efficacy. Dose adjustment is performed to achieve a target INR of 2.5 ± 0.5. The efficacy of LMWH is either equivalent or slightly superior to warfarin in total hip arthroplasty, and more definitively superior in total knee arthroplasty, albeit at the expense of a mildly increased risk of bleeding.[206]

Fondaparinux (2.5 mg once daily) was compared with enoxaparin (40 mg once daily or 30 mg twice daily) in hip and knee arthroplasty, and in hip fracture repair.[230–233] In a meta-analysis of the major trials, which included 7344 patients, there was a statistically significant 55% relative risk reduction (6.8% vs 13.7%) in the incidence of venographically detected DVT (and proximal DVT). However, there was no difference in the incidence of symptomatic VTE or fatal PE,

and major bleeding was more frequently encountered in the fondaparinux group compared to the enoxaparin group (2.7% vs 1.7%).[232,233] It remains an open question whether the higher efficacy at the expense of greater bleeding risk with fondaparinux is explained by the fact that the first dose was usually administered earlier than enoxaparin (6 hours vs 12 hours postoperatively).

Prolonged prophylaxis beyond the usual 7 to 10 days is a pertinent consideration for total hip arthroplasty patients, where the median time to diagnosis of symptomatic VTE (occurring in 2.8% of patients within 3 months) is 17 days postoperatively. In contrast, VTE after total knee arthroplasty (occurring in 2.1% of patients within 3 months) tends to occur much earlier, after a median of 7 days.[229] By meta-analysis, trials in which LMWH prophylaxis was extended for 30 to 42 days were associated with a significant reduction in the frequency of symptomatic VTE, without any increase in major bleeding.[234,235] This was especially true in total hip arthroplasty, where the absolute risk reduction in symptomatic VTE was approximately 2%.[234] Prolonged therapy with warfarin may be similarly effective, although some studies,[236] but not others,[237] have raised concerns about the bleeding risks. As yet, despite early indications of favorable cost-effectiveness, long-term prophylaxis with LMWH or warfarin is not widely used. As an alternative strategy during this period, aspirin is recommended.[238]

Recently, it has been demonstrated that patients with comparatively minor forms of lower-extremity orthopedic surgery, such as therapeutic arthroscopic knee procedures, are also at increased risk of VTE.[239,240] A recent meta-analysis concluded that the total incidence of asymptomatic DVT after knee arthroscopy was 9.9% (95% confidence interval, 8.1%–11.7%), with a proximal DVT incidence of 2.1% (95% confidence interval, 1.2%–3.0%).[241] Routine use of pharmacologic prophylaxis is probably not warranted, although it would be appropriately considered in a patient with a previous history of VTE, or other risk factors, such as prolonged tourniquet time (>60 min), a known thrombophilic disorder, or on estrogen therapy.

Trauma

Up to 60% of trauma patients suffer venographically demonstrated DVT within 14 days of admission,[242] although the range of reported VTE complication rate in trauma varies enormously in the literature, possibly reflecting not only variable study methodologies but also study subject heterogeneity.[243,244] Factors that appear to be independently associated with a greater risk of thrombosis following trauma include (a) age >40 years, (b) lower-extremity fracture, (c) major head injury, (d) more than 3 ventilator days, (e) venous injury, and (f) major surgical procedure.[245] Although there is general agreement that some form of prophylaxis is routinely warranted, there is confusion (even from prospective randomized clinical trials) whether pharmacologic prophylaxis is superior to nonpharmacologic prophylaxis,[243,246,247] and whether LMWH have a specific advantage over UFH.[248,249] Nonpharmacologic methods of prophylaxis may be difficult to apply in some cases with external fixation devices in the lower extremities, and it is therefore recommended that intermittent pneumatic compression alone be used only when both lower extremities are available. Routine surveillance using duplex ultrasound scans are not recommended unless VTE prophylaxis cannot be employed. An extensive review of the scientific evidence and development of evidence-based practice consensus guidelines in trauma surgery published in 2002 recommended that, where feasible, prophylaxis using LMWH rather than UFH be preferred for patients with pelvic, complex lower-extremity, or spinal fractures,[248,250] especially with partial or complete motor paralysis. However, the EAST guidelines acknowledge a paucity of Level 1 evidence to support the prophylaxis algorithms.[250] A subsequent registry of 743 high-risk trauma patients prescribed once-daily prophylactic dose LMWH, regardless of the need for invasive procedures and including those with stable intracranial injuries, did not document any exacerbations of head injury due to bleeding.[251] Notably in this study, the LMWH was initiated an average of 3.3 days after admission. However, for patients at very high risk for both VTE and bleeding with anticoagulation, IVC filter placement—generally using retrievable devices—may occasionally be justified.

Even without the associated risks of surgery, bony fracture and immobilization may be sufficient stimuli to increase the incidence of VTE. For example, a 19% rate of venographically demonstrated DVT was noted in patients requiring plaster immobilization or bracing after a leg fracture or ruptured Achilles tendon. This was reduced to 9% in a matched group treated with prophylactic LMWH throughout the period of immobilization.[252] Here again, however, the evidence overall does not clearly support the need for routine pharmacologic VTE prophylaxis in all patients treated for lower-extremity fracture.

Neurosurgery

Patients undergoing neurosurgery involving craniotomy, particularly when performed for high-grade glioma,[253,254] are also at high risk with respect to the risk for VTE. Symptomatic events occur in as many as 6% of patients within the first 3 months postoperatively.[253] The need for pharmacologic prophylaxis is tempered by the potentially disastrous consequences of intracranial bleeding as a complication of therapy. This concern has led some to recommend a conservative strategy of nonpharmacologic prophylaxis only. In a landmark randomized, placebo-controlled trial, Agnelli and colleagues demonstrated that Enoxaparin 40 mg daily (initiated within 24 hours postoperatively) was associated with a 49% relative risk reduction in venographically demonstrated DVT compared to placebo in patients undergoing elective cranial or spinal surgery (97% for tumors). The rate of symptomatic VTE was reduced from 6% to 1%, with no increase in bleeding.[255] Multimodal prophylaxis combining LMWH, compression stockings, and intermittent pneumatic compression may be even more effective.[256] Yet concerns remain that pre- or early postoperative administration of LMWH is associated with an increased risk of bleeding.[257] In this more than in other areas of surgery, the timing of initiation of heparin/LMWH, dosing, and duration of therapy are critical factors in determining the risk–benefit ratio. In fact, a recent analysis of the literature applied in a decision analysis model comparing mechanical prophylaxis to mechanical prophylaxis ± UFH or LMWH was marginally in favor of the use of pneumatic compression devices alone.[258]

General and Gynecologic Surgery

Rates of asymptomatic VTE in all comers undergoing general surgery without VTE prophylaxis (approximately 20%–25%) are lower than in major orthopedic surgery, although it should be noted that the rates are substantially lower in certain minor forms of surgery, such as appendectomy or abdominal wall surgery The increasing use of laparoscopic techniques has tended to lower the risks that were previously encountered with the corresponding open procedures. Patient-related risk factors include cancer, advancing age, a history of previous VTE, obesity, varicose veins, and estrogen use.

In several meta-analyses, thrombosis prophylaxis using LMWH is uniformly superior to placebo, and equivalent to subcutaneous UFH.[259–261] UFH is also equivalent to LMWH in high-risk urologic or gynecologic surgery. In moderate-risk gynecologic surgery, nonpharmacologic prophylaxis with intermittent pneumatic compression is as efficacious as LMWH,[262] although patients with a history of cancer or DVT, or age more than 60 years may be more prone to fail intermittent pneumatic compression alone.[263] Although bleeding rates are purportedly higher with LMWH than UFH in general surgery, this may be a function of administered dose. A lower dose of LMWH (<3500 anti-Xa units/day) may be as efficacious as UFH, with a bleeding rate that is actually somewhat lower.[260,261]

Cancer increases the risk of postoperative VTE by a factor of approximately 2,[177,264] and patients undergoing major abdominal or

pelvic surgery for neoplastic disorders should be considered to be at high risk. This risk may be related to enhanced activation of coagulation, more prolonged immobilization, and/or greater extent of surgery and duration of anesthesia. Low-dose UFH or LMWH combined with intermittent pneumatic compression appears to be ideal VTE prophylaxis.[261,265] Therapy is typically initiated 2 hours preoperatively. Approximately 40% of VTE occurs following discharge, suggesting a possible need for prolonged therapy. Indeed, recent evidence suggests that prolonged administration of Enoxaparin (40 mg once daily) results in a reduction of venographically demonstrated DVT (from 12.0% in the 1-week treatment group to 4.8% in the 4-week treatment group), without any increased risk of bleeding.[266]

Renal Transplantation

In the United States, approximately 14,000 renal transplants are performed annually. Published estimates of the incidence of postoperative VTE have varied from 0.6% to 25%. A retrospective analysis of more than 2000 renal allograft recipients found a 6.2% incidence of symptomatic DVT in patients undergoing kidney or simultaneous kidney–pancreas transplant without prophylaxis in the period between 1985 and 1995.[267] In this study, the incidence of symptomatic DVT following kidney transplantation (4.5%) did not appear to be significantly higher than the rate in general surgical procedures of a comparable magnitude; however, the rate in patients receiving kidney–pancreas allografts (18.1%) was considered to be excessively high.

A number of special considerations apply to the use of prophylactic anticoagulation in renal transplant recipients. Because renal function may remain impaired for several days or more following the procedure, impaired clearance of LMWHs may increase the risk of bleeding. Therefore, UFH may be a better choice for prophylaxis. Furthermore, prophylactic anticoagulation may be of theoretical benefit in the prevention of other vascular complications of renal transplantation. Specifically, it has been demonstrated that common inherited and acquired thrombophilias (factor V Leiden [FV G1691A], prothrombin G20210A mutation, and antiphospholipid antibodies) are associated with an increased risk of primary renal graft thrombosis, and acute vascular rejection. Primary renal graft thrombosis, defined as thrombosis of the renal graft vasculature in the absence of histopathologic evidence of rejection, usually occurs within 10 days of renal transplant, and virtually always results in loss of the graft. Thrombosis is as likely to be arterial as venous, and occurs in approximately 2% (range 1%–6%) of recipients. The usual presentation is with sudden-onset oliguria or anuria associated with a falloff in graft function. In the case of renal vein thrombosis, there may be pain at the graft site, hematuria, and even graft rupture. A number of retrospective case control studies,[268–270] and a prospective study,[271] have demonstrated that one or more of these thrombophilias are associated with an estimated 3- to 10-fold increased risk of renal graft thrombosis. With respect to acute vascular rejection, it is hypothesized that endothelial damage and microvascular thrombosis caused by the underlying thrombophilia increase the likelihood of graft malfunction or loss if the transplanted organ is challenged by an acute rejection episode. Inherited thrombophilias may increase the relative risk of acute vascular rejection by an estimated 4- to 12-fold.[271]

It has not been established by appropriate prospective randomized study whether antithrombotic prophylaxis can prevent early renal graft thrombosis and/or acute vascular rejection. However, small series have suggested that UFH, LMWH, or aspirin (>75 mg daily) may diminish the rate of early allograft thrombosis, compared with historical controls.[272,273] Prophylaxis may be particularly vital in high-risk patients, for example, those with identified thrombophilia, and/or a previous history of early graft loss or VTE.[274] However, the optimal intensity, duration, and composition of prophylactic regimens has not been determined, and opinions differ considerably, from long-term full-intensity anticoagulation begun in the early postoperative period to short-term lower-intensity heparin followed by longer-term aspirin therapy.[275]

COMPLIANCE WITH VENOUS THROMBOEMBOLISM PROPHYLAXIS

Most studies examining the question of compliance with nationally developed guidelines for VTE prophylaxis have concluded that thromboprophylaxis is underutilized, both in terms of the absolute number of eligible but undertreated patients, and the appropriateness (ranging from total omission to suboptimal choice, dose or duration) of therapy. In general, orthopedic services tend to be more (>85%) compliant with published guidelines, probably reflecting the longer history of utilization and widespread awareness of the benefits and risks of VTE prophylaxis by orthopedic surgeons.[276,277] In general surgery, compliance with grade A recommendations may be much lower, sometimes in the 30%–50% range.[278] This reluctance to utilize prophylaxis may be explained by a tendency to underestimate the thrombotic risk in high-risk patients.[204,276] Conversely, despite uncertainties regarding the optimal approach to prophylaxis in neurosurgical patients, 85% of practitioners in the United Kingdom regularly used some form of prophylaxis.[279] Improvement in compliance is probably best achieved by the application of surgical service-specific guidelines, developed in each institution to mirror its own patient population. Like all guidelines, the recommendations should be flexible enough to allow informed physicians to exercise their clinical judgment when assessing risks and benefits of a specific regimen in the case of an individual patient.

Treatment of Postsurgical Venous Thromboembolism

The principles of treatment of acute VTE occurring in the postoperative period do not differ materially from treatment under other circumstances (Chapter 135), with the exception that the bleeding risks associated with anticoagulation are increased. Although virtually all series agree that recent surgery is a risk factor for bleeding,[280] it is difficult to find relevant literature that quantifies the risk (with respect to the rate of decline in the risk after surgery). It is generally recommended that if surgery has involved a vital organ (eg, brain, eye), it is inappropriate to risk full-intensity anticoagulation for 5 to 7 days[254] (or longer—eg at least 7–10 days—when thrombolytic therapy is to be used). This recommendation is supported by animal data demonstrating that the risk of intracranial hemorrhage with full-intensity heparin anticoagulation in the postoperative period following craniotomy dropped off sharply between the 7th and 10th postoperative day.[281] If anticoagulation is strongly contraindicated, placement of an IVC filter may be the only available option. At the other end of the spectrum, anticoagulation after minor procedures in patients judged to be at low risk of bleeding can probably be initiated after 12 to 24 hours. UFH may have certain advantages over LMWH in these circumstances, most notably its short half-life and susceptibility to more complete reversal with protamine, which dictate that it will be more reversible in the event of bleeding.

CHAPTER 161

HEMATOLOGIC CHANGES OF PREGNANCY

Jacob Laubach and Johanna Bendell

The primary physiological hematologic changes during pregnancy relate to the expansion of plasma volume. The greatest increase in plasma volume occurs between 6 and 24 weeks' gestation. After 24 weeks the plasma volume increases, but at a slower rate. In a normal pregnancy the plasma volume increases 40% to 60%,[1] with the change in plasma volume proportional to fetal weight.[2] Erythropoiesis in the first trimester of pregnancy is similar to erythropoiesis in the nonpregnant woman, but increases in the second and third trimesters.[3] Coincident with changes in plasma volume, there is a simultaneous but less than proportional increase in red blood cell mass of 20% to 50%. As a result, a pregnant woman's hematocrit typically lies in the 30% to 32% range.[1] In addition to these physiologic changes, a prothrombotic state develops as pregnancy advances that is believed to prepare the mother and fetus for placental separation during delivery.[4]

ANEMIA IN PREGNANCY

Because of the physiologic decrease in hemoglobin and hematocrit during pregnancy, the Centers for Disease Control and Prevention (CDC) Pregnancy Nutrition Surveillance System has created new standard definitions for anemia in pregnant women.[5] Anemia during pregnancy is quite common; the World Health Organization (WHO) reports 35% to 75% of women in developing countries and 18% of women in industrialized countries develop anemia in pregnancy.[6] The effects of anemia on both the mother and fetus can range from mild to severe. Common maternal signs and symptoms of anemia include tachycardia, pallor, tachypnea, glossitis, fatigue, paresthesias, and headache. Hemoglobin levels less than 6 g/dL in pregnant women can be associated with significant maternal and fetal complications. At these levels, tissue oxygenation decreases and may lead to a state of high-output congestive heart failure in the mother. Meanwhile, multiple studies have shown a correlation between maternal anemia and increased rates of both preterm (<37 weeks' gestation) and low-birth-weight deliveries.[7–15] These studies indicate that anemia in the first or second trimester of pregnancy conveys an increased risk of preterm delivery, whereas third trimester anemia does not. Interestingly, they also demonstrate an increased risk of preterm delivery and low birth weight in women with a relatively high hematocrit (≥40%) in the second or third trimester. In interpreting results from such studies on anemia in pregnancy, it is important to consider confounding factors such as maternal nutrition and health, socioeconomic conditions, and environmental influences that can independently affect pregnancy outcomes.

IRON DEFICIENCY ANEMIA

Iron deficiency is the most common cause of nonphysiologic anemia in pregnancy, accounting for 75% of cases.[16] In the United States, the estimated prevalence of iron deficiency anemia in pregnancy ranges from 3% to 9% during the first trimester to 16% to 55% in the third trimester.[17,18] The prevalence of iron deficiency anemia increases in the setting of poor appetite and nutrition, nausea, and vomiting; second pregnancy in less than 2 years; and chronic illness. Iron deficiency anemia in pregnancy is also seen more often in African American, low-income, and adolescent women.[19–21] That the incidence of iron deficiency anemia increases as pregnancy progresses reflects heightened iron requirements during pregnancy. Total iron stores increase from 2.2 g in a nonpregnant woman to 3.2 g in a pregnant woman at term, creating a 900- to 1000-mg iron requirement during the course of pregnancy.[22] Between 500 and 600 mg are used to increase erythrocyte mass, whereas 300 mg are required by the fetus and placenta. For a woman with adequate iron stores, the average daily iron requirement increases 2 to 4 mg per day, increasing further in the third trimester to 6 to 8 mg per day.[23,24] In addition, iron absorption from the intestine increases as much as 40% during pregnancy.[25] Although a pregnant woman may have iron deficiency anemia, her fetus typically does not develop iron deficiency as a result of active iron transport across the placenta.[26–28] However, infants of iron-deficient mothers do have a higher risk of developing iron deficiency later in infancy.

Symptoms of iron deficiency anemia in pregnant women are similar to those observed in nonpregnant individuals and include fatigue, lethargy, headache, and pica, a condition defined as the consumption of nonnutritive substances such as ice, baking soda, baking powder, clay, or dirt. Exam findings such as pallor, glossitis, and cheilitis in a pregnant woman should prompt the clinician to further evaluate a woman for iron deficiency. Although uncommon, retinal bleeding, conjunctivitis, tachycardia, and splenomegaly can be seen in instances of severe iron deficiency.[29] Microcytosis distinguishes iron-deficiency anemia from physiologic anemia of pregnancy, which is normochromic and normocytic. In turn, iron deficiency must be differentiated from other causes of microcytic anemia such as chronic inflammatory conditions and hemoglobinopathies. A reduced serum ferritin concentration (normal value in pregnancy 55–70 μg/L) and transferrin saturation (<15% in iron deficiency) are useful indicators of iron deficiency in the pregnant patient as in nonpregnant individuals.[29]

Iron deficiency anemia diagnosed during pregnancy is treated as it would be in the nonpregnant woman. Oral iron therapy with 60 to 120 mg per day of elemental iron is recommended. Intravenous iron is appropriate in certain circumstances; evidence from a recently published randomized trial by Al et al supports the use of intravenous iron therapy to replenish iron stores in appropriately selected patients, including those who have not tolerated a trial of oral iron therapy and those with severe iron deficiency.[30]

Because the typical diet in the United States provides only 50% of daily iron requirements for the pregnant woman and because of the relatively high prevalence of iron deficiency among women of child-bearing age, routine iron supplementation in pregnancy is recommended.[16,25] Currently, the CDC, the American Dietetic Association, and the American College of Obstetrics and Gynecology recommend 15 to 30 mg daily of elemental iron to prevent adverse outcomes due to iron deficiency anemia.[31–35] Based on the results of a study by Casanueva et al, weekly therapy with 120 mg of iron appears to be a safe and effective alternative to daily therapy.[36] The side effects associated with iron therapy—constipation, diarrhea, nausea—are well known.

Multiple studies have shown that routine iron supplementation in pregnancy decreases the incidence of iron deficiency anemia.[37–41] Furthermore, in a recent randomized, double-blinded study in which 275 iron-replete pregnant women received either a daily iron supple-

ment or placebo from time of enrollment (all women were enrolled before week 20) to 28 weeks' gestation, the incidence of both low-birth-weight and preterm low-birth-weight infants was lower among women who received daily iron.[42] Nonetheless, there are limits to the effectiveness of routine iron supplementation. After all, the recommendation by prominent public health organizations for universal iron supplementation has not led to a commensurate decrease in the incidence of iron deficiency anemia in pregnancy[43,44] or an increase in maternal hemoglobin levels.[45,46] Clearly, compliance is an important factor in this discussion. A large, multicenter, randomized controlled trial on the benefits of iron supplementation during pregnancy in the United States is needed to draw more definitive conclusions.

MEGALOBLASTIC ANEMIA

Folate deficiency accounts for 95% of megaloblastic anemias in pregnancy.[47] Folate deficiency complicates between 1% and 4% of pregnancies in the United States and affects approximately one-third of pregnancies worldwide.[48] Like iron deficiency anemia, the incidence of megaloblastic anemia in pregnancy is increased in adolescents, women of low socioeconomic status, and women with multiple closely spaced births.[49] The folic acid requirement for the nonpregnant woman is 50 to 100 μg per day, but this increases to 150 μg during pregnancy as red cell mass in the mother increases and as fetal demands for folate grow with cell proliferation.[50]

Several trials have demonstrated a relationship between folic acid supplementation prior to and during pregnancy and a reduced incidence of neural tube defects.[51–54] These led in the early 1990s to a formal recommendation of this practice among women planning to become pregnant. The CDC currently recommends that a pregnant woman receive 400 μg of folate daily to reduce the risk of a neural tube defect.[55] To reduce elevated homocysteine levels observed in individuals with folate deficiency, 400 μg is thought to be the minimum daily dose required.[56] Moreover, it has been suggested that higher doses of folate—up to 5 mg daily—may provide greater benefit to pregnant women with respect to prevention of neural tube defects.[57] To date, though, this recommendation has not been implemented on a broad scale. Women for whom a previous pregnancy has been complicated by neural tube defects should receive 4 mg of folate daily as prophylactic therapy before and during subsequent pregnancies.

Although the mechanism by which folate exerts its protective effect is not fully understood, work by Rothenberg and colleagues has provided important insight in this area. Autoantibodies against folate receptors were found in 9 of 12 women in whom a current or previous pregnancy had been complicated by neural tube defect, whereas such antibodies were detected in only 2 of 20 control individuals.[58] The autoantibodies blocked binding of folate to receptors in an in vitro experimental model. The authors suggest that folate supplementation in individuals with such autoantibodies may exert its protective effect by overcoming this blockade.

The diagnosis of folate deficiency in pregnancy should not be based on serum folate levels, as they can be affected by acute nutritional deficiency, alcohol intake, or hemolysis. Red blood cell folate is a better marker of folate deficiency if low, but it too may be normal in megaloblastic anemia. Furthermore, it is a more useful determinant of folate levels for the previous 1 to 3 months, because red blood cell survival is 120 days. The combination of an elevated homocysteine level and normal methylmalonic acid level has a 99% sensitivity and specificity for diagnosis of folate deficiency.[59]

Vitamin B_{12} deficiency rarely causes anemia in pregnancy. The daily requirement for vitamin B_{12} is small because of large vitamin B_{12} stores within the body. Vitamin B_{12} also has a significant enterohepatic circulation, such that most vitamin B_{12} in bile is reabsorbed. It typically takes several years to manifest vitamin B_{12} deficiency.[60] Vitamin B_{12} deficiency is caused by poor intake, as seen in strict vegetarians who ingest little or no vitamin B_{12}-rich animal and dairy protein, and by poor absorption. Poor absorption of vitamin B_{12} can occur as a result of malabsorption syndromes such as pernicious anemia or Crohn disease. The requirements of vitamin B_{12} during pregnancy are minimal and do not usually affect overall body stores.[49] If vitamin B_{12} deficiency is suspected, a serum vitamin B_{12} level can be obtained, though these levels may be decreased in pregnancy without true body vitamin B_{12} depletion.[61,62] An elevated level of both homocysteine and methylmalonic accurately confirms the diagnosis of vitamin B_{12} deficiency.[56] A woman with vitamin B_{12} deficiency should receive vitamin B_{12} therapy for the duration of her pregnancy. A common repletion schedule involves intramuscular injections of cyanocobalamin or hydroxocobalamin, 1000 μg once weekly for 8 weeks, then monthly. The Shilling test to assess for intrinsic factor deficiency should be deferred during pregnancy so as to limit radiation exposure.

HEMATOLOGIC MALIGNANCIES

Hematologic malignancies are among the most common malignancies diagnosed during pregnancy.[63] They include Hodgkin and non-Hodgkin lymphoma, acute myelogenous leukemia (AML), acute lymphocytic leukemia, chronic myelogenous leukemia (CML), myelodysplastic syndrome (MDS), and essential thrombocytosis (ET).

Hodgkin and Non-Hodgkin Lymphoma

That hematologic malignancies are among the most commonly diagnosed cancers during pregnancy reflects to a large extent the relatively high incidence of Hodgkin lymphoma in women between the ages of 15 and 24.[64] Based on the results of several retrospective studies, Hodgkin lymphoma diagnosed during pregnancy appears to have no significant effect on pregnancy outcome.[65] A single-institution experience published by Dilek and colleagues, however, highlights complications that may occur in pregnant women with Hodgkin disease, as children born to three of five women with the disease had complications, including death.[66] Remission rates and 20-year overall survival among women diagnosed with Hodgkin disease during pregnancy are reportedly similar to those observed in nonpregnant women with the disease.[67,68] In rare instances, Hodgkin lymphoma metastasizes to the placenta, so the placenta and newborn infant should be examined for evidence of malignancy.[69] Staging during pregnancy can be performed with computed tomography, but magnetic resonance imaging is preferred to reduce to exposure of the fetus to radiation.

Like other malignancies managed during pregnancy, treatment of women with Hodgkin disease is challenging. Generally, chemotherapy at any point in pregnancy increases the risk of an unfavorable outcome.[66] The teratogenic effects of chemotherapy and radiation during pregnancy are a primary concern. However, the standard regimen of adriamycin, bleomycin, vinblastine, and dacarbazine does not appear to increase teratogenic risk when given in the second or third trimesters.

Non-Hodgkin lymphoma rarely occurs during pregnancy. There are case reports and case series of women with non-Hodgkin lymphoma who have been successfully treated with chemotherapy during the second and third trimesters of pregnancy.[70] Alkylating agents given in the first trimester can result in fetal malformations or death,[71] although there are reports of children who received chemotherapy in the first trimester with no subsequent deficits.[72] Based on available data, response and recurrence rates among women treated for non-Hodgkin lymphoma during pregnancy are similar to those seen in the treatment of pregnant women with Hodgkin disease.

Acute and Chronic Leukemia

Pregnant women with acute myelogenous leukemia, acute lymphocytic leukemia, and chronic myelogenous leukemia can be treated successfully with standard therapy; however, treatment carries the risk of teratogenic effects related to chemotherapy, including intrauterine

growth retardation, fetal malformation, cardiac toxicity, and death. There appears to be no influence of pregnancy on the course of leukemia.

As might be expected, the teratogenic risk associated with chemotherapy is greatest with treatment during the first trimester.[73] In the largest study of its kind, Aviles and Neri followed 84 children born to mothers with hematologic malignancies, including 29 women with acute leukemia and 38 who received treatment during the first trimester. Assessing growth and development, hematologic parameters, psychological characteristics, and cognitive function over 19 years, the authors found no significant, long-term, deleterious consequences related to treatment.[72] A more recent case report and literature review by Niedermeier analyzed the outcomes of 20 women treated for AML during the second or third trimester of pregnancy.[74] Within this series, 11 pregnancies resulted in infants with no abnormality, 4 involved infants with an abnormality, and 5 resulted in spontaneous abortion or stillbirth.

Among acute leukemias arising within the myeloid lineage, acute promyelocytic leukemia is unique in terms of clinical features—particularly disseminated intravascular coagulation and associated bleeding complications—and therapy, which involves all-*trans* retinoic acid (ATRA) in conjunction with traditional chemotherapy. Concern regarding the teratogenic effects of ATRA is warranted. In the 1980s, Lammer and colleagues noted an increased risk of fetal malformation following in utero exposure to the retinoid isotretinoin.[75] And a recent case report by Carradice et al describes a bleeding complication that occurred even after ATRA initiation in a pregnant woman with acute promyelocytic anemia.[76] However, a review of 13 women treated during pregnancy with ATRA for acute promyelocytic anemia found no evidence that the agent leads to fetal malformation when used in the treatment of pregnant women.[77]

Similar concerns regarding toxicity of therapy arise in managing pregnancies conceived prior to and during treatment of chronic myelogenous leukemia. Imatinib, a small-molecule inhibitor against the BCR/ABL tyrosine kinase, is the standard of care for treatment of chronic myelogenous leukemia. In animal studies, imatinib exhibited teratogenicity in rats and impaired spermatogenesis in dogs, monkeys, and rats.[78] Meanwhile, in a series of 19 pregnancies involving a mother or father undergoing imatinib-based therapy for CML, three pregnancies resulted in a spontaneous abortion whereas 2 others produced children with minor malformation.[79] The remaining 13 pregnancies resulted in the delivery of a healthy child. Among mothers in this study who had previously achieved a complete hematologic remission with imatinib and interrupted therapy during pregnancy, a majority (5 of 9) lost the hematologic remission. These findings highlight the important therapy-related implications for mother and fetus, which must be weighed carefully in determining an appropriate course of management. Currently, it is recommended by specialists in the field that patients undergoing treatment with imatinib for CML utilize proper contraception.[79]

Myeloproliferative Disorders

The non-BCR/ABL myeloproliferative disorders include polycythemia vera (PV), essential thrombocytosis (ET), and idiopathic myelofibrosis (MF). In 2001, the World Health Organization expanded its definition of myeloproliferative disorders to include the less common entities chronic neutrophilic leukemia, eosinophilic leukemia, systemic mastocytosis, and chronic myelomonocytic leukemia. Patients with these disorders may suffer from a variety of complications, including thrombosis and hemorrhage. Although their incidence peaks in the sixth or seventh decade, myeloproliferative disorders do occur sporadically in younger individuals and as such can affect pregnant women.

Most literature pertaining to non-BCR/ABL myeloproliferative diseases and pregnancy applies to essential thrombocytosis as it is most likely among this class of diseases to affect women of childbearing age. Data from pregnant women with polycythemia vera and idiopathic myelofibrosis are scant, making it more difficult to draw firm conclusions on pregnancy outcomes. Spontaneous abortion, intrauterine growth retardation, preterm delivery, and placental abruption all appear to occur more frequently in women with essential thrombocytosis than in the general population.[80] Although the precise mechanism has not been fully elucidated, dysregulated placental blood flow and thrombosis are thought to play a primary role in this pathogenesis.

Among pregnant women with an underlying BCR/ABL-negative myeloproliferative disorder, those whose history includes a previous venous or arterial thrombotic event, a prior hemorrhagic event, or a previous pregnancy-related complication are considered high risk for a subsequent complication related to their disease.[81] It is generally agreed that pregnant women with a myeloproliferative disorder should receive low-dose aspirin during pregnancy and for 6 weeks following delivery.[80] Low-molecular-weight heparin should be considered for individuals at high risk for thrombotic complications, though there have been no randomized trials or even large case–control trials to guide this practice.[80] Compressive stockings can be used in this setting as well. Cytoreductive therapy should be avoided during pregnancy if possible. If such therapy becomes necessary, interferon α represents the agent of choice in pregnancy.

Sickle Cell Disease

Many women with sickle cell disease experience more frequent vasoocclusive crises and other sickle cell-related complications during pregnancy.[82] The increased frequency of vasoocclusive crises, particularly during the latter half of pregnancy, likely results from heightened metabolic requirements in pregnancy, increased venous stasis, and the physiologic prothrombotic state of pregnancy. In addition, pathophysiologic changes in the renal and immune function of patients with sickle cell disease increase their susceptibility to urinary tract infections and pyelonephritis. In a recently published retrospective cohort study, Thurman and colleagues compared rates of asymptomatic bacteriuria and pyelonephritis among women with sickle cell trait with those among a cohort of pregnant control patients.[83] The implications of such a study are noteworthy because in the general population, bacteriuria in pregnant women is associated with increased morbidity and mortality for both mother and fetus.[83] The authors found equivalent rates of asymptomatic bacteriuria in the two groups. On the other hand, they detected a higher prevalence of pyelonephritis among the cohort with sickle cell trait.

Other significant complications occur in pregnant women with sickle cell disease as well. For example, the incidence of preeclampsia, thromboembolic events, placental abruption, intrauterine growth retardation, low birth weight, and postpartum infections is higher among women with hemoglobin SS, SC, and Sβ-thalassemia as compared to women without sickle cell disease. One study noted a higher incidence of stillbirths and perinatal mortality among patients with sickle cell disease,[84] whereas another one revealed an increased risk of preterm labor and premature rupture of membranes in women with hemoglobin SS disease.[85] By causing tissue hypoxia, sickling of red blood cells within the placental vasculature causes deleterious effects upon the fetus.[86]

Because of the increased risk for such complications, women with sickle cell disease should receive close medical attention throughout the prenatal period. This includes counseling about intrauterine diagnosis of sickle cell disease when appropriate. Pregnant women can undergo chorionic villi sampling as early as the 9th week of gestation or amniocentesis in the 15th to 16th weeks. A reticulocyte count along with hemoglobin, iron, and folate levels should be obtained to assess for deficiency states and bone marrow suppression. Urinalysis with urine culture is performed as often as every trimester to monitor for asymptomatic bacteriuria. Finally, beginning around 28 weeks of gestation, patients should make weekly clinic visits and begin serial ultrasonography.

Treatment of sickle cell disease during pregnancy warrants careful consideration. With regard to maintenance therapy, hydroxyurea has been used safely throughout pregnancy in patients with sickle cell

anemia, though formal studies of its use in this setting have not been performed to date.[87] Women should receive 5 mg of supplemental folic acid daily. Studies examining the benefit of prophylactic blood transfusions or exchange transfusions have not led to definitive conclusions.[82] Though they may lead to alloimmunization, prophylactic transfusions appear to decrease the incidence of vasoocclusive crises and decrease maternal and fetal morbidity and mortality.[88] A conservative approach reserves transfusions for the patient whose hemoglobin levels fall below 6 g/dL, the patient who develops progressive complications related to sickle cell disease, or the patient with obstetric complications.[89] Following this approach, 60% to 75% of women with sickle cell disease will require transfusion therapy during pregnancy. Patients with sickle cell crisis during pregnancy, meanwhile, should receive aggressive analgesic therapy, hydration, and oxygen while undergoing evaluation of infection or other precipitating influence.

At the time of delivery, the pregnant woman with sickle cell disease is managed in a manner similar to those with high cardiac output anemia. Supplemental oxygen, hydration, and adequate anesthesia should be given to prevent sickling of red blood cells and the associated complications. During the postpartum period, meanwhile, hemoglobin levels are followed closely and prophylaxis for venous thromboembolism is administered unless contraindications preclude it.

THALASSEMIAS

Pregnant women with an underlying thalassemia typically have β-thalassemia minor or α-thalassemia trait—conditions with a relatively benign clinical phenotype—rather than β-thalassemia major or hemoglobin H disease. Because of delayed pubertal growth or hypogonadism with associated anovulation, women with β-thalassemia major and hemoglobin H disease rarely become pregnant. Case reports indicate that when it does occur, pregnancy in women with hemoglobin H disease can be complicated by severe hemolytic anemia and hepatosplenomegaly. Pregnancy outcomes among women with β-thalassemia intermedia, meanwhile, were examined in a recently published study by Nassar et al. Following nine pregnancies in five patients with β-thalassemia intermedia, the authors noted a high incidence of intrauterine growth restriction (IUGR) and frequent requirement for red blood cell transfusion, even among women who had not been transfusion dependent prior to pregnancy.[90] One pregnancy resulted in intrauterine fetal demise at 36 weeks. These findings are consistent with previous observations made in reference to a population of pregnant women with thalassemia; an earlier review of the literature found that 50% of pregnancies in this patient population were complicated by preterm delivery, third-trimester stillbirth, or intrauterine growth retardation.[91]

Pregnancy is a common setting for the diagnosis of β-thalassemia minor or α-thalassemia trait in previously asymptomatic women who are found to be anemic on routine laboratory evaluation during pregnancy. Several studies indicate that the physiologic anemia of pregnancy may be exacerbated in women with thalassemia minor, though findings from at least one study suggest otherwise.[92] β-thalassemia minor and α-thalassemia traits do not have an adverse effect on fetal development, fetal morbidity and mortality, or maternal morbidity and mortality.[93,94]

Like those with sickle cell disease, women with thalassemia require vigilant follow-up throughout their pregnancy. This includes interval monitoring of maternal vital signs and fetal heart rate, maternal hemoglobin levels, and fetal growth as assessed by ultrasound beginning around the 24th week of gestation. Patients are screened for folate and iron deficiency. They should also be assessed for iron overload, which can develop in individuals with thalassemia as a result of increased intestinal iron absorption, frequent blood transfusions, and rapid turnover of plasma iron.[90] Prenatal genetic testing can be performed if desired, with results used to counsel parents of the child and guide optimal care of the fetus. In terms of therapy, there are no specific treatment recommendations for women with thalassemia during pregnancy aside from folate supplementation and supportive care. In pregnant women with evidence of iron overload, chelation therapy using deferoxamine has been safely used, though the potential for teratogenicity associated with the agent must be considered in this setting.[95]

OTHER HEMOLYTIC ANEMIAS

Hereditary Spherocytosis

Hereditary spherocytosis is the most common inherited hemolytic anemia among people of northern European descent.[96] Few cases of pregnancy in individuals with hereditary spherocytosis have been reported. Published reports indicate there may be an increased incidence of first-trimester fetal loss patients with hereditary spherocytosis.[97] Because some patients have only low levels of hemolysis under normal conditions, the disease may not become clinically apparent until pregnancy. Pregnant women with hereditary spherocytosis can exhibit a variety of clinical manifestations. These include folate deficiency related to the increased requirements of pregnancy superimposed on chronic hemolysis, hemolytic crisis, and aplastic crisis.[98,99] The results of two small series suggest that pregnancy outcomes for women with hereditary spherocytosis are generally good, with improvements in outcomes for splenectomized patients.[94,100] Care is primarily supportive.

Pyruvate Kinase Deficiency

Pyruvate kinase deficiency is a rare disorder resulting in impaired glycolysis and adenosine triphosphate (ATP) generation. Clinically, most patients with the disorder exhibit a compensated hemolysis. There are very few reports of pregnancy in women with pyruvate kinase deficiency. Published reports indicate that although such women experience increased levels of hemolysis and thus require transfusions, pregnancy outcomes are favorable for both mother and fetus.[101]

Glucose 6-Phosphate Dehydrogenase Deficiency

Favorable pregnancy outcomes observed in women with hereditary spherocytosis and pyruvate kinase deficiency stand in contrast to those in women with glucose 6-phosphate dehydrogenase (G6PD) deficiency. The deficiency of glucose 6-phosphate dehydrogenase in this disorder leads to hemolytic anemia in the face of oxidative stress. The condition increases the risk of spontaneous abortion, low birth weight, and neonatal jaundice.[102] Women with G6PD deficiency should be instructed to strictly avoid medications with oxidative potential. Complications following the ingestion of oxidative drugs can even occur in a carrier of the G6PD deficiency gene if her male fetus has inherited the disease.[103]

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare clonal disorder caused by somatic mutation in the membrane-anchoring protein *PIGA*. *PIGA* mutation leads, in turn, to deficient function of critical membrane proteins that in wild-type individuals are anchored by the gene product of *PIGA*. Features of the clinical phenotype include hemolysis, thrombosis, and bone marrow failure. Hemolysis results from deficiency in the membrane proteins CD55 and CD59, which renders affected individuals susceptible to complement-mediated intravascular hemolysis.

The clinical manifestations of PNH can have a devastating impact on pregnancy. Reported cases highlight the significant pregnancy-associated morbidity and mortality in women with this condition.

Complications include severe anemia, thrombocytopenia, thrombotic events, preterm delivery, low-birth-weight infants, neonatal death, and maternal death.[104,105] A study by Ray and colleagues reviewed pregnancy outcomes in 24 women with PNH and found a 20% maternal mortality rate.[105]

Owing to the high-risk nature of their pregnancies, women with PNH require close medical attention in the antenatal, perinatal, and postnatal periods. Prophylactic anticoagulation is recommended because of the high incidence of thrombotic events during pregnancy.[106] Warfarin is contraindicated because of its teratogenicity. Low-molecular-weight heparin, meanwhile, is favored over unfractionated heparin because it less frequently causes heparin-induced thrombocytopenia. Anticoagulation should be interrupted during the perinatal period but, in the absence of contraindications, reinitiated thereafter and continued for 6 weeks postpartum.[106]

Results of a phase III trial by Hillmen and colleagues demonstrated that eculizumab, a humanized monoclonal antibody against the terminal complement protein C5, can reduce levels of hemolysis, stabilize hemoglobin, minimize transfusion requirement, and improve quality of life in patients with PNH.[107] Although the drug offers promise for pregnant women with PNH, it has not yet been studied in this patient population and thus cannot be recommended for use. Red blood cell transfusions are used in the treatment of anemia. In the setting of thrombocytopenia and bleeding, platelet transfusions may also be necessary.

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia can occur during pregnancy and lead to anemia. The relatively small size of IgG immunoglobulin molecules allows them to cross the placenta; thus, the IgG subtype of autoimmune hemolytic anemia can adversely affect the fetus. In contrast, the larger IgM antibodies do not cross the placenta. Patients with autoimmune hemolytic anemia are treated with glucocorticoids and, if necessary, intravenous immunoglobulins. Supportive transfusions are administered when needed.[108] In rare instances, pregnancy appears to precipitate the development of autoimmune hemolytic anemia in a previously unaffected woman. The etiology of this phenomenon is not known.[109] Women in this circumstance have been treated in the standard fashion with favorable results.

THROMBOCYTOPENIA IN PREGNANCY

Thrombocytopenia occurs in approximately 7% to 12% of pregnancies. Most cases are attributed to gestational, or incidental, thrombocytopenia and require only routine monitoring.[110–112] On the other hand, several life-threatening syndromes associated with thrombocytopenia such as HELLP and disseminated intravascular coagulation can occur in pregnancy and require urgent evaluation. The various causes of thrombocytopenia during pregnancy are reviewed here.

Gestational (Incidental) Thrombocytopenia

Studies suggest that in up to 75% of cases, thrombocytopenia in pregnancy can be attributed to gestational thrombocytopenia.[112] Women with gestational thrombocytopenia typically have platelet counts in the 70,000 to 150,000/μL range, are otherwise healthy, and have no prior history of idiopathic thrombocytopenic purpura (ITP). Thrombocytopenia in these women most often develops late in the second trimester or in the third trimester. Although the etiology of gestational thrombocytopenia has not been clearly established, it is thought the condition results from pregnancy-related hemodilution and increased platelet clearance.[112]

Women with this condition can be reassured that gestational thrombocytopenia does not cause adverse effects on either the mother or fetus. Physicians could not always provide such reassurance; for many years, even mild thrombocytopenia in an otherwise healthy pregnant woman led to extensive evaluation and prompted concern about perinatal bleeding and adverse outcomes at the time of delivery. In an important study that changed this approach, Burrows and Kelton prospectively followed more than 2000 women who gave birth during a 1-year period at a single Canadian hospital. Eight percent of patients involved in the study were found to have mild thrombocytopenia that had no effect on the mother or fetus.[113]

Idiopathic (Autoimmune) Thrombocytopenic Purpura

Responsible for pregnancy-associated thrombocytopenia in approximately 3% of cases, idiopathic thrombocytopenic purpura (ITP) represents an important diagnostic consideration in this patient population. It is the most common cause of thrombocytopenia during the first two trimesters of pregnancy.[108,114] ITP can recur in a woman with previously documented disease or develop de novo during pregnancy. Pregnancy itself does not exacerbate the disease.

ITP may be difficult to distinguish from gestational thrombocytopenia, as patients with these conditions can present with similar clinical and laboratory findings. Elevated levels of platelet-associated IgG and antibody titers can be found in both conditions.[115] Furthermore, assays that detect antibodies against the glycoprotein receptors IIb/IIIa and Ib/IX are not specific for ITP.[116] Thrombocytopenia in the first trimester or early portion of the second trimester should raise suspicion for ITP, whereas thrombocytopenia that develops later in pregnancy should raise suspicion for gestational thrombocytopenia.

Women with preexisting ITP should be followed carefully during pregnancy, with monthly monitoring during the first two trimesters, biweekly in the third trimester, and weekly in the final weeks of pregnancy.[117] Management of ITP, meanwhile, depends on the maternal platelet count. Patients with severe thrombocytopenia (platelet count <10,000/μL) require immediate treatment. Options include corticosteroids, typically prednisone, at a dose of 1 mg/kg/day initially; high-dose intravenous immune globulin (IVIG) at an initial dose of 1 mg/kg; anti-D immune globulin in conjunction with steroids; or splenectomy for individuals who do not respond to other interventions. As one might expect, each of these therapies has limitations. IVIG, for example, has a relatively short duration of action (3–4 weeks) and thus may require readministration during the course of pregnancy. Though easily administered and relatively inexpensive, corticosteroids increase the incidence of gestational diabetes, pregnancy-induced hypertension, postpartum psychosis, and osteoporosis. Thus, corticosteroids should be avoided if possible. Anti-D immune globulin has been used in pregnant women with ITP, but large safety trials in pregnancy have not been performed.[110] Finally, splenectomy jeopardizes the life of the fetus, particularly when performed early in pregnancy. If it becomes necessary in the management of a pregnant woman with ITP, the procedure should be deferred until the second or third trimester if possible. Agents such as danazol, cyclophosphamide, and vinca alkaloids—though used in the management of ITP in nonpregnant individuals—are teratogenic and should be avoided during pregnancy.[117] Danazol may cause clitoral enlargement and labial fusion in female fetuses when given in the first trimester.[118]

Patients with mildly reduced platelet counts (60,000–100,000/μL) are followed without intervention. Individuals with slightly lower platelet counts (20,000–60,000/μL) do not require specific intervention either, but are more likely to require therapy as their pregnancy progresses. For these individuals, a single dose of IVIG 2 weeks prior to delivery or daily steroid therapy initiated 3 weeks prior to delivery can be administered to raise the platelet count above 50,000/μL.

As discussed previously, maternal antiplatelet IgG can cross the placenta and cause thrombocytopenia in the fetus.[119] Percutaneous umbilical blood sampling (PUBS) is the most accurate means to obtain the fetal platelet count. However, the procedure is associated with a high complication rate and 1% fetal mortality.[120] Intrapartum

fetal scalp sampling represents an alternative, but the accuracy of this technique is only 50% to 70%.[121] Meanwhile, the maternal platelet count and antiplatelet antibody level do not accurately predict the fetal platelet count.[122] Overall, 10% of babies born to mothers with ITP have a platelet count less than 50,000/μL whereas fewer than 5% have a platelet count less than 20,000/μL.[114] Treatment of the pregnant woman with IVIG or steroids does not appear to affect the platelet count of her fetus.[123,124] Thrombocytopenia places neonates at risk for bleeding events, including intracranial hemorrhage, though this complication is rare.[125]

In light of the bleeding risk to both mother and fetus, the method of delivery in women with ITP has been a matter of debate. Some clinicians have advocated fetal platelet count monitoring with Cesarean section in instances where the fetal platelet count lies below 50,000/μL. On the other hand, others have argued for vaginal delivery in all pregnant women with ITP, citing the risks associated with fetal platelet count monitoring and the low incidence of fetal intracranial bleeding even with severe thrombocytopenia. At present, available guidelines on the subject suggest that obstetric factors, rather than hematologic ones, should guide the manner of delivery.[126] Following the delivery of a child, cord blood platelet is checked and the newborn platelet count followed because thrombocytopenia most often peaks 4 to 6 days after delivery and resolves as maternal antiplatelet IgG is cleared.

Preeclampsia and HELLP Syndrome

Thrombocytopenia in pregnant woman also occurs in association with preeclampsia and HELLP syndrome, potentially severe multisystem disorders associated with pregnancy. In previously healthy nulliparous women, the incidence of preeclampsia is between 2% and 7%.[127] Thrombocytopenia is observed in 15% to 50% of patients with this condition.[110,128] Clinical manifestations include a maternal syndrome characterized by hypertension, proteinuria, and systemic abnormalities as well as a fetal syndrome characterized by fetal growth restriction, preterm delivery, and hypoxia-induced neurologic damage.[127,128]

In most instances, preeclampsia occurs during a woman's first pregnancy, though it can recur in a subsequent pregnancy or occur for the first time in a woman with one or more previously unaffected pregnancies. Risk factors for the disorder include, but are not limited to, preeclampsia in a previous pregnancy, a family history of preeclampsia, chronic hypertension, obesity, multifetal gestation, rheumatic disease, and preexisting thrombophilia.[127] With respect to thrombophilia, a case control study by Mello and colleagues suggests that the prevalence of an underlying thrombophilia is significantly higher among women who develop preeclampsia during pregnancy than among those who have uneventful pregnancies.[129]

HELLP syndrome—defined by hemolysis, elevated liver enzymes, and low platelets—represents a severe variant of preeclampsia. In the majority of cases, patients who develop the syndrome are Caucasian and multiparious.[130] The median age of affected patients is 25. Meanwhile, the time of presentation during pregnancy ranges from the midtrimester (15%) to term (18%). Thirty percent of patients develop HELLP within 2 days after delivery.[131] Patients typically exhibit vague symptoms such as malaise, fatigue, epigastric or right upper quadrant pain, nausea, vomiting, and flu-like symptoms. Because of the nonspecific nature of these symptoms, diagnosis is often delayed; one study found an average time to diagnosis of 8 days in women with HELLP syndrome.[132] Clinical findings at the time of diagnosis—weight gain or edema, hypertension, and proteinuria—are similar to those observed in preeclampsia.[131]

Although various criteria have been used in diagnosing HELLP syndrome, they generally share the following features: hemolysis as evidenced by schistocytes on the peripheral blood smear, serum LDH greater than 600 U/L and/or serum total bilirubin greater than 1.2 mg/dL, AST greater than 70 IU/L, and a platelet count lower than 100,000/μL.[133] Martin and colleagues have further defined HELLP syndrome on the basis of platelet count. According to this classification, patients with class 1 HELLP syndrome have a platelet count lower than 50,000/μL, those with class 2 disease have a platelet count between 50,000 and 100,000/μL, and individuals with class 3 HELLP syndrome have a platelet count higher than 100,000/μL.[131] As might be expected, women with Class 1 HELLP syndrome required a recovery period in the aftermath of their illness.

Although the precise mechanism through which preeclampsia develops is uncertain, research in the field continues to advance understanding of the underlying pathophysiology. Endothelial cell dysfunction following placentation appears to play a central role in the pathogenesis of the disease. During development of the placenta, placental trophoblast cells interface with the epithelial layer of the uterus, forming the decidua. Penetration and remodeling of maternal spiral arteries beginning at week 9 during pregnancy increases placental perfusion and improves oxygenation for the developing fetus under normal conditions.[134]

Several studies in the late 1990s demonstrated low levels of vascular growth factor ligands—including vascular endothelial growth factor (VEGF), placenta growth factor (PIGF), and vascular endothelial growth factor receptor (VEGFR)-1—in women with HELLP.[132,135,136] In addition, decreased levels of active matrix metalloproteinase were noted in preeclamptic placentas as compared to normal individuals.[137] More recently, attention has focused on the purported antiangiogenic effects of soluble fms-like tyrosine kinase-1 (sFlt-1), a soluble receptor that binds both VEGF and placenta growth factor (PIGF).[138] Circulating levels of sFlt-1 are elevated in women with preeclampsia whereas levels of both VEGF and PIGF are reduced.

The role of immunologic factors in the pathogenesis of preeclampsia has also received recent attention. For example, the interaction between fetal trophoblasts and maternal T cells—primarily NK cells—appears to play a critical role in normal placental development.[139] Studies indicate that decidual NK cells uniquely recognize the HLA groups of infiltrating trophoblasts and suggest that insufficient activation of maternal NK cells may contribute to the development of preeclampsia.[134]

Cellular abnormalities such as those described impair placental implantation and vasculogenesis, leading to fetal hypoxia and the release of vasoactive compounds such as endothelin, nitric oxide, and prostaglandins. High levels of endothelin, a potent vasoconstrictor, are seen in preeclamptic patients, and injection of endothelin into rabbits produces a syndrome similar to HELLP syndrome.[140,141] The activity of endothelin, nitric oxide, and prostaglandins leads to hypertension and platelet activation. In turn, injury to the vascular endothelium results in fibrin deposition, further platelet activation, and the release of additional vasoactive agents such as serotonin and thromboxane A_2. The etiology of thrombocytopenia in preeclampsia is likely related to increased antiplatelet IgG levels[142] or to activation of the coagulation cascade with subsequent consumption of platelets.[143,144]

These events lead to the multisystem dysfunction seen in patients with HELLP syndrome. Fibrin deposition in the hepatic sinusoids causes hepatocellular injury. Patients can develop right upper quadrant pain if intraparenchymal or subcapsular hemorrhage occurs. Disseminated intravascular coagulation (DIC) was observed in 21% of patients with HELLP in one series, whereas placental abruption was seen in 16% of patients.[145] Other manifestations of HELLP syndrome include acute renal failure, pulmonary edema, shock, cerebrovascular accident (CVA), eclampsia,[146] retinal detachment,[140] diabetes insipidus,[147] and increased incidence of cesarean section.[148]

HELLP syndrome is associated with high maternal and neonatal mortality. Maternal mortality ranges from 1.1% to 24.2%.[149] The immediate cause of death is most often rupture of the liver, DIC, acute renal failure, pulmonary edema/acute respiratory distress syndrome (ARDS), shock, or CVA. Perinatal deaths resulting from placental abruption, asphyxia, or extreme prematurity occur in 10% to 15% of patients.[146] Following delivery, infants born to women with preeclampsia or HELLP can develop a self-limited neonatal thrombocytopenia. Uncertainty exists as to whether infant thrombocytopenia in these instances results from preeclampsia/HELLP itself or from

a related complication such as neonatal sepsis.[150–152] HELLP recurs in subsequent pregnancies of affected women in 3% to 27% of cases. There is also an increased risk of preeclampsia, placental abruption, and preterm delivery in these pregnancies.[153,154]

In caring for the patient with preeclampsia or HELLP syndrome, the clinician's primary concerns are the mother's health and safety. The clinician must also consider the stage of pregnancy at time of diagnosis, the condition of the fetus, and desires of the patient in making management decisions. Definitive treatment for preeclampsia and HELLP involves delivery of the fetus; it is indicated for women who present after 34 weeks' gestation and those with evidence of multisystem dysfunction. However, conservative, supportive care without immediate delivery can be pursued for the woman who is relatively asymptomatic, hemodynamically stable, less than 32 to 34 weeks' gestation, and without evidence of abnormal coagulation.[155] Magnesium sulfate, which reduces cerebral vasoconstriction and ischemia, should be administered for seizure prophylaxis.[156] Parenteral labetalol or hydralazine is given for blood pressure control. Meanwhile, systemic corticosteroids appear to lessen the risk of maternal ARDS and reduce neonatal complications when administered to women who present at less than 34 weeks' gestation.[157] In addition to these measures, volume status is closely monitored to prevent overexpansion of plasma volume and ensure adequate urine output.

Persistent right upper quadrant pain—which may herald a liver hematoma or rupture, hemodynamic instability, coagulation profile abnormalities, or a decline in clinical status—should prompt delivery by cesarean section. As mentioned previously, delivery is also indicated if the fetus is at least 32 to 34 weeks of gestation at the time signs and symptoms of preeclampsia/HELLP develop. In a clinically stable woman, vaginal delivery can be attempted.[158] When cesarean section is required, transfusion of red blood cells, platelets, and fresh frozen plasma is performed as necessary prior to and during surgery. Severe hypofibrinogenemia should be treated with cryoprecipitate.

Patients are monitored closely in the postpartum period. Magnesium should be continued for 12 to 48 hours after delivery and blood pressure controlled appropriately. Although hypertension typically resolves within 6 weeks after delivery, some women require long-term antihypertensive therapy.[156] Coagulation and platelet abnormalities tend to resolve within the 24 to 48 hours following delivery. Some patients, however, experience an ongoing decline in the platelet count and should be followed until counts normalize. Postpartum eclampsia can occur for up to 48 hours after delivery; thus, patients and health care providers should remain vigilant in monitoring for suggestive signs and symptoms.[159] Treatment options in the setting of severe postpartum preeclampsia and HELLP include corticosteroids and plasmapheresis.[160,161]

In light of the morbidity and mortality associated with preeclampsia and HELLP, considerable research has focused on prevention of these conditions. The efficacy of various preventive strategies—including magnesium supplementation, low-dose aspirin, zinc supplementation, antihypertensive drugs, and heparin therapy among others—has been the focus of observational studies, systematic reviews, and randomized trials. Initial small studies suggested that low-dose aspirin reduces the risk of preeclampsia, although patients who received aspirin had a higher incidence of placental abruption and bleeding.[162] Larger, randomized trials failed to confirm the benefit of low-dose aspirin.[163,164] Antioxidants vitamin C and vitamin E have shown promise in small trials, but further testing needs to be done.[165] Calcium supplementation appeared to be beneficial based on a study of Ecuadorian pregnant teens,[166] but a subsequent randomized study performed in the United States showed no benefit to this intervention.[167] Some clinicians endorse calcium supplementation in patients with low dietary calcium intake, particularly for those expectant mothers at risk for preeclampsia.[168] Supplemental fish oil may lower the risk of preterm delivery in women with previous preterm delivery, twin pregnancies, intrauterine growth retardation, or preeclampsia, but further studies are needed to confirm this benefit.[169]

Thrombotic Thrombocytopenic Purpura–Hemolytic Uremic Syndrome

Thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) are also important considerations in the evaluation of pregnant women with thrombocytopenia. Like preeclampsia/HELLP, they are multisystem disorders associated with high morbidity and mortality in the absence of appropriate therapy. Microvascular injury and platelet agglutination with resulting thrombocytopenia and microangiopathic hemolytic anemia are pathologic hallmarks of TTP and HUS (Fig. 161–1). They are rare conditions overall, but the incidence of both increases in pregnancy.[170] In the case of TTP, in fact, estimates suggest that approximately 10% of cases occur in pregnant or postpartum women.[171]

Because they share many common clinical features, TTP and HUS are often categorized as a single entity, TTP-HUS. However, the pathophysiology underlying the two conditions appears to be distinctive. TTP is associated with unusually large multimers of circulating von Willebrand factor, which foster platelet aggregation and thrombus formation. Under normal circumstances, a von Willebrand factor-cleaving protease referred to as ADAMTS13 cleaves these multimers into smaller multimers of normal size. In TTP, function of the cleaving protease is impaired. ADAMTS13 deficiency characterizes familial TTP. Meanwhile, inhibition of ADAMTS13 protease activity by an autoantibody characterizes the acquired form of TTP. An inhibitory autoantibody can be found in 70% to 85% of patients with TTP.[172] On the other hand, impaired von Willebrand factor-cleaving protease activity does not appear to play a role in the pathogenesis of HUS.[173]

It can be difficult to distinguish TTP and HUS from HELLP syndrome. From a clinical standpoint, this represents an important distinction because accurate diagnosis dictates appropriate therapy. TTP tends to occur earlier in pregnancy, with a mean onset at 23.5

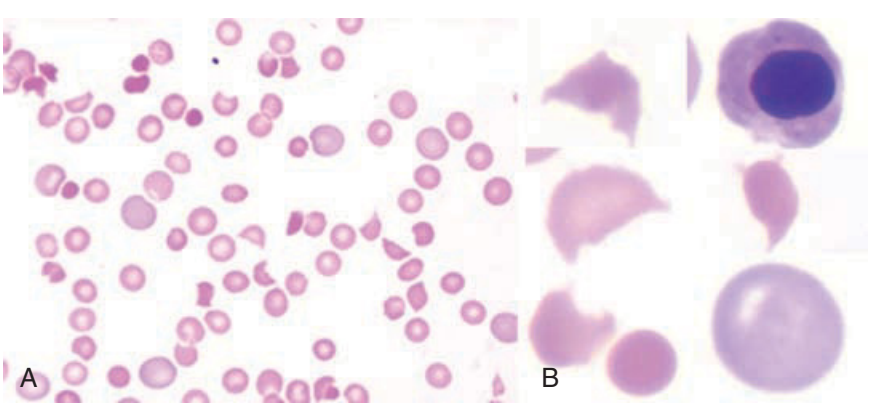

Figure 161–1 Microangiopathic hemolytic anemia, in pregnancy, peripheral blood smear (**A**–**B**). Evidence of microangiopathy with the formation of schistocytes, fragmented forms and spherocytes, associated with polychromasia and nucleated red blood cells (**A** and **B**, detail).

weeks, although it can occur at any point from the first trimester through the postpartum period.[174] HUS primarily occurs after delivery; 90% of cases occur in the postpartum period, with a mean onset at 26 days after delivery.[175] TTP and HUS do not cause hypertension or liver necrosis. Furthermore, TTP and HUS frequently persist after delivery whereas HELLP typically resolves in the postpartum period.

Early studies of pregnant women with TTP-HUS documented a maternal mortality rate of 44% and a perinatal mortality rate of 80%.[175] Occlusion of vessels within the decidua and resulting placental ischemia primarily account for fetal morbidity and mortality.[176] Treatment of TTP–HUS involves emergent plasmapheresis within 24 to 48 hours of diagnosis. The response rate among pregnant women treated with plasmapheresis for TTP is approximately 75%. By comparison, the overall response rate in patients with TTP is approximately 80% to 90%.[177–179] Long-term sequelae in surviving patients include chronic renal failure, hypertension, and recurrence of TTP–HUS. TTP–HUS recurs in approximately 50% of subsequent pregnancies.[180] Infusion of fresh frozen plasma represents an alternative to plasmapheresis, though plasmapheresis is the preferred treatment modality. The response rate following fresh frozen plasma infusion is 64%.[181] Corticosteroids (prednisolone 200 mg IV per day or prednisone 200 mg PO per day) have also been successfully used in the treatment of pregnancy-associated TTP–HUS, with a response rate of 26%.[179] Conversely, antiplatelet agents such as aspirin do not play a role in the treatment of pregnancy-associated TTP–HUS.[182]

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) in the pregnant woman can occur in various clinical settings, including HELLP syndrome, TTP–HUS, placental abruption, amniotic fluid embolism, uterine rupture, intrauterine fetal demise, sepsis, elective abortion, and acute fatty liver of pregnancy.

Severe placental abruption sufficient to cause fetal death occurs in 0.12% of all pregnancies.[183] This condition leads to a consumptive hypofibrinogenemia, and—when fibrinogen levels fall below 100 to 150 mg/dL—bleeding may ensue. Maintenance of adequate urine output and a hematocrit level greater than 30% are important components of care for the woman who has suffered a placental abruption. Either vaginal delivery or cesarean section is appropriate in the context of severe placental abruption. In a woman undergoing cesarean section following abruption, the platelet count should be maintained at 50,000/μL or above through platelet transfusion and fibrinogen replaced with fresh frozen plasma or cryoprecipitate.

Amniotic fluid embolism is a rare but often lethal condition with a mortality rate of approximately 80%.[184] Ten to 15% of these patients develop a coagulopathy. DIC in this setting most likely follows the release of thromboplastin-rich material into the maternal circulation. DIC seen in association with uterine rupture and intrauterine fetal demise presumably occurs through a similar mechanism.[185] On the contrary, bacterial endotoxin or exotoxin mediates sepsis-associated DIC in the pregnant woman with pyelonephritis, chorioamnionitis, endometritis, or septic abortion.[186] On rare occasions, elective abortions that employ hypertonic solution and those complicated by hemorrhage can be associated with DIC.[187]

Acute fatty liver of pregnancy (AFLP), or acute yellow atrophy, occurs in 1 of every 5000 to 10000 pregnancies, most often in the third trimester of primiparous women.[188] Maternal and fetal mortality are 5% and 15%, respectively. Although the pathogenesis of AFLP is not clear, microvesicular fatty infiltration of the liver's central zone is observed and presumably plays a central role in the development of this disease.[189] In some cases, fatty infiltration can be detected by ultrasound or computed tomography.[190] Patients present with a variety of symptoms, including malaise, fatigue, right upper quadrant pain, dyspnea, and mental status changes. Laboratory findings, meanwhile, include abnormal liver function tests consistent with cholestatic disease, elevated ammonia, low fibrinogen and antithrombin levels, and elevated prothrombin time, with evidence of DIC. Hepatic dysfunction can impair gluconeogenesis. Diabetes insipidus may be present. The clinical course of AFLP resembles that of HELLP, TTP, and HUS, although the microangiopathy and thrombocytopenia are not as severe.[191] With supportive care, the condition typically resolves within 10 days after delivery.

BLEEDING DISORDERS

von Willebrand Disease

Affecting approximately 1% of the population, von Willebrand disease (vWD) is the most common inherited disorder of coagulation. By mediating platelet adhesion and functioning as a carrier for circulating factor VIII, von Willebrand factor (vWF) plays a vital role in hemostasis. According to the most widely used classification by Sadler, there are 3 types of vWD: type 1 (partial deficiency of vWF), type 3 (severe deficiency of vWF), and type 2, which includes four subtypes that involve qualitative defects in vWF.[192] Factor VIIIc, vWF antigen (vWF:Ag), and the ristocetin cofactor activity (vWF:RCo) are important components of the laboratory diagnosis. vWD does not impair fertility or increase the likelihood of miscarriage.[193] Thus, the management of pregnancy in patients with the condition is an important feature of the overall care for these individuals.

For the pregnant woman with vWD, bleeding at parturition and in the postpartum period is of primary concern. Related concerns include the administration of anesthesia, perineal hematoma, episiotomy blood loss and healing, and bleeding at surgical sites. Approximately 75% of women with moderate to severe vWD will experience significant peripartum bleeding.[194] And overall, there is a 20% risk of postpartum hemorrhage in women with vWD. In a normal pregnancy, FVIIIc and vWF levels increase, beginning in the second trimester.[195] They peak as the pregnancy nears term. Among many pregnant women with vWD, particularly those with Type 1 disease, a similar increase in FVIII and vWF levels is observed. Factor VIIIc levels in pregnant women with vWD peak at 29 to 32 weeks' gestation whereas vWF:Ag levels peak at approximately 35 weeks' gestation.[196] The risk of peripartum bleeding is related to the level of these factors.[197] In most instances, vWF:Ag, factor VIIIc, and vWF:RCo levels should be assessed during the first and third trimester to determine bleeding risk for individuals with vWD. However, this may be less relevant for patients with Type 3 vWD, wherein levels tend to remain low throughout pregnancy. Patients without a documented bleeding disorder who suffer bleeding complications during pregnancy should be evaluated for vWD because many with the disorder have a mild clinical course and remain undiagnosed for a long period.[198]

As a general rule, therapy can be rendered either in the setting of a spontaneous bleeding event or in a prophylactic context for the high risk individual. Mainstays of therapy for pregnant women with vWD include DDAVP (1-deamino-8-D-arginine-vasopressin), a synthetic analogue of vasopressin, and vWF-FVIII concentrates (Humate-P, Alphanate). Cryoprecipitate can be used on an emergent basis if vWF–FVIII concentrates are unavailable, but is avoided if possible during pregnancy because it poses a small risk of bloodborne infection.[199] Meanwhile, although antifibrinolytic therapy plays a role in the management of individuals with vWD, it is also generally avoided during pregnancy and lactation because of its potential teratogenicity and effects on the newborn. Data concerning the toxicity of antifibrinolytic therapy in pregnancy is limited.

Exerting its effect through the type 2 vasopressin receptors, DDAVP rapidly and transiently increases levels of factor VIII and vWF.[200] It is administered by continuous intravenous infusion over 30 minutes in the setting of an acute bleeding event. On a prophylactic basis, it can be given subcutaneously or inhaled nasally.[200] Although highly effective when used in an appropriate clinical

context, DDAVP does have limitations. Patients who have never received DDAVP therapy should be tested for responsiveness to the agent during the second trimester. Because of its potential oxytocic effect, DDAVP is pregnancy risk category B.[196] Owing to its antidiuretic effect, meanwhile, DDAVP can cause fluid retention and hyponatremia. Finally, DDAVP has uncertain utility in the management of women with type 2 and type 3 vWD because of underlying genetic defect in these individuals. VWF–factor VIII concentrate is indicated for these patients.

Multidisciplinary care by an experienced obstetrician and hematologist should be provided for the pregnant woman with vWD. This becomes particularly important as parturition nears. In providing care for this population of patients, clinicians aim to control disease effects in the pregnant and postpartum mother. Factor VIIIc and vWF : RCo levels, PTT, type and cross match, and a complete blood count are obtained at the time of hospital admission. Women with vWD should be monitored for bleeding at the time of delivery, with transfusional products and DDAVP available for use as needed. vWF : RCo and factor VIIIc levels of 50 IU/dL generally serve as a target at parturition and in the postpartum period; expert opinion suggests that women with levels below this should receive replacement products.[201]

In the management of pregnant women with vWD, the provision of regional anesthesia during delivery is an important topic. Some anesthesiologists employ epidural anesthesia in patients with mild disease, with or without the use of DDAVP.[202,203] For patients with moderate to severe disease, an alternative form of analgesia may be considered. If epidural analgesia is utilized in a patient with moderate to severe disease, prophylactic therapy is indicated. The epidural catheter should be removed soon after delivery, as falling factor levels in the postpartum period increase the bleeding risk.[199]

The route of delivery is also an important matter in patients with vWD. To minimize the risk of neonatal hemorrhage, some obstetricians recommend cesarean delivery for patients with type 2, type 3, and clinically moderate type I disease. However, neonatal bleeding occurs in the setting of cesarean delivery as well, and delivery methods have not been rigorously compared.[196,202]

Prenatal testing is a challenge in women with vWD. The specific mutations involved in the pathogenesis of type 1 and type 3 vWD are not known. And multiple mutations are involved in the pathogenesis of type 2 vWD. Fetal blood vWF levels can be obtained in necessary, but there are inherent risks associated with the procedure.[204] Expectant mothers should be informed of these risks in making decisions about prenatal genetic testing (Fig. 161–2).

Hemophilias

The hemophilias (A and B) are X-linked recessive diseases characterized by hemarthrosis and subcutaneous and intramuscular bleeding.[205] Hemophilia A results from deficient production of factor VIII, and hemophilia B, from deficient production of factor IX. As X-linked disorders, hemophilia A and B occur most often in men, but they can occur in women under several circumstances, including X-chromosome inactivation (lyonization), X hemizygosity, and double heterozygosity as can occur in the female offspring of an affected father and carrier mother.[206] In the United States, women account for 1.7% of patients with hemophilia A and 3.2% of patients with hemophilia B.[207] Fifty percent of male offspring from a female carrier inherit the disorder, whereas 100% of male offspring from an affected mother inherit the disease. Female carriers in both disorders can be detected through laboratory screening and pedigree analysis.[208] Women with hemophilia and pregnant women with an affected fetus must be monitored closely during pregnancy for bleeding events that compromise the well-being of either the mother or fetus. Fetal umbilical blood sampling can be used to check factor VIII and factor IX levels. Chorionic villus sampling may also be used.[209]

At parturition, women with hemophilia A whose factor VIIIc level lies below 50% of the normal range should receive purified factor VIII. Levels should be greater than 80% for surgery and maintained at 30% to 40% for 3 to 4 days postoperatively. Rarely, thrombosis can occur in the aftermath of factor VIII replacement therapy.[210] Six to 10% of neonates with hemophilia have hemorrhagic complications in the perinatal period, including intracranial hemorrhage. Vacuum extractors, forceps delivery, and scalp electrodes should be avoided. To date, no studies have rigorously compared vaginal and cesarean delivery in this patient population. Neonatal blood should be assayed for factor VIIIc levels and PTT immediately after birth.[203] Neonates with low factor VIIIc levels may require serial cranial ultrasounds to rule out bleeding.[211]

Hemophilia B is treated in a similar fashion. However, it should be noted that cryoprecipitate contains low levels of factor IX and should not be used as replacement therapy in the management of this condition. Purified factor IX is the agent of choice for patients with hemophilia B. Meanwhile, individuals with other clotting factor deficiencies should receive fresh frozen plasma or specific clotting factor products to maintain factor levels at greater than 25%.[212] One exception to this pertains to the management of patients with factor XIII deficiency; the occurrence of spontaneous recurrent abortions and uterine bleeding in these individuals necessitates regular infusions of

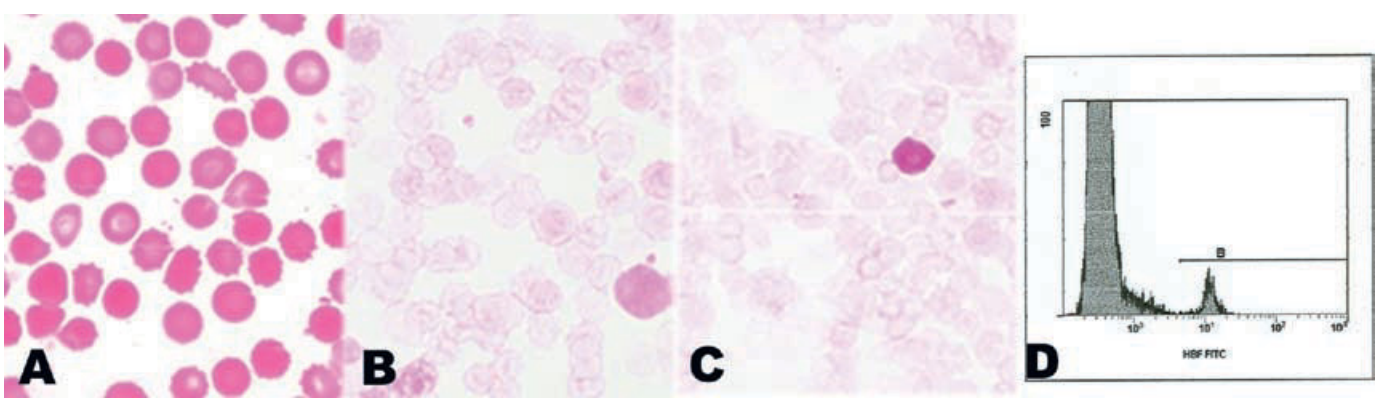

Figure 161–2 Evaluation of fetal–maternal bleed: Kleihauer–Betke test and flow cytometric analysis of Hgb F in red blood cells (**A**–**D**). The principle behind the Kleihauer–Betke test is that fetal cells are resistant to acid elution. In **A**, a fetal control specimen, none of the cells are eluted of their hemoglobin, whereas in a normal adult control, **B**, essentially all cells are lysed and negative. The rare weakly positive cells (see single cell, right side) are adult cells that contain increased Hgb F, but not at the level of a fetal cell. In the test case (**C**), rare fetal cells in the maternal blood can be detected and enumerated. Note the bight staining in the single positive cell. An alternative to this acid elution test is the direct measure Hgb F in red blood cells with an anti-HgbF antibody and flow cytometric analysis. The histogram shows a large negative peak (left) corresponding to adult cells containing only HgbA. There is an intermediate shoulder to the right corresponding to adult cells containing increased HgbF (**F** cells), and there are fetal cells in a distinct small positive peak, corresponding to cells from the fetal–maternal bleed.

fresh frozen plasma or factor XIII concentrate to maintain pregnancy.[213]

VENOUS THROMBOEMBOLIC DISEASE AND PREGNANCY

VTE disease is a leading cause of maternal morbidity and mortality.[214] The risk of venous thromboembolism increases two- to fourfold during pregnancy and the early postpartum period.[215] In women who have had a previous VTE event, pregnancy appears to increase the risk of a recurrent thromboembolic event.[216] Various factors account for the prothrombotic state associated with pregnancy. Increased estrogen levels early in pregnancy increase venous distention and contribute to venous stasis.[217] Increased plasma volume and compression of the inferior vena cava by the gravid uterus contributes to venous stasis as well.[218] In addition, studies have demonstrated decreased blood flow velocity in pregnant women, particularly in the left leg when pregnant women lie in a supine position. This phenomenon likely explains the increased risk of left leg thrombosis among pregnant women.[219] Furthermore, the concentration of coagulation factors changes during pregnancy. The concentration of vWF, fibrinogen, and prothrombin, along with factors V, VII, VIII, IX, X, and XII increases, whereas the concentration of factor XI and protein S decreases.[220–222] Finally, fibrinolytic activity decreases during pregnancy as the level of plasminogen activator inhibitors 1 and 2 increases.[223] Other factors—including high body mass index, smoking, immobilization, and age more than 35 years—should also be considered when assessing the thrombotic risk of a pregnant woman.

Because of the prothrombotic physiology associated with pregnancy, a clinician's concern for venous thromboembolism in a pregnant woman should prompt immediate evaluation. To assess for lower-extremity thrombosis, venous compression ultrasound remains the initial test of choice. Ultrasound poses no threat to the fetus and can detect thrombosis of the proximal common femoral and popliteal veins with a sensitivity of 95% and specificity of 96%. Despite the efficacy of ultrasound, limitations to its use do exist. The test is less effective for the diagnosis of calf vein thrombosis, with a sensitivity and specificity in the 60% to 70% range.[224] For this reason, a woman with suspected lower-extremity DVT should undergo serial ultrasounds if the initial evaluation is nondiagnostic.[225] Similarly, thrombus in the common iliac vein can evade diagnosis by venous compression ultrasound.

In such cases, other modalities such as contrast venography and magnetic resonance venography (MRV) can be considered. Although contrast venography exposes the fetus to radiation and should thus be used with caution during pregnancy, its use may be warranted when clinical suspicion for an underlying thrombotic event is high.[224] Serum D-dimer tests are often used in conjunction with imaging studies to assess for thrombosis in nonpregnant patients. The sensitivity of D-dimer tests for the presence of thrombus ranges from 85% to 95%.[226] However, several pregnancy-associated conditions elevate D-dimer levels, including preterm labor, placental abruption, and hypertension of pregnancy, thus undermining the utility of the test somewhat in pregnant women by decreasing its specificity.[223] Nonetheless, when normal, the D-dimer assay provides the clinician with useful information.

When lower-extremity imaging reveals no evidence of thrombus in a pregnant woman with suspected pulmonary embolism, the clinician has several options. Helical computed tomography (hCT) has become the standard modality for the diagnosis of pulmonary embolism in nonpregnant individuals at many centers. However, even with abdominal shielding, the procedure results in fetal radiation exposure (approximately 16 mrad) due to internal scatter.[227] Although this low level of radiation exposure probably does not cause harm to the fetus, repeated imaging during the course of pregnancy is to be avoided.[225] Ventilation-perfusion (VQ) scanning is frequently employed in the evaluation of pregnant women with suspected pulmonary embolism, but has limitations as well. Results of a prospective study indicate that when used in this patient population, VQ scanning infrequently yields a conclusively positive result (1.8% of cases) and is often nondiagnostic (24.8% of cases).[228] Finally, pulmonary angiography can be utilized in the evaluation of pulmonary embolism in rare instances when the previously described diagnostic tests yield nondiagnostic results in the face of a high clinical suspicion.

VTE in pregnancy is treated with heparin. Until low-molecular-weight heparin (LMWH) was introduced in the late 1980s, unfractionated heparin (UF) was the anticoagulant of choice for treatment of pregnant women with VTE. Because it does not cross the placenta, UF is nonteratogenic. However, drawbacks to UF therapy—including heparin-associated osteoporosis, heparin-induced thrombocytopenia (HIT), and the drug's unpredictable pharmacokinetics—are well documented.[214] Heparin-associated osteoporosis can develop in women who receive at least 1 month of therapy; it is likely related to a toxic effect of heparin on osteoblasts.[229] Because of its more favorable side-effect profile, reliable pharmacokinetics, and equal efficacy in treating VTE, LMWH now represents the most commonly used anticoagulant for treatment of VTE in pregnancy.[230] The risk of osteoporosis and HIT appears to be less with LMWH-based anticoagulation than with UF-based anticoagulation.[231,232] Though practice patterns vary, it is reasonable to base the initial dose of LMWH on early-pregnancy—rather than current—weight.[233] Because clearance of LMWH increases during pregnancy, twice-daily dosing regimens are preferred to once-daily regimens.[234] In terms of duration of therapeutic anticoagulation, many clinicians continue therapy at full dose through the entire pregnancy and puerperium based on the rationale that pregnancy itself represents a risk factor for recurrent VTE.[230] In contrast, other clinicians advocate initial anticoagulation with full-dose LMWH for a designated period followed by conversion to an intermediate dose. This approach may be beneficial for individuals susceptible to side effects of anticoagulation such as bleeding or osteoporosis.[214]

Warfarin is contraindicated in pregnant women. It crosses the placenta and can cause both fetal hemorrhage and nervous system abnormalities and other teratogenic effects.[235] Warfarin can be used in the postpartum period after initiating therapy with concurrent heparin, and in this setting does not appear to increase the risk of bleeding in children of lactating mothers.[224] Danaparoid, a heparinoid, is recommended for the treatment of HIT in the pregnant woman.[214] This agent does not cross the placenta and has little cross-reactivity with UF and LMWH.

Anticoagulation should be discontinued at the time of parturition. UFH and LMWH should, in most circumstances, be stopped 12 to 24 hours prior to delivery. If delivery is imminent, and there is question as to the level of anticoagulation, activated partial thromboplastin time (aPTT) or activated Factor Xa levels should be checked. Protamine sulfate can be used to reverse anticoagulation if necessary. If the risk of recurrent VTE is particularly high in a woman receiving LMWH, the clinician can convert to intravenous UFH and treat until 4 to 6 hours prior to delivery, minimizing the time off anticoagulation.

The risks of regional anesthesia must be weighed carefully in a woman receiving anticoagulation because therapy increases the likelihood of bleeding, hematoma formation, and potential neurologic compromise. In a woman undergoing elective delivery with discontinuation of anticoagulation 12 to 24 hours prior, epidural anesthesia may be used. UFH or LMWH may be reinitiated 6 to 12 hours after delivery or following removal of the epidural catheter. Then, after therapeutic levels of UFH or LMWH have been achieved, warfarin may be initiated.

PROPHYLACTIC ANTICOAGULATION DURING PREGNANCY

Given the prothrombotic state associated with pregnancy itself, prophylactic anticoagulation should be considered in pregnant women with a prior history of VTE. Recurrence rates for VTE during pregnancy may be as high as 12% based on the results of retrospec-

tive studies.[236] Conversely, Brill-Edwards and colleagues prospectively studied 125 pregnant women with prior VTE in a study that excluded women with known thrombophilia.[237] Study subjects did not receive prophylactic anticoagulation during the antenatal period, but did receive anticoagulation therapy for 4 to 6 weeks postpartum. The authors documented a VTE recurrence rate of 2.4%. Women who had a temporary risk factor at the time of their initial VTE event and lacked laboratory evidence of an underlying hypercoagulable disorder at the time of study enrollment experienced no recurrences during pregnancy. Based on the results of this study, routine prophylactic anticoagulation for women with a single previous VTE event is not recommended. However, patients with a known hypercoagulable state, those with multiple previous VTE events, and those considered high risk for recurrent VTE should receive prophylactic anticoagulation during pregnancy and for 4 to 6 weeks postpartum. As previously discussed, prophylactic anticoagulation can be discontinued at parturition and reinitiated 6 to 12 hours postpartum.

The management of pregnant women with prosthetic heart valves is controversial and deserves special attention, though a full review of the topic is beyond the scope of this review. Coupled with the prothrombotic physiology of pregnancy, the presence of a prosthetic valve places such women in an ultra-high risk category. Prior to the introduction of LMWH, options for anticoagulation in this patient population included (a) warfarin throughout pregnancy, (b) warfarin, with UFH during weeks 6 to 12, the period of major organogenesis, and (c) UFH throughout pregnancy.[214] More recently, LMWH has been utilized in this setting, though its safety and efficacy have been questioned on the basis of several studies. Overall, a lack of rigorous, comparative studies hinders evidence-based management of women with prosthetic heart valves. Current recommendations allow for one of three therapeutic strategies, initiated after a thorough discussion of risks and benefits with the patient: (a) warfarin, with LMWH or UF substituted during weeks 6 to 12, (b) dose-adjusted UFH throughout pregnancy, or (c) dose-adjusted LMWH throughout pregnancy.[214]

THROMBOPHILIA AND PREGNANCY

Thrombophilias, inherited and acquired, increase the risk of VTE in pregnant women and adversely affect pregnancy outcomes. Included within this category of diseases are factor V Leiden, prothrombin gene polymorphisms, antiphospholipid antibody syndrome, antithrombin deficiency, along with protein S and C deficiency.

Factor V Leiden Gene Polymorphism

The factor V Leiden gene polymorphism is the most common inherited genetic disorder among pregnant women with a history of VTE, occurring in approximately 44% of cases.[238] It is characterized by a guanine-to-adenine point mutation at position 1691.[239] The mutation, which occurs in 3% of low-risk obstetric patients, impairs cleavage of procoagulant factor Va by activated protein C.[240] The risk of thrombosis is 5- to 10-fold higher in factor V Leiden heterozygotes than in normal individuals and 50- to 100-fold higher in homozygotes than in normal individuals.[241] The incidence of thrombosis in pregnancy among patients with the factor V Leiden gene polymorphism is approximately 17%.[242] A progressive decrease in activated protein C during pregnancy compounds the prothrombotic effect of the factor V Leiden mutation.[243] Besides VTE, women with the Factor V Leiden mutation can develop placental thrombosis and, in turn, complications associated with placental hypoxia such as preeclampsia and HELLP, placental abruption, intrauterine growth restriction, stillbirth, and—likely—first trimester miscarriage.[243]

Women with a documented factor V Leiden polymorphism should receive anticoagulation during pregnancy. An individual with the disorder who has never experienced thrombotic complications receives prophylactic doses of UFH or LMWH. On the other hand, a woman who has experienced a serious thrombotic complication receives therapeutic anticoagulation throughout pregnancy and for 6 to 12 weeks postpartum. Given the frequency of this mutation, a pregnant woman who presents with either a family or personal history of VTE should undergo testing for the factor V Leiden polymorphism to ensure proper risk stratification and therapeutic management.

Antiphospholipid Antibody Syndrome

The antiphospholipid antibody syndrome is the most common form of acquired thrombophilia.[244] Antiphospholipid antibodies include lupus anticoagulant antibodies and anticardiolipin antibodies. They can occur as a manifestation of various conditions, such as systemic lupus erythematosus (SLE) and other rheumatic diseases, infection, and drug reactions. Antiphospholipid antibodies exert their prothrombotic effect through several mechanisms. For example, they inhibit the activity of anticoagulants thrombomodulin, protein S, protein C, β2-glycoprotein I, and prostacyclin.[245–247] They interact with phospholipids on the surface of platelets, increasing platelet adhesiveness and production of von Willebrand mulitmers.[248,249] And in the pregnant patient, antiphospholipid antibodies decrease levels of annexin V, a potent vascular endothelial anticoagulant produced by placental trophoblasts.[250] Nonpregnant individuals with antiphospholipid antibody syndrome can develop arterial and venous thromboses. In the pregnant woman, antiphospholipid antibody syndrome can manifest as thrombotic events, spontaneous abortion, preeclampsia and HELLP syndrome, and intrauterine fetal growth restriction.[251–254]

Antiphospholipid antibodies can be detected in 5% of healthy pregnant women and 37% of pregnant women with SLE.[255] Meanwhile, thrombotic events occur in approximately 5% of pregnant women with antiphospholipid antibodies.[254] All pregnant women with SLE should undergo testing for antiphospholipid antibodies. Women who sustain recurrent spontaneous abortions or a thromboembolic event during pregnancy should also undergo evaluation for the disorder. A history of either vascular thrombosis or fetal loss coupled with the presence of either lupus anticoagulant antibodies or anticardiolipin antibodies establishes the diagnosis of antiphospholipid antibody syndrome.[256] False-negative laboratory results do occur, and do so more frequently in pregnant than in nonpregnant women. This may be due to the increased concentration of clotting factors observed in pregnancy.[257] Women with antiphospholipid antibody syndrome who have sustained prior thrombotic events receive therapeutic anticoagulation during pregnancy. Those with antiphospholipid antibodies but no manifestations of the clinical syndrome should receive prophylactic anticoagulation.

Hyperhomocysteinemia

Homocysteine is a thiol-containing amino acid that plays an important role in several metabolic pathways, including pathways that involve cobalamin (vitamin B_{12}) and folate. In a normal pregnancy, the concentration of homocysteine decreases, presumably as a result of increased glomerular filtration, increased plasma volume and hemodilution, and perhaps uptake by the developing fetus.[258] Individuals who are homozygous for the thermolabile variant of methylenetetrahydrofolate reductase (MTHFR) can develop hyperhomocysteinemia, a condition associated with a number of pregnancy-related complications, including thrombosis, preeclampsia, spontaneous abortion, placental abruption, intrauterine fetal growth restriction, fetal neural tube defects, and stillbirth.[259,260] Although folate supplementation decreases the risk of fetal neural tube defects, it does not appear to decrease the incidence of thrombotic complications.

Prothrombin Gene Mutation

A polymorphism in the prothrombin gene (20210A) occurs in approximately 1% of pregnant women.[241] Among those who harbor the polymorphism, 3% to 10% will develop thrombotic complications during pregnancy. Studies demonstrate an increased risk of preeclampsia and HELLP syndrome,[261] spontaneous abortion,[262] and intrauterine growth retardation[263] in women with the prothrombin gene mutation. Such women are treated like those with the factor V Leiden polymorphism.

CHAPTER 162

HEMATOLOGIC MANIFESTATIONS OF CHILDHOOD ILLNESS

A. Kim Ritchey, Frank G. Keller, and Sarah H. O'Brien

The hematologic response to systemic illness in children is similar to that in adults. A number of disorders occur more frequently in children, however, and some are unique to the pediatric population. In addition, interpretation of the hematologic response is predicated on knowledge of the normal developmental changes that occur within the hematopoietic system throughout childhood (Table 162–1).

This chapter focuses on the hematologic manifestations of common or unique systemic diseases that occur in the neonate, child, or adolescent. Illnesses that often require hematologic consultation are emphasized. Systemic diseases that produce hematologic abnormalities that are similar in adults and children are discussed in other chapters (see Chapters 156–160). For a comprehensive review of the subject, the reader is referred to a published textbook.[1]

INFECTIOUS DISEASE

Infection, especially viral infection, is the most common problem encountered by the pediatrician. Although most infections do not produce significant hematologic sequelae, all classes of microorganisms have been implicated in the pathogenesis of hematologic abnormalities that range from mild and clinically irrelevant to severe and life-threatening. This section describes the changes seen in red blood cells (RBCs), white blood cells (WBCs), platelets, and the coagulation system that are routinely encountered, are associated with a specific infection, or have a potentially serious clinical impact.

CHANGES IN RED BLOOD CELLS

The anemia of chronic inflammation or infection in children is similar to that seen in adults in terms of both clinical and hematologic findings and pathogenesis.[2] However, anemia with acute infections occurs more commonly in children than in adults.

Anemia of Acute Infections

A mild to moderate anemia of uncertain etiology may occur in the setting of both acute viral infections and more serious bacterial infections. In a study of children with mild viral or bacterial infections in the outpatient setting, anemia was documented in 5% of children 4 to 12 years of age, 17% of children 6 months to 4 years of age, and 33% of infants 6 to 11 months of age.[3] In 14 of 15 young children, the anemia resolved within 3 to 4 weeks. However, multiple mild infections may predispose the infant to the development of a more chronic, mild anemia or low-normal hemoglobin that may be due to iron deficiency, thus warranting a trial of iron supplementation. Among children hospitalized with moderately severe inflammatory processes, the incidence of mild anemia (hemoglobin 10.1 to 11.0 g/dL) is as high as 78%.[4] Specific acute bacterial infections associated with a high incidence of anemia (44%–74%) include bone and joint infections, typhoid fever, brucellosis, and invasive *Haemophilus influenzae* infections.

The anemia associated with *H influenzae* meningitis has been the most thoroughly studied of the anemias of acute infection. A majority of children with *H influenzae* meningitis have mild anemia on admission, with hemoglobin in the 9 to 11 g/dL range, and up to 90% become anemic during the course of the illness.[5] This is in contrast with meningitis secondary to *Streptococcus pneumoniae* or *Neisseria meningitidis*, in which anemia is uncommon. The pathophysiology of the anemia of *H influenzae* disease appears to be multifactorial. Shurin and associates[6] have shown that *H influenzae* capsular polysaccharide, polyribosyl ribitol phosphate, binds to erythrocytes, which, in the presence of antibody and complement, can result in intravascular and extravascular hemolysis. They further hypothesize that polyribosyl ribitol phosphate alone may induce more rapid clearance of RBCs, perhaps on the basis of decreased RBC deformability. In addition, hypoferremia may limit bone marrow response to hemolysis.

Acute Hemolytic Anemia

Acute hemolysis has been observed with infections from all classes of microorganisms but is relatively uncommon. The anemia may be mild to severe, and the condition is manifested in children in either of two ways: (a) clinical presentation with symptoms and signs of infection predominating in a child subsequently found to have anemia or (b) clinical presentation with the manifestations of acute hemolytic anemia.

The mechanism of hemolysis in patients presenting with an infectious disorder depends on the infecting organism, but in most cases hemolysis is extravascular.[7] Reported mechanisms include the following:

- Release of hemolysins (*Clostridium perfringens* sepsis)
- Invasion of the RBC (malaria)
- Alteration of RBC surface:
  - Direct adherence by the organism (*Bartonella*)
  - Alterations of antigenic phenotype by neuraminidase (influenza virus)
  - Cold agglutinins (*Mycoplasma*, *Listeria*, Epstein-Barr virus [EBV], *Leptospira, Rubella*[8])
  - Absorption of capsular polysaccharide (*H influenzae*)
- Mechanical mechanisms (microangiopathy associated with disseminated intravascular coagulation [DIC] or hemolytic uremic syndrome)
- Oxidative damage in persons with congenital enzyme deficiencies (eg, hepatitis with glucose-6-phosphate dehydrogenase [G6PD] deficiency, *Campylobacter jejuni* infection in the neonate).

Acute, infection-associated hemolytic anemia in one study lagged behind the clinical infection by 3 to 7 days.[9] Most children were shown to have adsorption of microbial antigens to the RBC surface, suggesting an "innocent bystander" mechanism of erythrocyte sensitization, ultimately leading to hemolysis. A minority of patients in this series had classic autoantibody-mediated hemolytic anemia.

Autoimmune hemolytic anemia in children usually is transient, is not associated with underlying systemic disease, and carries a low mortality rate. Children frequently have a history of concurrent or recently resolved infection, especially viral upper respiratory tract infection. Anticytomegalovirus (CMV) immunoglobulin G (IgG) has

Hb, hemoglobin; Hct, hematocrit; MCV, mean corpuscular volume; PT, prothrombin time; APTT, activated partial thromboplastin time.

*The normal range for the PT and APTT varies between laboratories. The time at which normal adult values are attained is 1 week for the PT and 2 to 9 months for the APTT. The platelet count is within the adult range from birth.

Data from Rudolph AM, Hoffman JIE (eds.): Pediatrics, 17th ed. East Norwalk, Conn, Appleton-Century-Crofts, 1982, p 1036, and from Nathan DG, Oski FA (eds.): Hematology of Infancy and Childhood, 3rd ed. Philadelphia, WB Saunders, 1987, p 1679.

been implicated as the cause of acute autoimmune hemolytic anemia in an infant with CMV disease. In the typical acute, transient cases, 59% to 68% of children have a history of recent infection, whereas 0% to 20% of those with the less common chronic course have such a history of infection.

Aplastic Crisis

Temporary arrest of RBC production has been observed in children with infections, but anemia is uncommon because of the long RBC life span. In two situations, however, severe anemia has been linked with infection and cessation of erythropoiesis: (a) B19 parvovirus infection in patients with an underlying hemolytic anemia and (b) transient erythroblastopenia of childhood.

The B19 parvovirus has been a known pathogen in animals for years but has only recently been linked with human disease.[10] It is the etiologic agent of fifth disease (erythema infectiosum), a mild illness with a characteristic "slapped cheek" facial erythema and a generalized reticular rash. In normal volunteers infected with B19 parvovirus, a mild, transient, and clinically irrelevant drop in the hemoglobin and reticulocyte count was observed.[11] In normal children, this infection usually is not associated with hematologic abnormalities, although reports of both hematologic and nonhematologic effects are increasing.[12] In children with sickle cell disease, spherocytosis, and other hemolytic anemias, B19 parvovirus infection can produce a severe anemia associated with peripheral reticulocytopenia and marrow erythroblastopenia—the "aplastic crisis." Recovery within 1 to 2 weeks is the rule, but transfusion may be necessary.

B19 parvovirus infection also has been associated with prolonged anemia and reticulocytopenia in children with acute lymphoblastic leukemia in remission, those with solid tumors receiving chemotherapy, those with immunodeficiency, those who have undergone renal transplantation, and those with autoimmune hemolytic anemia, and as the initial manifestation of human immunodeficiency virus infection. Human parvovirus also has been identified as a cause of nonimmune hydrops fetalis.[13]

Transient erythroblastopenia in childhood (TEC) is a syndrome characterized by temporary arrest of RBC production with moderate to severe anemia in previously normal infants and toddlers. Although no specific infectious agent has been proved to cause TEC, the frequency of a history of infection within 1 to 3 months, the seasonal clustering, and the similarity to childhood idiopathic thrombocytopenic purpura (ITP) all suggest a possible viral etiology. B19 parvovirus has not been definitively associated with TEC.[14]

CHANGES IN WHITE BLOOD CELLLS

Children, as a rule, have the expected leukocyte response to infection. Infants and young children normally have a lymphocyte predominance (see Table 162–1), however, and any leukocyte response to infection must be judged on the basis of age-related normal values.

The predictive value of the peripheral WBC and differential counts in suspected bacterial infections has been extensively evaluated in infants and children. Todd has shown that in hospitalized children, a neutrophil count greater than 10,000/μL or band count greater than 500/μL is associated with an 80% chance of having a bacterial infection.[15] In children undergoing evaluation for possible meningitis, Lembo and colleagues[16] found that a ratio of immature to total neutrophils greater than 0.12 was more strongly associated with, and more sensitive for, bacterial meningitis than was the total WBC count or the total band count. Febrile children between the ages of 3 and 48 months are at increased risk for bacteremia, especially with *S pneumoniae*. McCarthy and associates[17] demonstrated a threefold increase in risk of bacteremia in febrile (with temperatures greater than 40°C) children, younger than 2 years of age, who had a WBC count of 15,000/μL or greater. In this setting, the WBC count was a more sensitive indicator of the presence of pneumonia or bacteremia than was the absolute neutrophil or band count. The degree of leukocytosis (ie, >25,000/mm² vs >15,000/mm²) probably has no further discriminating ability.[18] Other studies have found both WBC count and absolute neutrophil count to be of value in differentiating bacterial from nonbacterial infection, whereas band count was not helpful.

There are recognized exceptions to the anticipated leukocyte response to infection that may serve as a clue to the diagnosis. In typhoid fever and brucellosis, leukopenia and neutropenia are prominent early in the illness. Shigellosis is associated with a variable leukocyte count, but the count often is normal, with a greater percentage of bands than neutrophils. Illnesses associated with lymphocytosis include pertussis (whooping cough), infectious lymphocytosis, infectious mononucleosis, and other viral infections. Neutropenia can be seen in bacterial sepsis from meningococci, pneumococci, staphylococci, and other bacteria and is associated with a poor prognosis. Black children (and adults) normally have lower WBC and neutro-

phil counts than those seen in whites; leukocyte and neutrophil response to serious infection may be decreased.[19]

NEUTROPENIA

The most common cause of neutropenia (neutrophil count less than 1500/μL) in children is viral infection. A number of specific viruses are associated with neutropenia, including hepatitis, roseola, rubella, and mumps viruses and adenovirus, coxsackievirus A21, EBV, human herpesvirus-6 (HHV-6), and influenza virus.[20] The most common clinical setting, however, is the incidental discovery of neutropenia in the child with a nonspecific viral syndrome. Usually the neutropenia in this situation continues for less than 30 days and is rarely associated with infectious complications. Neutropenia also has been associated with a number of bacterial, rickettsial, and fungal infections.[21]

EOSINOPHILIA

The most common cause of eosinophilia worldwide is parasitic infection. In the United States, visceral larva migrans (*Toxocara* infestation) is the most common cause of exaggerated eosinophilia (WBC count 30,000–100,000/μL, with 50%–90% mature eosinophils) in children.[22] Mild to moderate eosinophilia (600/μL or greater) is most often seen in allergic children but also is characteristic of *Chlamydia* pneumonitis in infants.

CHANGES IN PLATELETS/COAGULATION

Thrombocytosis

Thrombocytosis (platelet count >500,000/μL) is known as an acute-phase reaction to infection, but it has been infrequently identified in children in the past. There is a particularly high incidence of thrombocytosis in patients with bacterial infections, especially pneumonia with emphysema, and *H influenzae* meningitis. Inflammatory cytokines, such as interleukin (IL)-1, IL-6, and thrombopoietin, may play an etiologic role in the reactive thrombocytosis of infection.[23] Thrombocytosis may be more common in simple acute infections than was previously recognized. Heath and Pearson documented a 13% incidence of thrombocytosis in ambulatory patients; children with an increased platelet count were more likely to have a diagnosis of infection.[24] In a Japanese study of greater than 15,000 platelet counts in more than 7500 hospitalized patients, 6% of patients had thrombocytosis with an age-dependent incidence: 12.5% in neonates, 35.8% in 1-month-old babies, 12.9% in 6- to 12-month-old infants, then decreasing to 0.6% in 11- to 15-year-old children. Infection was the cause of the thrombocytosis in 67.5% of the cases.[25] There were no apparent sequelae to the thrombocytosis, and antiplatelet therapy is not indicated. Although the most common cause of thrombocytosis in children is infection, the list of considerations in the differential diagnosis of an elevated platelet count is extensive[26] and rarely includes underlying childhood malignancy.

Thrombocytopenia

Thrombocytopenia can be seen in patients suffering from infections with all types of organisms. Common viral agents include varicella virus, EBV, rubella virus, mumps virus, measles virus (wild or vaccine strains), HHV-6, hepatitis A virus, and CMV. The primary mechanism of the thrombocytopenia is immune destruction, although a direct viral effect on the platelet, megakaryocyte, or hematopoietic stem cell has been demonstrated. Because childhood ITP is thought to be secondary to infection in most instances, the definitions of "thrombocytopenia with infection" and "childhood ITP" tend to merge. Thrombocytopenia from infection usually is transient, although instances of chronic thrombocytopenia from specific viral infections (eg, varicella) have been documented.[27]

Thrombocytopenia also is associated with bacterial sepsis. The low platelet count may be an isolated finding or associated with DIC. Corrigan documented a 61% incidence of thrombocytopenia in 45 children with sepsis.[28] The degree of thrombocytopenia was mild to moderate (64% had platelet counts greater than 50,000/μL), but platelet counts ranged as low as 8000/μL. There was no evidence of DIC in 39% of those with low platelet counts. Thrombocytopenia in the setting of bacterial sepsis probably is also mediated by an immune mechanism with elevated platelet-associated IgG.

Petechial bleeding without thrombocytopenia can be seen in both bacterial and viral disease, especially that due to meningococci, streptococci, and echoviruses. The explanation for the petechial rash in these infections is either vasculitis or platelet dysfunction.

Disseminated Intravascular Coagulation/Purpura Fulminans

DIC is uncommon after childhood infections and, if present, usually is accompanied by shock, with at least a 50% mortality rate. The most common organisms producing DIC are bacterial, especially the gram-negative bacteria (meningococci, *H influenzae*, *Aerobacter*, and others) but also gram-positive organisms (*Staphylococcus aureus*, group B streptococci, *S pneumoniae*, particularly in the asplenic host, and *Bacillus anthracis*). DIC also is associated with disseminated viral (varicella, measles, rubella), rickettsial (Rocky Mountain spotted fever), fungal, mycoplasmal, and parasitic infections.

Purpura fulminans is a rare syndrome, seen in extremely ill children with DIC. Purpura fulminans is characterized by the rapid progression of ecchymotic skin lesions, especially of the extremities, that may progress to gangrene, ultimately resulting in amputation.[29] This syndrome has been described as a postinfectious purpura, with scarlet fever, upper respiratory tract infection, and varicella as the most common preceding illnesses and a latent period of 0 to 90 days following infection. A similar clinical picture can be seen in children with DIC and acute bacterial sepsis, especially meningococcemia.

There is increasing evidence that DIC with purpura fulminans is associated with deficiency of the naturally occurring anticoagulants. Children with postvaricella purpura fulminans have been shown to have acquired protein S deficiency, anti–protein S antibody, or the presence of a lupus anticoagulant.[30] In children with infectious purpura, protein C activation is impaired as reflected in low levels of protein C, protein S, and antithrombin. These findings are consistent with downregulation of the endothelial thrombomodulin–protein C receptor pathway.[31] The severity of protein C deficiency has been associated with increased morbidity and mortality.[32] There are minimal data on the frequency of inherited thrombophilia in children who develop purpura fulminans. In one report, the frequency of factor V Leiden was not different from that in healthy children; presence of factor V Leiden was not associated with an increased mortality rate, although complications were increased.[33] In another study of 16 children with purpura fulminans 6 of 16 (37%) patients studied had the Factor V Leiden mutation. All of the children in this study survived, but 10 (63%) required amputation.[34]

Treatment of purpura fulminans consists of antibiotics for suspected bacterial infection, volume replacement for shock, and heparin. Although there is controversy regarding the routine use of heparin in DIC, its use in purpura fulminans has been associated with an improved outcome when it is started early in the course of the disease and continued for 2 to 3 weeks.[35] Theoretically to improve the efficacy of heparin, it is reasonable to infuse fresh frozen plasma or antithrombin III (AT III) concentrates[36] if the AT III level is low. There is anecdotal evidence that infusion of AT III concentrates or protein C concentrates partially corrects or normalizes the hemostatic abnormalities.[37,38] However, the KyberSept trial, a double-blind placebo-controlled trial of the use of ATIII concentrates in 2300 adults with sepsis, found no difference in mortality at day 28 after

diagnosis.[39] In a phase II trial of protein C concentrate in the treatment of sepsis and purpura fulminans in children, there was dose-dependent activation of protein C and normalization of coagulation imbalances. Although there was no improvement in mortality, the study was not powered to detect these changes.[40]

Recombinant human activated protein C (drotrecogin alfa activated) has been shown to reduce the mortality rate in adults with severe sepsis.[41] In pediatric trials of activated protein C for treatment of sepsis, there was no noticeable improvement in mortality (children have a lower mortality rate than adults) and there were significant bleeding risks.[42,43] Although activated protein C has been used in patients with purpura fulminans, the data do not suggest a beneficial effect on mortality.[44,45] It should be noted, however, that these studies did not address a potential benefit on amputation risk or cosmetic outcome. Recombinant tissue plasminogen activator has been used in an attempt to restore organ perfusion by dissolution of diffuse microvascular thromboses[46]; however, in a retrospective multicenter study of 62 patients with meningococcal purpura fulminans treated with systemic tPA, there was a high incidence of intracerebral hemorrhage without proven efficacy in reduction of mortality or incidence of amputation.[47] Other treatments, such as regional sympathetic blockade, topical nitroglycerin, and local infusion of tissue plasminogen activator, have been used to improve regional blood flow to the affected part. The mortality rate for postinfectious purpura fulminans has declined from 90% in the past to 18%.[29] The outcome for patients with acute bacterial sepsis and purpura fulminans has also improved, but mortality as high as 50% continues to be reported.

Coagulation Inhibitors

Acquired inhibitors of coagulation in children with infection are usually transient and mild, but may be associated with severe bleeding.[48] They are often detected after a viral illness, during antibiotic therapy, or incidentally (frequently prior to tonsillectomy/adenoidectomy). Both specific inhibitors of coagulation factors (especially factors VIII and IX) and lupus anticoagulants have been demonstrated. Although previously thought to be uncommon, studies have found 50% to 90% of children with infection have at least one positive test for an antiphospholipid antibody.[49,50] Significant bleeding is usually seen only in those children with specific factor inhibitors, although hemorrhage also has been described with lupus anticoagulants.[51] In symptomatic patients, treatment with prednisone has been associated with remission of bleeding manifestations. Complete resolution without recurrence is the most common event.

PANCYTOPENIA

Pancytopenia in a child should alert the clinician to the possibility of disorders such as leukemia, aplastic anemia, or disseminated neuroblastoma. Infectious causes of pancytopenia are uncommon, and disseminated disease is most often present. Organisms implicated in patients with pancytopenia include *Mycobacterium tuberculosis*, atypical mycobacteria, *Histoplasma capsulatum*, *Leishmania, Salmonella typhi*, *Mucor* species, *Brucella* species, *Fusobacterium necrophorum*, and *Ehrlichia canis*.[21] Virus-associated or reactive hemophagocytic syndrome is an additional, although rare, cause of pancytopenia. Children with human immunodeficiency virus (HIV) infection and concomitant infection with *Mycobacterium avium-intracellulare* or parvovirus B19 have been reported to have pancytopenia.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION IN CHILDREN AND ADOLESCENTS

Infection with HIV is more common in adults but is now recognized as a leading cause of immunodeficiency in infants and children.[52] Acquisition of HIV in a majority of infected children (most of whom are younger than 2 years of age) is by vertical transmission from an infected mother to her infant. Of children younger than 13 years with acquired immunodeficiency syndrome (AIDS), 80% have a parent with AIDS or AIDS-related complex (ARC), 13% have a history of blood transfusion, and 5% have hemophilia or another coagulation disorder.[53] With improvement in screening blood and blood donors for HIV, it is expected that vertical transmission from mother to infant will remain the primary method of transmission. Other "adult" routes of infection (homosexuality, intravenous needle use) are possible, especially in the adolescent and the sexually abused child.

Clinical manifestations of AIDS in children include oral thrush, chronic interstitial pneumonitis, hepatosplenomegaly, lymphadenopathy, and failure to thrive. Other clinical characteristics distinguishing pediatric from adult HIV infection include a shorter incubation period, more pronounced hypergammaglobulinemia, more serious bacterial and CMV disease, and the rare occurrence of Kaposi sarcoma or other malignancies. Multiple, serious bacterial infections and lymphocytic interstitial pneumonitis/pulmonary lymphoid hyperplasia are accepted as indicative of AIDS among children and adults. However, as in adults, there is a broad spectrum of disease manifestations, with all organ systems potentially affected and progressive immune and clinical deterioration.

The diagnosis of HIV infection is now possible in early infancy with the advent of assays to detect HIV DNA and RNA. Other advances in monitoring immune status and new therapies for HIV disease and opportunistic infections have resulted in a decrease in the number of children in the United States with AIDS. The focus of medical management of children with HIV is early aggressive therapy to prevent immunologic deterioration and the clinical manifestations of AIDS.[54] Guidelines for current antiretroviral therapy in children are available on the AIDSinfo Web site (www.aidsinfo.nih.gov).

The hematologic manifestations of AIDS in children are similar to those in adults (see Chapter 158) and depend on the stage of the HIV infection and the presence of coexistent disease.[54,55] Anemia is by far the most common finding (seen in 70%–90% of the cases), although the incidence has decreased with effective antiviral therapy.[56] Severe anemia (hematocrit less than 25%) in one study correlated with development of an opportunistic infection and death within 7 months.[57] Severe autoimmune hemolytic anemia has been described infrequently, but in one case was the presenting manifestation of HIV in a 5-month-old infant.[58] Leukopenia and neutropenia are commonly seen in HIV-infected children (occurring in 47% and 41%, respectively), with severe neutropenia associated with opportunistic infections. Immune neutropenia and also circulating anticoagulants have been described. Lymphopenia is progressive but less prominent in children than in adults until late in the course. Thrombocytopenia is present in 13% to 30% of pediatric AIDS patients and can be associated with clinically significant and even fatal hemorrhage. The mechanism of the thrombocytopenia in most cases is immune destruction, with a high percentage of patients having antiplatelet antibodies or immune complexes,[59] although amegakaryocytic thrombocytopenia has been reported.[60] Variable therapeutic responses to both corticosteroids and intravenous IgG have been demonstrated; some children will have spontaneous remissions.[59,61] Thrombosis has also been described and is associated with severe disease.[62] The evaluation and treatment of hematologic abnormalities in HIV-infected children have been reviewed by Laufer and Scott.[54]

Isolated thrombocytopenia as a presenting manifestation of HIV infection has been reported in a number of children, usually infants and even in a neonate.[63] There have been no associated clinical stigmata of AIDS or ARC, and patients have been responsive to standard treatment (intravenous IgG or prednisone), often with sustained remissions. In a few patients with prolonged follow-up, no further manifestations of HIV infection were seen. Although it has been suggested that HIV testing may be indicated in all children with ITP, it seems most reasonable to check the HIV status of those with risk factors for AIDS and those outside the typical age group for ITP, especially infants.

COLLAGEN VASCULAR DISEASE/ACUTE VASCULITIS

Juvenile Rheumatoid Arthritis

Juvenile rheumatoid arthritis (JRA) includes a group of disorders with varied clinical presentation, course, and outcome. Systemic JRA, which occurs in 30% of patients, is a multisystem disease characterized by fever, rash, polyarticular (often destructive) arthritis, hepatosplenomegaly, and lymphadenopathy. Patients with JRA commonly demonstrate hematologic abnormalities that are proportional to disease activity. In the polyarticular presentation, more than four joints are involved but the systemic findings are absent. This group, which accounts for 25% of patients, also may exhibit hematologic abnormalities. Pauciarticular JRA is characterized by involvement of fewer than four joints and is rarely associated with hematologic abnormalities.

The incidence of anemia is 50% to 60% in patients with systemic or polyarticular JRA and 10% in those with pauciarticular arthritis. The anemia usually correlates with disease activity, worsening during acute flare-ups; however, there is no relationship to the duration of illness. RBCs may be normochromic/normocytic or microcytic/hypochromic. The reticulocyte count usually is low. Iron studies often show low serum iron, increased free erythrocyte protoporphyrin, low-normal or elevated total iron-binding capacity, and normal or low serum ferritin. Serum erythropoietin levels usually are mildly elevated (but not as high as in iron deficiency). The bone marrow does not show erythroid hyperplasia in response to the anemia and has diminished (but not absent) iron stores. The etiology of the anemia may be chronic disease, iron deficiency, or both.

Although it is difficult to differentiate anemia of chronic disease from iron deficiency anemia, studies in patients with systemic-onset chronic JRA suggest defective iron supply as the primary cause.[64] Transferrin receptor levels are inversely related to hemoglobin levels in this population. Determination of serum transferrin receptor levels may be a discriminating assay for diagnosis of iron deficiency in JRA.[65] Oral iron has been effective in raising the hemoglobin in iron-deficient anemic patients with JRA, and intravenous iron has been effective in raising the hemoglobin level in children unresponsive to oral iron.[64] Excessive production of IL-6, as well as of other inflammatory cytokines, has been documented in patients with JRA and may provide an explanation for the abnormalities in iron metabolism. IL-6 may enhance ferritin synthesis and increase hepatic uptake of serum iron. Increased ferritin results in reticuloendothelial iron blockage and diminished iron absorption.[64]

Less common causes of anemia in JRA include erythroid aplasia, suppression of erythropoiesis by circulating inhibitors, hemolysis, and a macrocytic anemia probably related to increased folate clearance and low plasma and RBC folate levels.

In systemic JRA, leukocytosis with mean WBC counts up to 30,000/μL and neutrophilia with a left shift occur in 90% of patients, especially those with active disease. Leukocytosis is less common in polyarticular arthritis and usually absent in pauciarticular disease. Leukocytosis is so prevalent in systemic JRA that the presence of neutropenia should alert the clinician to question the diagnosis and ensure that other possibilities such as systemic lupus erythematosus (SLE) and acute lymphocytic leukemia (ALL) are not overlooked. ALL in children may manifest with fever, joint pain, hepatosplenomegaly, and isolated cytopenias. Because about 4% of children with ALL are misdiagnosed as having JRA, it is important to perform bone marrow aspiration to rule out leukemia in any patient thought to have systemic JRA before initiation of corticosteroid therapy.

Nonetheless, neutropenia has been reported in several patients with JRA.[66] Other causes of neutropenia are bone marrow suppression due to therapy with gold or nonsteroidal antiinflammatory drugs[67] and, in adults, Felty's syndrome, the triad of rheumatoid arthritis, splenomegaly, and neutropenia. Studies of neutrophil function have demonstrated mild defects in chemotaxis and phagocytosis.[68] About 50% of patients with systemic JRA have less than 5% eosinophils on the peripheral smear.[69] Basophilia and plasmacytoid lymphocytes also have been reported. Studies of cellular immunity are conflicting, demonstrating normal or increased T and B lymphocyte number, increased immunoglobulin synthesis and secretion, and either impaired or normal delayed hypersensitivity and lymphoproliferative response to mitogens.[70,71] Monocyte dysfunction with decreased Fc receptor expression, decreased superoxide production, and decreased complement-mediated phagocytosis has been described.[72]

The platelet count is elevated in about half of the patients with systemic JRA. IL-6, a cytokine that stimulates thrombopoiesis, is elevated in patients with active systemic JRA, and increased levels of IL-6 are correlated with elevated platelet counts.[73] Persistent thrombocytosis may serve as an adverse prognostic marker for long-term outcome in JRA.

Thrombocytopenia may result from bone marrow suppression by gold therapy, the rare consumptive coagulopathy, or platelet trapping in Felty's syndrome. Thrombocytopenia is also seen in the potentially life-threatening complication of macrophage activation syndrome (see macrophage activation syndrome below). Because thrombocytopenia is uncommon in JRA, however, an unexplained low platelet count should lead the clinician to consider alternative diagnoses, such as SLE or ALL. On the other hand, isolated thrombocytopenia may be the only presenting sign in a child who later develops JRA or another collagen vascular disease. Therefore, JRA and SLE should be considered in the differential diagnosis of ITP in the child who is older than 9 years and female. Appropriate screening tests for autoantibodies (eg, antinuclear antibody assay, direct Coombs test) should be performed at diagnosis and periodically if new symptoms develop.

DIC may occur in children with systemic JRA after hepatic damage, as part of the macrophage activation syndrome, from aspirin or gold therapy, or during disease flare-ups treated with nonsteroidal antiinflammatory drugs when serum albumin is low.[74] These patients often are very ill and may require early and aggressive medical therapy as well as platelet and coagulation factor replacement to control the coagulopathy. The incidence of coagulation abnormalities in nonbleeding patients with systemic JRA is controversial. One study demonstrated prolonged prothrombin time (PT) and activated partial thromboplastin time (APTT) and elevated fibrinogen, factor VIII, and fibrinopeptide A levels in up to 50% of these patients[75]; other reports have not confirmed such findings. Another study found elevation of D-dimer levels in 96% of systemic-onset JRA patients; serial measurements of D-dimer levels appeared to parallel response to treatment.[76] In apparent distinction, decreased fibrinolytic activity and increased plasminogen activator inhibitor have been found in patients with active JRA, especially those with the systemic form. Antibodies against factor VIII and the lupus anticoagulant are occasionally seen in children with JRA.

Macrophage Activation Syndrome

Macrophage activation syndrome (MAS) is a life-threatening multisystem disorder most closely resembling hemophagocytic lymphohistiocytosis (HLH) that occurs primarily in patients with systemic onset juvenile rheumatoid arthritis (sJRA). This syndrome usually occurs early in the course of active sJRA and can even be a presenting feature,[77] although it has been reported to occur later and during a quiescent phase.[78] It is estimated that approximately 7% of patients with sJRA develop MAS and mortality is between 10% and 20%.[79] MAS has also been reported in other systemic inflammatory disorders including systemic lupus erythematosus and Kawasaki disease.[77]

The main clinical features of MAS include high unremitting fever, hepatosplenomegaly, lymphadenopathy, bleeding, rash, and central nervous system manifestations. Neurologic symptoms include lethargy, irritability, disorientation, headache, seizures, and coma. Children with MAS are acutely ill and almost 50% require ICU care.[80] The diagnosis may be delayed because the presentation mimics an acute exacerbation of sJRA or severe infection. Of interest, some patients have shown a paradoxical improvement in the underlying inflammatory disease at the onset of MAS. Precipitating factors that have been implicated include a flare-up of the underlying disease,

aspirin or other nonsteroidal antiinflammatory drug toxicity, viral infections, a second injection of gold salts, methotrexate, and sulfasalazine therapy.[80]

Typical laboratory features include pancytopenia, hypofibrinogenemia (<250 mg/dL), elevated liver enzymes (>40 IU/mL), hypertriglyceridemia (>160 mg/dL), and marked elevation of ferritin (>10,000 ng/mL). Other laboratory findings with less sensitivity and specificity include coagulopathy, hyponatremia, and hypoalbuminemia. The hallmark of this disorder is the presence of hemophagocytic histiocytes usually seen in the bone marrow, although they can be found in the liver and other organs. These characteristic macrophages are regarded as confirmatory evidence rather than a requirement for a diagnosis, because they have not been documented in as many as 20% of patients with the classical clinical and laboratory findings of MAS.[80,81]

There are no accepted diagnostic criteria for MAS in sJRA. Preliminary diagnostic guidelines have been proposed (Table 162–2), although they have not been validated in prospective studies.[81] These guidelines are similar to criteria for the diagnosis of HLH,[82] although there are a number of differences that should be emphasized. Although the diagnostic criteria for HLH include documentation of hemophagocytic histiocytes in bone marrow or other tissue, this is not the case for the MAS guidelines. In MAS, clinical features are less strong discriminators than laboratory features. Although the presence of fever was universal in patients with MAS, it had a low specificity rate because of the high incidence of fever in patients with sJRA without MAS. The pattern of fever may be of more importance because patients with MAS tend to have nonremitting fever as opposed to the high spiking fevers seen in sJRA. The other clinical criteria may occur late in the course of MAS, resulting in abnormal laboratory findings being more helpful in making a diagnosis early in the course of the illness. Because blood counts are usually elevated in patients with sJRA, the decrease in counts seen with MAS may actually result in a "normal" blood count, although in patients with HLH cytopenias are usually well below the normal levels.

The pathogenesis of MAS is similar to that proposed for HLH.[82,83] Indeed it has been proposed that MAS be considered one of the subtypes of acquired HLH.[79] The presentation of MAS is a result of an ineffective immune response to an endogenous or exogenous stimulus leading to an exaggerated inflammatory state produced by a release of high levels of cytokines. These proinflammatory cytokines include tumor necrosis factor alpha (TNF-α), interleukin (IL) 6, IL-8, IL-12, IL-18, macrophage inflammatory protein (MIP 1- a), and interferon gamma (INF-γ) released by stimulated lymphocytes and histiocytes. Defective NK cell function and cytotoxic T-cell activity has been documented in patients with MAS as well as HLH and may be the common pathway leading to the clinical presentation.[84] NK function in patients with active sJRA but without MAS has also been found to be abnormal.[85] This may explain why MAS is almost exclusively seen in the systemic form of JRA and not the other subtypes of the disease. Mutations in the perforin gene have been described in some patients with HLH. The cytotoxic function of NK cells is mediated by the release of perforin and other cytolytic granules into the target cell leading to cell death. Abnormalities of perforin expression have been found in patients with MAS although no mutations have been identified in the few patients studied.[84]

Treatment of MAS should be started promptly and not delayed for lack of hemophagocytosis if the clinical and laboratory features are consistent with the diagnosis. Initial treatment should be high-dose corticosteroid therapy followed by cyclosporine A if there is not a rapid response. Intravenous methylprednisolone with doses from 2 to 30 mg/kg/day have been the most common corticosteroid reported in the literature and is usually effective in controlling hyperinflammation.[80] The corticosteroid of choice used in the treatment of HLH is dexamethasone, but the use of this corticosteroid has not been reported in MAS. Cyclosporine A has been very effective in inducing remissions either when used as initial treatment or in cases of corticosteroid failure.[78,80,86] In addition to immunosuppression, there should be withdrawal of any suspected triggering medications and treatment of infection. Intravenous immunoglobulin therapy has usually been ineffective, although it has been reported to induce a full recovery in one case of a child who failed high-dose corticosteroids.[87] Etanercept has also been reported to induce clinical responses in patients with MAS.[88,89] Etanercept is a recombinant-soluble TNF-α receptor fusion protein that binds to TNF-α, blocking its effect. Although use of this agent to reduce the elevated levels of TNF-α found in this disorder is attractive, it should be used with caution, because there are case reports of MAS developing after the initiation of etanercept.[90]

Table 162–2 Preliminary Diagnostic Guidelines for Macrophage Activation Syndrome in Systemic Juvenile Rheumatoid Arthritis[81]*

Laboratory Criteria
1. Decreased platelet count (≤262 × 10^9/L)
2. Elevated levels of aspartate aminotransferase (>59 U/L)
3. Decreased white blood cell count (≤4.0 × 10^9/l)
4. Hypofibrinogenemia (≤250 mg/dL)
Clinical Criteria
1. Central nervous system dysfunction (irritability, disorientation, lethargy, headache, seizures, coma)
2. Hemorrhages (purpura, easy bruising, mucosal bleeding)
3. Hepatomegaly (≥3 cm below the costal margin)
Histopathological Criterion
Evidence of macrophage hemophagocytosis in the bone marrow aspirate
Diagnostic rule
The diagnosis of MAS requires the presence of any two or more laboratory criteria or of ≥2 clinical and/or laboratory criteria. A bone marrow aspirate for the demonstration of hemophagocytosis may be required only in doubtful cases.
*The suggested criteria are useful only in patients with active sJRA. The laboratory thresholds are examples only and are not specific for the diagnosis. (See text)

KAWASAKI SYNDROME

Kawasaki syndrome is an acute multisystem disorder characterized by abrupt onset of fever unresponsive to antibiotics; bilateral conjunctival injection; reddening of the lips, tongue, or oral mucosa; reddening, induration, or peeling of the skin on the hands or feet; polymorphous truncal rash; and cervical lymphadenopathy. This disorder occurs most commonly in children younger than 2 years and has many features of a severe vasculitis. The most serious complication is development of coronary artery aneurysms, which occurs in 20% of children and is responsible for the 3% mortality rate; death often is due to coronary artery thrombosis or rupture. The etiology of Kawasaki disease is unknown. The immunologic and clinical characteristics of this disorder are similar to those of diseases associated with superantigen production, of which toxic shock syndrome is a classic example.[91]

Children with Kawasaki syndrome may have a mild normochromic, normocytic anemia with reticulocytopenia. Rare patients with autoimmune hemolytic anemia have been reported. Leukocytosis is almost universal, with mean neutrophil counts of 21,000/μL. Ninety-five percent of patients have neutrophilia, with a left shift persisting up to 3 weeks. The finding of vacuoles and toxic granulation in neutrophils is a helpful adjunct in the diagnosis of Kawasaki disease. Activated neutrophils and monocytes may play a role in aneurysm development through the production of elastase. Granulocyte colony-stimulating factor levels have been correlated with coronary artery dilatation during the acute phase of Kawasaki syndrome.[92]

Studies of cellular immunity show normal total T-cell numbers but decreased suppressor T cells, causing relatively elevated T helper-cell levels during the first 4 weeks of disease.[93] The change of T-cell

subsets plus B lymphocyte stimulation may contribute to the exaggerated production of all major immunoglobulin classes during the first 8 weeks of the disease.[94] An unusual infiltration of IgA-producing plasma cells within vascular tissue in Kawasaki syndrome, with an oligoclonal IgA response, suggests that the immune stimulation is antigen driven.[95] Circulating immune complexes and high C3 (but not C4) levels are found during weeks 1 and 3. During the acute phase, increased levels of the cytokines IL-1, IL-6, IL-8, interferon-γ, and tumor necrosis factor are noted in the circulation, and IL-1, IL-2, interferon-γ, and tumor necrosis factor in blood vessels and skin biopsies.[91] Declining serum IL-6 levels appear to correlate with clinical response after treatment with intravenous immunoglobulin (IVIG).[96]

Impressive thrombocytosis occurs in 85% of patients by the second week, peaking during the third. Platelet counts of up to 2 million are not uncommon, and the mean platelet count is 700,000/μL. Thrombocytosis may serve as a marker of possible atypical Kawasaki disease in infants less than 1 year of age. In a study of more than 25,000 infants with unexplained fever, 8.8% with a platelet count greater than 800,000/uL were found to have Kawasaki disease as opposed to 0.4% of those with a platelet count less than 800,000/uL.[97] Thrombocytosis is preceded by elevated thrombopoietin levels.[98] However, 2% of patients may have thrombocytopenia caused by a consumptive coagulopathy. Platelets demonstrate hyperaggregation on exposure to adenosine diphosphate, epinephrine, and collagen in vitro. These abnormalities may persist for as long as 9 months after diagnosis.[99] During the first month, levels of factor VIII, fibrinogen, thromboxane B_2, and thromboglobulin are increased. AT III and fibrinolysis activity are decreased. The PT, APTT, and thrombin time usually are normal.[100]

Prevention and treatment of existing coronary aneurysms constitute the primary therapeutic goal. Aspirin suppresses platelet aggregation but does not affect aneurysm formation. Combining aspirin with high-dose IVIG infusions reduces aneurysm formation, decreases fever, and normalizes laboratory signs of inflammation.[101] The use of corticosteroids is controversial, with conflicting data regarding increased aneurysm formation after steroid usage.[102–104] However, in a randomized double-blind, placebo-controlled trial a single pulsed dose of intravenous methylprednisolone, in addition to conventional therapy, did not improve coronary artery outcomes.[105] In subgroup analysis of children with persistent fever, coronary outcomes were better in the corticosteroid group. If children at highest risk of primary treatment failure could be identified initially, corticosteroid use may be of benefit in this group. Guidelines for the diagnosis, treatment, and long-term management of Kawasaki syndrome have been published.[106]

HENOCH–SCHÖNLEIN PURPURA

Henoch–Schönlein purpura (HSP) (anaphylactoid purpura) is a systemic vasculitis characterized by unique purpuric skin lesions, transient arthralgias or arthritis (especially affecting the knees and ankles), colicky abdominal pain, and nephritis. Recognition of HSP is important, not so much for its hematologic abnormalities (which are rare) as for the unusual nonthrombocytopenic purpuric lesions, which are frequently confused with the hemorrhagic rash of ITP.

This vasculitis occurs most commonly in children 3 to 7 years old, often 1 to 3 weeks after an upper respiratory tract illness. The presenting sign in 50% of children is a characteristic rash, which may begin as urticaria. As these eruptions fade, they are replaced by brownish-red maculopapular lesions and petechiae. The petechiae coalesce, forming areas of raised or "palpable" purpura on the buttocks, legs, and extensor surfaces of the arms, with a symmetrical distribution. The rash may fade but can recur for months, especially with increased activity. Children younger than 3 years of age often have painful soft tissue swellings of the scalp and face (especially periorbital areas) and on the dorsa of the hands and feet. Infantile acute hemorrhagic edema is an acute vasculitis affecting infants younger than 2 years, which may be a benign form of HSP.

Sixty-seven percent of patients experience colicky abdominal pain, often associated with vomiting, hematemesis, or melena from submucosal hemorrhage and edema of the small bowel wall. With severe edema, the bowel wall may become a leading point for intussusception.[107]

Renal involvement occurs in 50% of patients, especially boys and older children, and may present after initial systemic symptoms. Hematuria, either microscopic or gross, may occur with proteinuria during the first 3 weeks of the illness, but rarely after 6 months. With progressive involvement, hypertension, impaired renal function, and renal failure can occur in up to 15% of children, with an associated mortality rate of 3%.

In occasional patients, an acute scrotum that mimics testicular torsion may develop; however, surgical exploration may not be necessary if appropriate clinical and radiographic features are present. Other rare manifestations of HSP include neurologic, cardiac, and pulmonary events.

Anemia occasionally develops as a result of gastrointestinal tract blood loss or decreased RBC production caused by renal failure. The leukocyte count is normal. Despite the impressive purpura, the platelet count is normal or increased with normal platelet function. Coagulation factor levels usually are normal, although transient decreases in factor XIII activity and vitamin K deficiency from severe vasculitis-induced intestinal malabsorption have been reported. Signs of increased fibrinolysis, as evidenced by elevation of D-dimer and other markers, have been described.[108] Bleeding in the gastrointestinal tract, the lungs, or, rarely, the central nervous system is due to a necrotizing vasculitis and not a hemostatic defect.[107] Hypercoagulability does not play a role with normal frequency of MTHFR, prothrombin, and Factor V Leiden gene mutations.[109]

Henoch–Schönlein purpura is considered an IgA-mediated inflammation of small vessels. Biopsy of skin or other involved tissue reveals a leukocytoclastic vasculitis. Immune complexes of IgA with complement, IgG, or IgM have been found circulating in the serum[110] and deposited in blood vessel walls of kidney, and in intestinal and skin lesions.[111] The mechanism of production, accumulation, and deposition of IgA immune complexes in the blood vessel is unclear. It has been suggested that HSP may be a systemic form of IgA nephropathy.[112] Both disorders have identical features on renal biopsy and are characterized by mesangial proliferation, occasional focal sclerosis, and crescent formation.[113]

Treatment is mainly supportive, although corticosteroids have been found to provide symptomatic relief with severe joint, scrotal, or abdominal pain.[114,115] They do not alter skin involvement or prevent renal involvement. Recent studies have suggested that corticosteroids plus azathioprine, cyclosporin A, or cyclophosphamide may have a role in the management of severe renal involvement.[116–120] The prognosis is good for full recovery, except in the children with renal failure.

CARDIOPULMONARY DISEASE

Congenital Heart Disease

Congenital heart disease occurs in about 1% of live births. Structural heart malformation usually follows predictable patterns such that six defects account for 70% of all cardiac disorders: ventricular septal defect, atrial septal defect, tetralogy of Fallot, patent ductus arteriosus, pulmonary stenosis, and aortic stenosis. Children with cardiac abnormalities may be acyanotic or cyanotic, depending on the underlying lesion. Hematologic abnormalities occur most often in children with cyanotic congenital heart disease (CCHD).

Polycythemia is the bone marrow response to chronic hypoxemia in patients with CCHD. The decreased arterial oxygen content stimulates erythropoietin production, which in turn increases erythropoiesis. The resultant increased RBC mass increases the oxygen-carrying capacity of the blood, resulting in improved tissue oxygenation. With adequate compensation, erythropoietin levels fall to normal, while higher RBC production is maintained. A second compensatory

mechanism is an increase in 2,3-diphosphoglycerate (2,3-DPG) levels in the RBC when the arterial oxygen tension is less than 70 mm Hg. The higher 2,3-DPG level causes a right shift of the oxyhemoglobin curve, resulting in greater oxygen release to the tissues.

Polycythemia in the cyanotic child is beneficial up to a point. Because the relationship between the hematocrit and blood viscosity is hyperbolic, minor increases in the hematocrit above 70% cause marked increases in blood viscosity. This higher viscosity results in impaired perfusion within the microvasculature, with ultimately less tissue oxygen delivery. The impairment is magnified in severe polycythemia (hematocrit level greater than 75%) such that headache, irritability, dyspnea, and even formation of pulmonary, renal, or central nervous system thrombi may result.[121] To prevent these complications, the hematocrit level should be maintained around 60% through the use of exchange transfusions. Small aliquots of the patient's blood are slowly removed and replaced by equal volumes of plasma or 5% albumin. Care should be taken to remove blood slowly, because vascular collapse, cyanosis, stroke, and seizures have been reported with too rapid an exchange. Apheresis (erythrocytapheresis) also has been shown to be an effective means of decreasing viscosity in polycythemic patients.

Infants with CCHD are at risk of developing iron deficiency anemia. The deficiency may result from the combination of poor iron stores at birth (especially in premature infants), increased iron needed for enhanced erythropoiesis, poor iron intake due to poor feeding, and ongoing iron losses as a consequence of phlebotomy or exchange transfusion. These children may exhibit symptoms of iron deficiency (irritability, anorexia, poor weight gain) or worsening cyanosis. The hemoglobin may be normal for age but inappropriately low for the degree of hypoxemia. Low RBC indices and hypochromic, microcytic RBCs are the best indices of iron deficiency in this setting.[122] Polycythemic children with iron deficiency anemia are at increased risk for cerebral vein thrombosis because of the poor deformability of the iron-deficient RBC, which further increases blood viscosity.[123] To prevent this complication and to allow for maximal tissue oxygenation, all infants should be fed iron-rich infant formula and receive iron replacement therapy as needed to normalize RBC indices.

Hemolytic anemia, characterized by mechanical destruction of red blood cells and manifested by the presence of schistocytes in the peripheral blood smear, is occasionally seen after the placement of prosthetic heart valves.

Routine screening of patients with congenital heart disease has demonstrated coagulation abnormalities in 20% to 59% of children with acyanotic defects and in 40% to 50% of those with cyanotic heart disease (Table 162–3).[124] Only 11% of children with CCHD have any clinical evidence of bleeding preoperatively. However, children with underlying hemostatic defects have a greater frequency and severity of postoperative bleeding.[124,125] Presurgical screening tests should include at least a platelet count, platelet function assay (eg, closure time), PT, and APTT. Further investigations may be indicated if there is a history of bleeding or abnormal results on screening tests. Children with polycythemia have contracted plasma volumes; therefore, when blood samples are collected, extra care should be taken to ensure the proper 1 : 9 ratio of 3.8% sodium citrate to blood, to prevent artificial abnormalities in coagulation test results.

The etiology of the coagulation abnormalities in CCHD is unclear. Earlier reports suggesting a role for consumptive coagulopathy have not been confirmed. Protein C levels in 8 of 29 term infants with CCHD were significantly lower than in controls with no evidence of familial deficiency. Of these infants, two had thrombotic complications and four had consumptive coagulopathy.[126] Platelets have shortened survival times (even with normal counts), and normal to increased numbers of megakaryocytes in the bone marrow are reported.[127] This increased platelet destruction does not appear to be due to DIC. Both the platelet and coagulation abnormalities are directly proportional to the degree of hypoxemia and polycythemia. For example, children with oxygen saturation greater than 60% have a mean platelet count of 315,000/μL, whereas those with saturation less than 60% have a mean count of 185,000/μL.[127] The mild platelet and coagulation abnormalities usually are decreased or corrected after surgical repair of the heart defect.[124,128] With bleeding, or if surgery is not possible, the coagulopathy may be treated by correction of polycythemia to a hematocrit level of 60% by using slow plasma-exchange transfusion.[129]

Table 162–3 Coagulation Abnormalities in Congenital Heart Disease

Incidence (%)		
Abnormality	***Acyanotic CHD***	***Cyanotic CHD***
Prolonged bleeding time	11	28
Prolonged PT		20
Prolonged APTT		19
Thrombocytopenia	12–40	0–36
Abnormal platelet aggregation	14	38–70
Increased fibrinolysis	12	0–10
Abnormal clot retraction	10	
Low fibrinogen	16	12
Increased fibrin split products		Occasionally
Decreased factors II, V, VII, VIII, IX, X, XI, XII		Occasionally
Decreased protein C		25%*
Decreased large multimers of von Willebrand factor	100†	

CHD, congenital heart disease.

CYSTIC FIBROSIS

Cystic fibrosis (CF) is a multisystem disorder of exocrine gland dysfunction characterized by chronic pulmonary disease, pancreatic exocrine insufficiency, hepatic dysfunction, abnormal reproductive organ function, and intestinal obstruction associated with abnormally high sweat electrolyte levels. It is an autosomal recessive disease with an incidence of 1/2000 live births.

Severe hemolytic anemia due to vitamin E deficiency may be the presenting manifestation of CF. Dolan initially linked deficiency of vitamin E with severe hemolytic anemia in infants who presented with pallor, edema, hypoproteinemia, and thrombocytosis.[130] This complication can be seen as early as 6 weeks of age.

Many children with CF are chronically hypoxic, yet they do not have the expected augmented erythroid response. In a study by Vichinsky and colleagues,[131] none of 42 children with CF had polycythemia, and 30% (especially the boys and the older children) had a normochromic, normocytic or hypochromic, microcytic anemia with reticulocytopenia. In contrast with children with CCHD, there was no appropriate increase in RBC 2,3-DPG levels, no right shift of the oxyhemoglobin curve, and either a low or a normal erythropoietin level. In vitro assays showed normal erythroid progenitor cell numbers and no serum inhibitor of erythropoiesis. Up to 66% of the children studied had abnormalities consistent with iron deficiency, and all responded to oral or parenteral iron therapy.

It appears that the etiology of anemia in CF is multifactorial. A blunted erythropoietic response to hypoxia plus iron deficiency secondary to iron malabsorption or poor dietary iron intake may each be partially responsible for the development of anemia. If iron deficiency persists despite adequate oral supplementation, the possibility of ongoing blood loss, or of iron malabsorption that may necessitate

parenteral iron replacement, should be considered. Soluble transferrin receptor levels may be helpful in distinguishing iron deficiency from anemia of chronic inflammation in CF.[132]

Findings of studies of neutrophil function in children with CF are conflicting. Some reports indicate impaired chemotaxis, chemiluminescence, granule release, and superoxide production,[133–135] whereas others have demonstrated factors in patient sputum that actually enhance neutrophil and monocyte responses to stimulants.[136] Although these sputum factors may improve neutrophil killing ability, they also may worsen neutrophil-mediated lung damage through increased release of neutrophil elastase.[137] Evaluation of immune function has revealed impaired lymphoproliferative responses to *Pseudomonas* and other gram-negative bacterial antigens, defective opsonization, increased levels of circulating immune complexes, and decreased numbers of T helper cells in 30% of patients.[138] The contribution of these findings to frequent pulmonary infection is still under investigation.

Children with CF usually do not experience clinically significant bleeding owing to impaired hemostasis, despite the risk of liver disease and vitamin K deficiency from malabsorption. An exception may be infants under 1 year of age, in whom rare case reports of vitamin K-deficient hemorrhage have been reported in association with cystic fibrosis.[139–141] Routine coagulation tests usually yield normal results, with an occasional prolonged APTT reported. A study by Corrigan and colleagues[142] revealed that 60% of 24 patients had a more subtle deficiency of prothrombin activity, thought to be due to vitamin K deficiency. Other investigators, using direct measurement of vitamin K and PIVKA-II (protein induced by vitamin K absence-II), have reported conflicting percentages of patients to be vitamin K deficient.[143,144] Routine vitamin K supplementation is not recommended, although it may be indicated in persons with severe liver disease or confirmed coagulation abnormalities.

Children with CF may have a particularly high predisposition to recurrent venous thrombosis. In a study of 19 patients with recurrent venous thrombosis, 6 had CF, whereas none of 101 thrombosis patients without recurrence had CF. A striking association with respiratory tract colonization with *Burkholderia cepacia* was noted, as was the frequent presence of a central venous catheter. Several of the recurrences occurred while on therapeutic anticoagulation.[145]

GASTROINTESTINAL DISEASE

Milk Protein-Induced Enteropathy and Heiner Syndrome

The association of iron deficiency with dietary intake of cow's milk in young infants is established. A major contributing factor is the relatively poor bioavailability of iron in cow's milk as compared with breast milk. In addition, the rapid growth of infants and corresponding rapid increase in red cell mass necessitates an increased requirement for dietary iron. The role of cow's milk in inducing occult gastrointestinal blood loss in infants was carefully documented more than three decades ago in a sentinel paper that also demonstrated a correlation between the amount of milk ingested and the amount of fecal blood lost.[146] Gastrointestinal blood loss in response to cow's milk ingestion appears to be most prevalent in infants less than 6 months of age, and occurs with diminishing frequency in older infants.[147] The majority of affected infants will outgrow their milk protein sensitivity by 3 years of age. The gastrointestinal blood loss may be ameliorated by heat denaturing of the milk proteins. Occasionally toddlers and older children have been documented to have milk-induced gastrointestinal bleeding with associated iron deficiency anemia.[148,149] Substantially limiting cow's milk consumption and prescribing iron supplementation is sufficient to correct the iron deficiency and associated hypoproteinemia in most children.

A variety of gastrointestinal syndromes associated with cow's milk sensitivity, with varying manifestations and severity, have been described. Associated findings may include vomiting, diarrhea, poor growth, and hypoproteinemia; however, some patients may have occult blood loss and anemia without associated complaints. At the severe end of the spectrum a cow's milk protein-induced enterocolitis may occur.[150] Such patients may present with acute, severe bloody diarrhea, vomiting, abdominal distention, methemoglobinemia and shock, even in the absence of anemia.[150] Even minute amounts of cow's milk protein in human breast milk may be sufficient to precipitate a severe event.[151] In patients with chronic occult gastrointestinal blood loss esophagogastroduodenoscopy may reveal gastritis or gastroduodenitis, and colonoscopy may demonstrate modest histological abnormalities in the proximal colon.[149,152] The immunopathobiology of cow's milk protein allergy syndromes has not been fully elucidated. Most of these syndromes affecting the intestinal tract only are non-IgE mediated.[153,154] Wilson et al reported the frequent presence of precipitating antibodies to milk proteins in the study population as a whole.[155] However, the presence of such antibodies did not appear to predict milk-induced gastrointestinal bleeding. The roles that genetic predisposition, intestinal and immunologic immaturity in young infants, exposure to cow's milk protein in breast milk, gastrointestinal infections, or other factors may play in the development of milk protein enteropathy are not fully understood.

In 1962 Heiner et al described a syndrome in infants and young children that included chronic cough, recurrent lung infiltrates, poor growth, gastrointestinal symptoms and blood loss, iron deficiency anemia, and pulmonary hemosiderosis associated with multiple serum precipitins to cow's milk proteins.[156] Others have confirmed and further detailed this rare syndrome.[157,158] Additional manifestations may include intermittent wheezing, hilar lymphadenopathy, eosinophilia, elevated levels of serum IgE, IgM, or IgA, chronic rhinitis, adenoidal hypertrophy, hypercapnia, and cor pulmonale. A feature of this syndrome is rapid improvement of the pulmonary manifestations after eliminating cow's milk from the diet.

CELIAC DISEASE

Celiac disease, or gluten-sensitive enteropathy, is an inflammatory and malabsorptive process resulting from an aberrant intestinal T-cell immune response to ingested dietary gluten, leading to injury of the mucosa of the small intestine.[159] Classical celiac disease has been characterized as frequently affecting infants and young children, leading to steatorrhea, failure to thrive, weight loss, and nutritional deficiency. With the advent of improved screening techniques, the prevalence is recognized to be greater than previous estimates. Celiac disease broadly affects both children and adults, many of whom may have minimal classical symptoms of the disorder. Treatment is usually institution of a gluten-free diet, with resolution of the process in the majority of cases.

Iron deficiency is frequently present in celiac disease in children and adults and may be the sole recognized manifestation of the disorder.[160] Dietary iron absorption primarily occurs within the proximal small intestine, the same region most affected by celiac disease. As a result iron deficiency in celiac disease appears to be primarily due to impaired absorption of dietary iron, although a component of chronic gastrointestinal blood loss may also apply in a minority of patients.[160,161] Iron deficiency in celiac disease may be refractory to iron supplementation, and a significant percentage of children and adults with iron deficiency anemia that does not respond to therapeutic oral iron replacement have celiac disease.

Folic acid and to a lesser frequency vitamin B_{12} deficiency may also result from the malabsorptive process in celiac disease. Manifestations may include macrocytic anemia, leukocytopenia, and pancytopenia. Neurologic findings may be present with vitamin B_{12} deficiency. Other vitamin and micronutrient deficiencies, including copper and vitamin K deficiency, have been observed in celiac disease. Splenic hypofunction may occur with some frequency in adults with celiac disease, but appears to be less common in children. A number of case reports have suggested an association of pulmonary hemosiderosis with celiac disease.[162,163] The pathophysiology of this association in

not known, but the pulmonary process may improve with initiation of a gluten-free diet.

A high index of suspicion is important for diagnosing celiac disease in children, particularly those who are minimally symptomatic. In addition to correcting the nutritional deficiencies and growth failure in children with celiac disease, recognition of the disease and institution of a gluten-free diet may minimize the risk of some of the associated conditions of celiac disease, including the development of non-Hodgkin lymphoma involving the intestinal tract.

INFLAMMATORY BOWEL DISEASE

Anemia is a very common extraintestinal manifestation of inflammatory bowel disease (IBD), particularly in children with Crohn disease, in whom the historical prevalence of anemia approaches 70% to 80%.[164,165] A more recent series suggest that the prevalence of anemia may be declining in Crohn disease, perhaps due to more effective therapy.[166] The etiology of anemia in IBD appears to be multifactorial, but the most common contributing factors are iron deficiency related to chronic gastrointestinal blood loss or iron malabsorption due to intestinal mucosal injury, and decreased absorption and sequestration of iron stores as is seen in the anemia of chronic inflammation. These broad mechanisms for anemia may coexist, and it is sometimes difficult to determine the predominant mechanism. Measurement of serum transferrin receptor can be helpful in this setting to distinguish the contribution of iron deficiency anemia versus anemia of chronic inflammation.[167] Other contributing factors to anemia in IBD may also be present in individual patients, including immune-mediated hemolytic anemia, hemophagocytosis, malnutrition, folate and vitamin B_{12} deficiency, and the suppressive effects of medications on hematopoiesis.[168]

Specific treatment of anemia in IBD may be difficult. Oral iron supplementation is not always effective. Comparative studies of oral versus intravenous iron supplementation suggest the intravenous route may result in better short-term improvement in anemia; however long-term outcome data are lacking.[169,170] Some patients may respond to supplemental erythropoietin administration as well.[171] Patients with IBD may have impaired enterocyte-mediated intestinal absorption of iron, the degree of which appears to correlate with disease activity.[172] The role that induction of hepcidin expression by mediators of inflammation, particularly IL-6, plays in the anemia of IBD is an intriguing area of ongoing investigation.[172]

Other hematologic manifestations of IBD include leukocytosis and thrombocytosis, hyposplenism, an increased propensity toward thrombosis, and therapy-related leukopenia and thrombocytopenia. There may be an increased incidence of immune-mediated thrombocytopenia associated with IBD.[173] The recently described potential association between infliximab, an anti–tumor necrosis factor antibody, and hepatosplenic T-cell lymphoma, bears close observation, and suggests that biologic agents such as infliximab should be used only after careful consideration of the potential benefits and risks of the agent in the individual patient.[174]

ANOREXIA NERVOSA

Anorexia nervosa is a psychiatric disorder occurring in about 1/800 adolescent girls; it is characterized by an inability to maintain a minimal normal body weight, intense fear of being fat, body image distortion, and amenorrhea. The profound weight loss is accompanied by hypothermia, hypotension, edema, lanugo, and metabolic changes and is associated with a mortality rate of 5% to 18%. A mild, normochromic, normocytic anemia with reticulocytopenia occurs in 30% of patients.[175] Acanthocytes or spur cells have been reported and may be due to low serum β-lipoprotein levels. The causes of the anemia probably are decreased RBC production and a relative increase in plasma volume. A few patients have had slightly decreased RBC survival. Serum B_{12} and folate levels usually are normal. Despite low serum iron and decreased marrow iron stores in 80% of patients, iron deficiency anemia is uncommon except during recovery, when iron supplementation is necessary. The severe hypophosphatemia seen during refeeding of severely malnourished patients has been associated with hemolytic anemia.

Fifty percent of patients have leukopenia, with an absolute decrease in numbers of neutrophils, lymphocytes, and monocytes.[176,177] The neutropenia may be quite severe. An increased incidence of infection is not usual, although with increasing use of central venous catheters, more serious bacterial infections are being reported.[177] Bone marrow reserves are normal despite marrow hypoplasia and a normal to slightly decreased size of the marginal pool. Impaired neutrophil chemotaxis, intracellular killing of staphylococci, and decreased complement levels have been demonstrated in patients with anorexia. These findings are associated with occasional skin abscess formation.

Patients with anorexia nervosa have no apparent bleeding diathesis. The platelet count is normal to slightly decreased,[175,178] and in vitro platelet aggregation response to epinephrine, adenosine diphosphate, and collagen is exaggerated. Coagulation defects are uncommon, except for that related to vitamin K deficiency reported in bulimia.

The hematologic changes in anorexia nervosa are directly correlated with total body fat mass depletion.[179] A bone marrow pattern on magnetic resonance imaging suggestive of gelatinous transformation of bone marrow (serous atrophy) is seen in patients with the lowest hematologic parameters. Direct examination of the bone marrow reveals hypoplasia with loss of fat stores and replacement by a gelatinous acid mucopolysaccharide ground substance. Focal or extensive necrosis may be present.[180] Bone marrow histiocytes are relatively increased in number and have prominent blue-green granules. With nutritional supplementation, bone marrow hypoplasia reverses, the gelatinous material disappears, and the hematologic abnormalities, including neutrophil defects and low complement levels, resolve by 8 weeks.

THROMBOEMBOLIC COMPLICATIONS IN CHILDHOOD ILLNESS

Improvements in medical and surgical care, in particular advances in critical and supportive care, have led to increased survival among children with malignancy and chronic illnesses. However, the extended survival of these children has led to new comorbidities in the field of pediatrics, including thromboembolic complications. The increased risk of thromboembolism in children with chronic illnesses is multifactorial and may include the illness itself, medical and surgical interventions, or the central venous line used to administer therapy.

Unlike adults, in whom idiopathic thromboembolism occurs regularly, the majority of thromboembolic events in children are secondary to serious underlying conditions such as cancer, trauma, or surgery.[181] The Canadian Childhood Thrombophilia Registry contains more than 400 children.[182] In this population, over 50% had an underlying systemic illness, with malignancy (25%) and cardiac illness (20%) as the most common entities. This review will focus on four childhood illnesses commonly associated with thromboembolism: malignancy, congenital heart disease, nephrotic syndrome, and systemic lupus erythematosus. In addition to the diseases discussed in this review, other chronic illnesses of childhood have been associated with thromboembolism, including sickle cell anemia (see Chapter 43), juvenile rheumatoid arthritis, inflammatory bowel disease, and cystic fibrosis.

THROMBOEMBOLISM IN PEDIATRIC CANCER

Although thrombosis is a well-known complication of pediatric malignancy, the overall incidence is infrequent compared to adults with cancer. Surprisingly, there have been no large cohort studies to

assess the prevalence of thrombosis among all childhood cancer types. Small studies report an incidence of 7% to 14% based on clinical symptoms, which increases to 44% to 50% when children undergo routine radiographic screening.[183–189] Of note, all of these studies were focused on catheter-related thrombosis. As a result, the majority of thrombosis described in the literature is located in the upper venous system. Right atrial thrombi are also frequently seen, with a reported incidence of 9% to 14% in children with indwelling catheters.[185,188] Typically asymptomatic, these thrombi are often found incidentally on routine surveillance echocardiograms for children receiving anthracycline chemotherapy. Although the presence of a central venous line is the most important risk factor in the development of pediatric thrombosis, children with cancer are also at risk for thrombosis at sites other than their catheter.[188,191]

There are several mechanisms by which malignancy alone increases the risk of thromboembolism.[192] These include direct activation of the coagulation system, inhibition of fibrinolysis through secretion of plasminogen activator inhibitor-1, and the release of cytokines, which themselves induce procoagulant and antifibrinolytic activity. Malignant cells can also adhere to platelets, leukocytes, and the endothelium through adhesion molecules present on their surface. Finally, as tumors increase in size, they may compress or occlude blood vessels, leading to reduced blood flow and stasis.

In adults, solid tumors are associated with a higher risk of thromboembolism than hematologic malignancies.[193] In contrast, acute lymphoblastic leukemia (ALL) is the most common malignancy reported in association with thrombosis in children, with a reported incidence rate of 5.2% in a recent meta-analysis.[194] This may simply be due to the fact that ALL is the most common cancer seen in pediatrics. However, brain tumors, the most common solid tumor in children, do appear to have a relatively lower risk of thrombosis. Two large studies reported incidences of 0.6% and 2.8%, as opposed to the 18% to 28% incidence of thrombosis in adults with brain tumors.[195–197] Large cohort studies containing children with all types of malignancies are needed to better understand the true incidence of thromboembolism in pediatric malignancy.

As stated above, the majority of literature on thromboembolism in pediatric cancer focuses on children with acute lymphoblastic leukemia (ALL). As opposed to other types of cancer, cerebral venous thrombosis and stroke are frequently seen, particularly in the setting of asparaginase therapy. Asparaginase, an essential component of induction chemotherapy, reduces the synthesis of both coagulation factors and inhibitors as a consequence of asparagine depletion.[198] Higher incidences of thrombosis appear to be associated with lower doses of asparaginase given for long periods, as well as prednisone (when given instead of dexamethasone).[194]

When treating a thromboembolism in a patient with cancer, low-molecular-weight heparin (LMWH) is likely the best choice. Warfarin, although it is less expensive and can be given orally, is too difficult to regulate in the setting of multiple chemotherapy agents, changing vitamin K stores due to antibiotics and illness, and the frequency of invasive procedures.[189,199,200] A randomized clinical trial in adult cancer patients demonstrated that LMWH was more efficacious and as safe as warfarin in preventing recurrent thromboembolism.[201] There are no specific recommendations for duration of anticoagulation in pediatric cancer patients. However, it seems reasonable to continue or resume some type of anticoagulation in the setting of ongoing risk factors, such as a repeat course of asparaginase in ALL, or anticipated postoperative immobilization in an osteosarcoma patient undergoing resection. LMWH should always be held 24 hours prior to a lumbar puncture or other invasive procedure. However, there is no evidence regarding how to best adjust LMWH in the setting of chemotherapy-induced thrombocytopenia.

Because central venous lines are the most important risk factor in the development of pediatric thrombosis, investigators have sought to determine if thromboprophylaxis is effective in preventing this complication. Earlier studies did show that thromboprophylaxis is tolerable in children with cancer.[189] However, a recent randomized trial demonstrated no difference in the incidence of line-related thrombosis between pediatric cancer patients receiving low-dose warfarin (goal INR 1.3–1.9) and those in the control group.[183] Therefore, routine prophylaxis cannot be recommended at this time.

THROMBOEMBOLISM IN CONGENITAL HEART DISEASE

Although congenital heart disease (CHD) affects only 1% of live births, almost 50% of infants less than 6 months of age and 30% of older children who develop venous thromboembolism have underlying cardiac disorders.[202] Also, the majority of children receiving prophylactic anticoagulation are being treated for complex CHD or severe acquired cardiac diseases such as cardiomyopathy. Children with CHD are at risk for venous, arterial, and intracardiac thromboembolism, as well as embolism to the central nervous system. CHD is the most common associated diagnosis among children hospitalized with arterial ischemic stroke in the United States.[203]

Cardiac catheterization is the most common procedure performed in children with CHD, and is used for both diagnostic and therapeutic purposes. Access is typically obtained through the femoral artery. Historically, thromboembolism of the femoral artery was a common complication of this procedure, particularly in younger patients. In the 1970s, a randomized clinical trial demonstrated that the use of unfractionated heparin prophylaxis reduced the incidence of femoral artery thrombosis from 40% to 8% in children less than 10 years of age.[204] The current recommendation from the American College of Chest Physicians (ACCP) is that all children should undergo prophylaxis with unfractionated heparin prior to cardiac catheterization, using a bolus of 100 to 150 U/kg.[181] Additional doses may be required for prolonged catheterizations.

The Fontan procedure, which diverts systemic venous return directly to the pulmonary arteries, is the definitive palliative surgical treatment for most congenital univentricular heart lesions.[202] Unfortunately, thromboembolic events continue to be a major cause of morbidity and mortality in this procedure. The reported incidence of these complications in cohort studies ranges from 1% to 19%, and include venous thrombosis of the Fontan circuit, right atrial thrombosis, and stroke.[202] Thromboembolic events may occur anytime after the procedure but often present months to years later.[205]

There is no consensus as to the optimal type or duration of anticoagulation that Fontan patients should receive, nor are there any data that any one prophylactic regimen is effective in reducing thromboembolic complications. Institutional protocols, if they exist, range from no anticoagulation to aspirin to warfarin. The ACCP guidelines suggest either therapy with aspirin (5 mg/kg/day) or therapeutic heparin followed by warfarin to achieve a target INR of 2.5, but state that the optimal duration of therapy is unknown.[181] An ongoing multicenter study in Australia and Canada is comparing these two therapies in a randomized clinical trial.[202]

There is even less data on the role of anticoagulation or antiplatelet therapy in other cardiac procedures with the potential risk of thromboembolism. These include the placement of endovascular stents and Blalock–Taussig shunts, as well as Norwood and Glenn procedures, which are typically performed prior to the definitive Fontan procedure. The ACCP recommends perioperative heparin therapy for these procedures.[181] However, the need for ongoing aspirin therapy is not known.

In contrast, long-term anticoagulation therapy is clearly indicated for children with prosthetic heart valves. This population is treated according to adult recommendations. Children with biologic valves should receive 3 months of warfarin, followed by long-term aspirin therapy. Those with mechanical valves must remain on long-term warfarin, with target INRs of 2.5 or 3.0 depending on the specific type of valve.[206]

THROMBOEMBOLISM IN NEPHROTIC SYNDROME

The increased risk of thromboembolism in pediatric nephrotic syndrome is multifactorial.[207] The same urinary losses that lead to profound hypoalbuminemia in these patients also cause acquired

deficiencies of anticoagulants such as antithrombin and free Protein S. Most recently, acquired Protein Z deficiency has been reported, with correlation between Protein Z and albumin levels.[208] Increased levels of procoagulants, including fibrinogen, Factor V, and Factor VIII, as well as hypercholesterolemia and increased platelet aggregation, have all been described in nephrotic syndrome. Finally, the therapeutic interventions themselves can increase the risk of thromboembolism. Diuretics cause reduced intravascular volume leading to hemoconcentration, whereas steroids and cyclosporine increase procoagulant activities.

The incidence of thromboembolism in pediatric nephrotic syndrome ranges from 1.8% to 5.4% in published series.[207,209,210] This contrasts with adult nephrotic syndrome, in which incidence rates as high as 44% have been reported.[209] The most common locations in children are the deep veins of the lower extremities and renal veins. Pulmonary embolism, one of the most feared complications of nephrotic syndrome, was traditionally thought to be a rare event. Although clinically diagnosed in less than 1% of children, a frequency of 27% (7/26) was found in a series of nephrotic children who underwent screening with ventilation-perfusion scans.[211] These data suggests that pulmonary symptoms may not always be due to fluid overload in this population, and that pulmonary embolism should at least be considered in any nephrotic patient with a significant change in respiratory status.

Prophylactic anticoagulation is recommended for adult nephrotic syndrome as long as the patient has nephrotic proteinuria and/or severe hypoalbuminemia. The question of prophylactic anticoagulation with LMWH or low-dose aspirin has been raised for nephrotic children with similar features, and/or those with steroid-resistant disease.[212] However, no studies have been performed to evaluate the efficacy or safety of this practice. Therefore, prophylactic anticoagulation remains controversial in pediatric nephrotic syndrome and is generally not used in children without a prior history of thrombosis.[213] One reason for the controversy is that predictors of thrombosis have not been established in this population. Even decreased plasma concentrations of antithrombin, the most recognized risk factor, is not a constant finding in nephrotic children who develop thromboembolism.[212] The most consistent biological risk factor to date is the presence of severe hypoalbuminemia.[207]

For those patients who develop a thrombosis, the ACCP recommends unfractionated heparin or LMWH for 5 to 7 days, followed by LMWH or warfarin for 3 to 6 months.[181] Some form of anticoagulation, however, should be continued or resumed in the setting of active disease. To avoid hemoconcentration, diuretics must be avoided or used judiciously in patients who have experienced a thromboembolic event. Finally, it is important to remember that the efficacy of heparin, especially unfractionated heparin, can be impaired in the setting of decreased antithrombin levels.

THROMBOEMBOLISM IN SYSTEMIC LUPUS ERYTHEMATOSUS

The reported incidence of thromboembolism in pediatric systemic lupus erythematosus (SLE) ranges from 9% to 17%, similar to rates reported in adult SLE patients.[215,216] Compared with malignancy, congenital heart disease, and nephrotic syndrome, thromboembolism in SLE is more likely to be arterial and involve the central nervous system. These events can occur early in the disease process, often at the time of the SLE diagnosis.

The significant association between the presence of antiphospholipid antibodies and thromboembolism is well described in patients with SLE.[217] Antiphospholipid antibodies (APLA) are a heterogenous group of antibodies directed against plasma proteins and phospholipid complexes. They most frequently occur in the setting of SLE, but are also associated with juvenile rheumatoid arthritis, epilepsy, and other diseases.[218] There are multiple subtypes of APLA, including lupus anticoagulants, anticardiolipin antibodies, anti-B2-glycoprotein, and antiprothrombin antibodies. The exact mechanism of APLA-associated thromboembolism has not been elucidated, but recent data suggest that lupus anticoagulant antibodies interfere with the function of the protein C pathway, leading to an acquired activated protein C resistance.[219]

APLA are quite common in the pediatric SLE population. An analysis of 12 reported series of children with SLE reported a global prevalence of 48% for anticardiolipin antibodies, and 23% for lupus anticoagulants.[218] Recent work has focused on the predictive value of APLA subtypes for the risk of thromboembolic events. In a cohort of 58 children with SLE, 7 of whom had 10 thrombotic events, the presence of lupus anticoagulants had the highest predictive power for thromboembolism, with a sensitivity of 100% and a negative predictive value of 100%.[220] The presence of anticardiolipin antibody was also predictive, but only if the antibody was persistent (positive on at least two occasions 3 months apart). Other studies have confirmed the strong predictive power of APLA, in particular lupus anticoagulants, for the risk of thromboembolism.[215,221,222] The association appears to be even stronger than that reported for adult SLE patients, likely because of the lack of other confounders such as older age, pregnancy, and malignancy.[223] In fact, pediatric SLE patients who are negative for antiphospholipid antibodies rarely develop thrombotic events.

On the basis of the above data, it is recommended that children with SLE be routinely screened for lupus anticoagulants, and if antibodies are present on more than one occasion they should be counseled on the presenting symptoms of stroke and other thrombotic events.[222] Prophylaxis with low-dose aspirin may be reasonable, especially in the setting of other thrombotic risk factors. However, there is not yet data to support prophylactic anticoagulation in SLE patients with lupus anticoagulants in the absence of a history of thromboembolism.[215]

It is important to note that transient lupus anticoagulants, perhaps the result of infections or immunizations, have been well described in healthy children. These lupus anticoagulants are often found incidentally in the preoperative evaluation of an elevated APTT in a child undergoing tonsillectomy. These incidentally found antibodies have not been associated with an increased risk of thrombosis.

The management of thromboembolism in SLE patients and APLA is different from most other pediatric thromboembolisms. APLA syndrome, defined by the association of a persistent APLA with symptomatic thromboembolism, has a very high risk of thrombus recurrence off therapy, and most affected children are treated indefinitely.[224] However, the appropriate intensity of this prolonged therapy is not known. Children with systemic inflammatory disorders such as SLE, rheumatoid arthritis, and inflammatory bowel disease are also at risk for thrombus recurrence when their inflammatory process is exacerbated. Children with systemic inflammation and a history of thrombosis should receive prophylactic anticoagulation until the inflammation is well controlled.[181,224]

Hematologic Complications of Solid Organ Transplantation in Children

The frequency and the success of solid organ transplantation in children have been increasing over the last decade. In 2004 there were 1816 transplants in children representing 7% of all recipients.[228,229] This is an increase of 13% over the last decade. Of the transplants in 2004, the majority were renal transplants (765) followed by liver (529) then heart (250–290). The success rate has been also improving impressively, with 5-year survival after kidney transplant at 83% to 90%, liver transplant 79% to 83%, and cardiac transplant 70% to 75%.

Hematologic complications after solid organ transplantation are a common problem. Although most of the evidence regarding type, frequency, and etiology of these complications has been studied in adults, there are increasing reports in children. Following renal transplantation 60% of children are reported to be anemic. After liver transplant, 36% of children will have a hematologic problem and of these 54% are anemic events, 19% anemia and neutropenia, 12% thrombocytopenia, 8% neutropenia, and 2% pancytopenia.[230] After

Thrombophilia Screening in Children with Systemic Disease

In a child with an underlying systemic disease, the importance of prothrombotic traits in the pathogenesis of thromboembolism is unknown. Even the prevalence of thrombophilia among these patient populations is unclear. There does not appear to be an increased incidence of inherited thrombophilia in pediatric SLE patients with thrombophilia.[213] Nephrotic children have a prevalence of Factor V Leiden similar to the normal population.[223] In two studies describing the prevalence of thrombophilia in children with acute lymphoblastic leukemia, one reported 0% prevalence, compared with 84% in the other.[185,187,224] In the setting of leukemia, thrombophilia evaluation is further complicated because the anticoagulants Protein C and Protein S can be reduced by chemotherapy. Lipoprotein (a), another marker of thrombophilia, has been shown to vary depending on stage of disease and response to treatment.[227]

At this time, even screening for inherited prothrombotic traits in children with thromboembolism is of unproven benefit.[179] Therefore, any recommendations for universal thrombophilia screening in children with malignancy or other illness, and using the results to guide clinical management, are premature. It is hoped that future studies will investigate the usefulness of thrombophilia screening in selected populations, such as children with steroid-resistant nephrotic syndrome, or SLE and a positive lupus anticoagulant.

heart, heart–lung, or double lung transplant, 51% of patients have been reported to have hematologic problems: 49% anemia, 14% neutropenia, 14% thrombocytopenia, and 23% anemia plus neutropenia with or without thrombocytopenia.[231] The etiology of these hematologic problems is most commonly a result of infection followed by medication effect. Miscellaneous causes include blood loss, microangiopathic hemolytic anemia, autoimmune cytopenias, posttransplant lymphoproliferative disease (PTLD), and multifactorial.

In the next section, discussion of the hematologic complications of solid organ transplantation is divided into cell type and by organ type when feasible. Incidence, etiology, and natural history of the problem are addressed. Much of the data are derived from adult studies, but information from pediatric studies are emphasized.

RED CELLS

Anemia is a common problem after transplantation. The incidence is reported as follows:

Kidney
- –at time of transplant: 66% [232]
- –after transplant: 60% to 84% [233]

Liver 20% to 35% [230,234,235]

Heart/heart–lung/double lung 30% to 70% [231,236]

There are distinct patterns of presentation of the problems associated with red cells, including early posttransplant anemia, hemolytic uremic syndrome (HUS)/microangiopathic hemolytic anemia (MAHA), late anemia from immunosuppressant drugs, late anemia from other causes, and pure red cell aplasia.

Early Posttransplant Anemia

Early post-transplant anemia is defined as anemia that occurs within 6 months from the time of transplant. The etiologies include:

1) Post-operative hemorrhage
2) Hemolytic anemia secondary to
   a. Passenger lymphocyte syndrome
   b. HUS/MAHA
3) Infection
   a. Sepsis
   b. Viral, esp. CMV, EBV, parvovirus
4) Medication
   a. Immunosuppressive drugs
   b. Nonimmunosuppressive drugs
5) After renal transplantation:
   a. Iron deficiency
   b. Prior uremia/bone disease

Passenger Lymphocyte Syndrome

Passenger lymphocyte syndrome is a graft-versus-host reaction.[237,238] Antibodies made by donor B cells ("passengers") transplanted with the organ are made against host red blood cells. This direct antiglobulin-positive immune hemolytic anemia occurs within 3 to 24 days posttransplant. Rh antibodies, especially anti-D, are the most common type of antibody. The anemia can be mild to severe, but is self-limited lasting about a month. The incidence of this complication increases as the size of the transplanted organ increases:

	Antibody + (%)	Hemolysis (%)
Kidney	17	9
Liver	40	29
Heart/lung	70	70

The incidence also varies depending on blood type of donor and recipient:

–61% with O donor and A recipient

–22% with O donor and B recipient

–17% with AB donor and non-AB recipient

Pediatric cases have been reported following all types of solid organ transplant and the incidence appears to be the same in children and adults, at least following liver transplantation.

Treatment consists of observation alone if mild and transfusion if severe.[237] When transfusing red cells, the ABO type of the transfused product should be identical to or compatible with the recipient serum, regardless of donor type. When transfusing platelets or fresh frozen plasma, the product should be compatible with both recipient and donor. Empiric therapy employed in management of severe cases includes corticosteroids, plasma exchange, and red cell exchange.

Hemolytic Uremic Syndrome/Microangiopathic Hemolytic Anemia

HUS/MAHA following solid organ transplant has been described most often in adults who have the typical clinical presentation for this disorder.[239–241] The majority of cases have been described in renal transplant recipients (90% of cases reported), but it has been seen with all transplant types. The median time of onset is 30 day post-transplant ranging from 8 days to 9 months,[239] and 80% of cases are within 90 days and 96% within a year.[241]

Following renal transplant for HUS, 23% of patients will have a recurrence, but the incidence varies depending on the original type of HUS. When transplant is for diarrhea-associated HUS, the recurrence rate is less than 10%. The incidence increases when the original diagnosis is atypical adult HUS and increases even more with familial HUS (60% recurrence rate), especially if there is factor H deficiency. In children transplanted for HUS there was an 8.8% recurrence

rate,[242] although it was 80% for those transplanted for atypical HUS.

The calcineurin inhibitors cyclosporine (CsA) and tacrolimus (TAC) have triggered the HUS in all of the nonrenal transplant cases and half of the renal transplant cases. The possibility of an infectious trigger has been suggested for the development of MAHA.

Treatment consists of discontinuing or decreasing the dose, or switching the calcineurin inhibitor. Plasma exchange is an unproven therapy. The outcome for graft survival is 60% for de novo HUS, but only about 33% for recurrent HUS. In children transplanted for atypical HUS, almost all lost their grafts if they develop recurrent HUS.

Late Posttransplant Anemia

Anemia occurring greater than 6 months after transplant is termed late posttransplant anemia. Causes of late anemia that are common to all solid organ transplants include[230–232,234,236]:

1. Infection
   a. EBV
   b. Parvo
   c. Rarely, CMV
2. Drug effect
   a. Myelosuppression
   b. Hemolytic anemia
   c. Other drug effects (trimethoprim-sulfamethoxazole, dapsone, etc)
3. Rejection/PTLD
4. Anemia of chronic disease
5. Iron deficiency
6. Acute renal failure
7. Uncommon/multifactorial

Etiologies of late anemia in the renal transplant setting include:

1. End stage renal disease
2. Low erythropoietin levels (68% of patients will have levels <2 SD below norm)[232]

Young children postrenal transplant have less anemia than older children and young adults. This may be due to the large donor kidney with higher erythropoietin levels and creatinine clearance relative to the size of the patient.

Immunosuppressant Drugs

There is a wide variation in the reported incidence of anemia secondary to immunosuppressant drugs: 1% to 53%. This variation may be a result of the lack of a specific test for drug-associated anemia and the lack of prospective studies. Indirect evidence for the association, however, is quite strong, that is, the ISD is stopped or changed and the anemia improves. There is a clear association of HUS/MAHA with the immunosuppressant drugs CsA and TAC in the early posttransplant period, but there are a number of studies documenting the association of late anemia with these agents as well.

In a study of children after liver transplant, half of the cases of anemia were attributed to ISD.[230] The diagnosis was usually made by excluding other causes of anemia plus evidence of resolution of the anemia after change in the ISD dose or switch to an alternative drug (median time for resolution—4 months).

In a study of children and young adults following cardiothoracic transplantation, approximately a quarter of the cases of anemia was attributed to tacrolimus, primarily because no other etiology was found.[231] The nadir hemoglobin in these patients was 7.3 to 8.8 g/dL, with reticulocytes from 1.5% to 6.7%. Only one patient had a direct antiglobulin study performed and it was negative. Four of five patients with simultaneous anemia and neutropenia recovered counts within 5 weeks of switching to CsA.

In a study of 50 pediatric renal transplant patients, the prevalence of anemia was 60%, with 30% having hemoglobin levels below 10 g/dL. TAC dose was found to be significantly associated with the presence of anemia.[243]

The association of pure red cell aplasia (PRCA) and TAC was first reported in adults. Two children were reported to develop PRCA while on TAC 8 and 47 months after liver transplantation.[244] Neither had evidence of parvovirus B19 infection. When there was no evidence of spontaneous recovery after 2 to 3 months of observation, they were switched from TAC to CsA and both recovered within 3 weeks.

There are a number of case reports of autoimmune hemolytic anemia associated with the use of TAC in both children and adults. A child with a cold antibody-positive hemolytic anemia 1 year after kidney transplant did not improve when TAC was switched to CsA, but the anemia resolved after switching to sirolimus.[245] A 9-year-old girl with severe anemia related to cold agglutinin production after liver transplantation improved when TAC was stopped.[246] When TAC was subsequently restarted, the anemia worsened, but it resolved without recurrence after switching to CsA. Four children receiving TAC developed either autoimmune hemolytic anemia alone or with thrombocytopenia following liver or intestinal transplantation.[247] TAC was not stopped because of concern for rejection. These patients were treated with corticosteroids and rituximab with a good response, but relapses were seen in two and all required continuous corticosteroid administration. Finally, an 8-year-old developed a warm antibody autoimmune hemolytic anemia 7 years after cardiac transplant while on TAC.[248] The patient was treated with steroids, intravenous immunoglobulin, and rituximab. Although responsive, he had a chronic relapsing course.

Nonimmune hemolysis has also been documented in adults. In a retrospective study of 81 patients (median age 39 years; range 12–66) after lung transplantation, 20% developed hemolytic anemia in the first year after transplant.[249] All were on CsA and none received TAC. The anemia was mild to moderate and there was no evidence of autoantibody formation or MAHA and other causes of anemia were excluded. The authors postulate an auto- or alloimmune mechanism to explain this phenomenon.

Anemia has been reported to be associated with all of the currently used immunosuppressants, including mycophenolate mofetil and sirolimus. Although direct comparison of all of the drugs has not been performed, it appears that TAC and CsA have a similar incidence,[250] with anemia occurring less commonly with the others. One possible mechanism of the development of autoimmune antibodies posttransplant is the chronic T-cell suppression resulting for the use of these agents followed by release of B-cell control. As noted above, treatment has been empiric and has included the standard treatments for autoimmune hemolytic anemia, including rituximab. Reduction in dose or switching the type of the immunosuppressant drug appears to be an effective therapy.

Pure Red Cell Aplasia Associated With Parvovirus B19

PRCA was initially reported in adults in 1986 with multiple reports since that time. Review of the literature in 2006 revealed 91 cases of parvovirus B19 infection posttransplant reported in adults.[249] Seventy-four were in solid organ recipients, with the majority following kidney transplant (71%), followed by heart/lung transplant (16%), then liver transplant (12%). Ninety-nine percent were anemic, with a third also having leukopenia and 18% thrombocytopenia. The average time to onset was 1.75 months posttransplant with a range of 1 week to 96 months. The most reliable test to diagnose infection was the parvovirus B19 PCR, positive in 85% of cases; IgM was positive in 78% and IgG 39%. Treatment with intravenous immu-

noglobulin was used in 84% of patients and there was a recurrence in 28%. The three deaths were only seen in patients after liver transplant who developed myocarditis and cardiogenic shock. Of interest, in a prospective study of 47 solid organ transplant recipients, none were found to have molecular evidence of parvovirus B19 in the first year posttransplant.[251]

In a review of parvovirus B19 infection in children after transplantation, there were 16 case reports: 5 after liver, heart, and renal transplant each and 1 after bone marrow transplantation.[252] Onset was at a median of 8 months with a range of 1 to 24 months. Although only 3 of 14 tested with IgM positive, all were PCR positive. There were no associated symptoms in 7 of 14, but other reported symptoms include cytopenias, rash, myocarditis, and pneumonia. All 10 patients who received intravenous immunoglobulin treatment were cured.

PLATELETS

Problems with platelets including thrombocytopenia and thrombocytopathy have been reported posttransplant primarily in adults. Following liver transplantation, almost all patients will develop a transient thrombocytopenia. Delayed thrombocytopenia is much less frequent. It has been reported in 12% of children after liver transplant,[230] 8% after cardiothoracic transplant,[229] and outside of the setting of HUS/MAHA very infrequently after kidney transplantation. Causes of platelet problems posttransplant include medication effect, immune etiology, HUS/MAHA, infection, and other miscellaneous causes.

Immediate Thrombocytopenia After Liver Transplantation

More than 90% of adults have been reported to have thrombocytopenia within the first week after liver transplantation.[253–257] Nadir counts usually occur between days 4 and 6 posttransplant, with an average count of 58,000 cu mm (range 19–330). An increase in thrombopoietin is seen on day 4 to 6 and increased reticulated platelets are noted on day 7 to 8. There are few reported clinical sequelae from the mild thrombocytopenia, although the lowest platelet counts have been associated with the most severe and complicated posttransplant course. Resolution is usually seen in 2 weeks. Lack of resolution is associated with poor prognosis for graft and overall survival.

There is controversy regarding the etiology of this transient thrombocytopenia. One theory is that it is a nonimmune consumptive process reflected by increased markers of thrombin generation.[255] The liver may be the site of platelet sequestration. A second theory is that it is unlikely to be a consumptive process because of the lack of platelet activation after day 1. The thrombocytopenia is more likely a result of low levels of thrombopoietin seen pretransplant. With new production and rising levels of thrombopoietin from the new liver, there is a subsequent increase in platelet production resulting in normalization of the platelet count soon after transplantation. Although the specific etiology has not been clarified, there is general consensus that it is not immune mediated.

Lymphocyte-depleting antibodies such as rabbit antithymocyte globulin (rATG) are being used with increasing frequency as induction type therapy in pediatric liver and intestine transplantation. rATG does exacerbate the transient thrombocytopenia seen immediately following solid organ transplant, but resolves in a similar 1- to 2-week period.

Treatment of this transient thrombocytopenia is supportive. Platelet transfusions are of uncertain benefit. Although originally azathioprine was felt to be a cause of this thrombocytopenia, there is no evidence that alteration of azathioprine dose is necessary.

Delayed Posttransplantation Thrombocytopenia

Delayed thrombocytopenia is not a major problem after solid organ transplantation and most of the data are published in adult series. In one retrospective study of 36 adult liver transplant recipients, mild thrombocytopenia (<140,000 cu mm) was seen in 54% of patients at 1 year and 25% at 3 years posttransplant.[258] However, severe thrombocytopenia (<50,000 cu mm) was only seen in 9% of patients at 1 year and in no patients at 3 years posttransplant. The thrombocytopenia was associated with splenomegaly in some patients. No clinical bleeding problems were noted after 1 year from transplant.

In one report, 3 of 25 (12%) pediatric liver transplant recipients were found to have isolated thrombocytopenia.[230] The etiology of the thrombocytopenia in these children was cavernous transformation of the portal vein, autoimmune, and unknown. In two other children in this series, thrombocytopenia was associated with additional cytopenias and the cause was possibly related to TAC.

In a study of 126 children who underwent cardiothoracic transplantation, 9 (8%) were noted to have isolated thrombocytopenia. Infection was the most common etiology.[231] In patients with combined cytopenias including thrombocytopenia, two-thirds were related to either infection or PTLD and 20% possibly secondary to TAC.

Sirolimus has been associated with mild thrombocytopenia in adults although the reported frequency has varied. In a study of renal transplant recipients, 23% were reported to have mild thrombocytopenia,[259] whereas no liver transplant patients on the drug were found to be thrombocytopenic.[260] In 66 pediatric kidney transplant recipients on sirolimus, there were no reported cases of thrombocytopenia.[261] Low platelet counts are usually seen within the first 4 weeks of treatment and are associated with higher sirolimus blood levels.[262,263] Like TAC and CsA, sirolimus has been shown to potentiate agonist-induced platelet aggregation, although this is not the proven explanation for the thrombocytopenia.[264] Twenty-five percent to 50% dose reduction is often effective in resolving sirolimus-mediated thrombocytopenia.

Immune-Mediated Thrombocytopenia Posttransplantation

There are many case reports of immune-mediated thrombocytopenia after all types of solid organ transplantation, in children and adults, and either alone or in combination with other cytopenias.

Eight adults post–liver transplant were reported to have immune thrombocytopenia—incidence of 0.7%.[265] The low platelets were seen on average 53 months after transplantation with a range of 1.9 to 173 months. Three patients had demonstrable antiplatelet antibodies. Steroids provided effective therapy in 4 and rituximab in 4, although splenectomy was ultimately necessary in three. Seven of the eight survive with normal platelet counts. Five children were reported to have severe thrombocytopenia (<10,000 cu mm) within 2 to 4 months after starting TAC.[247,266] All were documented to have antiplatelet antibodies. Responses were seen to steroids, rituximab, or anti-D.

Following heart and/or lung transplantation, two cases in adults[267] have been reported. These cases occurred 60 to 460 days after transplant and responded to prednisone and intravenous immunoglobulin. Acquired Glanzmann thromboasthenia has been reported in two children post–cardiac transplantation.[268,248] Both were receiving TAC and had demonstrable antibodies against GPIIb/IIIa. One patient had multiple autoantibodies and the other subsequently developed additional antiplatelet antibodies. One child responded to prednisone therapy and switching from TAC to CsA. The other responded to rituximab after failing prednisone and intravenous immunoglobulin.

Alloimmune thrombocytopenia was reported in three recipients of organs from the same donor (two kidneys and a liver).[269] Development of HPA-1a (PL^{A1}) antibodies from donor B cells were

Treatment of Immune-Mediated Thrombocytopenia after Solid Organ Transplantation in Children

There is no standard approach to the treatment of immune-mediated thrombocytopenia that occurs after solid organ transplantation. First, all other causes of thrombocytopenia should be ruled out before beginning therapy for what is often a presumptive diagnosis of immune-mediated thrombocytopenia. If the thrombocytopenia is mild to moderate (>20,000–30,000/uL) with no associated bleeding symptoms, we usually observe without intervention and monitor the platelet count on at least a weekly basis. If the platelet count is lower than 10,000 to 15,000/uL or if there is bleeding, immediate treatment is initiated with high-dose corticosteroids: 4 mg/kg/day of prednisone (or IV equivalent) divided in 3 to 4 doses and continued for 4 days. If there is a response (ie, platelet count >20,000/uL), the corticosteroid is dropped to 2 mg/kg/day divided in 2 to 3 doses and then slowly tapered to zero over the subsequent 2 to 3 weeks. Intravenous gammaglobulin or anti-D in standard doses used for childhood ITP can be used if there is no response to high-dose corticosteroids.

For patients who have recurrent or chronic thrombocytopenia requiring multiple courses of treatment to maintain platelet counts greater than 10,000 to 15,000/uL, we have utilized vincristine (1.5 mg/M^2 [max. dose 2 mg] IV weekly ×6) with success. Rituximab (375 mg/M^2 IV weekly ×4) has infrequently been used in this situation. For patients on tacrolimus with refractory thrombocytopenia, serious consideration should be given to switching to an alternative immunosuppressant, since this may be necessary for resolution of the thrombocytopenia. Involvement of both the transplant team and the hematology team is necessary for ideal management of these complex patients.

documented in an example of passenger lymphocyte syndrome. The thrombocytopenia in these cases was particularly refractory to standard treatment except transfusion of HPA-1a-negative platelets. One patient died, another required splenectomy, and one patient's thrombocytopenia resolved after an episode of severe graft rejection.

Infection-Associated Thrombocytopenia Posttransplantation

Although there are few published reports, one would expect the same hematologic problems, including thrombocytopenia, associated with bacterial sepsis or other serious infections as seen in nontransplant patients. Infection with HHV6 and the herpesvirus group has been studied closely.

HHV6 is commonly seen posttransplant, mostly in stem cell transplant recipients. In adults after liver transplant, there are case reports of a syndrome of HHV6 infection with thrombocytopenia, fever, and encephalopathy.[270] This syndrome has not been reported in children with HHV6 infection.[271,272]

Herpesvirus infection after kidney transplantation in children is seen in about a third of patients, with CMV being the most common infection.[273] The hematologic abnormalities associated with herpesvirus infection include thrombocytopenia and leukopenia, with an incidence of 31% and 24% respectively. These and other symptoms of herpesvirus infection occur at the same frequency as nontransplant patients.

There is a case report of a child post–liver transplant who developed measles complicated by autoimmune thrombocytopenia and neutropenia.[274]

WHITE BLOOD CELLS

Leukopenia and neutropenia are uncommonly reported in the literature after solid organ transplantation, although this may not reflect the true incidence seen in practice.[275] In two reviews of hematologic complications in children after transplantation, isolated neutropenia was seen in 2/70 (3%) patients after liver transplant[230] and 9/106 (8%) patients after cardiothoracic transplant.[231] Neutropenia was also seen in combination with other cytopenias. Although there are predominantly case reports in the pediatric literature, in one review of neutropenia after 400 renal transplants in adults, 35 cases (9%) were reported.[276] The etiology of leukopenia or neutropenia is similar in children and adults: immunosuppressive agents, other myelosuppressive drugs (eg ganciclovir), infection (CMV, sepsis, etc), and less frequently interferon, PTLD, hypersplenism, interferon, and idiopathic. Use of TAC is often implicated as a possible contributing factor.

Both filgrastim (G-CSF) and sargramostim (GM-CSF) have been used to treat neutropenia in adults and children. In adults it has resulted in improvement of the white count in more than 90% of patients after three to four doses.[276,277] There was no evidence of precipitation of rejection. In the case reports in children, both agents have been found to be effective in most patients, but there is a suggestion that efficacy may be affected by continuation of TAC.[275,278,279]

Azathioprine is well known to cause myelosuppression and has been associated with moderate to severe neutropenia. Azathioprine is catabolized in vivo by xanthine oxidase and thiopurine methyltransferase (TPMT). TPMT activity can vary considerably depending on a genetic polymorphism. Approximately 0.3% of Caucasians are homozygous and 11% heterozygous for deficiency of TPMT. Severe myelosuppression, including fatal neutropenia, has been documented in transplant patients who are homozygous for TMPT deficiency and receiving azathioprine.[280] There are some data that suggest that monitoring 6-thioguanine nucleotides (the metabolites of azathioprine) may allow for individualized management of azathioprine dosing with fewer side effects, although this has not become common practice.[281,282]

Neutropenia has also been associated with the use of mycophenolate mofetil (MMF) and sirolimus. Neutropenia and thrombocytopenia have been noted as a side effect of MMF since 1998.[283] Leukopenia may affect 5% to 11% of patients on the drug [284] and pseudo-Pelger–Huet anomaly has also been noted.[285] The leukopenia is often seen within 2 to 8 months after starting the drug. Filgrastim has been effective in reversing the neutropenia although some cases required decreasing the dose or stopping the drug. Ganciclovir or valacyclovir are commonly utilized simultaneously with MMF to treat or prevent CMV disease. These drugs are also known to also be associated with neutropenia. There may be an interaction between these drugs that increase the risk for neutropenia.[286] It may be necessary to stop ganciclovir as well as MMF for the neutropenia to improve.[285] Of note, serious infections are infrequently encountered.

In two reports of the use of sirolimus in children, neutropenia was the most common toxicity along with hepatitis, hyperlipidemia, and mouth ulcers.[287,288] It is not clear whether the neutropenia is directly related to serum level of the drug. Most counts will improve with a decrease in the drug dose, although few patients need to have the drug discontinued.

Pancytopenia

Pancytopenia is seen in two settings after solid organ transplantation. The first is early after liver transplant for acute liver failure from acute infectious hepatitis.[289,290] This represents the known aplastic anemia that can be seen in as many as a third of patients after non-A–E hepatitis. Treatment and outcome are similar to patients with posthepatitic aplastic anemia who do not require liver transplantation. The second setting is delayed pancytopenia, which may be secondary

to infection with or without PTLD.[230] A number of cases have been associated with the use of TAC.[230,291]

HEMATOLOGIC ASPECTS OF POISONING

It has been estimated that about 6 million children, most younger than 5 years, ingest some toxin each year. The effects of toxins on the blood are diverse, usually nonspecific, and in most situations overshadowed by the nonhematologic manifestations of the exposure.[292] With certain toxins, however, bleeding, anemia, or change in the appearance (color) of the blood may be an important component of the clinical sequelae of an acute exposure.

The abnormalities of hemostasis after poisoning are numerous, and the mechanisms vary. Bleeding may be the only manifestation of warfarin toxicity secondary to an overdose of the drug or ingestion of a rodenticide-containing warfarin. Any hepatotoxic substance (eg, iron, acetaminophen) may lead to decreased synthesis of clotting factors and resultant coagulopathy. Bleeding in these circumstances is delayed for at least 24 hours, although there appears to be an early coagulopathy in iron poisoning that may be due to a direct effect on clotting protein function and not hepatotoxicity.[293] DIC has been seen after ingestion of mushrooms of the *Amanita* genus, or following a bite from the brown recluse spider (*Loxosceles reclusa*). Poisonous snake bites can result in coagulation abnormalities characterized by hypofibrinogenemia with or without thrombocytopenia or a DIC-like syndrome.[292] Severe thrombocytopenia has been described with elemental mercury poisoning.

Acute hemolytic anemia may be the presenting manifestation after exposure to drugs and toxins in children with G6PD deficiency or hemoglobin Zürich or (rarely) in normal children. Severe hemolytic anemia has been seen after the bite of the brown recluse spider and of a rattlesnake, and after a wasp sting.

Exposure to certain toxins may result in characteristic color changes of the blood, which in turn may be reflected clinically in abnormal skin color. The child with methemoglobinemia (see next paragraph) presents with a slate-gray cyanosis unresponsive to 100% oxygen administration. On exposure to air, the blood retains a distinct brown color. Patients with toxic exposure to carbon monoxide or cyanide have increased levels of carboxyhemoglobin or cyanhemoglobin, respectively, resulting in a cherry-red color of the blood and skin, but only with high concentrations of the offending hemoglobin.

Infants (up to 4 months of age) are at particular risk for developing methemoglobinemia because of a reduced amount (approximately 60% of normal) of cytochrome b_5 reductase present in neonatal RBCs. Methemoglobinemia has been described in infants with diarrheal illness and in infants exposed to exogenous agents.[294]

Yano and colleagues[295] described 11 patients with transient methemoglobinemia, all infants younger than 1 month of age, who presented with vomiting, diarrhea, and acidosis. In prospective studies of infants younger than 6 months of age with diarrheal disease, 64% had elevated levels of methemoglobin (with a mean ± SD of 10.5 ± 12.3%), 31% were cyanotic, most infants were small and/or failing to thrive, there was no association of methemoglobinemia and acidosis, and all children recovered from their illness.[296,297] Although most infants with endogenous methemoglobinemia can be managed with support and hydration, treatment with methylene blue (1 mg/kg) is indicated in the symptomatic or more severely affected child (ie, with methemoglobin greater than 20% to 30%).

Nursery epidemics of methemoglobinemia have been reported in normal newborns exposed to disinfectants or aniline dyes used to mark diapers. Infants fed formulas made with well water containing a high concentration of nitrates have developed methemoglobinemia. EMLA cream, a eutectic mixture of the local anesthetics lidocaine and prilocaine, has been effective in decreasing pain in infants undergoing circumcision. Methemoglobinemia has been reported with EMLA use in this situation, but only in overdose.[298] Other ingestions associated with methemoglobinemia include phenazopyridine (Pyridium), dapsone, metoclopramide, and nitroethane (an artificial fingernail remover). Although the list of oxidants reported to cause methemoglobinemia is long,[299] methemoglobinemia due to exogenous agents is uncommonly seen in infants and children.

LEAD POISONING

Lead poisoning in children has been a serious public health problem for decades. However, the most serious toxic effects of lead (eg, encephalopathy) commonly seen in the past are rarely encountered today, primarily because of measures instituted to decrease lead exposure (no-lead paint, no-lead gasoline) and screening programs in high-risk areas. Mean blood lead levels in the United States have declined, from 15 μg/dL between 1976 and 1982 to 3.6 μg/dL between 1988 and 1991.[300] Nonetheless, lead toxicity remains a problem, especially in high-risk children. There is increasing evidence that even low levels of lead exposure are associated with a significant decline in neurodevelopmental outcome,[301] and in 1991 the Centers for Disease Control and Prevention (CDC) lowered the intervention level of lead in the blood from 25 to 10 μg/dL. Reviews of the public health issues relating to lead poisoning in children have been published.[302]

The primary hematologic effect of lead is interference at multiple points along the heme synthetic pathway. The two most important effects are inhibition of δ-aminolevulinic acid (ALA) dehydratase and ferrochelatase, resulting in the accumulation of heme intermediates such as protoporphyrin. A shortened RBC survival time accompanies lead poisoning and probably is due to decreased activity of pyrimidine 5-nucleotidase (also resulting in basophilic stippling of the RBC) and possibly inhibition of G6PD and the pentose shunt.[303]

The anemia of lead poisoning has classically been described as a hypochromic, microcytic anemia, as might be expected from the effects of lead on heme synthesis. Although anemia has been said to be a common finding in lead intoxication, in reality, anemia is uncommon unless the lead poisoning is severe or there is associated iron deficiency.

A strong association exists between lead poisoning and iron deficiency in children. Both tend to occur in the same population of predominantly lower socioeconomic status. Experimentally, iron deficiency has been shown to increase lead absorption, retention in tissues, and toxicity. Iron deficiency also decreases lead excretion during chelation.[304] Lead may impede iron absorption and metabolism, leading to a vicious circle of increasing lead toxicity and worsening iron deficiency. In a study of children with lead poisoning (blood lead of 30 μg/dL or higher), 86% were found to have iron deficiency, and 100% of those with more severe lead poisoning (CDC risk classification III) were iron deficient.[305]

A number of reports in children with lead toxicity have documented the infrequent occurrence of anemia without concomitant iron deficiency. Cohen and colleagues[303] found anemia in 12% and microcytosis in 21% of iron-sufficient children with severe lead poisoning (CDC classes III and IV). The combination of anemia plus microcytosis, however, was found in only 1 of the 58 children in their series. In less severely affected children (CDC classes I to III), Yip and associates[306] found a 30% incidence of anemia, but of those with either mild or no iron deficiency, only 6% were anemic. Clark and coworkers,[307] using multiple linear regression analysis, found transferrin saturation to be the most important predictor of mean corpuscular volume, hemoglobin, and zinc protoporphyrin levels in children with lead poisoning.

Two important points emerge from the foregoing information: (a) children with significant lead poisoning may have neither anemia nor microcytosis and (b) children with documented lead poisoning should be screened for underlying iron deficiency. The immediate treatment and long-term management of lead poisoning can be found in a recent review.[308]

HEMATOLOGIC ASPECTS OF METABOLIC DISEASES

A number of congenital disorders of metabolism may manifest hematologic abnormalities as part of the clinical presentation. Such global metabolic defects have diverse manifestations; especially prominent are neurologic abnormalities, failure to thrive, and unexplained metabolic acidosis. Although the hematologic findings may be overshadowed by the systemic illness, the recognition of a characteristic pattern of signs and symptoms may lead expeditiously to the correct diagnosis. Table 162–4 is a compilation of inborn disorders of metabolism that may manifest in infancy or childhood with hematologic cytopenias.[309] Additional information regarding metabolic disorders is available through OMIM (Online Mendelian Inheritance in Man): www.ncib.nlm.nih.gov/omim/.

SPLENOMEGALY IN CHILDREN

Splenomegaly is a problem frequently encountered by both the pediatrician and the pediatric hematologist. Although the spleen is rarely a site of primary disease, it may reflect systemic involvement in a variety of disorders. The spleen is the largest collection of lymphoid tissue in the body, with a unique association between the bloodstream and the reticuloendothelial compartment of the spleen. Splenomegaly may result when there is antigenic stimulation of the lymphoid system (eg, infection), obstruction of blood flow within or distal to the spleen (eg, portal vein obstruction), exaggeration of one of the normal functions of the spleen because of an underlying abnormality (eg, hemolytic anemia, splenic sequestration), or infiltration of the spleen by a foreign cell (eg, leukemia, storage diseases).

The spleen tip normally is palpable in preterm infants; up to 30% of full-term neonates have a palpable spleen. A spleen can be felt in up to 5% to 10% of normal children, but most of these are in the infant or toddler age group. As a general rule, a spleen easily palpable below the costal margin in any child over the age of 3 to 4 years must be considered abnormal until proven otherwise. That some palpable spleens may indeed be normal is attested to by the study of McIntyre and Ebaugh, who found that 3% of healthy college freshmen have palpable spleens, of which about one-third persist.[310] "Pretenders" of splenomegaly include the left lobe of the liver, a left upper quadrant tumor such as Wilms tumor or neuroblastoma, the "wandering spleen," and the proptotic spleen (seen in children with a depressed diaphragm from obstructive pulmonary disease, such as asthma or bronchiolitis).

The most common cause of acute splenomegaly in children, especially young children, is a viral infection. Splenic enlargement in this setting is mild to moderate and usually transient. When the history and physical findings suggest a viral etiology, a complete blood count with differential, platelet count, and reticulocyte count should be performed to rule out unsuspected leukemia or hemolytic anemia and to determine whether there is an atypical lymphocytosis. The child should be reevaluated in approximately 4 weeks (or sooner if symp-

Table 162–4 Hematologic Manifestations of Metabolic Disease With Onset in Infancy and Childhood

Category	Disease	Defect	Hematologic Finding(s)	Associated Findings
Lysosomal enzyme defects	Gaucher disease, Type 1	Glucocerebrosidase deficiency	Anemia, thrombocytopenia	Splenomegaly, bone abnormalities, delayed puberty, lipid engorged macrophages (Gaucher cell) in bone marrow
	Niemann–Pick disease, Type A	Acid sphingomyelinase deficiency	Anemia	Feeding difficulties, hepatosplenomegaly developmental delay, neurodegenerative course, cherry-red macula, lipid-laden macrophages (foam cells) in bone marrow
	Wolman disease	Acid lipase deficiency	Anemia, thrombocytopenia	Emesis, diarrhea, hepatosplenomegaly, vacuolization of lymphocytes, lipid-laden macrophages in bone marrow, adrenal calcification
	Aspartylglucosaminuria	Aspartylglucosaminidase deficiency	Neutropenia	Recurrent infections, diarrhea, hemias, lens opacities, neurologic abnormalities, vacuolated lymphocytes
Defects of heme synthesis	Congenital erythropoietic porphyria	Uroporphyrinogen III cosynthase deficiency	Anemia, thrombocytopenia	Hemolysis, staining of diapers, photosensitivity, developmental delay, splenomegaly, erythrodontia
	Erythropoietic protoporphyria	Ferrochelatase deficiency	Anemia, thrombocytopenia	Hemolysis, photosensitivity, neurologic abnormalities, hepatobiliary dysfunction
Defects of amino acid metabolism	Tyrosinemia, Type 1	Fumarylacetoacetate hydrolase deficiency	Anemia, thrombocytopenia	Failure to thrive, emesis, hepatopathy, neurologic abnormalities, bleeding, "cabbage-like" odor, renal tubular dysfunction
Defects of organic acid metabolism	Isovaleric acidemia	Isovaleryl-CoA dehydrogenase deficiency	Anemia, thrombocytopenia, neutropenia, pancytopenia	Acidosis, emesis, neurologic abnormalities, odor of "sweaty feet"
	Methylmalonic acidemia	Methylmalonyl-CoA mutase deficiency	Anemia, thrombocytopenia, leukopenia, pancytopenia	Acidosis, neurologic abnormalities, failure to thrive, emesis
	Mevalonic aciduria	Mevalonate kinase deficiency	Anemia, thrombocytopenia	Acidosis, cataracts, neurologic abnormalities, hepatosplenomegaly
Defects of organic acid metabolism	Propionic acidemia	Propionyl CoA carboxylase deficiency	Anemia, thrombocytopenia neutropenia, pancytopenia	Ketotic hyperglycinemia, acidosis, neurologic abnormalities
	Pyroglutamic aciduria	Glutathione synthetase deficiency	Anemia, neutropenia	Hemolysis, neurologic abnormalities, metabolic acidosis

Table 162–4 Hematologic Manifestations of Metabolic Disease With Onset in Infancy and Childhood—cont'd

Category	Disease	Defect	Hematologic Finding(s)	Associated Findings
Membrane transport defects	Lysinuric protein intolerance	*SLC7A7* gene mutations	Anemia, thrombocytopenia, leukopenia, pancytopenia	Malabsorption, protein intolerance, hyperammonemia, neurologic abnormalities, glomerulonephritis, pulmonary hemorrhage, hemophagocytosis
Glycolytic pathway defects	Triosephosphate isomerase deficiency	Triosephosphate isomerase deficiency	Anemia	Hemolysis, neurologic abnormalities, myopathy
	Phosphoglycerate kinase deficiency	Phosphoglycerate kinase deficiency	Anemia	Hemolysis, neurologic abnormalities
Defects of vitamin metabolism	Cobalamin metabolic defects	Cobalamin transport and utilization defects	Anemia, thrombocytopenia, neutropenia, pancytopenia	Megaloblastosis, failure to thrive, neurologic abnormalities
	Folate metabolic defects	Folate transport and utilization defects	Anemia, thrombocytopenia	Megaloblastosis, ringed sideroblasts, diarrhea, failure to thrive, neurologic abnormalities
	Holocarboxylase synthetase deficiency	Holocarboxylase synthetase deficiency	Thrombocytopenia	Acidosis, hyperammonemia, respiratory distress, neurologic abnormalities, skin rash
Defects in metal metabolism	Wilson disease	*ATP7B* gene mutation	Anemia	Hemolysis, liver dysfunction, neurologic abnormalities, Kayser-Fleischer rings, arthropathy
Defects of purine and pyrimidine metabolism	Hereditary orotic aciduria synthase deficiency	Uridine-5′-monophosphate	Anemia, leukopenia	Megaloblastosis, orotic acid crystalluria, immunodeficiency
	Lesch–Nyhan syndrome	Hypoxanthine-guanine phosphoribosyltransferase deficiency	Anemia	Megaloblastosis, hyperuricemia, nephrolithiasis, neurologic abnormalities, self-mutilation
Defects of carbohydrate metabolism	Galactosemia	Galactose-1-phosphate uridyltransferase deficiency	Anemia	Hemolysis, failure to thrive, neurologic findings, jaundice, emesis, diarrhea, hepatic dysfunction, cataracts, gram-negative sepsis
	Glycogen storage disease Type 1b	Deficient hepatic transport of glucose—phosphate	Anemia, neutropenia	Hypoglycemia, acidosis, hepatomegaly, xanthomas, inflammatory bowel disease
	Hereditary fructose intolerance	Aldolase B deficiency	Anemia, thrombocytopenia	Poor feeding, emesis, failure to thrive, neurologic findings, hypoglycemia, liver dysfunction, ringed sideroblasts, coagulopathy, hemophagocytosis, shock
Mitochondrial disorders	DIDMOAD syndrome (Wolfram syndrome)	Mitochondrial DNA deletions	Anemia, thrombocytopenia, neutropenia, pancytopenia	Megaloblastosis, ringed sideroblasts, diabetes insipidus, diabetes mellitus, optic atrophy, deafness
	Pearson syndrome	Mitochondrial DNA deletions	Anemia, thrombocytopenia, neutropenia, pancytopenia	Ringed sideroblasts, vacuolization of marrow precursors, exocrine pancreatic dysfunction, metabolic acidosis
Lipoprotein disorders	Abetalipoproteinemia	Microsomal triglyceride transfer protein defects	Anemia	Hemolysis, acanthocytosis, bleeding, emesis, diarrhea, failure to thrive, neurologic findings
Miscellaneous disorders	Barth syndrome (endocardial fibroelastosis-2)	Tafazzin gene mutations	Neutropenia	Cardiomyopathy, endocardial fibroelastosis, skeletal myopathy, short stature, 3-methylglutaconicaciduria, abnormal mitochondria
	Cyclic hematopoiesis	Neutrophil elastase gene mutation	Neutropenia	Recurrent oral ulcers, poor dentition, recurrent fever, malaise
	Severe congenital neutropenia (Kostmann syndrome)	Neutrophil elastase gene mutation	Neutropenia	Severe invasive infections, acute leukemia
	Wiscott–Aldrich syndrome	*WAS* gene mutations	Thrombocytopenia	Eczema, infections, small platelets

CoA, coenzyme A; DIDMOAD, diabetes insipidus, diabetes mellitus, optic atrophy, deafness.

Table 162–5 Causes of Splenomegaly in Children

Disorders of the Blood
Hemolytic anemia: congenital/acquired
Thalassemia
Sickle cell disease
Leukemia
Osteopetrosis
Myelofibrosis/myeloid metaplasia/thrombocythemia
Infections: Acute and Chronic
Viral
Congenital (eg, TORCH association)
Mononucleosis (eg, EBV, CMV infection)
Virus associated hemophagocytic syndrome
Human immunodeficiency virus
Bacterial
Sepsis/abscess
Brucellosis
Salmonellosis
Tularemia
Tuberculosis
Subacute bacterial endocarditis
Syphilis
Lyme disease
Fungal
Histoplasmosis (disseminated)
Rickettsial
Rocky Mountain spotted fever
Cat scratch disease
Parasitic
Toxoplasmosis
Malaria
Leishmaniasis (kala-azar)
Schistosomiasis
Echinococcosis
Hepatic/Portal System Disorders
Acute/chronic active hepatitis
Cirrhosis/hepatic fibrosis/biliary atresia
Portal or splenic venous obstruction (Banti syndrome)
Autoimmune Disease
Juvenile rheumatoid arthritis
Systemic lupus erythematosus
Autoimmune lymphoproliferative syndrome (Canale–Smith syndrome)
Neoplasms/Cysts
Lymphomas (Hodgkin and non-Hodgkin)
Hemangiomas/lymphangiomas
Hamartomas
Congenital or acquired (posttraumatic) cysts
Storage Diseases/Inborn Errors of Metabolism
Lipidoses: Gaucher disease, Niemann–Pick disease, others
Mucopolysaccharidoses
Defects in carbohydrate metabolism: galactosemia, fructose intolerance
Sea-blue histiocyte syndrome
Miscellaneous Disorders
Histiocytoses
Reactive
Langerhans cell
Malignant
Sarcoidosis
Congestive heart failure
Familial Mediterranean fever

CMV, cytomegalovirus; EBV, Epstein-Barr virus; TORCH, toxoplasmosis, other infections, rubella, cytomegalovirus infection, herpes simplex.

Evaluation and Management of the Child With Splenomegaly

When evaluating the child with chronic splenomegaly, the clinician must consider all of the possibilities noted in Table 162–5. Clues from the history and physical examination may suggest a specific etiology and direct a tailored approach to the diagnostic laboratory evaluation. If, on the other hand, there is no apparent cause of the enlarged spleen, a number of screening laboratory tests should be performed, including a complete blood count with differential, platelet count, and reticulocyte count; evaluation of the peripheral smear; determination of sedimentation rate; liver function tests; determination of antibody titers to Epstein–Barr virus (EBV), cytomegalovirus (CMV), and *Toxoplasma*; antinuclear antibody assay; and ultrasound evaluation of the liver, spleen, and portal system (the last with Doppler flow technique). Further evaluation, including bone marrow examination, may be necessary if the screening tests do not reveal the cause of the splenic enlargement.

Management of splenomegaly usually is that of the underlying disease, when such treatment exists. Splenectomy may be indicated in selected conditions, but the potential benefits from splenectomy must be weighed against the risk of postsplenectomy sepsis, a rapidly progressive bacteremia, most commonly from *S pneumoniae*, with a mortality rate of approximately 50%. The risk of postsplenectomy sepsis depends on the age of the patient and the nature of the underlying disorder. Patients younger than 3 years of age and those with a compromised immune or reticuloendothelial system are most susceptible. When elective splenectomy is indicated, it is advisable (a) to postpone surgery until the patient is at least 5 to 6 years of age; (b) to administer pneumococcal, meningococcal, and *H influenzae* vaccines (if the patient was not previously immunized) at least 1 to 2 weeks before splenectomy; (c) to consider use of prophylactic penicillin for at least 4 years; and (d) to manage significant febrile illnesses as possible postsplenectomy sepsis at all times. In addition to the risk of postsplenectomy sepsis, the rare complication of postsplenectomy portal or splenic vein thrombosis must also be considered.

For children younger than 5 years of age with severe symptoms from hemolytic anemia, hemoglobinopathy, or hypersplenism, partial splenectomy should be considered. In a number of studies, up to 90% of the spleen has been removed safely, with a high rate of success and preservation of splenic function.[311,312] Regrowth of the spleen to variable degrees has been noted, with occasional need for reoperation.

toms persist). If splenomegaly persists beyond 4 to 6 weeks, the splenic enlargement may be considered chronic.

A list of causes of splenomegaly in children is presented in Table 162–5.[313] Symptoms from splenic enlargement are uncommon, although massive splenomegaly may cause abdominal discomfort and early satiety. If the spleen is sufficiently large, there may be increased destruction or sequestration of one or more of the formed elements of the blood (hypersplenism). Cytopenias tend to be mild to moderate, with the platelet count affected the most.

An approach to the pediatric patient with splenic enlargement is outlined in the box on Evaluation and Management of the Child with Splenomegaly.

CHAPTER 163

THE SPLEEN AND ITS DISORDERS

Susan B. Shurin

Galen described the spleen as the "organ of mystery," with functions related to mood and good or ill humors. It was not until the 18th century that the spleen's relationship to the immune and hematologic systems was appreciated. The complexities of splenic function continue to be the focus of research and observation. The spleen is not necessary to life because its many functions are redundant, overlap with the functions of other organs, and can be assumed by other organs. The spleen, however, is an important part of many disease processes as well as normal function of the immune and hematologic systems. The spleen efficiently phagocytoses erythrocytes, recycles iron, recognizes and destroys pathogens, and induces adaptive immune responses. An appreciation for the subtleties of its anatomy and function is important for the physician evaluating patients with many hematologic, immunologic, and hepatic diseases.

NORMAL SPLENIC ANATOMY AND FUNCTION

Embryology

The spleen arises from the mesoderm. By the ninth week of gestation, layers of the left dorsal mesogastrium condense, and blood vessels appear. Sheaths are formed around arterioles by reticular cells and fibers. Macrophages are present and are phagocytic by the end of the first trimester. Lymphocytes appear during the fourth month. Red and white pulp can be identified by the sixth month. Germinal centers do not develop during fetal life, but primitive inactive follicles are evident at birth.[1] In mice, a homeobox gene, *Hox11* (now known as *Tlx1*), which controls the genesis of the splanchnic mesodermal plate, is essential for development of the spleen.[2] Both the basic helix–loop–helix transcription factor capsulin,[3] and the Wilms tumor suppressor 1 gene (WT1) are indispensable for formation of the spleen.[4] The genetic basis for development of the human spleen is less well understood. The spleen is capable of supporting hematopoiesis during fetal life and, in a variety of pathologic states, postnatally. The circulation of primitive hematopoietic stem cells in peripheral blood during prenatal life through birth makes it difficult to distinguish hematopoiesis dependent on tissues in the organs and the incidental presence of hematopoietic cells within the circulation of those organs.[5,6]

Anatomy

The spleen is the body's largest filter of the blood.[7,8] Located directly below the diaphragm and adjacent to the stomach, it is covered by a fibrous capsule with blood vessels, lymphatics, and nerves coated by peritoneal mesothelium (Figs. 163–1 and 163–2). The splenic artery comes from the celiac axis, enters the capsule at the hilum, and branches into trabecular arteries. The trabecular arteries then branch into central arteries and enter the white pulp. The periarterial lymphoid sheath consists of a cuff of T lymphocytes, plasma cells, and macrophages around the central arteries. As the arteries branch, the sheath narrows. B-lymphocyte clusters appear in follicles along the periarterial lymphoid sheath at arterial branch points.

The components of the white pulp are connected by a reticular network and supporting stromal cells. On the cut surface of the normal spleen, white pulp is visible as white nodules 1 to 2 mm in diameter. Their size varies with age and antigenic stimulation. The nodules are fully developed at birth, increase in size in childhood (especially with immunizations and infections), peak at puberty, and involute in adulthood. Immunologically normal, uninfected adults normally have no evident germinal centers. A mantle zone of B lymphocytes surrounds the follicle, or secondary germinal center. Antigen trapping and processing take place in the marginal zone of the white pulp.[9,10]

The red pulp of the spleen consists of vascular sinuses, the cords of Billroth, and the terminal branches of the penicilliary arteries.[11,12] Vascular sinuses are lined with endothelial cells with long processes and a basement membrane with ring fibers that attach to macrophage dendritic processes. No tight junctions or interdigitations connect the cytoplasmic processes. Intact leukocytes, erythrocytes, and platelets are able to squeeze through the potential spaces between these cells and between the ring fibers. Processes of the reticular cells of the cords of Billroth are outside the sinus walls. Endothelial cells line the sinuses and pulp veins but not the cords. Circulation of blood through red pulp lined with endothelium, or closed circulation, is rapid. Circulation into the cords, or open circulation, is slower and permits the macrophages lining the cord to remove damaged or aged cells.

Functions

The functions of the spleen are summarized in Table 163–1.

The Red Pulp

The function of the red pulp is dominated by splenic macrophages, which are responsible for filtering of the blood, removal of bacteria, and iron recycling.

Removal of Damaged and Aged Formed Elements

The venous system of the red pulp enables it to filter whole blood, removing senescent erythrocytes and other blood cells. Arterial blood is delivered to the cords of the red pulp. The cords have an open system of reticular fibers, fibroblasts, and macrophages without an endothelial lining. Blood passes from the cords into the efferent venous sinuses, which are lined with endothelium with a discontinuous structure. Stress fibers extend beneath the basal plasma membrane and run parallel to the axis of the endothelial cells. These cords direct the blood into sinuses through slits formed by the stress fibers. In many animals, these stress fibers are contractile, and enable the spleen to serve as a reservoir of red cells and reduce blood viscosity when the animal is at rest. There is no evidence that the spleen serves such a function, or is capable of significant changes in volume with rest and exercise, in humans.

As erythrocytes and platelets age, they tolerate the hostile splenic environment less well than when they are healthy with metabolic reserve.[13] The spleen is acidotic (pH 6.8 to 7.2), hypoxic (Po_2 54 mm Hg), and hypoglycemic (glucose concentration approximately 60% of that in venous blood). Damage to aged anucleate cells includes changes in their membrane complex carbohydrates, which

facilitate recognition by splenic macrophages and removal from the circulation.[14,15] *Culling* describes the destruction of erythrocytes: the normal removal of aging cells or the removal of damaged cells in pathologic states. Most platelets and leukocytes are not removed by the spleen as they age but adhere to vessel walls and migrate into tissues, where they die. *Pitting* refers to the removal of inclusions from within erythrocytes, which are then released back into the circulation. The erythrocyte membrane is in close apposition to the macrophage membrane, so that aged or damaged glycoproteins, antibody, or complement on the surface of the cell are easily recognized and activate phagocytosis. Particulate matter—Howell–Jolly bodies, Heinz bodies, Pappenheimer bodies, and malarial and other parasites—can be removed and the cell returned to the bloodstream. Membrane-containing adsorbed antibody can be removed and the remainder of the cell released with changes in shape and volume. Internal vesicles near the erythrocyte membrane appear as if they were on the surface of the cell, and are termed *pits* or *pocks*.[16–19] The spleen also normally removes these, with the polished erythrocyte returned to the circulation. The lack of this polishing function can be used to assess splenic dysfunction, as the number of pits or pocks per erythrocyte is increased when the spleen fails to remove them.

Recycling of Iron

Both hepatic and splenic macrophages are important for recycling of iron as erythrocytes are phagocytized and hydrolyzed in the phagolysosome. Degradation of hemoglobin releases heme, which is catabolized into biliverdin, carbon monoxide, and ferrous iron (Fe^{2+}).

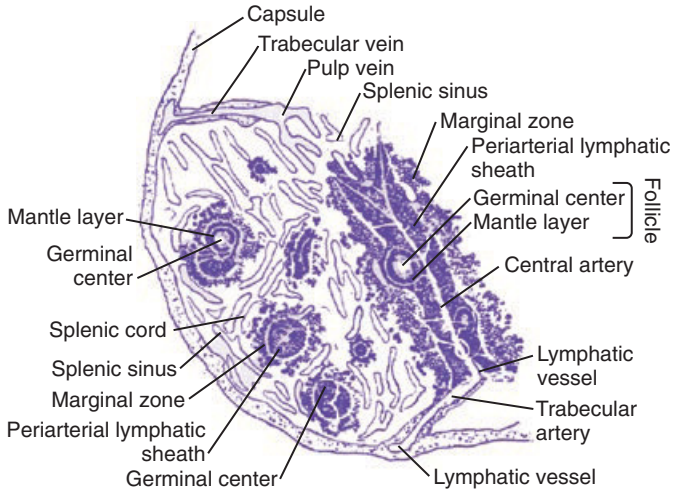

Figure 163–1 Anatomy of the spleen. (From Weiss L, Tavassoli M: Anatomic hazards to the passage of erythrocytes through the spleen. Semin Hematol 7:372, 1970, with permission.)

Iron is then either released as a low-molecular-weight species for rapid reuse or stored as ferritin. As ferritin accumulates, it aggregates into hemosiderin. Iron-laden macrophages are a feature of iron overload states in both the liver and spleen. Erythrocytes that are destroyed intravascularly release hemoglobin that binds to haptoglobin. CD163 on the surface of splenic macrophages mediates endocytosis of circulating hemoglobin and haptoglobin-bound hemoglobin.[20]

Iron is released from stores in splenic macrophages in response to the erythropoietic drive expressed by the bone marrow. The precise mechanisms are not well understood. Uptake of iron is mediated in most cells by a divalent cation transporter, natural-resistance-associated macrophage protein 2 (NRAMP2),[21] in recycling endosomes that express the transferrin receptor. NRAMP2 transports ferritin into the cytoplasm across the endosomal membrane. In addition to the more widely expressed NRAMP2, macrophages and monocytes express NRAMP1, which was initially described as an iron-transporting protein impacting resistance to intracellular pathogens.[22,23] A third molecule involved in iron metabolism in the spleen is lipocalin-2, which is secreted by macrophages and other myeloid cells when activated by exposure to bacterial metabolites. Lipocalin-2 binds to bacterial siderophores and sequesters iron from microorganisms.[24] These and related molecules tightly link the iron-recycling and host resistance functions of the red pulp of the spleen.

Antibody Production

After stimulation and differentiating into antigen-specific plasmablasts in the follicles of the white pulp, plasmablasts and plasma cells lodge in the red pulp, where they are closer to macrophages. A similar translocation occurs in lymph nodes where plasmablasts migrate to the medullary cords. This translocation occurs after upregulation of expression of CXC-chemokine receptor 4 (CXCR4), which binds CXC-chemokine ligand 12 (CXCL12) expressed in red pulp.[25,26]

The White Pulp

The lymphoid region of the spleen incorporates multiple components of the immune system that are organized to enhance recognition and/or response to pathogens. The white pulp contains lymphoid sheaths around branching arterial vessels, similar to the structure of lymph nodes. Specific chemokines attract B and T cells to their appropriate domains. The periarteriolar lymphoid sheath, or PALS, contains T cells that interact with dendritic cells and circulating B cells. T cells and dendritic cells are attracted to PALS through CC-chemokine ligands 19 and 21.[27] Follicles contain B cells where clonal expansion of activated B cells occurs. B-cell migration to follicles requires CSCL13.[28] Expression of all these homeostatic chemokines is reduced when signaling through the lymphotoxin receptor or tumor necrosis alpha receptor 1 is absent, which results in disorganization of the domains of the white pulp.[29–31]

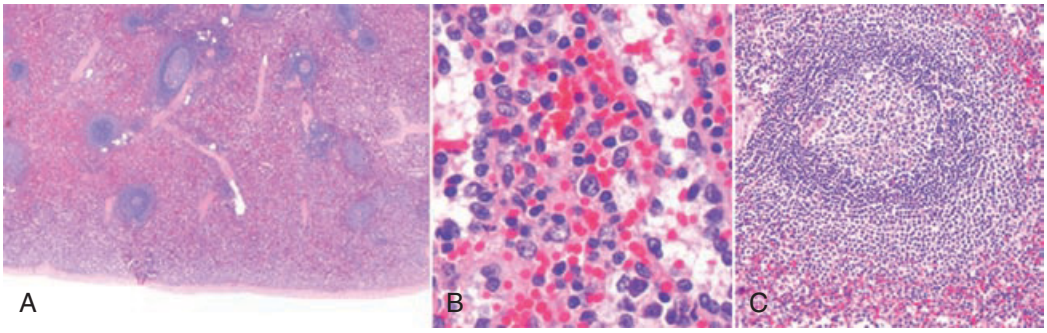

Figure 163–2 Spleen (**A–C**). Low power of spleen (**A**) removed from a patient with ITP. Note capsule (*bottom*), white pulp, and red pulp. High power of red pulp (**B**) showing splenic sinuses (*left* and *right*), and cords (*central*). Detail of white pulp (**C**) illustrating germinal center (*center*) surrounded immediately by mantle zone and then by marginal zone.

Marginal Zone

Leukocytes leave the bloodstream and enter the white pulp in the marginal zone of the spleen via G-protein-coupled receptor functions, similar to migration of leukocytes across endothelial barriers in inflammation. The marginal zone is both a transit area and contains resident cells with complex interactions. Marginal zone metallophilic macrophages form an inner ring close to the white pulp, marginal zone macrophages form an outer ring, and dendritic cells and B cells are located between the two sets of macrophages.[32,33] Both trafficking and retention of dendritic cells and B cells involve complex interactions with integrins and other adhesion molecules.[34,35]

Innate Immunity

The spleen is important in the recognition of antigens, especially when administered intravenously, in the production of antibody, and in the clearance of opsonized and unopsonized particles from the bloodstream (see Table 163–1).[36–38] The spleen is structured to facilitate monitoring of the contents of the blood, with blood flowing through the marginal zone directly along the white pulp. The white pulp is involved in adaptive immunity, whereas the marginal zone is involved in both innate and adaptive immunity (Table 163–2).

Trapping and processing of antigens is a major function of the marginal zone with its abundant blood supply (2 L/minute) and large number of macrophages. Antigens penetrate the germinal center where T lymphocytes predominate. Processing of carbohydrate antigens is a special function of splenic marginal zone lymphocytes.[39] Marginal zone macrophages express lectin receptors and scavenger receptors that efficiently bind polysaccharide antigens. These enable them to bind and clear pathogens—mycobacteria, bacteria, and viruses—without surface opsonins.[40–43] Toll-like receptors important for pattern recognition are expressed on splenic, as on all, macro-

Table 163–1 Functions of the Spleen

Category	Function	Effector Cells/Areas
Clearance/filtration	Antibody-mediated clearance Culling and pitting	Macrophages Reticular meshwork
Immune response		
Marginal zone	Interaction of antigens with effector cells Antigen processing Immune recognition	Monocytes, lymphocytes Macrophages T cells (periarteriolar sheath)
White pulp	Immunoregulation, antibody production Antigen processing, preservation	B cells (lymphoid follicles) Macrophages
Red pulp	Phagocytosis	Macrophages, monocytes, neutrophils
Hematologic	Hematopoiesis Storage of erythrocytes, platelets, leukocytes Finishing/polishing of erythrocytes	Cords and sinuses Reticular meshwork, red pulp Reticular meshwork, macrophages
Hemostasis	Production of factor VIII, von Willebrand factor	Endothelial cells

Table 163–2 Innate Immune Pattern Recognition Receptors That Are Highly Expressed on Splenic Phagocytic Cells*

Name	Abbreviation	Function	Splenic Cells Expressing	Recognizes or Affects	Pathogens Recognized
Toll-like receptor networks	TLR	Pattern recognition of pathogen-associated molecular patterns	Marginal zone macrophages Dendritic cells	Lipopolysaccharide Flagellin Double-stranded RNA	Multiple bacteria, especially gram negative
Natural-resistance-associated macrophage protein-1	NRAMP-1	Solute carrier family 11 (proton-coupled divalent metal ion transporters); phagolysosomal function	Macrophages	Lysosomal targeting	*Mycobacterium tuberculosis* *M avium* *M leprae*
Natural-resistance-associated macrophage protein-2	NRAMP-2	Proton-dependent cation transporter; iron absorption	Macrophages (apical duodenal cells, erythroid cells)	Impairs bacterial gene expression, protein synthesis	*Brucella* spp
Sialic acid binding Ig-like lectin-1; sialoadhesin	SIGLEC1, CD 169	Immunoglobulin superfamily	Splenic and peritoneal macrophages Many hematopoietic cells	Mannose	*Streptococcus pneumoniae*
Specific intercellular adhesion molecule-3 grabbing nonintegrin related 1	SIGNR1, CD 209b	ICAM-3 binding nonintegrin homolog, mannose receptor	Dendritic cells	Polysaccharide antigens, mannosylated lipoarabinomannan (ManLAM)	Fungi, other pathogens
Macrophage receptor with collagenous structure	MARCO	Type 1 scavenger	Marginal zone macrophages	Lipopolysaccharide	*Staphylococcus aureus* *Escherichia coli*

*These receptors contribute to resistance to infection with pathogens in the absence of prior exposure, specific immune responses, or surface opsonic immunoglobulin or complement.

phages; the expression of receptors that bind directly to components of unopsonized pathogens is a feature of splenic macrophages.

Splenic macrophages are more sensitive to small amounts of opsonic antibody or complement on the surface of particles than are macrophages in the liver, lung, or bone marrow.[44] In the absence of a spleen, nonimmune individuals may fail to remove bacteria with little opsonic coating.[45,46] The production of antigen-specific IgM is impaired in the absence of a spleen.[39,47] An asplenic individual has defective recognition of carbohydrate antigens, defective production of IgM early in infection, and defective removal of lightly opsonized particles—all crucial components of response to invasive infection with encapsulated organisms.

Marginal zone B cells are sensitive to detection of blood-borne pathogens. They rapidly differentiate into either antigen-presenting cells or IgM-producing plasma cells. After activation in the marginal zone, some B cells migrate into the white pulp, where they function to activate naïve CD4-positive T cells.[48] Similarly, blood-borne dendritic cells activated in the marginal zone migrate into the white pulp. This process appears to be important in control of certain parasitic infections. In *Leishmania donovani* infection, the spread of infection is inversely proportional to the up- or downregulation of CCR7 expression on activated dendritic cells and migration of APCs into the white pulp.[49]

Adaptive Immunity

The white pulp is both anatomically and functionally similar to lymph nodes.[50] However, all splenic cells enter the white pulp via the marginal zone, as opposed to through high endothelial venules and afferent lymphatic vessels. This exposes incident cells to an environment highly sensitive to detection of blood-borne pathogens. Circulating dendritic cells capture bacteria from the blood and transport them to the spleen, where they mediate the initial differentiation of B cells to plasmablasts or APCs. Activated APCs entering the white pulp activate T cells, resulting in changes in receptor expression that enables them to migrate to the edge of B-cell follicles. Contact between activated T cells induces an isotype switch in follicular B cells, which then migrate to the red pulp and marginal zones, or remain in splenic germinal centers.[51] The white pulp of the spleen is the largest mass of lymphoid tissue in the body. The B lymphocytes, which ultimately produce antibodies, predominate in the nearby germinal centers and mantle zones. These areas all increase in size and activity with immunization or infection. The complex interaction between the cells in close apposition, autocrine and paracrine signaling, and migration of cells into, between compartments of, and ultimately out of the spleen contribute to the extraordinary repertoire of innate and adaptive immunity within the organ.[52] Changes in splenic architecture are quite dramatic with septicemia; the most marked depletion of splenic B areas is seen in overwhelming enterococcemia. Bacterial virulence factors appear to contribute to depletion of B- and T-cell areas.[53]

Hematopoiesis

Active hematopoiesis can be seen in the fetal spleen throughout the second trimester, decreasing in the third trimester.[54] Erythropoiesis and megakaryocytopoiesis predominate, with myelopoiesis present to a lesser extent. As hematopoiesis moves from the hepatic phase into the bone marrow, it becomes less evident within the fetal spleen. The spleen is not normally a site of hematopoiesis in postnatal life in humans, but it is a rich source of hematopoietic stems cells and can support hematopoiesis in a number of pathologic states.[5,6] Extramedullary hematopoiesis is a significant cause of splenomegaly in bone marrow diseases (eg, myelofibrosis or osteopetrosis) and chronic hemolytic anemias (eg, thalassemia). The stromal cells of the spleen appear to be capable of supporting hematopoiesis and may produce the c-*kit* ligand,[55,56] as do marrow stromal cells. When splenic hematopoiesis occurs, the erythrocytes and platelets that circulate tend to be less mature than when hematopoiesis occurs in the bone marrow, which suggests that egress from the spleen is easier than from the marrow.

In rodents, the spleen continues to function as a hematopoietic organ during adult life. In higher mammals, including primates, the resident stem cells are capable of restoring hematopoietic and immunologic function after lethal irradiation.[57]

Storage of Cells

The normal adult spleen contains 20 to 40 mL of blood, and does not serve as a reservoir for blood volume or erythrocytes. This changes in many conditions associated with splenomegaly, especially if portal hypertension is also present. The widening of the pulp cords creates an organ with more storage volume. Vascular pooling of blood and formed elements occurs, regardless of the underlying cause of the splenomegaly.[58] Platelets and granulocytes, however, are normally stored in the red pulp of the spleen. As much as one-third of the total platelet mass may be stored in the spleen and released when cytokines affecting platelet adhesiveness are released.[59,60] The lack of musculature in the human splenic capsule prevents the distention and contraction that occur in many animals, such as dogs, although the spleen appears to contract in divers during periods of breath-hold apnea, with a rapid 20% decrease in volume observed in divers without decrease in splenic arterial blood flow.[61] After splenectomy, platelet counts and granulocyte counts rise significantly, then fall.[62] The circulating masses of these cell pools are chronically increased postsplenectomy, which may contribute to an increased incidence of atherosclerosis years after splenectomy.[63,64]

EXAMINATION OF THE SPLEEN

For adequate examination of the spleen, the patient must be fully supine, relaxed, with arms adjacent to the trunk, and the examiner must be on the patient's right side.[65] Beginning in the right iliac fossa, the examiner's hand gently advances toward the left upper quadrant. This minimizes the likelihood that a grossly enlarged spleen will be unappreciated, and the lower pole and medial border should be easily appreciated. If the spleen cannot be felt with this approach, the left hand of the examiner is placed on the left flank, lifting the lower part of the rib cage to displace the spleen medially toward the examiner's right hand. The splenic notch should be felt in the inferior medial border. Rotating the patient into the right lateral position while still recumbent may make it easier to palpate the spleen. The spleen should move with deep inspiration. It is dull to percussion. The degree of enlargement is usually measured in centimeters below the costal margin. It may be difficult to appreciate even significantly enlarged spleens, depending on the position of the spleen within the abdomen. Normal splenic size in an adult is up to 250 g, and up to 13 centimeters in its long axis. Up to half of spleens weighing 600 to 750 g are not palpable.[66] Greater degrees of splenomegaly are less difficult to appreciate on physical examination.

Up to 15% of normal children and 3% of young adults have palpable spleens, up to 2 cm below the left costal margin, without evidence of illness.[67] The spleen involutes with age, and a spleen that is palpable in an older person is less likely to be a normal variant and more likely to be associated with clinical disease.

IMAGING OF THE SPLEEN

Radionuclide scintigraphy assesses anatomic and functional aspects of the spleen.[68] The most common procedure is a liver–spleen scan in which ^{99m}Tc sulfur colloid is injected intravenously and taken up by hepatic and splenic macrophages. It is the phagocytic activity of macrophages—rather than the presence of the spleen itself or any aspects of lymphoid function—that is assessed. A dynamic ^{99m}Tc scan can also assess the distribution of blood within the portal system and suggest the presence of portal hypertension. Infusion of ^{99m}Tc-labeled

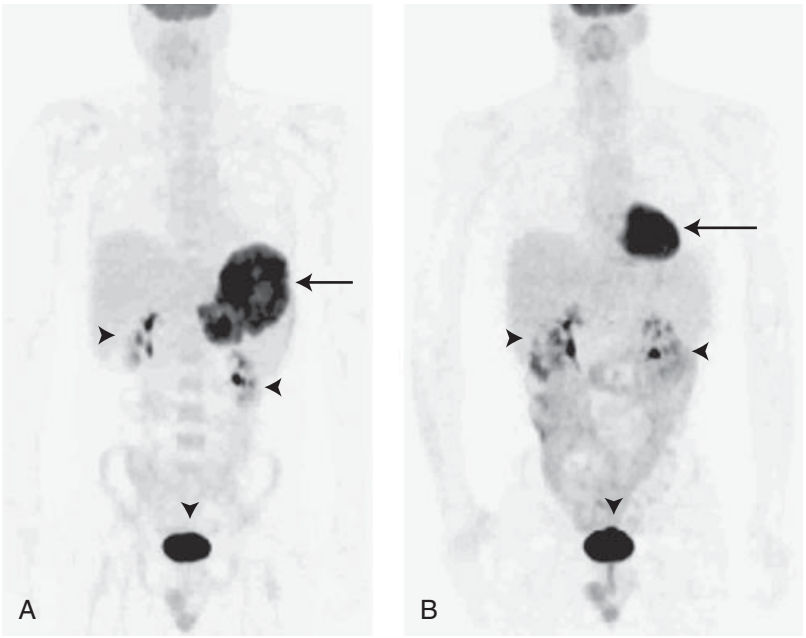

Figure 163–3 PET scanning to image areas of involvement in Hodgkin disease.[89] Panel A shows pretreatment and Panel B shows the same patient after 3 cycles of chemotherapy. The spleen is particularly well imaged on PET scan. *(From Friedberg JW, Chengagi V: PET scans in the staging of lymphoma: Current status. Oncologist 8:438, 2003)*[89]

or ^{111}In-labeled platelets with scintigraphy to determine their relative distribution in the liver and spleen has been used with considerable, but not absolute, success to predict the clinical efficacy of splenectomy in immune thrombocytopenic purpura.[69]

Ultrasonography readily shows the size, shape, and several aspects of splenic anatomy, including the presence of cysts and abscesses.[70] The procedure is noninvasive, painless, of low cost, avoids radiation exposure for patients, and is a good screening study when the spleen is thought to be enlarged. Accessory spleens tend not to be well visualized on routine ultrasonography. Endoscopic ultrasound-guided biopsy in the hands of a skilled operator permits accurate diagnosis of lesions as small as a centimeter or less, which compares well with results obtained using computed tomography (CT).[71–73] High frequency sonography has significantly better resolution, and can visualize both nodularity within the spleen, which occurs in childhood as immunity is acquired, and accessory spleens and splenosis after splenic rupture or trauma.[74]

CT imaging has the advantage of showing the anatomy and some aspects of splenic function.[75] Contrast material in the stomach, small bowel, and colon, given enterally, helps delineate splenic tissue when it impinges on these organs. Intravenous contrast material is required to delineate splenic lesions whose density is the same as normal splenic tissue. Abscesses have a rim of contrast agent enhancement.[76]

CT can be used to estimate the volume of the spleen. Accessory spleens have the same attenuation as a normal spleen, which is somewhat less than that of liver.[77] Accessory spleens are usually located in the gastrosplenic ligament near the hilum. Subcapsular and intrasplenic hematomas and splenic lacerations are clearly seen on CT. Leukemias and many inflammatory diseases produce diffuse splenomegaly. Granulomas and infarcted areas eventually calcify. Cysts, abscesses, and some malignancies have inhomogeneous patterns on CT scan.[78–80] Although not replacing other methods of staging, splenic enlargement on CT may direct follow-up studies and indicate prognosis.[81]

In addition to imaging the spleen, CT can be used to direct therapeutic interventions. Abscesses, hematomas, and cysts can be drained. As long as portal hypertension is not present and vascular lesions have been excluded, thin-needle aspiration under CT guidance is generally a safe intervention.

As with head injury, emergency room CT scanning of patients with abdominal trauma may avoid hospital admission and avoid laparotomy. With mild splenic injury, a single scan may be sufficient to direct management.[82]

Magnetic resonance imaging (MRI) is useful for identifying vascular lesions, which would otherwise require angiography, and splenic infections. It is more difficult to image the contents of the upper abdomen with MRI than with CT because of respiratory motion. With more rapid imaging technology, MRI has gained considerable utility for imaging infectious and vascular lesions of the spleen. Hepatosplenic candidiasis and other infections to which immunocompromised patients are susceptible can be identified noninvasively with modern MRI technology.[83–85]

Perhaps the most valuable use of MRI imaging of the spleen is to obtain a quantitative measurement of iron burden in organs that accumulate iron in iron overload.[86]

Positron-emission tomography (PET) scanning using ^{18}F2-deoxyglucose (FDG) has an increasing role in the diagnosis, staging, and monitoring of lymphoma, both non-Hodgkin and Hodgkin disease. It is more sensitive than CT scanning at identifying nodal disease, and superior to both lymphangiography and CT scanning at imaging the spleen. The availability of more sensitive, specific and less toxic approaches to imaging permits more precise staging of Hodgkin lymphoma without the complications of splenectomy (see Fig. 163–3).[87–89]

The place of PET scanning is expanding in other disorders as whole-body PET scanners and appropriate small-molecule markers for individual diseases are more widely available. Imaging studies in small-animal models are very promising; splenic involvement can be identified with high sensitivity in mice.[90]

TESTS OF SPLENIC FUNCTION

The peripheral blood smear may be the most sensitive tool for identification of functional or anatomic hyposplenia. The presence of Howell–Jolly bodies, which are nuclear remnants normally removed by the spleen, is an excellent indicator of hyposplenism (see Fig. 163–4).[17,18,91] These are rarely seen until the spleen is largely nonfunctional or overwhelmed by other phagocytic functions, such as extravascular hemolysis. Newborn infants commonly have visible Howell–Jolly bodies, and splenic function appears to be at least somewhat impaired in the first week of life.[92] Pappenheimer bodies (siderotic granules normally removed by the spleen) are often seen in hyposplenic states, particularly when a component of hemolysis exists.[93] Erythrocyte morphology reflects the lack of membrane polishing by the spleen, with the presence of acanthocytes and target cells.[14,16,61] Granulocyte and platelet numbers are increased

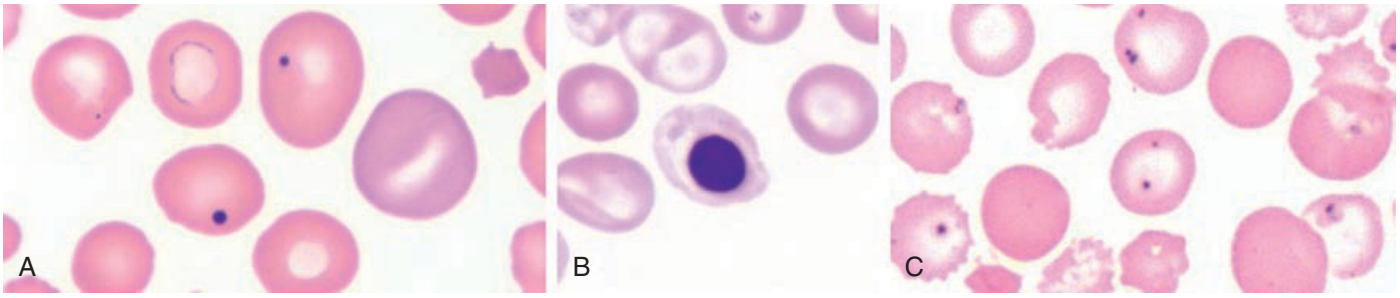

Figure 163–4 Red blood cells with Howell-Jolly bodies (**A**), Nucleated red blood cell (**B**), and cells with Pappenheimer bodies (**C**). Red blood cells with Howell-Jolly bodies are seen in patients with hyposplenism. The cytoplasmic inclusions (**A**) are nuclear remnants which are usually round and stain similar to the nucleus of a nucleated red blood cell (**B**). They occur normally during red cell maturation, but are typically removed by a normal spleen. Their presence in the blood indicates less than normal splenic function. Pappenheimer bodies (**C**), which can also be seen in hyposplenism, are siderotic granules that are irregular in shape, and frequently multiple.

during asplenic states, including splenic infarction and surgical splenectomy.[59,62]

To confirm suspected hyposplenism, the simplest test is a count of pitted or pocked erythrocytes. Fixation in 0.5% to 1.0% glutaraldehyde and examination under interference optics for surface pits reveals endocytic vesicles containing hemoglobin, ferritin, and remnants of mitochondria.[14] These form in mature erythrocytes and are normally removed by the functioning spleen. The number of pitted cells (not the number of pits per cell) is inversely proportional to splenic function, with normal persons having less than 2% pitted cells.

ASPLENIA AND HYPOSPLENIA

Congenital asplenia may be an isolated lesion or associated with severe cyanotic congenital heart disease and bilateral right-sidedness.[94] Life-threatening cardiac lesions, including transposition of the great vessels, pulmonary artery atresia or stenosis, septal defects, anomalous venous drainage, and single atrioventricular valve, are components of this condition. The liver is central, and both lungs have three lobes. The peripheral blood smear shows Howell–Jolly bodies and other signs of hyposplenism. There is considerable variation in the anatomic and functional findings, and it is difficult to predict with accuracy the degree of splenic dysfunction on the basis of the anatomy alone.[95] Children who survive the cardiac difficulties in the neonatal period have a significant incidence of sepsis secondary to a variety of organisms.[96]

Polysplenia is associated with bilateral left-sidedness. Dextrocardia, bilateral superior venae cavae, septal defects, and anomalous pulmonary venous return are associated cardiac lesions. Both lungs have two lobes, the liver is midline, and bowel malrotation is common. The splenic tissue is divided into two to nine masses.[197] The peripheral blood smear usually does not suggest hyposplenism, and no clear association with an increased risk of infection has been documented.

Asplenia occurring without heart disease is less likely to be detected before an infection develops than when associated cardiac lesions bring the patient to medical attention.[98,99] Some of these patients also have situs inversus. Isolated cases of asplenia discovered after death of an otherwise healthy adult or child from overwhelming sepsis with encapsulated organisms have been reported.[100] Familial instances of congenital asplenia are likely to be instances of genetic abnormalities (eg, Hox11/Tlx1), but these are not yet characterized. Examination of a blood smear for Howell Jolly bodies is a simple procedure and may be lifesaving in the rare patients affected with these disorders.[100]

Imaging to determine whether a spleen is present should follow identification of Howell–Jolly bodies on the blood smear of an otherwise healthy person. Immunization with polysaccharide vaccines and early intervention with antibiotics for apparent infection may prove lifesaving for these individuals.[94] Because approximately 20% of invasive pneumococcal infections in these patients are nonvaccine strains, a high degree of vigilance remains essential, even with more widespread immunization of healthy children.[101]

ACQUIRED HYPOSPLENISM

Infarction in Sickle Cell Disease

The course of sickle cell disease is marked by progressive dysfunction of multiple organs over many years.[102] One of the earliest organs to be affected is the spleen. Serial measurement of pitted erythrocytes in sickle syndromes demonstrates that splenic dysfunction develops progressively over the first few years of life in the major sickle syndromes (Figs. 163–5 and 163–6).[103] The hypoxic, acidotic, hypoglycemic environment of the spleen creates optimal conditions for tactoid formation and for sickling of the poorly deformable erythrocytes, which then block splenic blood vessels and infarct the tissues. Splenic environmental conditions that enhance acidosis or hypoxia, or additional erythrocyte membrane or enzyme abnormalities that promote irre-

Figure 163–6 Pocked erythrocytes in the sickle hemoglobinopathies. (From Sills R, Oski FA: RBC surface pits in the sickle hemoglobinopathies. Am J Dis Child 133:526, 1979, with permission. Copyright 1979, American Medical Association.)

versible sickling, enhance splenic infarction.[104] The hyposplenism is reversible with transfusion for at least the first few years of life, but becomes irreversible with progressive damage to blood vessels by 6 years of age in patients with sickle cell disease.[105–107]

Splenic sequestration is a manifestation of the infarctive process of sickling in the spleen that extends to involve larger veins.[108,109] The unimpeded flow of well-oxygenated blood in the splenic arterioles into the distensible splenic tissues results in pooling of a large amount of blood, whereas the venous drainage is occluded by sickled hypoxic erythrocytes. Unlike the chronic process of smaller-vessel infarction, the acute splenic sequestration crisis can be life threatening because a large amount of blood can collect in the highly distensible spleen. The tendency to recurrence and the potential for fatal outcome lead to the common recommendation for splenectomy in a patient who has had one severe splenic sequestration crisis, or more than one less severe crisis. Occlusion of venous drainage also occurs in the liver, but the less distensible capsule of the liver and the options for venous drainage through the portal system make this less likely to threaten life.

Immunologic and Autoimmune Diseases

Poor phagocytic function of the spleen is associated with impaired function of the Fc receptors on splenic macrophages in a variety of immunologic, rheumatic, and inflammatory disorders. Among those disorders in which hyposplenism has been clearly defined and associated with a risk of infection are systemic lupus erythematosus, rheumatoid arthritis, sarcoidosis,[110] systemic vasculitis, ulcerative colitis, celiac disease,[111] amyloidosis,[112] chronic graft-versus-host disease,[113] mastocytosis,[114] and congenital[115] and acquired immunodeficiency.[116] The diseases themselves and the immunosuppressive therapies that are used in their management may contribute to the risk of infection in these conditions. Immunization to polysaccharide antigens and recognition of the risk of bacterial infection are important to minimizing the risks of splenic hypofunction.[117]

Splenomegaly and the production of autoantibodies (such as to platelets in idiopathic thrombocytopenic purpura) are features of acquired immunodeficiency syndrome (AIDS). In the late stages of AIDS, atrophy of lymphoid follicles and depletion of T cell-dependent areas are common. It is not clear that impairment of phagocytic function is a component of this splenic atrophy in AIDS.

Therapy-Induced Splenic Hypofunction

Radiation therapy affects splenic function, depending on the dose administered.[118] In general, phagocytic cells are not affected by irradiation, but lymphoid cells are extremely sensitive. B-cell function is nearly ablated with as little as 500 cGy. T-cell lymphoblastogenesis is eliminated by administration of 3000 cGy. With doses of 2000 cGy, splenic hypofunction is usually transient because the macrophages and splenic stroma are not affected, and circulating B and T lymphocytes can repopulate the splenic follicles. Patients receiving irradiation to the bed of a left Wilms tumor are not hyposplenic. However, permanent splenic hypofunction develops with doses of greater than or equal to 4000 cGy, which is standard dosing for Hodgkin disease. The risk of infection is significant after such therapy.

Corticosteroid therapy impairs the affinity of the Fc receptors of splenic macrophages for opsonic immune globulin G (IgG), and decreases the adhesiveness of granulocytes and monocytes.[119,120] This creates a pharmacologic splenectomy acutely with administration of corticosteroids at common therapeutic dosages. The function of the Fc receptors on hepatic, pulmonary, and bone marrow macrophages is far less affected than that of splenic macrophages. The acute rise in platelet count or hemoglobin values seen with corticosteroid therapy in idiopathic thrombocytopenic purpura or autoimmune hemolytic anemia is due to decreased clearance of sensitized cells. With longer therapy, the production of antibodies by splenic lymphocytes is also affected, and splenic function continues to be impaired.

Intravenous IgG appears to decrease the phagocytic function of the spleen by binding to Fc receptors and impeding their recognition of opsonized particles.[121] This is a transient effect because the Fc receptors are internalized and recycled, and opsonic function returns to normal within 2 to 3 weeks.[122] Occupancy and impairment of function of Fc receptors is also seen with administration of anti-D immunoglobulin to Rh-positive patients, which induces a transient hemolytic anemia. Reticuloendothelial blockade, or occupancy of these receptors, refers to the impaired ability of the spleen to recognize and remove other IgG-coated particles, including bacteria, in the presence of these agents.[123]

SPLENOMEGALY AND HYPERSPLENISM

An enlarged spleen is not a disease state in itself but usually indicates some underlying pathology. The processes run the gamut from minor to life threatening, from congenital disorders to those at the end of life, and few organ systems are not represented in the underlying conditions. It is useful to approach splenomegaly by considering the processes that may cause splenic enlargement and then to focus on the specific diagnoses within those categories.

The spleen may be enlarged as a result of infiltration, hypertrophy of normal elements (macrophages and lymphoid components), extramedullary hematopoiesis, inflammatory or immunologic processes, and systemic or portal congestion. The degree of splenomegaly correlates well with involvement of the spleen in many malignant disorders, such as Hodgkin disease.[124] Rarely, anatomic abnormalities will cause splenomegaly. Splenomegaly is important to investigate because it is frequently the presenting finding of a serious disorder whose earlier recognition and treatment may prevent significant long-term morbidity and mortality. The diseases associated with splenomegaly are detailed in Table 163–3.

Hypersplenism refers to nonimmune, indiscriminate destruction of the formed elements of the blood by a spleen that is enlarged, affected by portal hypertension, or both. The bone marrow is hyper-

Table 163–3 Causes of Splenomegaly

Primary Process	Pathogenesis	Examples
Anatomic	Developmental anomalies	Cysts, pseudocysts, hamartomas, peliosis, hemangiomas
Hematologic	Hemolysis	Intrinsic (membrane, enzyme, hemoglobin disorders); extrinsic (immune)
	Extramedullary hematopoiesis	Myeloproliferative diseases/myelodysplasias, myelofibrosis, osteopetrosis
Infectious	Bacteria	Acute and chronic systemic infection, abscesses, SBE
	Mycobacteria	Miliary tuberculosis
	Spirochetes	Syphilis, Lyme disease, leptospirosis
	Viruses	EBV, CMV, HIV, hepatitis A, B, C
	Rickettsia	Rocky Mountain spotted fever, Q fever, typhus disseminated candidiasis, histoplasmosis, South American blastomycosis
	Fungi	
	Parasites	Malaria, babesiosis, toxoplasmosis, *Toxocara canis/cati*, leishmaniasis, schistosomiasis, trypanosomiasis
Immunologic	Collagen vascular diseases	Felty syndrome, SLE, mixed connective tissue disorder, systemic vasculitis, Sjögren syndrome, systemic mastocytosis
	Immunodeficiency	Common variable immunodeficiency
	Immune/inflammatory	Graft-versus-host disease, serum sickness, LGL lymphocytosis, Weber Christian histiocytoses
Neoplastic	Primary malignancies	Lymphomas, leukemias
	Metastatic malignancies	Breast, lung, skin, colon
Infiltrative	Storage diseases	Gaucher disease, Niemann–Pick disease, GM-1 gangliosidosis, glycogen storage disease type IV, Tangier disease, Wolman disease, mucopolysaccharidoses, hyperchylomicronemia types I and IV
Congestive	Portal hypertension	Intrahepatic cirrhosis, extrahepatic cirrhosis (Budd–Chiari syndrome)
	Systemic	Congestive heart failure

CMV, cytomegalovirus; EBV, Epstein–Barr virus; HIV, human immunodeficiency virus; LGL, large granular lymphocyte; SBE, subacute bacterial endocarditis; SLE, systemic lupus erythematosus.

plastic, and the peripheral blood cell counts are decreased as a consequence of destruction of mature formed elements. Splenectomy corrects the cytopenia. Any of the formed elements of the blood—erythrocytes, neutrophils, or platelets—can be affected, alone or in combination. Splenic hypertrophy results in pooling of formed elements and premature destruction of cells by splenic macrophages. Because a normal function of splenic macrophages is to remove senescent cells, this is an exaggeration of a process that is physiologic for splenic macrophages.

Hypersplenism develops in patients who receive chronic transfusion. There are several components to the development of hypersplenism. The antigenic load of allogeneic transfused cells stimulates the immune system. Transfused cells have shorter survival than normal red cells (mean of 60 instead of 120 days, unless specially prepared neocytes are used), which increases the work of splenic macrophages. Finally, iron overload causes hemosiderosis of both the spleen and the liver, so that portal hypertension may develop and further increase splenic pathology. Hypersplenism increases the transfusion requirement in patients who are transfusion-dependent.

SPLENECTOMY

Indications and Timing

Splenectomy should be performed for clinical indications rather than for specific diagnoses. In many instances, removal of the spleen will improve the condition of patients with hemolytic anemia due to intrinsic disorders of erythrocyte membranes and enzyme disorders, and of those with chronic conditions, such as storage diseases and portal hypertension. Specific clinical indices that require intervention should be identified, and parameters that can be used to identify clinical improvement (usually an increase in peripheral blood cell counts, growth, or energy level) should be determined before the procedure is performed. For patients with inherited erythrocyte membrane or enzyme disorders, such as hereditary spherocytosis or pyruvate kinase deficiency, marked reticulocytosis indicating significant metabolic energy required for erythropoiesis, somatic growth failure, or lack of exercise tolerance would be potential indications for splenectomy. Avoidance of formation of gallstones, formerly often considered an indication for splenectomy when a diagnosis of hereditary spherocytosis was made, is less important today because minimally invasive surgical procedures have improved the management of cholelithiasis. Patients with storage disorders such as Gaucher disease develop splenomegaly and hypersplenism. Cytopenias requiring intervention should be present before splenectomy is performed. The clinical benefit to be obtained from splenectomy should at least balance, and preferably outweigh, the potential long-term risks of postsplenectomy septicemia,[125–135] the increased incidence of arteriosclerotic cardiovascular disease,[63] and the shift of storage cells from the spleen to other organs, such as bone marrow, where they may do more harm in the absence of the spleen.[136–140] Not all patients with hemolytic anemias, such as hereditary spherocytosis, need splenectomy. If they develop an aplastic crisis, as with parvovirus B-19 infection, while their spleens are intact, they may need transfusion. Many patients with mild chronic hemolysis and well-compensated anemia may be better off with their spleens remaining intact. Patients with immune thrombocytopenic purpura should undergo surgical splenectomy when the risks of bleeding or of medical therapies (such as long-term corticosteroids) are such that the benefits of splenectomy exceed the risks. These indications for splenectomy are different in adults and in children and are affected by the presence of underlying disorders, such as systemic lupus erythematosus and HIV infection.

Splenectomy for sickle cell disease is usually performed for splenic sequestration that is severe, persistent, or recurrent. In some sickle syndromes, the spleen does not autoinfarct in childhood, and persistent splenomegaly may increase the degree of anemia. The risk of subsequent development of gallstones should be considered in patients with hemoglobinopathies and other hemolytic anemias so

that cholecystectomy can be performed simultaneously, if deemed indicated.[141]

The timing of splenectomy—when it is to be performed—should again be chosen to minimize risks and maximize benefits. Immunity to carbohydrate antigens, such as those in the cell walls of encapsulated organisms, such as *Streptococcus pneumoniae*, *Neisseria*, and *Haemophilus influenzae* type b, develops over the first 2 to 3 years of life. When splenectomy can be delayed until the patient is at least 2 and preferably more than 5 years of age, specific immunity and response to administered polysaccharide vaccines will improve host defenses and lessen the risk of postsplenectomy sepsis. When patients have storage diseases, such as Gaucher disease, or hemolytic anemia predisposing to iron overload, such as thalassemia, the presence of the spleen as a preferential site for storage of harmful cellular breakdown products may protect other organs from damage. Delaying splenectomy until a clear clinical indication is present will balance risks optimally.

Relative Contraindications

Extramedullary hematopoiesis is a relative contraindication to splenectomy. In some conditions, splenomegaly reflects the fact that the bone marrow is not the primary site of hematopoiesis. Intrinsic bone marrow pathology, such as myelofibrosis, renders the marrow cavity incapable of supporting hematopoiesis. Myeloid metaplasia may reflect the fact that the spleen has become a predominant site of hematopoiesis. Splenectomy under these circumstances may render the patient pancytopenic and produce massive hepatomegaly. The major conditions leading to this circumstance are malignant osteopetrosis in young children and myelofibrosis in adults. It is important to determine before splenectomy that the patient is not dependent on splenic hematopoiesis for survival.

Portal hypertension is not a contraindication to splenectomy, but it affects the surgical approach. It is helpful to determine before surgery whether the patient is likely to need a shunt to reduce portal hypertension and manage esophageal varices.

Surgical Options

When splenectomy is clearly indicated, acute complications are rarely a consideration in the decision to perform surgery. Nevertheless, advances in surgical procedures have minimized the short-term risks of the procedure itself and of postoperative complications, such as intestinal obstruction from adhesions. Subtotal splenectomy can be performed when total splenectomy is not desirable, such as for the removal of a cyst, a pseudocyst, or tumors; after trauma; or for Gaucher disease.[136,137] Wedge resection with mattress sutures and cyanoacrylate adhesions and microfibrillar collagen omental packs have greatly improved partial splenectomy procedures in the past decade. Laparotomy is required, when extensive peritoneal adhesions are present; for the staging of Hodgkin disease[142,143]; and for removal of most massively enlarged spleens.[144,145] A sufficiently large incision to permit full visualization and mobilization is essential when the spleen is very large or when inspection is a major part of the surgical procedure. A retroperitoneal approach is useful when the spleen is not massively enlarged but needs to be fully removed, such as when cytopenias are the indication for the procedure. This approach shortens the postoperative recovery time and avoids induction of peritoneal adhesions.

Minimally invasive procedures have become standard for most splenectomies. Laparoscopy is now the procedure of choice for splenectomy. Although the operative time is significantly greater than for laparotomy, the postoperative recovery time, the risk of damage to the pancreas, the likelihood of development of subphrenic abscess and peritoneal adhesions postoperatively, and the nutritional and metabolic challenges to the patient are considerably reduced. Laparoscopic splenectomy can be performed even in thrombocytopenic patients. The outcome of laparoscopic splenectomy in ITP is affected by the experience and skill of the surgeon and by obesity of the patient. Extensive presurgical use of corticosteroids may induce obesity and impair tissue healing, resulting in a higher risk of complications of laparoscopic splenectomy than in patients whose splenectomy is performed before these drug effects develop.[146]

Appreciation of the risk of postsplenectomy septicemia[147,148] and refinements in noninvasive, accurate radiologic monitoring techniques have led to more conservative approaches to splenic injury.[128,149] Nonoperative management has increased over time, and has acceptable mortality and complication rates in selected patients, although early discharge may put patients at risk of later complications.[150] Noninvasive imaging and minimally invasive surgical procedures have impacted heavily upon these trends. After traumatic rupture, splenic tissue may regenerate minisplenules in the peritoneal cavity, a process termed *splenosis*.[147,151] Although splenosis is partially protective against postsplenectomy infection in animals,[151,152] its protective value in humans is not known and depends on the adequacy of perfusion of splenic tissue (Fig. 163–7).[153] It is generally valuable to attempt preservation of splenic function when possible after traumatic rupture. Some surgeons are attempting to induce splenosis when traumatic splenectomy is unavoidable, in the hope of minimizing late complications.

As the late complications of splenectomy are better appreciated, surgeons have become increasingly creative at performing procedures that preserve or restore splenic function. Even large cysts that were indications for splenectomy until recently have been managed with spleen-conserving procedures, such as partial or total cystectomy, and can often be performed laparascopically.[154] Pancreatic surgery often requires sacrifice of the spleen; increasing numbers of procedures are being performed with salvage of the spleen.[155,156]

Splenic transplantation is being used as a means of developing immune tolerance, as well as to reduce the risk of infection, in organ transplantation. Allograft spleen has been transplanted within multivisceral grafts with only minimal graft-versus-host disease. To date, there are more animal than human data, and it is unclear how large an impact this approach may have on visceral, especially small bowel and pancreatic, allotransplantation.[157–160]

Complications After Splenectomy

Acute complications in the perioperative period include rupture of the spleen, the development of subphrenic abscess, and injury to the pancreas with the operative procedure. In a healthy patient, the acute risk of splenectomy is low. The degree of splenomegaly greatly affects the risk of rupture and pancreatic injury. The technical difficulty of splenectomy is much greater when the spleen is massively enlarged than when the spleen is small. Rupture of the spleen once the arterial supply has been ligated is rarely a problem. The splenic hilum is retroperitoneal, so that when the spleen is very large, mobilization to access the splenic artery and vein can be difficult. After recovery from surgery, intestinal obstruction due to formation of peritoneal adhesions is a complication that, if it is to occur at all, usually occurs within the first few months.

Two late complications of splenectomy give the greatest concern: overwhelming postsplenectomy septicemia and atherosclerotic heart disease. Both of these complications may develop many years after the splenectomy. The precise risk is not known, and preventive interventions are probably underutilized because patients may not be aware of the risks of splenectomy performed early in life.[161]

Postsplenectomy septicemia is rare but may be rapidly lethal. It is due to the inability of hepatic and pulmonary macrophages to effectively clear organisms from the bloodstream in the absence of protective levels of opsonic IgG antibody. Organisms that enter the bloodstream and would ordinarily be removed by splenic macrophages are able to evade recognition by macrophages whose Fc and C3b receptors appear to be less avid than those of splenic macrophages. Circulation of the blood through the liver and lung is more rapid than through the spleen, and there is little opportunity for macrophages to recognize organisms whose surfaces contain no IgG

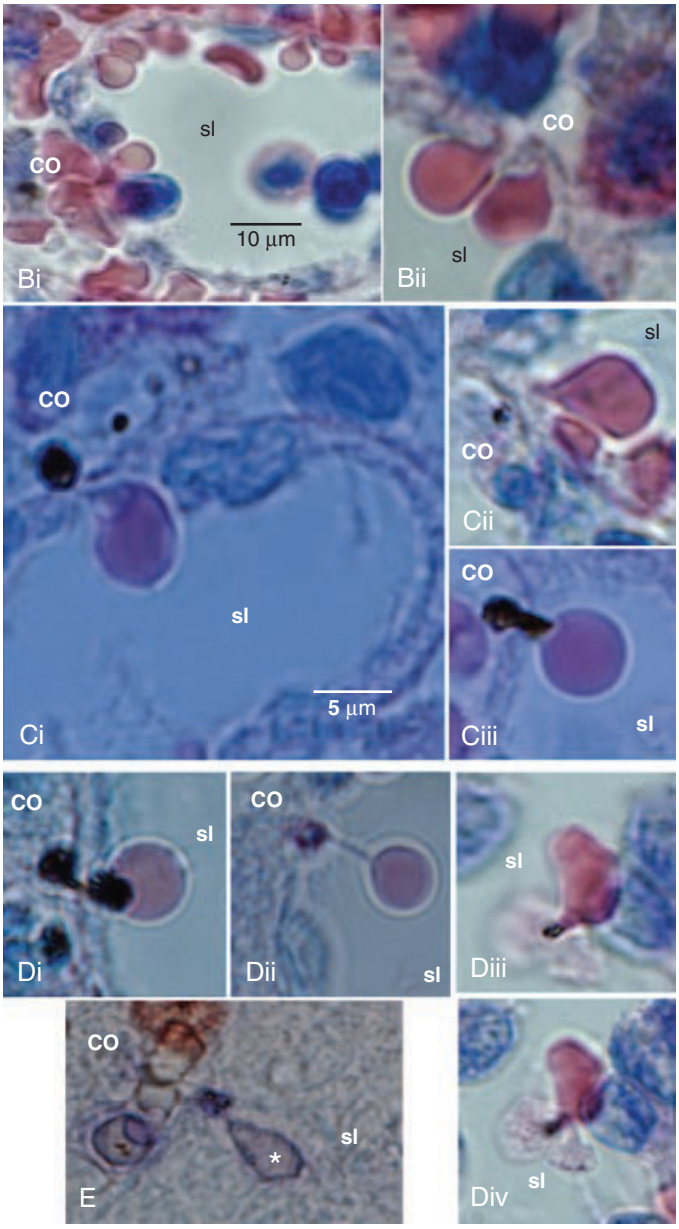

Figure 163–7 Removal of intraerythrocyte dead malarial parasites by isolated perfused human splenic tissue.[153]

and only small amounts of C3bi. Generation of cytokines, including tumor necrosis factor-α, and bacterial endotoxins lead to cardiovascular collapse and shock. It is rare to revive an asplenic patient once the patient is in shock, even with effective antibiotic therapy. The risk that this will happen varies with the indication for splenectomy (Table 163–4) and the patient's medical condition. Factors that impair host defenses significantly increase the risk of infection. These include deficient opsonins (hypogammaglobulinemia and specific antibody production deficiency), reticuloendothelial blockade related to increased phagocytic activity of macrophages in other organs, impaired antigen processing or recognition (AIDS, lymphoma, other malignancies, and some collagen vascular diseases), neutropenia, and high iron load (thalassemia). Patients at the lowest risk are those in whom splenectomy cures the underlying problem, such as isolated ITP, hereditary spherocytosis, and trauma. Patients undergoing splenectomy for trauma have a 50-fold greater risk of septic death than trauma patients with spleens intact. The risk in patients with sickle cell disease is increased 350-fold over that of the general population.

Table 163–4 Incidence of Postsplenectomy Sepsis

Indication for Splenectomy	Cumulative Incidence of Bacterial Sepsis (%)
Trauma	1.5
Hematologic disorders	3.4
Portal hypertension	8.2
Hodgkin disease	10
Sickle cell disease	15
Thalassemia	25

Data from Gorse GJ: The relationship of the spleen to infection. In Bowlder AJ (ed.): The Spleen: Structure, Function, and Clinical Significance. New York, Van Nostrand Reinhold, 1990, p 269, with permission.

Atherosclerosis developing many years after splenectomy may be related to the thrombocytosis that occurs, with enhancement of plaque formation. Statistically, the increased risk of atherosclerosis is not great,[63] but for individuals with other risk factors, such as hypertension, diabetes, high levels of cholesterol or homocysteine, heterozygous protein C or S deficiency, or factor V Leiden, splenectomy may pose a more significant risk. No data are currently available in this area.

Prevention of Complications

Postsplenectomy Septicemia

The major risk of postsplenectomy sepsis is infection with encapsulated organisms such as *Staphylococcus pneumoniae*, *Haemophilus influenzae* type b, and *Neisseria meningitidis*, which require opsonization for effective phagocytosis. Polysaccharide vaccines are available for all three groups (Table 163–4).[162–166] The highest risk period for children is in the first 2 years of life, when their ability to mount an antibody response to purified polysaccharides has not developed completely, so protein-conjugated vaccines are now in widespread use. This has significant potential benefit for patients whose asplenia is not recognized, as they may be immunized as part of their routine care. The antibody responses to vaccines, especially the conjugated vaccines, differ in IgG subclasses from those produced in natural infection. Overwhelming postsplenectomy sepsis, and death from sepsis in functionally hyposplenic patients, should be preventable.[167] It is recommended that immunization be done 3 weeks before the anticipated splenectomy to optimize antigen recognition and processing, and induce more effective immunity.[168] Adults are presumed to be immune to *H influenzae* type b, and may receive the pneumococcal and meningococcal vaccines alone. Reimmunization for children is recommended 2 to 5 years after initial immunization. Repeat administration of pneumococcal vaccine is recommended every 10 years.[169] Because these recommendations change with experience and vaccine usage, it is wise to consult current guidelines for individual patients.[170–172]

There are fewer data on the efficacy of prophylactic antibiotics for asplenic patients, except for young children with sickle cell disease, in whom antibiotics should be initiated as soon as the diagnosis is established. Present recommendations are that twice-daily oral penicillin or amoxicillin be continued in sickle cell patients until 6 years of age. High-risk patients with surgical or functional asplenia, including those with diagnoses of thalassemia, Hodgkin disease, other malignancies, immunodeficiency disease, or chronic graft-versus-host disease, should receive prophylactic antibiotics unless specific contraindications exist. Whether or not such patients receive prophylactic antibiotics, and regardless of their immunization status, they may develop overwhelming infections with other organisms, including gram-negative organisms and *Staphylococcus aureus*. Updated recommendations should be consulted for specific circumstances.

The single most important measure to prevent postsplenectomy septicemia is education of patient, family, and physician. Recognition of the risk, the institution of appropriate preventive measures, and the rapid administration of antibiotics to a patient who is showing signs of infection (fever and chills) can be lifesaving.

Atherosclerosis

The magnitude of the risk of development of atherosclerosis is not clear.[173] Appropriate preventive measures include identifying and minimizing concurrent risk factors, such as obesity, dietary patterns, a sedentary lifestyle, and the presence of other hereditary factors that would predispose to thrombosis. Low-dose aspirin could be considered, but no data exist regarding its efficacy in this situation.

CONCLUSION

Although very little novel information has emerged about clinical aspects of splenic function in recent years, advances in supportive care in several fields have had significant impacts on the management of disorders of the spleen. Better and more effective immunizations, administered widely for indications unrelated to splenic dysfunction, have improved prevention of serious complications of these disorders. Advances in imaging and surgery have transformed the management of splenic trauma and other anatomic disorders, as well as splenic surgery for diagnosis and staging of malignancies.

In contrast to the modest clinical gains, enhanced understanding of the complexity of cross-talk between the cells of the immune and hematopoietic system has transformed our appreciation of the molecular, cellular, system and network basis for long-standing clinical observations about splenic function. The ability of splenic macrophages, in concert with dendritic cells and B cells, to recognize and ingest a variety of microorganisms without specific immunity or previous exposure provides great insight into the reasons that the spleen protects against a variety of very specific infections. More detailed understanding of the impact of the microenvironment on cellular functions, the role of stromal infrastructure on the ability of cells to interact with and respond to invading pathogens, and the sensitive cellular cross-talk among components of the immune system has contributed to an appreciation of clinical observations about the role the spleen plays in normal biology. The sensitive interactions between hematopoiesis, recycling of aging cells, and iron metabolism is most clearly demonstrated in the spleen.

Although not necessary to life under baseline circumstances, the contribution of the spleen to homeostasis under stress is considerable. Ongoing efforts to preserve and manage splenic function will benefit from enhanced appreciation of the underlying biology.

*Numbers of leukocytes are in thousands per mm^3, ranges are estimates of 95% confidence limits, and percentages refer to differential counts. Neutrophils include band cells at all ages and a small number of metamyelocytes and myelocytes in the first few days of life.

**Normal ranges vary slightly depending on automated analyzer used. The total leukocyte count is used to convert percentage values to absolute counts. Some automated hematology analyzers provide a full or limited differential.

*Data from 188 pediatric outpatients (0–18 years of age) for whom all hematologic parameters are within age-appropriate reference ranges. Unpublished data from Lucile Packard Children's Hospital at Stanford. Analysis was performed on Beckton Dickenson FACSCAlibur flow cytometer. Results are expressed as mean +1 SD (min/max).

†Data from Herkner KR, Bock A, et al: Reticulocyte counting and maturity grading in pediatrics using the Sysmex R-1000 automated reticulocyte analyzer. Sysmex J Int 2:4, 1992.

Note: Flow cytometry may yield results 0.5% to 1.0% higher than microscopy following supravital staining.

Table 4 Estimated Blood Volumes

Age	Plasma Volume (PV) (mL/kg)	Red Blood Cell Mass* (RCM) (mL/kg)	Total Blood Volume (mL/kg)	
			From PV	From RCM
Newborn	41.3 46.0	43.1	82.1 78.0	86.1 84.7
1–7 days	51–54	37.9	82–86	77.8
1–12 months	46.1	25.5	78.1	72.8
1–3 years	44.4 47.2	24.9	73.8 81.8	69.1
4–6 years	48.5 49.6	25.5	80.0 85.6	67.5
7–9 years	52.2 49.0	24.3	87.6 86.1	67.5
10–12 years	51.9 46.2	26.3	87.6 83.2	67.4
13–15 years	51.2		88.3	
16–18 years	50.1		90.2	
Adults	39–50	20–35	68–88	55–75

The red cell volume, plasma volume, and total blood volume are calculated from hematocrit (packed cell volume) and isotope dilution after reinjection of red cells labeled with a radioactive isotope.

*Red cell volume is approximately 5 mL/kg less in females compared to males. Performance of a red cell mass is only occasionally indicated in the investigation of polycythemia to differentiate primary of secondary polycythemia (elevated red cell mass) from relative polycythemia (normal red cell mass). Data from Price DC, Ries C: Appendix. In Handmaker H, Lowenstein JM (eds.): Nuclear Medicine in Clinical Pediatrics. New York, Society of Nuclear Medicine, 1975, p 279. Red cell volume reference from ICSH. J Nuclear Med 21:793, 1980.

Table 5 Red Blood Cell Enzyme Activity in Adults and Term Infants*

Enzyme	Adults ($n = 20$)	Infants ($n = 10$)
Hexokinase	12.9 ± 2.1	34.0 ± 6.0
Phosphoglucose isomerase	406 ± 37	560 ± 112
Phosphofructokinase	148 ± 24.5	84.5 ± 24
Aldolase	24.5 ± 3.7	42.0 ± 10.0
Glyceraldehyde-3-phosphate dehydrogenase	885 ± 127	884 ± 245
Triosephosphate isomerase	26,323 ± 3240	29,111 ± 4100
Phosphoglycerate kinase	2795 ± 144	3926 ± 528
Phosphoglycerate mutase	751 ± 99	1049 ± 160
Enolase	252 ± 54	517 ± 121
Pyruvate kinase	179 ± 16	256 ± 50
Lactic dehydrogenase	2033 ± 287	2756 ± 425
Glucose-6-phosphate dehydrogenase	215 ± 18	328 ± 40

*Infant samples were obtained from newborns weighing more than 2800 g whose gestational age was 39 weeks or greater. Blood was drawn within 24 hours of birth. All the newborns were clinically healthy. Adult samples were obtained from healthy, normal volunteers. Units per 100 mL of red blood cells.
Data from Oski FA: Red cell metabolism in the newborn infant, V: Glycolytic intermediates and glycolytic enzymes. Pediatrics 44:84, 1969.

Table 6 Red Cell Glycolytic Intermediate Metabolites in Normal Adults, Term Infants, and Premature Infants*

Metabolite	Normal Adults (n = 10)	Term Infants (n = 10)	Premature Infants (n = 11)
Glucose-6-phosphate	24.8 ± 9.8	45.2 ± 8.7	66.8 ± 34.8
Fructose-6-phosphate	5.4 ± 1.0	9.9 ± 2.3	20.5 ± 8.9
Fructose-1,6-diphosphate	4.6 ± 1.0	3.8 ± 0.7	3.6 ± 0.8
Dihydroxyacetone phosphate	4.9 ± 3.5	11.9 ± 5.0	18.6 ± 10.7
Glyceraldehyde-3-phosphate	2.6 ± 0.7	1.9 ± 1.6	6.5 ± 3.2
3-Phosphoglycerate	61.6 ± 12.4	58.2 ± 14.4	47.5 ± 14.2
2-Phosphoglycerate	4.3 ± 1.8	4.9 ± 1.6	4.4 ± 2.5
Phosphoenolpyruvate	8.8 ± 2.6	7.6 ± 2.9	7.4 ± 3.0
Pyruvate	73.5 ± 33.1	70.4 ± 32.3	78.4 ± 4.15
2,3-Diphosphoglycerate	4423 ± 1907	3609 ± 800	3152 ± 2133

*Premature infants had birth weight below 2200 g and gestational age of <37 weeks and were clinically healthy at the time of investigation.
Data from Oski FA: Red cell metabolism in the newborn infant, V: Glycolytic intermediates and glycolytic enzymes. G6PD deficiency. Pediatrics 44:84, 1969; and Beutler E. Blood 84(11):3613, 1994. Units per 100 mL of red blood

*Data from Schroter W, Nafz C: Diagnostic significance of hemoglobin F and A_2 levels in homo- and heterozygous β-thalassemia during infancy. Helv Paediatr Acta 36:519, 1981.
†Data from Metaxotou-Mavromati AD, Antonopoulou HK, Laskari SS, et al: Developmental changes in hemoglobin F levels during the first 2 years of life in normal and heterozygous β-thalassemia infants. Pediatrics 69:738, 1982.
Note: Hemoglobin F increases with beta-thalassemias, hereditary persistence of fetal hemoglobin and bone marrow failure syndromes. Hemoglobin A_2 increases with beta-thalassemias, megaloblastic anemias, and thyrotoxicosis; it may be reduced with iron deficiency, lead poisoning, anemia of chronic disease, sideroblastic anemia, and hypothyroidism.

Table 8 Hemoglobin A Levels (%) in Normal and Heterozygous β-Thalassemia Infants During the First 2 Years of Life

Age (month)	Normal Mean ± SD	Heterozygotes Mean ± SD
1	0.8 ± 0.4	. . .
2	1.3 ± 0.5	1.8 ± 0.3
3	2.2 ± 0.6	3.8 ± 0.9
4	2.4 ± 0.4	4.0
5–6	2.5 ± 0.3	5.2 ± 0.7
7–9	2.7 ± 0.4	5.3 ± 0.7
10–12	2.7 ± 0.4	5.0 ± 0.6
13–16	2.6 ± 0.5	5.4 ± 0.8
17–20	2.9 ± 0.4	5.5 ± 0.6
21–24	2.8 ± 0.4	5.6 ± 0.9

HbA_2 is usually elevated in the β-thalassaemias, and in unstable B-chain hemoglobinopathies. Data from Metaxotou-Mavromati AD, Antonopoulou HK, Laskari SS, et al: Developmental changes in hemoglobin F levels during the first two years of life in normal and heterozygous β-thalassemia infants. Hemoglobin A2: origin, evolution, and after math. Pediatrics 69:736, 1982; and Steinberg MH, Adams JG: Blood 78:2165, 1991.

*Assessment of iron status may be complicated by the presence of an acute phase reactants and/or liver disease. Serum ferritin is generally the preferred test for assessing iron deficiency. Ferritin levels reflect bone marrow iron stores and are decreased in iron deficiency. Higher ferritin levels (up to 100 µg/L) may be found in patients with iron deficiency and inflammatory disease/malignancy (acute phase response). Soluble transferrin receptor levels are not affected in an acute phase response and therefore may be more useful in selected patient since levels are normal in anemia of chronic disease uncomplicated by iron deficiency.

**Using immunoassay techniques, Ferritin levels in adult women and men may range from 15–200 µg/L to 30–300 µg/L, respectively. Ferritin levels in women following menopause progressively approach those for adult males. Brugnara C: Iron deficiency and erythropoiesis: new diagnostic approaches. Clin Chem 2003 Oct; 49(10):1573--8. Clin Chem 49(10):1573, 2003; and Cook JD: The measurement of serum Narsferrin receptor. Am J. Med Sci. 1999 Oct; 318(4):269--76. Am J Med Sci 318:269, 1999.

***From Soldin SJ, Morales A, et al: Pediatric reference ranges on the Abbott Imx for FSH, LH, prolactin, TSH, T4, T3, free T4, free T3, T-uptake, IgE, and ferritin. Clin Biochem 28:603, 1995. Study was based on hospitalized patients. Values represent 2.5th and 97.5th percentiles.

†From Lockitch G, Halstead AC, et al: Age- and sex-specific pediatric reference intervals for zinc, copper, selenium, iron, vitamins A and E, and related proteins. Clin Chem 34:1625, 1988. Study was based on healthy children; children with anemia, microcytosis, and thalassemia syndromes were excluded. Values represent the 0.025 and 0.975 fractiles.

‡No significant differences between males and females; range derived from combined data.

§From Soldin SJ, Brugnara C, et al: Pediatric Reference Ranges, 2nd ed. Washington, DC, AACC Press, 1997, pp 100, 101, 143.

¶Transferrin saturation calculated from iron (µmol/L)/total iron binding capacity. Transferrin, transferrin saturation and total iron binding capacity results are misleading in patients receiving iron therapy. Note that the lower reference limits for serum iron and transferrin saturation in this study are below the limits used to define acceptable levels for nutritional health for these two analytes (see O'Neal RM, Johnson OC, Schaefer AE: Guidelines for the classification and interpretation of group blood and urine data collected as part of the National Nutritional Survey. Pediatr Res 4:103, 1970).

Table 10 Reference Ranges for Serum Haptoglobin by Age

	Hemoglobin-Binding Capacity (mg/dL)	
Age	***Mean***	***Range (95%)***
Cord blood	0	0
1–7 days	10	0–41
1–4 weeks	28	0–45
1–3 months	59	41–95
3–6 months	91	64–134
6–12 months	115	43–160
1–5 years	109	51–160
5–10 years	107	62–186
>10 years	110	41–165

Data from Kalil M, Badr-El-Din MK, Kassem AS: Haptoglobin level in normal infants and children. Alex Med J 13:1, 1967.

Note: Serum haptoglobin is often used to evaluate hemolysis (especially intravascular) but reduced levels can also result from hepatocellular disease, massive tissue hemorrhage and congenital deficiency states. High levels can be seen with pregnancy and in acute phase responses which may confound assessment for hemolysis.

Table 11 Plasma Levels of Folic Acid and Vitamin B_{12} in Children

Age	Males	Females
Folic Acid	***nmol/L***	***nmol/L***
0–1 years	16.3–50.8	14.3–51.5
2–3 years	5.7–34.0	3.9–35.6
4–6 years	1.1–29.4	6.1–31.9
7–9 years	5.2–27.0	5.4–30.4
10–12 years	3.4–24.5	2.3–23.1
13–18 years	2.7–19.9	2.7–16.3
Vitamin B_{12}	***pmol/L***	***pmol/L***
0–1 years	216–891	168–1117
2–3 years	195–897	307–892
4–6 years	181–795	231–1038
7–9 years	200–863	182–866
10–12 years	135–803	145–752
13–18 years	158–638	134–605

Data were collected from hospitalized patients; 2.5th to 97.5th percentile values adapted from the Hoffman technique. Specimens from >100 patients in each age group were analyzed by radioimmunoassay.

Data from Hicks JM, Cook J, et al: Vitamin B_{12} and folate: pediatric reference ranges. Arch Pathol Lab Med 117:704, 1993.

Note: Serum folate may be decreased despite normal red blood cell folate during periods of systemic illness and decreased short-term folate intake.

Table 12 Serum Erythropoietin Levels in Term Infants During the First Year of Life*

Days After Birth	Erythropoietin (mU/mL)	Hemoglobin (g/dL)	RBC ($\mu 10^6/\mu L$)
0–6	33.0 ± 31.4 (11)	15.6 ± 2.2 (11)	4.51 ± 0.74 (11)
7–50	11.7 ± 3.6 (7)	12.8 ± 1.1 (5)	3.92 ± 0.35 (5)
51–100	21.1 ± 5.5 (13)	11.4 ± 1.0 (10)	4.09 ± 0.51 (10)
101–150	15.1 ± 3.9 (5)	11.2 ± 1.1 (3)	4.21 ± 0.31 (3)
151–200	17.8 ± 6.3 (6)	—	—
>201	23.1 ± 9.7 (10)	11.8 ± 0.8 (9)	4.57 ± 0.24 (9)

*Values are expressed as means ± SD; parentheses enclose number of specimens. Patients were not transfused and weighed ≥2500 g.
Data from Yamashita H, Kukita J, et al: Serum erythropoietin levels in term and preterm infants during the first year of life. Am J Pediatr Hematol Oncol 16:213, 1994.

Table 13 Plasma Erythropoietin Reference Ranges in Children*

Age (year)	Number	Male Subjects	Number	Female Subjects
1–3	122	1.7–17.9	97	2.1–15.9
4–6	89	3.5–21.9	76	2.9–8.5
7–9	79	1.0–13.5	80	2.1–8.2
10–12	98	1.0–14.0	90	1.1–9.1
13–15	100	2.2–14.4	148	3.8–20.5
16–18	66	1.5–15.2	77	2.0–14.2

*Values are expressed in mIU/mL. Data were obtained from a total of 1122 hospitalized and outpatient children ages 1 to 18 years, using a commercially available enzyme-linked immunosorbent assay methodology. Values are 2.5th to 97.5th percentiles.

Data from Krafte-Jacobs B, Williams J, Soldin SJ: Plasma erythropoietin reference ranges in children. J Pediatr 126:601, 1995.

The measurement of erythropoietin is occasionally indicated in the differentiation of polycythemia vera (decreased) and secondary erythrocytosis (elevated) but in practice the test is unreliable with a broad overlap between the two groups. Erythropoietin levels are usually increased in anemia except in chronic renal failure patients with anemia. Erythropoietin levels may be used to monitor erythropoietin therapy in patients with chronic renal failure. The reference range is method dependent. Adult values are approximately 3 to 16 mIU/mL. Coles PM et al: N Engl J Med 315:283, 1986.

Table 14 Comparison of Selected Coagulation Factor Values in Newborns*

Study	Fibrinogen (mg/dL)	Factor II (U/mL)	Factor VIII (U/mL)	Factor IX (U/mL)	Factor XII (U/mL)	Antithrombin (U/mL)	Protein C (U/mL)

Hathaway and Bonnar (1987) and Manco-Johnson et al (1988)†	300 (120)	0.45 (0.26)	0.93 (0.54)	0.41 (0.20)	0.33 (0.23)	0.40 (0.25)	0.24 (0.18)
Andrews et al (1987, 1988)‡	243 (150)	0.45 (0.20)	1.1 (0.50)	0.35 (0.19)	0.38 (0.10)	0.38 (0.14)	0.28 (0.12)
Corrigan (1992)§	240 (150)	0.35 (0.21)	1.36 (0.21)	0.35 (0.10)	0.22 (0.09)	0.35 (0.10)	0.28 (0.12)

*Data are expressed as mean and lower limits of normal (in parentheses). Preterm, 30 to 36 weeks' gestational age.

†From Hathaway W, Bonnar J: Hemostatic Disorders of the Pregnant Woman and the Newborn Infant. New York, Elsevier Science, 1987; Manco-Johnson M, Marlar R, et al: Severe protein C deficiency in newborn infants. J Pediatr 113:359, 1988.

‡From Andrews M, Paes B, et al: Development of the human coagulation system in the full-term infant. Blood 70:165, 1987; Andrews M, Paes B, et al: Development of the human coagulation system in the healthy premature infant. Blood 72:1651, 1988.

§From Corrigan JJ Jr: Normal hemostasis in fetus and newborn: coagulation. In Polin RA, Fox WW (eds.): Fetal and Neonatal Physiology. Philadelphia, WB Saunders, 1992, p 1368; From Hathaway W, Corrigan J: Report of scientific and standardization subcommittee on neonatal hemostasis. Thromb Haemost 65:323, 1991.

Note: In summary, plasma levels of the vitamin K-dependent factors (including proteins C and S), contact factors and antithrombin are decreased at birth.

Table 15 Changes in Prothrombin Time (PT), Activated Partial Thromboplastin Time (aPTT), and Thrombin Time (TT) in Term and Premature Infants

	PT	aPTT	TT
Normal control	1	1	1
Term infants (ratio)	1.15–1.3	1.2–1.5	1.16–1.4
(increase in seconds)	(3–4 seconds)		
Small preterm (ratio)	1.30	1.4–2.4	1.31–1.50
(increase in seconds)	(4–5 seconds)		

Owing to the variability of normal values for these tests, the results are expressed as a ratio of the newborn clotting times to the mean value for adult controls. Small preterm: less than 32 weeks of gestational age; data from Hathaway W, Corrigan J: Report of scientific and standardization subcommittee on neonatal hemostasis. Thromb Haemost 65:323, 1991.

Table 16 Reference Values for Coagulation Tests in Healthy Children Aged 1–16 Years Compared With Normal Adults*

*All factors except fibrinogen are expressed as units per milliliter, where pooled plasma contains 1.0 U/mL. All data are expressed as the mean, followed by the upper and lower boundaries encompassing 95% of the population. Between 20 and 50 samples were assayed for each value for each age group. Some measurements were skewed due to disproportionate number of high values. The lower limit, which excludes the lower 2.5% of the population, is given.

APTT, activated partial thromboplastin time; HMWK, high molecular weight kininogen; PK, prekallikrein; PT, prothrombin time; VII, factor VII procoagulant; vWF, von Willebrand factor.

†Values that are significantly different from values in adults.

Data from Andrew M, Vegh P, Johnston M, Bowker J, Ofosu F, Mitchell L: Maturation of the hemostatic system during childhood. Blood 80:1998, 1992.

Consult this reference for additional reference range data for the anticoagulant and fibrinolytic systems in these age groups.

**Note: Owing to concerns regarding its reproducibility, sensitivity and specificity, the bleeding time is considered obsolete at many centers, and has often been replaced by tests such as the PFA-100® (see table 18).

Table 17 Reference Values for the Inhibitors of Coagulation in Fetuses, Full-Term Infants, and Adults*

Table 18 PFA-100® Closure Times in Healthy Neonates, Children and Adults

	Collagen/Epinephrine (seconds)	Collagen/ADP (seconds)
Term neonates ($n = 17$)	81 (61–108)	56 (48–65)
Children ($n = 57$)	117 (83–163)	91 (72–111)
Adults ($n = 31$)	106 (82–142)	85 (67–111)

Data from Carcao MD, Blanchette VS, Dean JA, et al: Br J Haematol 101(1):70, 1998. Mean and ranges given as 5th to 95th percentiles. Determination of site-specific reference ranges is recommended as longer reference closure times have also been reported. The assay assesses platelet and von Willebrand factor function under shear conditions but abnormal closure times may also occur with anemia, thrombocytopenia, and/or antiplatelet therapy.

Table 19 Complement Fractions C3 and C4 in Males and Females, by Age*

Study	Age	g/L
C3		
Zillow et al (1993)†	Healthy neonates	0.30–0.98
Lockitch et al (1988)†	0–5 days	0.26–1.04
	1–19 years	0.51–0.95
	Adult	0.45–1.8
C4		
Lockitch et al (1988)‡	0–5 days	0.06–0.37
	1–19 years	0.08–0.44
	Adult	0.11–0.5

*Interpretation: Reduced C4 with or without reduced C3 implies classical pathway activation as seen in SLE , immune complex disease and hereditary angioedema due to C1 inhibitor deficiency. Reduced C3 with normal C4 implies activation by the alternative pathway (eg, sepsis). Elevated C3 and/or C4 implies an acute phase response. Primary deficiency is rare and requires functional assay. Wen L, et al: J Allergy Clin Immunol 113:585, 2004.
†From Zilow G, Zilow EP, Burger R, Linderkamp O: Complement activation in newborn infants with early onset infection. Pediatr Res 1993 Aug;34(2):199–203. Results are 0th to 100th percentiles. Thirty-two healthy full-term newborns, birth weights between 2500 and 4020 g, were tested. All mothers (vagina, rectum) and infants (ear, gastric) were culture negative.
‡Lockitch G, Halstead AC, Quigley G, et al: Age- and sex-specific pediatric reference intervals: Study design and methods by measurement of serum proteins with the Behring LN nephelometer. Clin Chem 1988 Aug 34(8):1618–21. Results are 0.025 to 0.975 fractiles.

IgA levels and immunoglobulin levels in general are used for the assessment of patients with recurrent sinopulmonary infection, sepsis, gastrointestinal infection or other clinical presentations suggestive of immunoglobulin deficiency. If concern regarding presence of a paraprotein electrophoresis ± immunofixation is required. Reference intervals may vary with methodology and with the racial composition of the population.

13 years	6.1–11.5	0.9–7.9	0.2–1.1	0.1–0.8
Adults	4.8–9.5	1.1–6.9	0.3–0.8	0.2–1.1

*Values for males and females, expressed in g/L. Twenty schoolchildren from each age group were tested. Only samples with C-reactive protein within the reference range were included. Enzyme-linked immunosorbent assay methodology was used on serum.

From Miles J, Riches P: The determination of IgG subclass concentrations in serum by enzyme-linked immunosorbent assay: Establishment of age-related reference ranges for cord blood samples, children aged 5 to 13 years and adults. Ann Clin Biochem 31:245, 1994.

Performing IgG subclasses has a limited role for the assessment of antibody-mediated immune function in patients with recurrent sinusitis and respiratory infections. IgG subclass deficiency may be associated with recurrent bacterial infection. Seventy percent of serum IgG is IgG1—selective IgG1 deficiency is rare. The most frequent abnormality is IgG2 deficiency, or a combined IgG2-IgG4, deficiency. IgG2 deficiency may be associated with IgA deficiency in patients with chronic respiratory infection. Decreased IgG3 levels may be seen in primary immunodeficiencies (eg Wiskott–Aldrich syndrome) and in type I diabetes mellitus. The significance of decreased IgG4 in absence of IgG2 deficiency is uncertain. Maguire G. Ann Clin Biochem 39:4:374, 2002.

Table 25 Serum Levels of Immunoglobulin Light Chains in Males and Females*

Age	Kappa (g/L)	Lambda (g/L)	Kappa/Lambda Ratio
Newborn	8.10 (7.7–8.7)	4.70 (4.5–5.0)	1.74 (1.7–1.9)

15 years	10.18 (7.2–11.0)	4.75 (4.1–5.0)	2.25 (1.7–2.3)
16 years	9.37 (7.0–11.2)	5.09 (4.6–5.6)	1.89 (1.5–2.2)

*Median and ranges given as 10th to 90th percentiles.

Data from Herkner KR, Salzer H, et al: Pediatric and perinatal reference intervals for immunoglobin light chains kappa and lambda. Clin Chem 38:548, 1992.

The measurement of free light chains is predominantly performed for the diagnosis and monitoring of amyloid, non-secretory myeloma and light chain myeloma. The kappa/lambda ratio is critical since an excess of kappa versus lambda or excess lambda versus kappa light chains is consistent with a plasma cell dyscrasia. Bradwell D. et al: Lancet 36(4);89, 2003.

*Values are expressed as 95th percentile reference range.
%, relative percentage; A, absolute cell count $\times 10^9$/L.
Samples analyzed by Epics Profile (Coulter) flow cytometer following whole blood lysis.
Data from Kotylo PK, Fineberg NS, et al: Reference ranges for lymphocyte subsets in pediatric patients. Am J Clin Pathol 100:111, 1993. See also Denny T, Yogev R, et al: Lymphocyte subsets in healthy children during the first 5 years of life. JAMA 267:1484, 1992. Copyright 1992, American Medical Association.
Note: Values may also vary with gender, diurnal rhythm, and other physiological variables.

Table 27 Total Bilirubin in Premature and Full-Term Infants

	Premature	Full-Term
	mg/dL	***mg/dL***
Cord blood*	<2.0	<2.0
0–1 days*	<8.0	<6.0
1–2 days*	<12.0	<8.0
2–5 days*	<16.0	<12.0
>5 days*	<2.0	0.2–1.0
	μmol/L	***mg/dL***
Bottle-fed infants†	<212	<12.4
Breast-fed infants†	<253	<14.8

*Data from Behrman RE (ed.): Nelson Textbook of Pediatrics, 14th ed. Philadelphia, WB Saunders, 1992, p 1803.
†Data from Maisels MJ, Gifford K: Normal serum bilirubin levels in the newborn and the effect of breast feeding. Pediatrics 78:837, 1986. Represents 97th percentile rank for white neonates of >2500 g birth weight.
Note: A clinical practice guideline pertinent to the management of neonatal hyperbilirubinemia is available from the American Academy of Pediatrics: Pediatrics 114(1):297, 2004.

INDEX

histone deacetylase inhibitors for, 861–865, 862t, 863t
in Hodgkin lymphoma, 1245–1255, 1246t, 1248t, 1252t, 1253t, 1258–1259, 1261–1262
in hypereosinophilic syndrome, 1180t, 1182, 1184
hypomethylating agents for, 850
immune impairment with, 1461
immunomodulatory agents for, 852–853
in indolent non-Hodgkin lymphoma, 1286t, 1287, 1288
infection and, 1465–1470, 1466t, 1469f
in juvenile myelomonocytic leukemia, 1204
in Langerhans cell histiocytosis, 754b, 755–756, 755t
late effects of, 1539–1544, 1548t–1551t
low-molecular-weight heparin with, 1811
lymphopenia with, 2317–2318
in mantle cell lymphoma, 1298
mechanisms of action of, 843f
megaloblastosis with, 515, 515b, 516b
methylating agents for, 845–846, 872
monoclonal antibodies for, 856
in multiple myeloma, 1402–1408
in myelodysplastic syndromes, 1070, 1201
nausea with, 1512–1515, 1512b, 1513b, 1514b, 1515b
neurocognitive effects of, 1542, 1548t
neutropenia with, 707t, 918, 2317
nitrogen mustard for, 843–845, 844f, 874–875
in non-Hodgkin lymphoma, 1286t, 1287, 1288, 1324
nutritional complications of, 1476, 1477t, 1478
ocular effects of, 1542, 1548t
Omi peptide for, 856
oral complications of, 1465, 1510–1511
in peripheral blood hematopoietic cell mobilization, 1702
peripheral neuropathy with, 1511–1512, 1548t
platelet sparing with, 421
platinum analogs for, 849, 891–892
in polycythemia vera, 1101–1102, 1101b, 1102b, 1103, 1206
in posttransplant lymphoproliferative disorder, 1454
in precursor T-cell lymphoblastic lymphoma, 1300
in primary myelofibrosis, 1138–1141
proapoptotic agents for, 853–856, 854f, 855t
pulmonary toxicity of, 1540, 1549t
in pure red cell aplasia, 399–400, 399t
RAF1/MEK/ERK pathway inhibitors for, 859–861, 861f
Antineoplastic agents *(Continued)*
in relapsed Hodgkin lymphoma, 1258–1259
renal effects of, 1550t
resistance to, 868–872, 869t, 870f, 871f
survivin antagonists for, 856
in T-cell large granular lymphocyte leukemia, 408–409, 409f
teratogenicity of, 2387
thrombocytopenia with, 421, 2125t, 2127, 2318
thrombosis with, 2037–2038
thrombotic microangiopathy with, 2109
TRAIL for, 856
ubiquitin-proteasome inhibitors for, 851–852
vomiting with, 1512–1515, 1512b, 1513b, 1514b, 1515b
in Waldenström macroglobulinemia, 1418–1419
Antineutrophil antibodies, 401, 401t, 402
in autoimmune neutropenia, 711
in chronic benign neutropenia of infancy and childhood, 709
in systemic lupus erythrmatosus, 711
Antiphospholipid antibody (antibodies), 1979–1983, 1981t, 2129. *See also* Anticardiolipin antibodies; Lupus anticoagulant

Superwarfarins, 1976, 1976b
Support groups, 1494, 1498, 1499t
Sural nerve biopsy, in primary amyloidosis, 1437
Suramin, coagulopathy with, 1997
Surfactant, pulmonary, 97t
Surgery
anticoagulant management for, 2079, 2375–2379, 2376t
atrial fibrillation and, 2377
bleeding with, 1856–1857, 1859t
in cardiopulmonary bypass, 2375
intraoperative, 2374–2376
in liver transplantation, 2375
massive, 2375
preoperative evaluation for, 2369–2370, 2370t, 2373
prevention of, 2370–2373
aminocaproic acid in, 2371
antifibrinolytics in, 2371–2372
aprotinin in, 2371–2372
DDAVP in, 2370
fibrin sealants in, 2370–2371
recombinant factor VIIa in, 2372–2373
topical thrombin in, 2371
tranexamic acid in, 2371
risk for, 2369–2370, 2370t
dental, 1925, 2378
heparin-induced thrombocytopenia and, 2121
in kidney disease patient, 2373–2374
in liver disease patient, 2374
neutrophilia after, 703
orthopedic
anticoagulation with, 2380–2381
antifibrinolytic agents with, 2371
Surgery *(Continued)*
in platelet dysfunction patient, 2373
in polycythemia vera patient, 1094–1095, 1105
in prosthetic heart valve patient, 2377–2378
recombinant erythropoietin before, 911
spinal, 2375
in thrombocytopenic patient, 2373
after venous thromboembolism, 2376–2377
venous thromboembolism with, 2034–2035, 2376–2377, 2379–2382
epidemiology of, 2379
in gynecologic patient, 2050, 2381–2382
natural history of, 2379
in neurosurgical patient, 2050, 2381
in orthopedic patient, 2050, 2380–2381
prophylaxis against, 2049–2051, 2379–2381, 2379t, 2380t
in renal transplantation, 2382
in trauma patient, 2035, 2050, 2381
treatment of, 2051–2053, 2382
in von Willebrand disease, 1969–1970, 1969b, 1971t
Survivin antagonists, 856
Survivor
followup care for, 1546–1551, 1546b, 1547b, 1547t, 1548t–1551t
psychosocial factors and, 1491, 1494–1495, 1495t, 1544. *See also* Psychosocial factors/disorders
Sweet syndrome
in AML, 937, 937f
in myelodysplastic syndrome, 1057
in primary myelofibrosis, 1132
Switch culture systems, 205
Syndecan-1 (CD138), in multiple myeloma, 1389, 1389f, 1402
Syndesmos, endothelial, 1806
Synovectomy, radionuclide, in hemophilia, 1924–1925
Syphilis
paroxysmal cold hemoglobinuria and, 654–655, 656
screening for, 1471
transfusion-related, 2285
Systemic lupus erythematosus (SLE)
anticardiolipin antibodies in, 1979, 2398
autoantibodies in, 181, 1996, 2408
autoimmune hemolytic anemia and, 656
in children, 2408
complement deficiency in, 675
fibrin inhibitors in, 1996
hematopoietic cell transplantation in, 1573
immune thrombocytopenic purpura in, 2089–2090
lupus anticoagulant in, 1979. *See also* Lupus anticoagulant
neutropenia in, 711, 2315
platelet dysfunction in, 2157
pregnancy and, 1989–1990
thrombocytopenia in, 2089–2090, 2128–2129, 2315–2316
thromboembolism in, 2408
Systemic sclerosis, hematopoietic cell transplantation in, 1572

T

T cell(s), 98, 117–127, 151. *See also* B cell(s); T-cell receptor (TCR)
activation of, 139–140, 139t, 152, 153f
