1, grouped by gene defect thought to have a dominant and/or early effect in defining the biological and clinical characteristics of acute myelod leukemia (driver mutations); mutations in the genes NRAS and FLT3 are not included as they are acquired during clonal evolution, occur over a wide spectrum of leukemia types and do not define specific groups of AML; 2, Human Genome Organization accepted gene nomenclature/gene symbol; 3, common but not exclusively associated cytogenetic changes; 4, disease-defining molecular event; 5, salient morphologic, immunophenotypic and/or clinical features, not all listed; 6, of the more than fifty translocation partners of the MLL gene, only those most commonly associated with AML are listed; 7, the symbol indicates features similar to those described immediately above; 8, designated HOX AML group since the HOX gene, and not the NUP98 gene, appears to be responsible for leukemogenesis. APL, acute promyelocytic; AMML, acute myelomonocytic; AMKL, acute megakaryoblastic leukemia; MDS, myelodysplastic syndrome.

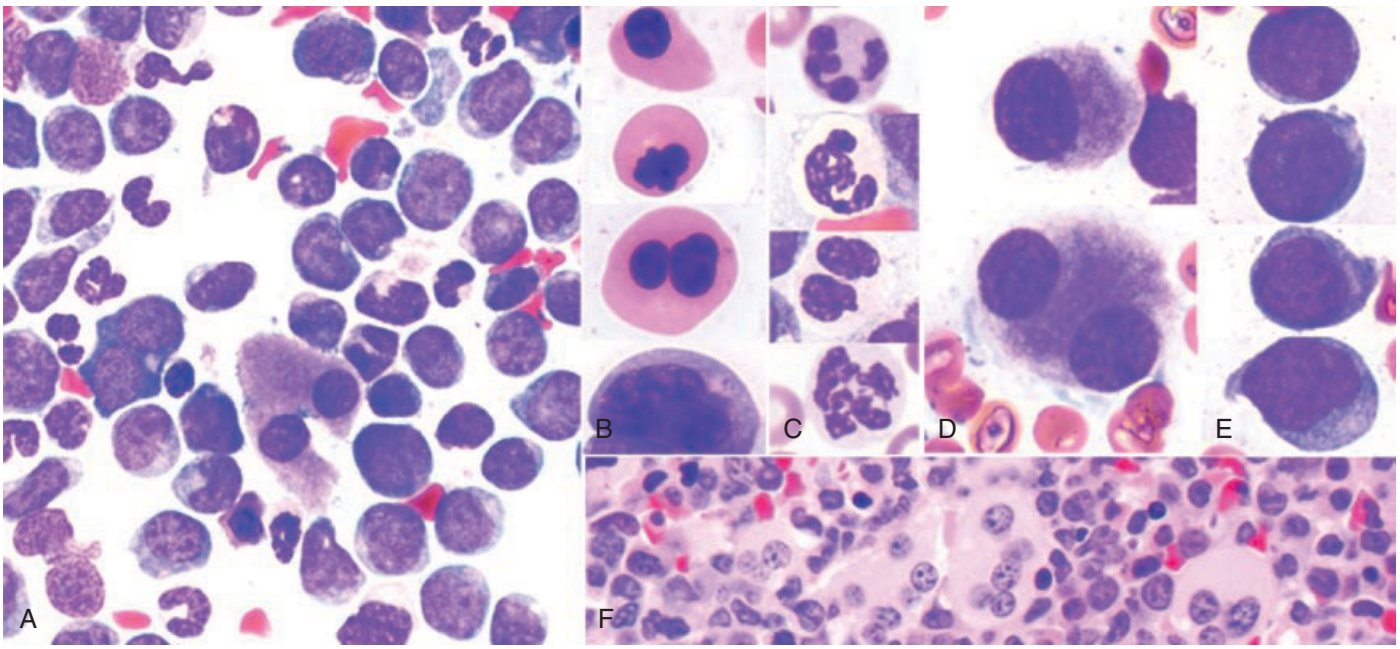

Figure 60–14 Acute myeloid leukemia with multilineage dysplasia. **A,** Bone marrow aspirate shows increased blasts and maturing cells with dysplastic features. **B–D,** Details of the dysplasia. **B,** Maturing erythroid elements exhibit megaloblastoid change and bizarre nuclear abnormalities. **C,** Dysplastic granulocytes (bottom three) are compared to a rare normal granulocyte (top). The dysplastic forms have pale cytoplasm and abnormal nuclear shapes with hypolobation, hypersegmentation, and prominent nuclear excrescences. **D,** Dysplastic micromegakaryocytes have single or double small nuclei but mature cytoplasm with platelet material within. **E,** Increased blasts. **F,** Dysplasia is difficult to appreciate on a biopsied section. This is true except for the megakaryocytes. Dysplastic megakaryocytes can be recognized on the biopsy sample by their abnormally small nuclei, which sometimes are multiple and widely spaced.

Cytogenetics and Genetics. AML-MLD typically exhibits gains and losses of entire or large segments of chromosomes found in MDS. Gains or losses of chromosomes are most common and include −5, −7/del(7q), +8, +9, +11, del(11q), del(12p), del(17p), −18, +19, del(20q), +21. Most of these partial or complete chromosome abnormalities are the same as those that characterize the alkylating agent–associated myelodysplastic syndrome (t-MDS) and secondary acute leukemia (t-AML).

Acute Myeloid Leukemia and Myelodysplastic Syndromes, Therapy-Related (30%–40% of Acute Myeloid Leukemias: M0 by FAB Classification)

The WHO recognizes the unique clinical and biologic features of the therapy-related leukemias (t-AML). This subtype results from prior exposure to cytotoxic chemotherapy and/or radiation therapy. A majority of patients have clonal cytogenetic abnormalities.[304] Secondary leukemias now account for approximately 40% of all AMLs.[305] The WHO recognizes two types of t-AML based on the type of prior exposure or treatment. Alkylating agent–related AML and topoisomerase II inhibitor–related AML have different clinical patterns and cytogenetic abnormalities (Table 60–10).

Alkylating Agent–Related Acute Myeloid Leukemia and Myelodysplastic Syndrome

Alkylating agent/radiation–related disorders occur 5 to 7 years after exposure and are generally preceded by a progressive MDS. The risk for developing AML is partly related to the total cumulative dose of the alkylating agent and the patient's age at the time of treatment.[305] A majority of patients present with dysplasia in two or more lines and are diagnosed with the MDS subtype refractory cytopenia with multilineage dysplasia. The majority of patients are older and respond poorly to chemotherapy. Expression of multidrug resistance glycoprotein 1 (MDR-1) is increased, and many cases are refractory to standard induction chemotherapy.[306]

Table 60–10 Secondary AML (Therapy-Related AML)

	Topoisomerase II Inhibitor	Alkylator
Latency	18–36 months	60–84 months
Morphology	Monocytic	Undifferentiated
Cytogenetics	11q23	Monosomy 7, 5q–, 7q–, trisomy 8
FAB type	M2, M3, M4	M0, M1
Prognosis	Variable–poor	Poor
Prior MDS	No	Yes

AML, acute myeloid leukemia; FAB, French-American-British; MDS, myelodysplastic syndrome

Morphology. The dysplastic changes usually are apparent on peripheral blood smear and include trilineage dysplasia with basophilic stippled red cells and prominent red cell shape abnormalities. Hypogranulated neutrophils with nuclear hypolobulation are common. Ringed sideroblasts are found in the majority of cases. The bone marrow usually is hypercellular for the patient's age. Bone marrow fibrosis occurs in approximately 15% of cases and results in teardrop-shaped red cells in the peripheral smear. Most patients present with a variable period of MDS, but some patients present with overt AML. Morphologically most of the cases correspond to acute leukemia with minimal maturation; however, the morphology may not be lineage specific.

Immunophenotype. The blasts usually express CD34 and myeloid markers, including CD13 and CD33. Aberrant expression of lymphoid markers, including CD56 and CD7, is common.

Cytogenetics and Genetics. More than 90% of patients have a clonal cytogenetic abnormality.[304] Abnormalities involving loss or

part of chromosomes 5 and/or 7 are most common. Deletions consisting of loss of all or part of the long arm of chromosomes 5 and/or 7 (5q–, 7q–) in addition to multiple complex chromosome abnormalities are common. As in the other subtypes of AML, the finding of complex cytogenetic abnormalities is associated with a poor response to chemotherapy and short overall survival.

Topoisomerase II Inhibitor–Related Acute Myeloid Leukemia

Topoisomerase II AML occurs in individuals all ages, has a short latency period, and is not generally preceded by an MDS or a period of pancytopenia. The time from exposure to the development of AML usually is 18 to 36 months. The most common drugs include the epipodophyllotoxins etoposide and teniposide and the anthracyclines doxorubicin and mitoxantrone. Morphologically most of the AMLs have a monocytic component, either acute monoblastic or acute myelomonocytic leukemia. APL and CBFB AMLs have been reported after administration of topoisomerase II inhibitors.

The most frequent cytogenetic finding is a balanced cytogenetic translocation involving 11q23 (*MLL* gene),[99] with the translocations t(9;11), t(11;19), and t(6;11) being the most common. Translocations involving 21q22 are the second most common.[307] The prognosis is variable and depends, in part, on the partner chromosome.

Acute Myeloid Leukemia Not Otherwise Categorized (Fig. 60–15)

AMLs that are not defined by previously noted criteria are subclassified into AML not otherwise categorized. The subclassification is similar to the FAB criteria and attempts to define the cell lineage using morphologic, immunophenotypic, and cytochemical criteria (see Table 60–8). The WHO not otherwise categorized criteria subdivide the myeloid leukemias according to their predominant cell type. Some cases of AML cannot be classified according to the WHO criteria. These unclassifiable cases are more frequent among patients with secondary leukemia and represent approximately 2% to 5% of all cases. The WHO includes the subclassification acute leukemia of ambiguous lineage to define a group of AML with blasts of indeterminate lineage. This group includes the hybrid or biphenotypic leukemias that cannot be classified on the basis of morphology or cytochemistry alone. The division between each of the myeloblast subtypes is somewhat arbitrary, and there is a spectrum of myeloid differentiation. The criteria are based on findings in the bone marrow aspirate and blood smear. The WHO does acknowledge that the biopsy is necessary for assessment of cellularity and for diagnosis of leukemias associated with fibrosis.

Acute Myeloblastic Leukemia, Minimally Differentiated (3%–5% of Acute Myeloid Leukemias; FAB M0 by FAB Classification)

Minimally differentiated AML (AML-MD) is a subtype of AML without morphologic or cytochemical evidence of myeloid differentiation. Myeloid differentiation can be ascertained only by immunophenotyping or, if necessary, by immunohistochemistry or ultrastructural cytochemistry.[308,309] AML-MD is more frequent in patients 60 to 80 years of age.[238] An elevated WBC count and extensive replacement of the bone marrow are common presenting findings.[238,310] The blast morphology is variable in this group but relatively homogeneous within each case.[309] The blasts have a pale basophilic to clear agranular cytoplasm without Auer rods. The nuclei chromatin texture usually is fine with prominent nucleoli. Multilineage dysplasia with prominent cytoplasmic budding is commpon.[309,310] Cytochemical stains reveal that less than 3% of the blast cells are MPO positive. Morphologically, the blasts may resemble megakaryoblasts or undifferentiated monoblasts or lymphoblasts. The majority of the cells express CD34, HLA-DR, CD13, and CD33. Coexpression of the lymphoid marker CD7 and TdT, a marker of immaturity, is present in more than one third of cases.[309,310] T- and B-cell lineage-specific markers are absent.[309]

AML-MD has no unique cytogenetic abnormality. The most common abnormalities are complex karyotypes, including abnormalities of chromosomes 7 and 8 and trisomy 13. A proportion of AML-MD with normal karyotype carries mutations of AML1 (RUNXS1) and/or FLT-3.[312] These findings suggest that AML-MD is composed of a group of disorders that represent an early stage of myeloid maturation that share a common morphologic phenotype but differ biologically and genetically. AML-MD is associated with a generally poor prognosis.[262,311]

Acute Myeloblastic Leukemia Without Maturation (10%–20% of Acute Myeloid Leukemias: FAB M1, M2 by FAB Classification)

AML without maturation is defined by ≥90% myeloblasts without evidence of maturation. The myeloid lineage is confirmed by greater than 3% of blasts staining with MPO or SBB. The bone marrow usually is hypercellular. The myeloblasts are poorly differentiated and contain rare azurophilic granules and occasional Auer rods. Nuclei are round or oval with fine chromatin and often, conspicuous nucleoli. There are less than 3% promyelocytes and less than 10% maturing granulocytes or monocytes. A distinctive but rare variant of leukemia with "cup-like" nuclei and fine azurophilic granules is classified in this morphologic category.[265,313] This variant can be easily confused both morphologically and immunophenotypically with the hypogranular variant of APL but has a normal karyotype.

Blast cells frequently express CD34, CD117, D13, and CD33. The mature monocyte markers CD14 and CD11b are rarely expressed, and, unlike AML-MD, the blasts rarely express TdT. Lymphoid lineage-specific markers are generally absent. Unlike AML-MD, more than half of the AMLs without maturation have a normal karyotype, and only 20% have complex karyotypes.[302] The prognosis is variable and depends on the prognostic variable of the specific case. Patients who present with hyperleukocytosis have a poor prognosis.

Acute Myeloblastic Leukemia with Maturation (25%–35% of Acute Myeloid Leukemias; FAB M2 by FAB Classification)

AML with maturation is defined by the presence of maturation to and beyond the promyelocyte stage (≥10%). Monocytes account for ≥20% of marrow or peripheral blood cells. This AML subtype is the largest group of morphologically defined AMLs.[302] This subtype is clinically heterogenous; 25% of patients younger than 25 years and 40% are older than 60 years. Hepatosplenomegaly and lymphadenopathy can be prominent presenting findings. Leukocytosis is present in half of patients, but leukopenia occurs in 25%.[314] Disseminated intravascular coagulation is present in up to 20% of patients. The percent of myeloblasts varies widely, but more mature neutrophils are always present and exhibit dysplastic features, including nuclear hyposegmentation (pseudo–Pelger-Huet anomaly) or hypersegmentation. Auer rods are present in 60% to 70% of cases. Azurophilic granules nearly always are present and range from few to many. Type II blasts may predominate in the bone marrow. Eosinophil precursors are increased but do not have the cytologic abnormalities characteristic of the eosinophils in AMML with inv^{16}. Increased basophils or mast cells may be noted and is associated with recurrent cytogenetic abnormalities, including t(6;9)(q22;q22) and translocations or deletions at 12p11–13. Rare cases present with erythrophagocytosis and are associated with t(8;16). The myeloblasts express the myeloid associated antigens CD13, CD33, and CD15. CD34, HLA-DR, and CD117 are variably expressed but less often than the immature AML subtypes. Up to 50% of cases have normal karyotypes, and

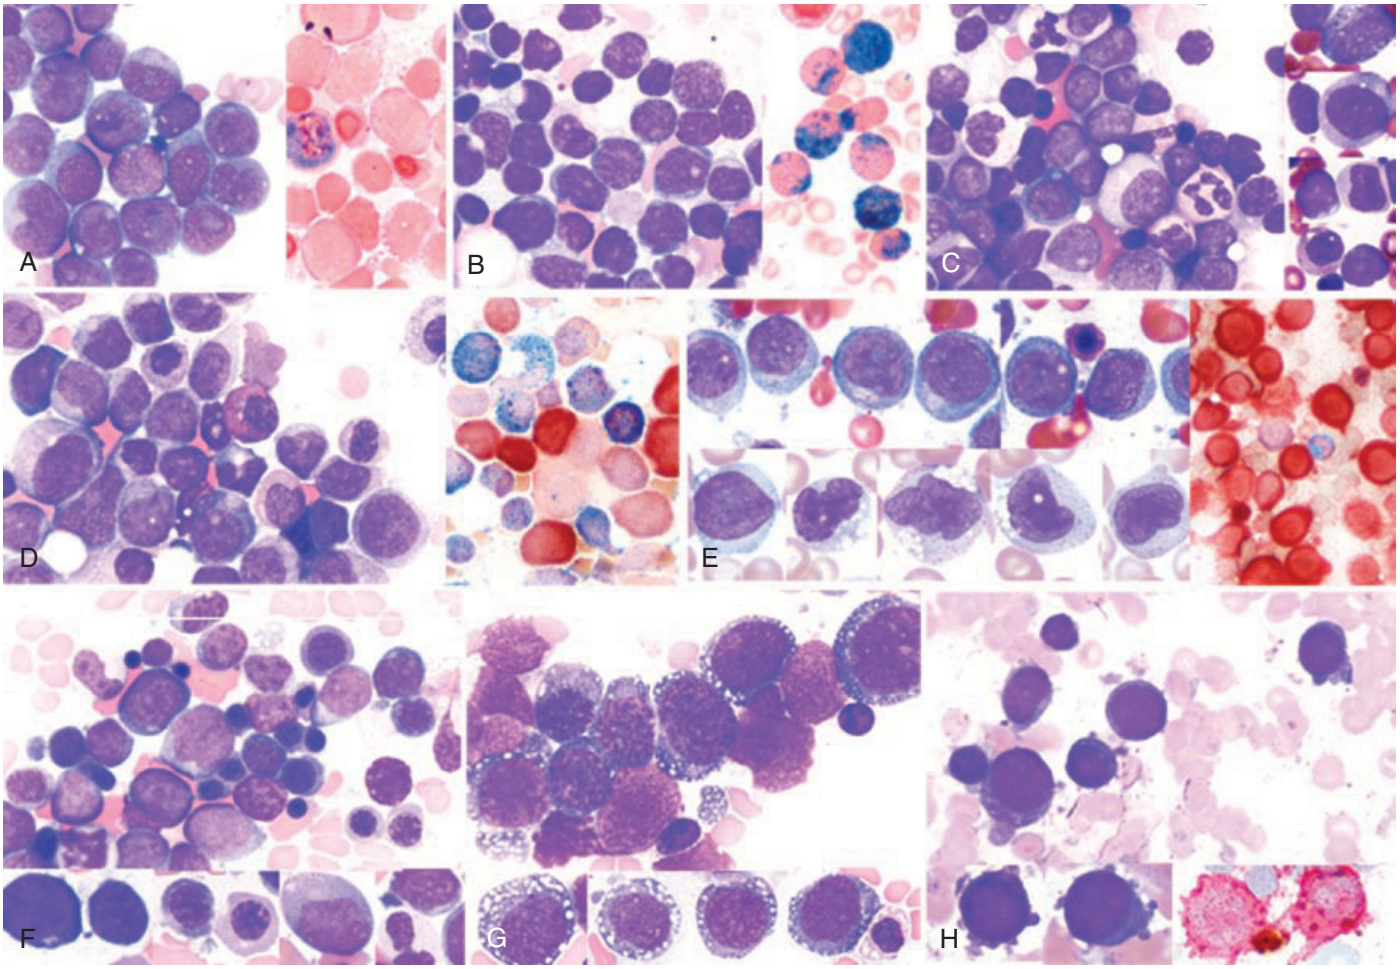

Figure 60–15 Acute myeloid leukemia not otherwise categorized (AML NOC). **A,** AML with minimal differentiation. Sheets of blasts are seen on the aspirate, and the myeloperoxidase reaction (right) is negative in the blasts. The rare positive neutrophil is useful as an internal control. To diagnose AML, flow immunophenotyping of the blasts must demonstrate myeloid markers. In this case, the blasts were CD13, CD33, and CD117 positive but negative for lymphoid markers. **B,** AML without maturation. Sheets of blasts are present, with fewer than 10% maturing granulocytes. The myeloperoxidase reaction (right) is positive in the blasts. **C,** AML with maturation. The aspirate (detail right) shows blasts, maturing granulocytes, and less than 20% monocytes. **E,** Acute myelomonocytic leukemia (AMML). The aspirate shows increased blasts, monocytes, and granulocytic maturation. The monocytic component may be difficult to see on Wright-stained aspirate smear but is obvious on the combined esterase reaction (**D,** right). The monocytes are butyrate esterase reaction positive (orange–brown), and the granulocytic cells are chloroacetate esterase reaction positive (blue). **E,** Acute monoblastic and acute monocytic leukemia. Cells from an acute monoblastic leukemia are illustrated in the top row and those from an acute monocytic leukemia are in the bottom row. Note the absence of differentiation above and differentiation to monocytes in the form of nuclear folding, cytoplasmic vacuolization, and faint granulation below. The combined esterase reaction for either type will show almost all monocytic cells with few granulocytes (right). **F,** Acute erythroleukemia, erythroid/myeloid type. Note that maturing erythroid precursors account for greater than 50% of cells, and that myeloblasts are increased in the nonerythroid component. **G,** Pure erythroleukemia. In contrast to the erythroid/myeloid type, pure erythroleukemia shows greater than 80% erythroid precursors, many of which are abnormal pronormoblasts with prominent vacuolization. **H,** Acute megakaryoblastic leukemia. Megakaryoblasts can sometimes resemble lymphoblasts, with dense nuclear chromatin and scant cytoplasm (top, center). Sometimes megakaryoblasts have cytoplasmic pseudopods or projections (bottom left). Flow cytometric analysis can be used to demonstrate a megakaryocytic origin of the cells, or immunocytochemistry can be used. In this case, the cells were positive for CD41 (bottom, right).

approximately 20% have complex karyotypes that are similar to those of more immature AMLs. Trisomy 8, monosomy 7, and del(5q) are the most common single chromosome abnormalities.[315] The prognosis of this subtype is variable. Cases with t(6;9)(p23;q34) and deletions of 12p have an overall poor prognosis.

Acute Myelomonocytic Leukemia (15%–20% of Acute Myeloid Leukemias; FAB M4 by FAB Classification)

AMML is characterized by differentiating neutrophilic and monocytic precursors. AMML is defined by the presence of ≥20% blasts, with both monocytic and granulocytic lineages each composing at least ≥20% of precursors. Anemia, thrombocytopenia, and leukocytosis (>90%) are typical. Serum and urinary lysozyme levels, which reflect the monocytic component, frequently are elevated.[302,315] Patients often present with extramedullary disease, gingival hypertrophy, leukemia cutis, and meningeal leukemia. Although this subtype occurs in individuals of all ages, it is more common in older patients (median >50 years). Some patients have a preceding history of chronic myelomonocytic leukemia. Morphologically there is a mixed population of myeloblasts, monoblasts, and more mature neutrophils, and monocyte precursors typically are present. Monoblasts are larger than myeloblasts and contain more abundant cytoplasm and a prominent centrally placed nucleolus. Some cells have morphologic features intermediate between myeloblasts and monoblasts. Auer rods are

present in the majority of cases. Cytochemical stains are helpful in identifying the monocytes in the peripheral blood and bone marrow. The bone marrow typically stains with the cytochemical markers for both neutrophilic and monocytic precursors, and the leukemic blasts stain positive with MPO, SBB, and CAE as well as the nonspecific butyrate esterase. The blasts cells usually express the myeloid antigens CD13 and CD33 and monocytic markers including CD14, CD4, CD11b, CD64, CD36, and lysozyme. A subset of undifferentiated blasts may express CD34, HLA-DR, and panmyeloid markers. AMML is genetically heterogeneous. This subtype has no defining cytogenetic abnormalities. The prognosis is variable in this group and dependent on other prognostic variables.

Acute Monoblastic Leukemia and Acute Monocytic Leukemia (2%–9% of Acute Myeloid Leukemias; FAB M5a, M5b by FAB classification)

In the WHO classification, acute monocytic and acute monoblastic leukemias are defined by the presence of greater than 80% cells of the monocytic lineage in the marrow, including monoblasts, promonocytes, and monocytes. A minor neutrophil component, not exceeding 20%, also may be present. This subtype of AML is more common in younger patients (median age 49 years).[302] A majority of patients present with an elevated WBC count, and up to 30% of patients present with WBC count greater than 100,000/μL and symptoms of hyperleukocytosis. CNS involvement occurs in up to 22% of patients.[316] Extramedullary disease involving the liver, spleen, and lymph nodes is more common in the monocytic leukemias than in other AMLs, occurring in up to 54% of patients.[317] Gingival hyperplasia and skin involvement are frequent features of the monocytic leukemias and in many patients may be the presenting findings. The WHO classification does not make a distinction between undifferentiated monoblastic leukemia and more mature monocyte leukemia. However, there are meaningful clinical differences between the two monocytic leukemias.[318] Patients with the monoblastic variant are younger, present with a higher blast count, and have an overall poorer prognosis.[317] The difference in prognosis may be due to the high prevalence of unfavorable cytogenetics within the monoblastic (FAB-M5a) leukemia group. The blasts in the monoblastic form usually are large and contain abundant pale to basophilic cytoplasm, which may contain vacuoles or form prominent pseudopods. Auer rods are absent. Finely textured, dispersed azurophilic granules often are present. In the more mature monocytic variant, the predominant cell type is the promonocyte, which has a characteristic oval or lobulated nucleolus with dispersed chromatin. Nucleoli are present but generally are not as prominent as in the monoblastic form. Monoblasts are variably NSE positive and MPO and SSB negative. Promonocytes are NSE positive and often weakly positive for MPO. Up to 20% of monoblastic/monocytic leukemias may lack NSE reactivity. The acute monoblastic and monocytic leukemias stain with more than one of the monocytic markers, including CD11b, CD11c, and CD64. The exception is CD14, which often is absent, particularly in the monoblastic form. The blasts are generally $CD34^{-}$. The blasts variably express myeloid antigens, including CD13, CD33, CD117, HLA-DR, and CD45, and lysozyme is positive. CD15 often is positive in the monocytic form but negative in the monoblastic form.

There is no characteristic cytogenetic finding. A majority of patients have a normal karyotype.[302] Trisomy 8 is present in as many of 6% of monoblastic cases and 23% of monocytic cases.[302] The monoblastic leukemias frequently have abnormalities of 11q23 but include subtype AML with recurrent genetic abnormalities.

The prognosis of the monocytic leukemias is generally poor. The prognosis reflects the poor prognostic features common in this subtype, including high blast count, extramedullary disease, and older age.

Acute Erythroid Leukemia (3%–6% of Acute Myeloid Leukemias; FAB M6 by FAB Classification)

The WHO classification of AML recognizes two forms of acute erythroid leukemia: acute erythroleukemia (erythroid/myeloid) and a pure erythroid leukemia. In the acute erythroleukemia (erythroid/myeloid), progenitors are committed to both the myeloid and erythroid lineages, whereas in the pure erythroid leukemia, progenitors are committed exclusively to the erythroid lineage. Erythroleukemia (erythroid/myeloid) is defined by the presence of more that 50% erythroblasts, usually at all stages of maturation, *and* more than 20% myeloblasts in the nonerythroid marrow cells. Pure erythroid leukemia, on the other hand, is defined by the presence of greater than 80% erythroid precursors among marrow cells, without evidence of a myeloblastic component.[319] Pure erythroid leukemia is extremely rare, can occur at any age, and usually does not evolve from a preceding MDS. Erythroleukemia (erythroid/myeloid) presents with a low WBC count, anemia, and thrombocytopenia. In the erythroleukemia (erythroid/myeloid), dysplastic erythropoiesis is prominent. The erythroid precursors are megaloblastic with prominent multinucleated forms. Nuclear-to-cytoplasm dyssynchrony, that is, immaturity of the nucleus for comparable cytoplasmic hemoglobinization, is common. Myeloblasts range from immature agranular myeloblasts to myeloblasts with prominent azurophilic granules with Auer rods. In the pure erythroid leukemia, early erythroblasts are highly dysplastic and contain round nuclei with immature chromatin and large blotchy nucleoli. The cytoplasm is abundant and deeply basophilic and often contains numerous vacuoles that may coalesce into large tubular structures. Maturation into intermediate and late erythroblasts often is impaired. Some cases of pure erythroid leukemia may demonstrate minimal morphologic erythroid differentiation and are difficult to differentiate from an undifferentiated leukemia or ALL. Staining the biopsy for hemoglobin A is helpful in differentiating erythroid precursors from myeloblast or lymphoblasts. Erythroid leukemias are MPO and SBB negative. NSE may be weakly reactive. PAS always is positive, with clear differences between the two subtypes, a feature that may help in their recognition and differentiation. PAS stain in the erythroleukemia (erythroid/myeloid) leukemia stain the cytoplasm with a diffuse or punctate pattern. In contrast, in the pure erythroid leukemia the PAS staining is coarse and in a block pattern ("block positivity"). Ring sideroblasts are common in the erythroleukemia (erythroid/myeloid), particularly when it has evolved from a prior MDS. The immunophenotyping reflects the dual population of blasts in the erythroleukemia (erythroid/myeloid) leukemia. Myeloblasts express myeloid markers CD13, CD33 and/or CD117, CD34, and HLA-DR are variably expressed. The erythroid blasts typically express high levels of CD71 (transferrin receptor), glycophorin A, and CD36. In contrast, the erythroblasts of the pure erythroleukemia subtype are rarely $glycophorin^{+}$ or strongly $CD71^{+}$. CD36, Gero antibody against the Gerbich blood group, usually is positive. CD36 is not specific for erythroid precursors and can be expressed on monocytes and megakaryocytes. In the pure erythroid leukemia, mature erythroid precursors are absent, and less than 3% of the blasts are MPO positive. Auer rods are usually not present. The proerythroblasts usually are positive for glycophorins A and B, antigens of the AB blood group system, which are strongly expressed on erythroblasts, and fetal erythrocytes. In rare cases, dysplastic differentiating erythroblasts account for more than 90% of marrow cells without an increase in myeloblasts. Patients with erythroleukemia (erythroid/myeloid) tend to be older at diagnosis (mean age >50 years) and frequently present with rheumatic and immunologic findings. One third of patients complain of diffuse joint pain and/or abdominal, back, and chest pain.[320] Many patients have a positive rheumatoid factor, increased polyclonal immunoglobulins, positive antinuclear antibody test, and positive Coombs test.[321] The erythroleukemias, which frequently are preceded by an MDS, represent 10% to 20% of secondary leukemias and 3% to 5% of all de novo AML cases.[320] Hepatomegaly and splenomegaly can be prominent but occur in less than 25% of patients. The red cells may demonstrate other prominent abnormalities, including basophilic stippling, abnormal red blood cell shape, and rare circulating undifferentiated blast forms.

Patients with this subtype generally respond poorly to therapy, with a short remission duration.[320] The response to treatment may reflect the increased incidence of secondary leukemias and patients with a prior MDS having this subtype.

Acute Megakaryoblastic Leukemia (3%–10% of Acute Myeloid Leukemias; FAB M7 by FAB Classification)

AMKL is characterized by greater than 50% marrow megarkaryoblasts.[322,323] The WHO recognizes the controversy regarding the relationship between acute panmyelosis with myelofibrosis and acute megakaryoblastic leukemia with fibrosis and defines a separate subtype: acute panmyelosis with myelofibrosis.[324] In the majority of cases, the predominant cell is the megakaryoblast and therefore should be subtyped as a megakaryoblastic leukemia (AMKL). Patients with a prior myeloproliferative disorder, myelofibrosis, or CML have a higher incidence of AMKL. AMKL is a common form of childhood leukemia that occurs in 7% to 10% of cases and is associated with a poor prognosis.[325] AMKL in adults occurs in an older population (median age 56 years). A majority of patients have an antecedent hematologic disorder or MDS. AMKL is associated with a lower WBC count at presentation, lower percent of bone marrow blasts, and fibrosis. The presenting WBC count usually is low (<5000/μL), and the platelet count is normal or increased in more than one third of cases (range 5000–2,292,000/μL). Hepatosplenomegaly is common in children but rare in adults unless there is a preceding myeloproliferative disorder. Children with DS have a higher incidence of AMKL that may be related to mutations of the hematopoietic transcription factor gene GATA1.[326] The *GATA1* gene located on the X chromosome is essential for normal erythroid and megakaryocytic differentiation. Somatic mutations in exon 2 of GATA1 are detected exclusively in trisomy 21–associated AMKL but not in non–DS AMKL.[327]

Megakaryoblasts are morphologically heterogeneous and vary from small round cells, resembling ALL or an undifferentiated AML, to large atypical megakaryocytes with or without cytoplasmic granules. Binuclear or multinuclear blasts with deeply basophilic cytoplasm, cytoplasmic projections, and vacuoles are common. Undifferentiated blasts may be surrounded by shed platelets and recognizable micromegakaryocytes. Megakaryocytic fragments are seen In the peripheral blood, as are large atypical cells with prominent cytoplasmic blebs representing megakaryoblasts. The bone marrow typically cannot be aspirated (dry tap), so biopsy is essential to make the diagnosis. The bone biopsy shows increased reticulin and fibrosis, the latter a result of stimulation of normal fibroblasts in the bone marrow by local secretion of platelet-derived growth factor by the leukemic megakaryoblasts.[244]

Megakaryoblasts are SBB and MPO negative, and the PAS reaction is often, but not universally, positive. In many cases the megakaryoblastic features of the blasts are not recognized by light or electron microscopy, so use of monoclonal antibodies specific for platelet glycoproteins is necessary to define this subtype. Immunophenotyping with monoclonal antibodies to platelet glycoproteins CD41 (glycoprotein IIb/IIIa) and/or CD61 (glycoprotein IIa), CD41, or factor VIII-related antigens may be needed to identify the megakaryoblasts.[269] The CD61 antibody reacts poorly in B5 fixed tissues. Moreover, von Willebrand factor (vWF) expression frequently is decreased in cases of AMKL with poorly differentiated blasts. α Granules store vWF, and their synthesis is decreased in immature megakaryocytes. CD42b is a better marker for detecting megakaryoblasts.[328] The ultrastructural platelet peroxidase reaction is technically difficult to perform and has been largely replaced by immunologic techniques. When flow cytometry is used to determine surface antigen profiles of leukemic cells, membrane staining must be demonstrated to distinguish adherent platelets that may cause false-positive results with antibodies to platelet glycoproteins.[329] Cytospin immunofluorescence techniques are needed to distinguish adherent platelets from true-positive cytoplasmic and membrane staining. Myeloid markers including CD13 and CD33 may be positive, but CD34, HLA-DR, and CD45 are negative. The platelet-associated antigen is variably expressed, and its presence is a marker for better prognosis and drug sensitivity in AMKL.[330] Cytogenetic abnormalities of chromosomes 3 and 21 have been associated with the AMKL subtype.[329] The clinical and hematologic features of the AMKL subtype are varied and reflect the evolution of AMKL from a prior myeloproliferative disorder. The clinical course is highly variable and atypical for an acute leukemia.[331] Some patients whose disease has evolved from a preexisting myeloproliferative disorder have a slowly progressive indolent disease that extends over a number of months to years. The response to conventional induction chemotherapy is generally poor, with a lower complete response rate and a shorter overall surival.[14,323,332] CR frequently is associated with reversal of the bone marrow fibrosis.

Variant: Acute Myeloid Leukemia/Transient Myeloproliferative Disorder in Down Syndrome

Patients with DS have an increased incidence of AMKL.[332] In some of patients the AMKL appears to originate in an early progenitor cell and expresses markers of mixed lineages; these patients may have a better prognosis. The WHO acknowledges that patients with DS are predisposed to developing a related transient myeloproliferative disorder (TMD). At least 10% of infants with DS develop a TMD, a disease in which megakaryoblasts accumulate in the liver, bone marrow, and blood. In most cases the TMD requires no treatment and goes into a spontaneous remission.[333] However, within 3 years of development of TMD, 30% of DS infants develop AMKL.

The TMD usually presents in the neonatal period with marked leukocytosis. Greater than 30% blast forms are present in the blood or bone marrow. The blasts in TMD are morphologically and phenotypically indistinguishable from AMKL blasts. The later appearance of AMKL in infants with TMD appears to be derived from the original TMD clone.[333]

Acute Panmyelosis with Myelofibrosis (Fig. 60–16) (<1% of Acute Myeloid Leukemias; M7 by FAB Classification)

Acute panmyelosis and myelofibrosis (APMF) is a rare form of AML. The WHO defines APMF as an entity distinct from acute megakaryoblastic leukemia. However, the clinical and hematopathologic finding partially overlap. APMF is primarily a disease of adults, but it can occur at any age. The disease can occur de novo or as a secondary AML in patients who have received prior alkylating agent chemotherapy.

Patients present with pancytopenia, lack of splenomegaly, bone marrow fibrosis, and normal erythroid maturation.[215] The disorder previously has been called acute myelofibrosis or acute myelosclerosis. The median age at presentation is greater than 70 years (i.e., 72 years; range 2–84 years). The common presenting symptoms are pancytopenia, fatigue, spontaneous bruising, and fevers. Red cell morphology reveals macrocytic red cells with teardrop forms. Neutrophils are dysplastic, with hypogranulation and pseudo–Pelger-Huet anomaly. Platelets frequently are abnormal, with hypogranular, hypergranular, and giant forms in the blood. Megakaryocytic fragments and platelet clumps are rare. Circulating blasts are rare and undifferentiated. The bone marrow cannot be aspirated in all cases (dry tap). The marrow biopsy is variably hypercellular with dysplastic atypical megakaryocytes. Usually a polymorphic cellular background is seen and includes erythroblasts, dysplastic megakaryocytes, and maturing myeloid precursors with foci of immature cells scatted throughout. The overall blast count may be difficult to estimate, but myeloblasts do not represent the majority of marrow cells. The WHO does not require precise determination of the number of blast forms for the diagnosis. The dysplastic megakaryocytes are a prominent feature, with nonlobulated nuclei and dispersed chromatin. The cytoplasm is uniformly eosinophilic. Distinguishing APMF from AMKL, chronic idiopathic myelofibrosis, and AML with fibrosis can be difficult. The lack of prominent splenomegaly helps to distinguishing APMF from

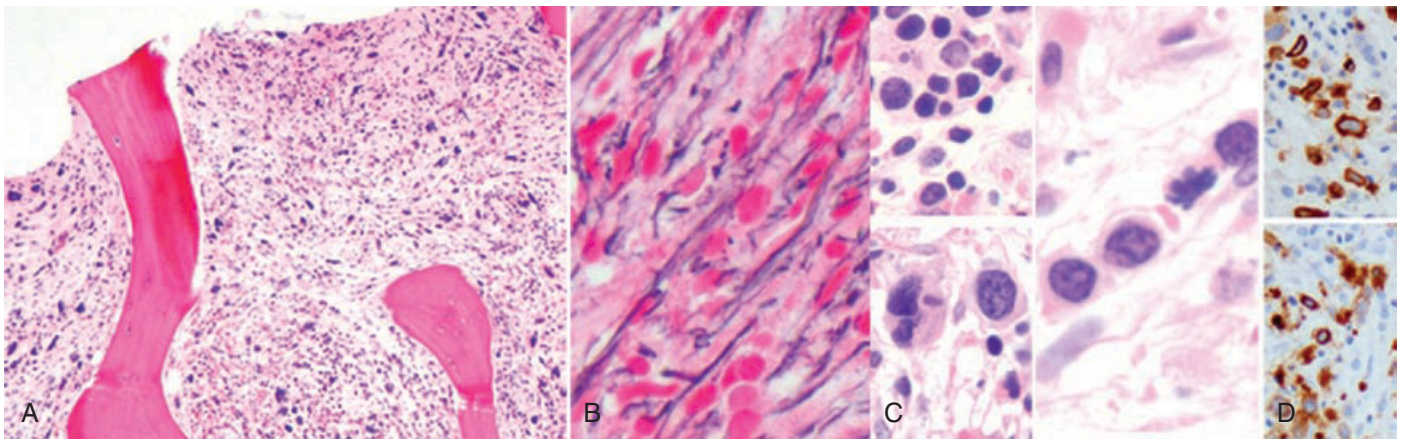

Figure 60–16 Acute panmyelosis with myelofibrosis. **A,** Bone marrow biopsy shows a loosely packed marrow with a swirling appearance to the cellular elements due to underlying fibrosis. B, The latter is illustrated on the reticulin stain. **C,** Proliferations of erythroid cells (top left), megakaryocytes (bottom left), and immature cells within the fibrotic areas (right). **D,** Immunohistochemical staining shows increased megakaryocytes (top, CD61) and increased blasts (bottom, CD34).

one of the myeloproliferative disorders. Moreover, the megakaryocytes in chronic idiopathic myelofibrosis have markedly convoluted nuclei with condensed chromatin.

Immunotyping reveals that the majority of the blasts are $CD34^+$. A variable proportion expresses MPO.[328] A majority of blasts express early myeloid or precursor antigens, including CD34, CD33, and CD117. Megakaryoblasts may be rare, in contrast to AMKL, in which megakaryoblasts are numerous.

Cytogenetics may be difficult to obtain due to the lack of circulating blasts and fibrotic bone marrow. The majority of patients reported have abnormalities of chromosome 5, 7, or 8 [del(5q), del(7q), trisomy 8]. The cytogenetics are consistent with a malignant myeloid disorder similar to MDS or MDS-related AML. APMF may represent a multilineage disease characterized by a heterogeneous blast population with secondary fibrosis.[334] The prognosis for patients with APMF is generally very poor, with a rapid progressive course.

Acute Basophilic Leukemia (<1% of Acute Myeloid Leukemias)

Acute basophilic leukemia (ABL) is a rare form of AML characterized by basophilic blasts. The FAB classification does not include this subtype, and cases usually were included in the M2 or M4 category.[335] Although ABL has been recognized for years, there were no specific guidelines for its diagnosis.[336] Many cases of ABL resemble the blast transformation of CML or AML with basophilia.[337] CML in the accelerated and blast transformation is characterized by an increase in circulating mature basophils. ABL has a high incidence of cutaneous involvement, organomegaly, and lytic bone lesions caused by hyperhistaminemia. The blasts are medium size, with a high nuclear-to-cytoplasmic ratio, round or bilobed nucleus with dispersed chromatin, and one to three prominent nuclei. The cytoplasm is moderately basophilic and contains a variable number of coarse basophilic granules. The blasts can be identified by either light microscopy or ultrastructure as deriving from the basophilic lineage. The peripheral smear usually shows both blast cells and maturing basophils that may be hypogranular. Mature differentiated circulating basophils are only moderately increased. The blasts are MPO and PAS negative by light microscopy but are generally positive with electron microscopy, which is a diagnostic feature of ABL.[336] Electron microscopy reveals numerous electron-dense granules containing varying intramembranous scrolls and the lamellae feature of immature mast cells. The most characteristic cytochemical feature is that the granules have metachromatic features with toluidine blue. Bone marrow biopsy reveals diffuse replacement with medium-sized blasts. Basophils may be increased in the bone marrow. In cases with mast cell differentiation, the mast cells are generally located close to the bone trabeculae and have an oval nucleus with elongated cytoplasm.

Immunophenotyping reveals the blasts are $CD33^+$, $CD13^+$, $CD34^+$, and variably $HLA\text{-}DR^+$. The blasts usually do not express lymphoid markers but may be $CD9^+$; some cases are TdT^+. Cytogenetics are helpful for excluding a missed CML, Philadelphia chromosome–positive t(9;22)(q34;q11). Chromosomal abnormalities include del(5q), monosomy 7, and del6(q22)t(6;9).[338] ABL is very rare, and information concerning prognosis or response to treatment is limited. The cases reported have had a poor prognosis.[336]

Myeloid Sarcoma (Fig. 60–17)

Myeloid sarcomas, also known as *granulocytic sarcomas* or *chloromas*, are an extramedullary tumor of immature myeloid cells. Myeloid sarcomas can occur concomitantly with AML or precede the development of systemic disease by months to years.[339] Myeloid sarcomas can occur with CML or other myeloproliferative disorders. When myeloid sarcoma occurs in the setting of MDS or a myeloproliferative disorder, the WHO considers it equivalent to blast transformation. The most common sites for myeloid sarcoma are the skin, subperiosteal bone, lymph nodes, and soft tissues.[339] The interval between the diagnosis of myeloid sarcoma and the development of overt AML can be months to more than 9 years. In some instances, no evidence of subsequent AML was found, but this may reflect the time of the reporting.[339,340] It is assumed that all patients subsequently will manifest findings of AML or systemic blast transformation of an underlying myeloproliferative disorder. The WHO defines three major types of myeloid sarcoma based on the degree of maturation: (a) blastic, composed primarily of myeloblasts and the most common; (b) immature, composed of myeloblasts and promyelocytes; and (c) differentiated, composed of promyelocytes mature neutrophils and the least common.[340] The diagnosis is based on the reactivity of blast cells as determined by cytochemical reactions or by immunophenotyping. Imprints of the mass are useful for cytochemical staining. The blasts have an antigenic profile similar to the underlying disease. MPO, lysozyme, CD43, and CD68 are helpful in identifying the tumor as a myeloid sarcoma.

Myeloid sarcomas are common in AML with t(8;21), are noted in 18% to 24% of cases and in patients with inv^{16} (M14Eo).[339] The monoblastic sarcomas may be associated with 11q abnormalities. Myeloid sarcomas have been reported following allogeneic stem cell transplantation and may be the first sign of recurrent disease.[341]

The prognosis is that of the underlying disease. When myeloid sarcoma occurs as an isolated lesion, local radiation therapy may

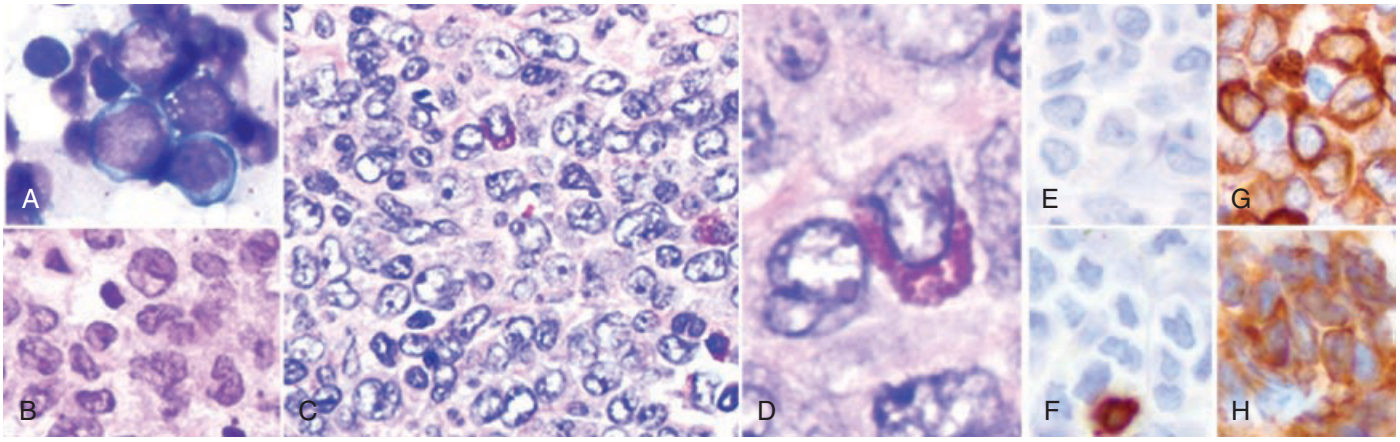

Figure 60–17 Myeloid sarcomas can sometimes present a diagnostic challenge. In this case, touch imprints **(A)** and frozen section preparation **(B)** from a mass lesion in the cecal area from a 44-year-old patient were thought to represent a high-grade lymphoma. However, initial immunohistochemical stains did not support the diagnosis. Closer inspection of the tumor and use of subsequent immunomarkers allowed a diagnosis to be reached. The tumor **(C)** is composed of sheets of noncohesive cells. A diagnostic clue to the origin was the presence of eosinophilic myelocytes **(D)**, which indicates that some tumor cells have the capacity to differentiate to eosinophils. The granules of neutrophilic myelocytes cannot be recognized on tissue section. Immunohistochemical stains showed the cell was $CD45^+$ (not shown), B and T marker negative **(E, F)**, but myeloid marker (myeloperoxidase and CD33) positive **(G, H)**. Cytogenetic analysis showed the case was inv(16)(p13;q22).

result in prolonged responses before systemic disease recurs or progresses. Optimal therapy depends in part on the clinical circumstances, underlying disease, and location of the myeloid sarcoma.

Acute Leukemias of Ambiguous Lineage (<5% of Acute Myeloid Leukemia Syndromes)

The WHO defines acute leukemias of ambiguous lineage as leukemias in which the morphology, cytochemical, and immunophenotyping features cannot classify the leukemia as either myeloid or lymphoid. The classification of AML attempts to assign a specific lineage to each subtype based on morphology, cytogenetics or cytohistochemical staining, and immunophenotyping. In some cases a specific lineage cannot be assigned based on these criteria. In an attempt to explain this phenomenon, a number of different terms have been used, including *lineage infidelity*, *mixed lineage leukemias*, *biphenotypic or bilineage leukemias*, *hybrid or biclonal leukemias*, and *lineage switches*.[236,342,343] This confusing and sometimes arbitrary terminology reflects the heterogeneous nature of these disorders and the lack of specificity of currently available markers.[236] The monoclonal antibodies that are used to characterize lymphoid or myeloid leukemias recognize hematopoietic differentiation antigens. These antigens, which are expressed on a number of epithelial cells and overlapping subsets of hematopoietic cells, have important roles in the biology of normal and malignant hematopoiesis.

The WHO has assigned the term *acute leukemias of ambiguous lineage* to define this population of leukemias. In the present classification, system lineage cannot be assigned in less than 5% of all acute leukemias. Acute bilineage leukemias are defined by detection of dual populations of blasts, with each population expressing markers of a distinct and different lineage. Biphenotypic include leukemias that have a population of myeloid and lymphoid blasts. The leukemic blasts lack markers that are considered lineage specific and may express HLA-DR, CD34, CD38, TdT, and CD7 or demonstrate cytochemical and phenotypic markers of both myeloid and lymphoid precursors. This phenomenon may reflect a fundamental abnormality of gene expression that is specific for the malignant clone.[236,344] The clinical significance of lymphoid antigen expression in myeloid leukemias is unclear. Lymphoid antigens may be positive in up to 48% of myeloid leukemias.[345] The most common lymphoid antigens expressed in myeloid leukemias are CD2 and CD7, which are expressed in 34% and 30% of patients with AML, respectively.[345,346] The leukemic cells may express markers of more than one lineage, reflecting the abnormal maturation of an earlier uncommitted stem cell prior to myeloid lineage commitment. Monoclonal antibodies and molecular probes have shown that leukemic cells can demonstrate characteristics of more than one hematopoietic lineage.[347] These cells may demonstrate Auer rods, stain with peroxidase and/or Sudan black, and react with monoclonal antibodies typical of both myeloid precursors and mature T cells. A number of classification systems have attempted to address the biphenotypic leukemias, but none has been widely accepted.[344] Many cases express myeloid and lymphoid antigens; these cases do not represent evidence of biphenotypia but reflect inappropriate expression of lymphoid antigens on immature myeloblasts. Biphenotypic leukemias express multiple antigens of more than one lineage. The biphenotypic leukemias are recognized as leukemias with true ambiguous lineage.

A majority of bilineage and biphenotypic leukemias present with cytogenetic abnormalities. Rearrangements of the *MLL* gene 11q23 and the Philadelphia chromosome t(9;22) are most common. Other cases can present with complex cytogenetic abnormalities. Moreover, molecular studies have demonstrated that some cases of AML have rearrangement of the Ig heavy-chain gene or T-cell receptor chain genes.[348,349] Bilineage leukemias can be suspected on morphologic grounds when two distinct populations of blast cells are noted. Biclonal leukemias represent approximately 7% of all adult acute leukemias.[345] In these cases, the malignant transformation presumably occurred in a progenitor cell capable of differentiating into separate myeloid and lymphoid progenitors. This is in contrast to mixed lineage or hybrid leukemias, in which the leukemic cell expresses characteristics of more than one lineage.

Lineage switch is the expression of markers of one lineage at diagnosis but markers of a different phenotype or lineage at the time of leukemic relapse.[346] This transformation, which usually occurs after a treatment interval of 1 year, may reflect the selection of a clone from a bilineage leukemia or modulation of antigens expressed on leukemic cells. Clinically the biphenotypic and biclonal leukemias present with the usual findings of AML. However, they may present with features of both myeloid and lymphoid leukemias, including prominent diffuse lymphadenopathy and higher circulating blast and platelet counts. Otherwise, the clinical presentations are indistinguishable from those of the other forms of AML.

Current models of hematopoietic differentiation are based on evidence that normal pluripotential precursors give rise to committed precursors of a single-cell lineage and then undergo a series of discrete developmental steps. The AMLs are believed to arise from a single clone that is arrested at a normal stage of committed differentiation. The currently used classification system is based on the premise that leukemic cells adhere morphologically and immunologically to a

single lineage. Cases of biphenotypic leukemias, mixed lineage, or lineage switch leukemias demonstrate the heterogeneity of these neoplastic disorders and support the concept that, in at least some acute leukemias, the transforming event occurs at the level of the pluripotential stem cell.

PREDICTORS OF RESPONSE

Treatment of patients with AML is divided into two phases: induction, and postinduction. The primary objective of induction therapy is induction of CR. CR is conventionally defined morphologically by the presence of less than 5% blasts in the bone marrow together with recovery of peripheral blood counts. The blood should have no circulating blast forms, hematocrit greater than 30 vol%, and platelet count greater than 100,000/μL without transfusion support. The term *complete remission–platelets* is applied to patients who have a platelet count less than 100,000 μL but meet the other criteria of CR. The outcome of induction therapy is dependent on a number variables. Patients must tolerate the side effects of chemotherapy and the prolonged period of neutropenia and thrombocytopenia resulting from the disease and the treatment. True resistant leukemia accounts for less than 20% of all induction failures. The major determinant of the outcome of remission induction therapy is the capacity of the patient to tolerate intensive therapy. A majority of patients who fail to attain CR do so because of the complications of therapy, which include infection and hemorrhage. Therefore, prior medical problems and performance status are important predictors of response. Factors that predispose to serious infections decrease the likelihood of a patient attaining CR. Whether administration of hematopoietic growth factors decreases the incidence of serious infections for all patients receiving induction chemotherapy is unclear. A number of clinical and biologic characteristics have been defined that are important prognostic factors predicting the likelihood that a patient will respond to induction treatment (Table 60–11). Cytogenetics are the most important independent prognostic factor for remission induction and duration.[350] Favorable cytogenetic abnormalities of the CBF, including t(8;21) and inv[16], are associated with a significantly better response and longer remission and survival, whereas abnormalities of chromosomes 5 and 7 and complex cytogenetic abnormalities are associated with a poor response to therapy and shorter overall survival. Other factors that are predictors of remission duration include the presence of extramedullary disease and a high blast count. Patients with the previously noted subtypes of undifferentiated AMKL and t-AMLs are associated with a poorer prognosis.

Age is an important predictor of response to induction therapy. The outcome for younger patients has improved with advances in supportive care and more intensive postremission therapy. However, the outcome for elderly patients continues to be poor (Fig. 60–18). The definition of a "elderly "patient varies among studies and is not uniform across cooperative groups. Generally, patients older than 60 years tolerate intensive treatment poorly and have an increased incidence of unfavorable prognostic variables, including unfavorable cytogenetics and expression of the multidrug resistance gene *MDR*.[351] Older patients with AML have an increased incidence of multilineage dysplasia, suggesting a more primitive stem cell origin or t-AML. Favorable cytogenetics are less common in elderly patients, and the proportion of patients with unfavorable cytogenetics is increased.[352] The combination of age greater than 70 years and poor prognosis cytogenetic was associated with a poor response to intensive chemotherapy and a limited survival benefit.[353,354] Cytotoxic chemotherapy in elderly patients is also associated with higher morbidity and mortality because of the presence of comorbid diseases, poor tolerance of prolonged pancytopenia, and perhaps altered drug metabolism and excretion.[355] Moreover, the majority of reports on treatment of elderly patients reflects selection bias. Most elderly patients do not participate in cooperative trials, and both patient and physician selection bias makes the generalization of findings in reported trials difficult. The true outcome of induction therapy and the survival of most elderly patients with AML are not known. Use of aggressive, intensive, induction therapy is of unclear benefit in elderly patients with AML.[355] Elderly patients with complex karyotype with at least three abnormalities or rare aberrations had a lower CR rate. Moreover, elderly patients with complex karyotype with more than five cytogenetic abnormalities or rare aberrations had a 0% 5-year survival rate.[355] Elderly patients with favorable cytogenetics, including abnormalities of CBF, had a 5-year survival rate of only 19%. The current treatments are of limited benefit in elderly patients with complex or rare cytogenetic abnormalities.[355] The CR rate was independently associated with older age and increasing WBC count. In elderly

Table 60–11 Prognostic Factors in Acute Myeloid Leukemia

Factor	Favorable	Unfavorable
Age	<55 years	>60 years
Leukemia	De novo	Secondary
White blood cell count	<25,000/μL	>100,000/μL
WHO subtype	Core-binding factor AML	AML with multilineage dysplasia, therapy-related-AML Acute megakaryocytic leukemia, acute erythroid leukemia, acute basophilic leukemia
FAB type	M3, M4Eo	M0, M5a, M5b, M6, M7
Cytogenetics	t(15;17), t(8;21), inv(16) Normal cytogenetics	Abnormalities of chromosomes 5 and 7, multiple >3 abnormalities, rare abnormalities 11q23, t(6;9)
Extramedullary disease	Absent	Present
Auer rods	Present	Absent
Phenotype	$CD34^-$	$CD34^+$ $CD56^+$
Other	Nucleophosmin 1 (NPM-1)	High lactate dehydrogenase level, low albumin level KIT mutations FLT-3 internal tandem duplication MDR-1 expression

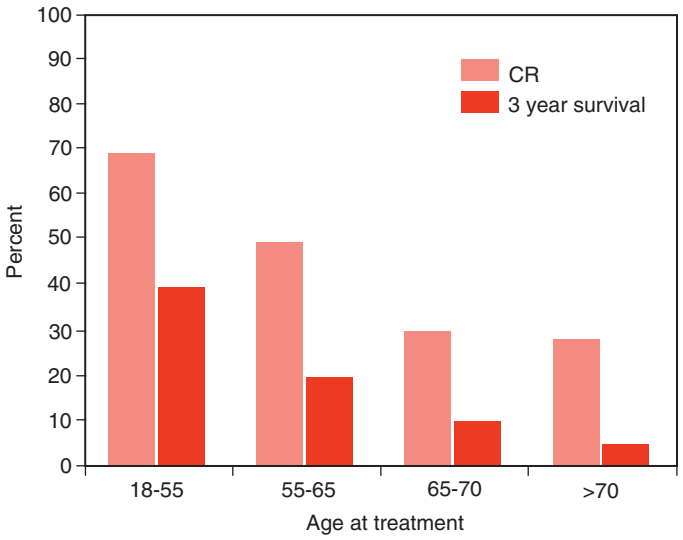

Figure 60–18 Age-associated complete remission and survival in acute myeloid leukemia.

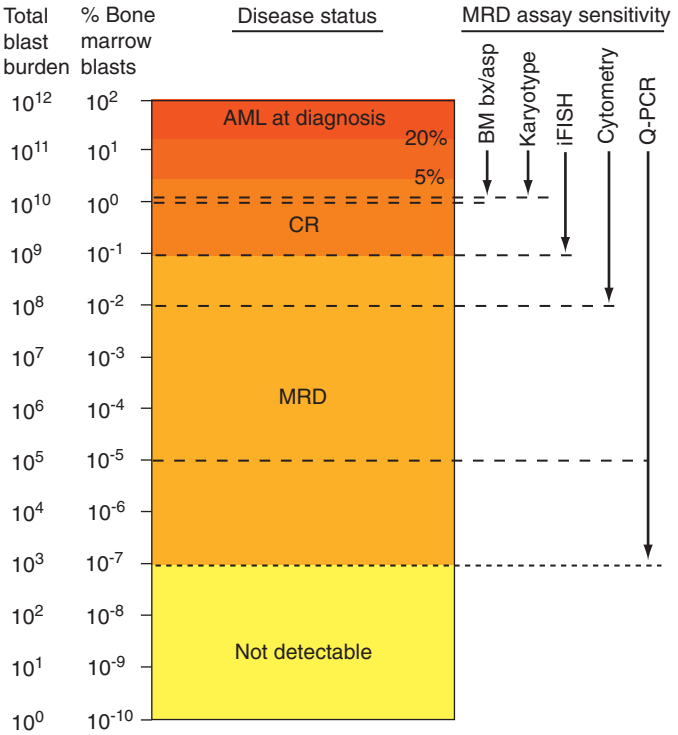

Figure 60–19 Hypothetical disease burden in acute myeloid leukemia (AML; assuming 100% blasts at the time of diagnosis) at different stages of disease evolution and approximate sensitivity levels of the assays used to monitor patients after remission induction. Blasts refer to leukemia blasts only. Segmented and dotted lines depict usual and optimized levels of detection by quantitative polymerase chain reaction (Q-PCR). iFISH and Q-PCR target AML-specific genome changes (translocations, deletions, mutations, etc.). Flow cytometry targets AML-specific aberrant phenotypes. Suitable targets for MRD assessment may not be available in all AML cases. BM bx/asp, combined assessment of marrow biopsy and aspirate smear; CR, complete remission; iFISH, interphase fluorescent in situ hybridization; MRD, minimal residual disease.

patients older than 60 years, the overall 5-year survival rate was 6% to 7%.[355,356] In elderly or high-risk patients, cytogenetics identify a group of patients who are unlikely to benefit from intensive chemotherapy and should be offered alternative treatments or supportive therapy.[354–356]

Attempts to reduce the toxicity of treatment in elderly patients are controversial. Use of colony-stimulating factors to improve neutrophil recovery and the outcome of treatment in elderly patients with AML remains controversial. Colony-stimulating factors have been shown to reduce the duration of neutropenia in elderly patients undergoing induction chemotherapy, but their overall effect on morbidity or mortality is unclear.[357–360] Less intensive chemotherapy has been administered to elderly patients in an attempt to decrease toxicity, with variable results.[360,361]

Patients with secondary AML or a history of a prior MDS or myeloproliferative disorder respond poorly to standard chemotherapy regimens. Pretreatment serum albumin and serum LDH levels and performance status are important predictors of response.[362] The lower the serum albumin level, the less likely the patient will attain CR and/or tolerate intensive chemotherapy. A poor performance status or elevated serum LDH level is associated with a lower complete response rate and shorter remission duration.[363] A leukemic cell count greater than 20,000/μL is associated with a lower CR rate and shorter duration of remission.[363]

The presence of c-KIT mutations and FLT-3 ITD mutations is associated with a higher relapse rate and decreased overall survival.[354,355] Expression of *MDR* has been implicated as a poor prognostic factor.[351] *MDR-1* encodes an ATP-binding transmembrane protein that extrudes a variety of antineoplastic compounds from the cells, including the anthracyclines. Twenty percent of de novo AML cases and 75% of secondary AML cases express MDR-1. MDR-1 expression is linked to expression of the CD34 antigen. The MDR-1 phenotype identifies a group of high-risk, poor-prognosis leukemias, but its role as an independent prognostic indicator is unclear. Moreover, expression of CD34 on leukemic cells is associated with a poor response to induction chemotherapy, but whether this is an independent predictor of response is unclear.[364] Prospective studies are needed before therapy can be altered based on prognostic factors.

Use of intensive postinduction therapy has resulted in longer remissions and improved overall survival. In most studies, 60% to 70% of patients younger than 60 years will attain CR with induction therapy, but 40% to 70% will relapse in the first 18 to 24 months. The factors that determine remission duration are highly controversial and dependent in part on the type of postinduction chemotherapy used.[365,366] Patients who require two courses of induction chemotherapy to attain CR appear to have shorter remission duration. The morphologic appearance of the bone marrow biopsy sample at the time of CR may be an important predictor of remission duration. The presence of morphologic dysplasia involving more than one cell line may be associated with shorter remission duration. However, chemotherapy can result in dysplastic features in the bone marrow; therefore, the finding of dysplastic erythroid and myeloid precursors following high-dose induction and consolidation therapy must be interpreted with caution.[225] All these prognostic factors are determined from retrospective studies. None of these variables has been critically analyzed in controlled prospective trials.

Patients in remission for more than 3 years have a markedly increased chance of prolonged survival; 75% to 80% of patients in CR at 3 years will have a prolonged disease-free survival.[367,368] However, patients continue to relapse 3 to 15 years after attaining CR. The biologic factors responsible for these late relapses are unknown and may reflect one or more of the etiologic events in the development of AML.[369]

Minimal Residual Disease Monitoring

Use of modern intensive induction chemotherapy regimens for AML results in CR rates greater than 60% in patients with AML. Intensive regimens lead to a 2- to 3-log decrease in leukemia cells. Accurate monitoring of minimal residual disease at the completion of induction or consolidation therapy may be important in the management of adults with AML. Minimal residual disease can be monitored in a number of ways, and each method has its advantages and disadvantages (Fig. 60–19). Minimal residual disease status, detected by either

multiparameter flow cytometry or real-time quantitative polymerase chain reaction (QPCR), at the completion of consolidation therapy is a better predictor of relapse. Detection of abnormal disease-specific phenotypes by multiparameter flow cytometry may be of greater value in the assessment of early clearance of myeloblasts after completion of induction therapy, whereas QPCR, which measures disease-specific genetic changes, may be more informative and a marker of "persistent" minimal residual disease after consolidation therapy. Selection of targets for QPCR also may be important. Future treatments will be directed by prognostic factors and may allow for risk-adjusted induction and consolidations regimens.

CHAPTER 61

THERAPY FOR ACUTE MYELOID LEUKEMIA

Jacob M. Rowe and Martin S. Tallman

Approximately 13,000 patients in the United States are diagnosed annually with acute myeloid leukemia (AML). The median patient age at presentation has been steadily increasing over the past 2 decades and now is approaching 70 years. In an analysis by the Eastern Cooperative Oncology Group (ECOG) of the outcome of approximately 3000 patients with previously untreated AML entered into five consecutive clinical trials, the 5-year overall survival (OS) rate among 2000 patients younger than 55 years improved from 11% in the 1970s to 37% in the 1990s (Figs. 61–1 and 61–2). The overall incidence of AML in the United States is 3.4 patients per 100,000 population; 1.2 patients per 100,000 at age 30 years and more than 20 patients per 100,000 population at 80 years.[1] Considerable progress has been made in the therapy for younger AML patients, yet two thirds of young patients still die of their disease. The treatment of older adults remains entirely unsatisfactory, and greater progress in the treatment of this age group is required.

OBJECTIVES OF TREATMENT AND CRITERIA FOR RESPONSE

The traditional goal of treatment of AML is to produce and maintain a complete remission (CR).Criteria for CR are platelet count higher than 100,000/μL, neutrophil count higher than 1000/μL, and bone marrow specimen with less than 5% blasts.[2] In the 1960s, Freireich et al.[3] demonstrated that patients who achieved CR lived longer than patients who did not. The difference in survival time was entirely attributable to the duration of time spent in CR, suggesting a correlation between achievement of CR and survival time.[3] These findings have been confirmed for patients treated in the 1980s and 1990s. In general, after 3 years have elapsed from the beginning of CR, the probability of recurrence sharply declines, becoming less than 10%. Patients who have been in continuous CR for 3 years can, for operational purposes, be considered potentially cured.[4] Only patients who reach CR are potentially cured. A partial remission, with blood counts as in a CR but with 6% to 25% blasts in the marrow, occurs so infrequently with conventional anti-AML chemotherapy regimens that its effect on survival is difficult to judge.

Other response criteria have been proposed, such as CR with incomplete platelet recovery (CRp).[5] Although they meet other criteria for CR, such patients have platelet counts higher than 30,000 rather than the 100,000/μL standard. CRp is relatively rare after typical therapies. Subsequent survival of patients given such therapies is worse than for patients who meet the criteria for CR.[6] However, the motivation for defining CRp is the advent of newer, targeted therapies. Such therapies may be more likely to produce CRp, and, with such therapies, survival may be independent of the distinction between CR and CRp. The former point remains to be proved, and results with at least one drug, gemtuzumab ozogamicin (Mylotarg), suggest the latter hypothesis is not accurate. A *cytogenetic CR* implies that in patients whose blasts have cytogenetic abnormalities, the abnormalities can no longer be detected on standard analysis after CR is achieved. It appears that cytogenetic CRs last longer than CRs in which an initial abnormality persists[7,8]; however, most CRs also are cytogenetic CRs. A *molecular CR* extends the concept of cytogenetic CR to the molecular level and is especially relevant in acute promyelocytic leukemia (APL). APL constitutes less than 10% of cases of AML, so our focus remains on CR.

Two types of events, sometimes indistinguishable, can interfere with the achievement and maintenance of a CR.[9,10] First, patients can die as a result of therapy administered to produce a CR; therapy-induced death in CR is less common. These events are classified as supportive care failures. Second, and more common, disease can be resistant to therapy. Resistance can manifest as failure to enter CR (i.e., primary refractory AML) but more often manifests as recurrent disease after a transient CR. These two types of resistance correspond to the two principal phases of chemotherapy: remission induction and therapy in remission.

Relapse-free survival, also called *disease-free survival (DFS),* is a better measure of the effectiveness of postremission therapy than remission duration. This is because when analyzing remission duration, patients who die in CR are *censored* at time of death. Such censoring assumes that patients who die in CR have the same underlying risk of relapse (had they lived) as patients who do not die in CR. This assumption has not been proved. In contrast, relapse-free survival counts relapse and death in CR as evidence that a regimen is ineffective.[11]

STANDARD REMISSION INDUCTION THERAPY

Cytosine Arabinoside

Modern remission induction therapy for AML usually consists of a combination of cytosine arabinoside (ara-C) and an anthracycline (see box on Induction Therapy for Adults with AML up to Age 60). Ara-C, an antimetabolite that is an analogue of the normal nucleoside cytidine, is converted to ara-C triphosphate (ara-CTP). Once converted to ara-CTP, ara-C is incorporated into DNA and causes cell death. Mechanisms of cytotoxicity that do not require ara-CTP formation also may exist. When originally used in the 1960s and 1970s,[12] ara-C was administered at daily doses of 100 to 200 mg/m^2 (i.e., standard-dose ara-C) by twice-daily intravenous infusions or by continuous intravenous infusion. The latter approach was used because of the drug's very short half-life (15 minutes). When given by continuous infusion, CR rates were higher when the same total dose of ara-C was given over 5 days rather than 2 days. Despite the pharmacologic rationale previously mentioned, whether administration of ara-C by continuous infusion is preferable to bolus (over 1–3 hours) infusion is unknown. Given at standard doses, the principal adverse affects of ara-C are myelosuppression and, rarely, nausea and vomiting or diarrhea.

Anthracyclines

Anthracyclines include drugs such as daunorubicin, rubidazone, and idarubicin. Anthracyclines, such as the related agents mitoxantrone and etoposide, appear to exert cytotoxicity by stabilizing the normally occurring complex between DNA and the enzyme topoisomerase II. Stabilization of the complex leads to cell death. Daunorubicin, when given at 60 mg/m^2 daily for 3 to 7 days, produces CR rates of 40%, similar to the rates seen with ara-C.[13] Anthracyclines and ara-C have

Induction Therapy for Adults with Acute Myeloid Leukemia Up to Age 60

- Aim of induction therapy is to reduce the number of leukemia cells to levels undetectable by morphology or standard cytogenetics (2–3 log cell kill).
- Once diagnosis is made, treatment should not be delayed.
- Gold standard remains treatment with an anthracycline and cytarabine.
- Daunorubicin 60 mg/m^2 for 3 days with cytarabine 100 mg/m^2 for 7 days (3 + 7) is a standard to which other regimens are compared.
- Multiple clinical trials suggest that daunorubicin 45 mg/m^2 is a suboptimal dose.
- There is no definitive evidence that therapy with another anthracycline or anthracenedione is superior.
- Standard 3 + 7 regimen is effective for all cytogenetic or molecular subtypes.
- Higher doses of anthracyclines (e.g., daunorubicin 90 mg/m^2) are safe, but no definitive data of improved efficacy are available.
- Induction therapy can be safely repeated at day 14 if unequivocal residual leukemia is present in a cellular marrow.
- No convincing data to indicate that addition of 6-thioguanine improves efficacy.
- Increasing the dose of cytarabine from 100 to 200 mg/m^2 does not improve outcome.
- Continuous infusions of cytarabine are preferable to bolus administration.
- Intensifying induction by using higher doses of cytarabine or addition of etoposide does not affect the remission induction rate.
- High doses of cytarabine or addition of etoposide may prolong disease-free survival.
- Administration of cytokines (granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor) shortens the period of neutropenia by 4 to 7 days and is useful as supportive care strategy during induction.
- Use of cytokines as priming agents remains controversial.
- Preliminary data suggest that addition of gemtuzumab ozogamicin during induction therapy may improve the disease-free survival in patients with favorable- and intermediate-risk cytogenetic abnormalities.

similar toxicities, but anthracyclines are more likely to cause mouth sores. They also produce alopecia and a cardiomyopathy that can be prevented by limiting the total dose administered.[14] Cumulative doses of at least 180 mg/m^2 probably can be safely given to patients younger than 70 years with no prior exposure to anthracyclines. The probability of congestive heart failure in these patients was zero compared with 10% to 20% at the same dose level in patients older than 70 years, with hypertension, or with prior exposure to anthracyclines.

3 + 7 Regimens

Effective induction therapy for patients with AML was introduced more than 3 decades ago and included a combination of 7 days of cytarabine 100 to 200 mg/m^2/daily and 3 days of daunorubicin.[15] The so-called "3 + 7" regimen remains the gold standard against which all new combinations of agents are compared. CR can be achieved in 30% to 40% of adults younger than 60 years using either of these drugs[16,17] alone as compared to approximately 60% to 80% using a combination of an anthracycline and cytarabine. The results of induction therapy are greatly influenced by prognostic factors, most importantly the leukemia cell karyotype at presentation (Tables 61–1 and 61–2).[18] Caution is required when comparing published results for any given subtype of AML with a particular induction regimen. These results may vary among the major cooperative oncology groups due to differing criteria for the establishment of a CR, including the requirement for central pathology review.

Although the most frequently used dose of daunorubicin has been 45 mg/m^2 for 3 days, a careful analysis of the available data suggests that this dose should be modified to a higher dose, nearer to 60 mg/m^2. Multiple randomized studies have compared daunorubicin at a dose of 45 to 50 mg/m^2 with other anthracyclines, including idarubicin,[16,17,19,20] amsacrine,[21] aclarubicin,[22] and mitoxantrone.[23] Each of these studies revealed superiority of these alternative anthracyclines or the anthracenedione mitoxantrone. This improvement was observed through significantly improved CR rate, improved DFS, improved OS, or more rapid response rate as measured by the number of courses required to attain CR (Table 61–3). Furthermore, sequential studies by the Southwest Oncology Group (SWOG) reported a substantially improved CR rate among patients younger than 50 years receiving daunorubicin at a dose of 70 mg/m^2,[24] compared with 45 mg/m^2.[25] Although this was not a randomized comparison, these

CR, complete remission.

data were generated by analyzing sequential studies, performed by the same cooperative group, in which only the dose of daunorubicin varied. Furthermore, sequential studies by ECOG have shown that the CR rate with idarubicin (12 mg/m^2 daily for 3 days) was identical to the historical control among a similar number of patients in the same age who used 60 mg/m^2 daily for 3 days of daunorubicin (Table 61–3).[26,27] Consequently, because of the question of dose equivalence, it is impossible to conclude from any of these studies whether any anthracycline or anthracenedione is superior.

Multiple attempts have been made to intensify induction therapy, but no unequivocal benefit has been demonstrated. Furthermore, reports of improved survival with an intensified induction regimen must be cautiously interpreted because OS might be influenced by the choice of postremission therapy.

Comparisons of dose intensity in AML therapy are fraught with hazards as multiple variables exist among the studies, including patient age and prognostic factors that lead to patient selection.

Although a higher dose of daunorubicin can be safely administered,[28] a direct comparison of 45 mg/m^2 with 90 mg/m^2, together with the identical dose of cytarabine, currently is being studied in a prospective fashion by both ECOG and the Dutch Haemato-Oncology Association (HOVON). DFS of AML patients can be improved by adding etoposide to standard induction therapy.[29,30] However, no data demonstrate that this strategy is superior to that which can be achieved by appropriate intensification therapy during the consolidation phase of AML therapy.

Caution is in order when interpreting what appears to be impressive data obtained by the completion of phase II studies. A study adding high-dose cytarabine directly after a standard 3 + 7 regimen was reported to yield a complete response rate of 89%.[31] However, this study, which was performed in a limited number of institutions, was compared with historical controls and could not be reproduced by several large cooperative group studies.[32]

3 + 7 Variants

Although 6-thioguanine often is included in the 3 + 7 regimen (spurring acronyms such as DAT and TAD), a Cancer and Acute Leukemia Group B (CALGB) study randomizing 427 patients to receive daunorubicin plus ara-C with or without 6-thioguanine found no difference in the CR rate, remission duration, or survival between the regimens.[33] Similarly, although an earlier Australian Leukemia Study Group (ALSG) trial suggested that patients younger than 55 years randomized to receive etoposide in addition to 3 + 7 had longer remissions and survival,[29] subsequent, larger randomized trials by the Medical Research Council (MRC) in Great Britain conducted with patients younger than 55 years[35] and older than 55 years[36] found that replacement of 6-thioguanine in DAT by etoposide had no effect on CR rate, remission duration, or survival. Such discrepancies emphasize the difficulty inherent in generalizing even from randomized trials while suggesting that any advantage gained by combining etoposide with the 3 + 7 regimen is relatively small at best. Although once cited as a possibility, neither the MRC nor ALSG found any benefit for etoposide in patients with French-American-British classification system (FAB) types M4 and M5.

Targeted delivery systems have been introduced for treatment of relapsed patients. Ongoing studies are using such systems as an adjunct to standard induction and consolidation therapy in young adults with AML. Preliminary data from a study conducted by the MRC in Great Britain reported a substantially improved DFS, except in patients with a high-risk karyotypic abnormality, with its use during induction with 3 + 7 of gemtuzumab ozogamicin, which consists of anti-CD33 conjugated to calicheamicin.[37] Additional followup and data from other cooperative groups are awaited before a definitive conclusion can be made on the usefulness of such therapy.

Similarly, new studies are about to be undertaken using targeted chemotherapeutic agents, such as tyrosine kinase inhibitors of the internal tandem duplication of FLT-3, as adjuncts to standard induction therapy. No data are yet available for such agents, which have minimal activity when used as single agents in patients with advanced disease.[38,39]

Causes of Failure

Between 40% and 45% of patients who fail to enter CR with 3 + 7 or the variants described die before response to induction therapy can be assessed; this proportion is heavily dependent on age and pretreatment performance status.[40,41] Death usually results from multiorgan failure, with the lung often the initially affected organ and pneumonia frequently the inciting event. The most commonly identified pathogens are fungi, particularly *Aspergillus* spp., and gram-negative bacilli.[42] Microbiological and autopsy studies essentially never implicate *Pneumocystis carinii* or viruses such as cytomegalovirus,[42] although the same techniques readily identify viral infections in allogeneic stem cell transplant patients or patients with chronic lymphocytic leukemia. In about half of the cases of fatal pneumonia studied at autopsy, no pathogen is identified.[42] Hemorrhagic exudation frequently contributes to pulmonary failure. Despite profound thrombocytopenia due to the disease and its treatment, this process usually is not accompanied by bleeding elsewhere. Central nervous system hemorrhage as a cause of death appears to be decreasing.[41] This suggests that pulmonary hemorrhage is an inflammatory response to underlying infection or to chemotherapy-induced lysis of tumor cells. The latter phenomenon most often occurs in the week after chemotherapy begins and is more likely in patients who present with high white blood cell (WBC) counts (>25,000–50,000/mL), particularly if accompanied by monocytosis.

With the exception of patients older than 75 years or patients of any age with a poor pretreatment performance status, the typical patient whose disease fails to respond to 3 + 7 will survive for at least 4 to 5 weeks, but not in CR due to resistant AML. These patients are divided into those in whom marrow hypoplasia is never observed and those in whom hypoplasia develops but is followed by reappearance of AML rather than achievement of CR. In clinical practice, a bone marrow aspirate usually is obtained 2 to 3 weeks after beginning therapy. A biopsy is needed only if the quality of the aspirate does not permit determination of cellularity. If the marrow continues to show blasts and is cellular, a second course of the same therapy is often given, sometimes at reduced total dose (e.g., 2 + 5 regimen). If the day 14 or 21 marrow is hypoplastic, therapy usually is delayed until it is clear that leukemia has reappeared, at which time the second course begins. A second course of therapy can produce remissions, but they usually are shorter in duration than are remissions produced after one course of therapy,[43] illustrating the connection between results of induction therapy and results of postremission therapy. The initial marrow sample obtained after a period of hypoplasia may demonstrate up to 10% to 20% blasts as a reflection of the regeneration of normal, not "leukemic," marrow, especially if cytokines have been given. In this circumstance, followup (e.g., at 1- to 2-week intervals) marrow samples show a reduction in percentage of blasts concomitant with a rise in the concentrations of neutrophils and platelets. If the patient presented with a cytogenetic abnormality, cytogenetic analysis may predict whether subsequent regeneration will be normal or leukemic.[44] The former possibility is suggested if the cytogenetic abnormality can no longer be detected in the followup marrow. In contrast, a persistent abnormality suggests that regeneration will be leukemic or that, if CR occurs, it will be short lived.

STANDARD POSTREMISSION THERAPY

Three types of postremission therapy can be distinguished. *Maintenance therapy* usually is defined as therapy that is less myelosuppressive than that used to produce remission. This typically is used in patients with APL and often in older patients. Most groups do not routinely use maintenance therapy for young adults with AML. The

terms *consolidation therapy* and *intensification therapy* often are interchangeable and refer to an intensive form of postremission therapy that is intensely myelosuppressive and includes drugs similar to those used in induction, often at higher doses.

Alternatively, postremission therapy may comprise an autologous or an allogeneic stem cell transplant, with or without prior standard consolidation therapy.

Alternative Strategies for Postremission Therapy

A variety of approaches to preventing relapse have been explored. Such strategies have included intensive consolidation chemotherapy or high-dose chemotherapy or chemoradiotherapy with either human leukocyte antigen (HLA)-matched sibling allogeneic hematopoietic stem cell transplantation (allo-HSCT) or autologous HSCT, or low-dose maintenance therapy.

Allogeneic Stem Cell Transplantation

Allo-HSCT provides the most potent antileukemic effect of any postremission therapy in AML, as demonstrated by the lowest rates of relapse (see box on Allogeneic Hematopoietic Stem Cell Transplantation for AML). The clinical impact of graft-versus-leukemia effect was convincingly demonstrated by the International Bone Marrow Transplant Registry (IBMTR).[45] The most important limiting factor for allo-HSCT still is the high transplant-related mortality. The mortality from established grade III to IV graft-versus-host disease has not changed significantly over the past 3 decades.

If an HLA-matched sibling donor (MSD) is available, this is the preferred therapy for most patients up to age 55 to 60 years, if they present with an intermediate-risk karyotype, the most common cytogenetic group, composing approximately 50% of all AML patients. Data have shown that this form of therapy provides the best antileukemic effect as judged by the relapse rate.[46–48] Similarly, allo-HSCT is the treatment of choice for patients with a poor-risk cytogenetic abnormality.[49] Although offering allo-HSCT to AML patients with unfavorable cytogenetics has been the standard of care, a paucity of prospective data support this approach. In fact, the MRC AML-10 study reported that among the group with unfavorable cytogenetic abnormality, allo-HSCT did not offer any advantage.[47] In contrast, a U.S. Intergroup study reported a clear advantage for patients undergoing allo-HSCT, resulting in a survival of 44% compared with 15% for patients undergoing chemotherapy.[48] However, these studies are based on small subgroups of fewer than 20 patients, so seemingly conflicting data are not unexpected. In contrast, prospective data from the EORTC/GIMEMA AML-10 trial demonstrated, for the first time in a significant cohort of patients, an unequivocal benefit for allo-HSCT in patients with unfavorable cytogenetic abnormalities (Fig. 61–3).[50]

Patients with favorable-risk cytogenetic findings usually are not offered allo-HSCT during their first CR (Table 61–4). Although the rate of relapse is significantly lower with this mode of therapy, the high transplant-related mortality abrogates the value of allo-HSCT in such patients.

The timing of allo-HSCT following induction has never been prospectively defined. Historically, some form of consolidation therapy was often given prior to allogeneic transplantation.[51,52] Some cooperative groups use an attenuated form of consolidation,[27] generally for logistic reasons such as to establish the availability of a donor and transplant center. Other groups proceed immediately to allo-HSCT if an HLA-matched donor is available.[53] A retrospective analysis from the IBMTR[54] as well as an analysis from the European Group for Bone and Marrow Transplantation (EBMT) registry[55] showed no benefit of administering consolidation therapy prior to allo-HSCT for patients in first CR. This issue remains open because it has never been studied prospectively. Furthermore, the data from the registries are applicable only to patients in first CR. No studies, prospective or retrospective, have addressed the need for consolidation therapy prior to allo-HSCT in patients beyond first CR. More importantly, no

Allogeneic Hematopoietic Stem Cell Transplantation for Acute Myeloid Leukemia

- Provides superior antileukemic therapy.
- Standard of care in first complete remission of young patients with intermediate and unfavorable cytogenetic abnormalities.
- Reduced-intensity conditioning is reserved for older patients or those with comorbidities.
- Emerging data suggest a role for alternative donor stem cell transplants for patients with unfavorable cytogenetics in first complete remission.
- Standard of care for all patients in second remission.
- High rate of relapse in patients in whom transplants are performed while in relapse.
- For relapsed patients who achieve a remission, alternative donor transplants are an acceptable and recommended option.

Table 61–4 Indications for Matched-Sibling Allogeneic HSCT in Acute Myeloid Leukemia

Remission Status	Prognostic Parameters	Decision to Proceed with Allogeneic HSCT
CR1	Favorable cytogenetics	No
	Intermediate cytogenetics	Young; ± poor prognostic factors—Yes
	Unfavorable cytogenetics	Yes
≥CR2	All	Yes
Relapse	If cannot reinduce	Yes

J Clin Oncol 23:3447, 2005.[56])*

data provide guidance as to when reduced-intensity conditioning should be applied.

Alternative sources of stem cell grafts has vastly increased the available pool of AML patients who can be offered allo-HSCT. The Center for International Blood and Marrow Transplant Research (CIBMTR) has reported data on the outcome of AML patients in first CR and beyond transplant with grafts from a matched unrelated donor (MUD) demonstrating a long-term probability of survival of 35% to 40% (Fig. 61–4). The performance of MUD HSCT has become widespread. Data suggest that the outcome with MUD is approaching that of sibling allo-HSCT from a matched related donor. However, no intention-to-treat analysis of MUD HSCT for AML has been performed. Currently, only a minority of patients for whom MUD HSCT is planned actually undergo such a transplant, because in many instances the disease progresses prior to the availability of a donor. More recently, encouraging results with MUD HSCT has been facilitated by the vast number of potential donors who are available through several worldwide registries, including the National Marrow Donor Program, which has more than seven million potential donors.

Data have offered another alternative for patients who do not have an HLA-matched sibling. A genetically haploidentical family member is readily available for more than 90% of patients. Furthermore, over the past decade significant strides have been made in increasing the safety and efficacy by overcoming many of the barriers to this procedure. The reported event-free survival of 45% to 50% in patients in CR in whom such a transplant was performed is comparable to data from MUD transplant (Fig. 61–5).[56]

Select patients with AML may benefit from allo-HSCT with reduced-intensity conditioning. Several phase II studies have demonstrated that such an approach is feasible (Table 61–5). Reduced-intensity conditioning allows patients to benefit from the graft-versus-leukemia effect, which is known to be potent against myeloid malignancies (Fig. 61–6).[45] Such a regimen is intended to be effective without being associated with the toxicities encountered with conditioning regimens used in fully ablative transplantation. Use of this strategy in AML has never been studied prospectively, but phase II studies have demonstrated that reduced-intensity conditioning transplantation can be performed with modest activity and acceptable toxicity in older adults or in patients with significant comorbidities (Fig. 61–7).[57,57a] Another study of patients older than 40 years who were treated with either reduced-intensity conditioning or a traditional conditioning regimen demonstrated no significant

Autologous Hematopoietic Stem Cell Transplantation for Acute Myeloid Leukemia

- Autologous stem cell transplantation provides a more potent antileukemic effect than chemotherapy.
- In most prospective studies of autologous stem cell transplant, high mortality rates are associated with use of bone marrow as the stem cell source.
- Mortality using peripheral blood stem cell grafts is only 1% to 2%.
- Mortality and morbidity are not greater than the rates with standard consolidation therapy using high-dose cytarabine with the exception of impact on fertility.
- Appears to have a role in consolidation for patients with favorable cytogenetic abnormalities and for those with intermediate-risk cytogenetic abnormalities who do not have a human leukocyte antigen-compatible donor.
- Definitive data in patients with unfavorable cytogenetic abnormalities are lacking, but it is reasonable to offer this to patients who are not eligible for some form of allogeneic stem cell transplant.
- Although leukemia cells may be present in the graft, a definitive role for purging grafts harvested during remission has not been demonstrated.

difference in patient outcomes between the two different approaches to conditioning (Fig. 61–8).[58]

Patients with unfavorable cytogenetic abnormalities have an extremely poor prognosis without allo-HSCT.[50,52,59] In fact, the data are identical to those of patients with Philadelphia chromosome-positive acute lymphocytic leukemia (ALL) who do not undergo allo-HSCT in first CR. In contrast to such ALL patients, AML patients with unfavorable cytogenetic abnormalities historically have rarely been referred for alternative donor HSCT in first CR. This reluctance likely will be overcome in the near future. A report from the German 01/99 study described a cohort of 250 high-risk patients, followed prospectively, who encountered an unequivocal benefit from allo-HSCT from MUD compared to other forms of postremission therapy.[60,61]

Autologous HSCT

After allo-HSCT, autologous HSCT offers the most potent form of postremission therapy, relying on the antileukemic effect provided by the myeloablative regimen (see box on Autologous Hematopoietic Stem Cell Transplantation for AML). Use of autologous HSCT has generated a fair amount of controversy, in part because of the difficulties in interpreting the historic outcome data and applying them to current day practice. Data are further confounded by the degree and intensity of prior chemotherapy and patient selection. Most of the major prospective studies reported over the past decade have described a lower relapse rate for patients undergoing autologous HSCT in comparison with chemotherapy (Table 61–6). The lower relapse rate following autologous HSCT has also been demonstrated in patients with favorable cytogenetic finding (Table 61–7). Thus, the preponderance of data suggests that autologous HSCT provides a more potent antileukemic efficacy than intensive chemotherapy alone.

In many instances, the overall outcome from these trials does not support a primary role for autologous HSCT, mostly because of the high mortality reported in patients undergoing an autologous HSCT: 18% in the MRC trial and 14% in the U.S. Intergroup study.[27,51] Other studies demonstrated superior DFS, but OS was not significantly improved due to subsequent rescue of patients who had relapsed and entered a second remission.[52,53]

Currently autologous HSCT performed in experienced centers is associated with a very low mortality rate, ranging from 0% to to 2%,[32] which is not greater than for patients undergoing intensive consolidation with cytarabine. Apart from the effect on fertility, some centers are reporting lower toxicity of autologous HSCT compared with intensive consolidation therapy.[62]

One of the major limitations of interpreting published data on transplantation is the very high dropout rate of patients in any transplant group. Because data are analyzed by intention-to-treat analysis, it is virtually impossible to assess the validity of such interpretation when 40% to 50% of patients who were randomized for transplant never received such therapy.[18] The strength of clinical trials in AML is the prospective nature of the data and reduction of selection biases. However, this fails to provide guidelines for a patient who presents to a clinician having successfully "selected" himself following induction, and possibly after some consolidation, and wishes to consider the most suitable further therapy.

Thus, based on the preponderance of the data demonstrating the potent antileukemic activity of autologous transplantation and the low morbidity and minimal mortality associated with this procedure using current technologies, there appears to be a clear role for this technique in patients with a favorable cytogenetic finding and for those with intermediate-risk cytogenetic abnormalities who are not suitable candidates for allo-HSCT. Some investigators have recognized the validity of autologous HSCT in AML but have suggested that it be "reserved" for patients who relapse.[63] Such considerations should be discouraged because of the very poor rate of survival for patients with relapsed AML, irrespective of their prognostic factors, when based on information that may be available at diagnosis.[64]

Intensification Therapy

A variety of studies have suggested that increasing the intensity of postremission therapy prolongs remission duration and improves OS in patients younger than 60 years with AML. Several studies have prospectively evaluated the role of intensive postremission consolidation with high-dose cytarabine (HiDAC). CALGB randomly assigned 596 patients in CR to receive four courses of cytarabine at one of three doses: 100 mg/m^2/day by continuous IV infusion for 5 days; 400 mg/m^2/day by continuous IV infusion for 5 days; or 3 g/m^2 as a 3-hour IV infusion twice daily on days 1, 3, and 5 (Fig. 61–9).[65] These consolidation courses were followed by four cycles of maintenance therapy. High rates of central nervous system toxicity were observed in patients older than 60 years randomized to the HiDAC regimen. Randomization subsequently was limited to patients 60 years or younger. DFS was 21% in the 100 mg/m^2 group, 25% in the 400 mg/m^2 group, and 39% in the 3 g/m^2 group. The results were most significant in patients with favorable cytogenetic abnormalities.[66] This trial demonstrated a dose–response effect for cytarabine in younger patients undergoing postremission therapy. Although the HiDAC regimen used in this trial has become widely adopted, it should be recognized that after the four courses of HiDAC, all patients received four monthly cycles of cytarabine 100 mg/m^2 every 12 hours for 5 days by subcutaneous injection and daunorubicin 45 mg/m^2 IV infusion on day 1. In an ECOG trial, patients without HLA-matched siblings were randomized to 2 years of continuous outpatient maintenance therapy with cytarabine and 6-thioguanine or a single course of intensive consolidation with cytarabine 3 g/m^2 IV every 12 hours for 12 doses followed by amsacrine 100 mg/m^2 per day IV for 3 days. The 4-year event-free survival at 4 years was 27% for the intensive consolidation arm and 16% for the maintenance arm ($P = 0.068$).[26] This difference was statistically significant in patients younger than 60 years. Data from the MRC suggest that HiDAC may not be required to achieve the best outcomes. In the AML-10 trial, patients who were not undergoing autologous HSCT were induced into CR with two cycles of either ADE (cytarabine, daunorubicin, etoposide) or DAT (daunorubicin, cytarabine, 6-thioguanine) then given consolidation with MACE (amsacrine, cytarabine, etoposide) and then MidAC (mitoxantrone, cytarabine), and then were randomized to either autologous HSCT or no further therapy. The highest dose of cytarabine was 1 g/m^2 every 12 hours for 3 days in MidAC. The 7-year DFS was 40%, similar to the results

reported in the CALGB discussed. These data suggest that among patients not receiving HSCT, the critical factor may be administration of intensive chemotherapy rather than the requirement for HiDAC.[67]

The number of courses of HiDAC, or any other form of intensive chemotherapy, required for optimal postremission therapy is uncertain and remains an important question for future large cooperative group studies. The Finnish Leukemia Group randomized patients younger than 65 years in CR after two courses of induction and two courses of HiDAC to four additional HiDAC consolidation courses.[68] No benefit was observed for patients randomized to the longer consolidation program, suggesting early intensive consolidation likely is the most important influence on outcome rather than the number of cycles of intensive chemotherapy. Furthermore, in the U.S. Intergroup trial among patients receiving chemotherapy only, one cycle of HiDAC resulted in a 5-year DFS of 52%.[27] Thus, although two to four cycles of intensive postremission chemotherapy are given commonly to most patients, no prospective data support this strategy.

Data suggest that the outcome of patients with core-binding factor (CBF) AML is very favorable when multiple (3–4) cycles of HiDAC (3 g/m^2 per dose) are administered. Byrd et al.[69] for the CALGB retrospectively reviewed their experience of patients with t(8;21). The 5-year DFS and OS for patients given ≥3 cycles of HiDAC (71% and 76%, respectively) was significantly higher than the rates for patients given one cycle of HiDAC followed by further cycles of chemotherapy without HiDAC (37% and 44%, respectively; $P = 0.03$ and $P = 0.04$, respectively; Fig. 61–10). However, similar favorable outcomes have been reported by the MRC in larger number of patients with regimens lacking HiDAC.

Maintenance Therapy

A prospective randomized trial conducted by the ECOG suggested that maintenance therapy with 6-thioguanine plus cytarabine 60 mg/m^2 once per week for 2 years offered a benefit in remission duration compared to no maintenance treatment (median remission duration 8.1 months vs 4.1 month; $P = 0.003$), although no significant survival difference was identified.[26] Buchner et al.[70] analyzed long-term followup data and observed a benefit to monthly maintenance for 3 years (5-year DFS 23% vs 6%). In an EORTC-HOVON trial, 76 older patients (age ≥61 years) achieving CR were randomized to no further therapy and 75 patients to eight cycles of low-dose cytarabine (10 mg/m^2 subcutaneously) every 12 hours for 12 days every 6 weeks following consolidation with the same agents used during induction.[71] An advantage in DFS was observed among patients receiving maintenance low-dose cytarabine every 6 weeks for 1 year (median DFS 20% vs 7% and 5-year DFS 13% vs 7%; $P = 0.006$). However, OS was not different (5-year OS 18% vs 15%; $P = 0.29$).[71] The AML-9 study conducted by the MRC randomized patients in CR to maintenance treatment for 1 year with eight courses of cytarabine 70 mg/m^2 subcutaneous every 12 hours and 6-thioguanine 100 mg/m^2 orally every 12 hours for 5 days per month followed by four courses of COAP (cyclophosphamide, vincristine, cytarabine, prednisone) or observation. Such therapy delayed, but did not prevent, relapse with no improvement in OS at 5 years. Therefore, contemporary studies using various maintenance regimens consistently show a benefit in DFS, but not OS, resulting from maintenance therapy.

Effect of multiple cycles of high-dose cytarabine. *(Data from Byrd JC, Dodge RK, Carroll A, et al: Patients with t(8;21) (q22;q22) and acute myeloid leukemia have superior failure-free and overall survival when repetitive cycles of high-dose cytarabine are administered. J Clin Oncol 17:3767, 1999.[69])*

SPECIFIC AML SUBTYPES

Based on the karyotype status, two major groups of AML can be discriminated: those with an abnormal karyotype, accounting for 52%–60% of patients, and those with a normal karyotype by conventional cytogenetics, composing 40%–48% of AML patients.[47,48,59,72a] Among the patients with an abnormal karyotype, 25% have balanced translocations [t(8;21),t(15;17),inv(16)], and 27% show unbalanced abnormalities [–5/del(5q), –7/del(7q) or complex karyotype]. Within the normal cytogenetic category, 45% to 63% have nucleophosmin (*NPM;* localized on chromosome 5, band q35*)* mutations, 23% to 33% show *FLT-3* (localized on chromosome 13, band q12) length mutations, 5% to 30% have *MLL* (localized on chromosome 11, band q23) tandem duplications, and 8% to 19% have CCAAT enhancer-binding protein (C/EBP; localized on chromosome 19, band q13.1) α mutations.[73a] The prognosis of patients with normal karyotype in the presence of each of these mutations is different. Patients with an *NPM* mutation alone have a favorable prognosis, especially if associated with the absence of *FLT-3* ITD, with 60% of patients living longer than 11 years.[73a,74a] In contrast, the presence of *FLT-3* and *MLL* mutations is associated with an adverse prognosis, and coexistence of *FLT-3* and *NPM* does not contribute toward better prognosis. In contrast to adults, in childhood AML with normal cytogenetics, *NPM* mutations are relatively uncommon, occurring at a frequency of 8%. Gene expression profiling and microRNA expression as diagnostic or prognostic indicators in patients with AML and a normal karyotype have limited or moderate accuracy, probably reflecting the molecular heterogeneity of this AML subtype.[88,88a]

The pretreatment karyotype constitutes an independent prognostic determinant for attainment of CR and risk of relapse and survival.[47,48,59] Four broad cytogenetic risk categories of AML are applied in clinical practice: favorable, intermediate, unfavorable, and unknown (see Table 61–1).[47,48] It is important to perform appropriate cytogenetic and fluorescent in situ hybridization studies to establish the correct cytogenetic risk category. Patients displaying normal karyotype are in the intermediate prognostic category because their survival probabilities usually are lower than those with t(8;21), inv(16)/t(16;16), or t(15;17). Their 5-year survival rate is only about 25%.[47,48,59] The incidence of intermediate- to high-risk AML increases with age (Fig. 61–11).

AML with Intermediate-Risk Cytogenetic Abnormalities

In the United States and Europe, between 40% and 50% of all AML patients have a normal karyotype (Table 61–8).

Patients with a normal karyotype are classified as having intermediate risk; however, unlike patients with favorable or unfavorable cytogenetics, such patients are heterogeneous and do not have a uniform prognosis.

Prognosis of AML patients with normal cytogenetics may be discriminated by the presence of the gene mutations resulting in *FLT-3* internal tandem duplication,[83,84] the partial tandem duplication of

Data from Rowe JM: Preface: Significant advances in the biology and therapy of AML over the past four decades. Best Pract Res Clin Haematol 19:259, 2006.

Acute Myeloid Leukemia with Intermediate-Risk Cytogenetic Abnormalities as Determined by Karyotypic Analysis

- Overall incidence increases with age but not to the same degree as acute myeloid leukemia (AML) with unfavorable cytogenetic abnormality.
- Intermediate-risk AML composes 45% to 70% of all AML cases.
- From 40% to 50% of all AML patients have a normal karyotype.
- Patients with a normal karyotype represent a group with diverse prognostic factors; thus, current classification is unsatisfactory.
- Prognostic factors for patients with normal cytogenetics include the following:
  1. Partial tandem duplication of the MLL gene
  2. Presence of the FLT-3 internal tandem duplication
  3. Wilms tumor antigen expression
  4. Multidrug resistance (MDR-1)
  5. Overexpression of other specific genes, such as BAX, BCL-2/BAX, BALC, EVI-1, KIT, ERG
  6. CD56 expression
- Prognostication can also be made by hierarchical cluster analysis using gene expression profiling.
- More favorable prognosis associated with expression of CCAAT enhancer-binding protein α (CEBPA) or nucleophosmin 1 (NPM1).
- Most young patients with intermediate cytogenetic abnormalities should be referred for an allogeneic stem cell transplant if a human leukocyte antigen (HLA)-compatible sibling is available.
- Stem cell transplants from a matched unrelated or haploidentical donor may be reasonable in young fit patients with other demonstrated unfavorable prognostic features.
- Autologous stem cell transplant is a reasonable option for those who do not have an HLA-matched donor.

the *MLL* gene,[85,86] or Wilms tumor gene (WT1) expression.[87] When gene expression profiling is used with application of hierarchical cluster analysis, distinct prognostic groups also can be discriminated among AML patients with a normal karyotype.[88,89] A more favorable prognosis is associated with the presence of gene mutations of NPM1[90] or C/EBP α (CEBPA).[91] The traditional classification of patients with a normal karyotype is rapidly evolving, resulting in a predictive model based on genetic analysis. Thus, young patients with a normal karyotype who have distinct poor prognostic features may be candidates for an alternative donor stem cell transplant if an HLA-matched donor is not readily available. Conversely, it may well be that patients with an intermediate karyotype who have a more favorable prognosis (presence of CEBPA or NPM1) may be offered postremission therapy that does not include allo-HSCT. It is likely that patients with a normal karyotype will be further defined by molecular markers, allowing for more precise prognostic classification over the next few years (see box on AML with Intermediate-Risk Cytogenetic Abnormalities as Determined by Karyotypic Analysis).

AML with Favorable-Risk Cytogenetic Abnormalities

APL is caused by translocations disrupting the retinoic acid receptor α *(RARA)* locus on chromosome 17, resulting in fusion products with other nuclear proteins such as the promyelocytic leukemia (PML) protein, whose gene is located on chromosome 15 in 99% of cases.[92] The PML-RARA fusion protein, acting in a dominant negative manner, causes APL, presumably by recruiting histone deacetylase activity and preventing transcription of genes important in promyelocyte differentiation.[93] Standard cytogenetic analysis demonstrates the 15;17 translocation [t(15;17)] in 95% to 100% of cases. Polymerase chain reaction (PCR) methodology provides a more sensitive means of detecting the PML-RARA rearrangement underlying the t(15;17). Its potential can be used to detect minimal residual APL in patients in CR. APL constitutes less than 10% of unselected cases of AML, and independent risk factors for a diagnosis of APL in a patient with AML are younger age, Hispanic background, and obesity. The chief clinical feature is a bleeding diathesis resulting from plasmin-dependent primary fibrinolysis and disseminated intravascular coagulation. In any case of untreated AML, particularly when a patient presents with such a picture, it is important to consider the typical morphologic pattern (i.e., abnormal promyelocytes containing coarse, large granules and numerous Auer rods) and the existence of a microgranular variant in which APL granules can be resolved only with electron microscopy. More importantly, cytogenetic analysis must be done to detect t(15;17). In the rare case in which such analysis does not show t(15;17) but the clinical or morphologic picture is suggestive, the POD test, which can be performed in a few hours, can detect by immunohistochemical techniques the characteristic disruption of PML in virtually all cases. Demonstration of t(15,17) or a positive POD or PCR test result is requisite for the diagnosis of APL. Recognition of APL is crucial because appropriate treatment is different from that used for other types of AML and is curative in most patients.

Acute Promyelocytic Leukemia

Hillestad[98] is credited with the first description of APL as a distinct clinical entity in 1957. Since then, more has been learned about the pathogenesis and therapy of APL than for any other subtype of AML.

Table 61–9 Distinctive Features of Acute Promyelocytic Leukemia

• 10%–15% of adult acute myeloid leukemia (1200 new patients per year in the United States)
• Leukopenia in 85%
• Coagulopathy (disseminated intravascular coagulopathy, fibrinolysis, proteolysis)
• t(15;17)
• Promyelocytic leukemia-retinoic acid receptor α (PML-RARA) fusion transcript
• Differentiation with all-*trans* retinoic acid
• Apoptosis with arsenic trioxide

Previously, this subtype of AML was highly fatal, primarily because a severe life-threatening bleeding disorder often manifested as intracerebral hemorrhage, which accounted for an induction mortality rate of 20% to 30%.[99] However, since the introduction of all-*trans* retinoic acid (ATRA) therapy in the early 1990s and its administration with anthracycline-based chemotherapy, APL is curable in the majority of patients.

APL is distinguished from other subtypes of AML in several ways, including the peculiar sensitivity of the leukemia cells to anthracyclines,[100] frequent presentation with leukopenia, presence of life-threatening coagulopathy, presence of the PML-RARA fusion transcript, which results from the t(15;17),[101,102] ability of leukemia cells to undergo differentiation with ATRA[103] and apoptosis with arsenic trioxide (ATO),[104] and high cure rate now achieved in the great majority of patients (Table 61–9).[105] Achieving CR without prior marrow aplasia also is unique to APL. This treatment approach has become a paradigm for directing therapy at the specific molecular abnormality and one of the true therapeutic triumphs in the treatment of malignant disease. Current therapy generally consists of three phases: induction, consolidation, and maintenance (see box on How to Treat Acute Promyelocytic Leukemia).

How to Treat Acute Promyelocytic Leukemia

1. Initiate treatment with all-*trans* retinoic acid (ATRA) as soon as the diagnosis is suspected without waiting for genetic confirmation in an effort to decrease the induction mortality most often related to the coagulopathy.
2. If coagulopathy is present, administer frequent platelet transfusions to maintain platelet count greater than 30,000 to 50,000/μL and cryoprecipitate to maintain fibrinogen level greater than 100 to 150 mg/dL. There is no role for routine use of heparin or antifibrinolytic agents.
3. For induction, administer anthracycline-based chemotherapy with ATRA. Give concurrent ATRA and chemotherapy for patients who present with a high white blood cell count greater than 10,000/μL. If a patient is older or unable to tolerate anthracyclines, consider ATRA plus arsenic trioxide.
4. Maintain a high index of suspicion for the retinoic acid syndrome. At the first sign of dyspnea, pleural or pericardial effusions, hypotension, or pulmonary infiltrates, initiate dexamethasone 10 mg twice daily.
5. For consolidation, give anthracycline-based chemotherapy with ATRA (1 week with each cycle) for two to three cycles until molecular remission is achieved.
6. For high-risk patients (presenting white blood cell count 10,000/μL or higher), consider either high-dose anthracyclines, intermediate- or high-dose cytarabine during either induction or consolidation, or administer arsenic trioxide.
7. For maintenance, consider either ATRA or ATRA plus low-dose chemotherapy with 6-mercaptopurine and methotrexate. Studies have suggested that patients in molecular remission may not benefit from maintenance therapy.
8. Patients can be monitored by checking the peripheral blood for promyelocytic leukemia-retinoic acid receptor α (PML-RARA) using reverse transcriptase polymerase chain reaction every 3 to 6 months, probably more frequently for high-risk patients.
9. For relapse, consider arsenic trioxide for two cycles until molecular remission is achieved, followed by high-dose chemotherapy and autologous hematopoietic stem cell transplantation. Consider prophylactic intrathecal chemotherapy for any patient who has relapsed.

Efficacy of ATRA Combined with Anthracycline-Based Chemotherapy for Induction in Patients with APL

Based on in vitro studies documenting differentiation of leukemic promyelocytes in the presence of retinoic acid, phase II clinical trials were initiated that demonstrated the remarkable effectiveness of ATRA initially in patients with relapsed and refractory APL and then in newly diagnosed patients in which the majority of patients achieved CR.[106–111] Subsequently, cooperative oncology groups carried out clinical trials comparing ATRA to conventional chemotherapy.[112–115] In a trial conducted by the North American Intergroup (protocol I0129), 350 patients were randomized to ATRA induction therapy or to conventional induction chemotherapy with daunorubicin and ara-C.[113,115] After two courses of intensive consolidation chemotherapy, patients were randomized to 1-year maintenance with daily oral ATRA or no maintenance. Patients who received ATRA during induction and during maintenance had the best outcome, and approximately 75% of these patients appear cured of their disease. The benefit of ATRA maintenance therapy also was demonstrated in the conventional chemotherapy group (5-year DFS 47% in maintenance group vs 16% in no maintenance group). The European APL group conducted a randomized trial comparing the sequential versus concurrent addition of ATRA to standard induction chemotherapy. They found benefit associated with the concurrent approach due to a decrease in the relapse rate rather than an increase in the CR rate.[114] In phase II studies the Spanish Cooperative Group PETHEMA (LPA96 and LPA99) and the GIMEMA investigated induction therapy with ATRA and idarubicin,[119,120] without cytarabine, prompted by the apparent peculiar sensitivity of leukemic promyelocytes to anthracyclines.[121]

ATRA plus idarubicin appears to be equally effective in inducing remission as was the combination of cytarabine, ATRA, and an anthracycline.[100,109] Furthermore, in the PETHEMA studies, no cytarabine was administered during any phase of treatment. However, in a prospective randomized trial by the European APL group, a higher relapse rate was observed among patients treated with ATRA plus daunorubicin than among patients treated with ATRA plus daunorubicin and cytarabine.[122] Enrollment in the noncytarabine arm was discontinued prematurely. Of the 11 relapses in the noncytarabine arm, nine were hematologic and two were molecular, compared to only one hematologic and one molecular relapse in the cytarabine arm. Possible explanations for the different results observed in the European APL group and PETHEMA studies include differences between idarubicin and daunorubicin, differences in the total cumulative doses of the two anthracyclines, and the fact that ATRA was used during consolidation in PETHEMA but not in the European group study. It appears that if idarubicin is used in the doses reported and perhaps daunorubicin is used in higher doses than previously reported, cytarabine is not needed.

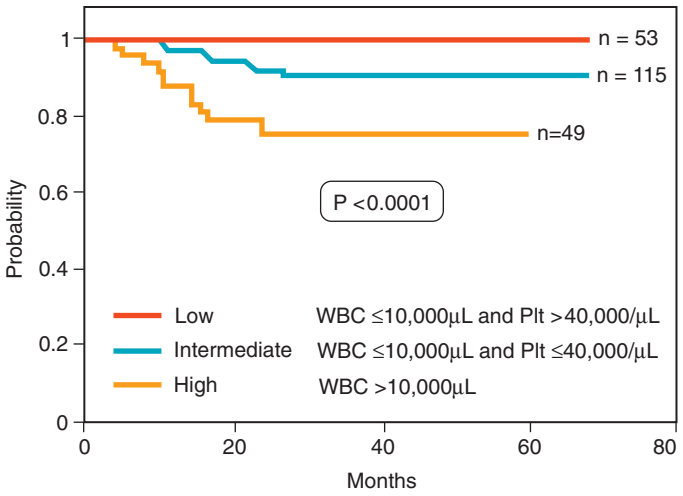

Figure 61–12 GIMEMA and PETHEMA study. Relapse-free survival of patients with acute promyelocytic leukemia by risk group. *(Data from Sanz MA, Lo Coco F, Martin G, et al. Definition of relapse risk and role of nonanthracycline drugs for consolidation in patients with acute promyelocytic leukemia: A joint study of the PETHEMA and GIMEMA cooperative groups. Blood 96:1247, 2000.[116])*

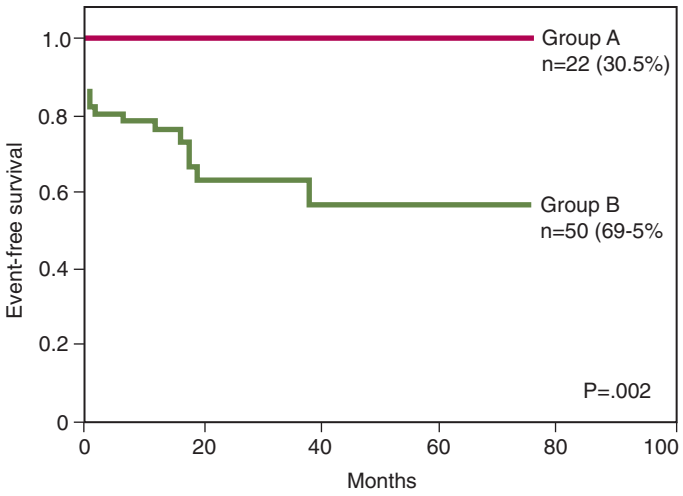

Figure 61–13 Comparison of event-free survival with single-agent arsenic trioxide therapy between good-risk acute promyelocytic leukemia patients (group A: white blood cell count <5000) and the rest (group B). *(Data from Mathews V, George B, Lakshmi KM, et al: Single-agent arsenic trioxide in the treatment of newly diagnosed acute promyelocytic leukemia: Durable remissions with minimal toxicity. Blood 107:2627, 2006.[138])*

The most important factor predicting outcome in APL is the WBC count at initial presentation. The GIMEMA and PETHEMA cooperative groups used both WBC count and platelet count to identify patients at low risk (WBC ≤ 10,000/µL, platelet count >40,000/µL), intermediate risk (WBC ≤ 10,000/µL, platelet count = 40,000/µL), or high risk (WBC > 10,000/µL) for relapse (Fig. 61–12).[116] Advanced age is another important unfavorable prognostic factor.[118] In addition, the FLT-3 internal tandem duplication mutation occurs in approximately 35% of patients with APL and appears to confer an unfavorable prognosis in patients with APL[117,123–126] The presence of the bcr3 isoform of the PML-RARA fusion transcript also has been reported to confer an unfavorable prognosis.[127]

Induction Therapy with ATO in Patients with APL

Excellent results have been observed with ATO as a single agent in patients with relapsed and refractory APL[128–133] In the U.S. multicenter trial of 40 patients with relapsed and refractory APL, all of whom previously exposed to ATRA, 85% of patients achieved CR after induction with ATO.[132] Furthermore, of 29 assessable patients who achieved CR, 86% achieved molecular remission after induction or consolidation with ATO. These data encouraged the studies of ATO as part of initial induction regimen.[134–138]

A number of studies have shown that single-agent ATO is a very effective therapy for patients with newly diagnosed APL (Table 61–10). Investigators in Iran treated patients with only two courses of ATO and found an 86% CR rate and a 92% molecular remission rate.[137] Investigators from India reported an identical CR rate among 72 patients given ATO for induction and up to six courses of ATO for consolidation.[138] In this study, CR rate and 3-year event-free survival, DFS, and OS rates were 80%, 75%, 87%, and 86%, respectively. The molecular remission rate was 76%. Patients with WBC count less than 5000/µL and platelet count greater than 20 × 10,000/µL had 3-year event-free survival, DFS, and OS rates of 100%, whereas patients not in this good-risk group had 3-year event-free survival, DFS, and OS rates of 63%, 80%, and 79% respectively (see Fig. 61–12). Investigators at the Shanghai Institute of Hematology conducted a trial in which 61 patients with newly diagnosed APL were randomized to receive ATRA, ATO, or the combination of ATRA plus ATO (Table 61–11).[136] All patients subsequently received intensive consolidation chemotherapy and maintenance therapy.

Table 61–10 Induction Therapy with Single-Agent Arsenic Trioxide of Untreated Acute Promyelocytic Leukemia Patients

Study	N	CR Rate (%)	PCR Negative (%)	Postremission Therapy
China[134]	124	88	NR	Chemotherapy
Iran[137]	111	86	92	ATO × 1
India[138]	72	86	76	ATO × 6

ATO, arsenic tetroxide; CR, complete remission; PCR, Polymerase chain reaction.

Patients randomized to the combination arm achieved complete hematologic remission in a significantly shorter median time period (25 days) than did those who received ATRA alone (40 days) or ATO alone (35 days). Furthermore, there was a significantly greater reduction in the amount of PML-RARA fusion transcript detected among patients in the combination arm. At median followup of 18 months, there were no relapses among the 20 patients who achieved CR after receiving combination therapy, whereas seven of the 37 patients who achieved CR with monotherapy relapsed.

A single small randomized study suggested that addition of ATRA to ATO in patients with relapsed and refractory APL did not improve outcome compared to ATO therapy alone.[142] However, in patients with untreated APL the combination appears to induce more rapid CR and results in a more profound molecular remission rate in newly diagnosed patients, with apparently no greater toxicity than experienced with each agent alone. Therefore, for patients who cannot be treated with anthracyclines (e.g., older patients, those with abnormal cardiac function) and who have low-risk or intermediate-risk disease, it is reasonable to consider treatment with a combination of ATO plus ATRA, or perhaps ATO alone if the patient has very low-risk disease (WBC < 5,000/µL; Fig. 61–13).

Consolidation Therapy for Patients with APL

The PETHEMA group suggested that addition of ATRA to consolidation chemotherapy may be beneficial for patients with intermediate- and high-risk disease.[120] In the LPA99 study, such patients received ATRA at the standard dosage of 45 mg/m^2/day on days 1 through 15, in combination with three courses of single-agent con-

ATO, arsenic tetroxide; ATRA, all-*trans* retinoic acid; CR, complete remission; PML-RARA, promyelocytic leukemia-retinoic acid receptor α.
Data from Shen ZX, Shi ZZ, Fang J et al: All-trans retinoic acid/As2O3 combination yields a high quality remission and survival in newly diagnosed acute promyelocytic leukemia. Proc Natl Acad Sci USA 2004;101:5328–5335.104.[136]

solidation chemotherapy. The impact of adding ATRA during consolidation was difficult to evaluate because patients in these groups also received an increased dose of idarubicin during the first course and 2 consecutive days of idarubicin during the third course, instead of 1 day as in their previous study (LPA96).[119] Nevertheless, the relapse rate was lower and the survival rate was better. However, the impact of both adding ATRA during consolidation and the higher doses of chemotherapy appeared to have less of an influence on patients with high-risk disease.

Therapy for Patients with High-Risk APL

Patients with high-risk APL currently are a major focus of clinical investigations. The 3-year cumulative incidence of relapse for patients with high-risk disease is approximately 21%. Three studies have suggested that administration of intermediate- or high-dose cytarabine to patients at high risk for relapse is beneficial.[122,143,144] The GIMEMA group administered intermediate-dose cytarabine during consolidation to patients with high-risk disease. The first course of consolidation included cytarabine 1 g/m^2/day for 4 days plus idarubicin; the second course included mitoxantrone and etoposide; and the third course included idarubicin, cytarabine 150 mg/m^2 every 8 hours subcutaneously for 5 days, and 6-thioguanine. Patients also received ATRA at conventional doses for 15 days during each consolidation course. After a median followup of 2 years, the cumulative incidence of relapse in high-risk patients was only 2%. The European APL group observed a low relapse rate among patients with WBC count greater than 10,000/μL who received consolidation with cytarabine at a dosage of 1 to 2 g/m^2 every 12 hours.[122]

In the completed North American Intergroup protocol C9710, patients received conventional ATRA, daunorubicin, and cytarabine induction therapy and then were randomized to receive or not receive two 25-day courses of ATO as an initial consolidation.[127] Patients subsequently received further consolidation with two 3-day courses of daunorubicin with 1 week of ATRA therapy. Preliminary results indicate a very low relapse rate among low- and intermediate-risk patients of 3% and 7%, respectively and a relapse rate of 16% in high-risk patients.[139a]

Maintenance Therapy for Patients with APL

Although the initial randomized trials suggested that maintenance therapy was beneficial, subsequent studies have indicated that maintenance may not be important for APL patients who have achieved a molecular remission after intensive consolidation.[141,147] In a trial conducted by the GIMEMA, between 1993 and 1997, 318 of patients were randomized to one to four maintenance arms: oral 6-mercaptopurine (6-MP) and methotrexate, ATRA alone, ATRA alternating with 6-MP and methotrexate, or no further therapy after consolidation.[147] Beginning in 1998, 268 patients in molecular remission after consolidation were randomized to ATRA alone or ATRA plus 6-MP and methotrexate. A total of 78 PML-RARA–negative patients were randomized to 6-MP plus methotrexate, 83 to ATRA alone, 81 to ATRA plus 6-MP methotrexate, and 76 to no further therapy. No difference in molecular DFS was observed among the randomized arms. A study conducted by the Japanese Adult Leukemia Study Group (APL97), which randomized patients in molecular remission to either six courses of intensive maintenance chemotherapy (no ATRA) or observation after consolidation, also could not demonstrate any benefit of maintenance.[141] These studies suggest that patients who have low- or intermediate-risk disease and who achieve molecular remission after consolidation therapy may not benefit from maintenance therapy. These results have important implications because reports have suggested a small percentage of patients may develop therapy-related secondary myelodysplastic disorders or AML.[139,140]

Treatment of Patients with Relapsed APL

ATO has become the treatment of choice for patients with relapsed or refractory APL. ATO has a greater likelihood of inducing a molecular CR (approximately 50% after a single 25-day course and 80% after two courses) and may be less toxic than chemotherapy (Table 61–12).[150] Once a molecular CR is achieved with ATO, high-dose chemotherapy followed by autologous HSCT should be considered considered.[145,150,152] For the unusual patient who remains molecularly positive following ATO, allo-HSCT appears to be an effective strategy.[146] CD33 is expressed on the surface of APL cells. For patients who experience a molecular relapse, gemtuzumab ozogamicin anti-CD33 antibody linked to calicheamicin is effective therapy.[148] Among 11 evaluated patients treated for molecular relapse with gemtuzumab ozogamicin, nine achieved a molecular remission after two doses, and these remissions were sustained. Although experience is limited, ATO also appears to be an effective approach.[149]

Prophylactic and intrathecal therapy should be considered for patients with bone marrow relapse because of an apparent increased incidence of extramedullary disease at relapse, particularly in the central nervous system.[153,154] Although not clearly beneficial, prophylactic intrathecal therapy also may be useful for patients who present with or who develop leukocytosis during the initial phase of treatment.

CBF Leukemias

CBF AML is associated with a good prognosis. AML with the specific translocation t(8;21) (Table 61–13) is associated with a younger median age at onset than many other subtypes of AML, extramedullary disease, and has a relatively favorable prognosis when treated with intensive consolidation chemotherapy in the absence of extramedullary disease.[151] Chloromas or extramedullary collections of leukemia cells, historically referred to as *granulocytic sarcomas,* may be associated with expression by leukemic blasts of CD56, which is a neural

Table 61–12 Studies with Arsenic Trioxide in Relapsed and Refractory Acute Promyelocytic Leukemia

Patients Achieving Complete After One Course of Arsenic Trioxide Therapy			
Study	***N***	**CR Rate (%)**	**Comments**
Zhang[134]	42	22 (52)	73% of the 30 patients with previously untreated achieved CR with As_2O_3
Shen[136]	10	9 (90)	Duration of As_2O_3 treatment needed to obtain CR was between 28 and 44 days (median 38 days)
Niu[131]	47	30 (85.1)	31 patients were treated with As_2O_3 alone: CR rate 83.9% 11 patients with combination of As_2O_3 and chemotherapy; CR rate 81.8% 5 patients with As_2O_3 and ATRA: CR rate 100.0%
Soignet[130]	12	11 (92)	8 of 11 patients in CR also tested negative molecularly by RT-PCR for the PML-RARA transcript
Soignet[132]	40	34 (85)	Using a 10^{-4} sensitivity level, 78% of patients exhibited molecular conversion form positive to negative by RT-PCR for the PML-RARA transcript

Table 61–13 Clinical, Biologic, and Molecular Characteristics of Acute Myeloid Leukemia with t(8;21)

Clinical Features
- Younger median age at onset
- 20% of adult and 40% of pediatric M2
- EMD
- Favorable prognosis

Biologic Features
- Most common cytogenetic abnormality associated with EMD
- EMD may have poor prognosis
- Expression of AML1-ETO fusion protein
- Leukocytosis may have poor prognosis
- Loss of sex chromosome common and may have poor prognosis
- EMD associated with CD56 expression

Molecular Features
- AML1 activates transcription
- ETO binds corepressor–HDAC complex
- HDAC removes hydrophobic acetyl groups from histones, suppressing transcription of AML1 target promoters
- AML1-ETO represses transcription

AML, acute myeloid leukemia; EMD, extramedullary disease; HDAC, High-dose Ara-C.

Table 61–14 Core-Binding Factor Leukemias

Translocation	Genes Involved
t(8;21)	AML1-ETO
t(3;21)	AML1-EAP, MDS1, EVI1
t(12;21)	TEL (ETV6)
inv(16) t(16;16)	CBFβ-MYH11

Current Treatment Recommendations for Adults with Core-Binding Factor Leukemias

- Induction therapy includes an anthracycline and cytarabine.
- Consolidation chemotherapy includes three to four courses of intensive chemotherapy.
- One effective regimen is high-dose cytarabine at a dose of 3 g/m^2, given twice daily over 1 hour for 4 to 6 days.
- The dose of cytarabine can be reduced to 1.5 g/m^2 twice daily for older adults ages 55 to 70 years.
- Patients older than 70 years can receive cytarabine at a dose of 1.5 g/m^2/day for 6 days.
- There is little role for allogeneic hematopoietic stem cell transplantation in first complete remission given the associated toxicity with the procedure.
- Autologous hematopoietic stem cell transplantation often used as postremission consolidation.
- The presence of extramedullary disease indicates a poorer prognosis and warrants more intensive therapy.

crest adhesion molecule that plays a role in trafficking of leukemic cells.[155,156] Insights into our understanding of the molecular features of leukemogenesis in patients with t(8;21) serve as a foundation for studying both leukemogenesis and chemotherapy resistance (see box on Current Treatment Recommendations for Adults with Core-Binding Factor Leukemias).

Molecular Features of t(8;21) and inv(16) or t(16;16)

The balanced reciprocal translocation between chromosomes 8 and 21 is the most common balanced translocation in de novo AML and is associated with fusion of the AML1 and ETO genes. AML with t(8;21), together with inv(16) or t(16;16), and t(12;21) also are classified as CBF leukemias (Table 61–14). The AML1 gene (also called $CBFA_2$) encodes the DNA-binding component of CBF-β, one subunit of a CBF complex that binds to DNA sequences and activates transcription of a number of genes important in hematopoiesis, including myeloperoxidase, the colony-stimulating factor (CSF)-α receptor, subsets of the T-cell antigen receptor, neutrophil elastase, interleukin-3, and granulocyte-macrophage colony-stimulating factor (GM-CSF), through recruitment of coactivators. Expression of AML1/CBF-β also may contribute to transcriptional repression and plays a major role in control of normal hematopoiesis. The normal function of the ETO gene remains elusive, but the gene is expressed as a nuclear phosphoprotein in brain tissue and in CD34$^+$ hematopoietic progenitor cells. The structure of ETO, as a nuclear zinc-finger-containing protein, implicates its role as a regulator of transcription. ETO can bind nuclear corepressor N-COR and Sin33A, which binds histone deacetylase. These observations suggest that in healthy cells, ETO functions as an adaptor protein within the nuclear corepressor complex to stabilize the interaction of these corepressor proteins. Therefore, the chimeric fusion protein AML1/ETO appears to repress transcription of genes normally activated by AML1/CBF-β. AML1/ETO inhibits CEBPA–dependent activation of the myeloid-specific NP-3 promoter and blocks granulocyte (G)-

Table 61–15 Complete Remission Duration by Cytogenetic Group According to Cytarabine Dose Randomization

Cytogenetic Group	Cytarabine Dose	No. of Patients	Median Time of CR (months)	5-Year CR (%)
Core-binding factor	3 g/m^2	18	NR	78
	400 mg/m^2	20	NR	57
	100 mg/m^2	19	14.3	16
Normal	3 g/m^2	45	18.2	40

	100 mg/m^2	47	12.5	20
Other	3 g/m^2	27	13.3	21
	400 mg/m^2	31	10.6	13
	100 mg/m^2	30	9.6	13

CR, complete remission; NR, No response.

Data from Bloomfield CD, Lawrence D, Byrd JC et al. Frequency of prolonged remission duration after high-dose cytarabine intensification in acute myeloid leukemia varies by cytogenetic subtype. Cancer Res 1998;58:4173–4179.49.

CSF–induced differentiation of myeloid progenitors and thereby contributes to leukemogenesis.[157]

As a result of the 8,21 translocation, AML fuses to ETO, not normally expressed by hematopoietic cells. Patients with CBF leukemias with alteration of either the AML1 or CBF gene, such as patients with AML M4Eo involving either inv(16)(p13;q22) or t(16;16)(p13;q22) and a fusion between MYH11 and CBF-β genes, have demonstrated a more favorable prognosis than patients with either normal or more complex karyotypic abnormalities when given repetitive cycles of intensive consolidation with high doses of cytarabine (Table 61–15).[158–160]

AML with Unfavorable Cytogenetics

Patients with unfavorable cytogenetics constitute approximately 30% of patients with previously untreated de novo AML.[48] The proportion of patients with an unfavorable karyotype increases with age.[161] Patients with unfavorable karyotypes have a poor prognosis. The definition of unfavorable karyotypes as defined by SWOG/ECOG includes −5 or deletion 5q, −7 or deletion 7q, t(6;9), t(9;22), abn3q, 11q, 20q, 17p, or 11q23 abnormalities and patients with complex karyotypes, which include three or more clonal cytogenetic abnormalities (see Table 61–1).[48] Some differences in cytogenetic classifications exist among various cooperative oncology groups. The MRC defines complex karyotype as ≥ 5 clonal abnormalities.[47] In addition, in this classification, del(7q) and del(9q) as well as 11q23 abnormalities are classified as intermediate risk. In the series by the CALGB, the outcome for patients with complex karyotypes as defined by ≥ 3 abnormalities fared slightly better than those with ≥ 5 abnormalities.[59] In the MRC series, the presence of an unfavorable karyotype constituted a heterogeneous group of patients with respect to outcome.[47] For example, patients with −5 had OS of 21% at 5 years compared to patients with a complex karyotype who had OS of only 4% at 5 years. The presence of an additional cytogenetic abnormality, even if complex, does not appear to have an unfavorable influence on outcome among patients with favorable cytogenetics.[59,162,163] Patients with unfavorable cytogenetic abnormalities have a poor probability of continuous complete CR.[47,48] Such patients appear to fare poorly with intensive chemotherapy or with MSD allo-HSCT. However, the U.S. Intergroup trial, the EORTC/GIMEMA AML-10 trial, and one small single institution study suggest that patients with unfavorable cytogenetic abnormalities may benefit from HLA-identical sibling HSCT.[48,50,164] The graft-versus-leukemia effect associated with MUD HSCT may be potent enough to overcome the otherwise poor prognosis associated with unfavorable cytogenetics.[165] Isolated trisomies of chromosomes 8, 11, 13, and 21 also have been shown to have adverse prognostic implications in adults with previously untreated AML.[166,167] However, SWOG found that the outcome of patients with sole trisomy 8 was similar to patients with an abnormal karyotype.[168] Patients with trisomy 8 and an associated favorable cytogenetic abnormality appear to have an outcome similar to that of patients with favorable cytogenetics.[167,168] Therefore, the prognosis of patients with trisomy 8 depends to a large extent on whether this abnormality occurs alone or in association with other cytogenetic abnormalities. The presence of unfavorable cytogenetic abnormalities also has prognostic importance in patients with therapy-related AML.[162,171] Expression of CD56, the neural crest adhesion molecule, has been associated with unfavorable cytogenetics abnormalities.[172]

Table 61–16 Therapy-Related Leukemia Versus De Novo AML by Cytogenetics Analysis

	Favorable	Intermediate	Unfavorable

3-year relapse risk	19%	62%	67%
3-year survival	79%	25%	14%

AML, acute myeloid leukemia.

Data from Grimwade D, Walker H, Oliver F et al: The importance of diagnostic cytogenetics on outcome in AML: Analysis of 1,612 patients entered into the MRC AML 10 trial. The Medical Research Council Adult and Children's Leukaemia Working Parties. Blood 92:2322, 1998.

Therapy-Related AML

Therapy-related AML is the most serious long-term complication of therapy for cancer. Almost all malignancies treated with cancer chemotherapy have been associated with development of AML. The optimal therapy for therapy-related leukemia continues to be debated.

The overall incidence of therapy-related leukemia in adults ranges between 5% and 10% of all patients with AML, although differences in the reported incidence likely are affected by the chosen definition of therapy-related leukemia. In essence, the ultimate prognosis of patients with true therapy-related leukemia is dependent on the cytogenetic and molecular prognostic factors at diagnosis, much like de novo AML (Table 61–16).[47] The definition of therapy-related leukemia in published series has been far broader, making comparisons and interpretation of appropriate therapies more difficult. The largest published series of therapy-related myelodysplasia or AML included

Data from Pedersen-Bjergaard J: Insights into leukemogenesis from therapy-related leukemia. N Engl J Med 352:1591, 2005.

306 patients reported from the University of Chicago.[173] Ninety-two percent of patients had cytogenetic abnormalities, the most frequent being abnormalities of chromosome 5 and 7 (Table 61–17). The OS of such patients remains dismal and is very similar to that of AML patients with unfavorable cytogenetics at presentation (Figs. 61–14 and 61–15). The two types of drugs most commonly associated with therapy-related leukemia are the alkylating agents and topoisomerase II inhibitors. Since the initial report of the association of therapy with melphalan and the development of AML,[174] virtually all the alkylating agents have been implicated (Table 61–18).[175] Similarly, since the earliest report implicating the epipodophyllotoxins in the genesis of leukemia, many other inhibitors of topoisomerase II, such as the anthracyclines, mitoxantrone, and the dioxopiperazine derivatives razoxane and bimolane, all have been associated with development of secondary AML (Table 61–18).

Definition

One of the major obstacles to progress in the treatment of therapy-related leukemia has been the variable definitions, as outlined in Table 61–19. It is clear that in the treatment of any AML, "patient issues" must be considered. Thus, any patient who had a prior malignancy or previously had been exposed to chemotherapy or radiation may have additional comorbidities that may affect the ultimate outcome. However, from a biologic standpoint, it is desirable to define therapy-related leukemia as any AML that has specific cytogenetic or molecular markers, usually associated with a poor prognosis, which define leukemogenesis as a secondary rather than a primary event. In essence, there is little biologic difference between a patient who presents with a true therapy-related leukemia and a patient with de novo AML who presents with unfavorable cytogenetic abnormalities. Although many reports have emphasized the dismal overall prognosis of patients with therapy-related leukemia,[176] the optimal treatment depends on biologic features, with the cytogenetic findings being most important. Patients with therapy-related leukemia who have a more favorable karyotype have a far better outcome than do patients with therapy-related leukemia who have an unfavorable karyotype (Fig. 61–16).[169,171] These data are consistent with older data that confirmed the favorable prognosis for patients with therapy-related leukemia who present with favorable cytogenetic abnormalities, such as t(8;21), inv(16), and t(8;18).[170,177] Whether patients with

Table 61–19 Therapy-Related Leukemia: Possible Definitions

• Any leukemia with a history of prior malignancy
• Any leukemia with a history of prior exposure to chemotherapy or radiation ("therapy-related leukemia")
• Any MDS with above
• AML that evolved from MDS
• AML or MDS with specific cytogenetic or molecular markers—usually associated with a poor prognosis—that define the leukemogenesis as a secondary rather than a primary event

AML, acute myeloid leukemia; MDS, myelodysplasia.

secondary leukemia have a poor prognosis independent of their cytogenetic findings continues to be debated (see box on Therapy of Secondary Leukemia—The Problem). In 2002 the MRC reported an apparently independent poor prognosis for patients with therapy-related leukemia.[178]

Induction and Postremission Therapy

Multiple induction regimens have been proposed for treatment of therapy-related leukemia (Table 61–20). Not surprisingly, the CR rate is best in the smallest studies and worsens as the studies accrue larger numbers of patients.

No evidence indicates that any form of therapy is more optimal than standard induction therapy using the classic 3 + 7 regimen or

Table 61–20 Therapy-Related Leukemia: Induction Therapy for Therapy-Related Acute Myeloid Leukemia

	N	Complete Remission (%)
Preisler[315]	11	73
De Witte[316]	22	62
Pederson-Bjergaard[317]	36	62

Therapy of Secondary Leukemia—The Problem

- Small numbers
- Much of the published literature based on premise and/or intuition
- No prospective randomized studies specifically directed at treatment of secondary leukemia
- Most reported studies are retrospective analyses
- Data often lumped together with myelodysplastic syndrome
- Variable definition

similar. Among patients younger than 60 years, the CR rate is approximately 55% for patients with unfavorable cytogenetic findings and significantly better for patients with intermediate and favorable cytogenetic findings. Thus, the overall direction when treating such a patient should be based on the prognostic indicators and the patient's overall performance status rather than the history.

Relapsed and Refractory AML

The majority of adults with AML who achieve CR eventually relapse, usually within 2 years. Furthermore, approximately 20% of patients never achieve a first complete remission (CR1). For such patients, effective therapies are limited. Allo-HSCT is considered the optimal curative strategy. However, many patients do not have a suitable donor or are not candidates for transplantation. Furthermore, allo-HSCT is most effective when the patient is in remission. The definition of refractory AML includes patients who fail to achieve CR with conventional induction chemotherapy, those with a short (<6–12 months) CR1 duration, and patients who have relapsed at least twice.[179]

The rate of CR in patients with recurrent AML with reinduction chemotherapy typically is lower than that achieved with initial induction therapy, and most patients have a shorter duration of second complete remission (CR2) compared to CR1.[180] If CR2 is achieved, the median duration of remission and DFS are generally short (<12 months). In addition, reinduction therapy often is associated with substantial treatment-related morbidity and mortality. These patients are candidates for clinical trials exploring innovative therapeutic strategies. There is no lack of new agents to explore.

Prognostic Factors in Patients with Relapsed or Refractory AML

With the exception of patients with APL, the prognosis for the majority of adults with relapsed or refractory AML with CR1 duration less than 12 months is poor whether treatment includes conventional cytotoxic chemotherapy such as high-dose cytarabine or investigational agents (Fig. 61–17).[181] Patients whose CR1 duration is between

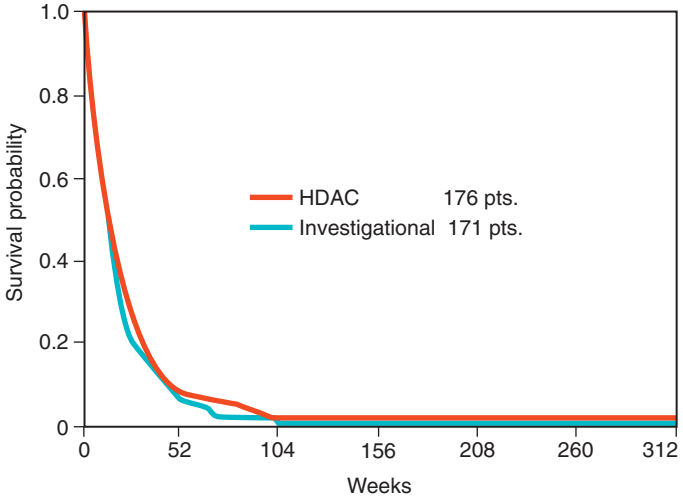

Figure 61–17 Survival of relapsed or refractory acute myeloid leukemia patients probability by type of salvage regimen (HDAC-based vs investigational) in relapsed acute myeloid leukemia patients whose initial CR was <1 year. *(Data from Estey EH: Treatment of relapsed and refractory acute myelogenous leukemia. Leukemia 14:476, 2000.[181])*

1 and 2 years are more likely to achieve CR2 with high-dose cytarabine than with investigational strategies. Identification of factors that predict a favorable or unfavorable outcome with salvage chemotherapy can guide therapy.

Almost 2 decades ago, Keating et al.[182] showed that advanced age, abnormal liver function tests, serum lactate dehydrogenase level, marrow karyotype, proportion of blasts plus promyelocytes, and shorter (<1 year) CR1 duration were significantly associated with response to therapy and survival after salvage chemotherapy. Two studies that reported the outcome of approximately 1200 younger patients with AML in first relapse based on four clinical parameters (length of relapse-free interval after first CR, cytogenetic findings at diagnosis, age at relapse, and whether HSCT had been performed) led to construction of the European Prognostic Index.[183,184] Prognostic scores ranged from 0 to 14 points based on strictly defined criteria, with higher scores predicting a worse prognosis. Using this stratification system, three risk groups were defined: favorable prognostic group (0–6 points), intermediate-risk group (7–9 points), and poor-risk group (10–14 points). In these studies, the 1-year OS rate was 70% and the 5-year OS rate was 64% for the favorable prognostic group, the 1-year OS was 49% and the 3-year OS was 18% for the intermediate-risk group, and 16% and 14% for the poor-risk group.

In addition to improving outcomes in patients with relapsed and refractory AML, efforts have been undertaken to identify quantitative methods that predict for relapse in patients who are in apparent morphologic CR. For example, a persistently abnormal karyotypic abnormality in patients in apparent CR by morphologic criteria predicts for relapse.[185]

Age

The CR rate with conventional cytotoxic salvage chemotherapy of patients who relapse during their first CR is inversely related to age (Table 61–21).[179,182,186–188] In a retrospective study by Rees et al.[188] that included a large number of patients in each age subgroup, the CR2 rate among 375 patients was 33% for younger patients compared to 19% among older patients.

Duration of CR1

The most important predictor of achieving CR2 with salvage chemotherapy appears to be the duration of CR1.[179,188,189–192] Patients with relapsed AML usually are categorized into one of two groups: those

Table 61–23 Impact of Diagnostic Cytogenetics on Second Complete Response Rate and Survival in Patients with First Relapse Acute Myeloid Leukemia

	Weltermann[196]		Kern[197]		Wheatley[194]
Risk Group	***CR Rate (%)***	***3-Year Survival (%)***	***CR Rate (%)***	***CR Rate (%)***	**5-Year Survival (%)**
Good	88	43	80	90	72
Intermediate	64	18	49	54	43
Poor	36	0	30	45	17

Good risk: Presence of t(15;17), t(8;21) or inv (16).
Intermediate risk: Presence of a normal karyotype or cytogenetic abnormalities not included in favorable or poor-risk groups.
Poor risk: Presence of a complex karyotype or abnormalities of chromosome 3, 5, or 7.
CR, complete remission.

with CR1 greater than 1 year or those with CR1 less than 1 year (Table 61–22).

Cytogenetic Abnormalities

Pretreatment cytogenetic abnormalities have important prognostic implications in patients with relapsed and refractory AML.[193–196] Kantarjian et al.[193] reported that a favorable karyotype was more frequent in patients whose first CR persisted for least 12 months, whereas the opposite was found in patients with an unfavorable karyotype. Other investigators have provided similar observations concerning the prognostic significance of pretreatment cytogenetic findings in patients with relapsed and refractory AML (Table 61–23).[194–196] Kern et al.[195] reported that unfavorable cytogenetic findings were associated with a lower rate of achieving a second CR and were a poor prognostic factor with regard to survival following first relapse. Kern et al.[197] suggested that cytogenetic findings at relapse tend to be predictive of outcome more strongly than cytogenetic finding at diagnosis. However, Estey et al.[198] found that a change in the cytogenetic pattern at first relapse did not influence the prognosis of therapy after first relapse in the majority of patients.

Treatment of Patients with Relapsed or Refractory AML

Conventional Cytotoxic Chemotherapy

Many salvage chemotherapy regimens have been studied in patients with relapsed or refractory AML, with modest success. No standard chemotherapy regimen provides a durable second or greater CR. One of the most active agents is high-dose cytarabine. Doses range from 500 mg/m^2 to 3 g/m^2 every 12 hours for up to 6 days, given either alone or in combination with other active agents including anthracyclines, asparaginase, etoposide, mitoxantrone, or amsacrine.[199–206] In general, CR rates in the range from 30% to 65% have been observed, with associated reinduction mortality rates of 12% to 25%. Whether the higher doses of cytarabine are more effective is not clear.

The German AML Cooperative Group trial compared cytarabine 3 g/m² with 1 g/m² administered twice daily on days 1, 2, 7, and 8 given with mitoxantrone in patients younger than 60 years. No substantial difference in CR rate (approximately 47%) was noted.[187] Therefore, although dose-intense cytarabine is viewed as an essential component of many conventional salvage programs, dose escalation to 3 g/m² may not be justified in many patients given the increased toxicity. It is desirable to select a salvage chemotherapy regimen with minimal toxicity because many suitable patients subsequently are offered HSCT.

Similarly, there is no definitive proof that additional agents given with intermediate- or high-dose ara-C improves OS. A large randomized trial conducted by SWOG did not show a benefit in OS with the addition of mitoxantrone to HiDAC every 12 hours for a total of 6 days.[204] Similarly, in a study of etoposide combined with HiDAC, a CR rate of 45% was observed compared to a CR rate of 40% with HiDAC.[206] Novel regimens with cytotoxic chemotherapy or other agents, including mitoxantrone plus etoposide, or purine analogues, have been explored, but there is no evidence that they represent an improvement over intermediate- or high-dose cytarabine-based regimens.[189,209–213]

Novel Agents Combined with Conventional Cytotoxic Chemotherapy

Several novel therapies have been combined with conventional chemotherapy in an effort to improve outcome (Table 61–24). These include targeted therapies, many of which are small molecules directed toward specific genetic abnormalities. Therapies to promote intracellular drug retention by inhibiting the efflux pump P-glycoprotein, a product of the multidrug resistance (MDR)-1 gene, have a particularly compelling rationale based on in vitro observations. Cyclosporine[208,214] and its analogue PSC-833 have been studied, but their use has not been associated with improved outcomes compared to conventional chemotherapy.[215,216] Other novel inhibitors, such as zosuquidar, which has pharmacokinetic properties such that concomitant chemotherapy need not be reduced as with other MDR inhibitors, also have not been associated with better outcomes.[217] Despite strong preclinical data, trials using MDR inhibitors alone or in combination with chemotherapy and gemtuzumab ozogamicin[218,219] have shown variable and generally disappointing results. A phase III trial conducted by the SWOG demonstrated significant improvement in relapse-free-survival and OS when cyclosporine was combined with daunorubicin and high-dose cytarabine,[208] but these results were not validated by other studies using a similar strategy.[214]

Allogeneic HSCT in Relapsed AML

Allo-HSCT remains the only known curative treatment of relapsed or refractory AML. However, only a minority of patients are candidates for this approach. Gale et al.[220] demonstrated significantly better leukemia-free-survival withMSD HSCT compared to chemotherapy in adults 30 years or younger and CR1 longer than 1 year (41% vs 17%; $P = 0.017$) or adults older than 30 years and CR1 shorter than 1 year (18% vs 7%). Three-year probabilities of treatment-related mortality with chemotherapy and HSCT were 7% versus 56%, respectively. It is reasonable to consider HSCT in early first relapse in young (age <60 years) adults if a suitable MSD is readily available. Clift et al.[221] demonstrated a 5-year DFS of 28% and a cure rate of 25% to 30% among 126 patients transplanted for AML in first untreated relapse. These results are comparable when MSD HSCT is carried out in CR2.[222] Reiffers et al.[223] demonstrated a 3-year DFS of 35% among 459 patients. Moreover, approximately 50% of patients in first relapse successfully achieved CR2, and 15% to 20% died during reinduction chemotherapy.

A routine strategy is reinduction with salvage chemotherapy to achieve CR2 followed by HSCT. There is no standard chemotherapy

Table 61–24 Studies with Novel Cytotoxic Drugs for Treatment of Relapsed/Refractory Acute Myeloid Leukemia

Agent	Class	Mechanism of Action	Comments
Clofarabine	Nucleoside analogue	Inhibits RNR	Phase II trials in combination with Ara-C, particularly in elderly underway[249,250]
Gemtuzumab ozogamicin	Immunoconjugates	Antitumor Antibiotic Calicheamicin	Odds ratio 30% in older adults in late first relapse[252–256]
Troxacitabine	Nucleoside analogue	Inhibits RNR	Odds ratio 18% in refractory acute myeloid leukemia; combination studies show antileukemia activity; causes hand–foot syndrome[250,251]
Cloretazine	Alkylating agent	DNA damage	Phase III trials underway evaluating chemotherapy ± cloretazine[260,261]
FLT-3 inhibitor	Small molecule inhibitor	Inhibits tyrosine kinase	Reduction in blasts in blood and marrow, but rare CR; in phase III trials evaluating chemotherapy ± inhibitor[39]
SU5416	Small molecule inhibitor	Inhibits vascular endothelial growth factor receptor	Modest clinical efficacy as a single agent[263]
Farnesyltransferase	Nonpeptidometric enzyme-specific linked inhibitor	Inhibits farnesyl protein transferase	Modest clinical activity but with few CR[264]; phase III trial in older adults in CR1 or any patient in CR2 after consolidation as maintenance underway
Oblimersen	Antisense	Inhibits bcl-2	Can be combined with chemotherapy[266]
Decitabine	Nucleoside analogue hypomethylating agent	Removes methyl groups from certain genes	Includes CR[267]

Ara-C, cytosine arabinoside; CR, complete remission; RNR, ribonucleotide reductase; FLT-3, fms-like tyrosine kinase 3.

regimen for this clinical setting. The selection of one regimen over the other is often based on CR1 duration and patient age. The FLAG ± idarubicin regimen (fludarabine, ara-C, G-CSF) had been used for cytoreduction, followed by either matched sibling or MUD HSCT, with some success.[224] Promising results have been reported with either autologous HSCT or allo-HSCT using a preparative regimen that includes increased radiation dose delivered by ^{131}I-labeled anti-CD45 antibody.[225,226] The role of autologous HSCT in younger patients with CR1 greater than 1 year is unclear because no randomized trials have compared this approach with MUD HSCT.

Interpretation of data comparing HSCT and chemotherapy as consolidation therapy is difficult. Differing results likely are attributable in part to patient selection and difficulties in defining duration of response in the chemotherapy arms because most patients proceed to other therapies, including HSCT.

Relapse After Transplantation

The best approach for patients relapsing after allo-HSCT is controversial. Without further therapy, their median survival is approximately 3 to 4 months. Options such as immunotherapy, donor lymphocyte infusion (DLI), or a second allo-HSCT after myeloablative conditioning have been studied but have limited effectiveness. Choi et al.[227] treated 16 patients who relapsed after allogeneic HSCT with cytoreductive chemotherapy followed immediately by G-CSF–primed DLI. Ten of the 16 patients achieved CR; four of the patients remained in CR at the time of publication. OS at 2 years was 31%. Duration of CR after HSCT (>6 months or <6 months) was the only significant prognostic factor for OS. All five patients who relapsed after chemotherapy followed by DLI strategy did so in extramedullary sites, as has been observed by other investigators.[228] Response rates to DLI for relapsed AML range from 15% to 30%. However, CR rates are durable only in a minority of patients.[229] Associated toxicities of DLI include acute graft-versus-host disease (>grade II in 30%), with treatment-related mortality rates estimated to be up to 20%. In young patients refractory to DLI or among those with longer CR duration after allo-HSCT, a second allo-HSCT should be considered.[230] However, both relapse and mortality rates associated with second transplants are high (42% and 30%, respectively) in the series from the CIBMTR,[231] and reduced-intensity conditioning transplantation frequently is required. Further investigation and development of new approaches for patients in this clinical setting to maximize the graft-versus-leukemia effect and to minimize graft-versus-host disease and toxicity are underway. Umbilical cord blood stem cells are another source of stem cells for transplantation for patients who lack a suitable MSD or MUD.[232,233] To increase the graft cell dose present in a single umbilical cord unit, double cord unit transplantations have been evaluated, with limited success.[234] None of these transplant approaches from alternative donor stem cell sources can be considered standard of care and remain investigational.

Refractory AML

Allo-HSCT offers the best chance for achieving sustained CR in patients with primary refractory AML. The outcome appears to be better among patients without peripheral blood blasts and with bone marrow containing less than 30% blasts prior to conditioning for transplant.[235] Forman et al.[236] reported a cumulative probability of DFS of 43% at 10 years in 21 young (age <41 years) AML (n = 16) and ALL (n = 5) patients after MSD HSCT. Biggs et al.[237] described 88 AML patients (age <52 years) who were refractory to at least two courses of cytotoxic chemotherapy and subsequently proceeded to MSD HSCT. The 3-year probability of leukemia-free survival in these patients was 21% (14%–31%), with 3-year treatment-related mortality rate of 44%. Cook et al.[238] showed that allo-HSCT can cure a small proportion of patients refractory to induction chemotherapy. On the other hand, relapsed patients who are refractory to reinduction have a dismal prognosis. Nevertheless, it is reasonable to offer some form of allo-HSCT if the patient has not undergone this procedure during CR1.

Similar to MUD HSCT, use of partially mismatched related donors expands the population of patients who potentially can benefit from allo-HSCT for primary refractory AML. This strategy is a reasonable alternative in patients with no MSD available and may result in a similar outcome.[239] In a retrospective trial by Singhal et al.,[240] the outcome of 24 MSD (median age 24 years) and 19 partially HLA-mismatched related donor (PMRD; median age 34 years; $P = 0.04$) allo-HSCT recipients with primary refractory AML and other hematologic malignancies were compared. All PMRD patients and 90% of the MSD patients achieved CR2. The advantage of PMRD transplantation over MUD HSCT is the rapid availability of the donor, a factor that is of critical importance in patients with refractory progressive acute leukemia. Haploidentical stem cell transplantation is another alternative strategy that has met with considerable success.[56,241,242] The emerging data suggest that this form of transplant may have some efficacy for AML.[213a]

Autologous HSCT

The exact role of autologous HSCT in younger patients with relapsed AML without an HLA matched donor for allo-HSCT is not established. Without randomized studies, the data are unclear and demonstrate variable results. The EBMT registry data show DFS probabilities in the range from 30% to 35% for patients undergoing autologous HSCT in CR2.[243,244] These numbers clearly are better than those reported in prospective nonregistry studies. When compared with chemotherapy, autologous HSCT has not been shown to lead to a statistically significant improved survival for patients in CR2.[245] Moreover, for the majority of AML patients who receive autologous HSCT in CR1 and relapse, a second autologous HSCT rarely is feasible. Data from the EBMT registry show that only 56 (3.5%) of 1579 AML patients who relapsed after an autologous HSCT in CR1 have been treated with a second autologous HSCT.[246]

An analysis by Lazarus et al.[247] for the CBMTR showed superior outcomes with autologous HSCT ($n = 668$) compared with MUD HSCT ($n = 476$) in patients in CR1 ($n = 692$) and patients in CR2 ($n = 452$). Multiple confounding factors may have accounted for these results, including limitations in defining the degree of match between unrelated donor–recipient pairs, accrual of older patients, and inclusion of patients with adverse cytogenetic findings among patients undergoing MUD HSCT.

Investigational Agents in Relapsed and Refractory AML (Table 61–24)

New Purine Analogues

Clofarabine (2-chloro-2′β-fluoro-deoxy-9-β-D-arabinofuranosyladenine) is a newer second-generation purine adenosine nucleoside analogue with improved toxicity profile.[210] The drug is highly resistant to cleavage by bacterial purine nucleoside phosphorylase and is resistant to deamination by adenosine deaminase. Clofarabine acts by inhibiting ribonucleotide reductase and DNA polymerase, depleting the amount of intracellular dNTPs available for DNA replication, resulting in premature DNA chain termination. In a phase II trial of relapsed and refractory patients with AML and other hematologic malignancies, an overall response rate of 48% was achieved, including a CR rate of 32%.[248] In a subsequent phase I/II trial of relapsed and refractory leukemias, predominantly AML, clofarabine was combined with cytarabine in an effort to modulate cytarabine triphosphate accumulation.[249] The overall response rate was 38%, with a CR rate of 22%. Dose-limiting toxicities include reversible hepatotoxicity and rash but no neurotoxicity.

Several other important cytotoxic agents have been introduced. Phase I/II trials with these novel agents have demonstrated some

therapeutic efficacy, and these agents currently are under further investigation in combination regimens (see Table 61–3). Troxacitabine is a novel L-nucleoside analogue with activity in refractory AML both as a single agent activity and combined with other cytotoxic agents.[250,251]

Gemtuzumab Ozogamicin

Gemtuzumab ozogamicin is an immunoconjugate of a humanized anti-CD33 monoclonal antibody chemically linked to the potent cytotoxic antitumor antibiotic calicheamicin.[252] The immunoconjugate is internalized into the leukemia cell expressing CD33, and the calicheamicin is freed intracellularly after the acid environment of the cell results in hydrolysis of the chemical linker.[253] A compilation of three phase II trials showed an overall response rate of approximately 26% (13% CR and 13% CRp among patients in first relapse who had a more favorable prognosis because they had a prolonged CR and did not have therapy-related AML or AML that had evolved from an antecedent hematologic disorder).[254]

These results led to the approval of this drug for use in older adults with AML in first relapse who were not candidates for intensive chemotherapy.[255] In a final analysis of 277 patients in first relapse treated with gemtuzumab ozogamicin, 26% achieved remission (13% CR and 13% CRp), with a median recurrence-free survival of 6.4 months for patients who achieved CR.[256] Data have shown that the results of gemtuzumab ozogamicin as monotherapy correlate with P-glycoprotein–mediated drug efflux.[257] Unique toxicities are hepatic venoocclusive disease and sinusoidal obstructive syndrome, which are rare (<1%), but the incidence is higher among patients who undergo allo-HSCT within 3.5 months of exposure to gemtuzumab ozogamicin.[258,259] Given the limited effectiveness of this agent as monotherapy, phase II studies exploring combinations of gemtuzumab ozogamicin with chemotherapy have been performed, with encouraging results. Therefore, gemtuzumab ozogamicin has been incorporated in ongoing randomized trials of untreated patients with AML evaluating its benefit when combined with induction chemotherapy and as an in vivo purging agent of grafts prior to autologous HSCT. Preliminary data from the MRC study using gemtuzumab ozogamicin in combination with standard induction chemotherapy were most encouraging.[37]

Novel Alkylating Agents

Cloretazine is a sulfonylhydrazine alkylating agent with modest activity in high-risk relapsed AML patients (CR1 duration <6 months) that may prove more effective when combined with other agents.[260,261]

Other Targeted Agents

Many other agents with novel mechanisms of action are being investigated in patients with relapsed or refractory AML (see Table 61–24).[262] They include FLT-3 inhibitors[39]; receptor tyrosine kinase inhibitors such as SU5416[263]; farnesyltransferase inhibitors, which interfere with Ras signaling[264,265]; agents that promote apoptosis, such as the bcl-2 antisense oligonucleotide, which downregulates bcl-2[266]; and methyltransferase inhibitors, such as decitabine, which induce hypomethylation of CpG-containing parts of the genome.[267] FLT-3 inhibitors such as CEP-701 have modest antileukemic activity as single agents, as demonstrated by reductions in peripheral blood and occasionally bone marrow blasts, but few, if any, patients achieve CR. Data suggest that combining these agents with cytotoxic chemotherapy may be useful.[268,269] Studies have explored the FLT-3 inhibitor PKC-412 combined with daunorubicin and ara-C in newly diagnosed patients. Ninety-one percent of patients with FLT-3 mutations achieved CR compared to 53% of patients without FLT-3 mutations. In a trial of CEP-701 (lestaurtinib) restricted to patients in first relapse, greater than 85% inhibition of FLT-3 occurred in 76% of patients. Decitabine is an exciting new hypomethylating agent with activity in patients with AML.[267]

Strategies to Detect Early Relapse in AML

Current remission criteria are inefficient in detecting residual leukemic cells, that is, minimal residual disease (MRD). More sensitive methods, such as cytogenetics, flow cytometry, and reverse transcriptase (RT)-PCR, are not routinely used. These methods, when combined with morphologic criteria for remission, may decrease the relapse rate and provide insight into the clinical efficacy of different therapeutic strategies and might improve overall prognostic stratification in AML patients. Marcucci et al.[276] retrospectively evaluated 118 AML patients with abnormal cytogenetic finding at diagnosis (n = 118). Patients who converted to normal cytogenetic findings at CR1 (NCR1; n = 103) were compared with those with abnormal cytogenetic findings at both diagnosis and CR1 (ACR1; n = 15). ACR1 patients had significantly shorter OS (P = 0.006) and DFS (P = 0.0001) and higher cumulative incidence of relapse (P = 0.0001). In multivariable models, the NCR1 and ACR groups were predictors for OS (P = 0.03), DFS (P = 0.02), and cumulative incidence of relapse (P = 0.05; Fig. 61–18). The relative risk of relapse or death was 2.1 times higher for ACR patients than for NCR patients (95% confidence interval 1.1–3.9). Notably, there was no significant difference in time of attaining CR1 between the NCR and ACR groups. At 3 years, all patients in the ACR1 group had relapsed compared to 61% in the NCR1 group.

The ability of immunophenotyping to identify a leukemia-associated phenotype has significantly increased the sensitivity of MRD detection in patients with AML. Buccisano et al.[270] used this technique to evaluate MRD at the end of induction and following consolidation in a total of 92 patients. The threshold discriminating MRD^- from MRD^+ cases was set at 3.5×10^{-4} residual leukemic cells. The results showed that the MRD status at the end of consolidation was the most significant predictor of outcome, with 5-year actuarial probability of relapse-free survival and OS at 5 years of 71% and 64%, respectively, for MRD^- patients compared to 13% and 16%, respectively, for MRD^+ patients. Interestingly, the majority of patients with MRD^+ status at the end of consolidation relapsed after autologous HSCT.

Controversy exists as to the prognostic significance of FMS-like receptor tyrosine kinase (FLT-3) mutations. Although the exact mechanism by which FLT-3 mutation leads to an increased relapse risk remains to be defined, it appears to relate to an increased proliferative potential caused by a cytokine-independent phenotype rather than resistance to conventional chemotherapy, making it another possible therapeutic target. Del Poeta et al.[271] suggested that the bax/bcl-2 ratio is a predictor of both OS and time to relapse. However, the value of this index in risk-stratifying AML patients remains to be determined. In patients with APL, the more sensitive method of RT-

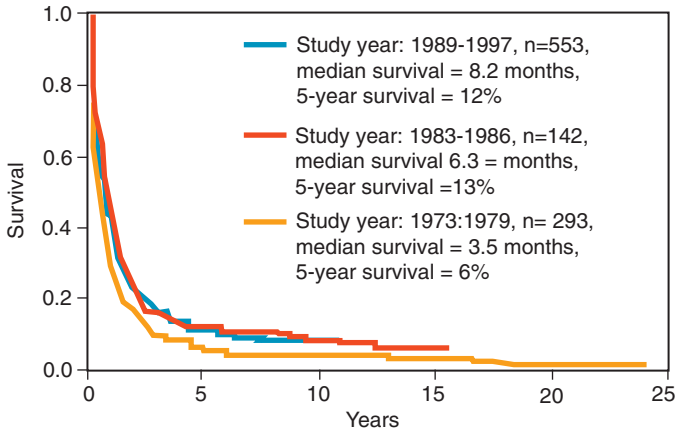

Figure 61–18 Patients older than 55 years with newly diagnosed acute myeloid leukemia treated with Eastern Cooperative Oncology Group (ECOG) protocols since 1973. *(Data from Appelbaum FR, Rowe JM, Radich J, et al: Acute myeloid leukemia. Hematology Am Soc Hematol Educ Program 62, 2001.)*

Table 61–25 Clinical and Biologic Features That Distinguish AML in Older Adults from the More Characteristic AML Occurring in Younger Adults

• More common
• Dismal long-term prognosis
• Published data often misleading
• More unfavorable prognostic factors
• Cytogenetics
• MDR-1
• Morphology
• Often indistinguishable from "classic" secondary leukemia
• Inability to withstand rigors of chemotherapy
• Inadequate postremission therapy

AML, acute myeloid leukemia; MDR, multidrug resistance.
Data from Rowe JM: Treatment of acute myelogenous leukemia in older adults. Leukemia 14:480, 2000.

PCR for detecting PML-RARA transcript, especially when increases in the quantity of transcript are observed serially, correlates with an increased probability of hematologic relapse.[272] Such data are used to identify patients who require early salvage therapy with ATO and subsequent HSCT. All these approaches are of value in detecting patients at high risk for relapse in whom an early therapeutic intervention would be justified.

AML in Elderly Adults

Elderly adults have dismal long-term prognosis that has not improved much over the past 3 decades (see Fig. 61–18). Such patients generally have more unfavorable prognostic factors at presentation, including a high proportion of intermediate-risk and unfavorable-risk cytogenetic findings; high incidence of antecedent hematologic disorders, such as myelodysplasia; high frequency of leukemic cells that express the MDR-1 gene; high incidence of trilineage dysplasia; and increased incidence of the FLT-3 internal tandem duplication. Furthermore, treatment of the elderly with AML Is made more difficult by the inability of the elderly to tolerate intensive chemotherapy. The type of postremission therapy that such patients receive is generally considered suboptimal. In essence, the difficulty of managing AML in older patients is due the suboptimal therapy offered to poor-risk patients (Table 61–25).[273]

Induction Therapy

Older adults who do not have significant comorbidities should be treated with standard induction therapy (see box on How to Treat Older Patients). The mortality from induction therapy is clearly related to the presence and severity of comorbidities.[274] In general, older patients tolerate induction therapy well. Full doses of 3 + 7 induction should be given. Dose attenuation does not shorten the period of aplasia and significantly reduces the likelihood of achieving CR. With such therapy, approximately 50% of patients can achieve CR (Table 61–26), except for older patients who have unfavorable cytogenetics in whom the CR rate is only 25% to 30%.[275–278]

Therapy for Patients Older Than 75 Years

A difficult but common dilemma is the optimal therapy for newly diagnosed AML patients older than 75 years. A strict age cutoff is to be discouraged; the decision should be based on the biologic status of the individual patient. Thus, a fit 75-year-old may tolerate induction therapy well, albeit with a higher mortality than a 30-year-old. The inherent improved quality of life for a patient in CR often will tip the scales in favor of standard induction therapy. The alternative to standard induction therapy usually includes a palliative approach with hydroxyurea, low-dose cytarabine, or similar agents, and supportive care with antibiotics and red cell and platelet transfusions. This therapy should be reserved primarily for patients who are deemed to have an excessive expected mortality from standard induction therapy. Such patients should be encouraged to enter clinical trails using some of the new targeted agents (see previous section Investigational Agents in Relapsed and Refractory AML) that are not severely myelosuppressive.

Table 61–26 CR Rate in Older Adults with Acute Myeloid Leukemia: Treatment in the Modern Era

	N	CR Rate (%)	CR, Unfavorable Rate (%)
MRC AML-11[276]	1314	55	26
CALGB[277]	388	52	
SWOG[278]	328	38	34
German AMLCG[70]	297	60	
ECOG[275]	348	42	30

CR, complete remission.

How to Treat Older Patients

- Older adults represent the greatest challenge in the management of acute myeloid leukemia (AML).
- Older patients represent the majority of AML patients.
- Little progress over the past 3 decades in treatment of AML in the elderly.
- Standard 3 + 7 induction therapy at full dose should be offered if patient has no serious comorbidities.
- Chemotherapy dose attenuation leads to a similar degree of aplasia but with a reduced chance of achieving remission.
- Patients with serious comorbidities should be treated with either hydroxyurea or low-dose cytarabine.
- In the group as a whole, 40% to 50% of patients can achieve a complete remission but only approximately 25% of those with unfavorable karyotypic abnormalities.
- No absolute data that any form of postremission therapy makes a difference.
- Standard of care is some form of postremission therapy.
- An effective regimen is cytarabine 1.5 g/m^2 given twice daily over 1 hour for 12 doses. Patients older than 70 years should receive six doses.
- Probably one cycle of consolidation therapy is appropriate; more is not better.
- Patients with unfavorable cytogenetic abnormalities should not receive standard consolidation therapy.
- Patients should be encouraged to enter studies for targeted therapy or maintenance therapy using low-dose cytarabine.
- Patients who have a histocompatible allogeneic stem cell donor should be encouraged to enter a clinical trial of allogeneic hematopoietic stem cell transplantation using reduced-intensity conditioning.

Postremission Therapy

The selection of postremission therapy for the elderly with AML remains a dilemma. Whether any form of postremission therapy

prolongs OS in older patients is unknown. In addition, the regimen and the number of courses of such a regimen have not been established.[279] Several studies have compared the role of intensive consolidation therapy in older adults.[70,276,277,280] Each of these studies demonstrated that further intensification of the dose of chemotherapy after a single course of consolidation was of no value. Thus, for postremission therapy for older adults, the correct approach likely depends on the patient prognostic factors at presentation. Assuming that the patient is fit, it is reasonable to offer one cycle of intensive consolidation therapy. Additional intensive chemotherapy consolidation should be considered investigational. For uncommon older patients who have favorable cytogenetic findings, maximal tolerated chemotherapy should be given, as, occasionally such patients may be cured.[47] At the other end of the spectrum, there probably is no justification to administering standard intensive consolidation therapy to older patients who have unfavorable cytogenetics and have achieved CR. Such patients have a uniformly poor prognosis, irrespective of the therapy offered.[276,283] These patients probably should be offered some form of experimental therapy or entered into a trial of maintenance therapy.[285]

Use of reduced-intensity HSCT[57a,58] has offered new opportunities to therapy for AML in older patients and may increase the number of patients who may achieve long-term DFS. However, prospective data in this regard are limited.

Autologous HSCT is feasible in older patients with a good performance status and offers significant promise. The EORTC-GIMEMA AML-13 study reported a 3-year DFS of 28%and OS of 39% among 35 patients who received an autologous HSCT.[286] More data are required to establish the optimal conditioning regimen as well as the timing of such a procedure.

To decrease morbidity and mortality in older adults, several investigators have explored other approaches to induction and postremission therapy.[287] Use of targeted agents, such as tipifarnib and lestaurtinib, clearly would be attractive due to their reduced toxicity. Data on the use of these agents during induction for previously untreated older patients have been disappointing.[281,284] Nontargeted agents that nevertheless have a significant cytotoxic activity, such as clofarabine,[282] decitabine,[288] ahnd cloretazine,[289] have undergone major trials and clearly hold major promise. Further studies with decitabine are awaited, especially because of the significant promise of this agent during treatment of patients with myelodysplasia.[290,291]

Maintenance Therapy

For patients who are not candidates to receive any form of intensive therapy, several therapeutic options are available. Hydroxyurea is an effective agent used by many. However, a prospective study by the MRC compared hydroxyurea with low-dose cytarabine given at a dose of 20 mg twice daily for 10 days. The study reported a superior outcome for low-dose ara-C therapy, with a greater percentage of patients who could achieve CR: 18% versus only 1% for hydroxyurea.[292] Whether this is due to the mechanism of action of ara-C or to the more profound myelosuppression associated with such therapy, which is not a goal when hydroxyurea is given, is unclear.

SPECIAL CONSIDERATIONS

Hyperleukocytosis and Leukostasis

Significant abnormalities may be observed when the blood count exceeds 100,000/μL. Many of these abnormalities are spurious. False elevations of platelet count arise because blast fragments may be sensed by electronic particle counters as platelets, based on size. This problem can be readily resolved by a manual platelet count or review of the peripheral blood smear. The serum glucose level and partial pressure of oxygen (pO_2) may be depressed due to consumption of glucose and oxygen by blast cells in the in vitro collection system.[293] Immediate placement of sample on ice at the time of collection may prevent these abnormalities. However, many patients with leukocytosis have true hypoxia due to pulmonary shunting and increased arterio-alveolar gradients. Therefore, careful clinical evaluation of an abnormal pO_2 is required. Pseudohyperkalemia can occur.

The hyperleukocytosis syndrome requires urgent reduction of the blast burden, which can be accomplished almost immediately by leukapheresis.[294] Each leukapheresis procedure should lower the blast count by approximately 20%, but the effect is transient and often requires serial procedures until cytoreductive therapy is effective. Although commonly used in practice, one publication reported lack of impact of leukapheresis on mortality and the incidence of intracranial hemorrhage.[295]

Hydroxyurea often is given immediately in doses of 4 to 8 g/day to lower the blast count. By approximately 36 hours a significant reduction in peripheral blast count usually will be accomplished, at which time the dose can be decreased. Historically, radiation therapy was used emergently for central nervous system leukostasis. However, since the advent of leukapheresis, this mode of therapy, although effective, is rarely used.[296,297] Another indication of emergently lowering of blast count in hyperleukocytosis is the potential for tumor lysis syndrome. Leukostasis may occur in patients with hyperleukocytosis, and patients with a rapidly increasing peripheral leukemic cell level (usually >50,000/μL) are at greatest risk.[272] The lungs and central nervous system are the areas most vulnerable to leukostasis because of sludging of blasts in the microvasculature of these organs. True hyperviscosity is uncommon in the hyperleukocytosis syndrome in AML due to the usual presence of concurrent anemia. Thus, the clinical effects of leukostasis are caused primarily by a mechanical obstruction of microvasculature rather than true hyperviscosity.[298]

Therapy of Tumor Lysis Syndrome

The optimal management of the tumor lysis syndrome is prevention. The goals are to reduce the formation of uric acid and to establish brisk urinary flow. The formation of uric acid from purine nucleic acids requires xanthine oxidase.

Allopurinol reversibly inhibits xanthine oxidase, causing a reduction of serum uric acid concentration. Patients who present with markedly elevated serum uric acid level may be candidates for recombinant urate oxidase (rasburicase), which converts uric acid to soluble allantoin.[299] Brisk diuresis is required to prevent renal tubular deposition of calcium phosphate and the metabolic intermediates xanthine and hypoxanthine that accumulate during therapy with allopurinol.

Therapy of Transfusion-Related Graft-Versus-Host Disease

There is no known therapy for this condition. The only effective strategy is prevention. In general, patients who are at risk for this condition must receive only cellular blood products that have undergone γ irradiation in order to interfere with cellular proliferation.[300] Lymphocyte proliferation in vitro assays indicate that an irradiation dose of 2500 cGy should be used. This dose inflicts only a minor degree of damage on other cellular components, such as red blood cells.[301] Blood component irradiation can be provided by most well-equipped and adequately staffed universities as well as community cancer centers.

Other newer methods that inhibit T-cell proliferation and prevent this syndrome, including photochemical therapy, appear to be promising.[302]

Treatment of Toxicity from High-Dose Cytarabine

The unique toxicities related to cytarabine are corneal toxicity and neurotoxicity. Corneal toxicity results from inhibition of corneal DNA synthesis and usually resolves within 1 to 2 weeks of discon-

tinuing cytarabine. Administration of corticosteroid eye drops given 12 hours before initiation of high-dose cytarabine therapy and at the time of each dose may virtually prevent the corneal toxicity.[303]

Primary midline cerebellar toxicity has been recognized as a serious neurologic complication of high-dose cytarabine and is one of the major limiting factors. It occurs most frequently in older patients and those with impaired hepatic and/or renal function. For younger adults, a total cumulative dose of 48 g/m^2 has been associated with an almost 10% incidence of cerebellar toxicity.[304] Older patients can safely receive 1.5 g/m^2 every 12 hours for 12 doses; those older than 70 years can receive six doses safely if they do not have hepatic or renal impairment.[305] In general, neurologic toxicity occurs after high-dose cytarabine is completed and usually resolves, but continuing high-dose cytarabine when cerebellar symptoms or objective findings occur during the course of treatment may lead to irreversible damage unless the treatment is stopped immediately. Although cerebellar dysfunction is the most common neurologic complication with high-dose cytarabine, optic neuropathy, somnolence, hemiparesis, coma, and other complications occasionally have been reported.[306]

CHAPTER 62

ACUTE MYELOID LEUKEMIA IN CHILDREN

Michael C. Wei, Gary V. Dahl, and Howard J. Weinstein

BACKGROUND

Acute myeloid leukemias (AMLs) represent a clinically and biologically heterogeneous group of diseases caused by the malignant transformation of a hematopoietic stem cell or myeloid progenitor cell.[1,2] The proliferative advantage of the leukemic stem cell, coupled with impairments in differentiation and inhibition of apoptosis, is thought to arise from acquired genetic alterations that lead to accumulation of immature or blast cells in the bone marrow. The blasts eventually suppress normal hematopoiesis and infiltrate other organs and tissues. Conventionally, the French–American–British (FAB) cooperative group classified AML into eight subtypes (M0–M7) based primarily on blast cell morphology and reactivity with histochemical strains. More recently, the World Health Organization (WHO) developed a new classification system that included cytogenetics and lowered the percentage of blasts in the marrow required to make a diagnosis of AML from 30% to 20%.[3] AML accounts for approximately 20% of acute leukemias in children and 80% of those in adults. The biology of AML, and its response to chemotherapy, is quite similar in children and young adults (age <50 years). One difference is the more frequent extramedullary involvement of AML in infants and young children as compared with adults. In contrast to cure rates for childhood acute lymphoblastic leukemia (ALL), cure rates for AML have improved only modestly over the past two decades.[4,5] Approximately 50% of children treated with chemotherapy alone appear to be cured of their leukemia.[6–9] The outcome is somewhat better for children who, while in their first remission, receive hematopoietic stem cell transplants from histocompatible sibling donors, with an 8-year actuarial survival rate of 60%.[10] However, because there is a greater risk of early mortality and long-term morbidity from bone marrow transplantation (BMT) compared to chemotherapy, allogeneic marrow transplants are now recommended in first remission for high-risk patients only. Greater understanding of the biologic and genetic heterogeneity of AML is leading to better classification schemes, new therapeutic strategies, and risk-adapted therapy.

CLASSIFICATION

Careful examination of both the blood smear and the bone marrow aspirate is required to establish the diagnosis of AML, because approximately 10% of patients with acute leukemia do not have circulating blasts at diagnosis. It is not unusual for the morphology of leukemic cells in the peripheral blood to differ from that of cells in the bone marrow. Various methods are available for characterizing the blast cell population in patients with acute leukemia. These include morphologic interpretation of Wright–Giemsa-stained specimens in conjunction with cytochemistry, chromosome analysis, immunophenotyping, and molecular genetic analysis. Precise diagnosis and classification are essential for successful treatment and biological investigation of the childhood leukemias.[5]

Acute myeloid leukemia has been traditionally classified by the pattern of myeloid lineage differentiation noted in the bone marrow (eg, myeloblastic or granulocytic, monocytic, erythroid, or megakaryocytic lineage). In 1976, the FAB cooperative group proposed a classification system based primarily on morphologic and cytochemical features of the blast cells, with subsequent revisions to include immunophenotypic or electron microscopic confirmation for the M0 and M7 subclasses.[11–13] The FAB group recognizes eight subgroups of AML and also requires a minimum of 30% bone marrow blasts for the diagnosis of AML (Table 62–1). This is an arbitrary cutoff point that is sometimes problematic. The distribution of FAB subtypes in most children is similar to that seen in young adults with AML, except for children younger than 2 years of age, who tend to have M4 or M5.[14] Infants and toddlers with M4- and M5-type disease often present with hyperleukocytosis and extensive extramedullary leukemia, especially leukemia cutis and central nervous system (CNS) disease. The M0 subtype is quite rare in children, and appears to confer a worse prognosis.[15] The M7 subtype is most common in children younger than 3 years of age, especially those with Down syndrome.[16]

The FAB system provides a morphological classification; however, in many cases there is no correlation between morphology and the underlying genetic abnormality. Recently, a new classification for hematopoietic and lymphoid neoplasms was developed by WHO in conjunction with the Society for Hematopathology and the European Association of Hematopathology. The basic principle of the WHO system is that the classification of hematopoietic neoplasms should utilize not only morphologic findings but also all available information including genetic, immunophenotypic, biological, and clinical features to define specific disease entities and provide better correlation with prognosis and underlying biology. The current WHO system classifies AML into four separate groups: recurrent cytogenetic translocations, multilineage dysplasia, therapy-related, and not otherwise categorized (Table 62–2). In the WHO classification, the blast threshold for the diagnosis of AML is reduced from 30% to 20% in the blood or marrow. In addition, patients with the clonal recurring cytogenetic abnormalities t(8;21)(q22;q22), inv(16)(p13;q22) or t(16;16)(p13;q22), and t(15;17)(p22;q12) are classified as having AML regardless of blast percentage.[3,17]

New methods for classifying AML include molecular and biological characterization that may supplant or augment traditional classifications. Gene expression profiling of pediatric AML has identified sets of genes whose expression patterns confer prognostic significance.[18–20] Whether expression-based classifications are better than traditional cytogenetics remains to be determined, although they may certainly be used as an additional diagnostic tool. Another classification schema based on the pattern of intracellular phosphoprotein phosphorylation measured by multiplex flow cytometry has described new subsets of AML.[21]

EPIDEMIOLOGY

Approximately 400 new cases of AML are diagnosed in children each year in the United States.[22] In contrast to the early-age peak (3–4 years) for childhood ALL, the incidence of AML is quite constant from birth throughout the first 10 years, with a slight peak in late adolescence. AML also appears to account for the majority of the very rare instances of congenital leukemia. The predominance of AML in this age group may in part be due to the inclusion of infants with the transient myeloproliferative disorder associated with Down syndrome (see discussion later in this chapter). The incidence and

Table 62–1 FAB Subtypes of Recurring Chromosome Abnormalities and Clinical Features

FAB Subtype	% of Total	Chromosome Abnormality	Clinical or Laboratory Features
M0	2	–5 or del(5), –7 or del(7)	Blasts often express CD34 and terminal deoxynucleotidyl transferase (TdT)
M1	10–18		
M2	27–29	t(8;21)(q22;q22) t(6;9)(p23;q34)	Myeloblastomas (especially orbital)
M3	5–10	t(15;17)(q22;q21)	Disseminated intravascular coagulation
M4eo		inv(16)(p13;q22) or t(16;16)(p13;q22)	CNS leukemia, eosinophilia
M4	16–25	t(9;11)(p22;q23) t(11;19)(q23;p13.1) t(10;11)(p12;q23)	Congenital leukemia and young age (<2 y), extramedullary leukemia (especially leukemia cutis), hyperleukocytosis
M5	13–22	t(9;11)(p22;q23) t(11;19)(q23;p13.1) t(10;11)(p12;q23)	Congenital leukemia and young age (<2 y), extramedullary leukemia (especially leukemia cutis), secondary leukemia after epipodophyllotoxins, hyperleukocytosis
M6	1–3		
M7	4–8	t(1;22)(p13;q13)	Infants <1 y old with t(1;22), myelofibrosis, Down syndrome
All		+8	Prior myelodysplastic syndrome
All		–5 or del(5)(q11-q35)	Older adults, toxic exposure, prior myelodysplastic syndrome
All		–7 or del(7)(q22-q36)	Older adults, toxic exposure, prior myelodysplastic syndrome

subtypes of acute leukemia in children do not have significant geographic variation. In Japan, Shanghai, and among the Maori of New Zealand, however, the rates of AML are the highest. In India and Kuwait, the lowest rates are reported.[23] Patterns of presentation also vary. For example, an unusually high percentage of children diagnosed with AML in Turkey and several African countries present with myeloblastomas or chloromas involving the orbital area.[24] There is no known relationship between race and the incidence of AML, although Hispanics experience the highest rate of leukemia per million population, from 1.3- to 1.7-fold higher than other racial/ethnic groups.

ETIOLOGY

As in other forms of leukemia, the precise cause of AML is unknown. The vast majority of children with AML have no obvious predisposing factors. Known risk factors include several congenital/genetic disorders, ionizing radiation, and certain drug or toxin exposures (Table 62–3).[25–38] For example, occupational exposure to benzene and treatment with alkylating agents or topoisomerase-2 inhibitors (especially the epipodophyllotoxins) are associated with an excess incidence of AML.[37,38] The likelihood of developing secondary AML from epipodophyllotoxin therapy (etoposide or teniposide) appears to be schedule- and cumulative-dose-dependent. Increased risk has been noted with twice-weekly or weekly administration of etoposide/teniposide.[38] In contrast to alkylating agent-induced AML, which generally causes chromosomal loss of 5q or 7q, the secondary leukemias observed after treatment with etoposide or teniposide are usually of the FAB M4 or M5 subtypes, have a shorter latency period (2–4 years), and usually have chromosomal translocations involving band 11q23 (*MLL* gene rearrangement). The *MLL* gene is also rearranged in 60% to 70% of cases of infant acute leukemia,[39,40] and de novo AML, most frequently in the FAB M5 and M4 subtypes (rearranged in 50% of M5 and 20% of M4).[41] In utero exposure to naturally occurring topoisomerase II inhibitors such as dietary flavonoids has been hypothesized to increase the risk of *MLL*-rearranged infant AML.[42,43] Children who were exposed to radiation from the atomic bombs in Japan had an increased incidence of leukemia, but no excess of leukemia was noted in Japanese children who were exposed prenatally to the atomic explosions.[35] Several studies have addressed whether exposure to low-frequency, nonionizing radiation (eg, electromagnetic fields) is leukemogenic.[44] Recent reports did not find an increased risk of acute lymphoblastic leukemia in children exposed to residential magnetic fields.[45,46]

Unusual concordance of AML has been observed in monozygotic twins and in children with certain genetic disorders. The increased concordance of acute leukemia observed in identical twins approaches 100% for infant leukemias, and a risk on the order of 1 in 10 for older twin pairs. These leukemias are the consequence of the transplacental passage of a single leukemic clone rather than a genetic predisposition in most cases.[26,47] Patients with diseases associated with chromosome fragility and impaired DNA repair mechanisms (eg, Fanconi anemia and Bloom syndrome) are predisposed to develop AML.[23] Children with congenital disorders of granulopoiesis and erythropoiesis, such as Kostmann syndrome and Diamond–Blackfan anemia, are also at increased risk for developing AML.[27,28] The cumulative incidence of myelodysplastic syndrome or AML in patients with severe congenital neutropenia receiving long-term G-CSF therapy is 21% after 10 years.[48]

Children with trisomy 21 or Down syndrome have an approximately 10- to 20-fold increased risk for developing acute leukemia compared with children without Down syndrome. Although most leukemia seen in children is lymphoid, in children with Down syndrome, more than 50% of cases are myeloid. From birth through 4 years of age, the incidence of AML (especially FAB M7 or acute megakaryocytic leukemia) is much greater than ALL in children with Down syndrome. In children with Down syndrome, the incidence of acute megakaryoblastic leukemia is up to 500-fold greater than in the general pediatric population. After 5 years of age, the ratio of ALL to AML reverts to that of the general pediatric population.

Some neonates with Down syndrome or trisomy 21 mosaicism may manifest a transient myeloproliferative disorder (TMD). This intriguing syndrome is diagnosed in 10% of neonates with Down

Table 62–2 WHO Classification of Acute Myeloid Leukemia

Acute myeloid leukemia with recurrent genetic abnormalities
Acute myeloid leukemia with t(8;21)(q22;q22), (AML1/ETO)
Acute myeloid leukemia with abnormal bone marrow eosinophils and inv(16)(p13;q22) or t(16;16)(p13;q22), (CBFβ/MYH11)
Acute promyelocytic leukemia with t(15;17)(q22;q12), (PML/RARα) and variants
Acute myeloid leukemia with 11q23 (MLL) abnormalities
Acute myeloid leukemia with multilineage dysplasia
Following MDS or MDS/MPD
Without antecedent MDS or MDS/MPD, but with dysplasia in at least 50% of cells in two or more myeloid lineages
Acute myeloid leukemia and myelodysplastic syndromes, therapy related
Alkylating agent/radiation-related type
Topoisomerase II inhibitor-related type (some may be lymphoid)
Others
Acute myeloid leukemia, not otherwise categorized
Classify as:
Acute myeloid leukemia, minimally differentiated
Acute myeloid leukemia without maturation
Acute myeloid leukemia with maturation
Acute myelomonocytic leukemia
Acute monoblastic/acute monocytic leukemia
Acute erythroid leukemia (erythroid/myeloid and pure erythroleukemia)
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma

syndrome, usually during the first week of life.[32,49] TMD cannot be readily distinguished from congenital AML. The blasts have been shown to be clonal in origin and there is complete clinical and hematologic recovery in approximately 80% of children with TMD within weeks to 3 months without therapy. Infants with TMD or transient leukemia may have very elevated white blood cell counts with circulating blasts (megakaryoblasts or erythroblasts), hepatosplenomegaly, and an increased percentage of blasts in the bone marrow. There is a small subgroup of infants with TMD who die from liver failure and multiorgan system failure. In some of these patients, hepatic fibrosis is associated with megakaryoblast infiltration of the liver. Because the majority of infants with TMD never require any therapy in the first months of life, these neonates should be observed and given supportive care. However, for the small group of infants with liver failure or hydrops fetalis, a course of low-dose cytarabine may be helpful.

Data from retrospective surveys indicate that 30% of infants with TMD eventually develop AML (mostly M7) before 4 years of age.[32] It is not known whether this is a recurrence of the original disease or the appearance of a new disease. Prior to the onset of AML, there is often a several-month prodrome characterized by thrombocytopenia and bone marrow myelofibrosis with dysplastic megakaryocytes. Mutations in the *GATA-1* gene, an erythroid/megakaryocytic transcription factor, are present in the blast cells from infants with TMD as well as patients with Down syndrome and AML (FAB M7).[50,51] An unexpected finding has been the high cure rate of AML in children with Down syndrome, including those who had TMD as neonates.[52–54] This may in part be due to an increased in vitro sensitivity of Down syndrome myeloblasts to chemotherapy, especially cytarabine and daunorubicin. In in vitro studies with cytarabine, there is greater generation of ara-C triphosphate (ara-CTP) compared to myeloblasts from children without Down syndrome.[55–57]

Children with neurofibromatosis 1 (NF1) are at increased risk for developing acute and chronic myeloid leukemias as well as certain benign and malignant tumors that primarily arise in cells derived from the embryonic neural crest.[34] In patients with NF1 and leukemia, loss of both *NF1* alleles in bone marrow blasts has been detected in some patients.[36] These data are consistent with a tumor-suppressor function for the *NF1* gene. Inactivation of *NF1* may contribute to leukemogenesis by aberrantly activating the *RAS* signaling pathway.

PATHOPHYSIOLOGY

Chromosomal Rearrangements

The chromosomal abnormalities detected in blasts from the majority of children with AML are important for diagnostic and prognostic purposes and have been equally important for cloning genes involved in leukemogenesis.[58,59] Common cytogenetic abnormalities observed in patients with AML in relation to the FAB classification are listed in Table 62–1. Monosomies or deletions of chromosomes 5 or 7 and trisomy 8 are not associated with a specific FAB subtype of AML and are most commonly detected in older adults. In contrast, the balanced translocations and inversions are more frequently observed in children and young adults with AML.[58] Younger children have a higher incidence of translocations involving 11q23.[60] Most of the described chromosome changes are not unique to a specific age group, except for the t(l;22)(pl3;ql3) translocation that has been reported only in infants with M7 AML.[61] Fluorescence in situ hybridization can detect cryptic abnormalities that are not evident in banding studies.[62] Many of the genes at the breakpoints of chromosomal translocations have been cloned and proved to be transcription factors involved in normal hematopoiesis and myeloid differentiation.[63,64]

The translocation t(8;21) is the most frequently occurring translocation in AML. Three-way rearrangements may occur, and the t(8;21) is frequently associated with loss of a sex chromosome. The t(8;21) produces a fusion protein involving *AML1* on chromosome 21 and *ETO* on chromosome 8.[65] The *AML1* gene encodes one of the DNA-binding subunits of the core binding factor transcription

factor complex. The chimeric fusion protein is thought to function as a transcriptional repressor and recruits corepressors, which interfere with normal *AML1*-dependent transcription, thereby inhibiting differentiation and enhancing self-renewal.[66] The *AML1/ETO* gene has been detected by molecular methods in patients with t(8;21) in long-term complete remission.[67] In patients with t(8;21) AML, qualitative minimal residual disease can be detected during and after chemotherapy. Minimal residual disease quantitation by real-time reverse-transcriptase polymerase chain reaction (RT-PCR) allows for identification of patients with a higher risk of relapse.[68]

Chromosomal abnormalities involving chromosome 16, inv(16)(p13;q22) or t(16;16)(p13;q22), comprise approximately 5% of AML and are associated with a favorable prognosis and characteristic morphology.[69] The morphology is of the FAB M4 subtype, with the distinctive presence of dysplastic eosinophils containing a dense infiltration of large, violet-purple eosinophilic granules. *CBFβ*, encoding the β subunit of core binding factor, is disrupted at the 16q22 breakpoint, and *MYH11*, encoding smooth muscle myosin heavy chain, is disrupted at the 16p13 breakpoint. The resultant fusion product, CBFβ–MYH11, exerts a dominant-negative effect on the core binding factor transcription factor complex, resulting in a block in myeloid differentiation. A high proportion of these leukemias have cooperating mutations thought to lead to increased cell proliferation.[70]

As noted earlier in this chapter, chromosome band 11q23 translocations are commonly seen in infants and toddlers with the M4 and M5 subtypes and secondary leukemias after epipodophyllotoxin therapy. The 11q23 translocation disrupts the *MLL* gene (mixed-lineage leukemia) that encodes a large protein with regions of homology to the Drosophila trithorax protein. In mammals, the wild-type MLL protein functions as a histone methyltransferase involved in maintenance of homeobox (Hox) gene expression and plays a critical role in definitive hematopoiesis.[71] *MLL* oncogenic rearrangements result in aberrant Hox gene expression. The most common chromosome 11 translocations observed in childhood AML are t(9;11)(p21;q23), t(11;19)(q23;p13.1), and t(10;11)(p12;q23), although more than 50 *MLL* translocation partners have been identified.[41,72] *MLL* translocations are found in both ALL and AML, and the precise reasons for development of one or the other is likely related to the cell of origin and the biology of the specific *MLL* translocation.

The translocation t(15;17)(q22 : q21) is uniquely associated with both the hypergranular and the hypogranular variants of M3 AML. The cloning of the breakpoint revealed rearrangement of a retinoic acid receptor gene (*RARa*), with fusion to the *PML* gene.[73] The *PML-RARa* hybrid gene is expressed in leukemic cells from most patients with APL, though rarely other fusion partners, such as t(11;17) or t(5;17) have been reported. The fusion protein is an abnormal retinoic acid receptor with decreased sensitivity to retinoic acid, thereby antagonizing normal differentiation. This molecular marker (*PML-RARa* transcript) provides a convenient assay for diagnosing acute promyelocytic leukemia (APL) and determining the presence of minimal residual disease.[74] Before the *RARa* gene was shown to be rearranged in t(15;17), observations were made that M3 AML cells differentiated in response to retinoic acid both in vitro and in vivo (see section on APL).[75] Now it is understood that the mechanism involves driving differentiation by saturating the retinoic acid receptor with pharmacologic levels of retinoic acid.

Cell of Origin and Biological Properties of Leukemia Stem Cells

Cytogenetic studies and assays using X-linked polymorphisms confirmed the clonal nature of AML.[58,76] The chromosomal changes vary but predominantly involve balanced translocations, deletions, or inversions.[58] These cytogenetic findings are restricted to the leukemic cells. The bone marrow karyotype returns to normal when the disease is in complete remission. At relapse, the original clone reappears (plus or minus additional genetic changes), suggesting that the leukemic clone was suppressed, but not eliminated, by treatment.

At what stage of hematopoiesis the initiating leukemogenic event occurs is unknown. There is evidence that the cell of origin in AML is a primitive hematopoietic stem cell (HSC). In several adult patients with AML, a clonal marker has been detected in both erythroid and granulocytic cells, suggesting transformation of a less-committed progenitor (colony-forming unit granulocyte, erythroid, megakaryocyte, macrophage).[77] Studies of human AML leukemic stem cells (LSC) transplanted into immunodeficient mice indicated that the LSC closely resembles primitive HSC immunophenotypically.[1] However, model systems of human AML using AML oncogenes introduced into phenotypically defined populations of mouse bone marrow cells has demonstrated that both primitive HSC and more differentiated granulocyte-macrophage precursors can be transformed and give rise to AML.[78] Thus, more committed progenitors have the potential to be transformed, but whether this occurs in human disease remains uncertain.

As discussed in the section above, many of the oncogenic chromosomal rearrangements in AML give rise to chimeric proteins involving nuclear transcription factors that alter their normal function. These chimeric nuclear oncoproteins are thought to initiate leukemic transformation by impairing the ability of hematopoietic progenitors to differentiate and enhance their self-renewal. Transformation of granulocyte-macrophage precursors with the MLL-AF9 oncogene gives rise to AML leukemic stem cells that share properties with more undifferentiated stem cells, suggesting that the transformative oncogene has reactivated a stem cell program in a committed progenitor cell.[78] In another model of MLL-AF9 leukemia, alteration of a cell-matrix interaction has been implicated in the transformation process, and it is likely that the microenvironmental niche is important in an instructive or supportive role for leukemia-initiating cells.[79]

Although bulk leukemic blasts have limited capacity for self-renewal, leukemia stem cells have the ability to self-renew and generate precursors that give rise to the entire leukemic hierarchy. These LSC cells are thought to be quite rare,[80] but that view is being challenged.[79] Many AML LSC are found in a quiescent state,[81] which may explain why some patients relapse after treatment with agents that target rapidly dividing cells. Identification of LSC and targeting therapy to these cells is a major goal of AML research.

Cooperating Mutations

Some oncogenic AML translocations can be generated in utero, indicating a long latency for the development of disease.[82] Given this latency, additional secondary mutations are thought to be required for an initiated cell to progress to overt leukemia. A cooperativity model of leukemogenesis suggests that there are two types of mutations required, one conferring a proliferative or survival advantage and another that impairs hematopoietic differentiation.[83] Although most chromosomal translocations act to impair differentiation, many cooperating mutations affect cellular proliferation. The most frequent known examples in pediatric AML include *KIT*, *RAS*, and FMS-like tyrosine-kinase 3 (*FLT3*) mutations. A review of 170 pediatric AML samples showed that 40% harbored a mutation in one of these three genes.[84] Mutations in *RAS*, a critical mediator of growth signal transduction mutated in many cancers, were found in 37 of 99 pediatric AML samples.[85] Mutated *RAS* synergizes with nuclear fusion genes to accelerate leukemia latency in mouse models.[86] *FLT3* is a receptor tyrosine kinase important for cell proliferation and differentiation. Mutations including the internal tandem duplication (ITD) or activating loop mutations are thought to lead to constitutive activation of the receptor. *FLT3* ITD overexpression by itself induces a myeloproliferative disease (but not frank AML) in mice[87]; however, *FLT3* ITD increases the penetrance of acute promyelocytic leukemia in a *PML–RAR* model.[88] Somatic *FLT3* mutations are found in 5% to 44% of pediatric AML, and most studies have found a lower frequency than that in adult AML.[19,89–91] Certainly other signaling path-

ways beyond *KIT*, *RAS*, and *FLT3* are likely to be affected in AML. Loss of heterozygosity at multiple loci has been observed in AML samples, representing another mechanism whereby cooperating mutations are generated.[92]

CLINICAL FEATURES

History and Physical Exam

The initial signs and symptoms in the majority of children with AML include some degree of pallor, fatigue, skin or mucosal bleeding, or fever or infection that has not responded to appropriate antibiotic therapy (Table 62–4).[93] These signs and symptoms reflect the anemia, thrombocytopenia, and neutropenia secondary to diminished production of normal blood cells due to bone marrow infiltration with leukemic blasts. AML, in contrast to chronic myelogenous leukemia, is rarely diagnosed as an incidental finding on a routine complete blood cell count in an asymptomatic child. Bone pain and arthralgias are less common presenting symptoms in children with AML than those with ALL. Massive hepatosplenomegaly is uncommon except in infants with AML.[94] Ocular pathology includes retinal hemorrhages due to coagulopathy, leukostasis, and leukemic infiltration, which may be asymptomatic.[95,96]

Congenital Leukemia

The clinical manifestations of leukemia diagnosed in the first 4 weeks of life differ in varying degrees from the typical findings in infants older than 6 months of age and older children with AML.[94] Approximately one half of newborns and infants younger than 2 months of age with AML have leukemia cutis.[97] These babies have been described as looking like a "blueberry muffin" (Fig. 62–1). The skin lesions are described in the following sections. It is important to note that these lesions may precede bone marrow manifestations of leukemia. Transient spontaneous remissions of leukemia cutis may occur but are usually followed within weeks by their reappearance in association with overt bone marrow involvement.[97] In one review of 117 patients with congenital leukemia, there were six spontaneous remissions.[98] Other signs and symptoms of congenital leukemia include hepatosplenomegaly, lethargy, pallor, and failure to thrive.

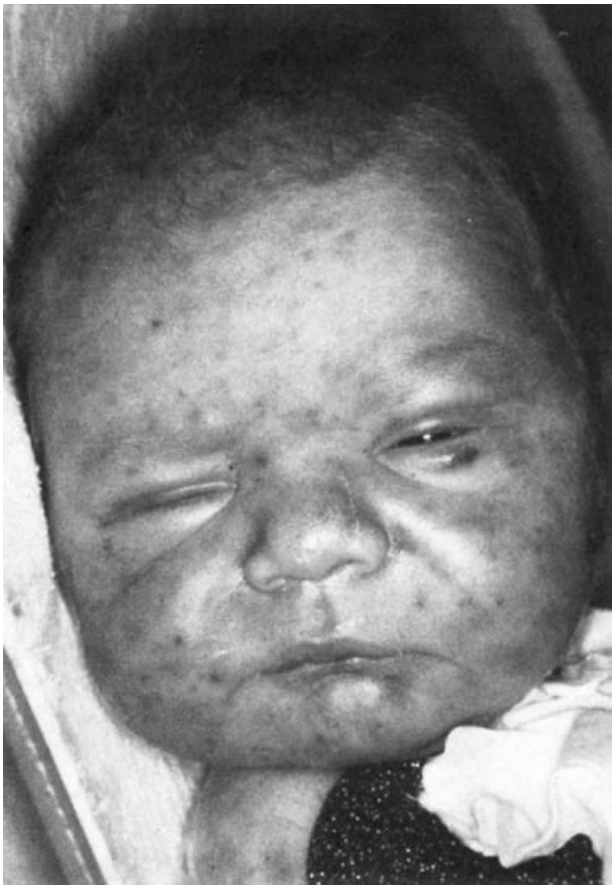

Figure 62–1. Leukemia cutis as commonly seen in congenital leukemia.

Extramedullary Leukemia

The most common sites of extramedullary leukemia in children with AML include skin, gingiva, and CNS and myeloblastomas in the head and neck area (Fig. 62–2). Extramedullary involvement with AML is more common in infants than in older children. In a review of 29 infants with AML at St. Jude Children's Research Hospital, 13 were found to have leukemia cutis and 11 presented with CNS leukemia.[94] The skin lesions are often widespread, range in size from several millimeters to several centimeters, and are palpable as freely mobile, generally painless subcutaneous nodules. The color of the overlying skin may be salmon, red-brown, or bluish to slate gray in color. Testicular involvement is extraordinarily rare in children with AML and, like CNS leukemia, is commonly associated with the M4 and M5 FAB subtypes.

The most common pathologic finding of AML in the CNS is that of meningeal infiltration by blasts, but epidural or brain parenchymal myeloblastomas have also been described. The incidence of meningeal leukemia at diagnosis in children with AML ranges from 5% to 15%,[99–101] but most children are asymptomatic. The diagnosis of CNS leukemia is made by examining a cytocentrifuged specimen of cerebrospinal fluid (CSF) (Fig. 62–3). A currently accepted definition of CNS leukemia is CSF with five or more white blood cells (WBCs) per microliter and definite blasts, cranial nerve palsy, signs of meningeal disease, or a nonhemorrhagic CNS mass or chloroma. If the CSF is contaminated with more than 10 red blood cells per microliter

and leukemic blasts, the lumbar puncture is considered traumatic. The rare symptomatic patient with CNS leukemia may have headache, vomiting, papilledema, or a cranial nerve palsy (facial nerve is most common). In contrast, patients with cerebral leukostasis present with seizures, somnolence, or stroke secondary to areas of hemorrhage and infarction in brain tissue.

Fewer than 5% of newly diagnosed patients with AML have myeloblastomas, also known as granulocytic sarcomas or chloromas.[102] These "solid tumors" of myeloid blasts may occur anywhere but are primarily detected in the bones and soft tissues of the head and neck (often orbits), and in intracranial or epidural locations.[102,103] Myeloblastomas may herald overt bone marrow involvement with AML by weeks to months and are associated with FAB M2 and t(8;21) and, in infants, with M4 and M5 subtypes.[14,104]

Laboratory Evaluation

The initial WBC count at presentation in children with AML is variable (1000 → 500,000 μL^{-1}). Approximately 15% to 20% of children have WBC counts higher than 100,000 μL^{-1}.[60,93] Marked leukocytosis is associated with the FAB M4 and M5 subtypes and congenital leukemia, whereas lower leukocyte counts are commonly seen in patients with M3 or APL. The leukocyte differential in most patients includes fewer than 1000 neutrophils per microliter and a variable percentage of blasts. In approximately 10% of patients, no peripheral blasts are detectable.

Most patients with AML have a normocytic anemia, with occasional teardrop forms and nucleated red blood cells noted on the peripheral smear. In one large series of children with AML, initial hemoglobin levels range from 2.7 to 14.3 g/dL (median, 7 g/dL). The rare hemolytic anemia associated with AML is usually microangiopathic, secondary to disseminated intravascular coagulation (DIC).

Approximately 50% of children with AML present with platelet counts of fewer than 50,000 μL^{-1}. Thrombocytopenia is the usual cause of hemorrhage in patients with AML. Bleeding is usually not observed until the platelet count falls below 20,000 μL^{-1} unless there is an associated coagulopathy. The other major cause of bleeding in children with AML is DIC. Patients with APL (FAB M3) are most at risk for DIC, but infants with M4 and M5 types are also at increased risk.[75,105] Prior to the use of all-trans-retinoic acid (ATRA) for patients with APL, prophylactic low-dose heparin and transfusion of fresh frozen plasma and platelets were recommended by several groups of investigators.[106] ATRA appears to downregulate tissue factor expression and thereby reduces the severity and duration of DIC in APL patients. At present, all patients should be carefully followed with serial coagulation studies (partial thromboplastin time, prothrombin time, fibrinogen, and fibrin split products). The optimal management of coagulopathy is controversial. Heparin usage is discouraged now that all patients receive ATRA.

The definitive diagnosis of acute leukemia is made by examination of the bone marrow aspirate.[107] In most patients, the bone marrow is hypercellular, with 30% to 90% blasts. The bone marrow biopsy may be hypocellular, especially in patients with a history of prior MDS, Fanconi anemia, or paroxysmal nocturnal hemoglobinuria. Dysplastic changes have recently been reported in patients with de novo AML and appear to have no prognostic significance. For a diagnosis of hypocellular AML, there need to be less than 20% blasts.

Immunophenotypic Analysis

Normal hematopoietic cells undergo changes in expression of cell surface markers as they mature from stem cells into cells of a committed lineage. Monoclonal antibodies have been developed that react with lineage-specific and stage-specific lymphoid and myeloid activation and differentiation antigens.[108] By using a combination of monoclonal antibodies recognizing B-cell, T-cell, and myeloid antigens, it is possible to confirm the diagnosis of AML and to differentiate AML from ALL if morphology and traditional immunohistochemistry are inconclusive (<15% of cases).

Several unusual immunophenotypes of AML blasts have been described that are FAB subtype-specific and associated with unique chromosomal changes. For example, M2 AML with t(8;21) is characterized by expression of the myeloid and stem cell antigens CD13, CD15, CD34, HLA DR, and expression of the B-cell antigen CD19 and the neural adhesion molecule CD56.[109] In adult AML studies, CD56-positive AML with t(8;21) and t(15;17) translocations was associated with shorter remissions and decreased overall survival.[109,110]

It has been estimated from several studies that 5% to 15% of patients with acute leukemia have morphologic, cytochemical, immunophenotypic, or genetic evidence of more than one hematopoietic lineage. Approximately 10% to 25% of AML patients demonstrate lymphoid antigen expression on myeloid blasts, and similarly 4% to 25% of ALL patients demonstrate expression of at least one myeloid antigen on the blast cell surface.[111–113] The expression of lymphoid antigens in AML lacks prognostic significance.[114] In most instances of hybrid or mixed-lineage acute leukemia, there is coexpression of lymphoid and myeloid markers on the same blast, but in rare cases there have been two distinct populations of blasts.[113] The pathogenesis of these mixed-lineage leukemias remains poorly understood. They may represent a leukemic transformation in a primitive stem cell, or the aberrant expression of a lymphoid gene in a myeloid leukemia. Because few instances of true biphenotypic leukemia have been described, the prognosis is unclear. In a pediatric study, 14 of 16 patients with lymphoid antigen-positive AML expressed a T-cell marker.[113] Interestingly, several of these patients had a poor response to AML induction therapy but subsequently responded to an ALL induction regimen. Despite this, children with AML whose blasts express lymphoid antigens should be treated initially on AML protocols.

Differential Diagnosis

The diagnosis of AML is usually straightforward after an examination of the peripheral blood and bone marrow.[107] Other diagnoses that can sometimes cause diagnostic difficulty include the myeloproliferative disorders (eg, juvenile myelomonocytic leukemia), myelodysplastic (preleukemic) syndromes, and overwhelming bacterial infections that result in leukemoid reactions or neutropenia secondary to a bone marrow maturation arrest in granulocytic precursors. In the last situation, the bone marrow may be confused with APL, but with resolution of the infection, granulocytic maturation ensues. The differential diagnosis of congenital leukemia is somewhat more challenging, in part because of the leukoerythroblastic peripheral blood picture noted in neonates with hypoxia or sepsis. Congenital viral infections, including cytomegalovirus, herpes simplex, human immunodeficiency virus (HIV), and rubella, need to be ruled out as well as the transient myeloproliferative disorder associated with trisomy 21.[115,116]

Prognosis

The prognostic significance of several clinical and biologic features in children with AML is summarized in Table 62–5. In contrast to childhood ALL, very few clinical, laboratory, or treatment-associated factors have been consistently related to prognosis.[117,118] A WBC count greater than 100,000 μL^{-1} at diagnosis, monosomy 7 or 5, del(5q), 3q rearrangements, a complex karyotype, FAB M0 subtype, non-Down syndrome FAB M7, an FLT3 internal tandem duplication, and secondary AML are associated with lower remission rates.[15,91,119–122] Favorable factors for predicting complete remission include FAB M1 with Auer rods, chromosome findings of inv(16) or t(8;21), and the combined use of ATRA and chemotherapy for APL (FAB M3).[120,123,124]

In some studies, the M4 and M5 FAB subtypes, high initial leukocyte count, age younger than 2 years, extramedullary leukemia (other than CNS) at diagnosis, and longer time to enter remission (more than one induction cycle) were found to have an adverse impact on remission duration.[117] In the German BFM studies, two risk groups were identified.[120] The BFM favorable risk group includes children with FAB M1 or M2 with Auer rods, M3 and M4eo, with 5% blasts or less in the bone marrow on day 15 after induction chemotherapy, and Down syndrome. Included in this favorable group are patients with t(8;21) and inv(16). The United Kingdom Medical Research Council trials have separated good-, standard-, or poor-risk groups based on karyotype and response to the first round of induction.[125] The good-risk patients (32%) had karyotypes t(8;21), inv(16), t(15;17), or FAB M3 morphology, and this was irrespective of response to induction course 1. The poor-risk patients (19%) had karyotypes -5, -7, del(5q), abn(3q), and complex karyotype, or more than 15% bone marrow blasts after course 1 but without favorable genetics. The standard-risk patients (49%) included those with neither favorable nor unfavorable cytogenetics and less than 15% bone marrow blasts after course 1. The good-, standard-, and poor-risk patients had overall survival from complete remission at 10 years of 77%, 58%, and 30%, respectively.[125]

Table 62–5 Patient Characteristics Relating to Duration of Remission

Characteristics	Favorable Value
Cytogenetics	t(15;17), t(8;21), inv(16)
Leukocyte count	<100,000 μL^{-1}
Secondary acute myeloid leukemia	Not present
FAB subtype	M1 or M2 with Auer rods, M3 and M4eo
FLT3	Wild-type
Courses to complete remission	1

The presence of acute mixed-lineage or biphenotypic leukemia (AML with lymphoid-associated antigens) does not influence prognosis.[72,112] Age 10 years or more is associated with increased risk of death or recurrence.[126] The role of ethnicity in survival is controversial. Retrospective analysis at St. Jude showed no difference between black and white children in multiple studies.[127] Black children had inferior EFS and OS on recent Children's Cancer Group studies, possibly because of decreased availability of matched bone marrow donors.[128] Several groups of investigators have reported that children with AML and Down syndrome have a very good outcome after treatment with chemotherapy alone.[52,53] Reducing chemotherapy is advisable in Down syndrome AML patients, who appear to be more susceptible to treatment-related mortality, especially in intensive-timed regimens.[53,129,130]

Minimal residual disease (MRD) is being compared to traditional prognostic factors to predict relapse risk. MRD analysis detects leukemic blasts at much higher sensitivity than traditional bone marrow morphological analysis. MRD can be measured with flow immunophenotyping or PCR for specific translocations or genes associated with disease. Assays with RT-PCR for many of the common gene rearrangements in AML are now available for diagnostic purposes and for following minimal residual leukemia.[131] Genetic markers suitable for RT-PCR studies are found in almost 50% of AML patients. Flow immunophenotyping can detect an aberrant leukemic phenotype in more than 85% of AML patients at 0.1% to 0.01% residual cells, and detection of more than 0.1% minimal residual disease after one round of induction or at end of consolidation was associated with a significantly worse risk of early relapse and overall survival.[132–134] Importantly, immunophenotyping detected residual leukemia in 23% of cases in morphological remission. The BFM group, however, has suggested that MRD is not more predictive of relapse than other traditional prognostic factors such as cytogenetics.[135]

Additional mutations or aberrant gene expression beyond the characteristic chromosomal translocation are found in AML that have biologic and prognostic significance. As discussed above, patients who bear a somatic *FLT3* internal tandem duplication produce an abnormal protein with extra amino acids at the juxtamembrane region that confers constitutive activation, and *FLT3* mutant leukemia has poor prognosis regardless of the FAB type (Fig. 62–4).[89–91,136–138] The St. Jude collaborative group now places patients with *FLT3* mutation into a poor-risk category and is evaluating this risk stratification prospectively. A large review of *FLT3* mutation status indicated that mutant *FLT3* by itself is not an

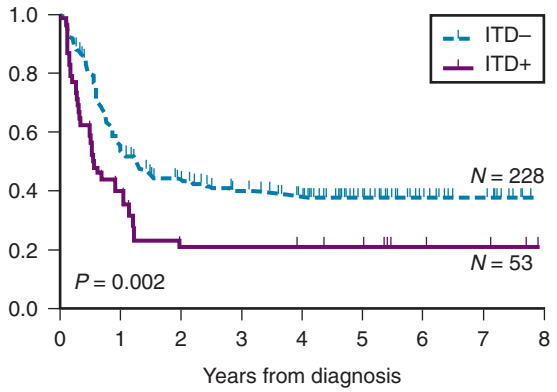

Figure 62–4. Kaplan–Meier estimate of event-free survival (EFS) according to the presence of FLT3/ITD from Pediatric Oncology Group Protocol 9421. Log-rank *P* values are shown.

indication for hematopoietic stem cell transplantation (HSCT) over chemotherapy.[139] The Wilms tumor suppressor gene *WT1* has been found to be overexpressed at diagnosis in 78% of patients in one study; those patients with continued overexpression of *WT1* during therapy had higher risk of relapse and death.[140] However, another study reached the opposite conclusion that *WT1* expression was associated with favorable cytogenetics and better survival.[141] Nucleophosmin is a nucleocytoplasmic shuttling protein that regulates the *P53-ARF* tumor suppressor pathway. Mutations in nucleophosmin have been found that alter its intracellular localization, and mutated nucleophosmin is associated with better response to induction and survival.[142–145] Overall, the use of MRD and specific gene markers to predict patients with higher risk of relapse must be further studied prospectively. Eventually such studies may be used to stratify high-risk patients for more intensive or targeted therapy or HSCT.

THERAPY

The long-term survival (>5 years) rate for children with AML has increased from less than 10% to approximately 50% during the past 30 years.[4,6,9,125,146–148] This improved cure rate has resulted from more effective remission induction chemotherapy and better strategies to prevent relapse. Improvements in supportive care have been equally important, making it safe and feasible to treat patients with myelosuppressive doses of chemotherapy.[149,150] All children with AML should be referred to a pediatric oncology center for treatment and are usually enrolled on a cooperative group clinical trial, such as those of the Children's Oncology Group, Berlin–Frankfurt–Muenster (BFM) Group, and the United Kingdom Medical Research Council, or collaborative institutional protocols.

Supportive Care

Before chemotherapy is started, the infant or child should be stabilized with regard to renal, metabolic, hematologic (anemia, bleeding, DIC, leukostasis), and infectious disease issues. Excellent supportive care to facilitate children surviving therapy without significant morbidity is of paramount importance. A double-lumen indwelling central venous catheter should be placed early in the treatment course. The metabolic derangements associated with leukemic cell death (tumor lysis syndrome) include hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia.[151] The tumor lysis syndrome is seen more often in children with ALL (especially T cell and mature B cell) than in those with AML. Uric acid nephropathy is avoided by prompt attention to hydration, alkalinization of the urine, and administration of allopurinol. A new agent, recombinant urate oxidase (Rasburicase) converts uric acid to more soluble allantoin and is now used with outstanding efficacy in children expected to have tumor lysis syndrome. Children with AML are at especially increased risk of bacterial and fungal infections during therapy and leukemia-induced neutropenia. The most commonly encountered fungal infections are due to *Candida* and *Aspergillus* species. Given the high risk of fungal disease, it is reasonable to provide antifungal prophylaxis during AML therapy; however, there is no standard antifungal prophylactic regimen. Fluconazole is effective against most *Candida* species, but has no activity against *Aspergillus* species. Current commercially available agents with anti-*Aspergillus* activity that have been used in AML patients include the triazoles (itraconazole, voriconazole, and posaconazole), the echinocandins (caspofungin, micafungin, and anidulafungin), and amphotericin B deoxycholate or the lipid preparations of amphotericin. In patients with AML, septicemia due to α-hemolytic streptococcal organisms is associated with high-dose cytarabine, a component of most AML therapeutic protocols. The α-hemolytic streptococcal infections have a high rate of recurrence and associated toxicities during subsequent episodes of intensive chemotherapy. There is no known prophylactic regimen to prevent this infection. Physicians caring for these children must maintain a high index of suspicion and be prepared to institute appropriate antibiotic coverage in the event of fever or unexplained illness. Prolonged periods of neutropenia have been treated with hematopoietic growth factors (granulocyte- or granulocyte-macrophage colony-stimulating factor) during induction and after cycles of intensification chemotherapy, although not all protocols use them. Blood products should all be leuko-poor and irradiated to prevent transfusion-associated graft-versus-host disease. Platelet transfusions are recommended prophylactically if the platelet count is lower than 10,000 μL^{-1}.

One to 2% of children with AML still die within the first several days to a week after diagnosis. These early deaths usually result from intracranial hemorrhage from either a coagulopathy or CNS leukostasis.[152] If the leukocyte count is greater than 100,000 μL^{-1}, it is important to initiate urgent measures to prevent leukostasis. Leukostasis refers to plugging of blasts in vessels with invasion of vessel walls, leading to hemorrhagic infarction of the brain, lung, or other organs. Children with AML who have leukocyte counts higher than 200,000 μL^{-1} are much more susceptible to leukostasis than patients with ALL and comparable WBC counts.[151] The most clinically relevant target organs for leukostasis are the brain and lung, with signs and symptoms including somnolence, seizures, stroke, tachypnea, and hypoxemia. Treatment should include immediate measures to lower the WBC count, and exchange transfusion or leukapheresis if the patient is symptomatic. Oral hydroxyurea combined with leukapheresis is very effective for rapidly lowering the blast count in patients with AML and preventing the clinical manifestations of leukostasis.[153,154] Although extremely elevated WBC counts and leukostasis are rare in APL, leukapheresis should be avoided in these patients to prevent an exacerbation of DIC.[155]

Remission Induction

Because of the narrow therapeutic index of the active agents in AML, all induction regimens (except for FAB M3) are designed to produce rapid bone marrow hypoplasia, an apparent prerequisite for successful remission induction. A major concern is the appropriateness of current dose adjustments made in chemotherapy protocols for infants less than 1 year of age (generally based on mg/kg arbitrary dose reductions of 25%).[60] The combination of cytarabine (7 days) and daunorubicin (3 days), known as the "7+3" regimen, has been the traditional backbone of induction chemotherapy and results in a complete remission rate of approximately 80%, with a recent survey of protocols showing a range of 70% to 93%.[156] Approximately one-third of these patients require two courses of induction to achieve a remission. Recent protocols using intensified induction by timing or dose intensity have demonstrated improved remission rates, approaching 90%, with superior overall survival.[8,10] The addition of a third agent such as etoposide or thioguanine during induction is now widely used, and a randomization of DAT (daunorubicin, cytarabine, thioguanine)

versus ADE (cytarabine, daunorubicin, etoposide) showed no significant differences between the two induction regimens.[8] Although attempts to increase the intensity of induction have not significantly improved complete remission rates, there is evidence that induction intensity improves ultimate outcome. Patients receiving intensified induction have had statistically significant increases in disease-free survival compared with those patients randomized to standard 7+3 induction. These data are consistent with the hypothesis that more effective early leukemic cell kill reduces the likelihood of a subsequent relapse in children and adults with AML.[60] Lower remission rates are seen in patients with secondary AML, a history of a prior myelodysplastic syndrome (MDS), and certain cytogenetic findings (see section on Prognosis). Because of the requisite period of bone marrow hypoplasia and the greater impairment of bone marrow reserve in patients with AML, the remission induction phase of therapy is more toxic than for patients with ALL. Prospectively controlled pediatric and adult cooperative group studies have shown that daunorubicin is preferable to doxorubicin because it is associated with less oral mucositis and gastrointestinal toxicity.[157] The most disturbing gastrointestinal toxicity during induction is an enterocolitis involving the distal ileum, cecum, and proximal colon. This syndrome is referred to as typhlitis or the right lower quadrant syndrome and is noted in approximately 10% of patients.[158] The signs and symptoms of typhlitis develop approximately 10 to 14 days after the start of chemotherapy. Treatment recommendations include bowel rest and double-coverage broad-spectrum antibiotics for gram-negative organisms. Surgery is rarely needed and is reserved for intestinal perforation, abdominal wall fasciitis, or massive bleeding. Several adult and pediatric AML studies have explored the benefits of substituting either mitoxantrone or idarubicin for daunorubicin.[159,160] Mitoxantrone is at least as effective as daunorubicin. Idarubicin is not superior to daunorubicin for remission induction and is associated with more marrow toxicity and greater number of days until neutrophil recovery.

Acute Promyelocytic Leukemia (FAB M3)

In the past, approximately 65% to 75% of patients with M3 AML (also called APL) entered remission after a standard induction with daunorubicin and cytarabine. The remission induction period, however, was associated with significant early mortality secondary to hemorrhagic complications.[161] The use of ATRA alone during induction for patients with acute APL (*PML/RARa*-positive) results in a similar or even higher rate of complete remission with a different toxicity profile and substantially lower mortality rate during induction.[75] The ATRA-induced remissions are associated with differentiation of the blasts/promyelocytes and a peripheral blood leukocytosis during the first two weeks of therapy. European and American clinical trials have established the current standard front-line therapy, which combines ATRA with anthracycline-based chemotherapy for remission induction and consolidation chemotherapy and with ATRA continuing during maintenance, resulting in overall survival higher than 80%.[162,163] Recent results support a potential role for the addition of cytarabine during induction.[164] ATRA is associated with several life-threatening complications, including severe respiratory distress and capillary leak syndrome and pseudotumor cerebri (more common in pediatric patients). The retinoic acid syndrome (respiratory distress and weight gain) has been successfully managed in most patients by temporary cessation of ATRA and administration of dexamethasone. The symptoms of pseudotumor cerebri disappear within days after withdrawal of ATRA, and the drug can usually be safely restarted at a reduced dose.[165,166] This syndrome has also been seen in response to treatment with arsenic trioxide and thus might better be termed the "differentiation syndrome."[167] Patients whose disease is induced into remission with ATRA alone remain PCR-positive for PML/RARa after induction and all eventually relapse if no consolidation chemotherapy is added. The combined use of ATRA and chemotherapy during remission induction followed by consolidation chemotherapy and ATRA maintenance results in an improved disease-free survival rate when compared with the use of ATRA alone either during induction or maintenance.[123] The ability to detect PML/RARa messenger RNA by RT-PCR is a useful method of monitoring the efficacy of therapy. When used at the 10^{-4} sensitivity level, persistent positive RT-PCR findings after the consolidation phase strongly predict hematologic relapse.[74,168] Arsenic trioxide (As_2O_3 or ATO) can be used to achieve remissions in those patients who relapse after ATRA treatment.[169] APL cells express CD33, and gemtuzumab ozogamycin has been used successfully in both untreated and relapsed APL in adults.[170,171]

Central Nervous System Leukemia

There is no evidence that CNS-directed therapy with either intrathecal chemotherapy alone or in combination with cranial irradiation prolongs disease-free survival in children with AML.[5,118,172] Most pediatric AML studies, however, still include intrathecal chemotherapy because isolated CNS relapse occurs in approximately 20% of children with AML who did not receive any CNS-directed therapy.[99,100] Using historical controls, the BFM AML group has made a case for using prophylactic cranial irradiation and tested their hypothesis in a prospectively controlled clinical trial.[173] The current results (including CNS relapse) of recent pediatric AML trials, using intrathecal chemotherapy without CNS irradiation, are similar to those of patients treated on the BFM AML trial that used cranial irradiation for prevention and treatment of CNS involvement.[159] In contrast to ALL, the finding of blasts in the CSF at diagnosis in children with AML does not adversely affect prognosis.[101] An accepted approach for the treatment of CNS leukemia is weekly intrathecal methotrexate or cytarabine until the CSF is clear of blasts. In some protocols, this is followed by CNS irradiation at the end of systemic chemotherapy.[118]

Treatment in Remission

Without further treatment after standard induction chemotherapy, more than 90% of patients relapse within 1 year, and the remainder relapse by 2 years. The intensity and duration of chemotherapy in remission, as well as the role of BMT in first remission, have been areas of active investigation and controversy during the past decades. In the 1970s, pediatric AML studies tested whether modestly myelosuppressive combination chemotherapy given in remission would improve overall survival. These protocols led to a plateau in disease-free survival of 15% to 20% at 5 years.[157,172,174] In an effort to improve upon these disappointing results, other approaches were explored, including early intensification or consolidation chemotherapy and HSCT. Allogeneic HSCT provided an opportunity for delivering very high doses of chemoradiation and possibly stimulating a graft-versus-leukemia effect.[175–177] Although the initial studies were not randomized, the results suggested a benefit for either the intensification of chemotherapy or HSCT early in first remission.[178] Cytarabine, the single most active agent in AML, was the prototype drug for intensification, because laboratory and clinical studies indicated that a log increase in its dose could overcome certain mechanisms of resistance.[179,180] Approximately 40% of patients with AML who are refractory to standard doses of cytarabine achieve a complete remission with high-dose cytarabine.[180] The superiority of high-dose compared to standard-dose cytarabine has also been confirmed in a prospective randomized clinical trial in adults with AML.[181] Most pediatric AML studies that were initiated in the late 1980s included several consolidation cycles of high-dose cytarabine. These protocols resulted in 5-year leukemia-free survival plateaus of 35% to 60%.[182–184] Clinical studies in the most recent decade have evolved and indicate that timed sequential induction[10] and therapies utilizing repeated courses of intensive consolidation[8,159,185] result in 5-year event-free survival rate of 50%. High-dose cytarabine is given in combination with other agents such as mitozantrone, amsacrine, etoposide, or asparaginase, and noncytarabine containing consolida-

tion cycles are used as well. The optimal number of consolidation chemotherapy cycles has not been determined, but is usually three to four cycles. Maintenance chemotherapy with oral thioguanine and standard doses of cytarabine given after consolidation chemotherapy has not been shown to further increase the proportion of patients in long-term remission. Patients who receive maintenance have a poor salvage rate if relapsed because of clinical drug resistance.[185]

Hematopoietic Stem Cell Transplantation in First Remission

Allogeneic HSCT from a histocompatible family donor was first evaluated in children and young adults with AML in first remission in the mid-1970s.[175–178,183] Published data from many pediatric AML bone marrow transplant series show 5-year event-free survival rates ranging from 56% to 74%.[8,159,186–188] Many of the early transplant studies, however, were not prospectively designed, and therefore were biased in their selection criteria, were not controlled for the timing of HSCT in first remission, and excluded patients who were eligible for a transplant but who relapsed before the procedure. In an effort to avoid these and other biases, it was suggested that the outcomes of studies comparing HSCT to chemotherapy be analyzed according to the intention-to-treat analysis, which includes all eligible patients (ie, those having a matched family donor) and not just individuals who actually received the transplant.[183,184] When the data are analyzed in this way, there is still a statistically significant survival advantage for allogeneic HSCT compared with chemotherapy in most studies.

Allogeneic HSCT early in first remission using an HLA-matched related donor results in a significantly better disease-free survival rate as compared with chemotherapy but is limited to approximately 20% of patients with a suitable donor. For those children with AML who have a relatively favorable prognosis after treatment with chemotherapy [eg, t(15;17), t(8;21), inv(16), Down syndrome] or standard risk patients without unfavorable risk factors, it is reasonable to reserve HSCT for early relapse or second remission. In addition, a limited donor pool of histocompatible related individuals, and the acute toxicities (eg, acute graft-versus-host disease, interstitial pneumonia, hepatic veno-occlusive disease) and late effects of HSCT, continue to be major limitations in the more widespread application of this procedure in patients with AML.[189,190] The late effects of HSCT in young children may include growth problems, gonadal toxicity, secondary malignancy, and chronic graft-versus-host disease.[190–193] Because of these issues, many pediatric oncologists are recommending chemotherapy alone, especially for children with a relatively favorable prognosis, and reserving HSCT for those children who have a relapse. In particular, children with promyelocytic leukemia who receive ATRA plus chemotherapy and those with Down syndrome AML are often successfully treated with chemotherapy regimens. Given the current status of biologic characteristics and aggressive chemotherapy regimens, it appears that HSCT should be used in first remission only for children with high-risk features and be reserved for use in second remission or early relapse in all others.[194] Up to 50% to 60% of patients with AML who achieve second remission and receive allogeneic transplantation appear to be long-term leukemia-free survivors.[195] Patients with refractory disease or who relapse after intensive therapy within a year of diagnosis have a very poor prognosis with any form of therapy, including HSCT.

For patients who lack suitable donors (<5 or 6 antigen-matched family member), purged autologous HSCT became an attractive option in first remission, after it was reported to be effective in some patients with AML in second remission (5-year survival rates of 30%–40%).[196] However, the results of three randomized trials in pediatric AML have concluded that autologous HSCT is not superior to intensive chemotherapy in first remission.[10,184,197] Finally, another study indicated that the addition of autologous BMT to four courses of intensive chemotherapy substantially reduces the risk of relapse in patients with AML, leading to an improvement in long-term survival.[198] Because of the good chance of salvage for children who relapse after completion of chemotherapy and the morbidity, mortality, and late effects of autologous BMT, the authors suggest that delay of the autograft until second remission may be appropriate.

The Role of Hematopoietic Stem Cell Transplantation in Pediatric AML

Outcomes in pediatric AML show a benefit for allogeneic transplant in first remission for select patients, but the risk of treatment-related mortality with transplant must be weighed against the improved outcomes with chemotherapy alone because of sequential dose-intensive regimens. The choice of chemotherapy versus hematopoietic stem cell transplantation (HSCT) in first remission therefore depends on prognostic factors and the availability of a suitable donor. The authors recommend matched-related or, if a sibling donor is unavailable, matched-unrelated HSCT for patients with high-risk features, including monosomy 7, *FLT3* internal tandem duplication mutation, and patients with refractory disease after two courses of induction. Allogeneic HSCT in first remission should also be considered for non-Down syndrome patients with FAB M7 morphology given recent reports of poor outcomes with this subtype. Favorable-risk patients (ie, Down syndrome M7, inv(16), t(15;17), t(8;21)) should be treated with chemotherapy alone. All other patients without high-risk features in first remission should be treated with consolidative chemotherapy alone, because multiple studies have shown equivalent outcomes compared to autologous or allogeneic transplant. For these patients without high-risk features, matched-related or matched-unrelated HSCT should be reserved for relapsed disease. An autologous transplant should be considered in second remission when there is no suitable allogeneic donor. Haploidentical transplants are still considered experimental but show promise as an alternative especially with a KIR mismatch.

Management of Relapse

The prognosis for children who do not enter remission with frontline chemotherapy or who suffer an on-therapy relapse is very poor.[199,200] Intensive reinduction therapies and HSCT for second complete remission are associated with significant treatment-related morbidity and mortality. Many different chemotherapy regimens have been evaluated in children and adults with refractory or relapsed AML. Relapse regimens that have been investigated include high-dose cytarabine with L-asparaginase or mitoxantrone, etoposide (VP-16) and amsacrine with or without azacitidine, fludarabine and cytarabine, and 2-chlorodeoxyadenosine (2-CDA). An anti-CD33 monoclonal antibody linked to the chemotherapy agent calicheamicin (gemtuzumab ozogamicin) is an effective agent but is associated with hepatic toxicity (veno-occlusive disease, or sinusoidal obstruction syndrome) in a subset of patients, particularly after HSCT.[201,202] Clofarabine is a nucleoside analog that shows promise in relapsed leukemia as monotherapy or in combination with other agents.[203,204] Other investigational agents include farnesyltransferase inhibitors, inhibitors of the mammalian target of rapamycin, kinase inhibitors, proteasome inhibitors, and epigenetic modifiers.[205]

The best predictor of response to chemotherapy after relapse is the duration of the first remission. Children who relapse within 1 year after achieving remission have a substantially lower likelihood of achieving a second remission when compared with those patients who relapse later.[206–208] The complete remission rate is 30% to 40% for the former group and 60% to 70% for the latter group. Fewer than 20% of the complete responders are projected to remain in remission for more than 2 years, unless they receive an HSCT.[208]

The projected 5-year survival rate after an allogeneic or autologous BMT in second remission is 40% to 60%.[199] Because of the higher

rate of relapse after an autologous compared to an allogeneic HSCT, there is a growing experience with matched unrelated donor transplants using bone marrow or cord blood.[209,210] In selected patients (short duration of first remission or early relapse), it is reasonable to undertake an HSCT without an attempt at inducing a second remission. This is feasible only if a transplant option is immediately available and the patient is clinically stable. A second transplant for multiply relapsed AML is feasible.[211]

For relapsed patients without a matched related or unrelated donor, haploidentical transplants have become an option. Outcomes are typically worse compared to matched related transplants.[212] However, mismatch at the KIR locus has been suggested to lead to improved outcomes in haploidentical transplants owing to natural killer (NK) cell alloreactivity.[213,214] A subset of killer immunoglobulin-like receptors (KIR) expressed on NK cells will inhibit NK cell function when engaged by specific major histocompatibility (MHC) class I proteins. In HSCT, NK donor cells are thought to help eliminate recipient leukemia cells if the recipient cells do not express the cognate MHC epitope for the donor's inhibitory KIR. For matched unrelated transplants, the effect of KIR mismatch is not as clear.[214,215]

Approximately 5% of patients who achieve remission develop isolated CNS relapse.[216] Risk factors for CNS relapse include age less than 2 years, hepatosplenomegaly, CNS disease at diagnosis, high WBC, FAB M5 morphology, and chromosome 11 abnormalities. Initial CNS status does not seem to matter.[101] Outcome following CNS relapse following systemic versus local therapy was similar, and thus the rare patients with CNS relapse are typically treated with local therapy alone.[216]

FUTURE DIRECTIONS

The major challenge for the future is to continue improvement on all fronts for the care of patients with AML, including understanding the biology of the leukemic stem cell, disease classification, supportive care, development of more effective therapies, and how to deliver the optimal combination of therapy for an individual patient. Although improved over past rates, the 5-year event-free survival rate is still only approximately 50%, and a substantial portion of children with AML continue to relapse and ultimately die from their disease. The primary cause of relapse is the development of drug resistance. Newer insights into the multiple mechanisms of drug resistance are beginning to be elucidated. Not to be overlooked is the importance of optimizing supportive care, as the treatment-related mortality with AML is still substantial.[152]

In addition to new clinical trials exploring therapy timing and dose issues, investigations are ongoing with new therapeutic agents that interfere with leukemia-related biologic processes. Gemtuzumab ozogamycin is being studied in combination with conventional chemotherapy during induction and consolidation. Lestaurtinib, a small molecule inhibitor of *FLT3*, has selective toxicity against *FLT3* ITD AML cell lines and in mouse models, but cells can develop resistance to *FLT3* inhibition.[217,218] The proteasome regulates the levels of many intracellular proteins, including NF-κB, and proteasome inhibition has been effective in myeloproliferative disorders. Bortezomib is a proteasome inhibitor that has in vitro activity and synergy with chemotherapeutic agents against primary AML cell lines.[219] Regulation of epigenetic modifications with histone deacetylase and DNA methyltransferase inhibitors is also another promising area of research. Intriguing, novel efforts to screen libraries of small molecules based on their effect on gene expression signatures has yielded unexpected compounds active in promoting differentiation of AML.[220,221] Many of these new agents are being tested up-front in high-risk patients in a risk-adapted strategy and in the relapse setting.[222] Eventually, it may be possible to target the genetic lesions of leukemic cells in other AML subtypes, as exemplified by the use of all-trans-retinoic acid in APL or imatinib in chronic myelogenous leukemia. In a completely different approach, the use of NK cells has been studied as a cell-based therapy outside of HSCT. NK cells from haploidentical donors, but mismatched at the KIR locus, can be isolated and infused into recipients and expanded in vivo using a combination of immunosuppressive agents and IL-2 to provide an antileukemia effect.[223]

The improved ability to measure minimal residual disease by PCR, immunophenotyping, or specific genetic alterations, should result in giving therapy when leukemic burden is smaller and selected intensification of therapy in the presence of residual leukemia. Through the development of new agents, improved monitoring, intelligent use of biologic response modifiers, and limiting the use of BMT to high-risk patients, therapy can be closely tailored to improve outcome. For high-risk patients, the increasing availability of alternative sources of hematopoietic stem cells from unrelated bone marrow or cord blood donors will greatly expand the use of hematopoietic stem cell transplantation in all phases of therapy. Strategies based on preclinical models are also being developed that will hopefully achieve a more favorable balance of the graft-versus-host and graft-versus-leukemia reactions.[224]

CHAPTER 63

PATHOBIOLOGY OF ACUTE LYMPHOBLASTIC LEUKEMIA

Alejandro Gutierrez, Adolfo Ferrando, and A. Thomas Look

Normal lymphoid precursors undergo somatic recombination at their immunoglobulin (*Ig*) or T cell receptor (*TCR*) gene loci,[1] and the successful completion of V(D)J recombination, with the resultant formation of a functional immunoglobulin or T cell receptor, is required for the survival of lymphocyte precursors. Positive and negative selection steps ensure that only lymphocytes with immunoglobulin or T cell receptors that function appropriately within the context of an individual's immune microenvironment are allowed to proceed through the proliferation and differentiation steps required for the development of mature lymphocytes. This developmental process generates a repertoire of lymphocytes with unique variations in the antigen-recognition portions of the immunoglobulin or T cell-receptor genes, which form the foundation of a fully competent adaptive immune system that can recognize a countless variety of foreign antigens.

The acquisition of somatic genetic alterations involving oncogenes or tumor suppressors can lead to the dysregulated proliferation and clonal expansion of lymphoid precursors that is characteristic of acute lymphoblastic leukemia (ALL). Many genes that are critical to leukemogenesis have been identified through the cloning and characterization of genetic alterations induced by recurrent chromosomal translocations.[2–5] In addition, a number of translocations have prognostic significance and are used in modern ALL treatment protocols to adjust the intensity of therapy. In many cases, the malignant transformation of lymphoid cells is the result of altered expression of transcription factors that play critical roles in normal B- and T-cell development, although it may also involve the aberrant expression of otherwise quiescent genes. More recent evidence has implicated members of signal transduction pathways in leukemogenesis.[6–8] Although the incidence of specific genetic alterations in ALL varies according to patient age, evidence is accumulating that the pathogenesis underlying malignant transformation in similar genetic alterations is similar across age groups.[9,10]

CLONAL ORIGIN OF LEUKEMIC LYMPHOID CELLS

Human ALL arises from a single progenitor cell that has acquired somatic genetic changes, which lead to dysregulated proliferation and differentiation arrest. The clonal origin of leukemia was first suggested by the identification of the Philadelphia chromosome in chronic myeloid leukemia.[11] Subsequently, numerous lines of

FUTURE DIRECTIONS

The immediate applications of the emerging molecular information include a redefinition of risk classification schemes to emphasize the roles of somatically acquired genetic abnormalities that carry a defined prognosis and likelihood of therapeutic failure. Currently, patients are assigned to treatment according to their initial clinical features and, increasingly, the genetic and biologic properties of their leukemic cells. We are now in a position to view ALL as a group of heterogeneous diseases defined by discrete molecular lesions. As these lesions have been systematically analyzed in larger numbers of patients, it has been possible to devise new classification schemes for ALL that reflect prognosis with exquisite precision. The development of new drugs based on the molecular biology of ALL is clearly a priority for the future, and will likely take the form of compounds developed to specifically interfere with oncoproteins expressed by each patient's leukemic blasts. In addition, the discovery that several kinases play important roles in ALL pathogenesis has provided new opportunities for targeted drug development. The opportunity is now at hand to improve therapy through randomized trials coordinated on a nationwide or even worldwide scale that focus on key subsets of acute leukemia patients whose lymphoblasts harbor specific genetic abnormalities.

Clinical Risk Assignment in Childhood Acute Lymphoblastic Leukemia

Risk Group	*Features*	*Recommended Therapy*
Low risk	• Simultaneous trisomies of chromosomes 4, 10, and 17 • *TEL–AML1* fusion	Less intensive antimetabolite-based chemotherapy
Intermediate risk	• Standard-risk age/leukocyte count, without other genetic risk features	Intermediate antimetabolite-based chemotherapy
High risk	Presence of any of the following: • Age >10 years • T cell immunophenotype • White blood cell count >50,000 mm^{-3} • CNS leukemia	Intensified multiagent chemotherapy with cranial radiation
Very high risk	• *BCR–ABL* translocation* • *MLL* translocations†,‡ • Hypodiploidy <45 chromosomes • Induction failure or elevated minimal residual disease at the end of induction chemotherapy	Allogeneic bone marrow transplantation in first remission

*Bone marrow transplantation in first remission is clearly beneficial in *BCR–ABL*-positive ALL.

†Current evidence suggests that bone marrow transplantation in first remission may not improve outcomes for children with *MLL*-rearranged ALL.

‡Although *MLL* translocations are almost always associated with very poor outcomes, patients with T-cell ALL who have the t(11;19) MLL–ENL translocation appear to have excellent outcomes with conventional chemotherapy.

evidence have provided additional support for this theory, which is now generally accepted. Uniform structural and numerical chromosomal abnormalities are frequently demonstrated in all leukemic lymphoblasts from an individual patient. Identical rearrangements of *Ig* or *TCR* genes, which are somatic in origin, have been demonstrated in ALL cell populations.[2,12] In addition, identical patterns of X-chromosome inactivation have been demonstrated within all cells of individual patients with ALL by allelic analysis of the glucose-6-phosphate dehydrogenase gene on the X chromosome.[13] As X-inactivation occurs in early embryogenesis, before somatically acquired mutations begin to promote the transformed phenotype, this is particularly strong evidence for the clonal origin of leukemia. In addition, the methylation patterns of restriction-fragment-length polymorphisms in X-linked genes, as detected by Southern blot analysis, have been used to show that even rare ALL cases with two completely different cytogenetic clones probably arise by clonal evolution from a single transformed progenitor.[14]

LINEAGE-SPECIFIC FEATURES OF LEUKEMIC LYMPHOBLASTS

An important advance in the understanding and treatment of ALL was the realization that malignant lymphoblasts share many of the features of normal lymphoid progenitors.[15–17] Thus, ALL cells rearrange their *IG* and *TCR* genes and express components of antigen receptor molecules and other differentiation-linked cell-surface glycoproteins in ways that correspond to features of developing normal B and T lymphocytes. In many cases, leukemic cells appear to represent the clonal expansion of a lymphoid progenitor that has arrested its development at an early stage of B- or T-cell differentiation.[18] Furthermore, research continues with the goal of defining stem cell populations in lymphoblastic leukemia, such as those that have been identified in acute myeloid leukemia.[19] However, with better understanding of the normal patterns of antigen-independent lymphoid cell development, it has become clear that leukemic lymphoblasts can show asynchronous gene expression with subtle variations in phenotype.[20] Hence, it should not be surprising that in some cases of ALL, the blast cell phenotypes differ from those of normal lymphocyte progenitors, which is likely a result of aberrant regulation of gene expression. Still, the general concept that leukemic cells should be classified according to their "normal" developmental stage remains an important one, providing a basis for the study of immunophenotype-specific genetic changes.

B-Cell Acute Lymphoblastic Leukemia

The diagnosis of mature B-cell ALL is based on the detection of surface immunoglobulin on leukemic blasts. This rare phenotype accounts for only 2% to 3% of ALL cases, and the lymphoblasts generally have distinctive morphology, with deeply basophilic cytoplasm containing prominent vacuoles; this morphologic pattern is designated L3 in the French–American–British system.[21–23] Prominent clinical features include concomitant extramedullary lymphomatous masses in the abdomen or head and neck, frequent involvement of the central nervous system and cranial nerves, and tumor lysis syndrome, often complicated by acute renal failure due to uric acid nephropathy.

Acute B-cell leukemia appears to be a disseminated form of Burkitt lymphoma, as these conditions share common cytogenetic, molecular genetic, immunologic, cytologic, and clinical features.[24] Acute B-cell leukemia does not respond well to chemotherapy traditionally used for childhood ALL. However, good outcomes have been obtained with treatments designed for Burkitt lymphoma, which involve relatively brief but intensive regimens that emphasize cyclophosphamide and the rapid rotation of antimetabolites in high dosages.[25–29] Thus, B-cell leukemia is the first form of ALL to be recognized as a distinct clinical entity based on immunophenotypic and cytogenetic features, and the first to be treated by separate protocols designed specifically for the leukemia's unique features.

Pre-B and Early Pre-B Acute Lymphoblastic Leukemia

Approximately 80% of ALL patients have lymphoblasts with phenotypes corresponding to those of B-cell progenitors.[23,30] These cases can be identified on the basis of cell surface expression of CD19 and at least one other recognized B lineage-associated antigen: CD20, CD24, CD22, CD21, or CD79[23,30]; most B-lineage ALL cases also express CD10 (CALLA, or Common ALL Antigen). The lymphoblasts may also express nuclear terminal deoxynucleotidyl transferase (TdT) or CD34. Approximately one-fourth of B-progenitor ALL cases express cytoplasmic Igμ heavy-chain proteins and are designated pre-B cell ALL. Pre-B cases were originally shown to have a worse long-term response to therapy compare to early pre-B cases, an observation that was later attributed to the presence of the t(1;19) translocation that forms the *E2A–PBX1* fusion gene in approximately one-fourth of the pre-B cases.[31] However, with the introduction of more intensive, risk-adjusted treatment regimens, the prognosis for patients with t(1;19)+ ALL has improved significantly.[32,33]

DNA rearrangement of immunoglobulin (*Ig*) genes occurs before heavy-chain gene expression in B-cell development, providing a genetic marker of B-lymphocyte ontogeny. Korsmeyer and coworkers[34,35] pioneered the use of heavy- and light-chain gene rearrangements to support an early B-lineage origin of most ALL blasts. This work was extended to establish synchrony between *Ig* gene rearrangements and the expression of B lineage-restricted cell surface antigens. However, *Ig* heavy-chain gene rearrangements have also been documented in approximately 15% of T-cell ALL cases and a similar percentage of AML cases.[36–38] Thus, caution must be exercised when assigning cell lineage on the basis of studies of *Ig* gene rearrangement.

The identification of specific immunophenotypic, genetic, and clinical features that predict response to therapy in patients with B-lineage ALL, and the incorporation of these predictors into clinical decision making, is now widespread in modern ALL treatment protocols. This ability to predict outcome in these patients has been closely tied to the remarkable improvements in therapy for children with this disease, which 50 years ago was universally fatal. However, many subgroups of pediatric and adult patients face a much poorer prognosis, and much progress remains to be made.

T-Cell Acute Lymphoblastic Leukemia

Leukemias of T-cell precursors can be identified and classified according to the sequence of expression of T cell-associated surface antigens during normal thymocyte ontogeny.[39,40] In this tightly regulated process, the earliest T-cell precursors are characterized by the lack of expression of CD4 and CD8 surface markers. These double-negative (DN) thymocytes express CD7, TdT, and cytoplasmic CD3, and proceed through four different stages of development (DN1 to DN4) defined by the expression of CD44 and CD25. During the DN stages, the TCR-β gene becomes rearranged, driving the production of intermediate single-positive cells (ISPs) with a surface $CD4^+$, $CD8^-$, $sCD3^-$ phenotype. These cells then differentiate into early double-positive ($CD4^+$, $CD8^+$) cells, at which point the *TCR-α* gene rearrangement occurs. Subsequently, these DP progenitors acquire surface CD1 and then differentiate into late cortical thymocytes showing a loss of CD1 and a gain of surface CD3 expression. This thymic T-cell developmental process ends when mature $CD4^+$ or $CD8^+$ single-positive cells are produced,[40,41] although further T cell differentiation occurs in the periphery upon antigen presentation. Numerous investigators, using a battery of monoclonal antibodies specific for T-cell surface glycoproteins, have confirmed the close relationship between the recognizable patterns of surface antigen expression on leukemic T cells and the normal stages of thymocyte development.[42–45]

Lymphoblasts with a T cell phenotype comprise approximately 15% of cases of ALL. These are often associated with distinctive clinical features that include high circulating leukocyte counts, a male predominance, central nervous system involvement, and a radiographically evident thymic mass in many cases at presentation. Historically, patients with T-cell ALL had an adverse prognosis by comparison to patients with B-lineage ALL, but this gap has narrowed with the intensification of therapy for these patients.[46–48] Although several groups have associated the expression of various cell surface antigens in T cell ALL with outcome in retrospective studies,[46,47,49–51] the validation of these markers in prospective studies remains elusive, as does the identification of other clinical or genetic markers of prognosis.[52,53]

The human antigen-specific TCR molecule is a heterodimer composed of disulfide-linked α- and β-polypeptide subunits. Each of these genes undergoes site-specific recombination that generates, at the DNA level, the sequence diversity that allows a wide repertoire of antigen specificity, in a manner analogous to the *Ig* genes. Hence, rearrangement of the *TCR-α/β* genes can be used to establish clonality and lineage derivation within leukemias of T-cell progenitors. Although *TCR-β* genes are generally in a germline configuration in B-lineage leukemic cells, rearrangements at this loci can be seen in approximately 10% of B-cell ALL cases.[54,55] Clonal rearrangements of the *TCR-γ/δ* genes are even less restricted to the T-cell lineage, being observed in a significant number of B-lineage ALL cases.[56,57]

Mixed-Lineage Leukemia

Acute mixed-lineage leukemias are defined by blast cells that coexpress markers of both the lymphoid and myeloid lineages. Two distinct forms of these leukemias are recognized: those with lymphoid morphology that coexpress myeloid-associated antigen[58,59] and those with myeloid morphology and reactivity to myeloperoxidase staining that coexpress cell-surface antigens normally restricted to lymphoid cells. The origin of mixed-lineage leukemias has not been established. One possibility is malignant transformation of pluripotent hematopoietic stem or progenitor cells that retain the ability to differentiate in both the myeloid and lymphoid lineages; another is immortalization of rare progenitor cells that normally coexpress features of both lineages; and a third is aberrant gene expression as a result of specific genetic alterations.[60] There was initially considerable controversy over whether cases of lymphoid leukemia with expression of one or more myeloid cell surface antigens (eg, CD13, CD33, or CD14) had an adverse prognosis. However, most recent data suggest that the coexpression of myeloid antigens in acute lymphoblastic leukemia does not carry an adverse prognosis in the setting of contemporary treatment regiments.[61–63] The expression of lymphoid markers in predominantly myeloid leukemias is relatively rare, and although some studies reported an adverse effect of T-lymphoid markers on outcomes,[64] more recent analyses did not demonstrate a significant prognostic value to lymphoid antigen expression in AML.[65]

GENETIC BASIS OF LYMPHOID LEUKEMIA

Multiple acquired genetic abnormalities are responsible for the aberrant proliferation and differentiation arrest characteristic of ALL. These include chromosomal rearrangements detectable by conventional cytogenetics, as well as lesions that are evident only by molecular analysis. The ability to identify these changes, and the discovery that many of these can be used to predict response to therapy, has led to risk-adapted therapy for ALL. It is worth noting that the vast majority of patients with leukemia have normal constitutional karyotypes, indicating that the genetic abnormalities in ALL lymphoblasts are usually acquired somatically, and thus are restricted to the malignant clone.

Chromosomal translocations are found in 75% of ALL cases (Fig. 63–1).[22,66] They can be broadly classified as recurrent lineage-restricted abnormalities, which account for approximately two-thirds of the translocations in ALL, or as "random" translocations, which have been identified only in single or very small numbers of cases. The characterization of genes that span the breakpoints of recurrent translocations has allowed the identification of genes that play critical roles in leukemogenesis.[3–5]

Central Role of Transcription Factors

Molecular studies on recurrent chromosomal translocations in ALL have demonstrated a central role for the aberrant expression of transcription factors in the pathobiology of leukemia (Table 63–1). The dysregulated expression of these transcription factors, which are often functionally normal, leads to an abnormal proliferation and differentiation arrest of leukemic lymphoid and myeloid progenitors.[3–5] Conserved amino acid sequence motifs within the sequence-specific DNA-binding domains of these nuclear trans-activating proteins allow them to be grouped into families that in many cases, appear to be involved in similar regulatory processes. Thus, the transcription factor genes in Table 63–1 are grouped according to shared structural features of their DNA-binding domains: basic region helix–loop–helix (bHLH), cysteine-rich (LIM), homeodomain (HOX), basic region–leucine zipper (bZIP), zinc-finger, A-T hook minor groove, ETS-like, or runt homology. Another important association is the lineage restriction of transcription factor genes affected by specific chromosomal translocations, suggesting that the proteins they encode disrupt the differentiation of specific lymphoid progenitors. This interpretation implicates a central role for transcription factors in the initiation of leukemia, and suggests that the normal developmental programs of progenitor cells of different lineages are controlled by different regulatory programs.

Rabbitts[67] has aptly described a key group of regulatory transcription factors as the products of "master genes." In his model, the nuclear proteins encoded by these genes act positively to upregulate critical target genes or negatively to interfere with normal regulatory pathways. The net effect is disruption of gene regulatory cascades that control and coordinate the expression of large numbers of proteins required for completion of lymphoid cell differentiation programs. Disruption of transcription factors in leukemic blasts occurs by at least two distinct mechanisms: the dysregulated expression of intact genes and the creation of chimeric transcription factors.

Developmental Biology of Oncogenic Transcription Factors

A surprising connection has emerged from studies of oncogenic transcription factors and the developmental proteins regulating segmentation in *Drosophila*, as the DNA-binding domains of these proteins often show striking homology. The proteins participating in leukemogenesis interfere with a highly regulated network of hematopoietic transcription factors leading to arrested cell development at stages corresponding to those of early lymphoid or myeloid progenitors. Recent evidence implicating the major *HOX* genes in the control of hematopoiesis as well as embryogenesis, together with the established roles of *Drosophila* segmentation genes in controlling *HOM-C* gene expression, suggests that the *HOX* loci may serve as proximal targets of a wide spectrum of hybrid and dysregulated transcription factors in the acute leukemias.[5] In this model, the oncogenic transcription factors inappropriately activate or suppress the expression of *HOX* genes, which in turn regulate gene programs with pleiotropic effects on normal hematopoietic cell development.

The mechanisms that lead to the activation of oncogenic transcription factors in ALL tend to vary according to the ALL subtype. In mature B-cell ALL and in T-cell ALL, genetic lesions that lead to the aberrant expression of structurally intact genes predominate, whereas the chromosomal translocations that often occur in B-precursor ALL generally lead to the formation of chimeric proteins, which are produced as a result of the translocation-induced fusion of the coding sequence of 2 genes.

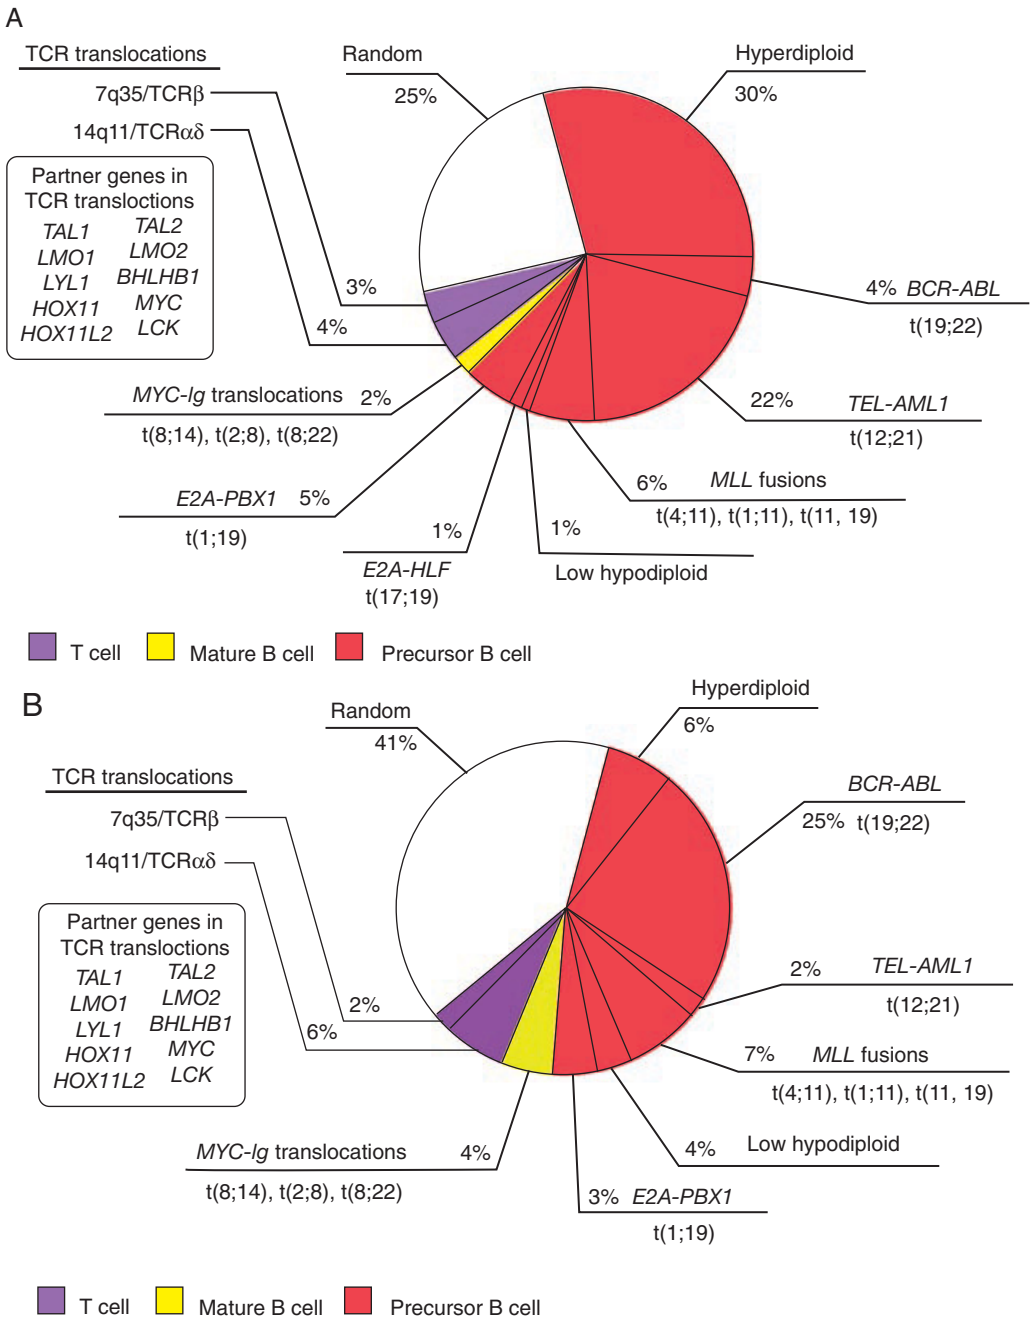

Figure 63–1 Frequency of the major chromosomal translocations in (**A**) pediatric and (**B**) adult ALL. The genes affected by chromosomal translocation are shown in boldface type. TCR translocations in T-ALL can activate a number of different protooncogenes as shown in the insert, including *TAL1*, *LMO1/2*, *HOX11*, *HOX11L2*, and *MYC*.

Dysregulated Expression of Structurally Intact Genes

Activation of MYC in B-Cell Acute Lymphoblastic Leukemia

The vast majority of cases of mature B-cell ALL and Burkitt lymphoma are characterized by a translocation that places one allele of *MYC* from chromosome 8 under the control of the regulatory elements of an *Ig* gene, either the heavy-chain gene on chromosome 14q32 or the κ or λ light-chain genes on chromosomes 2 and 22. This leads to the aberrant expression of *MYC*, a prototypical basic helix–loop–helix oncogenic transcription factor.[68–76] In the predominant t(8;14) translocation, the involved *MYC* locus is translocated into the heavy-chain gene on chromosome 14, adjacent to the coding sequences of the *Ig* constant region.[68–70] The coding sequences of the *Ig* variable region generally are reciprocally translocated to the distal tip of chromosome 8. In variant translocations, the *MYC* gene remains on chromosome 8, and portions of the respective light-chain genes are translocated to that chromosome downstream of the *MYC* locus.[71–75]

Although the *MYC* coding region is not structurally altered by translocation in most cases of B-cell ALL/Burkitt lymphoma, point mutations in the N-terminal phosphorylation domain of *MYC* commonly arise in these tumors at codons 58 or 62.[77–79] These codons are phosphorylation sites involved in the regulation of the activation and degradation of the protein,[80] and these mutations lead not only to the aberrant stabilization of MYC protein[81–83] but also inhibit the ability of MYC to activate the proapoptotic *BIM* gene, although its ability to stimulate proliferation remains intact.[84]

Table 63–1 Transcription Genes Affected by Chromosomal Breakpoints in the Acute Lymphoblastic Leukemias

Family*	Translocation	Affected Gene	Disease
Basic helix–loop–helix (bHLH) proteins	t(8;14)(q24;q32)	*MYC*	Burkitt
	t(2;8)(p12;q24)	*MYC*	lymphoma
	t(8;22)(q24;q11)	*MYC*	and B-cell ALL
	t(8;14)(q24;q11)	*MYC*	T-cell ALL
	t(7;19)(q35;p13)	*LYL1*	T-cell ALL
	t(1;14)(p32;q11)	*TAL1*	T-cell ALL
	t(7;9)(q35;q34)	*TAL2*	T-cell ALL
	t(14;21)(q11.2;q22)	*BHLHB1*	T-cell ALL
Cysteine-rich (LIM) proteins	t(11;14)(p15;q11)	*LMO1*	T-cell ALL
	t(11;14)(p13;q11)	*LMO2*	T-cell ALL
	t(7;11)(q35;p13)	*LMO2*	T-cell ALL
Homeodomain (HOX) proteins	t(10;14)(q24;q11)	*HOX11*	T-cell ALL
	t(7;10)(q35;q24)	*HOX11*	T-cell ALL
	t(5;14)(q35;q32.2)	*HOX11L2*	T-cell ALL
	t(1;19)(q23;p13)	*E2A–PBX1*	Pre-B-cell ALL
Basic-region/leucine-zipper (bZIP) proteins	t(17;19)(q22;p13)	*E2A–HLF*	EPB ALL
A–T hook minor groove binding proteins†	t(4;11)(q21;q23)	*MLL–AF4*	EPB ALL
	t(11;19)(q23;p13.3)	*MLL–ENL*	ALL or AML
ETS-like (TEL, ERG) proteins	t(12;21)(p13;q22)	*TEL–AML1*	ALL
Runt homology (AML1)	t(12;21)(p13;q22)	*TEL–AML1*	ALL

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; EPB, early pre-B.
*Based on the DNA-binding domain.

The mechanisms by which *MYC* exerts its potent growth-promoting effects are complex and only partially understood. *MYC* is estimated to regulate the expression of 15% of the genome,[85] and leads to the transcriptional activation of a large number of genes involved in cell division, growth, metabolism, adhesion, and motility,[86] although it also leads to the transcriptional repression of many other genes, such as the cell cycle inhibitors *p27* and *p21*. Many experts currently believe that the potent effects of *MYC* are mediated by relatively subtle effects on a large number of target genes and networks, rather than by large effects on a small number of targets. *MYC* exerts its transcriptional activity via the formation of heterodimers with its DNA-binding partner protein MAX. MYC:MAX heterodimers bind to canonical hexameric E-box DNA sequences (5′-CACGTG-3′) where they activate transcription.[87] MAX can also heterodimerize with other bHLHZip proteins, including MAD,[88] MXI-1 (MAD2),[89] and MNT.[90] Whereas transcriptional activation by MYC:MAX complexes promotes proliferation, binding by MAD:MAX and other MAX heterodimers produces opposite effects; for example, MAD inhibits MYC function both by competing with MYC for binding to MAX and by directly inhibiting transcription.

BHLH, LIM, and HOX Genes in T-Cell Acute Lymphoblastic Leukemia

In leukemias with a T-cell phenotype, chromosomal breakpoints consistently involve the *TCR* enhancer (7q34) or the *TCRα/δ* enhancer (14q11), both of which are highly active in committed T-cell progenitors and can cause dysregulated expression of transcription factor genes located at the breakpoint on the reciprocal chromosome involved in these phenotype-specific rearrangements.[91] The affected transcription factors include (a) genes encoding basic helix–loop–helix (bHLH) family members, such as *TAL1*,[92,93] *TAL2*,[94] *LYL1*,[95] *MYC*,[96–98] and *BHLHB1*[99]; (b) LIM-only domain (*LMO*) genes, such as *LMO1* and *LMO2*[100]; and (c) the orphan homeobox genes *HOX11* and *HOX11L2*.[37,101–106] The observation that T-ALL oncogenes act as master transcriptional regulators during the embryologic development of specific organ systems suggests that their aberrant expression in T-cell precursors may contribute to the onset of leukemia by disrupting the mechanisms that control cell proliferation, differentiation, and survival during the discrete steps of normal T-cell development. Gene expression profiling and mutational analyses have shown that cases of T-ALL can be separated into five subtypes according to the pattern of multistep genetic abnormalities that occur (Fig. 63–2).

The best characterized of the oncogenic transcription factors involved in T-ALL is *TAL1* (also known as *SCL*), which is altered by the t(1;14) or by site-specific deletions in approximately one-fourth of childhood T-ALL cases.[107–112] *TAL1* is aberrantly expressed in the leukemic cells of 60% of children and 45% of adults with T-ALL, and its expression is required for maintenance of the leukemic phenotype in human cell culture studies.[113] TAL1 acts as a master regulatory protein during early hematopoietic development and is required for the generation of all blood cell lineages.[114,115] However, it does not seem to be required for the generation and function of hematopoietic stem cells during adult hematopoiesis.[116] This class II basic helix–loop–helix (bHLH) transcription factor binds to DNA by forming heterodimers with class I bHLH factors such as E2A.[117] Although TAL1 binding to promoter sites that are normally occupied by TAL1, E2A, or HEB can lead to either repression or activation of transcription,[113] TAL1 appears to exert its leukemogenic effects largely via the inhibition of E2A activity.[118] The observation that loss of E2A function induces T-cell leukemias in mice,[119,120] and that the DNA-binding domain of TAL1 is dispensable for transformation in transgenic mouse models,[121] gives additional support to the notion that TAL1-mediated inhibition of E2A plays a central role in its pathogenesis in T-ALL.

The LIM-only domain genes, *LMO1/RBTN1/TTG1* and *LMO2/RBTN2/TTG2*,[100,122,123] encode proteins that possess duplicated cysteine-rich LIM domains involved in protein–protein interactions. LMO2 interacts with TAL1 in erythroid cells and in T-cell leukemias.[124–126] Moreover, homozygous disruption of *LMO2* in mice causes the same phenotype as described above for *TAL1* knockouts, indicating that a multiprotein complex is required for normal hematopoietic development that involves LMO2, TAL1, and other

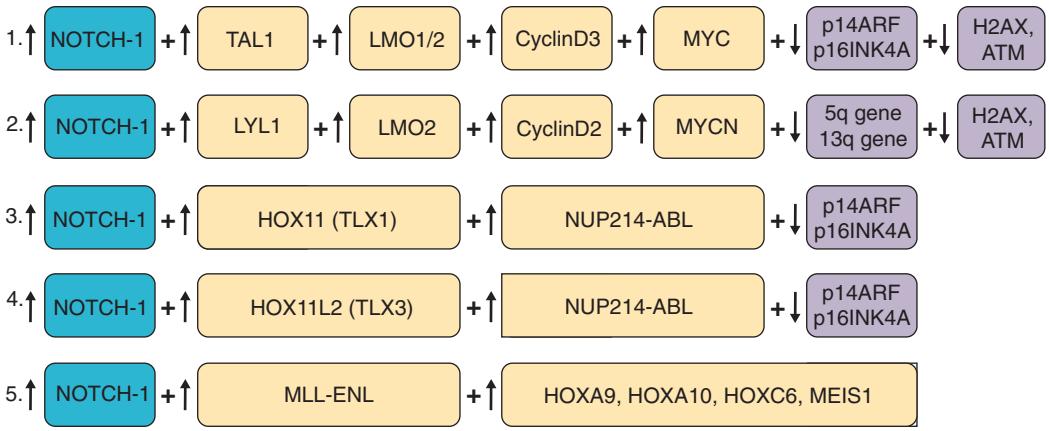

Figure 63–2 Multistep oncogenic pathways in T-cell ALL. Gene expression profiling and mutation analyses have revealed that five different multistep molecular pathways can lead to the malignant transformation of developing thymocytes. *NOTCH1* mutations are seen in samples from all five T-ALL subtypes. *HOX11*, *HOX11L2*, and *TAL1*-overexpressing cases show high levels of *MYC* expression and share the loss of the tumor suppressor genes *p16/INK4A* and *p14/ARF* on chromosome 9p. *HOX11* and *HOX11L2* are often associated with a novel *NUP214–ABL* episomal fusion gene, which may render these T-ALLs sensitive to imatinib. *LYL1+* cases show high levels of expression of *N-MYC* and frequently have deletions affecting as yet unidentified loci on chromosomal arms 5q and 13q. Finally, *MLL–ENL+* cases have a clearly distinct gene expression profile characterized by low expression of *MYC* and other genes involved in cell growth and proliferation, but high expression of *HOXA9*, *HOXA10*, and *HOXC6* in concert with the HOX gene regulator *MEIS1*. Adapted from Armstrong SA, Look AT: Molecular genetics of acute lymphoblastic leukemia. J Clin Oncol 23:6306, 2005, with permission.

proteins such as GATA1.[127–130] In addition, overexpression of *LMO1* or *LMO2* in thymocytes of transgenic mice leads to T-cell lymphomas, recapitulating human T-cell tumors,[131–135] and accelerates the onset of leukemias in *TAL1* transgenic mice lines.[126]

The homeodomain gene *HOX11*, located on chromosome 10, band 24, is one of the more interesting proteins activated by translocation into the vicinity of the *TCR* loci.[37,102,104–106] *HOX11* is the founding member of a family of *HOX* genes that includes *HOX11L1* and *HOX11L2*[106] and whose family members are characterized by the presence of a threonine in the third helix of the homeodomain, which confers specific DNA-binding properties. *HOX11* was originally isolated from the recurrent t(10;14)(q24;q11) in T-ALL[37,102,104,105] and is aberrantly expressed in 5% of pediatric and up to 30% of adult T-ALL cases.[101,136,137] The relatively low frequency translocations involving the *HOX11* locus on 10q24, 2% to 5% in childhood T-ALL[105] and 14% in adult cases,[138] suggest that alternative mechanisms leading to *HOX11* overexpression account for the activation of this transcription factor oncogene in a significant fraction of T-ALL cases.

Like other *HOX* genes, *HOX11* plays an important role in embryonic development, and functions as a master transcriptional regulator necessary for the genesis of the spleen.[139,140] In the mouse embryo, *Hox11* expression can be detected in the branchial arches, restricted areas of the hindbrain and the splenic primordium,[141,142] where it is required for the survival of early splenic progenitors.[140] The *HOX11* oncogenic transcription factor is associated with T-cell leukemogenesis at the early cortical thymocyte stage and relies on specific homeodomain–DNA interactions for its leukemogenic effects.[143] In addition, *HOX11* also directly interacts with the catalytic subunits of the serine/threonine phosphatases PP2A and PPA, which mediate disruption of the G2/M cell-cycle checkpoint.[144]

A second *HOX11* family member, *HOX11L2*, has also been implicated in the pathogenesis of human T-ALL through characterization of the t(5;14)(q35;q32), a cryptic chromosomal rearrangement detectable only by fluorescence in situ hybridization or by chromosome painting techniques.[103] This translocation leads to the ectopic expression of *HOX11L2*, possibly by bringing it under the influence of regulatory elements in the *CTIP2/BCL11B* gene, which is highly expressed during T-lymphoid differentiation. In contrast to the predominance of *HOX11* expression in adult T-ALL cases, both the t(5;14) and expression of *HOX11L2* can be detected in 20% to 25% of children but in only 5% of adults with T-ALL.[101,137,145–147] The role of HOX11L2 as a master transcriptional regulator upstream of important pathways involved in cell fate determination is supported by its importance during embryonic development.[148] In mice, *Hox11l2* expression is essential for normal development of the ventral medullary respiratory center.[148] Mice deficient in this protein die soon after birth as a result of respiratory failure that resembles congenital central hypoventilation syndrome in humans.

HOX11 and HOX11L2 are closely related in structure, and have a high degree of homology at the amino acid level, especially in the homeobox domain, where their sequences differ by only three amino acids. The high level of structural homology in their DNA-binding domains supports the hypothesis that HOX11 and HOX11L2 may induce T-ALL through regulation of the same transcriptional targets. However, activation of *HOX11* and *HOX11L2* seem to be associated with clinically relevant differences that may result, at least in part, from differences in their mechanisms of action. The expression of HOX11 is associated with a favorable prognosis both in children and in adults.[17,91,136] On the other hand, reports on the prognostic significance of *HOX11L2* expression in T-ALL show conflicting results,[17,145,147,149] and in the absence of more definitive data, it would appear prudent to avoid incorporating *HOX11L2* expression into treatment algorithms.

Recently, the analysis of gene expression profiling using oligonucleotide microarrays has shown that the expression of different transcription factor oncogenes such as *TAL1*, *LYL1*, *HOX11* and *HOX11L2* is associated with distinct gene expression profiles. These unique signatures resemble those of thymocytes blocked at discrete stages of T-cell development (Fig. 63–3),[17] and suggest that transcription factor oncogenes contribute to the pathogenesis of T-ALL by interfering with critical regulatory networks that control cell proliferation, survival, and differentiation during T-cell development.[17] On the basis of the patterns of aberrant gene expression, human cases of T-ALL can be classified into five different subtypes (see Fig. 63–2).

HOXA Cluster Translocations in T-Cell Acute Lymphoblastic Leukemia

A recurrent inversion on chromosome 7 that places the *HOXA* cluster in the vicinity of the T cell-receptor beta gene regulatory elements, and that leads to activation of the entire *HOXA* cluster, was recently discovered in approximately 5% of cases of T-ALL.[150,151] Many of these cases also carried cooperating oncogenic lesions consisting of *NOTCH1* gene mutations and deletions of 9p21.[152] This new trans-

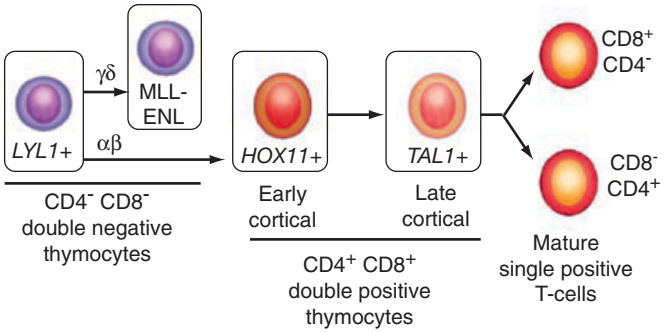

Figure 63–3 Thymocyte development is a tightly regulated process in which progenitor cells undergo sequential stages of differentiation, proliferation, lineage commitment, and selection that result in the production of functionally competent mature T cells. Microarray gene expression profiling shows that T-ALL lymphoblasts expressing high levels of the LYL1 transcription factor oncogene undergo an early arrest at the double-negative thymocyte ($CD4^-$, $CD8^-$) stage of development. In T-ALL cases with aberrant expression of HOX11, the leukemic cells show a developmental arrest at the double-positive ($CD4^+$, $CD8^+$) early cortical stage of thymocyte differentiation, whereas those with aberrant expression of TAL1 are arrested at the double-positive late cortical stage. T-ALL cells with expression of the *MLL–ENL* fusion gene are characterized by an early arrest of differentiation with a gene expression signature that indicates commitment to the gamma-delta lineage. Adapted from Ferrando AA, Neuberg DS, Staunton J, et al: Gene expression signatures define novel oncogenic pathways in T cell acute lymphoblastic leukemia. Cancer Cell 1:75, 2002, and Ferrando AA, Armstrong SA, Newberg DS, et al: Gene expression signatures in MLL-rearranged T-lineage and β-precursor acute leukemia: dominance of HOX dysregulation. location that directly activates *HOXA* gene expression provides additional evidence for the role of aberrant *HOXA* activation in leukemogenesis and in the pathogenesis of *MLL*- and *CALM–AF10*-rearranged leukemias.

Other Genes Activated by Translocation

Transcription factors are not the only genes activated by translocation to the sites of the *IG* or *TCR* genes. In cases of B-precursor ALL carrying the t(5;14), for example, the *IL-3* gene is activated by juxtaposition with the *IG* heavy-chain locus.[153,154] Similarly, relocation to the *TCRB* locus activates expression of the *LCK* tyrosine kinase genes in T-ALL cases with the t(1;7).[155–157]

Chimeric Transcription Factor Genes

Formation of chimeric proteins whose functional domains come from two normally separate genes represents a second mechanism of aberrant transcription factor activation, which is more prevalent in B-precursor ALL. These chromosomal translocations result in the production of a chimeric protein by fusing the DNA-binding, dimerization, and trans-activation regions of discrete genes. This process is facilitated by the molecular structure of transcription factors, in which discrete coding regions of each gene encode particular functional domains; this molecular structure likely arose for evolutionary reasons.

E2A–PBX1 Fusion Genes in Pre-B Cell Acute Lymphoblastic Leukemia

A well-known example of a chimeric transcription factor with oncogenic potential is the *E2A–PBX1* rearrangement, which results from the t(1;19)(q23;p13) chromosomal translocation present in approximately 5% of all B-lineage ALLs and in 25% of cases with a pre-B (cytoplasmic immunoglobulin-positive) phenotype.[32,91,158] This translocation fuses the transactivation domain of the *E2A* transcription factor on chromosome 19 to a homeobox gene (*PBX1*) on chromosome 1, leading to the expression of several forms of hybrid E2A–PBX1 oncoproteins.[159–161] *PBX1* is related to the *Drosophila exd* gene, a homeobox gene that plays a role in lymphocyte development.[162,163] The hybrid proteins resulting from the t(1;19) retain the amino-terminal trans-activation domains of E2A (AD1 and AD2), but not the bHLH DNA-binding or protein interaction domain.[160,161,164] The bHLH domain is replaced by the homeobox DNA-binding domain of PBX1, enabling the fusion protein to function as a chimeric transcription factor.[165–167]

The transforming potential of *E2A–PBX1* was first demonstrated by the rapid induction of AML in lethally irradiated mice repopulated with bone marrow stem cells that had been infected with recombinant retroviruses containing *E2A–PBX1* genes.[168] The fusion has also been shown to transform NIH-3T3 fibroblasts and induce T-cell lymphomas in transgenic mice.[169,170] Additional studies have shown that deletion of one of the E2A activation domains diminishes its transforming activity, whereas deletion of the PBX1 homeodomain has no effect.[170,171] However, the homeodomain and flanking sequences are required for interactions with other HOX proteins and for optimal binding of E2A–PBX1 to specific DNA sequences.[172–176] It thus appears that complex interactions between E2A–PBX1 and other HOX proteins target the fusion protein to specific target genes whose activation is critical to lymphoid cell transformation. The presence of the *E2A–PBX1* translocation was originally associated with poor prognosis.[31] However, this translocation no longer imparts an adverse prognosis in the setting of modern risk-adjusted protocols for childhood ALL.[32,177–179]

E2A–HLF Fusion Genes in Early Pre-B Acute Lymphoblastic Leukemia

The t(17;19) is a rare recurrent chromosomal translocation that fuses the amino-terminal transactivation domains of E2A to the C-terminal DNA binding and dimerization domains of HLF,[180,181] which belongs to the PAR subfamily of bZIP transcription factors. Although E2A–HLF can bind DNA either as a homodimer or as a heterodimer with HLF and related proteins, no other PAR proteins are expressed in hematopoietic cells, and the E2A–HLF fusion binds DNA as a homodimer in cells harboring the t(17;19). Like E2A–PBX1, E2A–HLF can transform NIH–3T3 fibroblasts, a process that requires the HLF leucine zipper domain and the E2A transactivation domains.[182] E2A–HLF can also induce lymphoid tumors in transgenic mice.[183]

A major consequence of the activation of E2A–HLF in lymphoid precursors is dysregulation of the mechanisms that control programmed cell death in lymphoid progenitors. Expression of a dominant-negative form of E2A–HLF in t(17;19)-carrying cell lines blocks E2A–HLF function and results in apoptosis.[184] In normal pro-B lymphocytes, expression of E2A–HLF reversed IL-3-dependent and p53-induced apoptosis. HLF is the mammalian homologue of the nematode protein ces-2, which regulates the death of specific nerve cells in *Caenorhabditis elegans*.[184–186] Ces-2 is necessary for the death of the sister cells of a specific pair of serotonergic neurons during worm development. Ces-2 induces apoptosis by inhibiting the expression of *ces-1*, a prosurvival gene that normally inhibits programmed cell death by antagonizing the activity of the proapoptotic factor *egl-1*. This pathway, which is highly conserved through evolution, is disrupted by E2A–HLF fusion. Thus, in contrast to the proapoptotic role of ces-2 in the worm via repression of ces-1, E2A–HLF blocks apoptosis by inducing the expression of *SLUG*, a *ces-1* homologue normally responsible for protecting hematopoietic progenitors from DNA-damage-induced apoptosis.[187–190]

The t(17;19) is seen in less than 1% of ALL cases, typically occurs in adolescents, and is associated with disseminated intravascular coagulation and hypercalcemia at diagnosis. The t(17;19) seems to impart unfavorable prognosis, because each of seven patients whose

blasts expressed *E2A–HLF* died of leukemia despite aggressive therapy.[91] It seems likely that resistance to chemotherapy in these cases is mediated by the role of E2A–HLF in driving the expression of *SLUG* and inhibiting apoptosis.[190]

MLL Fusion Genes

Translocations involving chromosome 11 band q23 occur in approximately 80% of infant ALL cases, 5% of AML cases, and 85% of secondary AML cases that occur in patients treated with topoisomerase II inhibitors.[91] The gene bisected by 11q23 translocations is designated *MLL* (also known as *HTRX* or *ALL-1*) and encodes a protein that shares significant sequence homology with trithorax, a *Drosophila* regulator of homeobox gene function during fly embryogenesis.[191–194] Trithorax regulates homeobox genes in the *Antennapedia* and *Bithorax* complexes of the fly and is required for normal head, thorax, and abdomen development.[195] The MLL protein shares three regions of homology with trithorax, including two central zinc-finger domains and a 210-amino acid C-terminal SET domain. Interestingly, a SET domain is also found in the *Drosophila* enhancer of zeste protein that, like trithorax, regulates genes in the *Antennapedia* and *Bithorax* complexes.[196] The *MLL* SET domain contains a histone H3/lysine 4 methyl transferase activity that plays a critical role in the regulation of *HOX* gene expression.[197] Other structural features of *MLL* include three A-T hook domains near the N terminus that are thought to bind the minor groove of DNA in AT-rich regions, and a 47-amino acid region of homology with the noncatalytic domains of human DNA methyltransferase.[198,199] MLL localization and stability depend on proteolytic posttranslational processing by Taspase1, a specialized protease that cleaves the MLL protein into N-terminal and C-terminal fragments that remain associated through intramolecular protein–protein interaction domains.[200–202]

Translocation breakpoints cluster in an 8.5-kilobase region of *MLL* between exons 5 and 11 and fuse the N-terminal region of *MLL*, containing the A-T hook and methyltransferase domains, to a variety of partner proteins. Although the role of each partner protein in leukemogenesis has not been fully determined, it appears that at least some of them may contribute functional domains to the fusion. For example, the t(4;11), t(9;11), and t(11;19)(q23;p13.3) fuse *MLL* to *AF-4*, *AF-9*, and *ENL*, respectively. All three of these partners are small serine- or proline-rich proteins with nuclear localization signals, suggesting that they may function as transcriptional transactivators. An unrelated gene, *ELL*, is fused to *MLL* by the t(11;19)(q23;p13.1).[203,204] *ELL* was also independently isolated as an RNA polymerase II elongation factor.[205] Still other partners seem to have no transcriptional activity but to contribute a dimerization domain to the fusion protein that results in homo-oligomerization of the N-terminal portion of MLL.[206,207]

Homologous recombination techniques have recently been used to create mice lacking one or both copies of *Mll*, the murine homologue of *MLL*. *Mll* heterozygous mice demonstrated the effects of haploinsufficiency, including anemia, thrombocytopenia, and reduced numbers of B lymphocytes. The mice also showed homeotic transformations of the cervical, thoracic, and lumbar regions that reflected shifts in the pattern of *Hox* gene expression, establishing a crucial role for *Mll* in *Hox* gene regulation. These results are consistent with other data suggesting a role for *Hox* genes in normal hematopoiesis. Mice with homozygous inactivation of *Mll* died in utero and lacked *Hox* gene expression, further supporting a key role for *Mll* in *Hox* regulation.

Formal proof that *MLL* fusions play a critical role in the development of leukemias has come from the generation of murine models of *MLL*-induced leukemias. Chimeric mice harboring a *MLL–AF9* fusion gene generated by homologous recombination developed leukemias with a latency of 4 to 12 months.[208] Retroviral transduction of *MLL–ENL*, *MLL–ELL*, and *MLL–CBP* fusion genes in hematopoietic precursors induces transformation upon transplantation into recipient mice.[209–211] Similar results were recently obtained with a model in which chromosomal translocations involving the *Mll* locus are induced by directed interchromosomal recombination in mice, a strategy that reproduces experimentally the initiating events in the pathogenesis of *MLL*-rearranged leukemias.[212] Interestingly, the introduction of MLL–AF9 into committed granulocyte-macrophage progenitors in the mouse leads to the reactivation of a subset of genes normally expressed only in hematopoietic stem cells, and transforms these committed precursors into AML leukemic stem cells by imparting the properties of self-renewal,[213] suggesting that the leukemogenic lesion in MLL–rearranged leukemia might occur in a committed progenitor rather than in a pluripotent hematopoietic stem cell.

Gene expression profiling using oligonucleotide microarrays facilitates the measurement of relative levels of gene expression of thousands of genes in a single assay and has became a powerful tool for the molecular characterization of human malignancies. The analysis of gene expression profiles using DNA arrays in *MLL*-rearranged B-lineage leukemias has shown that these tumors have a characteristic gene expression signature that includes the upregulation of several *HOX* genes and the expression of numerous myeloid markers.[214–216] Both early B- and T-cell ALLs with MLL rearrangements showed a characteristic upregulation of specific *HOX* genes, including *HOXA9*, *HOXA10*, *HOXC6*, and the *HOX* gene regulator *MEIS1*.[214–216] These results, together with the demonstration that HOXA9 plays important roles in the transformation of hematopoietic precursors by MLL fusion oncogenes in murine leukemia models,[217,218] emphasize the central role of *HOX* gene dysregulation in the pathogenesis of *MLL*-rearranged leukemias. In addition, as discussed later in this chapter, overexpression or activating mutations of the *FLT3* receptor tyrosine kinase are frequent in *MLL*-rearranged leukemias,[214,215,219,220] and a model of the multistep pathogenesis of *MLL*-rearranged ALL is depicted in Fig. 63–4.

The presence of MLL rearrangements is associated with dismal outcomes despite aggressive chemotherapy in most cases of ALL.[23,221–223] Additionally, bone marrow transplantation in first remission in these patients is not clearly beneficial, and may actually be associated with a decrease in event-free and overall survival when compared to chemotherapy alone.[223,224] One notable exception is the t(11;19) translocation in T cell ALL in particular. Although this translocation represents a poor prognostic indicator in patients with B-precursor ALL, the largest series published to date demonstrated a surprisingly good outcome in patients with T cell ALL with this translocation.[225]

CALM–AF10 Fusion Gene in T-Cell Acute Lymphoblastic Leukemia

The t(10;11)(p13;q14) detected in approximately 3% to 10% of T-ALL cases and in occasional AML cases results in the fusion of *CALM*, encoding a protein with high homology to the murine clathrin assembly protein ap3, with *AF10*, a gene identified as an MLL partner in the MLL–AF10 fusion resulting from the t(10;11)(p13;q23).[226] Although the mechanism of action of CALM–AF10 remains incompletely understood, the expression of this fusion transcript has been associated with early arrest in T-cell development and to differentiation into the gamma–delta lineage in T-ALL.[227] In addition, recent evidence suggests that aberrant upregulation of HOX gene expression appears to be involved in CALM–AF10-mediated leukemogenesis, at least in acute myeloid leukemia cells that carry this translocation.[228] Interestingly, analysis of a mouse model of CALM–AF10-induced acute myeloid leukemia suggests that the leukemia stem cell in this model has lymphoid characteristics, and cells from human patients with AML can be identified that have similar characteristics to the disease-propagating cell in this animal model.[229]

TEL–AML1 (ETV6–RUNX1) Fusion Gene in Early Pre-B Acute Lymphoblastic Leukemia

Although most t(12;21) translocations cannot be detected by standard cytogenetic analysis, this translocation is detectable by molecular

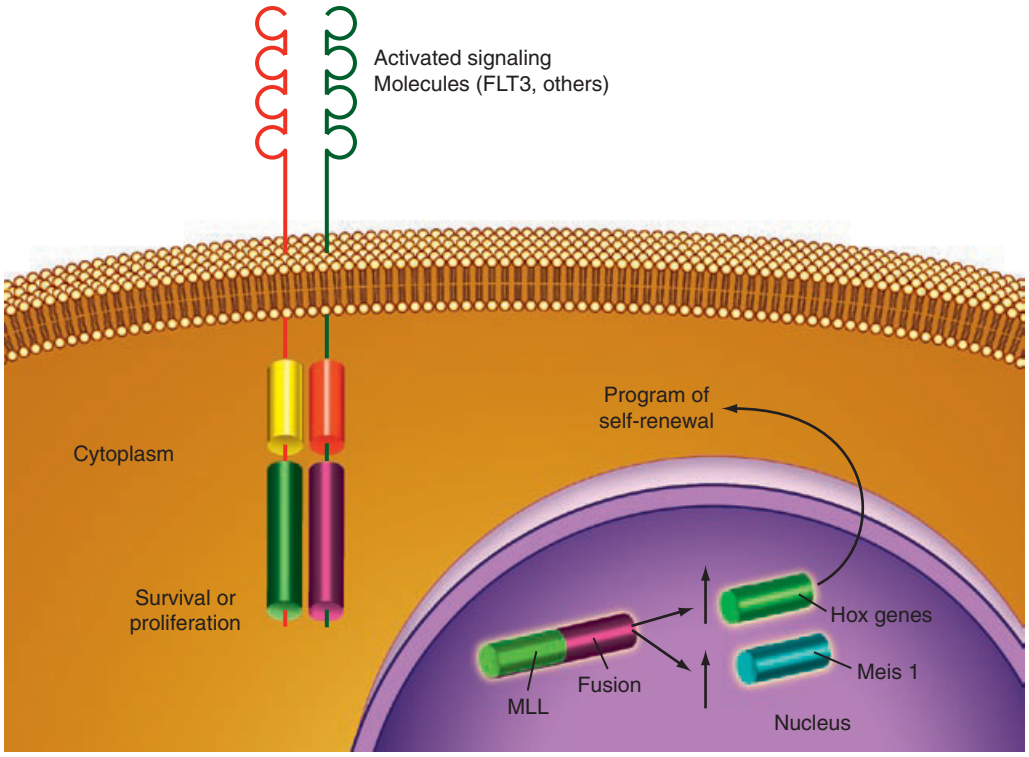

Figure 63–4 Multistep pathogenesis of *MLL*-rearranged ALL. MLL translocations induce self-renewal in hematopoietic progenitors as a first step in leukemogenesis. The presence of FLT3 mutations in *MLL*-rearranged ALLs support activation of FLT3 or other kinases as cooperating events in this disease. Clinical trials designed to assess the efficacy of FLT3 inhibitors in *MLL*-rearranged ALL are being developed. Adapted from Armstrong SA, Look AT: Molecular genetics of acute lymphoblastic leukemia. J Clin Oncol 23:6306, 2005, with permission.

techniques in approximately 25% of childhood B-lineage ALL, which makes this the most common genetic lesion in pediatric ALL.[91] The *TEL–AML1* translocation often arises prenatally and is probably the initiating mutation in ALL, as evidenced by the identification of identical *TEL–AML1* translocations in identical twins with concordant ALL,[230] and in retrospectively analyzed neonatal blood specimens of children diagnosed with ALL.[231] However, *TEL–AML1* is insufficient in causing leukemia, because the incidence of detectable *TEL–AML1* fusions in the blood of normal newborns is approximately 100-fold greater than the incidence of leukemia.[232]

The molecular mechanisms mediating *TEL–AML1*-induced leukemogenesis remain poorly understood. This fusion gene encodes a chimeric protein that contains the helix–loop–helix (HLH) domain of *TEL* fused to nearly all of *AML1* (also known as *RUNX1* or *CBFA2*), including both the transactivation domain and the DNA- and protein-binding Runt homology domain. Both of these genes are found in other leukemia-related translocations, and both are essential for normal hematopoiesis. *TEL* was first identified in the t(5;12) in chronic myelomonocytic leukemia, where it is fused to the platelet-derived growth factor receptor gene (*PDGFRB*), and is also fused to *ABL*, *MN1*, and *EVI1* in AML, and to *JAK2* in T-ALL.[233] The role of TEL in hematopoiesis has been demonstrated with a conditional mouse model in which the absence of TEL in early development leads to the absence of fetal hematopoiesis. Interestingly, the inactivation of TEL in adult mice leads to the selective loss of hematopoietic stem cells from adult bone marrow, whereas hematopoiesis is sustained by committed precursors.[234] Most *TEL–AML1* leukemias show loss of the normal *TEL* allele, suggesting that the leukemogenic effect of *TEL–AML1* may be mediated in part by loss of function of the *TEL* gene.[235–238]

AML1 is the DNA-binding component of the AML1-CBFβ transcription factor complex disrupted by the t(8;21), t(3;21), and inv(16) in AML, making it the most common target of chromosomal translocations in leukemia. AML1 is a transcription factor that has been shown to be required for the expression of several hematopoietic genes involved in myeloid and lymphoid development, including *PU.1* and interleukin 3, although it can also act as a transcriptional repressor in some settings.[239] Homozygous disruption of the murine *AML1* gene or *CBFB* gene results in the lack of definitive hematopoiesis, indicating that genes regulated by AML1 are essential for normal hematopoietic development.[240,241] In addition, rare familial mutations in the *AML1* DNA-binding domain lead to the familial platelet disorder and predisposition to myeloid malignancy syndrome.[242] However, the molecular pathways mediating *TEL–AML1*-induced leukemogenesis remain incompletely understood.

The presence of the *TEL–AML1* translocation is associated with an excellent prognosis, with event-free survival rates of approximately 90% in a variety of studies.[91,243,244] However, *TEL–AML1* may not represent an independent predictor of prognosis when age and white blood cell count at the time of diagnosis are taken into account in multivariate analysis.[244] Nevertheless, this translocation identifies a large subset of children with B-precursor ALL who appear to represent good candidates for less intensive therapy. The *TEL–AML1* translocation is associated with lower expression of the *MDR-1* multidrug resistance gene[245] and of genes involved in purine metabolism,[246] which might account for the particular efficacy of these cases to current combination chemotherapy regimens that rely heavily on methotrexate and mercaptopurine, agents that inhibit de novo purine synthesis.

Tyrosine Kinase Genes

BCR–ABL in B-Precursor Acute Lymphoblastic Leukemia

The 22q- chromosomal marker, often called the Philadelphia (Ph) chromosome, which arises from the t(9;22)(q34;q11), was originally identified in patients with chronic myelogenous leukemia (CML), although it is also found in approximately 4% of childhood cases and

25% of adult cases of ALL,[91] which are almost always of the B-precursor subtype. The t(9;22) generates a *BCR–ABL* fusion gene, consisting of 5′ (upstream) sequences from *BCR* and 3′ (downstream) sequences of *ABL*. The t(9;22) breakpoints on the distal tip of the long arm of chromosome 9 are scattered over a distance of nearly 200 kb within the first intron of the *ABL* protooncogene, upstream of the tyrosine kinase domain.[247–249] The breakpoints in the *BCR* gene on chromosome 22 cluster in two separate regions of that gene, known as the major breakpoint cluster region (M-bcr) or minor breakpoint cluster region (m-bcr). In two-thirds of cases of Ph-positive ALL, the breakpoint in the *BCR* gene occurs in the minor breakpoint cluster region (m-bcr), whereas in all cases of chronic myeloid leukemia and approximately one-third of cases of ALL, the breaks occur in the major breakpoint cluster region (M-bcr).[250] The fusion transcript more commonly present in ALL (m-bcr) encodes a 190-kd protein (p190), whereas the transcripts found in CML and some cases of ALL (M-bcr breakpoint) encodes a 210-kd hybrid protein (p210).[251–253,254] Both types of fusions generate chimeric oncoproteins that are activated as a tyrosine-specific protein kinase, similar to the v-abl protein.[255–257]

The ABL tyrosine kinase is localized both in the nucleus and in the cytoplasm of proliferating cells. It is normally activated by DNA damage downstream of ATM and appears to promote p53-mediated growth arrest.[258–261] Mice deficient in ABL develop a wasting syndrome and die soon after birth.[262,263] In contrast to the nuclear and cytoplasmic distribution of normal ABL, the BCR–ABL fusion oncoprotein has a cytoplasmic location and shows increased tyrosine kinase activity.[264,265] When expressed in murine hematopoietic precursors, both p190 and p210 transform hematopoietic cells in vitro and induce a syndrome similar to CML in mice.[266–269] Transformation by the BCR–ABL oncoprotein involves activation of the RAS/MAPK pathway, PI-3 and JUN kinases, c-CBL and CRKL, JAK-STAT, NFκB, Src, and cyclin D1.[270–277] Among these targets, RAS, JUN-kinase and PI-3 kinase pathways are involved in the induction of cell proliferation.[278] The BCR–ABL oncoprotein affects multiple aspects of cell homeostasis, including apoptosis, differentiation, and cell adhesion. An important cellular effect of BCR–ABL is the induction of cellular resistance to DNA damage agents such as cytostatic drugs and irradiation. After DNA damage, BCR–ABL extends the duration of the G2/M cell cycle checkpoint and facilitates DNA repair. It also upregulates the antiapoptotic *BCLXL* gene, contributing to the suppression of apoptotic cell death.[279]

The factors that determine whether the *BCR–ABL1* translocation leads to B-precursor ALL or CML remain incompletely understood. Clinical observations, mutational studies, and mouse models present a complex picture, and it has been difficult to ascertain whether features of the fusion gene itself, the cell type in which the translocation occurred, or other factors determined whether this translocation led to CML or ALL. However, it has recently been demonstrated that the *BCR–ABL1*-mediated activation of several SRC kinases, including Lyn, Hck, and Fgr, plays crucial roles for the ability of *BCR–ABL1* to induce B-precursor ALL but not CML in the mouse.[280,281]

The presence of the Philadelphia chromosome is associated with an extremely poor prognosis in ALL patients despite treatment on contemporary protocols for high-risk disease.[282–284] Although a relatively small subset of these patients may be cured with the use of standard intensive chemotherapy, particularly those with a low white blood cell count at diagnosis and good initial steroid response,[285–288] bone marrow transplantation in first remission from a matched related donor is clearly beneficial for patients in all risk groups.[286,289,290] In addition, evidence is accumulating that transplantation of Ph-positive ALL using an alternative bone marrow donor is also an advantageous approach.[291,292]

The development of imatinib mesylate (STI-571/Gleevec), a pharmacologic tyrosine kinase inhibitor targeting the BCR–ABL oncoprotein, has opened novel therapeutic opportunities for the management of Ph-positive ALL, especially for patients who are not candidates for bone marrow transplantation. Initial phase I clinical studies with this agent showed marked antileukemic activity in patients with CML[293] or BCR–ABL-positive ALL.[294] Although the effectiveness of imatinib mesylate against BCR–ABL-positive leukemias has been confirmed in phase II trials,[295–297] its utility as a single agent is limited by the rapid development of drug resistance.[298,299] Novel "second-generation" BCR–ABL1 kinase inhibitors that can circumvent drug resistance in many cases of CML are under active clinical development.[300,301] However, not all mutations in *BCR–ABL1* that confer drug resistance can be overcome with newer agents, underscoring the need for both more effective inhibitors and for the integration of these into combination chemotherapy regimens for BCR–ABL-positive leukemias.[302–305] Given the recent recognition of the role of SRC kinases in Ph-positive ALL,[280] the novel kinase inhibitors that are active against both SRC and BCR–ABL kinases may be particularly effective in cases of Ph-positive ALL.[306,307]

NUP214–ABL1 in T-Cell Acute Lymphoblastic Leukemia

Although the *BCR–ABL1* translocation is rare in T-cell ALL, amplified episomes containing *NUP214–ABL1* fusion genes have recently been described in approximately 6% of children and adults with T-cell ALL.[308] These episomes appear to arise via a mechanism in which the genomic region of chromosome 9q34, which contains both the *NUP214* and *ABL1* genes, is circularized in a manner that leads to the fusion of these 2 genes. The breakpoint in the *ABL1* gene in all of these cases occurs in intron 1, which is the same breakpoint observed in Philadelphia-positive CML and B-precursor ALL, whereas the *NUP214* breakpoints are variable. The wild-type NUP214 protein is a component of the nuclear pore complex and may contribute oligomerization motifs to the *NUP214–ABL1* fusion oncogene. The NUP214–ABL1 fusion protein has constitutively activated ABL1 tyrosine kinase activity, which is inhibited by the BCR–ABL kinase inhibitor imatinib.[308] The therapeutic potential of imatinib or second-generation tyrosine kinase inhibitors for NUP214–ABL1-positive T-cell ALL is of considerable interest.

FLT3 in *MLL*-Rearranged Acute Lymphoblastic Leukemia

FLT3 encodes a receptor tyrosine kinase that is highly expressed in early hematopoietic precursors, where it plays important functional roles.[309,310] Multiple studies have shown that activating mutations of *FLT3*, which lead to constitutive receptor tyrosine kinase activity even in the absence of ligand, are common in leukemic myeloblasts in patients with AML, but are rare in adults with ALL.[311–313] However, gene expression studies demonstrated high expression of *FLT3* in most cases of ALL that involve MLL gene rearrangements or hyperdiploidy.[214,215,219] In addition, activating mutations were identified in 18% of infants with *MLL*-rearranged ALL,[220] in 21% to 24% of hyperdiploid ALL cases,[7,220] and in all three cases of the prothymic CD117/KIT$^+$ subtype of T-cell ALL in adults that were examined.[314]

In the absence of FLT3 ligand, wild-type FLT3 receptors are inactive because of autoinhibition mediated by the juxtamembrane domain of the receptor. Upon binding of FLT3 ligand, normal FLT3 receptors homodimerize, become activated by phosphorylation, and lead to the activation of signal transduction pathways that promote proliferation and cell survival.[315] Activating mutations of *FLT3* found in leukemias occur in 2 separate regions of the gene. In-frame tandem duplications in the juxtamembrane domain lead to loss of the autoinhibiton mediated by this domain, with subsequent dimerization and receptor activation in the absence of FLT3 ligand.[316] Alternatively, point mutations or insertions in the second tyrosine kinase domain of the FLT3 receptor lead to autophosphorylation and activation of downstream signaling in the absence of FLT3 ligand.[6,313,317] Small-molecule inhibitors of the FLT3 kinase lead to apoptosis in AML cell lines in vitro, and are currently undergoing phase I and II

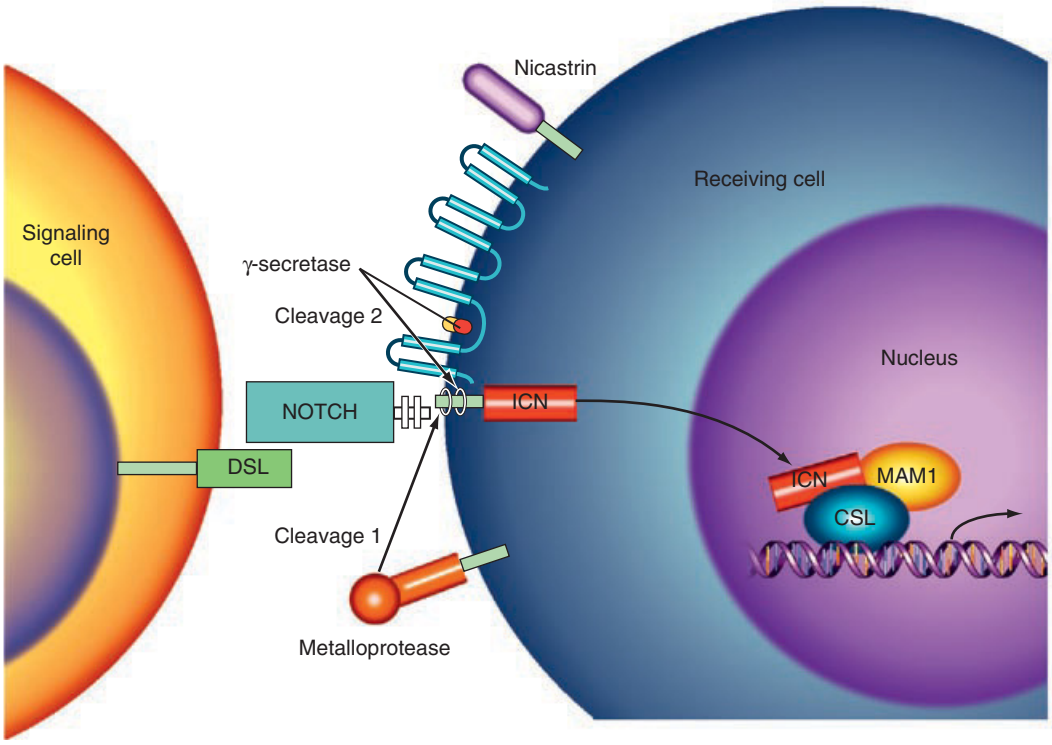

Figure 63–5 Activation of NOTCH signaling via extracellular and intracellular proteolytic cleavage and nuclear translocation of the intracellular NOTCH domain (ICN). Interaction with delta serrate ligand (DSL) stimulates proteolytic cleavage of NOTCH by metalloproteases and γ-secretase. This leads to the release of the intracellular ICN domain, which translocates to the nucleus, where it acts as a transcription factor to regulate gene expression. Adapted from Armstrong SA, Look AT: Molecular genetics of acute lymphoblastic leukemia. J Clin Oncol 23:6306, 2005, with permission.

testing in adults with AML and MDS.[318] These small-molecule inhibitors are also active against *MLL*-rearranged ALL cell lines,[219,319] and hold promise as targeted therapies for cases of ALL that rely on aberrant activation of FLT3.

Mutated Genes

The activation of cellular protooncogenes by point mutation is difficult to detect, because such lesions lack the cytogenetic abnormalities that signal other forms of transforming alterations. Genes of this type must first be identified in experimental systems, so that investigators know in advance the types of activating point mutations that are likely to occur in human tumors. The prototypic genes of this class are *NOTCH1* and members of the RAS family, with mutations that affect defined functional domains of the corresponding proteins.

NOTCH1 in T-Cell Acute Lymphoblastic Leukemia

The *NOTCH1* gene was discovered as a partner gene in a t(7;9) chromosomal translocation that is found in exceedingly rare cases of T-ALL, in which *NOTCH1* is truncated and placed under the control of the T cell-receptor β locus.[320] *NOTCH1* plays several critical roles in promoting T-cell development[40,321–323] and is highly leukemogenic when expressed in murine T-cell precursors.[324] Despite the rarity of translocations involving this gene, a search for activating NOTCH1 mutations demonstrated that these are present in more than 50% of cases of T-ALL, and these occur in all molecular subtypes of T-ALL.[8] NOTCH1 is a transmembrane protein that is proteolytically processed during its transit to the cell surface, where it exists as a heterodimer consisting of extracellular and transmembrane subunits (Fig. 63–5). Upon ligand binding, the transmembrane subunit undergoes additional proteolytic cleavage within the plasma membrane, which leads to the release of its intracellular domain, known as ICN1, into the cytosol. ICN1 subsequently translocates into the nucleus where it is active as a transcription factor. Activating *NOTCH1* mutations in T-ALL can occur as either missense mutations in the heterodimerization domain, which allow constitutive proteolytic activation of the ICN1 domain,[8,325] or as frameshift mutations or stop codons that lead to truncation of the PEST domain,[8,326] which impair the degradation of ICN1. Mutations in both regions are often found on the same allele in cases of T-ALL, and, in experimental systems, mutations in both domains of the same gene indeed are synergistic.[8] Recent work has demonstrated that *MYC* is an important transcriptional target of *NOTCH1*, and it mediates many of the leukemogenic properties of *NOTCH1* in human T-ALL cell lines.[327–329]

The proteolytic activation of the ICN domain of NOTCH1 upon ligand binding is mediated by γ-secretase, and γ-secretase inhibitors have previously been developed because of the role of this enzyme in the pathogenesis of Alzheimer disease. These inhibitors inhibit the growth of many T-ALL cell lines,[8,330] and trials of γ-secretase inhibitors in patients with T-ALL are currently under way.

FBW7 in T-Cell Acute Lymphoblastic Leukemia

FBW7 is an E3 ubiquitin ligase that targets the transcriptionally active intracellular form of NOTCH (ICN) , MYC, and cyclin E for degradation, and this gene is inactivated by mutation or deletion in approximately 10% of T-ALL cases.[331] In T-ALL cell lines, *FBW7* mutation or homozygous deletion leads to resistance to NOTCH pathway inhibition by γ-secretase inhibitor therapy, likely because intracellular NOTCH protein levels remain high in the absence of FBW7-mediated degradation despite inhibition of γ-secretase activity. In addition, tumor-derived FBW7 mutations maintain their ability to bind MYC but do not lead to its degradation, and these may act as dominant negative mutants that protect MYC from degradation.[331]

RAS Gene Mutations

Human tumor DNAs were initially found to contain activated homologues of either *HRAS* or *KRAS*,[332,333] protooncogenes that were identified on the basis of their homology with viral oncogenes. Gene transfer methods identified an additional member of the RAS gene family, called *NRAS*,[334,335] that had not been observed as a component of a transforming retrovirus. Protooncogenes of the RAS family—*HRAS*, *KRAS*, and *NRAS*—encode 21-kd proteins that are associated with the inner surface of the cytoplasmic membrane and are involved in growth factor receptor signaling.[336] The *RAS* protooncogenes are activated to the status of transforming oncogenes by somatic mutations that alter the amino acids specified by codons 12, 13, or 61. Mutated *RAS* genes lose their intrinsic GTPase activity and become insensitive to GAP proteins, thus accumulating in their active, GTP-bound conformation, even in the absence of growth factor binding to surface receptors. Aberrant RAS-mediated signaling contributes to transformation through activation of the PI3K, Raf–MEK–ERK, and RALGDS pathways.[336]

Activated *NRAS* genes appear to be preferentially involved in hematopoietic malignancies. They have been detected in myeloid cell lines,[337,338] in fresh leukemic cell samples from patients with AML or CML,[339–341] and in patients with myelodysplastic syndromes.[342] In acute lymphoblastic leukemia, mutations of codons 12, 13, or 61 of *NRAS* have been found in approximately 10% of patients, whereas *KRAS* mutations have been identified in 5% to 10% of patients.[343,344] RAS mutations are particularly common in cases of *MLL*-rearranged B-precursor ALL, in which 40% of cases have *KRAS* mutations and an additional 10% have *NRAS* mutations.[344] In addition, RAS mutations have also been associated with high hyperdiploidy.[345] The presence of RAS mutations does not appear to have prognostic significance in the setting of contemporary treatment regimens.[343]

Gene Amplification

Gene amplification at the DNA level provides the cell a means to increase expression of critical genes whose products are ordinarily tightly controlled. Clinically important examples of protooncogene amplification have been documented in solid tumors of both adults and children. The *MYCN* gene, for example, is amplified from 10- to 300-fold in tumor cells from approximately one-third of cases of childhood neuroblastoma; such amplification has been linked to an advanced stage of disease and a poor prognosis.[346] However, the cytogenetic hallmarks of gene amplification—double-minute chromatin bodies and homogeneously staining regions—are rarely found in karyotypes of human leukemia cells, making it unlikely that high-level amplification of cellular protooncogenes is widespread in ALL. However, as noted earlier, the *NUP214–ABL1* fusion oncogene is amplified as a small, cytogenetically undetectable episome in T-ALL.

MYB Duplication in T-Cell Acute Lymphoblastic Leukemia

A duplication of the *c-MYB* gene was recently discovered in cases of T-ALL,[347–349] and a chromosomal translocation that juxtaposes *c-MYB* to the T cell-receptor β gene regulatory elements was also identified in a small number of patients.[348] The discovery of this gene duplication involving a small region of the chromosome was made possible by recent technologic advances that now allow the high-resolution detection of small regions of focal amplifications and deletions. The *MYB* transcription factor is the cellular counterpart of the avian *v-MYB* avian myeloblastosis virus, which causes a rapidly fatal monoblastic leukemia in chickens and is essential for normal hematopoiesis, including T-cell development. The *MYB* duplication is mediated by homologous recombination between identical sequence regions that flank the gene,[349] and its expression appears to be important in preventing T lymphoblast differentiation, as knockdown of *MYB* expression in T-ALL cell lines induces T-cell differentiation.[347]

Tumor Suppressor Genes

Much attention has been focused on tumor suppressors, whose loss of function via deletion or mutational inactivation leads to malignant transformation. Knudson first proposed that inactivation of both alleles of a single locus is needed to initiate the development of retinoblastoma, basing his hypothesis on the observed frequencies of hereditary and sporadic forms of this disease. Allelic loss of defined regions of many different chromosomes has been linked to specific types of human tumors. By analogy with the findings in retinoblastoma, a reasonable hypothesis is that each of these regions harbors a tumor suppressor gene whose product is uniquely involved in the inhibition of cell cycle progression and promotion of terminal differentiation of the normal cells that give rise to these different types of tumors. Tumor suppressor genes that play an important role in ALL include *p53* and the *p16* locus.

The p53 Tumor Suppressor

p53, located on chromosome 17, band p13, is mutated or lost through chromosomal deletion in a wide variety of human tumors,[350] including colon cancer, lung cancer, breast cancer, and osteosarcoma. Heritable cancer-associated changes of the *p53* tumor suppressor gene occur in families with Li-Fraumeni syndrome—an unusual aggregation of sarcomas, brain tumors, leukemias, adrenocortical carcinomas, and premenopausal breast cancers.[351–354] *p53* encodes a 53-kd transcription factor that functions as a cell cycle and apoptosis checkpoint regulator.[350,355–359] The p53 protein is induced by DNA damage, blocks cell division at G1 to allow DNA repair, and activates apoptosis in cells that have sustained DNA damage.[360–365] The mechanism of p53 activation is triggered by the loss of activity of MDM2 after DNA damage (via ATM) or oncogenic stress (via p14/ARF). As a negative regulator of p53, MDM2 induces the ubiquitination of p53 and its degradation by the proteasome. Hence, when MDM2 activity is abolished, p53 accumulates and certain cell cycle regulatory genes such as *p21*(*WAF1/CIP1/SDI1/CAP20*) and proapoptotic factor genes such as *BAX*, *PUMA*, and *NOXA* are transcriptionally activated.

p53 is also inactivated in a variety of hematopoietic malignancies, including B-cell ALL and Burkitt lymphoma, but is mutated or deleted in less than 3% of pediatric B-precursor or T-cell ALL cases at diagnosis.[366–368] It thus appears to play a limited role in the etiology of pediatric leukemia. However, *p53* mutations are seen in approximately 25% of relapsed T-cell ALL cases, suggesting a role for *p53* inactivation in the development of resistant disease.[366,367] In addition, *p53* mutations were detected in 3 of 10 ALL patients who failed on induction therapy or suffered early relapse, further supporting a role for *p53* inactivation in disease progression.[369,370]

The Cyclin-Dependent Kinase Inhibitors

The cyclin-dependent kinase inhibitors, which include p15 (INK4B/MTS2), p16 (INK4A/MTS1/CDKN2), p18 (INK4C), p19 (INK4D), p21 (WAF1/CIP1/SDI1/CAP20), p27 (KIP1), and p57 (KIP2), constitute a family of tumor suppressors that negatively regulate the cell cycle by inhibiting cyclin-dependent kinase (CDK) phosphorylation of pRB.[371] The *INK4A* locus, located on the short arm of chromosome band 9q21, contains two different tumor suppressor genes, *p16INK4A* and *p14ARF* (*p19ARF* in mice),[372,373] each with a distinct promoter and first exon but common second and third exons. Despite this close relationship at the genomic level, p16 and p14 have totally unrelated amino acid sequences, as they use different reading frames in their common second and third exons.[374] A third tumor suppressor gene, the cyclin-dependent kinase inhibitor *p15INK4B*,

also resides in this region.[375,376] p16INK4A and p15INK4B directly inhibit cyclin D-CDK4/6 complexes and interfere with cell cycle progression. Cyclin D-CDK4/6 complexes promote entry into S phase through phosphorylation of the retinoblastoma protein, PRB, leading to the release of transcription factors, such as E2F, that promote entry into S phase. By contrast, p14ARF lacks a direct effect on the cell cycle machinery, acting instead to stabilize and upregulate p53 through the inhibition of MDM2.[375–379] The role of the *INK4a* locus in tumorigenesis was substantiated when mice with targeted disruption of exon 2 in *p16* developed tumors (primarily lymphomas and fibrosarcomas) whose induction was enhanced by the topical application of carcinogens and ultraviolet light.[380,381] The phenotype of the *p16/p19*$^{-/-}$ mice could be duplicated by selective mutation of the *p19ARF* gene (by targeting the first exon),[372] although mice deficient in *p16INK4A* with intact *p19ARF* also showed increased susceptibility to cancer.[380,381]

The short arm of chromosome 9 is the most frequent target of chromosomal alterations in human cancer. In particular, the human leukemias and lymphomas show a high frequency of 9p21 deletions involving both the *p16INK4A/p14ARF* and the *p15INK4B* loci. Epigenetic silencing of these tumor suppressor genes through hypermethylation of their promoter sequences represents an alternative mechanism of gene inactivation. Although *p16INK4A/p14ARF* and *p15INK4B* are homozygously deleted in 20% to 30% of B-precursor ALL cases and in 70% to 80% of T-cell ALL cases, epigenetic silencing of the p15INK4B promoter has been observed in 44% of primary B-lineage ALLs.[382–394]

The clinical impact of *p15INK4B* and *p16INK4A/p14ARF* deletions in ALL remains controversial.[394] On the one hand, homozygous p16 deletion is related to high-risk features at diagnosis and to an increased risk of relapse and death in childhood ALL,[393,395,396] and on the other, *p15INK4B* and *p16INK4A/p14ARF* deletions were not associated with clinical outcome in a study of adult ALL cases.[397] Interpretation of the clinical significance of the inactivation of these tumor suppressor genes must also take into account alternative mechanisms of gene inactivation, such as aberrant methylation of *p15INK4B* promoter sequences, which has been associated with epigenetic silencing of this locus and a worse outcome in adult ALL cases.[398]

Loss of SMAD3 Protein in T-ALL

Loss of the SMAD3 protein has been described in all 10 cases of T-ALL that were analyzed, although RNA levels of this protein were normal in many of these samples.[399] Both RNA and protein levels of this protein were detectable in normal T cells and in most cases of B-precursor ALL and AML, and the mechanism through which Smad3 protein levels are suppressed whereas RNA levels remain normal in T-ALL is unknown.[399] SMAD3 is one of several of the receptoractivated SMAD proteins that bind to the cell surface receptor for transforming growth factor β (TGF-β) and, upon ligand binding, move to the nucleus, where they regulate transcription.[400] TGF-β signaling leads to tumor-suppressor effects that are mediated at least partly through the transcriptional induction of the cyclin-dependent kinase inhibitors p15INK4b and p21, and by the inhibition of *MYC* expression.[401] However, the specific mechanisms through which SMAD3 mediates the tumor-suppressor effects of TGF-β signaling and through which SMAD3 loss contributes to leukemogenesis remain unknown.

PAX5 and Other B-Cell Developmental Gene Alterations in B-Precursor ALL

A recent high-resolution genome-wide analysis of B-precursor ALL cases using single-nucleotide polymorphism arrays identified copy number alterations in a number of genes that play important roles in B-cell development.[402] Genes involved in B-cell development were found to be altered by deletion, amplification, mutation, or rearrangement in 40% of cases of B-precursor ALL. The most common abnormalities identified were deletions at the *PAX5* locus, and upon further analysis in other cases, other mechanisms that led to inactivation of *PAX5* were identified. These included a number of translocations that led to fusion proteins that maintained the ability to bind to PAX5 transcriptional targets but lost regulatory ability, thus having dominant negative activity, and inactivating point mutations that altered the transcriptional activity of *PAX5*. Deletions were also detected in the *TCF3*, *EBF1*, *LEF1*, *IKZF1*, and *IKZF3* genes, all of which play important roles in B-cell development.

Other Tumor Suppressors

As discussed previously, *FBW7*, which mediates the degradation of the NOTCH and MYC oncoproteins, is mutated in a subset of cases of T-ALL. In addition, the identification of recurring chromosomal deletions in human ALL indicates that other tumor suppressor loci may be involved in this disease. These recurrent deletions, which affect the long arm of chromosome 6, the short arm of chromosome 9, or the short arm of chromosome 12, can be found in leukemic cells from approximately 10% of patients with ALL, making them among the most frequent cytogenetic abnormalities in this disease. Functional deletion can result either from interstitial deletion of the involved chromosome arm or from derivative chromosomes that result from unbalanced chromosomal translocations. For each chromosome, the deleted regions overlap a single target region, which may contain key genes of the tumor suppressor type, whose loss could be an important step in leukemic transformation.

Deletions of the long arm of chromosome 6 are consistently found in approximately 10% of cases of ALL.[403] Interstitial deletions affecting bands 6q15-q24 have been reported most frequently; translocations with breakpoints within this region are also common. Band q21 of chromosome 6 seems to be involved in each of the abnormalities, suggesting that the target gene(s) resides in this region. Deletions of chromosome 6q occur with equal frequency in pro-B, pre-B, and T-cell cases.

Deletions or translocations involving the short arm of chromosome 12 are also found in approximately 10% of ALL cases, with most clustered around band 12p13.[403] These cases generally have a B-precursor phenotype, and the blast cells usually express CD10 and HLA-DR on the cell surface. Abnormalities of the short arm of chromosome 12 are rarely found in T-ALL cases. Translocations involving chromosome 12p13 may be balanced or unbalanced and can involve multiple different donor chromosomes. Molecular studies, however, have revealed that the majority of translocations involving 12p13 are cryptic 12;21 translocations, resulting in the *TEL–AML1* fusion. In the cases with unbalanced translocations, DNA sequences distal to the breakpoint are lost from the affected homologue and subsequently from the leukemic cell genome, so the result is similar to that of interstitial deletion. The frequency of deletions involving the 12p13 region suggests that these lesions primarily inactivate one allele of a tumor suppressor gene in this chromosomal region. Although the *TEL* and *p27KIP1* genes may be targets of deletion in these cases, neither locus is inactivated by point mutations in childhood ALL cases with loss of heterozygosity (LOH) in 12p,[235,404] implicating additional tumor suppressor genes in this region, although *TEL* or *p27KIP1* haploinsufficiency could also contribute to leukemic transformation.[235,404]

Abnormalities of Leukemia Cell Ploidy

Abnormalities of chromosome number, which generally occur in the absence of specific chromosomal translocations, have important prognostic implications in childhood ALL. Found in 25% to 30% of childhood ALL cases, hyperdiploidy greater than 50 chromosomes in the leukemic clone is one of the most powerful means for identifying

patients with a very good prognosis.[91,243] In particular, trisomies of chromosomes 4, 10, and 17 impart a particularly good prognosis, and hyperdiploidy in the absence of these trisomies is less of a favorable prognostic factor.[405] As mentioned previously, activating mutations of *FLT3*, a receptor tyrosine kinase, are common in these patients. Patients with hyperdiploidy typically present with favorable prognostic indicators, such as age between 2 and 10 years, a low white blood cell count, and an early pre-B immunophenotype, and can expect cure rates that approach 90%.[406–408] The mechanism accounting for the favorable outcome of patients with hyperdiploid ALL remains elusive, but may reflect an increased sensitivity to antimetabolite therapy[409] and a greater propensity to undergo apoptosis.[410] Conversely, hypodiploidy (< 45 chromosomes) carries an extremely poor prognosis.[411,91,243] Overall, adults with ALL have significantly fewer numeric chromosomal abnormalities than do children; however, abnormalities of ploidy do appear to have prognostic significance in adults also, as one large series demonstrated a favorable prognostic impact of hyperdiploidy, whereas adults with hypodiploidy had extremely poor outcomes.[33]

CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA: A MODEL FOR GENE-BASED RISK ASSESSMENT

Many of the chromosomal and molecular genetic abnormalities in the leukemic blasts of patients with ALL are important predictors of response to currently available chemotherapy. Lymphoblasts from each new case of childhood ALL should be examined for molecular prognostic markers, including leukemia cell ploidy, *MLL* gene rearrangements, and the presence of *BCR–ABL* and *TEL–AML1* fusion transcripts. Additional clinical criteria that have prognostic significance, such as the age of the patient, the peripheral blood white blood cell count at diagnosis, and the presence of central nervous system involvement, are used by modern pediatric ALL treatment regimens to further adjust the intensity of therapy to an individual patient's risk of relapse. In the future, high-density SNP arrays and gene expression arrays may be performed on samples from each patient, to identify genomic alterations and gene expression patterns that have prognostic significance, such as *HOX11* expression in the case of T-ALL.[412] It is worth noting that ALL in patients less than 1 year of age is associated with an extremely poor prognosis secondary to an exceedingly high rate of relapse, and these patients are often treated with unique treatment regimens designed specifically for infant ALL. Finally, response to treatment has independent prognostic significance. Induction failure, defined in pediatric protocols as any morphologic evidence of leukemia at the end of the initial month of induction chemotherapy, represents a very poor prognostic factor and is an indication for bone marrow transplantation once remission is achieved in most centers. In addition, sensitive flow-cytometric and PCR-based methodologies for the detection of minimal residual disease are now available, and the level of minimal residual disease after induction chemotherapy has recently been shown to provide an additional means of identifying patients at low or high risk of relapse.[413,414] With the availability of these prognostic indicators, there remains little justification for uniform treatment of newly diagnosed cases of ALL. Rather, modern trials emphasize risk-based therapy to reduce toxicity in patients likely to become long-term responders, and to intensify therapy for those at high risk of relapse.

A risk classification scheme based on a patient's clinical features and on the genetic features of leukemic blasts has been proposed for patients with B-precursor or T-cell ALL that are 1 year of age or older. Patients with *TEL–AML1* positivity or with simultaneous trisomies of chromosomes 4, 10, and 17 constitute the lower-risk group and are candidates for reduced-intensity treatment regimens. The intermediate-risk group includes patients between the ages of 1 and 9 with standard-risk age and leukocyte count, as defined by the criteria of the National Cancer Institute, and whose leukemic lymphoblasts lack prognostically important genetic features. The high-risk group comprises patients who meet any of the following criteria: age 10 years or older, high leukocyte counts at diagnosis, a T-cell immunophenotype, or a slow early response to therapy. Patients in the very high-risk group, defined by extreme hypodiploidy, *MLL* gene rearrangements, the *BCR–ABL* translocation, or high minimal residual disease at the end of induction chemotherapy are eligible for bone marrow transplantation in first remission. It is worth noting that the evidence supporting a benefit for bone marrow transplantation in first remission is especially strong in the presence of the *BCR–ABL* translocation, although its role in *MLL*-rearranged ALL remains controversial. Among several exceptions to this risk stratification criteria are T-ALL patients with the t(11;19) and expression of *MLL–ENL*, who have a favorable prognosis,[17,415] and infants younger than 1 year of age, in whom separate risk stratification criteria have been devised (reviewed in reference 416). Recent progress in the risk assessment of different subtypes of ALL predicts that gene expression profiling by oligonucleotide microarray analysis[215] will further improve the power of current molecularly based systems of risk classification. The incorporation of highly predictive risk stratification methods into clinical trials, together with the development of novel molecularly tailored therapies, should eliminate the still-significant risk of relapse in patients with newly diagnosed ALL, ensuring permanent cure without the hazard of acute or chronic complications.

CHAPTER 64

CLINICAL MANIFESTATIONS OF ACUTE LYMPHOBLASTIC LEUKEMIA

Karen R. Rabin, Stacey Berg, C. Philip Steuber, and David G. Poplack

BACKGROUND

Before the institution of modern chemotherapy, acute lymphoblastic leukemia (ALL) was a uniformly fatal disease, with most patients surviving only 2 to 3 months. Over the past 40 years, successive studies of improved treatment regimens have been conducted that have not only resulted in improved survival of children with ALL but have also served as a paradigm for the conduct of clinical research in cancer. With current chemotherapy, the majority of children with ALL have prolonged disease-free survival and up to approximately 85% are considered cured.[1]

EPIDEMIOLOGY AND ETIOLOGY

ALL is the most common malignancy of childhood, with about 2400 new cases diagnosed annually in the United States.[2] In the pediatric population, ALL is four times more frequent than acute nonlymphoblastic leukemia (ANLL; or acute myelocytic leukemia [AML]). In contrast, ALL accounts for less than 1% of all adult malignancies, and for less than 20% of the acute leukemias in this population.[3–5] In children, the peak incidence of ALL occurs at approximately 2 to 3 years of age.[2] In adults, the greatest number of cases occur in those older than 65 years.

Children with certain chromosomal abnormalities are at higher risk than the general population for developing leukemia. These include Down syndrome,[6] Bloom's syndrome,[7] Fanconi anemia,[8] ataxia telangiectasia,[9] and neurofibromatosis.[10] In addition, siblings, especially twins, of children with leukemia are at greater risk of developing leukemia, although this risk may be only approximately twice that of the general population.[11] Some cases of childhood ALL may be related to hereditary or acquired mutations in the p53 gene.[12]

Because concordance is only about 25% in monozygotic twins, who share identical genetic makeup, environmental factors clearly also play an important etiologic role. A few environmental exposures have been definitively linked to ALL, including ionizing radiation and certain toxic chemicals and chemotherapeutic agents (although these are far more often associated with development of AML). Most other proposed environmental associations are controversial or relatively modest. Only in a few specific cases have infectious agents been causally linked to ALL: HTLV-1 in adult T-cell ALL/lymphoma, and Epstein–Barr virus (EBV) in mature B-cell ALL/Burkitt lymphoma.

Interestingly, childhood ALL has been shown to originate *in utero* in some cases.[13] Studies of twins concordant for ALL have demonstrated the presence of identical unique gene rearrangements in leukemic cells from both twins, suggesting origin in a single prenatal clone shared via a common blood supply.[14–18] Preleukemic clones have also been detected in archived neonatal blood spots in nontwin cases of ALL.[19] The gene rearrangements detected in these preleukemic clones are presumably the initiating leukemogenic events, but a "second hit" is generally necessary in order for progression to overt leukemia. Greaves has hypothesized that an abnormal immune response to common infections may provide this second hit.[20] A variety of epidemiologic data is consistent with this hypothesis, particularly evidence that early daycare attendance, with its attendant frequent infections, is protective against development of ALL (reviewed in reference 20).

CLASSIFICATION

Morphology

ALL cells are heterogeneous and have been subclassified on the basis of differences in their appearance under the light microscope. The most widely used system, developed by the French-American-British (FAB) Cooperative Working Group divides lymphoblasts into three categories: L1, L2, and L3 (Table 64–1 and Fig. 64–1). The L1 morphology is predominant, occurring in approximately 85% of childhood ALL cases. The L2 subtype represents nearly all the remainder, with the rare L3 subtype constituting only 1% to 2%. Although there is no apparent correlation of the L1 and L2 morphology with particular immunologic cell surface markers, cells of the L3 variety possess cell surface immunoglobulin and other characteristic mature B cell markers, and are identical cytomorphologically to Burkitt lymphoma cells.

Immunophenotype

Immunophenotyping plays a major role in the diagnosis of the acute leukemias. The use of monoclonal antibodies specific for various stages of B-cell, T-cell, and myeloid differentiation enables the clinician to determine more definitively whether a leukemia is lymphoid or myeloid in origin (Table 64–3 and Fig. 64–2). In most cases, immunophenotyping also permits assignment of the relative stage in the process of B- or T-cell differentiation from which the leukemic clone is believed to have arisen or reached a differentiative block. Approximately 80% to 85% of childhood ALL is believed to develop from the monoclonal proliferation of B-cell precursors. In contrast, only approximately 1% to 2% of cases manifest surface immunoglobulin and are classified as mature B-cell ALL. The remainder of cases are of T-cell origin. A variety of classification schemes have been developed that define both B-cell precursor ALL and T-cell ALL according to their degree of differentiation or maturation.

Most cases of ALL express surface antigens and molecular markers that help to identify them as derived from a specific lineage. However, lineage infidelity is not uncommon.[21,22] Lymphoid leukemias may aberrantly express a few myeloid markers, and vice versa, so no single marker can be relied upon consistently across all cases. Accurate classification of lymphoid and myeloid leukemia depends instead on a panel of markers, in conjunction with morphologic and cytogenetic features. Biclonal leukemia, characterized by two separate clones of distinct lineages, is much less common. It occurs in perhaps 1% to 2% of childhood and adult ALL, and generally responds poorly to treatment.[23]

The development of recombinant DNA technology has led to identification of immunoglobulin gene and T-cell receptor (TCR) gene rearrangement in leukemic cells. Although it is possible to relate the patterns of immunoglobulin and TCR gene rearrangement to the stages of development of B-cell precursor and T-cell ALL, respectively, immunoglobulin gene rearrangement is seen in some cases of

PT1: Diagnostic Evaluation of the Patient with Acute Leukemia

The diagnostic evaluation of a patient with acute leukemia is a comprehensive process that includes a detailed history and complete physical examination, morphologic and laboratory assessment of peripheral blood and bone marrow, blood chemistries, comprehensive clotting studies (PT, PTT, thrombin time, and fibrinogen), a lumbar puncture and cerebrospinal fluid (CSF) examination, chest radiograph, and other studies necessary to ensure that the newly diagnosed patient will receive optimal supportive care.

History and Physical Examination

When leukemia is suspected, a detailed history and physical examination should be performed. The history should include the nature of presenting symptoms and their duration, with specific attention to signs and symptoms of anemia, thrombocytopenia and neutropenia. A detailed family history, including the occurrence and nature of any malignancies among family members, should be obtained, as well as any history of environmental exposures (eg, chemicals, radiation). Physical examination should include signs of bone marrow dysfunction like pallor, bleeding (eg, petechiae, and/or purpura) and any evidence of infection. Lymphadenopathy and hepatosplenomegaly should be carefully documented. Generalized lymphadenopathy is more common than regional enlargement in leukemia. In children, palpable small axillary, cervical, and inguinal nodes are common, but enlargement of posterior auricular, epitrochlear, or supraclavicular nodes is abnormal. Careful examination of the optic fundi to rule out evidence of retinal hemorrhages secondary to thrombocytopenia and/or leukemic infiltration is important. The oropharynx should be evaluated, including the gingivae, a common site of hypertrophy in patients with acute myelomonocytic or monocytic leukemia.

Hematologic Evaluation

A complete blood count (CBC) will usually reveal evidence of varying degrees of anemia, thrombocytopenia, and anemia. Isolated thrombocytopenia without any other abnormalities on physical examination or CBC is rare. In most patients, leukemic blasts will be seen on the peripheral blood smear. A bone marrow aspirate prior to the start of therapy is usually required for adequate immunophenotyping and cytogenetic studies, although in patients with very high white blood cell counts consisting almost entirely of blasts, peripheral blood sampling may be adequate. The anterior or posterior iliac crest is the preferred site for marrow aspiration. In cases where aspiration does not yield sufficient material for evaluation, bone marrow biopsy is performed. Bone marrow biopsy also is helpful in assessment of the degree of marrow cellularity. Once the diagnosis of leukemia is confirmed, definitive assignment of the type of leukemia is crucial if appropriate treatment is to be delivered.

Detailed immunophenotyping using a panel of monoclonal antibodies is undertaken in all newly diagnosed cases of acute leukemia. Use of a sufficiently comprehensive monoclonal antibody panel capable of detecting the major lymphoid (both B and T cell), myeloid, and platelet-related antigens enables a definitive lineage assignment to be made in most cases of acute leukemia (Table 64–3). Molecular phenotyping may provide useful information regarding the status of the immunoglobulin or T-cell receptor gene rearrangement in lymphoid leukemic cells. Cytogenetic analysis, including evaluation of both chromosomal number and structure, plays a critical role as discussed below.

Lumbar Puncture

Lumbar puncture (LP) is performed in all newly diagnosed patients because the presence of central nervous system (CNS) leukemia alters treatment. In patients with marked thrombocytopenia, platelet transfusions may be considered prior to performing the LP. The CSF cell count and protein and glucose levels are determined. Examination of a cytocentrifuged specimen of CSF is always performed as this technique increases diagnostic sensitivity.

Other Diagnostic and Laboratory Studies

A chest x-ray is routinely obtained in newly diagnosed patients, particularly prior to administration of sedation or anesthesia. When significant mediastinal enlargement is detected, computed tomography (CT) can help to define its extent more accurately. Patients presenting with significant bone pain often undergo radiologic examination of the involved site. All newly diagnosed patients have a comprehensive battery of blood chemistries performed including uric acid, electrolytes, calcium, phosphorus, blood urea nitrogen, serum creatinine, and liver function tests (including lactate dehydrogenase). In addition, MRI or CT imaging of the brain at diagnosis may be useful, particularly as a baseline for comparison in the event of CNS relapse or toxicity.

Supportive Care

The blood type of all patients is determined and appropriate cross-matching instituted if transfusion is required. Packed red cell transfusions are utilized to maintain an adequate hemoglobin. Platelets are often administered prophylactically to maintain the platelet count at more than 10,000 to 20,000/mm^3. If the patient becomes refractory to random donor platelets, single-donor or HLA-matched platelets may be useful.

All newly diagnosed patients receive vigorous hydration and allopurinol or urate oxidase to prevent uric acid nephropathy and complications from tumor lysis. In patients with extremely high initial white blood cell counts (eg, >100,000/mL) leukapheresis or, in very young patients, exchange transfusion, is sometimes helpful, although its role is controversial, especially in ALL.[124,125]

Newly diagnosed patients who are febrile receive an extensive evaluation to rule out infection. The febrile neutropenic patient is placed on broad-spectrum antibiotic coverage.

The diagnosis of leukemia places extraordinary stress on patient and family alike. Starting at the time of initial diagnosis, careful attention is given to evaluating the psychosocial profile of patient and family so that appropriate psychosocial support for both can be instituted. Optimal psychosocial support requires a concerted, coordinated effort of physician, nurses, social workers, clergy, child life, and other skilled health care personnel.

T-cell ALL and TCR gene rearrangement in some cases of B-cell precursor ALL. Thus molecular phenotyping to assign B- or T-cell lineage is not completely reliable.[3,24]

Cytochemistry

Special histochemical stains once played a primary role in determination of lymphoid versus myeloid lineage (Table 64–2). Since the advent of immunophenotyping, they have been principally helpful in providing supporting information in the relatively small number of cases where immunophenotyping is not diagnostic. The periodic acid–Schiff (PAS) stain is positive in approximately 50% of cases of ALL and often shows a characteristic pattern of block positivity. The PAS reaction may be negative in ALL, however, and has been positive in rare cases of AML, limiting its diagnostic utility. TdT (terminal deoxynucleotidyl transferase) is usually detectable in lymphoblasts of T- and B-cell precursor lineage, but not in mature B-cell ALL or in ANLL. The myeloperoxidase stain detects myeloperoxidase in primary granules and is considered specific for cells of the myeloid lineage. Classically, an acute leukemia in which 3% or more of cells in the bone marrow are myeloperoxidase-positive has been considered

Table 64–1 French–American–British Classification of Acute Lymphoblastic Leukemia

Cytologic Features	L1	L2	L3
Cell size	Small cells predominate	Large, heterogeneous in size	Large and homogeneous
Nuclear chromatin	Homogeneous in any one case	Variable—heterogeneous in any one case	Finely stippled and homogeneous
Nuclear shape	Regular, occasional clefting or indentation	Irregular; clefting and indentation common	Regular—oval to round
Nucleoli	Not visible, or small and inconspicuous	One or more present, often large	Prominent; one or more
Amount of cytoplasm	Scanty	Variable; often moderately abundant	Moderately abundant
Basophilia of cytoplasm	Slight or moderate, rarely intense	Variable; deep in some	Very deep
Cytoplasmic vacuolation	Variable	Variable	Often prominent

Data from Bennett JM, Catovsky D, Daniel MT, et al: French-American-British (FAB) Cooperative Group: The morphological classification of acute lymphoblastic leukaemia—Concordance among observers and clinical correlations. Br J Haematol 47:553, 1981.

Table 64–2 Morphologic, Cytochemical, and Biochemical Characteristics Helpful in Distinguishing Acute Lymphoblastic Leukemia from Acute Myelocytic Leukemia

MORPHOLOGIC FEATURES	ALL	AML
Nuclear/cytoplasmic ratio	High	Low
Nuclear chromatin	Clumped	Spongy
Nucleoli	0–2	2–5
Granules	–	+
Auer rods	–	+/–
Cytoplasm	Blue	Blue-gray
CYTOCHEMICAL REACTION		
Peroxidase	–	+
Sudan Black B	–	+
Periodic Acid–Schiff	+/–	–
Naphthyl AS-D chloroacetate esterase	–	+/–
α-Naphthyl acetate esterase	–	+/–
α-Naphthyl butyrate esterase	–	–
Terminal deoxynucleotidyl transferase	+*	-

Table provides information on characteristics that may be useful in differentiating acute lymphoblastic leukemia (ALL) from acute myelocytic leukemia (AML) (see text for details). Wide variation in morphology is encountered in both disease categories. Diagnostic evaluation should include more refined classification of disease according to FAB subtype.
*Terminal deoxynucleotidyl transferase is usually negative in FAB L3 ALL.

Table 64–3 Monoclonal Antibodies Frequently Used in Immunophenotyping of Acute Leukemia in Children

Cluster of Differentiation (CD) Designation	Cell Lineage
2, 3, 4, 5, 7, 8	T cell
10, 19, 20, 22, 24	Precursor B cell
10, 19, 20, 22, Kappa or Lambda	Mature B cell
11, 13, 14, 15, 33, 34, 41, 42, 117	Myeloid
71 (and other myeloid markers)	Erythroid
42 + 61 (and other myeloid markers)	Megakaryocytic

to be myeloid, although this definition is arbitrary and may cause confusion in cases of mixed-lineage leukemia. The Sudan black stain sometimes has been used as a substitute for myeloperoxidase, but because rare cases of ALL demonstrate Sudan black positivity, the myeloperoxidase stain is preferred. Naphthyl AS-D chloroacetate esterase is an enzyme found in cells of neutrophilic lineage that may help define myeloid disease but is generally considered less sensitive than the myeloperoxidase stain. The α-naphthyl acetate esterase and α-naphthyl butyrate esterase stains are helpful particularly in defining monocytic lineage.

Cytogenetics

As molecular technology has improved, the cytogenetic analysis of ALL, as with other malignancies, has become increasingly important in identifying prognosis and tailoring therapy appropriately. The standard laboratory workup of ALL now includes analysis of both chromosome number and chromosome structure. Chromosome number, or ploidy, can be assessed either by karyotype analysis, or by flow cytometry using a measure called the DNA index (DI), which is the ratio of nuclear fluorescence in leukemic blasts compared to normal diploid cells. Chromosome structure is analyzed by chromosome banding, fluorescence in situ hybridization (FISH), and other molecular cytogenetic techniques, including genomewide techniques such as array comparative genomic hybridization.[25] Further discussion of specific recurrent chromosomal abnormalities and their prognostic significance can be found in the Prognosis section below and in Chapter 63.

Genomewide Expression Patterns

Microarray-based analysis of gene expression patterns is a powerful tool that is starting to be used in the classification of ALL. Microarray studies have both provided biological validation of existing ALL subtypes, and identified new subtypes.[26,27] Another research focus has been identification of sets of genes associated with good and poor prognosis within existing subgroups, such as ALL with MLL rearrangement.[28] Expression array studies also aim to identify highly overexpressed genes that are candidate molecular targets for development of new therapies (eg, FLT3, a receptor tyrosine kinase, in hyperdiploid and MLL-rearranged ALL).[29] Finally, microarray analysis is being used to identify expression patterns that correlate with chemotherapy sensitivity versus resistance.[30]

PATHOPHYSIOLOGY

Leukemia is believed to develop from expansion of a single abnormal lymphoid progenitor cell, which accumulates mutations that allow unregulated proliferation. The pathogenesis of ALL is discussed in further detail in Chapter 63.

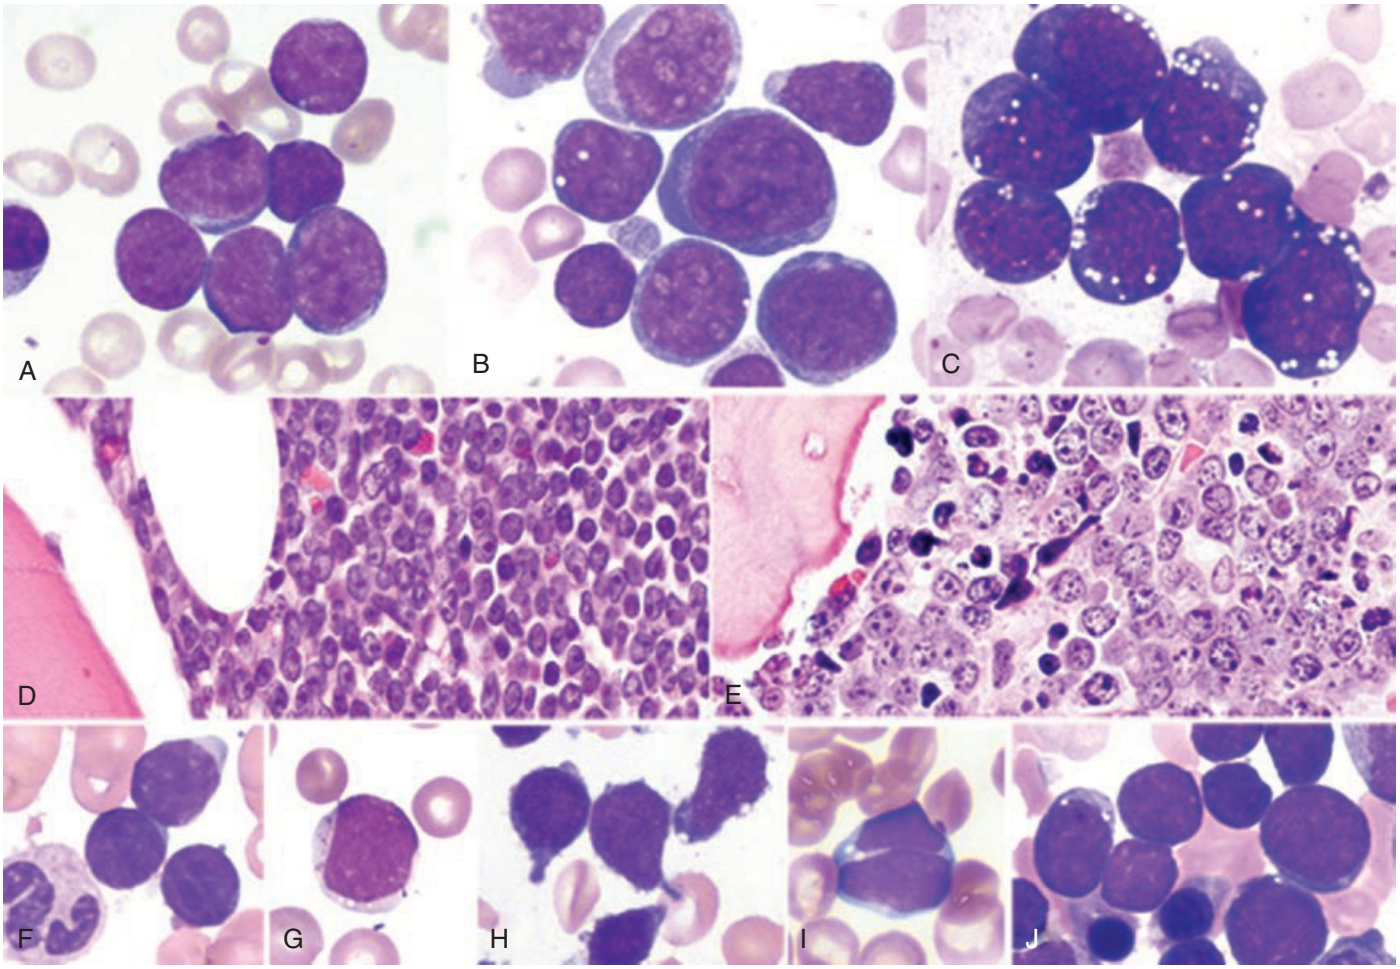

Figure 64–1 Morphologic aspects of acute lymphoblastic leukemia (ALL) (**A–J**). Typical uniform lymphoblasts (**A**) with intermediate-sized nuclei, fine but "smudgy" chromatin, absence of nucleoli, and scant cytoplasm. In the older FAB classification scheme, these would have been considered L1 blasts. Lymphoblasts with more cytologic variation (**B**), including variability in size, number of nucleoli, and amount of cytoplasm. These would have been considered L2 lymphoblasts. Burkitt leukemia/lymphoma cells for comparison (**C**). The cells have intermediate size, more dense chromatin, and deep blue cytoplasm with vacuoles. Histologic features of ALL (**D**) and Burkitt leukemia/lymphoma (**E**) in bone core biopsy. Additional cytologic variants of ALL include a lymphocyte-like variant with small nuclei (**F**), a variant with faint cytoplasmic granules (**G**), and the hand-mirror variant (**H**). The latter might be an artifact of preparation. Lymphoblasts can have deep groves or clefts (**I**). Malignant lymphoblasts must be distinguished from reactive hematogones, or regenerating immature lymphoid cells (**J**).

CLINICAL FEATURES

Patients with ALL present most frequently with signs and symptoms of the uncontrolled growth of leukemic cells in bone marrow, lymphoid organs, and other sites of extramedullary spread. Bone marrow involvement results in varying degrees of anemia, thrombocytopenia, and granulocytopenia that may be manifested by pallor and fatigue, petechiae, purpura or bleeding, fever, and infection. Liver, spleen, and nodal enlargement are present in the majority of patients and are the most common sites of extramedullary disease spread. Hepatosplenomegaly, which occurs in approximately two-thirds of patients, and lymphadenopathy, clinically detectable in over half of presenting cases, are usually asymptomatic. Bone pain, however, is a common presenting feature, particularly in the young child with ALL whose first symptom may be the onset of a limp or refusal to walk.[31] Notably, isolated thrombocytopenia in an otherwise well child with normal white blood cells, red blood cells, and physical examination is very rarely a manifestation of ALL.

Symptoms may be present from a few days to several months before the diagnosis of ALL is made. The nonspecific nature of the signs and symptoms of ALL occasionally leads to delay in diagnosis. In addition, because ALL may imitate a variety of disorders, there may be diagnostic confusion (Table 64–5).[32] For example, arthralgias arising from leukemic infiltration of the joints may be confused with juvenile rheumatoid arthritis or osteomyelitis. In rare cases, ALL has presented with unusual symptoms such as aplastic anemia or hypereosinophilia (Table 64–6).

Extramedullary Spread

ALL frequently involves organs other than bone marrow. Most patients have some extramedullary disease at diagnosis, and extramedullary relapse is a known complication of the disease. The most commonly affected extramedullary sites of disease include the central nervous system, testes, lymph nodes, liver, spleen, and kidney. Of these sites, the central nervous system (CNS) and the testes have the greatest clinical significance. The incidence of occult extramedullary involvement in patients presumed to be in clinical remission is difficult to ascertain, but has been estimated to be as high as 50%, although this is likely treatment-dependent.[33–35] Organ dysfunction due to leukemic involvement is rare, and usually occurs only in patients with progressive, end-stage disease. The occurrence of an extramedullary relapse is most significant because it frequently heralds the development of bone marrow relapse.

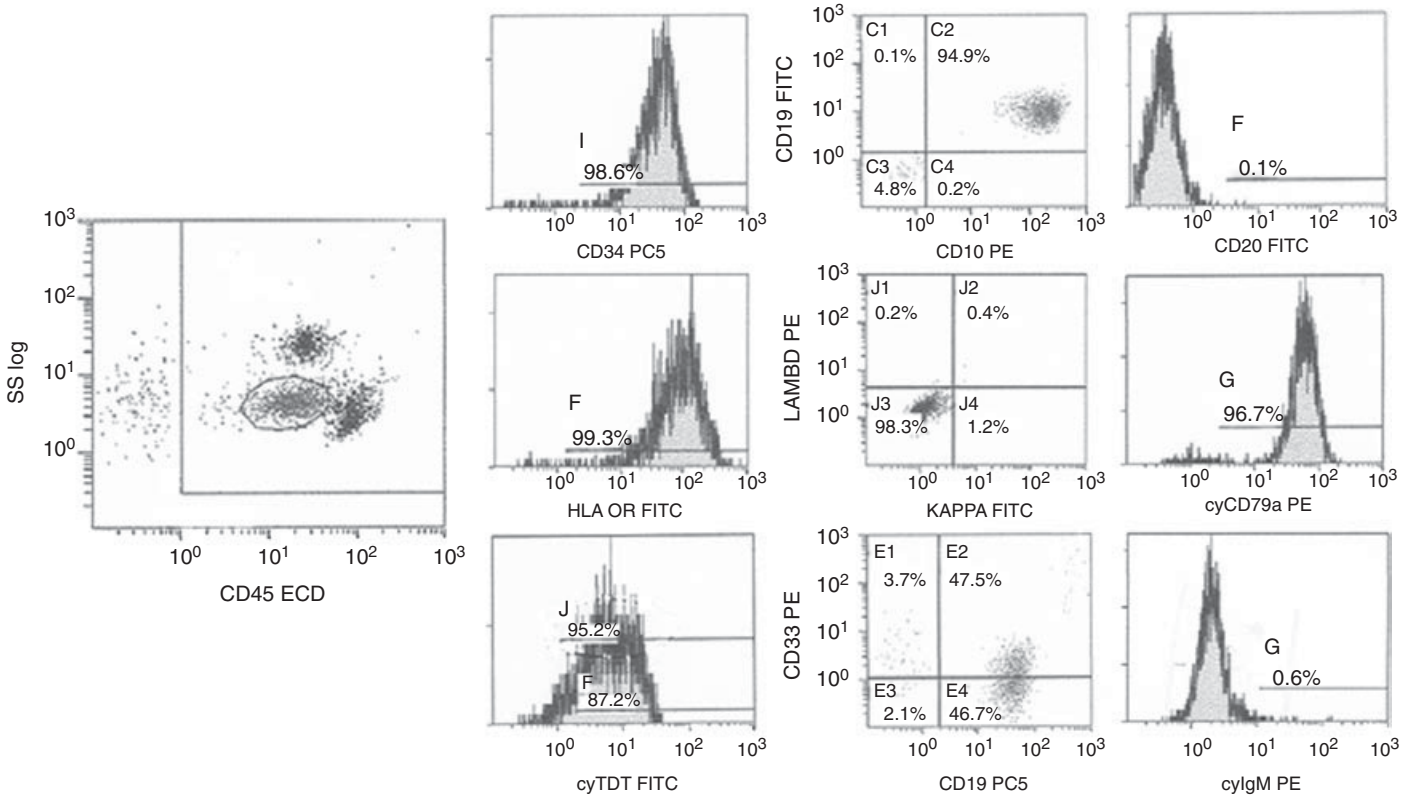

Figure 64–2 Flow data from a typical case of precursor-B acute lymphoblastic leukemia (ALL). The CD45 side-scatter histogram, left shows a distinctive blast population (circled) with weak CD45 reactivity and low side scatter. This is easily distinguished from lymphocytes, monocytes/granulocytes, and nucleated red blood cells. In this case the blasts phenotype was CD34$^+$, HLADR$^+$, TdT$^+$, CD19$^+$, CD10$^+$, CD20$^-$, cyCD79A$^+$, Kappa$^-$, Lambda$^-$, and cyIgM$^-$. There is weak and partial reactivity for a myeloid marker, CD33.

Table 64–4 Uniform Assessment of Risk Factors in Childhood Acute Lymphoblastic Leukemia

Risk Factor	Associated With Better Outcome	Associated With Worse Outcome
Age	1–9 years	≥10 years
WBC	<50,000/μL	≥50,000/μL
DNA index	>1.16	≤1.16
Trisomy 4 and 10	Present	Absent
M1 marrow day 7 or 14	Yes	No
Peripheral blasts at day 8	Absent	Present*
Cytogenetics		t(9;22) t(4;11) t(1;19)
Immunophenotype	B-precursor	T cell*
CNS leukemia	CNS 1	CNS 2* CNS 3

Central Nervous System

CNS leukemia is presumed to develop either from hematogenous spread, through "seeding" of the meninges by circulating leukemic cells, or by direct extension from involved cranial bone marrow.[36] The meninges are the primary site of disease but, particularly in advanced disease, other sites within the brain parenchyma and spinal cord may be involved.[37] Signs and symptoms, if present, are usually caused by increased intracranial pressure and include headache, nausea and vomiting, lethargy or irritability, papilledema, and nuchal rigidity. Cranial nerves, most commonly the seventh, third, fourth, and sixth, may be involved and may on rare occasions be an isolated site of CNS leukemia at diagnosis or relapse. The hypothalamic-obesity syndrome, in which infiltration of the hypothalamus produces hyperphagia and pathologic weight gain, is a rare complication of CNS leukemia. Because of its varied symptomatology, CNS leukemia must be considered as a possible diagnosis in any patient with ALL who develops neurologic signs and symptoms.

The diagnosis of CNS leukemia is made by evaluation of cerebrospinal fluid (CSF) obtained by lumbar puncture. In symptomatic patients, the opening CSF pressure is usually increased, the CSF cell count is usually elevated, the CSF protein is frequently elevated, and the CSF glucose may or may not be decreased. CSF examination following concentration of cells by cytocentrifugation reveals leukemic lymphoblasts. Because routine CNS surveillance is standard, the diagnosis of CNS leukemia is commonly made in asymptomatic patients. In such cases, the CSF opening pressure, cell count, and protein and glucose levels may all be normal and only examination of a cytocentrifuged CSF specimen may help identify leukemic lymphoblasts.

CNS leukemia is often classified into 3 groups: CNS 1, in which there are less than 5 WBC/μL of CSF and no blasts are seen; CNS 2, in which there are less than 5 WBC/μL of CSF but blasts are present; and CNS 3, in which there are 5 WBC/μL of CSF or more and blasts are present, or cranial nerve palsies are noted. CNS involvement is relatively uncommon at diagnosis, occurring in less than 5% of children and up to 15% of adults.[37] Unless adequate CNS preventive therapy is administered, however, the majority of patients will eventually develop overt CNS disease. Because the blood–brain barrier creates a pharmacologic sanctuary that prevents many systemically administered antileukemic agents from penetrating adequately into the CNS, specific CNS treatment—in the form of intrathecal chemotherapy, high-dose systemic chemotherapy, and/or cranial radiation—is required to prevent the development of CNS leukemia. Patients with CNS 3 status are clearly at increased risk for future CNS relapse and require more intensive CNS-directed therapy, often including cranial radiation. The significance of CNS 2 status, in contrast, has been controversial, with evidence for an increased risk of CNS relapse on some treatment regimens but not others (reviewed in reference 38). Traumatic lumbar puncture (TLP) has been identified by some as an additional, distinct category of initial CNS involvement. Some studies indicate that TLP carries an increased risk of CNS relapse, due to introduction of blasts from the peripheral blood into the cerebrospinal fluid, whereas others suggest that intensive treatment may negate the risk associated with TLP.[38] Isolated CNS relapse was previously a herald of subsequent systemic relapse and poor survival, but with more intensive multimodal therapy, the survival for patients with CNS relapse, especially when it occurs late in treatment, approaches that of newly diagnosed patients.[39,40]

Testicular Leukemia

Clinically evident testicular involvement is rare at initial diagnosis, but occult testicular disease has been reported in up to 25% of newly diagnosed boys.[41] When clinically overt, testicular leukemia presents as a painless testicular enlargement which is usually unilateral. Diagnosis of testicular involvement is made by wedge biopsies, which should be done bilaterally because of the high incidence of contralateral testicular involvement.[42] Testicular leukemia is characterized by infiltration of leukemic cells into the interstitium; involvement of the seminiferous tubules occurs in more advanced disease.[43] Although it had been believed that the testes are a leukemic sanctuary site, protected from systemic chemotherapy by a blood–testes barrier, animal studies suggest this is not the case.[44] In addition, although at one point the testes appeared to be a major site of disease recurrence, it appears that the incidence of this complication has decreased as systemic therapy in general has become more intense.[45]

Testicular disease frequently occurs as an "isolated" clinical relapse in patients in bone marrow remission. The actual incidence of true isolated testicular disease, however, may be less than previously believed. A high percentage of patients with presumed isolated testicular relapse may in fact have occult leukemia present in the bone marrow[46] or other reticuloendothelial organs.[47] The frequent diagnosis of testicular involvement may simply reflect the relative ease with which recurrence can be detected clinically at this anatomic site. In contrast to the case of CNS leukemia, where routine surveillance for occult disease is essential, routine surveillance for occult testicular disease either during therapy or at the end of maintenance therapy is no longer standard. The reason for this is that there is no survival advantage when testicular leukemia is diagnosed at the occult stage rather than at clinical presentation.[48–50]

Lymph Nodes

Nodal involvement is a characteristic feature of ALL and is often responsible for bringing the patient to medical attention. Leukemic involvement usually results in obliteration of the normal microscopic structure of the node. Typically, the lymphadenopathy is generalized and enlarged nodes are painless and freely moveable.

Liver and Spleen

Hepatosplenomegaly is common in newly diagnosed patients with ALL. Pathologically, these organs show diffuse enlargement secondary to infiltration by leukemic lymphoblasts. In the spleen, the normal distinction between red and white pulp is lost. In the liver, leukemic infiltration of the portal areas is common. Even in cases associated with marked hepatomegaly, liver function abnormalities, if present, are usually mild.

Kidneys

Renal enlargement at diagnosis is common and represents diffuse infiltration by leukemic blast cells. Preferential involvement of the

cortex occurs. Renal dysfunction due to leukemic cortical infiltration is rare, although many patients, especially those with a high tumor burden, do have renal dysfunction due to uric acid nephropathy.

LABORATORY EVALUATION

Hematologic Findings

Over 90% of patients with ALL have clinically evident hematologic abnormalities at diagnosis. These usually reflect the degree to which normal marrow is replaced with leukemic cells. Anemia, usually normochromic and normocytic and characteristically accompanied by a low reticulocyte count, is present in approximately 80% of cases. In approximately 50% of patients, the initial leukocyte count is elevated; in up to 25% it is greater than 50,000/mL at presentation. Patients with a profoundly elevated leukocyte count at diagnosis (>50,000/mL) have a worse prognosis. Despite the elevation in leukocyte count at diagnosis, however, many patients present with severe neutropenia (<500 granulocytes/mm^3) and are at significant risk of serious infection. Thrombocytopenia is extremely common; over three-fourths of patients present with platelet counts <100,000/mL. Only approximately one-third of patients have a platelet count <50,000/mL at diagnosis. Although petechiae and purpura are present in many patients, severe bleeding is unusual at initial presentation, even when the platelet count is <20,000/mL, unless fever, infection, or an accompanying coagulopathy, such as disseminated intravascular coagulation (DIC), are also present.

Examination of the peripheral blood smear will reveal the presence of leukemic lymphoblasts in most patients at diagnosis. Definitive diagnosis generally requires examination of the bone marrow, which is usually hypercellular and infiltrated with leukemic lymphoblasts. Technically, the presence of greater than 5% leukemic blast cells confirms the diagnosis. Most institutions, however, require at least 25% blast cells before a definitive diagnosis is rendered. More than three-fourths of patients have greater than 50% lymphoblasts in their bone marrow at initial presentation. Occasionally, it is necessary to repeat bone marrow examinations in order to arrive at the definitive diagnosis.

Other Laboratory Studies

At the time of diagnosis, many patients with ALL have elevated serum uric acid levels. The degree of uric acid elevation reflects the extent of tumor burden, higher levels occurring in patients with high initial leukocyte counts and pronounced lymphadenopathy and hepatosplenomegaly. In order to prevent uric acid nephropathy and renal failure, hyperuricemia must be corrected by vigorous use of hydration and administration of either the xanthine oxidase inhibitor allopurinol or urate oxidase (rasburicase), an enzyme that catalyzes the oxidation of uric acid to allantoin.[51]

A variety of metabolic abnormalities, including elevated serum levels of calcium, potassium, and phosphorus, may be observed in the newly diagnosed patient with ALL. These are more frequently encountered in those patients with a high leukocyte count and extensive tumor burden. Hypercalcemia may be due either to extensive infiltration of bone or to the ectopic release of a parathormone-like substance by leukemic lymphoblasts.[52] Hyperphosphatemia may accompany the extensive destruction of tumor cells. It may occur either as a result of ineffective leukopoiesis or as a consequence of chemotherapy-induced tumor lysis.[53] Hyperkalemia also can occur as a result of extensive leukemic cell lysis, although spurious hyperkalemia due to lysis of blasts *in vitro* must be considered when serum potassium levels appear elevated.[54] Lactic acidosis may also be present at diagnosis or relapse.[55]

Other laboratory abnormalities are also occasionally present at diagnosis. Low serum immunoglobulin levels at diagnosis have been reported in up to 30% of children with ALL.[56,57] Significant coagulation abnormalities are not a typical feature of ALL at diagnosis. Although DIC may occur, it is infrequent. Clotting abnormalities are observed, however, in many patients under active treatment with L-asparaginase.[58] Abnormalities in a number of lysosomal enzymes are also evident at diagnosis. Serum lactate dehydrogenase (LDH) is frequently elevated. The degree of elevation appears to correlate with tumor burden.[3,59] In addition, isoenzyme I, an acid hydrolase hexosaminidase, is frequently elevated in B-cell precursor ALL.[60]

Certain radiographic findings can also be strongly suggestive of ALL, including leukemic lines on plain films, and marrow signal abnormalities on MRI.[61]

PROGNOSIS

A number of clinical and laboratory features evident at diagnosis have prognostic value for predicting the remission duration of patients treated for ALL. Some prognostic factors may be related rather than independent. Changes in treatment strategies may result in previously significant risk factors losing their prognostic value. Furthermore, advances in technology, especially in molecular genetics, have led to more precise definition of some risk factors. It seems likely that many clinical features associated with prognosis may be "surrogate markers" for an underlying biologic feature, such as a translocation resulting in abnormal intracellular signal transduction, that actually determines prognosis.

Many clinical features have been related to prognosis. The initial leukocyte count at diagnosis has proven to be an important prognostic factor in virtually all ALL studies. In general, the prognosis is inversely related to the leukocyte count. Those patients with initial leukocyte counts greater than 50,000/mL have a particularly poor prognosis.[62,63] The relationship between white count and prognosis appears to be continuous.

Age at diagnosis also has prognostic importance. Patients who are very young (<1 year) and older patients (>10 years) tend to have a worse prognosis.[64–67] Abnormalities of chromosome band 11q23, such as the t(4;11) translocation, are especially common in the infant age group, and this association may in part be responsible for their poor prognosis.

Immunophenotype also correlates with prognosis.[68–70] ALL patients with either mature B-cell or T-cell immunophenotypes generally have a worse prognosis than patients with B-precursor ALL, although the prognostic influence of T-cell phenotype is less striking after adjusting for its association with high initial leukocyte count. Moreover, on some recent, more intensive treatment protocols, the T-cell phenotype lacks prognostic significance.[71] Highly aggressive treatment also improves the outcome of patients with mature B-cell ALL.[72–74]

The expression of myeloid markers on ALL cells may be associated with a poor prognosis in children with ALL, although this is not apparent in all analyses.[22,75,76] There is also a relationship between morphologic subtype and prognosis. The FAB L3 subtype is associated with mature B-cell ALL and thus conveys a relatively poorer prognosis. In many studies of childhood ALL, the L2 subtype has also been associated with more resistant disease and poorer survival compared to L1.[77,78] However, several studies suggest that L2 morphology does not have prognostic significance independent of other risk factors such as age, sex, and white blood cell count.[79,80] In some studies, low serum immunoglobulins, particularly low IgM levels, have also been associated with poor event-free survival.[56,57,81]

Gender and race may also influence outcome. Female patients have a more favorable prognosis. This appears to be related to the impact of testicular relapse and to the higher incidence of T-cell disease in male patients.[66,82,83] Ethnicity appears to be an important prognostic determinant. African American and Hispanic patients have a lower remission induction rate and a higher likelihood of experiencing bone marrow relapse.[84–86] The reasons for this poor outcome are related in part to the more frequent recurrence of very elevated initial leukocyte counts, mediastinal masses, and L2 morphology in this population.[84,87,88] However, even when these factors are adjusted for, there still appears to be an increased risk of treatment failure for nonwhite patients.[89]

In the past, tumor burden as reflected by hepatomegaly, splenomegaly, massive lymphadenopathy, and/or mediastinal mass demonstrated prognostic significance. However, on multivariate analysis they are closely related to the initial leukocyte count,[90–93] and hence in the current National Cancer Institute classification scheme for ALL, neither organomegaly nor lymphadenopathy is viewed as a primary prognostic factor (Table 64–4).[63]

Advanced molecular diagnosis is providing new insight into prognosis. The association between chromosomal number and prognosis is well characterized. Hyperdiploidy occurs in about 35% of pediatric ALL and is an independent positive prognostic factor, particularly high hyperdiploidy, which has been variously defined in the literature as exceeding a threshold of between 50 and 55.[94–96] More recently, particular trisomies have been identified that appear to be more significant than total chromosome number as predictors of favorable outcome: trisomies 4 and 10,[97] trisomies 10 and 17,[94] and the triple trisomies of 4, 10, and 17.[98]

In contrast, patients with hypodiploidy fare less well.[99] Cases lacking only a single chromosome have similar prognosis to diploid cases, but those with less than 45 chromosomes have a significantly inferior outcome, with the worst outcome in near-haploid cases (24–28 chromosomes).[99,100] Rare cases with near triploidy (68–80 chromosomes) or near tetraploidy (>80 chromosomes) have also been associated with very poor outcome,[101] although a recent large series found a favorable outcome in the B-lineage cases.[102]

Abnormalities in chromosome structure, as well as number, convey important prognostic information. Recent technical advances have led to the identification of previously unappreciated, prognostically significant gene rearrangements. A number of chromosomal translocations are associated with both a high rate of induction failure and early relapse, including the t(8;14) translocation associated with B-cell ALL, the t(9;22) *BCR-ABL* gene rearrangement found in Philadelphia chromosome positive ALL, the t(1;19) *E2A-PBX1* gene rearrangement occurring in B-precursor ALL, and the t(4;11) *MLL* translocation occurring most frequently in infants. In contrast, the t(12;21) translocation, which results in the *TEL-AML1* rearrangement, is present in approximately 25% of cases of B-cell precursor ALL and is associated with improved outcome.[26,103–109] These recurrent genetic lesions are discussed in greater detail in Chapter 63. Identification of the fusion proteins and other functional abnormalities produced by these chromosomal abnormalities may radically change therapy for ALL in the future. Proof of this principle is the remarkable success of imatinib mesylate (Gleevec), a rationally designed inhibitor of the *bcr-abl* fusion tyrosine kinase produced by the t(9;22) translocation.[110]

Perhaps one of the most significant prognostic factors is the response to initial treatment, although strictly speaking it is not a presenting feature of patients with ALL. Nonetheless, patients who fail to achieve complete remission after completing an initial course of induction therapy have markedly reduced remission duration and survival. The rapidity of initial cytoreduction appears to be extremely important. For example, the presence of residual leukemia in the marrow on day 7 or 14 of induction therapy has been associated with shorter event-free survival compared with patients whose marrow shows no evidence of residual disease at that time.[87,90,111,112] In some studies, response to initial therapy has been the overriding prognostic factor regardless of initial disease features.[113,114]

Morphologic examination of the bone marrow is the classic approach to assessing response to treatment, with remission defined as less than 5% blasts. Newer molecular definitions of remission based on minimal residual disease (MRD) detection are far more sensitive in identifying patients at risk of ultimate morphologic relapse. Precisely how and when MRD should be measured in clinical practice remains unresolved, but it is clearly an important disease parameter to follow. MRD can be measured by assessing for the presence of aberrant combinations of immunophenotypic markers by flow cytometry, for clone-specific immunoglobulin or T-cell receptor rearrangements by PCR, or for fusion proteins generated by translocations, also using PCR.[115] Persistent MRD bears adverse prognostic significance at all time points that have been studied, ranging from early induction to 24 months into treatment.[116–120] Conversely, rapid achievement of MRD negativity before the end of induction identifies a favorable prognosis group with a high probability of cure, who might be spared the adverse effects of high-intensity regimens.[121]

CONCLUSION

Current treatment regimens for childhood ALL use prognostic factors to define different risk groups that are subsequently treated according to their relative risk of failure.[122] In turn, improved treatment strategies may reduce the impact on survival of a given prognostic factor. In most centers, patients with poor risk features receive more intensive treatment, while those with good risk features receive treatment designed to be effective yet minimize treatment-related adverse sequelae. The use of different prognostic factors for stratification of risk groups may lead to difficulty in comparing the results of different approaches to therapy. A uniform approach to risk factor assessment based on a combination of clinical and laboratory criteria has recently been developed (Table 64–4),[123] and further characterization of molecular markers of prognosis is a major current research effort. The success of this risk-based strategy and the general principles of treatment in childhood ALL are detailed in Chapter 65.

CHAPTER 65

TREATMENT OF CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA

Sima Jeha and Ching-Hon Pui

INTRODUCTION

Steady progress in the development of treatment strategies for childhood acute lymphoblastic leukemia (ALL) started in the 1950s, when complete remissions were achieved using single chemotherapeutic agents.[1,2] Combining and cycling these agents, with the addition of central nervous system (CNS) prophylaxis, significantly prolonged remissions resulting in cure rates of approximately 50% in the 1970s.[3] Drugs developed over 30 years ago, such as mercaptopurine, methotrexate, vincristine, corticosteroids, anthracyclines, and asparaginase, still constitute the backbone of contemporary ALL protocols resulting in long-term, event-free survival rates exceeding 80%.[4] This progress was accomplished with serial clinical trials using outcome predictors to stratify therapy.[5–12] A uniform risk classification approach based on age and leukocyte count at diagnosis was adapted at a National Cancer Institute-sponsored workshop held in 1993, based on the observation that patients with high presenting leukocyte counts are at greater risk for subsequent relapse than those with lower leukocyte counts at diagnosis, and that children between 1 and 10 years of age have a better outcome than infants, or older patients.[13] This classification proved to be insufficient because up to a third of patients designated as standard-risk may relapse and this criteria cannot be applied to T-cell ALL. With improved understanding of the immunology and molecular pathways involved in ALL, current risk classification typically include age, leukocyte count at diagnosis, blast cell immunophenotype and genotype, as well as early treatment response. The most common form of acute leukemia in children is B-precursor cell, which is frequently associated with extra chromosomes (hyperdiploidy), or expression of *ETV6–CBFA2* (*TEL–AML1*). As discussed in Chapter 63, *E2A–PBX1* and *BCR–ABL* rearrangements are not common in children with ALL, and the *MLL(HRX)* gene rearrangement is predominant in young infants. Hypodiploidy (less than 44 chromosomes per leukemic cell) and rearrangement of *BCR–ABL* or *MLL* are unfavorable prognostic indicators.[14,15] Hyperdiploidy (more than 50 chromosomes) and the *TEL–AML1* gene fusion are associated with favorable outcomes; however, 10% to 15% of these patients relapse despite contemporary therapy. Early response to therapy, as measured by minimal residual disease (MRD) evaluation, has played an increasingly important role in risk stratification of ALL. Accordingly, patients are divided into three risk groups: low-, intermediate-, and high-risk (also referred to as standard-, high-, and very high-risk categories in other risk classification schema). Current childhood ALL therapy emphasizes early and vigorous assessment of the risk of relapse in individual patients, to improve outcome of patients with high-risk leukemia while minimizing long-term sequelae and enhancing the quality of life in patients at low risk of relapse.[4]

PRINCIPLES OF TREATMENT

Accurate assessment of relapse hazard is an integral part of ALL therapy, so that only high-risk patients are treated aggressively, with less toxic therapy reserved for cases at lower risk of failure. The prognostic impact of age and, to a lesser extent, leukocyte count can be explained partly by their association with specific genetic abnormalities. For example, the poor prognosis of infants is associated with *MLL* rearrangement (detected in 70%–80% of patients in this age group), and the overall favorable outcome of patients aged 1 to 9 years is related to the preponderance of cases with hyperdiploidy greater than 50 or *TEL–AML1* fusion.[4,14] As mentioned earlier, primary genetic features do not entirely account for treatment outcome. Although up to 15% of patients with hyperdiploidy greater than 50 or *TEL–AML1* fusion suffer recurrences of their leukemia, a substantial proportion of the patients with the t(9;22) and *BCR–ABL* fusion who are 1 to 9 years old and have low leukocyte counts at diagnosis may be cured with intensive chemotherapy alone.[16] Among patients with *MLL–AF4* fusion, infants and adults have a worse prognosis than children.[17–19] Genetic polymorphisms of drug transporters, receptors, targets, and drug-metabolizing enzymes can influence the efficacy and toxicity of antineoplastic agents.[14] Interindividual variability in the pharmacokinetics and pharmacodynamics of many antileukemic agents might partially explain the heterogeneity in treatment response among patients with specific genetic abnormalities and the difference in outcome by age group. We and others have identified multiple polymorphisms associated with relapse risk, acute toxicity, and late effects.[20–25] Individualizing therapy on the basis of germline genetic status may help optimize treatment (as discussed in Chapter 9). The prime example is the use of polymorphisms of thiopurine methyltransferase, an enzyme that catalyzes the methylation of thiopurines, such as mercaptopurine and thioguanine, to guide treatment.[24] Concomitant administration of drugs that induce cytochrome P450 enzymes (eg, phenobarbital and phenytoin) significantly increases the systemic clearance of several antileukemic agents and may adversely affect treatment outcome. Hence, response to therapy is determined by several factors including the leukemic cell biologic features, the pharmacogenetics of the patient, the treatment regimens administered, and compliance to therapy. Indeed, the degree of reduction of the leukemic cell clone early during remission induction therapy has shown greater prognostic strength than any other individual biological or host-related feature.[26] Assessing MRD by flow-cytometric detection of aberrant immunophenotypes or analysis by polymerase chain reaction of clonal antigen-receptor gene rearrangements provides a level of sensitivity and specificity that cannot be attained by traditional morphological assessment of treatment response.[26] Patients who are in morphological remission but have a postinduction MRD level of 1% or more fare as poorly as those who do not achieve clinical remission by conventional criteria (>5% blasts). Approximately half of all patients show a disease reduction to 10^{-4} or lower after only 2 weeks of remission induction, and they appear to have an exceptionally good treatment outcome. Although MRD positivity is strongly associated with known presenting risk features, it has independent prognostic strength and is increasingly used to intensify ALL therapy in contemporary regimens.

PHASES OF THERAPY

Recognition that ALL is a heterogenous disease and the identification of reliable prognostic factors have led to wide use of risk-directed therapy. With the exception of mature B-cell ALL cases, which are treated with short-term intensive chemotherapy (including high-dose methotrexate, cytarabine, and cyclophosphamide),[27,28] therapy for

Minimal Residual Disease

The rapidity of response to induction therapy is an important independent predictor of outcome. There is strong concordance between the assessment of MRD by flow cytometry and by polymerase chain reaction methods. We monitor MRD using primarily a flow cytometry method, which is simple and rapid, and we reserve polymerase chain reaction methods for the few patients (less than 5%) whose leukemic cells lack a suitable immunophenotype. Approximately half of all patients show a disease reduction to 10^{-4} or lower after only 2 weeks of remission induction, and these patients appear to have an exceptionally good treatment outcome. Persistence of MRD of 10^{-4} or more at 4 months from diagnosis is associated with an especially dismal outcome. The adverse prognosis of high-risk slow early responders can be improved with intensification of induction and consolidation. Standard-risk cases may be spared the increased risk of early morbidity and mortality from intensive induction, provided that they receive postinduction intensification therapy.

Drug Interactions

We have not yet reached a full understanding of the contribution of genetic polymorphisms to interindividual differences in drug effects that allows us to translate this new knowledge into clinical practice. However, by simply avoiding drug interactions, one can prevent increased toxicity or reduced efficacy of chemotherapy. Phenytoin and phenobarbital induce the activity of cytochrome P450 enzymes, significantly increasing the systemic clearance of several antileukemic agents that may adversely affect treatment outcome. We substitute these anticonvulsants with gabapentin in patients receiving antileukemic therapy. On the other hand, azole compounds (eg, fluconazole, itraconazole, ketaconazole) can inhibit cytochrome P450 enzymes and increase the toxicities of various antileukemic agents, especially vincristine.

Dose Schedule

The biologically equivalent doses between the different formulations of corticosteroids, thiopurines, and asparaginase are not known. Trials comparing such agents should be cautiously interpreted taking into account the dose schedule used, and the effect of variability in the pharmacokinetic profile and potency among the agents involved. Simple modification of dose or schedule may result in significant difference in efficacy and toxicity. Also, when comparing regimens containing high-dose intravenous methotrexate, the dose schedule of leucovorin rescue should not be ignored, as it plays a crucial role in modulating the activity and toxicity of methotrexate.

High Risk CNS

Patients with the following characteristics are at increased risk of CNS relapse and require more intense CNS-directed therapy:

1. Patients with high-risk genetic features
2. Large leukemic cell burden
3. T-lineage ALL
4. CNS-3 status (>5 WBC/microliter CSF with presence of lymphoblasts on cytospin)
5. CNS-2 status (<5 WBC/microliter CSF with lymphoblasts)
6. Traumatic CSF with blasts

Consolidation Therapy

The importance of a consolidation phase following remission induction is undisputed, but the treatment regimen and duration varies in the different childhood ALL studies. Commonly used strategies include high-dose methotrexate plus mercaptopurine, frequent pulses of vincristine and corticosteroid plus high-dose asparaginase for 20 to 30 weeks, and reinduction treatment with the same agents given during initial remission induction. Reinduction treatment has become an integral component of contemporary protocols. In one randomized study, double reinduction further improved treatment outcome in patients with intermediate-risk ALL, whereas additional pulses of vincristine and prednisone after a single reinduction course were not beneficial, suggesting that the increased dose intensity of other drugs, such as asparaginase, was responsible for the observed improvement. An "augmented" regimen including Capizzi methotrexate (escalating-dose intravenous methotrexate with no rescue, followed by asparaginase) and additional doses of vincristine and asparaginase during periods of myelosuppression, improved outcome of patients with a slow early response to therapy.

ALL typically consists of a brief remission-induction phase followed by intensification (or consolidation) therapy to eliminate residual disease, and then prolonged continuation treatment to maintain remission. All patients also require treatment directed to the CNS early in the clinical course to prevent relapse due to leukemic cells sequestered in this site.[4]

Contemporary protocols stratify therapy based on risk groups defined by age, leukocyte count, immunophenotype, leukemic genotype, and response to early remission induction therapy.[5–12] The standard or lower risk category includes patients between 1 and 10 years of age with an initial leukocyte count less than $50 \times 10^9\ L^{-1}$, and the remaining patients are considered higher risk. Additional features used by some investigators to stratify patients as lower risk include hyperdiploidy greater than 50 (DNA index > 1.16) and trisomy of chromosomes 4 and 10. Conversely, other characteristics such as T-cell phenotype, adverse cytogenetic translocations [t(9;22) and t(4;11)], overt CNS leukemia at diagnosis, and slow early response to induction chemotherapy have been used to stratify patients as high risk.

Remission Induction

Remission induction therapy aims at eradicating more than 99% of the initial leukemic cell burden and restoring normal hematopoiesis. This treatment phase typically lasts 4 to 6 weeks, and includes the administration of a glucocorticoid (prednisone or dexamethasone), vincristine, and at least a third drug (asparaginase or anthracycline, or both). A two-drug remission induction regimen of weekly vincristine and daily prednisone results in remission in 80% to 90% of children with ALL.[29,30] Addition of a third agent, such as asparaginase or an anthracycline, increases the remission rate to approximately 95%.[31,32] In addition to improving remission rates, intensified induction regimen also prolong remission duration. In a study in which children were randomly assigned to receive identical therapy except for induction drugs, one group received vincristine and prednisone and the other received those two drugs plus an anthracycline.

Although the complete remission rates for both groups exceeded 90%, there was long-term benefit for the more intensively treated group.[32,33] A three-drug induction regimen appears sufficient for most standard-risk cases, provided they receive intensified postremission therapy.[34] The benefit in long-term survival of using 4 or more drugs during induction is widely accepted in higher-risk patients but less clear in lower-risk patients.[35] Among the studies with the best reported outcomes, most rely on at least four drugs for remission induction for all patients, regardless of their risk group status.[5,10,12] Children with high-risk ALL are treated with four or more drugs for remission induction.[4] Addition of a tyrosine kinase inhibitor has greatly improved the remission induction rate, duration of disease-free survival, and quality of life of patients with Philadelphia positive (Ph+) ALL.[36,37]

On the basis of reports of more potent in vitro antileukemic activity and better CNS penetration,[38–41] dexamethasone has replaced prednisone in some induction and many continuation regimens.[12,42–44] However, the biologically equivalent doses between dexamethasone and prednisone are not known, and one study suggested that prednisone can yield results comparable to dexamethasone, provided a higher dose is used (ie, 60 mg/m^2/d).[45] Not surprising, dexamethasone given at higher dose was associated with increased incidence of hyperglycemia, hypertension, myopathy, bony morbidity, severe behavioral changes, and infectious complications.[46] As with glucocorticoids, the pharmacodynamics of asparaginase differ by formulation.[47] The native *Escherichia coli* asparaginase has been the most commonly used preparation. Polyethylene glycol-conjugated asparaginase, a long-acting and less allergenic form, is progressively replacing the native product and is being increasingly administered intravenously instead of intramuscularly.[48] Asparaginase derived from *Erwinia chrysanthemi* has a short half-life and its use is currently limited to patients who are allergic to the *E coli* formulations. The dose schedule for asparaginase should take into account the variability in the pharmacokinetic profile and potency among the different preparations.

The rapidity of response to induction therapy, as measured by clearance of peripheral and bone marrow blasts, is an important predictor of outcome,[4,5] although intensification of postinduction therapy can improve the adverse prognosis of slow early responders.[49] With modern chemotherapy and supportive care, 97% to 99% of children can be expected to attain complete morphological remission (ie, <5% blasts in bone marrow) at the end of remission induction, that is, those who do not have a poor outcome.[50,51] Hence, most investigators offer these patients the option of allogeneic hematopoietic stem cell transplantation at the end of extended induction treatment.[52] We and others have found that patients with 1% blasts identified by MRD studies had an outcome as poor as those with induction failure[53,54] and the patients may also be candidates for allogeneic transplantation.

Consolidation (Intensification)

Following remission induction, consolidation (or intensification) is given to eradicate drug-resistant residual leukemic cells. Therapy is tailored to the leukemia subtype and risk group. Intensifying asparaginase therapy during the early phase of treatment improved results in the Dana Farber Cancer Institute studies.[55] Adding doxorubicin to asparaginase favorably influenced the outcome of high-risk patients, particularly those with T-cell disease.[56,57] Significant improvement was also reported in the outcome of patients receiving early intensification consisting of intermediate-dose or high-dose antimetabolite therapy.[57–60] The optimal dose of methotrexate depends on the leukemic cell genotype and phenotype, as well as host pharmacogenetic and pharmacokinetic parameters. Methotrexate at 2.5 g/m^2 is adequate for most patients with standard-risk B-cell precursor ALL, but a higher dose (5 g/m^2) may benefit those with T-cell or high-risk B-cell precursor ALL.[5] This observation is consistent with the finding that T-lineage blast cells accumulate methotrexate polyglutamates less avidly than do B-lineage blast cells.[61] The increased ability of hyperdiploid ALL blasts cells to accumulate methotrexate polyglutamate could partially explain the excellent outcome of children with hyperdiploidy greater than 50 ALL treated on low-intensity antimetabolites-based regimens.[62–64] The relatively low accumulation of methotrexate polyglutamates in blast cells with either *TEL–AML1* or *E2A–PBX1* fusion suggests that patients with these genotypes may also benefit from an increased dose of methotrexate.[65] Leucovorin rescue is necessary after treatment with high-dose methotrexate; however, overzealous rescue might counteract the antileukemic activity of methotrexate.[66]

Delayed intensification, pioneered by the Berlin–Frankfurt–Münster consortium, consists of using drugs similar to those used in remission induction therapy after 3 months of a less intensive, interim maintenance chemotherapy.[5] The Children's Cancer Group confirmed the efficacy of delayed reinduction therapy in low-risk cases,[67] and showed that double-delayed intensification with a second reinduction at week 32 of treatment improved outcome in patients with intermediate-risk disease.[68] An augmented intensification regimen consisting of the administration of additional doses of vincristine and asparaginase during the myelosuppression period following delayed intensification, and sequential escalating-dose parental methotrexate followed by asparaginase (Capizzi methotrexate), improved the outcome of high-risk patients whose disease had responded slowly to initial multiagent induction therapy.[49]

Continuation (Maintenance)

Continuation or maintenance phase consists of 2 to 2.5 years of low-intensity metronomic chemotherapy designed to eradicate any residual leukemic cell burden. Weekly low-dose methotrexate and daily oral mercaptopurine form the backbone of most continuation regimens. Adjusting chemotherapy doses to maintain neutrophil counts between 0.5 and 1.5×10^9 L^{-1} has been associated with a better clinical outcome.[4,69] Overzealous use of mercaptopurine, to the extent that neutropenia necessitates chemotherapy interruption, reduces overall dose intensity and is counterproductive.[70] It is generally recommended to give mercaptopurine at bedtime to patients with an empty stomach[71] and to avoid taking it together with milk or milk products containing xanthine oxidase, an enzyme that can degrade the drug.[72] Approximately 10% of the population inherit one wild-type gene encoding TMPT and one nonfunctional variant allele, resulting in intermediate enzyme activity, whereas 1 in 300 people inherits two nonfunctional variant alleles and is completely deficient of this inactivating enzyme.[73,74] Patients with heterozygous and especially homozygous deficiency of thiopurine methyltransferase are at high risk of severe myelosuppression. Identification of these patients allows selective reductions in mercaptopurine dosage without modifying the dose of methotrexate.[24,75] Patients with thiopurine methyltransferase deficiency are also at greater risk of developing therapy-related acute myeloid leukemia and radiation-induced brain tumors, in the context of intensive thiopurine therapy.[24,76–78] Conversely, patients with higher levels of enzyme activity might be at a greater risk for relapse as a result of decreased exposure of leukemic cells to active drug metabolites.[5] Substituting thioguanine for mercaptopurine during continuation therapy was associated with a high incidence of profound thrombocytopenia and hepatic veno-occlusive disease.[79–81] Thioguanine use has therefore been limited to short pulses administered during consolidation therapy in some trials, whereas mercaptopurine is selected for prolonged administration.

Many groups add regular pulses of vincristine and corticosteroids to this regimen although the benefit of these pulses in the context of contemporary therapy has not been established.[82] The optimal duration of therapy remains unknown. Attempts to shorten therapy duration from 24 months to 12 or 18 months have resulted in a significant increase in relapses.[83] Many studies extend treatment for boys to 3 years because of their generally poorer outcome compared with girls,[84,85] although the benefit of this approach remains to be demonstrated. Several studies showed no advantage to prolonging treatment beyond 3 years.[86,87]

Central Nervous System-Directed Therapy

The importance of therapy directed to the CNS was first demonstrated by investigators at St. Jude Children's Research Hospital in the 1960s, when the incidence of CNS leukemia as an initial site of relapse became progressively more common as more effective chemotherapeutic regimens resulted in longer duration of hematologic remissions. This was attributed to the CNS's acting as a pharmacologic sanctuary, poorly penetrated by conventional doses of systematically administered chemotherapeutic agents.[88,89] Radiation therapy was the first modality to successfully prevent CNS relapse.[91] The effectiveness of 2400 cGy cranial radiation as preventive therapy was offset by substantial late effects in long-term survivors, including learning disabilities, multiple endocrinopathy, and an increased risk of second malignancies. Subsequent trials demonstrated that, in the context of intensive systemic and intrathecal therapy, cranial irradiation can be reduced[5,92] or even omitted altogether.[5,8,92,93]

Patients with high-risk genetic features, large leukemic cell burden, T-lineage ALL, and leukemic cells in the cerebrospinal fluid (CSF) even from iatrogenic introduction from a traumatic lumbar puncture at diagnosis are at increased risk of CNS relapse and require more intense CNS-directed therapy.[94] Approximately 2% to 3% of patients will present with CNS-3 status (detectable CNS leukemia defined as >5 WBC per microliter CSF with the presence of lymphoblasts on a cytospin preparation) and an additional 5% to 10% with CNS-2 status (<5 WBC per microliter CSF with lymphoblasts) or traumatic lumbar puncture with blasts.[94,95] These patients are at an increased risk of CNS relapse and benefit from more aggressive CNS-directed therapy.[93] Special care is being taken to minimize traumatic lumbar punctures, to deliver intrathecal therapy optimally, and to intensify systemic and intrathecal therapy in high-risk cases.[96] Studies have successfully used triple intrathecal therapy or intrathecal methotrexate alone. A randomized study did not resolve the controversy over the optimal type of intrathecal therapy as the benefit from reduction in CNS relapse was offset by a higher rate of medullary relapse in the patients randomized to receive triple intrathecal therapy with methotrexate, hydrocortisone, and cytarabine.[80] Systematically administered agents, including high-dose methotrexate,[97–99] dexamethasone,[38] and asparaginase,[100] may contribute to the prevention of CNS relapse.

ALLOGENEIC HEMATOPOIETIC STEM-CELL TRANSPLANTATION

Comparisons between allogeneic hematopoietic stem-cell transplantation and intensive chemotherapy have yielded inconsistent results owing to the small numbers of patients studied and differences in case selection criteria.[101,102] Allogeneic transplantation during initial complete remission may improve outcome of children with poor response to initial induction chemotherapy, t(9;22), early hematologic relapse, or T-cell ALL with poor early response or hematologic relapse.[16,37,103] The benefit of allogeneic hematopoietic stem-cell transplantation in infants with t(4;11) ALL remains controversial.[18,104–106] Matched unrelated-donor or cord blood transplantation has yielded outcomes comparable to those obtained with matched related-donor transplantation and should be considered reasonable alternatives if a matched donor is not available.[107,108] Autologous transplantation has failed to improve outcome in ALL.[101] With improving prospects for effective targeted therapy, the need for allogeneic transplantation should be continuously reevaluated.

INFANT ALL

Infant ALL comprises approximately 4% of childhood ALL, and is associated with a high WBC count at presentation, a high frequency of an immature B-cell precursor phenotype characterized by the lack of CD10 expression, and the presence of *MLL* rearrangements.[109,110] Rearrangements of the *MLL* gene on chromosome 11q23 occur in 70% to 80% of infants with ALL, and are mostly associated with the t(4;11) translocation with *MLL–AF4* fusion.[109] Whereas the outcome of the 15% to 20% infants with *MLL* germline ALL is comparable to that of older children with ALL, those with very young age (<6 months), high initial leukocyte count (WBC > 300×10^9 L^{-1}), *MLL* rearrangement, and a poor early response to therapy have a dismal prognosis with less than 20% survival rates.[18,104,109,110] As mentioned earlier, the use of hematopoietic stem-cell transplantation in infants is controversial. Two recent publications suggest that the use of hematopoietic stem-cell transplantation contributed to a favorable outcome in infant ALL.[106,107] However, these studies did not have a control arm in which patients only received chemotherapy and the data were not corrected for waiting time to hematopoietic stem-cell transplantation. Moreover, in one of these studies total body irradiation was used and led to substantial late effects in infants.[107] Data from a large retrospective intergroup analysis did not show differences between infant *MLL*-rearranged patients who did or did not receive hematopoietic stem-cell transplantation.[18]

RELAPSE

Most relapses occur during treatment or within the first 2 years after its completion, although relapses have been reported as late as 10 years after an initial ALL diagnosis.[111] The most common site of relapse is the bone marrow. Relapse in extramedullary sites, such as the CNS and testes, has decreased to less than 5% and 2%, respectively.[112] Leukemia relapse occasionally occurs at other sites, including the eye, ovary, uterus, bone, muscle, tonsil, kidney, mediastinum, pleura, and paranasal sinus. Extramedullary relapse in children with ALL frequently presents as an isolated clinical finding. However, in studies that included an MRD assay, many extramedullary recurrences were associated with MRD in the bone marrow.[113] A small fraction of patients experience a recurrence of acute leukemia with an immunophenotype different from that determined at diagnosis. Some of the cases represent relapse of original leukemic clones with a shift in immunophenotype, but others are secondary malignancies caused by the mutagenic effects of leukemia treatment especially from epipodophyllotoxin.[114] Patients with isolated bone marrow relapse generally fare worse than those with combined bone marrow and extramedullary relapse.[113] Factors indicating an especially poor prognosis are a short initial remission and a T-cell immunophenotype. Other adverse factors include t(9;22). The presence of minimal residual disease at the end of second remission induction is also a strong adverse prognostic indicator.[115,116] Salvage regimens are mostly based on different combinations of the same agents used in frontline therapy, and are associated with significant morbidity and dismal long-term survival rates in most cases. Patients with early or multiple relapses and heavy prior chemotherapy exposure have an expected median survival of 9 to 10 weeks even when multiagent chemotherapy is used. Although chemotherapy may secure a prolonged second remission in children with ALL who experience late relapse (defined as more than 6 months after cessation of therapy), allogeneic hematopoietic stem cell transplantation is the treatment of choice for patients who experience hematologic relapse during therapy or shortly thereafter and for those with T-cell ALL. Patients with late-onset isolated CNS relapse who had not received cranial irradiation as initial CNS-directed therapy have a very high remission retrieval rate, with long-term prognosis approaching that of newly diagnosed patients in those who had a long initial remission before the CNS event.[101,117,118]

SUPPORTIVE CARE

Supportive care is especially important during remission induction treatment, when there is an increased risk from cardiovascular, metabolic, and infectious complications. Rapid turnover of leukemia cells before and immediately after the initiation of chemotherapy leads to metabolic disturbances including hyperkalemia, hyperuricemia,

hyperphosphatemia, and hypocalcemia.[119] Patients with high levels of uric acid are at risk for the development of acute renal failure secondary to uric acid deposition in the kidneys. All patients require intravenous hydration to prevent or treat hyperuricemia and hyperphosphatemia. Allopurinol, a xanthine oxidase inhibitor, can prevent uric acid formation. Rasburicase, a recombinant urate oxidase that breaks down uric acid to allantoin (a readily excretable metabolite with 5- to 10-fold higher solubility than uric acid), is more effective than allopurinol but is associated with methemoglobinemia or hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency because hydrogen peroxide is a byproduct of the uric acid breakdown.[120] Phosphate binders should also be used to prevent or treat hyperphosphatemia.

Transfusions should be administered slowly in patients with severe anemia to prevent congestive heart failure. In patients with extreme hyperleukocytosis, packed red blood cell transfusion should be delayed until after leukocyte count is decreased by leukapheresis, exchange transfusion, or chemotherapy to prevent complications of leukostasis. We limit the use of leukapheresis to patients presenting with a leukocyte count of $400 \times 10^9\ L^{-1}$ or greater, because they have a high risk of intracranial bleeding, pulmonary complications, and neurologic events as a result of leukostasis.[121] Exchange transfusion is preferred in smaller children. Mechanical reduction of leukocyte count is a short-acting supportive measure and should not delay prompt initiation of chemotherapy. All blood products should be irradiated in patients who are receiving immunosuppressive therapy to prevent graft-versus-host disease.

Patients should avoid foods that may be contaminated with pathogens[122] and reduce salt intake, which could induce hypertension and resultant seizure in patients receiving glucocorticoids during induction.[123] Adolescents, obese individuals, and Down syndrome patients are at increased risk of hyperglycemia and other complications.[124] All febrile patients should be given broad-spectrum intravenous antibiotics until an infectious disease is excluded. Prophylaxis with trimethoprim-sulfamethoxazole successfully prevents *Pneumocystis carinii* pneumonia.[125] Dental evaluation at diagnosis and meticulous oral hygiene during chemotherapy minimizes the oral complications of leukemia and its treatment. Oral candidiasis occurs frequently, especially in young children. Azole compounds (eg, fluconazole, itraconazole, ketaconazole) are frequently used to treat fungal infections. It should be recognized that they can inhibit cytochrome P450 enzymes and increase the toxicities of various antileukemic agents, especially vincristine.[126] Photosensitive skin rash can occur during antimetabolite therapy. The rashes are erythematous, maculopapular, similar to atopic eczema, and most prominent on the face. Children with a history of atopy appear to have a higher incidence of this complication. Topical administration of simple emollients or a weak steroid preparation, and avoidance of external exposure to sunlight should improve the skin condition. Patients with Down syndrome tolerate methotrexate poorly; appropriate dose adjustment is indicated.[127,128] Please refer to Chapters 64, 91, 92, 96, 148, and 152 for more details on supportive measures in children with cancer.

LATE EFFECTS OF TREATMENT

The most problematic late effects of contemporary ALL therapy include neuropsychological impairments, bone morbidity, and obesity.[129–133] Although neuropsychologic deficits are well-recognized side effects of cranial irradiation, intrathecal and systemic chemotherapy (especially methotrexate) can also cause brain atrophy and spinal cord dysfunction.[129,130] Severe CNS toxicity has been attributed to cranial irradiation at doses of 2400 cGy or higher, but lower doses have also been associated with long-term neuropsychological impairments, especially in younger children. Systemic and intrathecal chemotherapy contribute to the development of neurocognitive toxicities.[130] Obesity, most prevalent among female survivors of childhood ALL, may be related to cranial radiation and corticosteroids. Osteopenia, fractures, and osteonecrosis has been observed in up to 30% of survivors of childhood ALL.[131] Osteonecrosis, which can lead to significant pain, loss of function, and total joint replacement, has been reported in approximately 8% of children with ALL, with the highest frequency observed in those diagnosed in adolescence.[132,133] Ovarian and testicular function are relatively unaffected by most antileukemic therapy. Offspring of patients successfully treated for childhood ALL are expected to be normal as general population.[134] Second malignant neoplasms, including malignant gliomas, meningiomas, and AML, occur with increased frequency in patients treated on regimens that included irradiation, epipodophyllotoxins, or alkylating agents.[135–139] Please refer to Chapter 97 on late effects of therapy.

FUTURE DIRECTIONS

The treatment of childhood ALL is based on the concept of tailoring the intensity of therapy to a patient's risk of relapse. As the cure rate approaches 90%, treatment response assessed by MRD measurements of submicroscopic leukemia has emerged as a powerful and independent prognostic indicator for gauging the intensity of therapy. Children at high risk of relapse may now benefit from early intensification of therapy. The next goal is to reduce the intensity of therapy in children at very low risk of relapse, hence avoiding undue toxicity. The successful elimination of preventive cranial irradiation indicates that treatment reduction is feasible if done with caution and appropriate substitution with less toxic alternatives. Gene expression profiling could enhance the accuracy of risk stratification of pediatric ALL. Expanding the application of pharmacogenomics—a science that aims to define the genetic determinants of drug effects—will allow further individualized therapy in the future.[140] Although optimizing the use of old drugs continues through serial studies, new formulations of existing agents are being tested to improve the efficacy and reduce the toxicity of the parent compounds. Such modifications include improving drug transport and delivery, or altering the molecular structure to improve the therapeutic index.[140] Ongoing trials are studying the benefit of the two novel nucleoside analogs, clofarabine and nelarabine, in high risk ALL and T-cell ALL respectively.[140–142] In addition to refining leukemia classification, studies of global gene expression help identify potential molecular targets for therapy. It remains to be determined whether the success in targeting BCR–ABL with tyrosine kinase inhibitors will translate to other pathways, including NOTCH and FLT3. The development of monoclonal antibodies and cellular immunotherapy that exploits the expression of leukemia-associated antigens to stimulate the antitumor activity of cytotoxic T-lymphocytes or natural killer cells offers a new modality of targeted therapies that are under investigation. The challenge is to combine our current knowledge with technology to design effective risk-targeted therapies based on the biological features of leukemic cells, host genetics, and early response to therapy.

CHAPTER 66

ACUTE LYMPHOCYTIC LEUKEMIA IN ADULTS

Dieter Hoelzer and Nicola Gökbuget

Acute lymphocytic leukemia (ALL) is a malignant disease characterized by an accumulation of lymphoblasts. In the early 1980s adult ALL was largely an incurable disease with an overall survival (OS) of less than 10%. After pediatric protocols were adopted the OS in adults improved to 30% to 40%. Progress has been made in the tools used to diagnose ALL. In addition, a variety of new drugs for the treatment of ALL are now under evaluation. The prerequisite for comprehensive therapy of ALL, however, requires more than ever standardization and quality control of treatment strategies. Rapid diagnosis and classification is not only important for clinical practice but also helpful in identifying prognostic factors, defining targets for evaluation of minimal residual disease (MRD) and for creation of novel therapeutic agents.

EPIDEMIOLOGY

According the National Cancer Institute, the age-adjusted overall incidence of ALL in the United States was 1.6/100,000 (1.8 in males and 1.4 in females). The incidence is higher in whites compared with blacks. After an initial peak in children younger than 5 years of age (8.3/100,000), the incidence decreases continuously. It increases again above the age of 65 to a second peak in the age group above 85 years (2.0/100,000).[1]

BIOLOGIC AND MOLECULAR ASPECTS

Preferred Approach to Diagnosis

Classification of the phenotype of the blast cells in acute leukemia requires morphologic and cytochemical evaluations, immunophenotyping, cytogenetic analysis, and molecular genetic analysis. Morphology remains the means by which acute leukemia is initially detected and, together with cytochemical reactions, is the major tool in distinguishing between ALL and acute myeloid leukemia (AML) (see Fig. 66–1). For more precise subclassification of ALL into B or T lineages and further subtypes, immunologic techniques must be used to detect lineage-specific antigens as well as surface or intracytoplasmic molecules. These methods also offer the opportunity to identify leukemia-specific surface markers for the detection of minimal residual disease (MRD). Cytogenetic analysis is still part of the diagnostic characterization of ALL, but molecular genetic techniques for identification of particular subsets of ALL (eg, *BCR–ABL*-positive ALL) are of greater importance. Molecular markers, particularly rearrangements of T-cell receptor (TCR) and immunoglobulin heavy chain (IgH) genes, are the most frequently used tools to evaluate MRD.

Morphology

The cytologic features of leukemic blast cells in ALL and their division into L1 to L3 according to the French-American-British (FAB) classification are discussed in Chapter 64. The distribution of L1 and L2 subtypes is of minor relevance for prediction of outcome. The subtype L3, observed in up to 5% of adult ALL patients, should be distinguished because it is indicative of a mature B-cell ALL, which requires different treatment options, but should be confirmed by surface marker analysis. According to the WHO classification ALL is grouped together with lymphoblastic lymphoma as either precursor B-cell or T-cell neoplasm. B-cell ALL is referred to as precursor B-lymphoblastic leukemia/lymphoma. L3-ALL is classified as Burkitt cell leukemia together with Burkitt lymphoma. T-ALL is grouped together with T-cell lymphoblastic lymphoma as precursor T-lymphoblastic lymphoma/leukemia.

Cell Surface Marker Analysis

ALL is divided into subtypes by immunologic criteria based on the presence of specific receptors or antigens on the cell surface of leukemic blast cells. Within the B or T lineage ALLs, the subtypes are defined according to their stage of differentiation. For more details on the immunologic classification of ALL, see Chapters 63 and 64.

The frequency and definition of ALL subtypes in adult and childhood ALLs are outlined in Table 66–1. In the German multicenter trials for childhood ALL (BFM) and adult ALL (GMALL), the phenotypic characteristics of 1756 children and 946 adults with ALL were analyzed prospectively. B-precursor ALL is the most frequent subtype in children and adults (85% and 70%, respectively). T-lineage ALL has a higher incidence in adults (25%). Within the B and T lineages, the more immature subtypes, pro-B ALL and early T ALL, occur more frequently in adults. The European Group for the Immunological Characterization of Acute Leukemia has proposed a unified classification of ALL immunophenotypes.[2] The use of such uniform classifications is of utmost importance to permit results in different trials to be comparable. Immunophenotypes in ALL are often associated with clinical characteristics such as disease manifestations, course of disease, and biologic markers such as cytogenetic and molecular aberrations as illustrated in Table 66–1.

B-Lineage Acute Lymphoblastic Leukemia

Pro-B ALL, also termed *pre-pre-B ALL* or early pre B, lacks B-, T-, and pre-B-cell markers but expresses the human leukocyte antigen (HLA-DR), TdT, and CD19 and has rearranged immunoglobulin genes (Table 66–1). It occurs in approximately 11% of adult and 5% of childhood ALL.

Common ALL is the major immunologic subtype in childhood, as well as in adult ALL. It comprises greater than 50% of cases of adult ALL. Common ALL is characterized by the presence of CD10 (see Table 66–1). Common ALL blast cells do not express markers that characterize relatively mature B cells, such as cytoplasmic immunoglobulins or surface membrane immunoglobulins. The blast cells are positive for CD19 and TdT.

Pre-B ALL is characterized by the expression of cytoplasmic immunoglobulins, which is absent in common ALL, but is identical to common ALL with respect to the expression of all other cell markers (see Table 66–1). Rarely CD10 may be absent in this subtype. Pre-B ALL comprises nearly 10% and 15% of adult and childhood ALL, respectively.

Mature B-cell ALL is found in approximately 4% of adult and 3% of childhood ALL patients. The blast cells express surface antigens of mature B cells, including surface membrane immunoglobulin. CD10

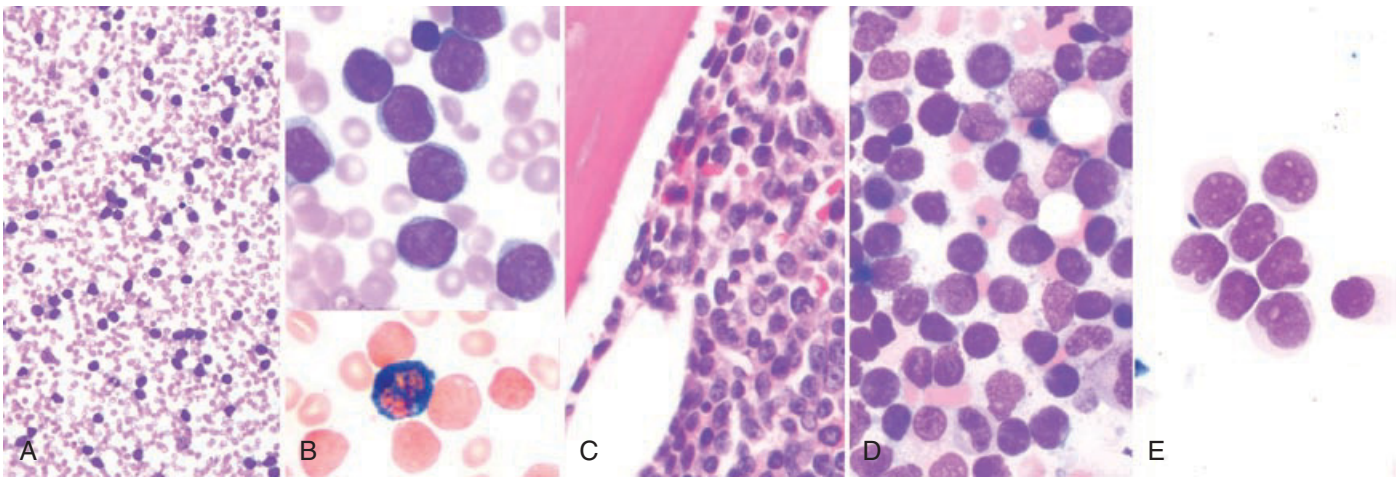

Figure 66–1 Acute lymphoblastic leukemia: peripheral blood, bone marrow biopsy and aspirate, and cerebral spinal fluid (**A**–**E**). The illustration is from a 37-year-old male who presented with a WBC of 170,000/μL and over 90% blasts with lymphoid morphology (**A** and **B**, top). An initial myeloperoxidase reaction (**B**, bottom) showed the blasts to be negative (positive cell is a segmented neutrophil that serves as an internal control). The bone marrow was packed with blasts as seen on the biopsy and aspirated material (**C** and **D**). The blasts were immunophenotyped by flow cytometry and were shown to be precursor-B lymphoblasts with the following phenotype: $CD34^+$, $HLA\text{-}DR^+$, TdT^+, $CD19^+$, $CD10^+$, $cyCD79A^+$, $cyIgM^-$, and sIg^-. Cytogenetic studies illustrated the t(9;22), and molecular analysis revealed the p190 *BCR/ABL*. A spinal tap showed a WBC count of 120/μL with an RBC count of 37/μL. The differential showed 80% blasts. The morphology of the blasts on the cytospin of the cerebrospinal fluid (**E**) is somewhat altered by the preparation. Note the absence of significant red blood cells in the specimen. Given the high number of blasts in the peripheral blood, a more traumatic tap would have made it difficult to distinguish between central nervous system disease and contamination of the cerebrospinal fluid specimen by blood.

Table 66–1 Immunologic Subtypes of Acute Lymphocytic Leukemia and Corresponding Cytogenetic/Molecular Markers

Subgroups	Most Important Markers	Incidence in Children (n = 1756)*	Incidence in Adults (n = 946)*	Cytogenetic/Molecular Marker†
B-Lineage	$HLA\text{-}DR^+$, TdT^+, $CD19^+$ and/or $CD79a^+$ and/or $CD22^+$	85%	72%	
Pro-B (B-I)	$CD10^-$, no other differentiation markers	5%	11%	6% t(4;11)/ALL1-AF4 (70% in pro-B) (20% Flt3 in MLL^+)
Common ALL (B-II)	$CD10^+$	65%	51%	33% t(9;22)/BCR-ABL (30–50% in c/pre-B)
Pre-B (B-III)	cy IgM^+	15%	10%	4% t(1;19)/PBX-E2A
Mature B	cy or s kappa or lambda	3%	4%	5% t(8;14)/c-myc-IgH
T-Lineage	cy or s $CD3^+$, $CD7^+$		26%

may be present, as well as occasional cytoplasmic immunoglobulins (see Table 66–1).

T-Lineage Acute Lymphoblastic Leukemia

Approximately 25% of adult ALL cases have blast cells with a T-cell phenotype. All cases express the T-cell antigen gp40 (CD7), and they may, according to their degree of T-cell differentiation, express other T-cell antigens (eg, the E rosette receptor [CD2] or the cortical thymocyte antigen T6 [CD1]) (see Table 66–1). A minority of T-cell ALL blast cells may also express CD10 together with T-cell antigens. In most cases of T-cell ALL, one or more of the T-cell receptor genes are rearranged. These properties make it possible to classify T-cell ALLs according to their stage of differentiation.

Early T-precursor ALL (or pre-T ALL) comprises 7% and 1% of adult and childhood ALL, respectively, and shows no further differentiation markers.

Thymic T-ALL (or cortical T-ALL) accounts for 13% of adult ALL and is characterized by CD1a expression. Because this subtype is associated with a better prognosis, its identification is of particular importance.

Mature T-ALL forms 7% of adult ALL and shows expression of surface CD3.

Cytogenetic and Molecular Genetic Analyses

Cytogenetic abnormalities are independent prognostic variables for predicting the outcome of adult ALL.[3] In some cases, cytogenetic or molecular genetic analysis contributes to confirmation of the diagnosis, for example, the correlation between t(8;14) and mature B-ALL. In four multicenter studies, clonal chromosomal aberrations could be detected in approximately 62% to 85% of adult ALL patients[4–7]; 15% to 38% of the cases had normal metaphases. The major cytogenetic abnormalities in ALL are clonal translocations such as t(9;22) (20%–30%), t(4;11) (3%–4%), t(8;14) (5%), t(1;19) (2%–3%), and other structural abnormalities such as 9p- (5%–15%), 6q- (4%–6%) und 12p aberrations (4%–5%). If none of the structural aberrations are present, the abnormalities can be classified according to the modal chromosomal number (<46, 46 with other structural abnormalities, 47–50, or >50).

Molecular analyses, detecting gene rearrangements in ALL by the polymerase chain reaction (PCR), Southern blot analysis, or fluorescent in situ hybridization with chromosome-specific DNA probes, are useful approaches in establishing a more precise diagnosis and in defining the quality of remission, and they may also provide insights into the pathophysiology of the leukemic process (eg, the mechanisms of leukemic cell stimulation by BCR–ABL fusion proteins). The most frequent molecular markers in ALL are BCR–ABL and ALL1–AF4.

The *Ph chromosome t(9;22)(q34q11)* results from a translocation involving the breakpoint cluster region of the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. The *BCR–ABL* gene rearrangement can be demonstrated by molecular techniques. PCR analyses revealed an incidence of 20% to 26% BCR–ABL-positive ALL in adults[8–10] compared with 3% in childhood ALL patients. One-third of adult ALL patients with a Ph chromosome show M (major)-*BCR* rearrangements (resulting in a 210-kd protein), similar to patients with chronic myeloid leukemia (CML), whereas two-thirds have m (minor)-*BCR* rearrangements (resulting in a 190-kd protein). It is noteworthy that *BCR–ABL* is more frequently detected than the corresponding chromosomal abnormality (t[9;22]) because of occasional difficulties in obtaining sufficient material for cytogenetic analysis.

The most frequent form of 11q23 abnormalities in ALL is *t(4;11)(q21;q23)*. The involved gene on chromosome 11 is named *MLL* for "mixed-lineage leukemia." Synonyms are *ALL-1*, *HRX*, and *HTRX1*. The *MLL* gene is fused to a gene located on chromosome 4 that is named *AF-4* (also referred to as *FEL*). The translocation is frequently detected in infant leukemia and in patients with the early pre-B subtype (CD10 negative). The overall incidence in adults is approximately 5%. Typical molecular aberrations in ALL with associated cytogenetic translocations and immunologic subtypes are summarized in Table 66–1.

The role of cytogenetic analysis has to be reevaluated critically. The most frequent cytogenetic aberrations and those with the greatest prognostic impact can also be detected by the corresponding molecular genetic aberrations, such as *BCR–ABL* for t(9;22) and ALL1–AF4 for t(4;11). These techniques are more reliable and have a greater sensitivity, for example, a detection level of 10^{-4} to 10^{-6}. They are, therefore, more useful for initial detection of the aberrations and for follow-up analysis of MRD.

Minimal Residual Disease

Molecular and immunologic techniques have allowed the detection of minimal residual disease (MRD), defined as leukemic cells undetectable by morphologic examination. MRD evaluation is most frequently based on detection of leukemia-specific constellations of surface markers by flow cytometry (FACS), fusion genes related to specific chromosomal translocations (eg, BCR–ABL in t(9;22) by polymerase chain reaction [PCR]) and individual rearrangements of immunoglobulin (IgH, Igκ) and T-cell receptor genes (TCR-β -γ, -δ) by PCR and recently by real-time PCR. These methods reach, in ideal cases, a sensitivity of 10^{-4}, which refers to the detection of 1 malignant cell in 10,000 normal cells. Overall, more than 90% of the ALL patients have at least one target for MRD evaluation.

ETIOLOGY

The cause of ALL remains unknown. However, a number of factors are associated with an increased risk to develop acute leukemia (ALL and AML).[11,12]

Genetic Predisposition

In epidemiologic studies, patients with some rare congenital chromosomal abnormalities have an increased risk for development of acute leukemias, including ALL. In children with leukemia (predominantly AML), there is an 18-fold higher incidence of Down syndrome than would be expected.[13] There is also an increased risk of ALL associated with inherited disorders, such as Klinefelter syndrome, Fanconi anemia, Bloom syndrome, ataxia-telangiectasia, and neurofibromatosis. The impact of genetic predisposition on the pathobiology of ALL may also be inferred from reports of the simultaneous development of ALL in identical twins. Molecular analyses have demonstrated that the disease is not related to genetic predisposition but probably to the exchange of a malignant stem cell between the twins. This was demonstrated for rearrangement of the MILL gene[14] and the TEL–AML1 fusion gene.[15] Particularly in infant leukemias, prenatal molecular aberrations are probably the basis and lead after additional postpartum events to development of leukemia.

Irradiation

The incidence of acute leukemias, mainly AML, but also ALL, was increased almost 20-fold in survivors of the atomic bomb explosions (>1 Gy exposure) in Japan,[16] with a peak incidence occurring 6 to 7 years after the radiation exposure. Induction of leukemia by emissions from nuclear power stations has also been raised as a possible environmental leukemogenic risk; this has never been demonstrated unequivocally. Whether radiation exposure after the Chernobyl accident led to an increased incidence of leukemia is still controversial.

Chemical

The risk for the development of ALL may also be increased after exposure to chemical agents, such as benzene or other agents capable of producing bone marrow aplasia, including chemotherapeutic drugs. Secondary, therapy-related AMLs but also ALLs can occur after exposure to alkylating agents, such as cyclophosphamide, epipodophyllotoxins, topoisomerase II inhibitors, and, rarely, anthracyclines,[17,18] which are used for treatment of other preceding neoplasias.

Viral

There is no direct evidence that a virus causes human ALL. Indirect findings, however, suggest involvement of a virus in the pathogenesis of two lymphoid neoplasias.[19] In the endemic African type of Burkitt lymphoma, the Epstein–Barr virus, a DNA virus of the herpes family, has been implicated as a potential causative agent.[20] The endemic

infection with human T-cell leukemia virus I (HTLV-I) in Japan and the Caribbean has been shown to be an etiologic agent for adult T-cell leukemia/lymphoma.[21]

CLINICAL MANIFESTATIONS

Most adult patients initially present with clinical symptoms resulting from bone marrow failure. Physical findings such as pallor, tachycardia, weakness, and fatigue are due to anemia; petechiae or other hemorrhagic manifestations are attributable to thrombocytopenia; infectious complications are due to neutropenia. Clinical signs of leukemia related directly to infiltration of organs with leukemic blasts, such as lymphadenopathy, splenomegaly, and hepatomegaly, are present in most patients but are infrequently the problems for which the patient first seeks medical advice.

Symptoms and clinical manifestations of 938 adult ALL patients, 15 to 65 years of age, entering two consecutive German multicenter trials, are listed in Table 66–2. One-third of the patients had infection or fever at presentation, and one-third presented with hemorrhagic episodes. Weight loss was observed only occasionally. Approximately one-half of the patients presented at diagnosis with lymphadenopathy, splenomegaly, and hepatomegaly, and hilar lymph node enlargement or a thymic mass (detected on chest radiographs or computed tomography scans) in approximately 14% of patients. Most (85%) patients with mediastinal masses had T-cell ALL. Massive thymic enlargement can cause dyspnea, especially when associated with pleural effusions. Although 7% of ALL patients at presentation had CNS involvement (as demonstrated by leukemic blast cells in the cerebrospinal fluid), only 4% of these initially had CNS symptoms, such as headache, vomiting, lethargy, nuchal rigidity, and cranial nerve or peripheral nerve dysfunction.

Virtually any organ can be infiltrated by ALL blast cells, and approximately one-tenth of the patients had such organ involvement (see Table 66–2). Most often a pleural effusion was observed in those patients with mediastinal enlargement and T-cell ALL. Some of those patients also had a pericardial effusion. Bone or joint pain was rarely observed as compared with childhood ALL; bone lesions could be found in only 1% of cases. Initial involvement of the testes was very rare (<1%). Leukemic infiltration of the retina, skin, tonsils, lung, or kidney was observed only occasionally, particularly in mature B-cell ALL and to a lesser extent in T-cell ALL, all of them associated with a poorer outcome.

LABORATORY EVALUATION

The peripheral blood cell values at diagnosis of the same cohort of patients are shown in Tables 66–3 through 66–5. The leukocyte count (Table 66–3). was elevated in 59%, 14% had normal counts, and 27% had leukopenia. In 92% of the patients, leukemic blast cells were seen in the blood smear. Thus, "aleukemic" leukemias account for only a small proportion of cases of adult ALL. With automated blood counting, the diagnosis may be missed in patients with normal or decreased white blood cell (WBC) counts and with low or zero blast cells in peripheral blood. For this reason, the need for microscopic examination of blood smears in people suspected of having acute leukemia should be stressed. An elevated blood count (>100,000 $\times$ 10^6/L) was observed in 16% of the patients, and, occasionally, WBC counts greater than 500,000 $\times$ 10^6/L have been observed. In general, a high WBC count is found more frequently in T-cell ALL patients than with B-lineage ALL patients.

Neutrophils (Table 66–4) less than 500 $\times$ 10^6/L were seen in 23% of the patients, and thrombocytopenia, less than 25,000 $\times$ 10^6/L, in

30% of the patients, corresponding roughly to the symptoms of infection and bleeding present at diagnosis.

Bone marrow aspiration or biopsy is mandatory for a diagnosis of ALL. In less than 15% of patients, the bone marrow cannot be aspirated and a biopsy must be performed. Dry taps are due to densely packed blast cells, fibrosis, or inadequate technique; the first two resolve after therapy. Most patients have greater than 50%, or even greater than 90%, of blast cells in the bone marrow (see Table 66–3). In less than 3% of cases, the blast cells constitute less than 50% of the nucleated marrow cells.

A lumbar puncture should be done to determine whether the CNS is involved. If there is a risk of bleeding due to a very low platelet count or of blast cell contamination due to a high leukemic blast content in the peripheral blood, lumbar puncture should be postponed. When the leukocyte count in the spinal fluid is low, or the morphologic detection of blasts is inconclusive, demonstration of an immunologically defined blast cell population can confirm a diagnosis of CNS involvement.

The most frequent metabolic abnormality is an increased serum uric acid level, which occurs in approximately one-half of the patients; hypercalcemia was rare. Serum lactate dehydrogenase may be elevated as a result of cell destruction in patients with a large tumor mass, particularly in B-cell ALL. Because of liver infiltration some patients may show elevation of liver enzymes. In a small proportion of patients (Table 66–5), the initial fibrinogen level may be less than 100 mg/dL. Disseminated intravascular coagulopathy and other disturbances of coagulation are rarely observed at diagnosis.

DIFFERENTIAL DIAGNOSIS

Difficulty is rarely experienced in establishing the diagnosis of ALL. The differentiation from lymphocytosis, lymphadenopathy, and hepatosplenomegaly due to viral infections and other acute or chronic leukemias can usually be done by lymphocyte surface markers.

Aleukemic pancytopenic ALL patients without blast cells in peripheral blood (less than 10%) must be distinguished from those with aplastic anemia, which may also be a preleukemic syndrome. In contrast to ALL, the bone marrow is hypocellular in aplastic anemia. In rare cases with a limited bone marrow infiltration, an arbitrary distinction between ALL and NHL is usually made according to the degree of infiltration, more or less than 25%.

In approximately 29% of the patients blast cells coexpress myeloid surface markers such as CD13 and CD33 (>20%). Distinct subtypes of ALL are associated with a higher incidence of myeloid marker coexpression, for example, early T-ALL, pro-B-ALL, and Ph/BCR–ABL-positive ALL. These cases of ALL with myeloid marker coexpression must be differentiated from mixed or hybrid leukemias in which blast cells express lymphoid as well as myeloid antigens; they may also be termed *biphenotypic* or *bilineage* leukemias. The European Group for the Immunological Characterization of Acute Leukemia has suggested a score to unequivocally identify this rare subgroup.[2] Biphenotypic leukemias may be allocated to a treatment strategy for either for ALL or for AML and outcome seems to be poor with both approaches.

Occasionally difficulties can occur in distinguishing Ph/BCR–ABL-positive ALL from primary lymphoid blast crisis of CML. Sometimes final diagnosis can be made only after the initiation of treatment. In ALL patients achieving complete clinical remission (CR), the peripheral blood count are normal values, whereas CML cases revert to a chronic phase with a pathologic left shift.

THERAPY

Initial Evaluation and Supportive Therapy

At diagnosis, the evaluation of an adult with ALL should include a history and a careful physical examination. Speed in clinical evaluation and diagnosis is important to initiate supportive measures and to decide on appropriate therapy. Only in a few cases is the leukemic process so far advanced that immediate treatment of leukemia is necessary (eg, in patients with symptoms due to a large mediastinal mass and pleural effusions or to a rapidly progressing B-cell ALL).

A few general measures should be initiated at once. Sufficient fluid intake to guarantee urine production of 100 mL/hour throughout induction therapy should be maintained to reduce the danger of uric acid formation. Parenteral fluid administration may be required when the patient's oral intake is inadequate because of nausea or difficulty in swallowing. Placement of an implantable port system is advantageous when anticipating a long period of induction therapy or when part of the therapy will be carried out on an outpatient basis.

Patients should receive allopurinol to reduce the formation of uric acid and avoid the danger of urate nephropathy. Allopurinol blocks the enzyme xanthine oxidase, which mediates the generation of uric acid from xanthine as a product of purine catabolism. Allopurinol should be given at a dose of 300 mg/day, which may be increased to 600 mg/day if high leukocyte counts or organomegaly persist. The dose of allopurinol has to be reduced when 6-mercaptopurine is given because it potentiates the action of 6-mercaptopurine. Rasburicase is a new recombinant uratoxidase enzyme that catalyses the oxidation of uric acid to allantoin. It has been demonstrated that rasburicase can reduce high uric acid faster and more safely than allopurinol, thereby preventing a tumor lysis syndrome in almost all cases.[22] Therefore it could be an alternative to allopurinol in patients with a high risk of tumor lysis syndrome.

Approximately one-third of adult patients present with infection and bleeding. They are at high risk for infectious and hemorrhagic complications during the induction period because thrombocytopenia and granulocytopenia are aggravated by chemotherapy. In general, platelet transfusions should be given in response to bleeding episodes and to prevent bleeding when platelet counts fall to less than $10{,}000\ \mu L^{10}$ and to less than $20{,}000\ \mu L^{10}$ when there is a bleeding tendency or the patient is febrile. HLA-matched platelets are given to patients who become refractory to random donor platelets. The incidence of fatal hemorrhage during induction therapy has been significantly lowered by these measures.

Infection Management

The use of more intense chemotherapeutic regimens has resulted not only in improved response rates of malignancies but also in higher infection-associated morbidity and mortality. Long-term neutropenia is the most important risk factor, but CD4 lymphopenia, antibody deficiency, and immunosuppression in allogeneic stem cell transplantation also lead to severe and lethal infections. Before the 1990s, gram-negative microorganisms were the leading cause of febrile

neutropenia, but since then gram-positive bacterial infections caused mostly by staphylococci have increased, frequently correlated to indwelling central venous access. The number of multiresistant bacteria is increasing. Invasive fungal infections are increasing in frequency, particularly mold infections.

ALL patients should receive antibacterial and antifungal prophylaxis depending on the expected duration of neutropenia. In febrile neutropenia, thorough and early diagnostic procedures are necessary. They include physical examination, microbiologic investigations, imaging procedures, and biopsies. Cultures of blood, urine, sputum, and other infected areas are mandatory. Successful treatment of febrile neutropenia is based on immediate empirical administration of broad-spectrum antibiotics.

Hematopoietic Growth Factors

The use of hematopoietic growth factors, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), is a valuable component of supportive therapy during the treatment of ALL. There is no indication that these CSFs stimulate leukemic cell growth in a clinically significant manner.

Most clinical trials demonstrate that the prophylactic administration of G-CSF significantly accelerates neutrophil recovery[23–28] and several prospective, randomized studies also show that this is associated with a substantially reduced incidence and duration of febrile neutropenia and of severe infections in ALL[24,26,27] and also reduced in mortality during induction.[23,26–28]

The advantage of G-CSF administration was particularly evident in select high-risk patients receiving multiple treatment cycles,[24] whereas clinical effects appeared to be negligible in patients at low risk of infectious complications in one study in childhood ALL.[29] Conversely, the results of the St. Jude trial show that even in cases of acute leukemia with a greater than 40% probability of severe neutropenia, not all patients benefit from G-CSF treatment.[30] A comparison of this study with other trials[26,27] highlights the great importance of CSF scheduling. When CSFs are first given at the end of a 4-week induction chemotherapy regimen, potential benefits are limited.[30] Therefore, it is noteworthy that G-CSF may be given even in conjunction with chemotherapy without aggravating the myelotoxicity of these specific regimens[25–27] and that this scheduling is an important determinant of the clinical efficacy. Alternatively, it was demonstrated that after short consolidation cycles G-CSF application may be postponed from day 12 after high-dose cytarabine/mitoxantrone to day 17 without negative effects on duration of neutropenia.[31] Similar results were reported for consolidation therapy with the Hyper-CVAD regimen.[32] A closer adherence to the dose and schedule of chemotherapeutic regimens should be theoretically possible with the use of G-CSF. So far, no trial has demonstrated a benefit of increased dose intensity made possible by G-CSF application in terms of leukemia-free survival (LFS).

G-CSF is regularly used for mobilization of stem cells in candidates for autologous stem cell transplantation. There are some hints that prophylactic application of G-CSF after intensive chemotherapy cycles or in parallel may reduce the incidence of severe mucositis. Thus, delayed application of G-CSF during induction therapy has led to an increased risk of mucositis.[32]

Chemotherapy

Chemotherapy of ALL is usually divided into several phases, beginning with remission induction. The objective of induction chemotherapy is to achieve complete remission, that is, eradication of leukemia as determined by morphologic criteria and, more recently, also by molecular markers. Although the induction phase is usually well defined, postremission therapy can be subdivided into intensification and maintenance phases. Usually prophylactic CNS treatment is added (Table 66–6).

Remission Induction Therapy

Exact diagnosis and management of initial complications are the prerequisites for successful induction therapy. A cautious cell reduction phase is recommended for patients with a large leukemic cell burden or a high leukocyte count (>25,000 × 10^6/L). Patients with extreme leukocytosis (>100,000 × 10^6/L) have been treated initially with leukapheresis. However, in the majority of patients the cell count can also be reduced with steroids alone or in combination with vincristine or cyclophosphamide.

Standard induction therapy for ALL includes prednisone, vincristine, anthracyclines (mostly daunorubicin), and also L-asparaginase. Other drugs, such as cyclophosphamide, cytarabine (either conventional or high-dose), mercaptopurine, and others, are added in many protocols, sometimes called early intensification. Several new approaches are currently being explored in adult ALL to improve CR rates and thereby remission quality.

Steroids, mostly prednisone and prednisolone, have been administered, although *dexamethasone* (DEXA) has a higher antileukemic activity in vitro and a better penetration to the cerebrospinal fluid.[33] In pediatric trials, the replacement of prednisone by DEXA has led to a decrease of the CNS relapse rate and improved survival.[34] The DEXA schedule has to be designed carefully because continuous application of higher doses may lead to long-term complications[34] and to increased morbidity and mortality due to infections.[35]

Anthracycline dose intensity and schedule may play an important role in induction therapy of ALL.[36] The most frequently used anthracycline is daunorubicin (DNR). Many groups have replaced weekly applications by higher doses of DNR (30–60 mg/m^2 on a 2- to 3-day schedule).[28,37,38] A particularly high CR rate (93%) was reported with intensive anthracycline therapy (270 mg/m^2 for 3 days)[38] from a single-center study, but not confirmed in a larger multicenter trial.[39] Intensive anthracycline therapy may be associated with a higher mortality during the induction phase. Therefore, intensive supportive care and probably the use of growth factors are recommended with these protocols. Overall it remains open whether intensified anthracycline therapy is beneficial—for all subgroups and particularly in terms of achieving a molecular remission.

Asparaginase (A) does not affect the CR rate but improves LFS, and if not used during induction therapy, it is often included as part of the consolidation treatment. The addition of A to conventional induction therapy did not improve the CR rate in one trial in adult ALL. There was, however, a trend toward a higher LFS in patients treated with A.[40] Three different A preparations with significantly different half-lives are available: Native *Escherichia coli* A (1.2 days), *Erwinia* A (0.65 days), and *PEG-L-A* (5.7 days).[41] To reach equal efficacy, the treatment schedule has to be adapted, which is generally daily for *Erwinia*, twice daily for *E coli*, and once weekly for PEG-A. The importance of A pharmacokinetics is illustrated by a randomized trial in childhood ALL, where significantly lower survival rates were achieved with *Erwinia* compared with *E coli* A, both given at the same schedule, which is due to underdosing of *Erwinia*.[42] A randomized trial comparing PEG-A with *E coli* A in childhood ALL showed a higher earlier response rate for the latter but no difference in long-term outcome.[43] Thus, it remains open for debate whether PEG-A is superior to *Erwinia* A or native *E coli* A. During induction, A is often given concurrently to steroids in patients, inducing additional toxicities such as coagulation disorders and hepatic dysfunction, which are not predictable. It may thereby lead to treatment delays and compromise dose intensity in individual patients.

The role of cyclophosphamide (C)—generally administered at the beginning of induction therapy—has been evaluated in several studies. A randomized study by the Italian GIMEMA group comparing a three-drug induction regimen with and without C did not show a difference in terms of CR rate (81% vs 82%).[44] However, in several nonrandomized trials, high CR rates (85%–91%) were achieved with regimens including C pretreatment,[28,45] particularly in adult T-ALL.

High-dose treatment during induction refers particularly to *high-dose cytarabine* (HDAC; 1–3 g/m^2, usually for 12 doses) before

or after the standard induction therapy. This approach has resulted in a median CR rate of 79%, which is not superior to that obtained with conventional treatment, and it remains uncertain whether and for which subgroups it could be beneficial for LFS.[46] Upfront treatment before conventional chemotherapy yielded higher CR rates[37,47–49] than treatment afterward,[45,50,51] which was, in part, related to a higher induction mortality with the latter approach. Any type of induction therapy with HDAC may lead to an increased incidence of severe neutropenias after subsequent chemotherapy cycles.

With current regimens, the remission rate in ALL is 85% to 90% (see Table 66–6), with low failure rates and a variable early mortality up to 11%. Beyond mortality, even morbidity, for example, due to extended cytopenias, and subsequent infections such as fungal pneumonias may compromise further treatment and dose intensity. Options for increasing the rate of CR are limited in adult ALL. Therefore in the future increased molecular CR rates will be the most important goal. It may be defined as a burden of MRD below the detection limit of 10^{-4} (0.01%); the frequency of molecular CR in adult ALL ranges from 50% for Ph+ ALL treated with imatinib[52] to 60% for standard-risk ALL.[53]

Five percent to 15% of adult ALL patients do not achieve CR after induction therapy, compared with less than 3% of children with ALL, and 5% to 10% of adult ALL patients die during the induction period. Mortality during induction is age dependent, increasing with age from less than 3% in adolescents to 20% in patients greater than 60 years of age. The main cause of death in approximately two-thirds of the patients is infection, often fungal infection. The remaining nonresponders may achieve a partial remission or may be refractory to standard treatment. These patients have an extremely poor prognosis and are, therefore, candidates for new, experimental treatment approaches and are also considered for SCT, even if not in complete remission.

Intensification Therapy

Consolidation therapy refers either to high-dose chemotherapy, to the use of multiple new agents, or to readministration of the induction regimen, also called reinduction. These measures are aimed at eliminating clinically undetectable residual leukemia after induction chemotherapy and thereby preventing relapse, as well as emergence of drug-resistant cells.

Intensive consolidation is standard in the treatment of ALL based on pediatric studies and historic comparisons although randomized trials often failed to demonstrate a benefit of intensification[44,54]; this is probably due to the low number of patients in whom these concepts were evaluated. Consolidation cycles in large studies are very variable and it is impossible to evaluate their individual efficacy (see Table 66–6). Intensification schedules include teniposide, etoposide, amsacrine (*m*-AMSA), mitoxantrone, idarubicin, and HDAC, or intermediate- or high-dose methotrexate (HDM). Allogeneic SCT from sibling or unrelated donors or autologous SCT is now the major approach for intensive postinduction therapy in high-risk patients. Before SCT, a consolidation therapy is usually delivered to achieve a CR with good remission quality. High-dose chemotherapy has been used mainly to overcome drug resistance or to achieve therapeutic drug levels in the cerebrospinal fluid.

High-Dose Cytarabine

Although there is considerable experience with HDAC for the consolidation treatment of ALL,[46] it still remains uncertain what dose is optimal; usually doses ranging from 1 to 3 g/m^2 every 12 hours for 4 to 5 days are given within several combinations. HDAC has been included in several trials in adult de novo ALL as part of consolidation therapy (see Table 66–6). It seems that specific subgroups of ALL profit from HDAC treatment; thus, encouraging results are achieved for pediatric B-cell ALL. It remains uncertain to what extent HDAC contributes to the effects of HDM in these disease subtypes. Apparently, also for adult pro-B ALL, HDAC is beneficial because cure rates of 50% can be achieved.[55]

An additional argument for the use of HDAC might be its effectiveness in treating CNS leukemia. There is evidence that in ALL and NHL, higher levels of AC triphosphate can be reached with 3 g/m^2 as compared with the lower dose of 1 g/m^2 AC; in addition, with the higher dose, the cerebrospinal fluid can be cleared of blast cells.[56]

High-Dose Methotrexate

In general, it seems that intensive application of HDM is beneficial. It has been extensively studied for the treatment of childhood ALL and, to a lesser extent, in adult ALL. HDM appears to be effective in preventing systemic and testicular relapses. However, in adults dosages are probably limited to 1.5 to 2 g/m² if given as a 24-hour infusion. Otherwise toxicities, particularly mucositis, may lead to subsequent treatment delays and decreased compliance. Toxicity, but also efficacy, is reduced with a shortened infusion time, for example, 4 hours.[57] The situation may change when improved prophylaxis of mucositis, for example, with keratinocyte growth factor, becomes available.

The effect of HDM on CNS leukemia may contribute to the favorable results reported with its use. HDM at a dose of 6 g/m^2 resulted in an 80% CR rate given in children with CNS relapse,[58] indicating that systemic application yields cytotoxic levels in the cerebrospinal fluid. Several studies have investigated the efficacy of HDM as consolidation (Table 66–6). Most favorable results have been achieved in small trials with HDM as part of intensive multidrug consolidation regimens.

Asparaginase

From pediatric ALL trials, there is increasing evidence that intensified application of *Asparaginase* leads to improved overall results.[59,60] In adult ALL this approach appears to be useful particularly in consolidation, where less toxicity can be expected compared to induction.

Reinduction

Pediatric trials and one randomized trial in adults also underline the efficacy of repeated induction also named reinduction or late intensification.[61]

The role of HD anthracyclines and epipodophyllotoxins in consolidation remains open. Overall in adult ALL, stricter adherence to protocols during consolidation with fewer delays, dose reductions, and omission of drugs because of toxicities would be an important contribution to therapeutic progress.

Maintenance Therapy

Maintenance therapy even after intensive induction and consolidation is standard for ALL patients. Some groups even prolong maintenance therapy beyond 2 years of total treatment. MTX preferably given intravenously (IV) and mercaptopurine (MP) given orally are the backbone of maintenance regimens. The potential effects of further intensification cycles for specific subgroups of ALL remains open. It may be useful to aim for leukocyte counts below 3000/µL during maintenance[62] to achieve optimal suppression of residual disease.

Attempts to omit maintenance therapy altogether after induction and consolidation therapy have resulted in inferior results.[63–65] On the other hand the role of periodic cycles of intensive chemotherapy during maintenance remains to be defined.

In a large, multicenter Italian study (GIMEMA 0183), after intensive consolidation treatment, patients were randomly assigned to postconsolidation therapy with conventional maintenance therapy or to additional alternating treatment courses of different intensities.[66] In this report, there was no difference in the survival rate at 10 years between the treatment groups (27% for conventional and 28% for more intensive maintenance), which may suggest that after adequate

early consolidation therapy the intensity of the maintenance therapy has no influence on survival. However, only a few patients actually received these regimens as scheduled; adults often show poor compliance to intensive maintenance because of toxicities and moreover social reasons. Therefore maintenance with less intensive cycles with vincristine, for example, and steroids may be more practicable.

Currently, maintenance therapy in adult ALL is being revisited based on the burden of MRD (eg, none for MRD-negative patients), the subtype of ALL, and the use of new therapeutic options (eg, a tyrosine kinase inhibitor for BCR–ABL-positive ALL). It is still open whether and to what extent maintenance therapy is necessary in ALL subgroups.

Prophylaxis of Central Nervous System Leukemia

Central nervous system leukemia occurs in 6% (1%–10%) of patients with adult ALL at diagnosis, with a higher incidence in T-cell ALL (8%) and mature B-cell ALL (13%).[67] Treatment and prophylaxis of CNS leukemia may consist of intrathecal (i.th.) methotrexate alone or in combination with AC or prednisone, similar intraventricular therapy administered by an Ommaya reservoir, cranial irradiation, or systemic treatment with HDAC or HDM.[68]

Adult ALL patients who do not receive specific prophylactic CNS treatment have a CNS relapse rate of 30% (29%–32%),[67] similar to that observed in children without CNS prophylaxis.[69]

With i.th. chemotherapy alone, the rate of isolated and combined CNS relapses can be reduced to 13% (8%–19%). Intermittent treatment during maintenance therapy improves the outcome compared with administration of only a few doses during induction treatment. In most adult ALL trials, additional prophylactic CNS irradiation (24 Gy) has been administered. This combined approach further reduces the CNS relapse rate to 9% (3%–19%). There is some evidence that early irradiation after remission induction is superior to delayed irradiation during consolidation treatment.[70]

In many recent trials, combined treatment approaches have shown greater efficacy. For high-dose chemotherapy together with i.th. therapy, the rate of CNS relapses was 7% (2%–16%); with additional CNS irradiation, the relapse rate was 6% (1%–13%). The efficacy of intensified CNS prophylaxis was also demonstrated in a retrospective analysis from the MD Anderson Cancer Center, where the lowest CNS relapse rate (2%) was achieved in a trial with early high-dose chemotherapy and i.th. therapy for all patients.[71]

Because the risk for CNS relapse is associated with other risk factors, such as T-cell ALL, B-cell ALL, extreme leukocytosis, high leukemia cell proliferation rate, high serum lactate dehydrogenase levels, and extramedullary organ involvement, a risk-adapted CNS prophylaxis has been suggested.[71] This approach, however, compared with childhood ALL, is not widely used in adults. It should be kept in mind that effective CNS prophylaxis not only reduces the risk of isolated CNS relapse but also improves general outcome. Deescalation of CNS prophylaxis should therefore be done carefully. In the future, the use of liposomal cytarabine for i.th. therapy may help reduce the number of i.th. applications and thereby the risk of contamination and improve efficacy with the aim to replace CNS irradiation in defined populations. Due to toxicity risks liposomal cytarabine should not be combined with systemic high-dose therapy.

The risk of CNS relapse can also be affected by skill in the performance of the administration of i.th chemotherapy. Thus, contamination of the CSF with blood at the initial lumbar puncture can be associated with a poor outcome. The Lumbar puncture should be done by experienced physicians; platelet transfusions should be given before in case of low platelet counts; and patients should remain in prone position after i.th. therapy.[72]

Therapy for Relapsed and Resistant Leukemia

Patients who fail to achieve CR or those who relapse subsequently have been treated with a variety of protocols.[73,74] The repetition of regimens, including vincristine, anthracyclines, and steroids, similar to standard induction treatment, have led to CR rates of 61% in earlier studies.[73,74] The use of single-agent HDM, HDAC, and probably the anthracycline derivatives-mitoxantrone and rubidazone have resulted in a second remission in less than or equal to 30% of patients, whereas other agents, such as amsacrine, teniposide, and etoposide are effective in 10% to 15%.of patients.

High-dose AC has been extensively studied in relapsed adult ALL. From several small pilot studies comprising 90 patients in total, the weighted mean CR rate was 37%.[75] Higher CR rates (50%–60%) were achieved with combination regimens that included HDAC and mitoxantrone, amsacrine, or vincristine plus steroids, again with a wide variation that may be attributed to patient selection and nonuniform intensity of pretreatment. Because HDAC is increasingly administered during frontline treatment, its efficacy following relapse may be limited. Therefore, new combinations with idarubicin (46%–64% CR rate)[76–78] or fludarabine (67%–83% CR rate)[79,80] have been evaluated. Median remission duration or survival has been reported by only a few groups, but did not exceed 5 months and 16%, respectively.

HDM followed by rescue with folinic acid combined with asparaginase lead to response rates of 22% to 79% in resistant ALL in early studies.[73] This combination is no longer administered to relapsed patients but is now incorporated in several regimens for patients with de novo ALL.

The most significant predictive factor for treatment response in relapsed patients is the duration of the first remission. Patients with longer previous remission (>18 months) have a higher CR rate and longer remission duration compared to those with a short previous remission (<18 months).[81,82] Therefore decision making concerning therapy should consider the duration of first remission, age, further options (eg, SCT), and other factors as summarized in Table 66–7. In patients with late relapse, a modified induction is often successful whereas in patients with early relapse, during intensive chemotherapy, new, experimental, or more intensive regimens should be considered. Fortunately, at present a variety of new drugs for ALL are being evaluated (reviewed in references 83–85).

For all chemotherapy regimens, the duration of second remission is usually short (<6 months) and the only curative approach for adult patients with relapsed or resistant ALL is SCT. The major aim of relapse treatment is the induction of a second remission with sufficient duration to permit preparation for SCT. Three large study groups have reviewed the outcome of relapsed ALL patients recently. The MRC UK-ALL found in 609 patients with first relapse a 5-year survival rate of 7%. Survival was poor in all subgroups, for example, younger (<20 years) versus older patients (12% vs 3%), short (<2 years) versus longer duration of first remission (11% vs 5%) or immunophenotype. Hundred twenty patients were able to receive an SCT after relapse, with survival rates of 15% for autograft, 16% for unrelated, and 23% for sibling allogeneic SCT after 2 years.[86] Also the French group reported a rate of second remission of 44% in 421 relapsed patients with an LFS of 12% after 4 years. They identified transplantation during second CR and a longer duration of CR (>1 year) as favorable prognostic factors.[87] The German group observed an improvement of outcome for relapsed T-ALL after more frequent application of experimental drugs, including nelarabine and perfor-

Table 66–7 Factors for Decision Making on Therapy of Relapsed Acute Lymphocytic Leukemia Patients

- Duration of first remission: ≥18 months
- Prior therapy (drugs /cycles) not used before
- Available targets
  - Subtype: B-precursor vs T-ALL
  - Antigens: Available monoclonal antibodies
  - Molecular markers: Available kinase inhibitors
- Localization of relapse

Table 66–8 Results of SCT in Adult Acute Lymphocytic Leukemia Patients

Type of SCT	Stage	No.	TRM	Relapse Rate	LFS
Allogeneic					
Family donor	CR1	1100	27%	24%	50%
	≥CR2	1019	29%	48%	34%
	Rel/Refr.	216	47%	75%	18%
Unrelated donor	CR1	318	47%	10%	39%
	≥CR2	231	8%	75%	27%
	Rel/Refr.*	47	64%	31%	5%
Autologous	CR1	1369	5%	51%	42%
	≥CR2	258	18%	70%	24%
Nonmyeloablative	All stages	232	28%	49%	31%

LFS, leukemia-free survival; SCT, stem cell transplantation; TRM, transplant-related mortality.
*One trial.[185]

mance of SCT in up to 70% of the patients achieving a second CR.[88] Thus all attempts—including experimental drugs—should be directed toward obtaining a second remission and proceeding with SCT.

Stem Cell Transplantation

SCT has gained an increasingly important role in the treatment of patients with adult ALL. Although the majority of large prospective studies in adult ALL addressed the issue of indications for SCT in first CR, scheduling and procedures are still not defined satisfactorily. To circumvent the problem with comparability of SCT and chemotherapy, several groups have constructed prospective trials with a "genetic" randomization, offering allogeneic SCT in first CR to all patients with a sibling donor. The study results certainly depend on the "conventional" treatment approach used in the chemotherapy arm. Some groups scheduled autologous SCT only and others a randomized comparison of autologous SCT and chemotherapy.

The most difficult outcome parameter is the OS of the total patient cohort in a prospective trial that answers the question whether an SCT-based treatment concept is able to improve overall outcome. OS of studies with genetic randomization have not documented that transplant is superior to chemotherapy[85]; this may be partly due to the fact that allogeneic SCT was implemented in only 11% to 38% of the patients.[54,89–94] Even if allogeneic SCT yielded favorable results, because of its infrequent implementation the impact on OS is too small.

Allogeneic Stem Cell Transplantation From Sibling Donors

The outcome of allogeneic SCT for patients with ALL depends on the age and remission status of the patient. The best results have been obtained in patients transplanted during the first remission. In a total of 1100 patients collected from published trials, the LFS rate was 50%, albeit with wide variations (21%–66%). The relapse probability (RP) was 24% and the transplant-related mortality rate (TRM) was 27% (Table 66–8). In more recent studies, results are improving, most probably because of a reduction in TRM.[95] According to the data of the International Bone Marrow Transplantation Registry (IBMTR) for HLA-identical sibling SCT between 1996 and 2001, the 3-year probability of survival was 48% for ALL recipients older than 20 years of age who were transplanted during their first remission.[96]

There is evidence that graft-versus-leukemia (GvL) effects are also operational in ALL patients receiving an allograft because several studies have shown that the RP is lower in patients with limited graft-versus-host disease.[97–100] Age is another important prognostic factor for outcome after SCT. The LFS is 62% for patients below and 48% for those above 20 years of age.[96] Nevertheless, age limits for allogeneic matched sibling SCT have been increased continuously up to 50 to 55 years. Experience of transplant centers may also have a role. Specialized centers in the United States report LFSs of 61% to 64% for sibling SCT in ALL in first remission.[101–103]

The LFS rate is 34% after allogeneic SCT in second remission. In advanced ALL (refractory or in relapse), allogeneic SCT results in an 18% long-term survival rate (see Table 66–8). Despite this, SCT is the treatment of choice in patients with relapsed or refractory ALL.

Matched Unrelated Stem Cell Transplantation

SCT using grafts from matched unrelated donors can result in long-term survival of 39% of patients with a lower RP (10%) as compared to allogeneic sibling SCT whereas TRM (47%) is higher. Both facts are probably due to more pronounced GvL and graft-versus-host (GvH) effects. It should be considered, however, that matched unrelated (MUD) series generally include selected high-risk patients, for example, with a high proportion of Ph/BCR–ABL-positive ALL. In the IBMTR registry, for adults older than 20 years, the 3-year probability of survival after MUD SCT in first CR was 42%.[96] In the largest series so far the results of MUD SCT were analyzed retrospectively in adult poor-risk ALL (mainly Ph/BCR–ABL-positive) patients with a median age of 34 years. They were particularly favorable for patients in first CR (42% at 2 years), whereas in second or subsequent CR, the LFS was only 17%.[104] The RP of only 6% for patients in first CR may be due to a more pronounced GvL effect. The high TRM of approximately 40%[104,105] is still the major obstacle to MUD SCT (see Table 66–8). This might be reduced by the use of different, less toxic preparative regimens, including nonmyeloablative SCT, better management of graft-versus-host disease (GvHD), and improved supportive care.

Overall, the results of MUD SCT in ALL are encouraging, particularly considering that these are often patients with advanced stages of disease. There is increasing evidence that results of MUD SCT are approaching those of sibling SCT, particularly if adjusted for bias. MUD SCT is therefore the treatment of choice for high-risk patients in first CR, including Ph/BCR–ABL-positive ALL—and probably also other high-risk patients—if a sibling donor is not available.

In later remission or relapse, MUD SCT may lead to long-term survival of 27% whereas outcome after transplantation in relapse is only 5% (see Table 66–8).

Autologous Stem Cell Transplantation

Another attempt to overcome the limited availability of bone marrow donors is autologous SCT. The results for autologous SCT in first remission are surprisingly good, with an LFS of 42% and a low TRM (see Table 66–8). The major problem is a high RP (51%). Similar results with an LFS rate of 42% in standard-risk ALL (n = 280) and 40% in high-risk ALL (n = 174) have been reported by the European Bone Marrow Transplant Group (EBMT).[106] Favorable results have been achieved in a trial with autologous BMT or PBSC transplantation in adult ALL patients in first CR followed by a 2-year maintenance treatment with 6-mercaptopurine and methotrexate.[107]

The TRM after autologous SCT is very low (3%) and is similar to that of conventional intensification therapy. With the increasing number of MUD transplants being performed and the advantage of GvL effects, the role of autologous SCT is decreasing. However, because of the low TRM, this is still a reasonable approach for elderly patients and probably patients with negative MRD status in autologous bone marrow graft. Several prospective randomized trials in

adult ALL showed equal outcomes for chemotherapy consolidation and autologous SCT.

In the second remission, few patients obtain long-term survival with auto SCT (see Table 66–8). It may be considered as interim therapy before an allogeneic SCT if autologous stem cells have been collected during first CR.

Nonmyeloablative Stem Cell Transplantation

Nonmyeloablative SCT or reduced intensity conditioning regimens (NMSCT) is a novel approach that deserves evaluation in ALL and may lead to an extension of indications for allogeneic SCT. In contrast to conventional SCT, which mainly relies on cell kill by high-dose chemotherapy and total body irradiation (TBI), NMSCT uses GvL effects. Immunosuppression (eg, with purine analogs, other cytostatic drugs, or low-dose TBI) is followed by the infusion of stem cells from sibling or MUD donors with adapted immunosuppression to establish host tolerance.[108]

There is, however, the general opinion that GvL effects are less pronounced in ALL as compared to other malignancies. Nevertheless, these effects are present as indicated by lower RR in patients with acute or chronic GvHD,[98–100] lower RR after MUD SCT, induction of remissions by withdrawal of GvHD prophylaxis, or donor lymphocyte infusions (DLIs) in single patients with relapsed ALL.

NMSCT is being increasingly considered as an option for elderly patients with contraindications for conventional SCT. Initial results indicate that in first CR, stable remissions can be achieved in some patients.[109] These studies show an LFS of 31% for patients in all stages, with a 28% TRM and a 49% RR (Table 66–8). According to an EBMT analysis the LFS in 97 adult ALL patients with a median age of 38 years was 37%, with 28% TRM and 49% relapse rate.[110] The LFS was in both studies considerably higher if NMSCT was performed in patients in first remission.[109,110]

Results of Umbilical Cord Blood and Haploidentical Stem Cell Transplantation

The experience with umbilical cord blood (UCB) transplantation in ALL mainly comes from pediatric patients. Registry results of younger adults with acute leukemia indicate, however, that UCB (single or double) can be considered as an alternative donor source—if available.[111]

The experience with haploidentical SCT is restricted mainly to pediatric patients, where it may be considered in patients without a donor and with an urgent need of SCT. In adult patients with acute leukemia, a retrospective analysis indicated that—if feasible—autologous SCT is preferable to haploidentical SCT; despite a higher RR, the overall outcome was slightly superior.[112] According to the available experience, both approaches should be restricted to specialized centers, later stage of disease, and performed as part of a clinical trial.

Comparison of Different Transplantation Procedures and Transplantation Versus Chemotherapy

Allogeneic Sibling and Matched Unrelated Stem Cell Transplantation

Owing to improved supportive care, better donor selection, and extension of indications beyond very high-risk patients, the results of MUD donor SCT are similar to allogeneic sibling SCT. The prospective MRC/ECOG study of SCT showed in 321 patients with allogeneic sibling donor SCT a survival of 55% (standard and high-risk ALL) compared to 46% with MUD donor SCT in 67 patients with very high risk (Ph/BCR–ABL positive) ALL.[92] A study of nine German centers showed in first CR a higher proportion of MUD donor SCT (60% vs 27%) and there was no difference regarding LFS (45% vs 42%).[113] The TRM for allogeneic sibling SCT ranged in prospective trials between 15% and 26%[54,89–94] and reaches 35% in MUD SCT.[92] Several factors such as intensity of therapy before SCT, preparative regimens, immunosuppressive therapy after SCT, and also the experience and conditions at SCT centers may play a role. It can be summarized, however, that MUD SCT is a reasonable option for high-risk patients without a sibling donor.

Donor Versus No Donor Comparisons

This type of comparison represents the intent-to-treat analysis that is an adequate approach only if a significant number of patients actually receive the assigned treatment option. Several trials did not show differences in outcome for patients with (intent to treat: allogeneic sibling SCT) or without donor (intent to treat: randomization of auto SCT and chemotherapy).[54,94,114–116]

The Pethema study for high-risk patients even showed a trend toward an advantage for patients without a donor.[93] In contrast, several other studies demonstrated an advantage of SCT in high-risk patients.[90,91,115]

Recently the large ECOG/MRC group reported their results comparing patients with donor (allogeneic sibling SCT) to those without a donor (randomized comparison of chemotherapy and auto SCT). The special feature of this trial was the use of age (≥35 years) as a prognostic factor. Standard-risk patients were by definition younger than 35 years with a WBC count less than 30000/μL for B-precursor and less than 100,000/μL for T-ALL. Overall, patients with a donor had a superior OS (53%) compared to those without donor (45%) mainly because of a lower RP (29% vs 54%). The difference was particularly evident in standard-risk (62% vs 52% OS) but not in high-risk (41% vs 35%) patients,[117] a finding that is in contrast to all other trials. Because a younger age was the major factor for definition of standard risk, this result can be interpreted in two ways: (a) outcome of SCT is better in younger patients, which is a well-known fact, and (b) the outcome of young standard-risk patients with a donor is not superior to chemotherapy in other trials. A third issue is the fact that the performance of SCT was limited (321 allogeneic sibling SCT of 1508 evaluable patients).[92] The TRM reached 20% even in standard-risk patients. The OS of 39% in this trial was similar to other studies.[118]

Chemotherapy or Allogeneic Sibling Stem Cell Transplantation Versus Autologous Stem Cell Transplantation

In several randomized studies, no significant difference was detected in studies comparing chemotherapy and autologous SCT.[89,90,93,94] In the large randomized ECOG/MRC trial, the outcome of autologous SCT was inferior (33%) compared to chemotherapy (42%) in terms of LFS mainly because of a higher RP.[117] Comparisons of allogeneic and autologous SCT have shown an inferior outcome for autologous SCT. In two trials with an intent-to-treat comparison, the results of autologous SCT were poor (30% and 33%).[91,119]

Preferred Approach to Stem Cell Transplantation

A recently published evidence-based review emphasized that SCT offers an advantage as compared to chemotherapy in high-risk patients and in patients in second remission. The analyses also revealed the lack of prospective, controlled trials for SCT in ALL.[120] This is probably due to the fact that every study design that includes SCT by definition has too many variables, such as donor availability, individual patient condition, and patient wish. Not surprisingly, a meta-analysis of 7 studies[54,90,91,93,94,115,121] showed a broad variation in rates of performance of allogeneic (68%–96%) and autologous (9%–81%) SCT. The meta-analysis showed a correlation of outcome with compliance to allogeneic SCT. Again the OS for SCT was superior

Table 66–9 Indications for Stem Cell Transplantation in the German Multicenter Trials for Adult Acute Lymphocytic Leukemia Patients

	Indication	Priorities*
First remission		
High risk	All patients within 3–4 months from diagnosis	1. Allogeneic sibling† 2. Allogeneic unrelated† 3. Autologous 4. NMSCT
Standard risk	Molecular nonresponders	See above
Relapse, including molecular relapse	All patients in second CR (if necessary in good PR or beginning relapse)	See above (consider cord blood or haploidentical SCT if no donor available)

*Decision depends on age, patient's general condition, and donor availability.
†Matched or one mismatch.

to chemotherapy, with a particular advantage in high-risk patients.[122] Thus the role of allogeneic SCT in standard-risk ALL remains unclear.

In ongoing trials, indications for SCT in first remission are not uniformly defined. The advantages of SCT (short treatment duration, favorable outcome in some trials) must be compared to disadvantages (TRM, late complications, poorer quality of life). The major question is whether all patients with sibling donor should proceed to SCT or only those with specific risk factors.

When considering SCT, one has to balance the expected reduced relapse risk and the increased anticipated mortality. Also, late effects are more pronounced in SCT patients, the quality of life seems to be poorer, and the risk of procedure-related death is 20% to 30%. SCT in first CR from sibling or unrelated donor seems to be justified in subgroups of ALL with OS below 40% with chemotherapy and should probably not be offered to patients with OS after chemotherapy above 50%. These outcomes clearly depend on the different chemotherapy regimens used.

Therefore, in the majority of trials SCT indications are determined by the presence of adverse prognostic factors. The status of MRD is of increasing importance as an indication for the SCT. It remains open to further studies whether SCT is really a favorable option in patients with high MRD and whether patients with high-risk features but negative MRD status are still candidates for SCT. Allogeneic sibling and MUD SCT are considered in a similar way. Although outcome after SCT is better in younger patients, there is a trend to treat adolescents with pediatric-type intensive chemotherapy protocols and to proceed less with transplantation. For older, high-risk patients and those with contraindications, nonmyeloablative SCT is a reasonable alternative, with an expected LFS of 34% in first CR.[110]

There is general agreement that all patients in second or later remission are candidates for SCT. Depending on donor availability and general condition, experimental procedures such as NMSCT, cord blood SCT, and haploidentical SCT may be considered.

Table 66–9 outlines the indications of SCT in the German multicenter study group for adult ALL as an example for a risk-adapted approach.

OUTCOME OF ALL SUBTYPES AND PROGNOSTIC FACTORS

Age is probably the most important prognostic factor for achievement of CR and long-term outcome.[62] Other prognostic factors are of greater importance for duration of remission and survival (Table 66–10). Appreciation of the impact of such risk factors (Table 66–11) on the results in the majority of adult ALL trials have led to the generation of risk-adapted treatment protocols (Table 66–12).

Table 66–10 Outcome of Adult Acute Lymphocytic Leukemia Patients According to Subgroups*

Subgroup	No. of Patients	CR Rate	No. of Patients	LFS
Age				
<30	669	88%	510	42%–60%***

SCT in CR1	None	Allogeneic SCT (if matched related or unrelated donor) Autologous SCT After additional (if no donor and negative MRD, consolidation)		None
Maintenance	6-MP/M + intensification for 2–2½ years		imatinib	None

AC, cytosine arabinoside; ALL, acute lymphocytic leukemia; CR, complete remission; HDM, high-dose methotrexate; SCT, stem cell transplantation; MRD, minimal residual disease; Thy ALL, thymic ALL.

*Intrathecal therapy with M or triple combination (M, AC, steroid) continued during maintenance therapy; additional CNS irradiation and/or high-dose chemotherapy according to subgroup.

Age

Recent studies have shown that survival of patients with adult ALL decreases continuously with increasing age, from 34% to 57% below 30 years to 15% to 17% above 50 years.[28,44,54,118,123] Some groups used age above 30 to 35 years as an indication for SCT in first CR.[91,93] This is probably counterproductive because the outcome of SCT significantly decreases with age.[117] Increasing attention is being paid to the definition of specific treatment approaches for adult ALL patients at both ends of the age spectrum—adolescents at one and elderly patients on the other.

Table 66–13 Treatment Results in Elderly Acute Lymphocytic Leukemia Patients

Approach	No. of Studies	No. of Patients	CR	ED	OS
Palliative	4	94	43%	24%	7 months
Intensive chemotherapy	11	519	56%	23%	14%
Prospective studies	5	187	58%	16%	22%

CR, complete remission; OS, overall survival.

Elderly Patients

The CR rate is approximately 50% in patients at the age of 50 to 88 years, with a remission duration of 3 to 12 months and a survival rate below 10% (reviewed in references 124 and 125). It is difficult to define an age limit when a change in prognosis occurs. Almost all studies use a cutoff point at the age of 55 to 65 years to determine eligibility for allogeneic HSCT. This age seems to be practical because younger patients are candidates for intensified treatment approaches, such as SCT, whereas for the older group, new strategies need to be explored, carefully weighing the gain in survival against quality of life. Elderly patients at the age of 55 to 65 years or even older who have achieved a CR and are in good clinical condition are potential candidates for autologous SCT or NMSCT.

Several factors such as comorbidity, higher risk of complications, and increased risk of early mortality are associated with the inferior results in elderly patients. The major cause of death is infections. Therefore the increased hematologic toxicity with prolonged severe cytopenias is of particular relevance in elderly patients. Often it cannot be distinguished whether these are due to toxicity or to lack of response. There is the dilemma that on one hand the disease is more resistant in the elderly and on the other hand the tolerability of therapy is lower and there is a higher risk of organ toxicities, for example, of the liver or heart. Altogether, comorbidities and complications lead to treatment delays, omission of single drugs, and prolonged intervals between therapy cycles, which contribute to poorer long-term results. There is also a lower incidence of favorable prognostic subtypes such as T-ALL in the elderly, whereas the incidence of unfavorable subtypes is higher.[126]

Palliative therapy is associated with a short survival (Table 66–13).[124] With the use of intensive chemotherapy protocols developed for younger patients, the CR rate in the elderly was 56%, with 23% early mortality and a median survival of 9 months. It can be assumed that only elderly patients in good general condition were accepted to these trials. Thomas et al showed in three successive treatment periods that the remission rates of elderly patients could be improved by the adoption of specific age-adapted protocols.[127] Fortunately there is a new trend to develop prospective trials for elderly patients to offer a curative option on one hand and to limit toxicity, early mortality, and duration of hospitalization on the other

to maintain quality of life. With these approaches, a more favorable remission rate of 58% and survival of 22% have been achieved.[124]

Further improvement of results in the elderly is urgently required. Innovative strategies are based on targeted, subgroup-specific elements with the aim not to increase the typical chemotherapy-associated toxicity. This includes use of the abl-kinase inhibitor imatinib for Ph+ ALL, and antibody therapy for CD20-positive ALL (rituximab). The German study group reported a remission rate of 63% in CD20-positive (Ph/BCR–ABL-negative) elderly patients and a survival of 54% after 1 year with a regimen combining age-adapted chemotherapy and eight doses of rituximab before the chemotherapy cycles.[128] In elderly patients with Ph/BCR–ABL-positive ALL, the remission rate can be improved to above 90% with imatinib monotherapy.

Adolescent Patients

In the recent years the optimal approach to treatment of adolescents has been discussed extensively. Several groups have compared the outcome of adolescents treated with so called "adult" protocols with those treated with "pediatric" protocols. Although entry criteria were quite similar, the outcome was always significantly inferior in those participating in the adult trials (EFS 34%–71%) as compared to the pediatric trials (EFS 64%–80%).[129] The conclusion was that pediatric trials include higher doses of VCR, ASP, and HDMTX and a higher time–dose intensity. However, the poor outcomes associated with adult protocols selected for comparison is probably also due to suboptimal approaches in these specific studies. The GMALL reported a survival of 64% in 417 young adults (15–25 years), with significant differences in outcome for subgroups ranging from 74% for standard risk, 49% for high risk, and 55% for Ph+ ALL.[130] Results are superior to most of those reported from adult protocols in adolescents.

One solution could be the extension of age limits of pediatric protocols to 25, 35, or even higher ages as currently attempted by several US groups. It remains open to question whether a sufficient number of adults will actually be treated in these studies and whether the application of such intensive regimens will be restricted to selected patients and selected, highly experienced pediatric care providers.

The other option, which is currently followed by several adult study groups, is to adopt more successful pediatric treatment elements to their protocols and to aim for a higher time and dose intensity with fewer treatment interruptions and omissions, particularly in adolescents and young adults. Interim results of such studies were reported recently. The CR rates (82%–92%) and EFS (66%–72%)[131–133] are promising but considerable toxicity, for example, neuropathies, and thrombosis was observed, indicating that these protocols may probably not be transferable to all adults.

White Blood Cell Count

An elevated white blood cell count (WBC) at diagnosis (>30,000–50,000/μL) is associated with a higher relapse risk.[28,44,54,89,123] It was even considered as the most deleterious prognostic factor in B-precursor ALL, with an OS of 19%–29%,[118,134] whereas in T-ALL WBC has no significant effect on outcome in a GMALL multivariate analysis.[134] The biological reason for the highly resistant behavior of B-precursor ALL with high WBC is unclear. In the GMALL studies, these patients show a high relapse rate but also seem to have a higher mortality with chemotherapy and SCT.[135] In these patients, evaluation of MRD, use of experimental drugs, and SCT modalities seem to be particularly important.

IMMUNOPHENOTYPE AND CYTOGENETICS

The immunophenotype is an important independent prognostic variable in ALL. In ongoing trials it is used to adjust treatment regimens accordingly (eg, separate regimens for mature B-cell ALL). A further example for clinical application is the identification of patients for antibody therapy (eg, anti-CD20 in CD20-positive B-lineage ALL or B-cell ALL, and anti-CD52 in B- and T-lineage ALL).

T-Lineage Acute Lymphoblastic Leukemia

Results of treatment of T-cell ALL have substantially improved as compared with survival rates of 10% 20 years ago. Many groups have confirmed the superior outcome of T-lineage ALL as compared to B-lineage ALL.[118,134] There is, however, a substantial difference in outcome for the T-ALL subtypes. Thymic T-ALL, which accounts for one-half of the adult T-ALL patients, has a favorable outcome, with CR rates of 85% to 90% and survival rates greater than 50% at 5 years. Early T-ALL and mature T-ALL have poorer outcomes, with CR rates of 70% and LFS rates of approximately 30%.[134] The biologic importance of immunophenotype was underlined by the fact that elevated expression of HOX11, HOX11L2, SIL-TAL1, and CALM-AF10 is associated with subtypes (ie, maturation states) of thymocytes.[136] Other groups observed inferior outcomes for early T-ALL[137,138]; coexpression of CD13, CD33, and/or CD34[137]; HOX11L2- and SIL-TAL-positive T-ALL.[138] The German group reported poor survival associated with overexpression of ERG and BAALC.[139,140] Overexpression of HOX11, which is associated with thymic T-ALL, may confer a favorable prognosis. Notch1-activating mutations with so far unclear prognostic relevance were identified in up to 50% of T-ALL cases.[136] They may be targeted by γ-secretase inhibitors. Five percent of T-ALL show the NUP214-ABL1 aberration, which may identify a target population for imatinib therapy.[141]

The addition of cyclophosphamide and AC to the usual cytostatic drugs for ALL are mainly responsible for the improved outcome in T-ALL. HDM contributed to the improvement of survival in children[142,143] as did HDAC.[144,145] For adults, the benefit of HDM in T-cell ALL has to be confirmed in larger trials. With current treatment regimens, CR rates of more than 80% and an LFS above 50% can be achieved in T-ALL. New treatment approaches in adult T-ALL include purine analogues, such as nelarabine,[132] Forodesine,[146] or antibody therapy (eg, anti-CD52).

B-Lineage ALL

In *common* and *pre-B-ALL*, CR rates in adults have improved to 80% or more, but patients still relapse in most studies over a period of up to 5 to 6 years, and only one-third of these patients survive. With B-precursor ALL, prognostic factors are decisive for outcome; high-risk patients with adverse prognostic features, such as high WBC (>30,000/μL), late achievement of CR (>3–4 weeks), and Ph/BCR–ABL-positive status (see Table 66–11) have a survival rate of 25% or less, whereas standard-risk patients without any of those features have a 5-year survival of greater than 50%.[134]

Philadelphia chromosome/BCR–ABL-positive ALL had until recently been associated with the worst prognosis in children as well as in adults. Outcome is now improved dramatically.

Adults with the subtype *pro-B-ALL* or the *t(4;11)* translocation had a poor prognosis, as do infant ALL patients.[147] With intensive regimens, including HDAC and mitoxantrone as consolidation therapy, the results for adults seem to be improving.[55] Pro-B-ALL patients benefit from allogeneic SCT in first CR with survival rates of 60% in transplanted patients.[148] The adverse impact of the translocation t(4;11) seems to have changed with new treatment modalities.

In mature *B-cell* ALL, CR remission rates were low (40%) a decade ago, and remission duration was short (11 months).[149] A change was brought about by innovative childhood B-cell ALL studies that significantly improved outcome, with CR rates of 80% to 94% and an LFS rate of 63% (weighted mean).[149] The drugs responsible for the improvement were high doses of fractionated cyclophosphamide, HDM (0.5–8 g/m^2), and HDAC in

conjunction with the conventional drugs for remission induction in ALL given in short cycles at frequent intervals over a period of 6 months.

The application of these childhood B-cell ALL protocols in original or modified form also brought a substantial improvement in adult patients with B-cell ALL. CR rate reached 75% (62%–83%) and the LFS 55% (20%–71%).[149–151] Adverse-outcome prognostic factors were late CR (more than two cycles of chemotherapy), high WBC ($>30 \times 10^9$/L), and age more than 50 years. B-cell ALL has a higher incidence of CNS involvement at diagnosis and of CNS relapse. Therefore, effective measures against CNS disease, such as HDM and HDAC, as well as i.th. therapy, are important components of treatment regimens. Maintenance treatment has been omitted. Because relapses occur almost exclusively within the first year in childhood, as well as in adult B-cell ALL studies, patients thereafter can be considered to be cured.

Further significant improvement was achieved by the addition of antibody therapy with anti-CD20 (rituximab) because more than 80% of the patients are CD20-positive. With these regimens, survival rates above 70% to 90% can be achieved in adults with mature B-ALL or Burkitt lymphoma.[152,153]

The translocations t(8;14), t(8;2), and t(8;22) or c-myc aberrations are present in most cases of mature B-cell ALL and in Burkitt lymphoma. They may add information in cases with uncertain diagnosis. They have lost their poor prognostic significance, however, because of the improved treatment for patients with B-cell ALL or Burkitt lymphoma.

TREATMENT RESPONSE AND MINIMAL RESIDUAL DISEASE

Besides age, the most relevant prognostic factor in ALL is still the achievement of CR. Further prognostic factors related to treatment response are delayed time to CR or response to prednisone therapy. A more accurate approach to assess individual response is evaluation of MRD[62,154] because this is an independent prognostic factor that reflects primary drug resistance as well as individual completion of therapy and unknown host factors. The methods for detecting the burden of MRD have been described earlier and are summarized in Table 66–14.

Table 66–14 Methods for Detection of Minimal Residual Disease in Acute Lymphocytic Leukemia Patients

Method	Target	Sensitivity	Application B-Lineage ALL	T-Lineage ALL
Flow cytometry	Leukemia-specific immunophenotype	10^{-3}–10^{-4}	~35%	>90%
PCR	Fusion transcripts	10^{-4}–10^{-6}	~30%	~10%
PCR	Ig rearrangements (IgH, IgK)	10^{-4}–10^{-6}	>90%	~20%
PCR	TCR rearrangements (TCR-β, -δ, -γ)	10^{-4}–10^{-6}	~50%	>90%

ALL, acute lymphocytic leukemia; IgH, immunglobulin gene; PCR, polymerase chain reaction; TCR, T-cell receptor gene.

Data from Campana D, Pui C-H: Detection of minimal residual disease in acute leukemia: Methodological advances and clinical significance. Blood 85:1416, 1995; Beishuizen A, van Wering E, Breit TM, et al: Molecular biology of acute lymphoblastic leukemia: Implications for detection of minimal residual disease. In Hiddemann W et al (eds.): Acute leukemias. V. Experimental Approaches and Management of Refractory Disease. Berlin, Springer-Verlag, 1996, p 460.

Identification of High-Risk Patients as Candidates for Stem Cell Transplantation or Experimental Therapy

After start of consolidation a high burden of MRD ($>10^{-4}$) at any time point is associated with a high relapse risk of 66% to 88%[53] and the predictive value increases at later time points (months 6–9).[155] In the GMALL studies, patients with a high burden of MRD ($>10^{-4}$) after induction and first consolidation were identified as high risk and were considered candidates for SCT in first CR.[156]

Identification of Low-Risk Patients in Whom Treatment Intensity Reduction May Be Justified

This aim is more difficult to reach. An early and rapid decrease of MRD during induction is associated with a relapse risk of only 8%.[53] However, this course is observed in only 10% of the patients. In the GMALL studies, patients with negative MRD status after induction, which is repeatedly confirmed during the first year and measured with two sensitive markers, are considered as MRD low risk. It remains open whether any treatment reduction is justified in adult AU.

Assessment of Molecular Clinical Remission and Thereby Evaluation of Different Induction Therapies and Detection of Molecular Relapses

These are two important, new items for follow-up analysis in adult ALL. Molecular response provides a more individual impression of the response and is particularly important, because nowadays 85% to 90% of adult ALL patients achieve a cytologic CR. Even in phase II studies, "molecular relapse" is already an inclusion criterion. This makes sense because patients with an increase of MRD burden above 10^{-4} after achievement of a molecular CR are at a high risk for relapse (>80%), and therapeutic action should be taken.[157]

Risk Stratification According to Minimal Residual Disease

The approaches to integrate MRD analysis in prospective risk stratification of adults can be different in terms of (a) the time points sampled, (b) the selection of patients for MRD risk stratification, (c) combination of MRD-based and conventional risk factors, and (d) the MRD-based treatment decisions. It is hardly possible to identify adult low-risk patients in whom reduction of the intensity of therapy would be justified. In the GMALL study, these patients are defined according to very strict criteria to omit maintenance therapy. However, 20% to 30% of these patients relapsed. The major aim in MRD-based studies is therefore to identify patients with high risk of relapse for treatment intensification with SCT. It remains to be demonstrated that this is an effective strategy because patients with high MRD before SCT have an increased risk of relapse and might probably benefit from additional conventional, even experimental, therapy to reduce tumor load. On the other hand, it has to be questioned whether patients who are candidates for SCT based on conventional risk factors including Ph+ ALL should receive allogeneic SCT if they are MRD negative. The best strategy remains unknown.

Evaluation of the burden of MRD has not been without problems. The technical procedure is time-consuming, expensive and requires highly specialized staff. The predictive value depends on the technical quality such as sensitivity, 10^{-4} number of targets (at least two for immunoglobulin or TCR-rearrangements) and on the frequency of evaluations (3-monthly). At least in multicenter studies, these prerequisites can often not be fulfilled. Sensitivity of the evaluation of MRD with the exception of BCR–ABL based analysis is also

Table 66–15 Expression of Surface Antigens on Acute Lymphocytic Leukemia Blast Cells

Subgroup	Antigen	Expression on >20% of LBC*
B-Lineage	CD19	95% precursor

not sufficient to evaluate the efficacy of consolidation cycles because in most patients MRD is below the detection limit.

DRUG RESISTANCE

MDR-1 function has been associated with a poorer prognosis.[137,158] In vitro sensitivity testing was able to identify patients with resistance to conventional cytostatic drugs that were associated with an inferior prognosis. More recently it was demonstrated that in vitro resistance is associated with distinct gene expression profiles.[159] In vitro resistance testing is also increasingly used for effectivity testing of new cytostatic drugs. In the future, a prediction of response to induction regimens may be possible to adapt therapy to individual susceptibility.

NEW THERAPEUTIC APPROACHES IN ADULT ACUTE LYMPHOBLASTIC LEUKEMIA TREATMENT WITH MONOCLONAL ANTIBODIES

ALL blast cells express a variety of specific antigens such as CD20, CD19, CD22, CD33, and CD52 that may serve as targets for treatment with monoclonal antibodies (MoAb) (Table 66–15). MoAb therapy is an attractive approach because it is targeted, subtype specific, and compared to chemotherapy has different mechanisms of action and side effects. One prerequisite for Ab therapy may be the presence of the target antigen in at least 20% to 30% of the blast cells. Application may be most promising in a stage of low MRD level.[160]

Anti-CD20

Most experience has been had so far with rituximab, which is a chimeric MoAb to CD20 that is expressed on normal and malignant B lymphocytes. It exerts significant antitumor activity and its use has led to an improvement of results in B-cell non-Hodgkin lymphoma (NHL). CD20, defined as expression on more than 20% of the blast cells, is, however, also present on one-third of B-precursor ALL blasts, particularly in elderly patients (40%–50%), and the majority of mature B-ALL blast cells (80%–90%).

The anti-CD20 antibody has been successfully integrated in the therapy of mature B-ALL and Burkitt lymphoma. It is now also being explored in several pilot studies for CD20-positive B-precursor ALL. In a GMALL protocol for elderly patients, rituximab is administered prior to chemotherapy cycles starting during induction for a total of 8 treatments. Also the combination of Hyper-CVAD regimen with rituximab in B-precursor ALL was feasible and a favorable outcome with CD20-positive ALL was reported (reviewed in reference 161).

Anti-CD52

The CD52 antigen is expressed by most lymphatic cells and to a higher degree in T- compared with B-lymphoblasts. CD52 antibodies were first used for ex-vivo T-cell depletion of allogeneic bone marrow grafts to prevent GvHD without further GvHD prophylaxis. The humanized antibody Campath-1H has antitumor activity in CLL, T-PLL, and other T-NHL. Several studies with anti-CD52 therapy in adults with ALL are ongoing, either during relapse or at the time of MRD. The CALGB has integrated anti-CD52 therapy as consolidation in their frontline therapy and demonstrated its feasibility in a dose-finding study. Efficacy data are not available.[162]

Additional MoAbs (B43[anti-CD19]-Genistein, B43[anti-CD19]-PAP, and anti-B4-bR [anti-CD19]) have been investigated in phase I–II pilot trials in ALL. Antibodies developed for other diseases, such as anti-CD22 in lymphoma and anti-CD33 in AML, may be applicable in ALL because these antigens are expressed in 17% and 16% of adult ALL cases, respectively.

Antibody treatment could be administered as single agents or in combination with chemotherapy, for purging, and as posttransplant therapy and may be particularly effective in low burden disease (MRD-positive patients).

IMATINIB IN PH/BCR–ABL-POSITIVE ALL

In Ph/BCR–ABL-positive leukemia, the BCR–ABL fusion gene is causally involved in leukemogenesis and is considered to be essential for leukemic transformation. With a selective inhibitor of the Abl tyrosine kinase (STI571, imatinib), the cellular proliferation of BCR–ABL-positive CML and ALL cells can be inhibited.

Clinical Experience With Imatinib in Advanced Ph-Positive Acute Lymphoblastic Leukemia

In a multicenter phase II study, 56 patients with relapsed or refractory Ph+ ALL received imatinib at an initial daily dose of 400 mg PO, which was later increased to 600 mg; 60% of Ph+ ALL patients achieved a hematologic response. A complete hematologic remission with normalization of peripheral blood (PB) counts (ANC >1.5/nL, platelets >100/nL) was noted in 19% of patients. Rapid blast cell clearance occurred within 1 week of treatment in the majority of patients. It is noteworthy that the PB response did not necessarily correspond with a marrow BM response. Median estimated time to progression for ALL patients was 2.2 months.[163] Despite the rapid development of relapse, which occurs within weeks in many patients, some of these patients went on to SCT.[164] Response to imatinib therapy can be closely monitored by quantitative PCR.

Hematologic toxicity (grades III and IV) was frequent, but was rarely associated with serious infectious or hemorrhagic complications. Nonhematologic toxicity attributed to imatinib consisted primarily of mild to moderate gastrointestinal discomfort, peripheral and facial edema, and muscle cramps, and was readily manageable. No patient discontinued therapy because of nonhematologic adverse events. There were no imatinib-related deaths. Thus imatinib was well tolerated even in heavily pretreated patients.

Imatinib in the Treatment of Ph-Positive Acute Lymphoblastic Leukemia

In *younger patients* imatinib was first administered between chemotherapy cycles. However, with this approach no molecular remissions

were achieved. Therefore, studies with parallel application of chemotherapy and imatinib were started, leading to CR rates above 91% to 96% and molecular CR of 38% to 50%.[52,165–167] All studies reported an improved OS of 55% to 65% compared with 15% in studies before the imatinib era. No trial described increased toxicity compared to chemotherapy alone or negative effects on subsequent SCT.

In *older patients* outcomes with de novo Ph+ ALL treatment results have been previously extremely poor, with particularly high induction mortality. Therefore, induction chemotherapy was replaced by single-drug therapy with imatinib. The remission rate was 92% in an Italian trial.[168] The German study group (GMALL) conducted a randomized trial comparing dose-reduced chemotherapy and imatinib monotherapy. After induction, all patients received chemotherapy combined with imatinib. The remission rate for the imatinib arm was 93% as compared to 54% with chemotherapy.[169] The survival was superior to previous trials without imatinib, but in both arms the relapse rate was high and there was no difference in outcome.

At present, combination of chemotherapy and imatinib is the standard for treatment of younger patients with Ph+ ALL. Patients are still referred for SCT in first CR if possible. In elderly patients, imatinib monotherapy for induction seems reasonable—at least if a rapid response is observed. However, it remains unknown whether the high relapse rate may be decreased by a combination of imatinib with mild chemotherapy during induction or by intensification of consolidation. Furthermore, transition to the use of treatment with other tyrosine kinase inhibitors in case of molecular relapse or detection of mutations of BCR/AB2 is important.

Imatinib and Allogeneic Stem Cell Transplantation in Ph-Positive Acute Lymphoblastic Leukemia

It is known that MRD after SCT in Ph+ ALL is associated with a relapse probability exceeding 90%. Starting imatinib in the setting of MRD may decrease this high relapse rate. In a prospective study conducted by the GMALL, 27 Ph+ ALL patients received imatinib upon detection of MRD after SCT. MRD became undetectable in 52% after a median of 1.5 months. Each of these patients remained in remission at least for the duration of imatinib treatment. Failure to achieve MRD negativity shortly after starting imatinib predicted relapse, which occurred in 92% of these patients after a median of 3 months. LFS was 91% after 1 year in the molecular responders compared with 8% in the nonresponders.[170]

It remains unknown whether imatinib should be started in all patients after SCT or only in case of MRD detection. Anyway, continued MRD positivity after 2 to 3 months of imatinib identifies patients who will ultimately experience relapse and in whom additional or alternative antileukemic treatment should be initiated.

Mechanisms of Resistance to Imatinib

MRD detection often leads to early detection of molecular resistance or molecular relapse. Additional treatment can then be initiated before overt relapse occurs. Nowadays, an additional search for mutations of the tyrosine kinase domain of BCR/ABL is required because these mutations can confer resistance to imatinib and partly to the second-generation tyrosine kinase inhibitors Dasatinib and Nilotinib.[171,172] Both drugs have an increased efficacy compared to imatinib and are active in the majority of mutations—with the exception of the T315I mutation. The remission rate achieved with these drugs in patients who fail imatinib is approximately 30%. These second-generation drugs are currently being evaluated in patients who have relapsed, but trials for de novo Ph+ ALL are starting.

New Cytotoxic Drugs

In the past 10 years a variety of new drugs has been developed for use in ALL (reviewed in 83, 84, and 85). Nelarabine is a purine analogue that acts specifically on T lymphoblasts with a remission rate between 30% and 40% in relapsed T-ALL.[132,173] Treatment was generally well tolerated although neurotoxicity occurred in some patients. At present, application in frontline therapy is being evaluated. BCX1777 (Forodesine) is an inhibitor of the enzyme purine nucleoside phosphorylase and thereby acts on the similar system as purine analogues.[146] Clofarabine is a purine analogue without subgroup-specific effects. Other new drugs are liposomal preparations that may improve feasibility of treatment, for example, liposomal vincristine, daunorubicin, or liposomal cytarabine for i.th. application.

Future Risk Stratification and Treatment Concepts for Adult Acute Lymphoblastic Leukemia

The treatment of adult ALL has already become more sophisticated and complicated and will be even more so in the future. Treatment strategies depend on factors unrelated to the disease, such as the availability of a stem cell donor, patient-related factors, disease markers, treatment response, and availability of targeted drugs. Prognostic factors and patient characteristics therefore no longer only serve as the basis for identification of candidates for SCT in first CR but to define individualized treatment approaches, which are discussed in the following examples.

- *Subgroup-adjusted and targeted treatment*: Use of targeted drugs such as tyrosine kinase inhibitors, subgroup-specific purine analogues such as nelarabine, or monoclonal antibodies such as CD20 in mature B-ALL to increase subgroup-specific activity of treatment. These approaches have already led to significant improvement of outcome and will be refined in the future.
- *Age-adapted treatment*: In similar ways to subgroup-adapted treatment, therapies have to be defined for patients at both ends of the age spectrum, that is, for both elderly and adolescent patients. In elderly patients the major focus is on effective targeted therapy with as much quality of life as possible, whereas in adolescents the major aim is to deliver time- and dose-intensive chemotherapy based on pediatric protocols.
- *Individualized treatment*: New methods offer the option to adopt intensity and duration of therapy to individual response as measured by the presence of MRD or to add or omit specific drugs according to the results of an evaluation for drug resistance.
- *New integrated risk classification*: A variety of molecular markers newly detected by microarray analysis have been proposed as prognostic factors.[174] They may possibly be integrated in a conventional risk model that aims to identify patients for SCT in first CR and may rather stimulate analysis of underlying mechanisms, drug targets, or invention of treatment adaptations.
- *Risk-adapted indications for SCT*: Indications for SCT have to be defined carefully, taking into account not only long-term results but also acute and long-term toxicities. At present the majority of study groups stick to risk-adapted indications for SCT.
- *Evaluation of new cytostatic drugs*: Many of these drugs fit in subtype-adjusted, targeted therapies. Taking the number of targets and drugs into account, evidence-based priorities for clinical evaluation in relapsed ALL and for integration in frontline therapy have to be set.

Risk- and subtype-adjusted treatment strategies has led to considerable improvement in the outcome of patients with mature B-ALL, T-ALL, and Ph-positive ALL but to a lesser extent in adult patients with B-precursor ALL. Future strategies will integrate a variety of additional factors, thereby resulting in a more complex, flexible, and patient-specific treatment approach.[85] Besides these sophisticated approaches, a better adherence to protocols, support of patients to improve their compliance, and documentation of compliance would be warranted in adult ALL. Treatment should be done at experienced

centers, and closer cooperation between internal medicine and pediatric physicians including cooperative studies would be desirable.

Also, the design of prospective trials will be challenging because they will focus on even smaller subgroups of ALL and phase I studies with new drugs. These trials will only be possible in larger, international study groups that are able to recruit sufficient patient numbers. To enable any intergroup comparison, international efforts similar to that utilized to study childhood ALL are required to define uniform criteria for diagnostic classification, definition of subgroups, and even prognostic factors.

CHAPTER 67

MYELODYSPLASTIC SYNDROMES: BIOLOGY AND TREATMENT

Daniel J. DeAngelo and Richard M. Stone

Over the past several decades, many terms have been used to describe the bone marrow failure syndromes, which often terminate in an overt acute leukemia. The terms include refractory anemia (RA), preleukemia, smoldering acute leukemia, oligoblastic leukemia, refractory dysmyelopoietic anemia, and myelodysplastic syndrome.[1–5] Patients typically present with varying degrees of anemia, leukopenia, and thrombocytopenia, rendering many transfusion dependent or susceptible to infection or hemorrhage. The term *myelodysplastic syndrome* (MDS) is the currently accepted norm that is used to describe this clinical entity. MDS may arise either de novo or secondary to ionizing radiation, toxins or chemotherapeutic drug exposure.[6–11] The natural history of these syndromes ranges from an acute precipitous decline over several weeks to a chronic condition that lasts many years. The actual incidence of MDS is unknown. Unfortunately, the incidence rates of MDS were not reported to the National Cancer Institute's Surveillance Epidemiology and End Results (SEER) Program until 2001. Estimates in Europe range from 3 to 20 cases per 100,000, whereas in the United States, greater than 10,000 new cases are diagnosed each year (median age 76 years).[12–14] The incidence in men is significantly higher than in women (4.5 vs 2.7 per 100,000). MDS is rarely seen in patients younger than 50 years but rapidly increases with advancing age and may equal the incidence of acute myelogenous leukemia (AML) by the eighth decade.[15–17] For example, the age-specific incidence rates of MDS are approximately 5 per 100,000 for ages 60 to 69 years but increase to approximately 50 per 100,000 for ages 70 to 79 years.[18]

The various pathologic entities of MDS previously were classified by the French-American-British (FAB) Cooperative Group into five subtypes based on a set of criteria that included bone marrow morphology and the percentage of myeloblasts,[19] with the presence of greater than 30% myeloblasts classified as AML. The FAB classification scheme, based largely on the histologic changes within the bone marrow, has been extremely useful in assessing prognosis in patients with MDS, but the arbitrary division between MDS and AML based on the presence or absence of 30% myeloblasts is biologically inconsistent. In large studies, patients with refractory anemia with excess blasts in transformation (RAEB-T) and AML have similar outcomes. As a result, the World Health Organization (WHO) has adopted the definition of AML in a patient with 20% or greater myeloblasts and have removed the antiquated term RAEB-T.[20]

Most patients with MDS have progressive cytopenias, and a large fraction of patients eventually develop overt AML.[21] Patients with secondary AML from an underlying MDS typically are treated with multiagent chemotherapy in an attempt to delete the leukemic clone.[22] Nevertheless, the same problems exist as with MDS: advanced age, therapy-related toxicity, and resistant disease. Stem cell transplantation (SCT) remains the best chance for cure, but this strategy is not appropriate for the majority of patients due to their advanced age. Treatment of MDS ultimately is intended to extend overall survival by both improving the peripheral blood cytopenias and delaying the leukemic transformation. However, the more immediate goal of therapy is to relieve symptoms and improve the quality of life while minimizing side effects.

BIOLOGY

Pathogenesis

Myelodysplasia is the result of a transformation of a myeloid stem cell. A hematopoietic stem cell is capable of self-renewal and can give rise to more differentiated progeny.[23–26] As the stem cell differentiates it becomes lineage specific. An early pluripotent stem cell can give rise to both lymphoid and myeloid cells. However, the neoplastic transformation of the myeloid stem cell is the initial event that leads to myelodysplasia.[27] MDS rarely transforms into acute lymphocytic leukemia, thus suggesting that the MDS myeloid stem cell has lost its lymphopoietic potential.[28,29] Poorly defined transforming event(s) affects the pluripotent myeloid stem cell in MDS, thus conferring a growth advantage that eventually leads to development of monoclonal hematopoietic progeny. Many genetic mutations regulate this process, and these alterations determine both the biology and clinical aspects of the disease.[30]

The clinical hallmark of patients with myelodysplasia is the development of ineffective hematopoiesis (Fig. 67–1). Interestingly, cellular turnover within the bone marrow often is increased in most patients with myelodysplasia.[31] Cell kinetic studies have revealed a dramatic increase in the rate of cell division. The peripheral cytopenias are thought to be secondary to an increase in apoptosis, or programmed cell death, resulting in a futile increase in cell cycling.[32,33] Impaired cellular function is another important clinical feature of myelodysplasia. Erythroid precursors have a decreased response to erythropoietin (Epo), which may contribute to subsequent anemia.[34] In addition, terminally differentiated cells in MDS have functional defects. Mature granulocytes have decreased myeloperoxidase activity,[35–37] and platelets may have impaired aggregation properties.[38] The oncogenic pathway is not a single-step process. Sequential genetic changes are required to change a transformed myelodysplastic stem cell into a true neoplasm that often leads to development of AML.[39]

MDS is a clonal hematopoietic disorder.[40] Bone marrow cytogenetic analysis has been a great asset in the evaluation of the clonal nature of the MDS stem cell.[41–43] The clonal nature of MDS has been best elucidated by the use of X-inactivation studies.[44,45] These studies use restriction fragment length polymorphism (RFLP) analysis to study the differences between the methylation patterns of inactive versus active X chromosomes. RFLP analysis using the phosphoglycerate kinase and hypoxanthine phosphoribosyltransferase genes as well as the polymorphic genes of glucose-6-phosphate dehydrogenase all have demonstrated clonal hematopoiesis within the granulocyte, monocytic, erythroid, and megakaryocytic lineages in patients with MDS.

Apoptosis

Programmed cell death, referred to as *apoptosis*, is an important and active cellular process that regulates cell and lineage population.[46] The rate of apoptosis is finely regulated by the ratio of proapoptotic pro-

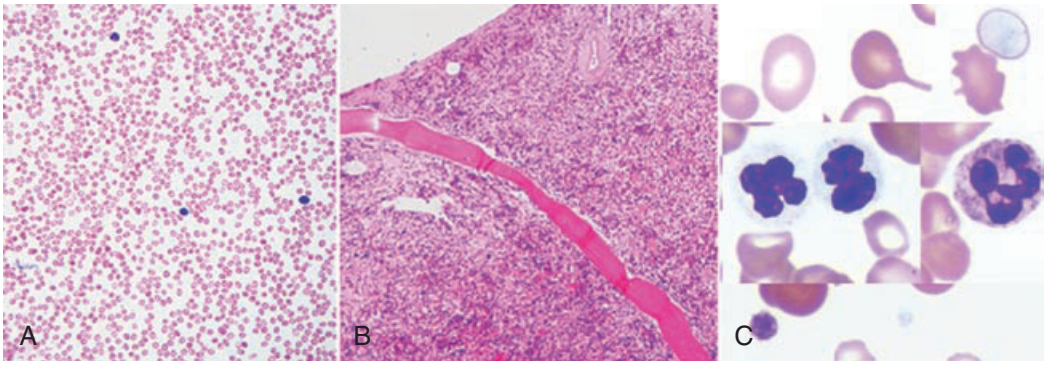

Figure 67–1 Elements of myelodysplastic syndrome. **A–C,** Myelodysplastic syndromes are generally characterized by cytopenias (**A**) due to ineffective hematopoiesis (**B**), which is related to multilineage dysplasia (**C**). **A,** This patient presented with a white blood cell count of 1,500/μL, hemoglobin 8.9 g/dL, and platelet count 47,000/μL. **B,** The bone marrow was hypercellular, indicating ineffective hematopoiesis. **C,** Evidence of trilineage dysplasia was apparent on the peripheral smear. Anisocytosis with macro-ovalocytes and poikilocytosis is seen in the red blood cells (**C, top**). The latter included the somewhat uncommon finding of Cabot ring forms (**right**). A large proportion of the granulocytes were severely hypogranular (**C, middle left**) compared to some normal forms still in the circulation (**right**). Platelets (**C, bottom**) were decreased in number, and many were severely hypogranular (**middle,** barely visible) compared to residual normal platelets (**left**).

teins, such as c-Myc, p53, Bax, and Bad, to the antiapoptotic proteins, which include Bcl-2 and Bcl-X_L.[47–50] Increased apoptosis has been documented within $CD34^+$ bone marrow cells in patients with MDS.[51] This increased apoptosis seems to be highest in patients with RA compared to those with RAEB and may account for the cytopenias that are the hallmark of early-stage MDS.[52–55] For example, the intracellular ratio of c-Myc to Bcl-2 is higher in $CD34^+$ cells in patients with MDS compared to those from normal patients or patients with AML.[56] In addition, an increased level of apoptosis is associated with increased levels of inhibitory cytokines, such as tumor necrosis factor (TNF)-α.[57] TNF-α is increased across all MDS subtypes and may inhibit the development and maturation of the hematopoietic precursors. TNF-α may increase the production and secretion of other proapoptotic cytokines, such as interleukin (IL)-6, transforming growth factor β, interferon γ, and Fas ligand. Use of growth factors, such as erythropoiesis-stimulating agents (ESAs) and granulocyte colony-stimulating factor (G-CSF), has been shown to decrease the rate of apoptosis in some patients.[58–60] These findings suggest that increased levels of apoptosis is associated with early-stage MDS, whereas decreased levels of apoptosis may help propagate the transformation from MDS to AML.[52,54,61–63]

Hematopoiesis

The colony-forming capacities of the pluripotent hematopoietic stem cells and their progeny are low or absent in many patients with MDS.[64] The bone marrow cells as well as peripheral T cells from patients with MDS seem to produce lower levels of granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, macrophage colony-stimulating factor (M-CSF), and IL-6. The colony-forming unit granulocyte-macrophage (CFU-GM) is less responsive to both G-CSF and GM-CSF in patients with MDS.[65,66] These findings are more dramatic in patients with RAEB or RAEB-T. In addition, the erythroid progenitor cell, burst-forming unit-erythroid (BFU-E), is less responsive to Epo in vitro.[64] There also seems to be a direct correlation between the size of the BFU-E and the Epo level in patients with MDS. These findings may help explain the peripheral blood cytopenias in patients with MDS and the observation that additional Epo is of limited clinical benefit.

Epigenetic

The term *epigenetics* is the alteration of gene expression without altering the primary DNA sequence.[67–70] These modifications can occur at multiple levels, the most common involving DNA methylation. DNA methylation involves the addition of methyl groups to a cytosine residue.[71–73] Cytosine methylation typically occurs when a cytosine is followed by a guanine in the so-called CpG pair. CpG pairs are underrepresented within the human genome, but when they do occur, they occur clustered in so-called CpG islands. These CpG islands typically are located proximal to gene promoter regions and regulate gene expression.[74,75] For example, methylation of CpG islands is associated with gene silencing. The process of gene silencing may be physiologic in the case of both imprinted genes as well as regulating gene dosage of genes on the X chromosome in females.[67] Tumor suppressor genes are thought to undergo this aberrant gene silencing mechanism, leading to abnormal physiologic consequences.

Epigenetic changes in MDS and AML have become increasingly important. For example, the promoter methylation of the α-catenin gene *CTNNA1* may be an important underlying abnormality involving the loss of chromosome 5.[76] Other examples include promoter methylation of the p15INK4B gene.[72,77,78] This gene often is hypermethylated in patients with therapy-related MDS or therapy-related AML. In addition, methylation changes of this gene are seen more frequently in patients with loss of chromosome 7 and in patients who progress from RA to RAEB.[78]

Genetic Pathways Involved in Disease Progression

The genetic changes that occur in patients who transform from MDS to AML are numerous, complicated, and involve a multistep process characterized by activation of specific oncogenes as well as inactivation of tumor suppressor genes.[39] RAS mutations are frequently identified in patients with hematologic malignancies.[79–81] In patients with MDS, RAS was mutated in as many as one third of the cases, with the highest frequency in patients with chronic myelomonocytic leukemia (CMML).[82] The FMS oncogene encodes for M-CSF and, like RAS, is most preferentially seen in patients with CMML. Mutations involving the p53 tumor suppressor gene on chromosome 17p is rarely identified in patients with MDS, but when seen they often correspond with disease progression and resistance to chemotherapy.[83,84] Although the FMS-like tyrosine receptor III (FLT-3) is the most common single mutated gene in patients with AML, it is mutated in less than 3% of patients with MDS.[85–88]

Most patients develop genetic alterations that include the gain or loss of part or whole chromosomes as well as specific gene mutations and promoter methylation changes.[89] For example, patients with abnormalities involving chromosome 5 and 7 often acquire additional mutations in p53, RAS, or both, followed by promoter methylation changes of p15.[87,90] This process often is involved in patients

with therapy-related MDS who previously received alkylating agent therapy and typically occurs 3 to 5 years after chemotherapy exposure.[88]

Genetic mutations that are commonly seen in patients who previously received a topoisomerase II inhibitor, such as the anthracycline doxorubicin, involve the complex acquisition of chromosomal translocations often involving the mixed lineage leukemia (MLL) gene on 11q23.[91–101] More than 30 different translocations have been identified that involve 11q23, and they account for approximately 5% of all translocations that occur in acute leukemia. Reciprocal translocations involving the 11q23 gene have been described in patients with acute lymphoblastic leukemia (ALL), AML, acute biphenotypic leukemia, and MDS. Other chromosomal translocations that are seen less commonly after anthracycline exposure include the AML1 gene on 21q22 often leading to translocation of t(3;21),[91] the core-binding factor β (CBF-β) gene on chromosome 16 leading to inversion of chromosome 16 [inv(16)],[92] and the retinoic acid receptor α (RAR-α) gene on chromosome 17 characterized by translocation t(15;17) and development of acute promyelocytic leukemia.[93–95] In addition, mutations of the NUP98 gene on chromosome 11p15 have been associated with exposure to topoisomerase II inhibitors.[96,97] These cytogenetic changes characterized by specific chromosomal abnormalities, with the notable exception of NUP98 on 11p15, subsequently develop RAS, BRAF, c-KIT, or FLT-3 mutations, followed by changes in the methylation pattern within the p15 promoter.[98,99]

Patients with a normal cytogenetic karyotype or other nonspecific chromosomal abnormalities often evolve from an MDS to an AML phenotype with a different and distinct process. These patients typically develop acquisition of a RAS mutation or another mutation involving a transcription factor,[100] which are known as class II mutations, or mutations involving tyrosine kinases, which are known as class I mutations. Examples of class I mutations include FLT-3, c-KIT, c-FMS, and JAK2.[101,102] Also included are genes further downstream within the RAS-BRAF-MEK-ERK pathway. They include N-RAS, K-RAS, BRAF, and PTPN11. This class of mutations results in the constitutive activation of the cell cycle leading to an increase in cell proliferation. For example, mutations in RAS are commonly seen in monocytic subtypes of AML and in CMML, whereas PTPN11 genes are commonly mutated in juvenile myelomonocytic leukemia.[103,104] The class I mutations are considered "late events" in the pathogenesis of leukemia but are thought to cooperate to a high degree with class II mutations. Examples of class II mutations that can be seen in patients who transform from MDS to AML include CCAAT enhancer-binding protein α (CEBPα), AML1, and rarely internal tandem duplications of MLL (MLL-PTD).[105–107]

As expected, patients with de novo and therapy-related MDS and AML have heterogeneous clinical presentations but often have similar cytogenetic abnormalities.[89,108,109] Although three distinct cytogenetic subgroups can be identified (chromosome 5/7, MLL gene on 11q23, and normal karyotype), many different genetic pathways have been outlined for patients with therapy-related MDS and therapy-related AML. Some of these changes are more consistent with the clinical presentation of MDS (e.g., −5/5q− or −7/7q−), whereas other abnormalities are more often related to the presentation of overt AML [e.g., translocations involving 11q23, inv(16), and t(15;17)]. However, the frequent association of both class I and Class II mutations argues strongly for their cooperative nature in the development of MDS and AML.[110]

DIFFERENTIAL DIAGNOSIS

Before a diagnosis of MDS can be made, it is important to consider alternative diagnoses, especially if the patient is younger than 50 years (Table 67–1). Although most patients with MDS have a normal or hypercellular bone marrow, approximately 10% to 15% of patients have a hypocellular bone marrow that may be difficult to distinguish from aplastic anemia.[111] The presence of a clonal chromosomal abnormality will confirm the diagnosis of MDS.[112] In addition, patients with aplastic anemia typically have greater TNF receptor expression than do patients with MDS.[113] It is important to rule out the diagnosis of paroxysmal nocturnal hemoglobinuria (PNH).[114] Patients with hypocellular MDS have a clinical presentation similar to patients with aplastic anemia and have a better overall prognosis compared to other patients with MDS, especially patients who respond to immunosuppressive therapy.[115,116]

Similarly, the presence of myelofibrosis may make adequate assessment of the bone marrow aspirate difficult.[117,118] Patients with significant fibrosis within the marrow cavity often have an unaspiratable and/or aspicular aspirate specimen. Therefore, the ability to analyze the bone marrow aspirate for dysplastic features is markedly limited. However, in some patients, the diagnosis of myelodysplasia can be easily made, and the bone marrow biopsy shows an increased number of reticulin fibers.[119] Reticulin stain, typically by silver impregnation, is an important method for identifying underlying marrow fibrosis but should be distinguished from marked collagen fibrosis, which is seen often in patients with chronic idiopathic myelofibrosis (agnogenic myeloid metaplasia with myelofibrosis). Extensive mature collagen fibrosis can be demonstrated by trichrome stain and is extremely uncommon in patients with MDS. Although marrow fibrosis can be seen in all subtypes of MDS, it is more frequent in CMML and therapy-related MDS.[120] Patients with MDS and fibrosis can be distinguished from patients with chronic idiopathic myelofibrosis.[121] The latter entity is associated with marked splenomegaly, an unusual feature in patients with MDS regardless of the degree of marrow fibrosis. The absence of splenomegaly and an unusually rapid progressive clinical course helps distinguish patients between MDS and chronic idiopathic myelofibrosis, which usually is more indolent. Other disorders to consider in cases of extensive fibrosis include chronic myelogenous leukemia (CML), especially accelerated phase disease, and acute megakaryocytic leukemia (FAB-M7).[122]

Table 67–1 Predisposing Factors and Epidemiologic Associations of Patients with Myelodysplastic Syndrome

Heritable
Constitutional Genetic Disorders
Trisomy 8 mosaicism
Familial monosomy 7
Down syndrome (trisomy 21)
Neurofibromatosis 1
Germ cell tumors [embryonal dysgenesis del(12p)]
Congenital Neutropenia
Kostmann syndrome
Shwachman-Diamond syndrome
DNA Repair Deficiencies
Fanconi anemia
Ataxia-telangiectasia
Bloom syndrome
Xeroderma pigmentosum
Pharmacogenomic polymorphisms (GSTq1-null)
Acquired
Senescence
Mutagen Exposure
Alkylator therapy (chlorambucil, cyclophosphamide, melphalan, N-mustards)
Topoisomerase II inhibitors (anthracyclines)
β Emitters (^{32}P)
Autologous stem cell transplantation
Environmental/occupational (benzene)
Tobacco
Aplastic anemia
Paroxysmal nocturnal hemoglobinuria

Variants of CML as well as atypical CML can be difficult to distinguish from CMML.[123] The WHO currently lists CMML in its own category; therefore, it is no longer considered part of the myelodysplastic syndromes.[20] Nevertheless, the differential is important. CML is distinguished by the presence or absence of a BCR-ABL fusion gene.[124] The term *atypical CML* represents a diffuse group of disorders that are BCR negative.[125] Their clinical prognosis is somewhat worse than in patients with BCR-ABL given the inability to target a tyrosine kinase. Patients with atypical CML often have a short overall survival and poor response to therapy. Clinically, they can be distinguished from patients with other forms of MDS by an increase in basophilia and progressive leukocytosis as well as organomegaly, specifically splenomegaly.[126] These patients typically have marked thrombocytopenia and eventually develop marrow failure without transformation to AML. In a review of 76 BCR-negative patients from the MD Anderson Cancer Center, the median overall survival was 24 months, with AML transformation in eight patients. Chromosomal abnormalities were seen in 30% of patients, with trisomy 8 the most common abnormality identified. Patients with atypical CML can be difficult to separate clinically and pathologically from patients with MDS or other myeloproliferative disorders.

Dysplastic hematopoiesis is a common finding accompanying human immunodeficiency virus (HIV) infection.[127,128] An HIV serologic test must be obtained in order to exclude HIV infection, especially in patients with high-risk lifestyles, as well as young patients. The typical bone marrow aspirate and biopsy findings in patients with HIV infection include a hypercellular marrow and evidence of trilineage dysplasia, which is most predominant within the erythroid lineage.[129,130] The erythroid hematopoiesis almost always is megaloblastic, and reticulated fibrosis is often seen in bone marrow biopsies. Most patients have polyclonal plasma cell expansion, and lymphoid aggregates and/or granulomas are often seen. The differential diagnosis of erythrodysplasia in patients with HIV infection includes medications, opportunistic infections, or a direct effect of HIV on the hematopoietic progenitor cells. These findings reaffirm the need for serologic screening for HIV in patients with unexplained cytopenias.

A number of drugs can cause erythrodysplasia and complicate the evaluation and diagnosis of a patient with cytopenias. These medications include valproic acid,[131] mycophenolate mofetil,[132] ganciclovir,[132,133] alemtuzumab,[134] nucleoside analogues such as fludarabine and cytarabine, and the anti-metabolites mercaptopurine and methotrexate. The bone marrow changes associated with these medications include macrocytic anemia, reduced neutrophil lobation, and frank neutropenia and thrombocytopenia. In fact, some patients may have trilineage dysplasia, making an accurate diagnosis difficult.

Nutritional deficiencies must be excluded in any patients in whom the diagnosis of MDS is being entertained. These include vitamin B_{12} and folate deficiency[135] and copper deficiency.[136,137] Copper deficiency in adult patients is rare but can occur after gastrectomy, prolonged parenteral nutrition, or even enteral feeding if copper is not included in the formulation. Rarely, copper deficiency develops after ingestion of large amounts of zinc supplements, as zinc excess results in concomitant copper deficiency. Clinically, patients with copper deficiency present with signs and symptoms of profound anemia. In addition, copper deficiency may cause a variety of neurologic complications, including central nervous system demyelination, peripheral neuropathy, myelopathy, and even optic neuritis. In patients with severe cooper deficiency, hemoglobin levels may fall as low as 3.5 g/dL. The mean corpuscular volume often is normal or slightly increased, and the red cells on the peripheral smear are hypochromic and microcytic. Patients typically present with mild neutropenia with neutrophil counts of 1000/mL. Bone marrow examination will reveal a cellular marrow with early erythroid vacuolization and moderate numbers of ringed sideroblasts.

A number of drugs may induce sideroblastic anemia, including isoniazid[138] and chloramphenicol.[139,140] Cycloserine and pyrazinamide also have been implicated in rare cases. With isoniazid, the anemia is modest, with hematocrits typically in the 26% range, low mean corpuscular volume, and dimorphic red cell morphology. Abundant ringed sideroblasts are present within the bone marrow, and typically the anemia is rapidly reversed with discontinuation of the offending agent. However, administration of large doses of pyridoxine up to 200 mg/day may accelerate reversal of the anemia.

Although chloramphenicol typically produces a ringed sideroblastic anemia, an idiosyncratic marrow failure syndrome associated with chronic administration also can be seen. When this occurs, a prominent feature within the bone marrow is vacuolization, specifically of the early erythroid precursors. Patients often have marked reticulocytopenia and increased serum iron levels. In most cases, the anemia is reversed with discontinuation of the drug; however, some patients may have profound, long-lasting evidence of marrow failure.

Sideroblastic anemia is associated with alcoholism with or without folate and vitamin B_{12} deficiency.[141] As many as one third of patients who are chronic alcoholics may have sideroblastic changes within the bone marrow, including dimorphic erythroid cells. Patients often have a markedly elevated mean corpuscular volume, which is impressively uniform. The ringed sideroblasts often disappear within days to weeks after discontinuation of alcohol intake.[142] However, concurrent vitamin deficiencies and/or liver disease may further affect the peripheral blood cytopenias and, importantly, the recovery phase.

CLINICAL FINDINGS IN PATIENTS WITH MDS

Erythroid Cells

The diagnosis of myelodysplasia in patients with anemia, neutropenia, thrombocytopenia, or a combination thereof depends on the demonstration of dysmorphic features within the bone marrow (Table 67–2 and Fig. 67–2). Both a bone marrow aspirate and a biopsy should be obtained. An aspirate usually can assess cellular morphology and quantitation of myeloblasts, but accurate assessment of bone marrow cellularity and localization of immature precursors

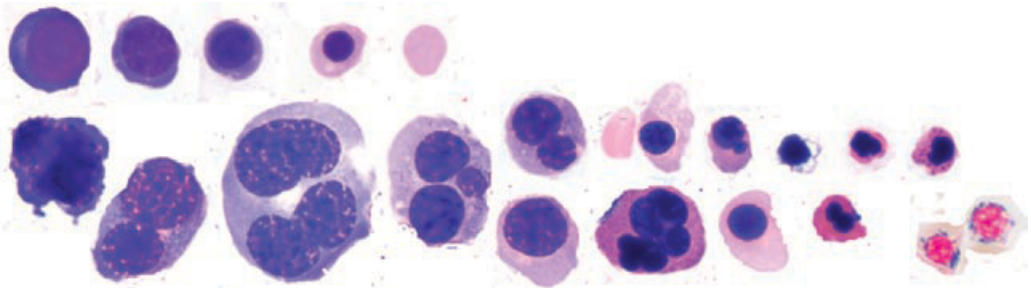

Figure 67–2 Erythroid dysplasia. Examples of dysplastic erythroid precursors (**bottom**) compared to those with normal morphology in the sequence of erythroid maturation (**top**). The dysplastic forms include (**left to right**) abnormal immature forms with multinucleation, maturing forms with multinucleation and nuclear-to-cytoplasmic dyssynchrony, and more mature forms with megaloblastoid change, nuclear budding, cloverleaf forms, cytoplasmic vacuolization, and cytoplasmic stippling. Ringed sideroblasts (**far right**) also are evidence of erythroid dysplasia. Photographs from a patients with refractory cytopenia with multilineage dysplasia and ringed sideroblasts.

Medical History
Duration of symptoms
History of blood disease
History of exposure to occupational toxins or cytotoxic agents
Medication history
Alcohol intake
Comorbid conditions
Physical Examination
Pallor
Petechiae
Purpura
Bruising
Tachypnea
Signs of infection
Splenomegaly
Laboratory Testing
Complete blood count with a manual differential
Reticulocyte count
Vitamin B_{12} and folate levels
Consider methylmalonic acid and red blood cell folate levels
Iron, total iron-binding capacity, and ferritin level
Thyroid-stimulating hormone level
Lactate dehydrogenase
Antinuclear antibody
Coombs test and haptoglobin
Serum erythropoietin level
Human leukocyte antigen (histocompatibility antigens) typing in appropriate patients
Paroxysmal nocturnal hemoglobinuria screen
Bone Marrow Testing
Hematopathology
Percentage of blasts on 200 cell aspirate differential
Presence or absence of Auer rods
Percentage of cellularity of bone marrow biopsy
Iron stain on aspirate (ringed sideroblasts)
Iron stain on biopsy (storage)
Dysplastic features (% and number of dysplastic lineages)
Cytogenetics (karyotype of 20 metaphase cells)
Fluorescent in situ hybridization
Flow cytometry (not useful for quantitation)

require a review of the biopsy sections. Occasionally multiple sampling is required to make a definitive diagnosis because the affected bone marrow is distributed unevenly or the patient develops progressive dysplastic features over time.

Almost all patients with MDS (>90%) present with fatigue and lethargy, which is associated with chronic anemia.[143] The anemia most often is macrocytic, with a significantly reduced reticulocyte index. The most recognized morphologic abnormality of the red blood cells (RBCs) on examination of the peripheral blood smear consists of oval macrocytes; however, in rare cases, teardrop cells or dacrocytes, elliptocytes, and acanthocytes are seen.[144] It remains essential to exclude other causes of macrocytic anemia in this population, including vitamin B_{12} and folate deficiency.[145] The anemia in patients with MDS is a result of ineffective erythropoiesis. Epo levels usually are normal or elevated.[3,146] In addition, most patients have evidence of abnormal iron utilization. Other patients have evidence of increased fetal hemoglobin synthesis,[147] abnormal red cell antigens,[148] increased red cell fragility, and low levels of pyruvate kinase. The latter two abnormalities may result in an abnormal Ham test secondary to increased hemolysis.[149]

It is important to exclude the diagnosis of PNH even in patients without a history of thromboembolic disorders. The most efficient test is the absence of polyinositol glycol-associated antigens by flow cytometric analysis due to the absence of the PIG-A gene. PNH is diagnosed by the absence of CD55 and CD59 on red blood cells, and the absence of CD11b on monocytes.[150,151] Some patients have a small clone of PNH cells, but this finding is of unclear clinical significance.[152,153] Other possible features of MDS include disordered α- and β-globin chain synthesis[154,155] and hemoglobin H inclusions.[156]

Morphologic features within the bone marrow aspirate include megaloblastic erythroid precursors, often with multiple nuclei or asynchronous maturation of the nucleus and cytoplasm. Occasionally, ringed sideroblasts, which are red cell precursors with iron-laden mitochondria, can be identified.[157] Ringed sideroblasts are defined by the presence of at least five Prussian blue-staining iron granules encircling more than one third of the nucleus of an erythroblast. The presence of ringed sideroblasts without morphologic features of dysplasia also can be seen in unrelated congenital and malignant hematologic conditions. RA and refractory cytopenia with multilineage dysplasia (RCMD) typically are differentiated from refractory anemia with ringed sideroblasts (RARS) and refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-S) by the presence of greater than 15% ringed sideroblasts.[158]

One unusual feature of the FAB classification scheme occurs when greater than 50% of the total cellularity is composed of erythroid precursors.[19] In this case, if greater than 30% of the nonerythroid cells are myeloblasts, a diagnosis of erythroleukemia is made (FAB-M6A). This differs from the pure erythroleukemia described by Deguglielmo (FAB-M6B).

Myeloid Cells

A large proportion of patients, approximately 50%, with MDS either present with neutropenia or develop neutropenia as a result of disease progression.[159] Not only is MDS associated with a quantitative neutrophil defect but also with qualitative defects. Patients with MDS often have a reduced inflammatory response to infections. Patients with MDS have diminished production of many hematopoietic growth factors, and these likely account for the qualitative neutrophil defects and their reduced phagocytic properties. In spite of this, recurrent infections occur in only 10% of patients,[160] but this is the cause of death in approximately one-fifth of the patients with MDS.[161]

The most common infections in patients with MDS are bacterial, usually from the lower respiratory tract, skin, or perineal area. Recurrent infections can occur even in the absence of severe neutropenia, likely from granulocyte functional impairment. In patients with CMML,[162,163] the monocytes are also derived from defective hematopoietic stem cells and similar qualitative defects in terms of cell adhesion and phagocytic and cell killing properties leading to an increased rate of infections.

Abnormalities of the myeloid series range from subtle to rather striking (Fig. 67–3).[19] They include a left shift toward more immature forms, even without an excess of myeloblasts. The myeloid precursors also may show asynchronous maturation of the nucleus and cytoplasm as manifested by a lack of granule formation. The nucleocytoplasmic dyssynchrony is most clearly represented in the early myeloid cells, or *abnormal promyelocytes*. Their granular cytoplasm, reticulated nucleus, and prominent Golgi apparatus characterize these dysplastic promyelocytes. The more mature granulocytes often are hypogranulated and may be hypolobated as well. Granulocytes with a bilobed nuclear structure are referred to as pseudo–Pelger-Huet cells.[164] There is a congenital abnormality in pediatric patients in which all of the neutrophils are bilobed or hyposegmented; this is termed the Pelger-Huet anomaly, which is a benign condition.

The most critical finding in patients with MDS is the presence and quantification of the myeloblasts. The absolute proportion of

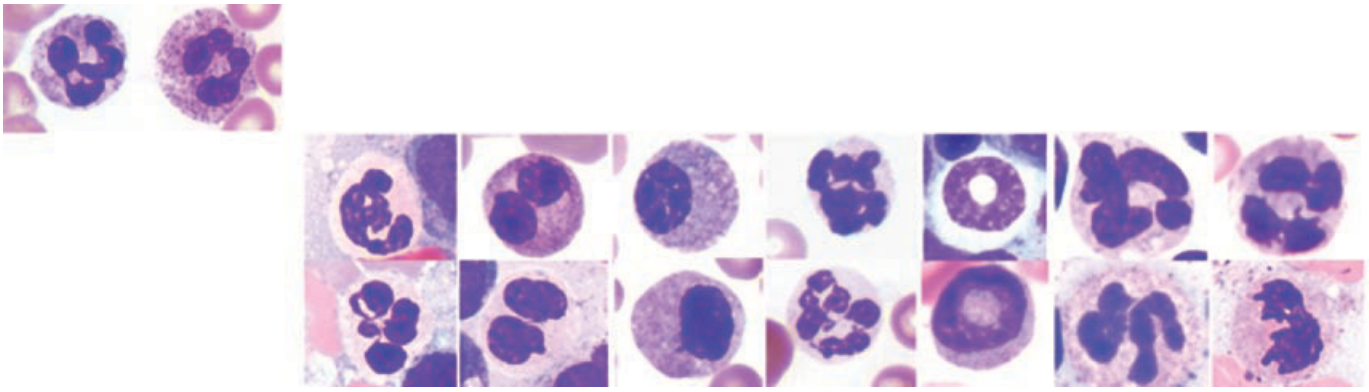

Figure 67–3 Granulocytic dysplasia is most evident in mature neutrophils (**bottom**) and can be contrasted to features of normal forms (**top**), which usually still are present as a subpopulation of the total cells in most cases. Granulocytic dysplasia is characterized by (**left to right**) reduced cytoplasmic granulation, nuclear hypolobation (resulting in the binuclear or single-lobed pseudo–Pelger-Huet forms), hypersegmentation, ringed forms ("rodent cells"), cells with nuclear twinning, and cells with excessive nuclear excrescences. Photographs from a number of cases of refractory cytopenia with multilineage dysplasia and refractory anemia with excess blasts.

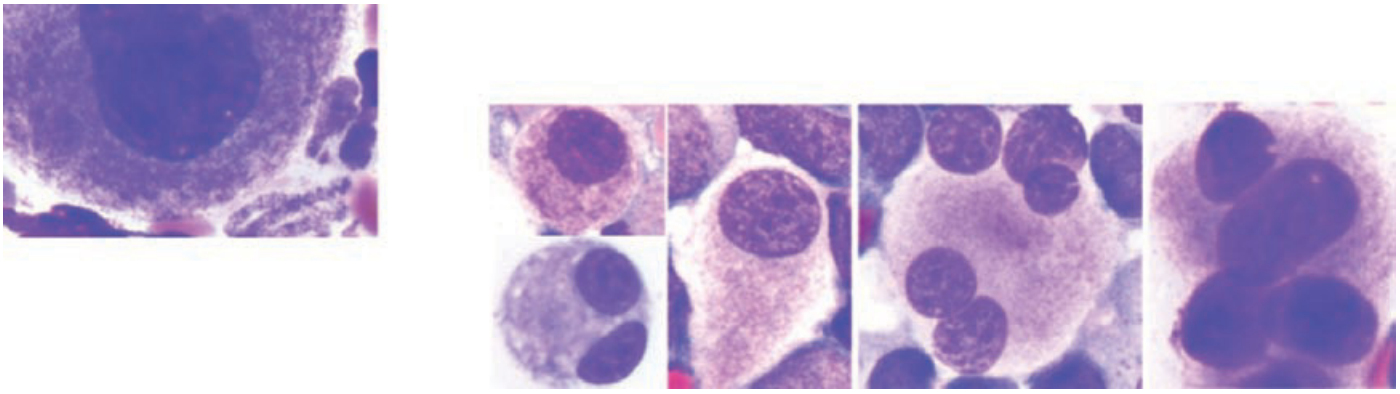

Figure 67–4 Megakaryocytic dysplasia. Dysmegakaryopoiesis is most obvious with the presence of micromegakaryocytes and abnormal larger forms (**bottom, right**). These are compared to a normal megakaryocyte (**top, left**). Micromegakaryocytes have single, two or four small nuclei, which indicate a low ploidy level. Normal low-ploidy megakaryocytes can be seen in the bone marrow, but these are immature forms and do not have mature granular cytoplasm with platelet material, as do the micromegakaryocytes. Larger dysplastic megakaryocytes have multiple, small, widely spaced nuclei. Photographs from a number of cases of refractory anemia with excess blasts and refractory cytopenia with multilineage dysplasia.

myeloblasts reflects the defect in the differentiation capacity of the abnormal hematopoietic stem cell and represents the most important prognostic finding. The diagnosis of AML is established if there are more than 20% myeloblasts based on the WHO classification scheme or greater than 30% based on the older FAB criteria.[19,20] Quantification of myeloblasts should be performed on a cellular and spicular bone marrow aspirate and not by flow cytometric analysis, because the latter can be effected by peripheral blood dilution of the sample.

Megakaryocytes

Thrombocytopenia is present in approximately half of patients with MDS and may represent the only cytopenia in 5% of cases.[165] The finding of thrombocytosis is uncommon and typically associated with either the 5q syndrome[166] or a JAK2 mutation, as is the case in patients with refractory anemia with ringed sideroblasts and thrombocytosis (RARS-T).[167] As in the case with neutrophils, patients with MDS often have both a quantitative as well as a qualitative defect with their platelets.[38] The latter can be identified by careful examination of the peripheral blood smear, on which giant or agranular platelets often are identified. Upon examination of the bone marrow, the megakaryocytes often are small or micromegakaryocytic and contain fewer nuclear lobes (hypolobated) than their normal counterparts (Fig. 67–4).[19,164,168] In patients with the 5q syndrome, the megakaryocytes are nonlobated and mononuclear.[166]

Patients may have disproportionately prolonged bleeding times and abnormalities in platelet aggregation studies.[38,169–171] These may be present even in patients with normal platelet counts. The hallmark is an acquired Glanzmann defect, characterized by abnormal platelet glycoprotein IIb/IIIa. A falling platelet count often is a marker of disease progression. Patients with MDS are at risk for spontaneous bleeding and have increased risk for hemorrhage following surgery and trauma. Again, this is true even in patients without thrombocytopenia.

Autoimmune Manifestations

Immunologic and rheumatologic complications occur frequently in patients with MDS.[172–174] Patients can present with acute episodes of seronegative oligoarthritis or polyarthritis[175,176] as well as symptoms of cutaneous vasculitis, polymyositis, or peripheral neuropathies. Lupus-like symptoms have been reported at the time of the presentation of cytopenias in patients complaining of systemic features of fever, polyarthritis, polychondritis, pleuritis, pericarditis, or even hemolytic anemia. Presentations involving mucocutaneous ulcerations, iritis, polymyositis, peripheral neuropathy, inflammatory bowel disease, and red cell aplasia have been reported in patients with MDS.[177] In addition, cases of relapsing polychondritis, polymyalgia rheumatica,[172,178,179] Raynaud phenomenon, pyoderma gangrenosum, Sjögren syndrome, and glomerulonephritis have been reported, but their association is less clear.[180] Although these paraneoplastic

processes may complicate the initial clinical presentation of MDS, they are often responsive to immunosuppressive agents such as corticosteroids.[181]

Dermatologic Manifestations

Cutaneous complications of MDS are rather uncommon.[182] Neutrophilic dermatosis (Sweet syndrome) is one exception. It is characterized by painful plaque-like lesions that often are associated with fever and arthralgias. These lesions can be present on the face, neck, or upper or lower extremities. Sweet syndrome usually responds to corticosteroid or dapsone therapy. It is often present in patients who are transforming to AML. Other dermatologic presentations include monocytic infiltrates, which are more common in patients with CMML[163,183,184]; chloroma or granulocytic sarcoma, which if present would constitute AML; and petechial lesions, which are common in any patient who presents with severe thrombocytopenia.

Findings on Physical Examination

The physical examination of a patient with MDS typically is rather unrevealing (see Table 67–2). Most patients will pallor due to anemia; petechiae is less commonly present as a result of thrombocytopenia.[185] Signs and symptoms of an infectious process, either bacterial or fungal, should be ruled out. Splenomegaly, hepatomegaly, and lymphadenopathy are rather uncommon, except for patients with CMML.[163]

CLASSIFICATION AND PROGNOSIS OF PATIENTS WITH MDS

Classification Systems

The myelodysplastic syndromes are a heterogeneous group of clonal hematologic disorders characterized by persistent peripheral blood cytopenias and proliferation of myeloblastic leukemia cells.[21] Since the early 1980s, several groups have developed classification schemes for patients with MDS that can be used for prediction of survival as well as rate of transformation to overt AML. The FAB consensus conference in 1982 described a classification scheme that includes both acute myelogenous leukemia and myelodysplasia.[19] Five categories of MDS were described based on the bone marrow morphology of bone marrow aspirates, specifically requiring patients to have >10% dysplasia within two or more cell lines. Patients were separated into five groups primarily based on the percentage of myeloblasts within the bone marrow aspirate. These categories are RA, RARS, RAEB, RAEB-T, and CMML (Table 67–3). The diagnosis of acute leukemia required at least 30% myeloblasts within the bone marrow or peripheral blood; patients with 30% or fewer myeloblasts were classified as myelodysplasia.

With the exception of RARS and CMML, the subgroups of MDS are stratified by the percentage of blasts within the peripheral blood or bone marrow. The first two categories, RA and RARS, have fewer than 5% myeloblasts in the bone marrow. Patients with RA and RARS tend to have a longer median overall survival and a lower rate of progression to acute leukemia than patients in the other categories. Patients with RAEB and RAEB-T have between 5% and 20% or between 21% and 30% myeloblasts within the bone marrow, respectively. These patients often have more severe cytopenias, increased risk of progression toward acute leukemia, and shorter overall survival time. Patients with CMML represent a heterogeneous group.[162,163] Some patients have a more MDS-like picture, with significant pancytopenia and trilineage dysplasia within the bone marrow. Other patients have more of a myeloproliferative-like picture, with elevated white blood count, peripheral monocytosis, splenomegaly, and hypermetabolic symptoms. The median survival of patients with MDS-CMML was 23 months versus 15 months for patients with myeloproliferative disorder (MPD)-CMML ($P = 0.31$), and both groups had nearly identical risk of progression to AML.[186,187]

The FAB classification scheme led to marked improvement in the diagnosis of myelodysplasia. It also served as a general prognostic predictor. However, there still exists considerable variation within the groups with respect to overall survival and clinical features. Several prognostic systems have been devised to better predict the outcome of individual patients. For example, prognosis is inversely related to the number of bone marrow myeloblasts, and cytogenetics have an extremely important impact on overall survival.[188] The International Myelodysplastic Syndrome Risk Analysis Workshop (IMRAW) has developed an International Prognostic Scoring System (IPSS) based on an analysis of more than 800 patients (Table 67–4).[189] This analysis revealed that the most important variables for overall prognosis were specific cytogenetic abnormalities, percentage of myeloblasts within the bone marrow, and number of the lineages involved in the cytopenia. Other adverse prognostic features include age greater than 60 years and male sex. Isolated loss of the Y, 5q, or 20q chromosome or the presence of a normal karyotype is associated with a favorable prognosis. Adverse prognostic cytogenetic features included abnormalities of chromosome 7 or complex cytogenetic changes defined as having more than three cytogenetic anomalies. This scoring system divided patients into four categories: low, intermediate-1, intermediate-2 and high-risk groups. The overall median survival for these groups was 5.7, 3.5, 1.2, and 0.4 years, respectively.[189] There are several limitations of using the IPSS for individual patients. First, the IPSS is heavily weighted on the percentage of blasts within the bone marrow aspirate.[190] Second, only a limited number of cytogenetic abnormalities were described within the IPSS, and their prognostic importance is significantly underestimated. Finally, the various cytopenias not only have the same impact on the overall IPSS score, but by themselves they are clinically meaningless.

A significant limitation of the FAB classification scheme derives from the arbitrary boundaries imposed within the continuum of disease categories. Patients with RAEB, RAEB-T, and AML likely represent a similar biologic process. Use of 30% myeloblasts within the bone marrow as the division between myelodysplasia and acute

Table 67–3 French-American-British Classification Criteria

Subtype	Abbreviation	Peripheral Blood	Bone Marrow
Refractory anemia	RA	Blasts <1%	Blasts <5%
Refractory anemia with ringed sideroblasts	RARS	Blasts <1%	Blasts <5%, and >15% ringed sideroblasts
Refractory anemia with excess blasts	RAEB	Blasts <5%	Blasts 5%–20%
Refractory anemia with excess blasts in transformation	RAEB-T	Blasts >5%	Blasts 20%–30% or Auer rods
Chronic myelomonocytic leukemia	CMML	Monocytes >1 × 10^9/L	Any of the above
Acute myelogenous leukemia	AML		Blasts >30%

Description of syndromes from Bennett et al.[19]

Table 67–4 International Prognostic Scoring System for Myelodysplastic Syndrome

Overall Score[a]	Median Survival (Years)	25% AML Evolution (Years)
Low (0)	5.7	9.4
Intermediate-1 (0.5–1.0)	3.5	3.3
Intermediate-2 (1.5–2.0)	1.2	1.1
High (≥2.5)	0.4	0.2

The percent of myeloblasts are scored as follows: <5% = 0; 5%–10% = 0.5: 11%–20% = 1.5: 21%–30% = 2.0.

Cytogenetic features associated with good prognosis are scored as 0 and include normal karyotype, loss of Y, 5q–, or 20q–; those associated with a poor prognosis are scored as 1.0 and include abnormalities of chromosome 7 or three or more cytogenetic changes; all other cytogenetic abnormalities are scored as 0.5 and are of intermediate prognosis.

A score of 0 refers to a patient with either zero or one cell lineage cytopenia, and a score of 0.5 is assigned to two or more lineage cytopenias. Lineage cytopenias are defined as hemoglobin <10 g/dL, absolute neutrophil count <1800/mm^3, and platelet count <100,000/mm^3.

AML, acute myelogenous leukemia.

[a]The overall score is the sum of the scores from the percent of bone marrow myeloblasts, karyotype, and cytopenias.

Data from Greenberg et al.[189]

Table 67–5 FAB and WHO classifications

FAB	WHO	Dysplasia(s) (>10%)
RA	5q– syndrome	Erythroid lineage only
	RA	Erythroid lineage only
	RCMD	2–3 lineages
	MDS-U	1 lineage only
RARS	RARS	Erythroid lineage only
	RCMD-RS	2–3 lineages
RAEB	RAEB-1	1–3 lineages
	RAEB-2	1–3 lineages
RAEB-T	AML	

The World Health Organization (WHO) has reclassified chronic myelomonocytic leukemia (CMML) within the myeloproliferative disorders (MPD) and RAEB-T to "AML with multilineage dysplasia." AML now is classified as ≥20% myeloblasts.

The following are considered AML regardless of blast percentage: t(8;21)-AML1/ETO, t(15;17)-PML/RARA, inv(16) or t(16;16)-CBFβ/MYH11, 11q23-MLL.

AML, acute myelogenous leukemia; FAB, French-American-British; MDS-U, myelodysplastic syndrome unclassifiable; RA, refractory anemia; RAEB, refractory anemia with excess blasts; RAEB-1, 5%–9% myeloblasts; RAEB-2, 10%–19% myeloblasts; RAEB-T, refractory anemia with excess blasts in transformation; RCMD, refractory cytopenias with multilineage dysplasia; RS, ringed sideroblasts.

From Harris NL, Jaff ES, Drebold J, et al: World Health Organization classification of neoplastic diseases of the hematopoietic and lymphoid tissues: Report of the Clinical Advisory Committee meeting-Airlie House, Virginia, November 1997. J Clin Oncol 17:3835, 1999; and Germing U, Gottermann H, Minning H, et al: Problems in the classification of CMML—Dysplastic versus proliferative type. Leuk Res 22:871, 1998.

Table 67–6 World Health Organization Criteria for Diagnosis of Chronic Myelomonocytic Leukemia

Peripheral blood monocytosis >1000/mL.
No evidence of Philadelphia chromosome or BCR-ABL gene.
Less than 20% myeloblasts, monoblasts, and promonocytes within the peripheral blood or bone marrow.
Dysplastic changes in one or more myeloid lineages. If myelodysplasia is absent or minimal, the diagnosis of CMML can be made if the above three criteria are met and: Acquired clonal cytogenetic abnormality is present in bone marrow cells, or Persistent monocytosis for >3 months and all other causes of monocytosis have been excluded
CMML-1: Blasts <5% in peripheral blood and <10% in bone marrow
CMML-2: Blasts 5%–19% in peripheral blood or 10%–19% in bone marrow

From Vardiman JW, Harris NL, Brunning RD: The World Health Organization (WHO) classification of the myeloid neoplasms. Blood 100:2292, 2002.

leukemia is not biologically consistent and often leads to confusion in the recommendation of treatment options. The European Association of Hematopathologists and the Society for Hematopathology developed a new World Health Organization (WHO) classification scheme.[20] The WHO defines AML as having a myeloblast count of 20% or greater and drops the RAEB-T category (Table 67–5). Inclusion of CMML in MDS under the older FAB classification scheme was problematic, so within the new WHO classification scheme, CMML has been removed from the MDS category and placed within the myeloproliferative disorders (Table 67–6). This change seems more consistent with not only clinical presentation but also with the many treatment choices that are offered to patients with CMML. A new category, refractory cytopenia with multilineage dysplasia (RCMD), also was proposed. This category allows for the classification of patients with morphologic dysplasia within their bone marrow aspirate but who present with isolated neutropenia or thrombocytopenia instead of the typical anemia.

In addition to the number of myeloblasts, the FAB and WHO classification scheme are based on the degree of hematopoietic dysplasia. The FAB classification required patients to have 10% or greater dysplasia in two or more hematopoietic lineages. The WHO modified this requirement, and unilineage erythrodysplasia now is classified as RA or RARS depending on the presence or absence of ringed sideroblasts. Importantly, the dysplasia must have been present for more than 6 months, and no other causes of erythrodysplasia could be present. The WHO introduced a new category of refractory cytopenia with multilineage dysplasia with or without ringed sideroblasts: RCMD and RCMD-S, respectively. Although often subtle, patients with multilineage dysplasia have a significantly poorer overall survival as well as leukemia-free survival compared to patients with unilineage dysplasia.

The WHO classification system has been modified using prognostic scoring variables based on transfusion requirements as well as similar cytogenetic abnormalities within the IPSS.[191] The newer WHO classification-based scoring system (WPSS) is able to stratify patients into five risk groups (Table 67–7). The very-low-risk group has a survival of 11.3 years and 7% risk of transformation into AML at 10 years, whereas the very-high-risk group has a survival of 0.7 years and 50% risk of transformation into AML at 8 months. Although this scoring system has been validated on a separate cohort of patients, use of the WPSS has not gained widespread popularity. What is clear from the WPSS is that the definition of RBC transfusion "dependency" requires further confirmation and prospective large cohort studies.

Other parameters for evaluating the prognosis of MDS have been assessed in a series of scoring systems that follow different clinical and/or cytogenetic features, which include white blood cell count, hemoglobin, platelet count, age, sex, lactate dehydrogenase, and immunophenotyping.[190,192–196] For example, the CD44 antigen, which is a transmembrane glycoprotein, is expressed on bone marrow mononuclear precursor cells as well as peripheral granulocytes and erythrocytes.[193,197] Serum CD44 levels typically are increased in patients with MDS as well as acute myeloid leukemia and acute lymphoblastic leukemia. Increased expression of CD44-6v has been associated with shorter survival in patients with AML. Flow cytometric analysis has been used to evaluate expression of CD44 on early myeloid cells that coexpress CD66. CD66 typically is expressed on monocytes as well as immature myeloid cells. Low CD44 coexpression on CD66 myeloid cells typically is seen in the early stages of MDS as opposed to increased CD44 expression on CD66-weak

Table 67–7 WHO-Based Prognostic Scoring System for Predicting Survival in Patients with Myelodysplastic Syndrome

	Points			
Variables	***0***	***1***	***2***	***3***
WHO subtype	RA, RARS, 5q–	RCMD, RCMD-RS	RAEB-1	RAEB-2
Transfusion requirement	None	Yes[a]	—	—
IPSS cytogenetic risk	Good	Intermediate	Poor	—

[a]Defined as 1 unit of red blood cells every 8 weeks over a 4-month period.
IPSS, International Prognostic Scoring System; RA, refractory anemia; RAEB, refractory anemia with excess blasts; RAEB-1, 5%–9% myeloblasts; RAEB-2, 10%–19% myeloblasts; RCMD, refractory cytopenias with multilineage dysplasia; RS, ringed sideroblasts; WHO, World Health Organization.

myeloid cells, which often is seen in the later stages of myelodysplasia, that is, in patients with increased number of blasts. A shift in CD44 expression therefore often has been associated with a trend toward immaturity or increased number of blasts in patients with MDS; therefore, CD44 expression profiling may be useful as a separate prognostic marker for patients with MDS. However, large prospective studies are warranted.

The angiogenic process is extremely important in the growth and metastasis of many solid tumors.[198,199] Its role in hematopoietic malignancies is less well characterized. Both vascular endothelial growth factor and basic fibroblast growth factor are expressed by myeloblasts. Furthermore, analysis of bone marrow samples from patients with untreated AML showed increased microvessel density.[199,200] Vascular endothelial growth factor has been linked to the promotion of atypical localization of immature myeloid precursors, which is a poor prognostic marker in patients with MDS, especially for signaling out those patients who are at highest risk for disease progression.[119,201,202] Furthermore, microvessel density is markedly higher in patients with RAEB-T compared with the other MDS subtypes, suggesting a role between angiogenesis and transformation to acute leukemia in patients with MDS.

RBC Transfusion Dependence

RBC transfusion dependence is associated with a poorer overall survival in patients with MDS. In a retrospective study of 239 patients with low-risk MDS 19% were RBC transfusion dependent and had shorter survival than did patients who had not recently undergone transfusions.[203] A similar retrospective study of 467 patients by Malcovati et al.[191] also demonstrated that RBC transfusion dependency in patients with MDS had a negative impact on both overall survival and leukemia-free survival. The negative effect was dependent on the number of transfusions per month and was an independent prognostic variable regardless of cytogenetic risk assessment.

The etiology for the shorter survival in patients with MDS who are RBC transfusion dependent is unclear. Some patients had secondary hemochromatosis as assayed by increased serum ferritin levels, and some patients developed cardiac dysfunction or arrhythmias.[203] Although iron overload is suggested to be a significant component in the increased mortality of transfusion-dependent patients with MDS, prospective studies are needed to accurately assess the effect of iron chelation on survival and subsequent prognosis in patients with MDS who are RBC transfusion dependent.

CYTOGENETIC AND MOLECULAR ABNORMALITIES

Careful examination of the bone marrow aspirate to detect cytogenetic abnormalities is a critical part in establishing the diagnosis of MDS. Although approximately 60% of patients with MDS have a normal karyotype, the presence of characteristic cytogenetic abnormalities may establish the diagnosis in cases where the dysplastic changes within the bone marrow aspirate are subtle (see Table 67–4).[21] Furthermore, documentation of additional cytogenetic changes may imply an evolving clonal evolution and development of a neoplastic process.

Abnormal karyotypes are identified in about half of all cases of MDS and in more than 80% of therapy-related cases.[6,188] The most common abnormality is trisomy 8. Other common abnormalities include monosomy 5 or 7, loss of the Y chromosome, or deletions involving the long arms of chromosomes 5, 7, 11, 13, and 20. Complex karyotypes, defined as three or more abnormalities, are seen in approximately 15% of cases of MDS and portend an unfavorable prognosis. Chromosomal abnormalities are most often associated with the FAB subtypes RAEB and RAEB-T. The presence of a deletion of the long arm of chromosome 5 (5q–) as the sole abnormality is seen most often in patients with RA[145] ; monosomy 7 is rarely seen in this MDS subgroup. Translocations involving platelet-derived growth factor receptor-β (PDGFR-β) have been identified in 5% to 10% of patients with CMML. The first case was identified in a patient with a translocation involving the transcription factor TEL on chromosome 12,[204] but many other fusion partners have now been described. The TEL–PDGFR-β receptor gene product produces a chronic myeloproliferative disorder in mice and is a potential target for tyrosine receptor kinase inhibition with imatinib therapy.

Therapy-related MDS is associated with specific chromosomal abnormalities.[108] Patients who develop MDS or AML after exposure to alkylator therapy often have either a partial loss or complete monosomy of chromosome 5 or 7.[6,7,109] Patients who were exposed to topoisomerase II inhibitors typically present with a monocytic acute leukemia and not MDS. These patients have a high frequency of chromosomal rearrangements involving the MLL gene on 11q23[91] or less commonly the AML1 gene on 21q21. Other chromosomal abnormalities associated with therapy-related MDS include 3p14-21, 6p21, 12p11-17, and 19p13. Mutations involving p53 on chromosome 17p have been described and are associated with a long latency period between toxin exposure and the diagnosis of MDS or AML.[205,206]

Several diagnostic tests have increased the ability to detect cryptic cytogenetic anomalies. Fluorescent in situ hybridization uses specific DNA probes to identify each chromosome individually.[207] This method can screen hundreds of cells and does not depend on analysis of dividing cells during metaphase. Thus, the sensitivity can be dramatically increased, but use of fluorescent in situ hybridization is limited to detection of standard cytogenetic abnormalities. Polymerase chain reaction analysis can detect specific gene translocations

in either the bone marrow or blood. This assay is rapid and can detect abnormalities present in fewer than 1 : 10,000 cells but also is limited to detection of standard cytogenetic abnormalities.

It is important to realize that a normal karyotype does not exclude the diagnosis of MDS. Normal karyotypes are see in about half of all cases of MDS. This is thought to be due to the limitations of standard G banding or the failure of the neoplastic clone to divide in culture. Spectral karyotype analysis or "chromosomal painting" can identify cryptic balanced and unbalanced translocations in most patients with MDS.

Cytogenetic Correlation with Prognosis

One of the limitations with the IPSS is the limited information that was available on cytogenetic data. Cytogenetic analysis since has been performed in more 2000 patients with MDS and was successful in 97% of these patients.[208] Clonal cytogenetic abnormalities were seen in 52.3% of patients. These included numeric as well as structural chromosomal abnormalities. The limitation in terms of prognosis is the varying degree by which patients receive therapy; therefore, the impact of karyotypic abnormalities on the natural history of myelodysplasia was studied in 1286 patients treated with supportive care only (see Table 67–4). Therefore, how overall and leukemia-free survival are affected by therapeutic intervention is unclear.

In patients with a normal karyotype (N = 612), median survival was 53 months. This is compared to an 8.7-month survival for patients with complex abnormalities. The most frequent abnormality involved deletion of chromosome 5q, which occurred in 30% of patients who had a cytogenetic abnormality or 58% of all patients with successful cytogenetic analysis. Isolated deletion of 5q was seen in 14% of patients with clonal abnormalities. Other frequent abnormalities included monosomy 7 or 7q deletion in 21% and trisomy 8 (+8) in 16% of patients with MDS. Less common abnormalities are listed in Table 67–8.

Favorable prognosis measured as a median survival of approximately 3 years was seen in patients with translocations involving chromosome 1q, translocation involving 7q, any chromosome 12 abnormality, translocation involving 17q with a noncomplex karyotype, monosomy 21, trisomy 21, as well as for loss of chromosome X. Median survivals had not been reached for patients with del9q, del12p, and del15q. The favorable survival for these patients was seen only if patients has no additional abnormalities. In addition, 21 other chromosomal aberrations were identified, but their rarity did not allow for prognostic relevance. Therefore, even though numerous cytogenetic abnormalities have been identified, the rarity of a few cytogenetic abnormalities makes prognostic impact limited.

Abnormalities with intermediate prognosis, defined as median survival between 1 and 3 years, was seen in patients with chromosome 3q rearrangements, translocations involving 11q23 as a noncomplex karyotype, and trisomy 19. In addition, regardless of the specific aberrations, an overall correlation was seen between prognosis and extent of abnormalities. Patients with three or more abnormalities had a median survival of 17 months, patients with four to six abnormalities had a median survival of 9 months, and patients with more than six abnormalities had a median survival of only 5 months. This analysis further demonstrates the cytogenetic impact of a complex karyotype on the prognosis of patients with MDS. Cytogenetic analysis remains an important factor in treatment selection as well as monitoring response to therapy. What is unclear from this type of analyses is the impact of pharmacologic therapy on the prognosis of patients with MDS based on their cytogenetic abnormalities.

CLINICAL SYNDROMES

Patients with MDS often present with symptoms of ineffective hematopoiesis.[209] They usually seek medical attention complaining of recurrent infections, bleeding, easy bruising, progressive fatigue and lethargy, or dyspnea on exertion. Occasionally, patients present without symptoms but with abnormal peripheral counts, such as neutropenia, anemia, thrombocytopenia, or a combination of all three. It is important to realize that bleeding can also occur in nonthrombocytopenic patients due to dysfunctional platelets. Patients will either die of progressive bone marrow failure or progress to overt AML. A subgroup of patients with less than 5% myeloblasts, RA, or RARS may die of nonhematologic causes which typifies this affected elderly patient population. In general patients with MDS have a shorter overall survival than age-matched controls, suggesting that bone marrow failure may be additive to other comorbid diseases.[21]

MDS has been reported to coexist with other hematologic malignancies, the most frequent being multiple myeloma, even in previously untreated patients.[210,211] MDS also has been described in patients with hairy cell leukemia, chronic lymphocytic leukemia,

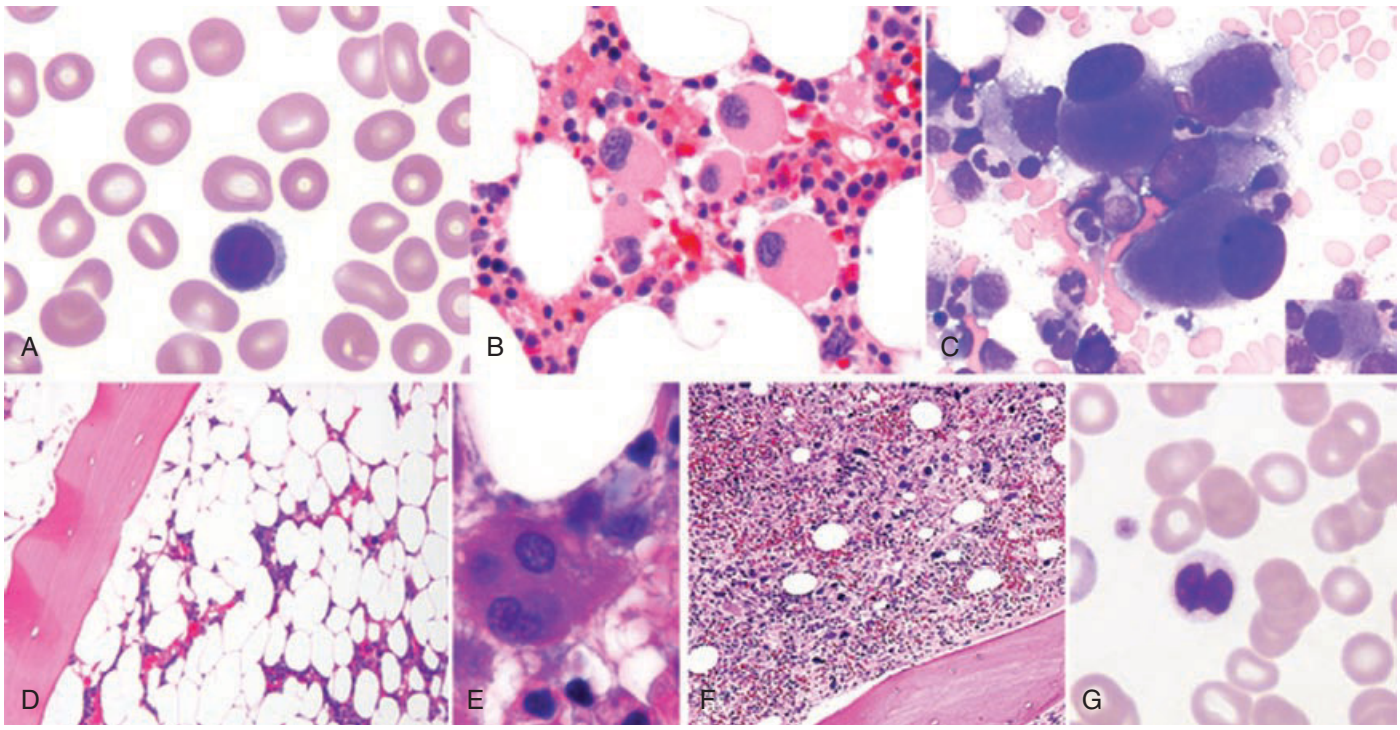

Figure 67–5 Specific syndromes. 5q− syndrome (**A–C**); hypocellular myelodysplastic syndrome (**D, E**), and myelodysplastic syndrome with fibrosis (**F, G**). The 5q− syndrome has specific morphologic correlates. There is a macrocytic anemia (**A**), and a cellular bone marrow characterized by increased small monolobated megakaryocytes (**B, C**). The megakaryocyte nuclei have little segmentation and are fairly round. Although some true micromegakaryocytes may be present (**C, insert,** same magnification), the typical monolobated forms are not as tiny as the micromegakaryocytes. Hypocellular myelodysplastic syndrome (**D, E**) can present a diagnostic problem and differentiation from aplastic anemia. Dysplasia may be difficult to evaluate if the smears are paucicellular. The finding of dysplastic megakaryocytes (note small widely separated nuclei, **E**) on the biopsy sample can be helpful. Myelodysplastic syndrome with fibrosis (**F**) can be difficult to differentiate from myeloproliferative neoplasms. However, the lack of large megakaryocytes, which typically are see in the myeloproliferative diseases, along with presence of dysplasia in the circulating neutrophils (**G**) are useful clues to the correct diagnosis.

non-Hodgkin lymphoma, and large granular lymphocytic leukemia.[212] The association of MDS with these other hematopoietic malignancies suggests a common myeloid/lymphoid stem cell as the transforming cell. However, the association may simply be a statistically random association or be therapy related in some cases. The coexistence of MDS with another hematologic malignancy significantly complicates the treatment options.

5q− Syndrome

Patients with myelodysplasia represent several unique clinical cohorts. Patients with an isolated loss of the short arm of chromosome 5 [del5(q31-q35), or 5q−] are characterized by a prolonged clinical course that progresses to acute leukemia in less than 25% of cases.[213,214] Interestingly, anemia seems to be the principal laboratory abnormality. Neutropenia, if present, typically is mild, and platelet counts often remain elevated. The striking pathologic feature is the presence of mononuclear micromegakaryocytes identified in the bone marrow biopsy (Fig. 67–5, *A–C*).

Women account for a larger proportion of cases, up to 70%.[215,216] Patients with 5q− deletions must be distinguished from patients with additional cytogenetic abnormalities, because these patients often have a more rapid progression to AML. The large arm of chromosome 5 is rich in genes encoding both cytokines and cytokine receptors.[217] Haploinsufficiency of the ribosomal protein encoding RPS14 gene has been shown to cause the phenotypic features of 5q− syndrome.[218] RNA-medicted interference (RNAi) screening technology confirmed the notion that 5q− syndrome is caused by a defect in ribosomal protein RPS14. In addition, a link has been established between acquired 5q− syndrome and congenital bone marrow failure syndromes such as Diamond-Blackfan anemia. Because of the uniqueness of the 5q− syndrome, it often is considered separately from the other myelodysplastic disorders. Patients typically require RBC transfusion as their principal treatment, so careful attention must be paid to management of iron overload. Lenalidomide (Revimid) has been approved for patients with a chromosome 5q abnormality who are transfusion dependent, and its use is discussed in treatment section.[219,220]

Hypocellular MDS

The majority of patients with myelodysplasia have a hypercellular or normocellular bone marrow. A hypocellular bone marrow is found in a minority of patients (<15%) and is referred to as *hypoplastic myelodysplasia* (see Fig. 67–5, *D and E*).[221] In this subgroup of patients, the morphologic features of the bone marrow may be difficult to differentiate from aplastic anemia, and the definitive diagnosis can sometimes be made from cytogenetic analysis. Cytogenetic abnormalities are rarely found in patients with aplastic anemia. The differential diagnosis of patients with a hypoplastic bone marrow includes not only aplastic anemia but also drug toxicity, PNH, and T-cell large granular lymphocytic leukemia.[222,223] These entities usually can be excluded by flow cytometric analysis of the bone marrow aspirate. The natural history of hypoplastic myelodysplasia is similar to that of the standard variants.

MDS with Myelofibrosis

Substantial reticulin fibrosis is rarely found in patients with myelodysplasia (see Fig. 67–5, *F and G*), although there is an increase incidence in patients with CMML. Myelodysplasia with myelofibro-

sis can be difficult to distinguish from chronic idiopathic myelofibrosis (agnogenic myeloid metaplasia with myelofibrosis).[121,224] The presence of trilineage dysplasia and the absence of hepatosplenomegaly support the diagnosis of myelodysplasia. However, some cases, may reflect an evolving transformation to a leukemic process, with profound bone marrow fibrosis such as is often seen in acute megakaryocytic leukemia (FAB-M7). Myelofibrosis can occur in all MDS subtypes, and mild fibrosis is seen in more than two thirds of cases. Marked fibrosis is much rarer and is thought to be present in only approximately 10% of cases.

Patients who develop MDS with myelofibrosis often have rapidly progressive cytopenias, usually without splenomegaly, and often have a poor prognosis.[117,118] Peripheral blood smear usually reveal the heralded "teardrop" cell, and the bone marrow is markedly hypercellular with fibrosis and often dysplastic megakaryocytic proliferation with hypolobated megakaryocytes; many patients have an increased number of myeloblasts. The differential diagnosis is complicated and includes idiopathic or primary myelofibrosis, postpolycythemia vera myelofibrosis with myeloid metaplasia, post-essential thrombocythemic myelofibrosis with myeloid metaplasia, accelerated phase CML, acute leukemia (usually M7 or AML with dysplasia), and acute myelofibrosis.

MDS/MPD Overlap Syndromes

CMML is the quintessential disorder having characteristic findings of both MDS and MPD (Fig. 67–6, *A*).[158,162,163] Because the majority of patients with CMML have evidence of trilineage dysplasia, the FAB cooperative group categorized CMML as a subtype of MDS. The FAB criteria for diagnosis included a peripheral monocyte count of 1000 per mm^3, less than 5% blasts in the blood, less than 20% blasts in the bone marrow, and absence of Auer rods. The new WHO classification system places CMML with juvenile myelomonocytic leukemia and atypical or BCR-negative CML into the new subgroup MDS/MPD (see Table 67–6).[21]

Many patients with CMML also present with splenomegaly, hepatomegaly, lymphadenopathy, tissue infiltration, or serous effusions.[162,186,187,225] Pleural, pericardial, synovial, and ascitic effusions all have been reported in patients with CMML and are associated with a high circulating monocyte count. Patients with CMML can have vastly different presentations. Certain patients with CMML present with profound cytopenias and marked dysplasia, whereas other patients have a predominately myeloproliferative form. Because of these two rather distinct clinical presentations, some clinicians separate CMML into two separate entities, with the proliferative form characterized by white blood cell WBC count greater than 12,000 per mm^3, presence of organomegaly, and constitutional symptoms. The nonproliferative form of CMML is characterized by a low white blood cell count with a relative monocytosis, and complications from cytopenias tend to dominate the clinical picture. The overall prognosis of both forms of CMML is similar, with median overall survival of 19 months, and the absolute number of marrow blasts is the dominant prognostic feature.[187]

A subgroup of patients, usually with the proliferative form of CMML, is characterized by the balanced translocation t(5;12)(q33;p13).[204] The consequence of the t(5;12) translocationis fusion of the tyrosine kinase domain of PDGFR-β to a member of the *ETS* family of transcription factors TEL. Fusion of TEL to PDGFR-β constitutively activates the tyrosine kinase domain of PDGFR-β, leading to increased myeloid proliferation. PDGFR-β on chromosome 5q33 also is disrupted by t(5;7), t(5;14), and t(5;10) translocations, resulting in fusion of the tyrosine kinase domain of PDGFR-β to HIP1, CEV14, and H4/D10S170, respectively.[226] The understanding of these findings has led to novel therapeutic approaches using the tyrosine kinase inhibitor imatinib mesylate, with remarkable efficacy and durable responses.[183,227] Unfortunately, PDGFR-β is present in only a minority of cases of CMML.

Therapy-Related MDS

Therapy-related MDS is becoming more important, given the increased dose density currently being administered to patients, for example, those with breast carcinoma.[228–231] Furthermore, the use of myeloid growth factors may inadvertently increase this risk.[232] Therapy-related MDS and AML remain one of the most serious long-term complications of current cancer therapy and often are induced by well-defined chemotherapeutic agents and/or radiation. The incidence of secondary or therapy-related MDS is increasing.[228] The term *secondary myelodysplasia* refers to the development of disease following either exposure to environmental or therapeutic toxins or from a previously diagnosed hematopoietic disorder. The term *therapy-related* should be specifically attributed to the presentation of MDS or AML following the use of intensive chemotherapy or radiation therapy.

Many patients with therapy-related MDS/AML have common chromosomal aberrations and/or gene mutations. Most importantly, patients with therapy-related MDS behave in a more aggressive fashion regardless of FAB or WHO classification subtype. Patients with therapy-related MDS are not included in the IPSS schema; therefore, specific prognostic factors are limiting. The risk of secondary MDS is highest in patients who already have been exposed to alkylating agent therapy. The cytogenetic abnormalities of alkylating agent-related therapy-related MDS/AML are quite distinct.[6,10,109]

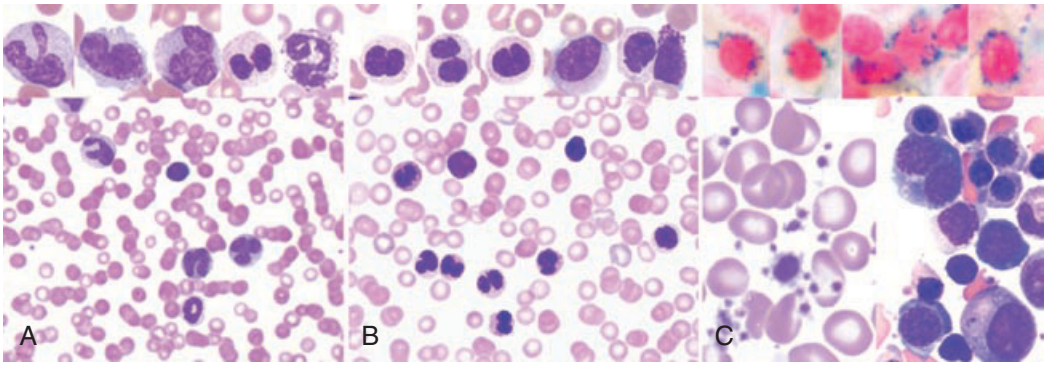

Figure 67–6 Overlap syndromes. Chronic myelomonocytic leukemia (**A**), "atypical chronic myelogenous leukemia" (**B**), and refractory anemia with ringed sideroblasts and thrombocytosis (**C**). In chromic myelomonocytic leukemia there can be granulocytic dysplasia and cytopenias (e.g., anemia, thrombocytopenia), but the characteristic feature is the presence of an absolute monocytosis (**A**). "Atypical chronic myelogenous leukemia" (BCR/ABL-negative) is essentially a "high-count" myelodysplastic syndrome. There typically is severe granulocytic dysplasia. The absence of an absolute monocytosis excludes chronic myelomonocytic leukemia from the diagnosis. The case shown is characterized by numerous pseudo–Pelger-Huet cells, immature hypogranular granulocytic precursors, and some basophils (**B**). The case was shown to be associated with i(17q) as a sole abnormality. Refractory anemia with ringed sideroblasts and thrombocytosis is characterized by anemia and thrombocytosis in the blood (**C, left**), hypercellular marrow with erythroid proliferation (**C, right**), and ringed sideroblasts (**C, top**).

They include either a total loss or a deletion of the long arm of either chromosome 5 or 7. A higher than normal risk for developing therapy-related MDS/AML has been described in long-term survivors of Hodgkin lymphoma, non-Hodgkin lymphoma, multiple myeloma, and gastrointestinal cancers, specifically those treated with semustine (methyl-CCNU).[233–236] The estimated actuarial risk in patients treated for Hodgkin lymphoma is between 6% and 9%. A 17% actuarial risk has been reported in patients treated for multiple myeloma.

The risk of developing MDS following adjuvant treatment of breast cancer, small cell lung cancer, testicular cancer, or ovarian cancer is low but increases with use of regional radiation therapy. Topoisomerase II inhibitors also can induce therapy-related AML[91] but typically involves a balanced translocation of chromosome band 11q23 and less commonly involves 3q26 and 21q22. The topoisomerase II inhibitors include the epipodophyllotoxins and anthracyclines. As opposed to prior exposure from alkylating agents, MDS seldom precedes therapy-related AML caused by the topoisomerase II inhibitors.

Use of adjuvant therapy for treatment of early-stage invasive breast carcinoma has been associated with therapy-related MDS/AML. The incidence of therapy-related MDS/AML after treatment of early-stage breast cancer with mastectomy alone is only 0.27%.[229,237,238] A case-control study of 82,700 women treated for early-stage breast cancer during the 1970s and 1980s reported that the typical cyclophosphamide, methotrexate, and fluorouracil (CMF) regimens with a low cumulative dose of cyclophosphamide is associated with an additional five cases of leukemia for every 10,000 women treated over 10 years.[239] However, with the current use of anthracycline-based adjuvant chemotherapy regimens (cyclophosphamide, epirubicin, fluorouracil [CEF]; or fluorouracil, Adriamycin [doxorubicin], cyclophosphamide [FAC]), the risk of therapy-related MDS/AML has increased compared to the classic CMF regimen. Rates of therapy-related MDS/AML now approach 1.5% after 5 to 10 years of follow-up. There is an even greater risk in women who received radiotherapy.[240,241] In patients who receive four cycles of standard anthracycline and cyclophosphamide therapy (cyclophosphamide 600 mg/m^2 and doxorubicin 60mg/m^2 per cycle), the risk appears quite low. In one study, the incidence of therapy-related MDS/AML in patients who receive four full cycles of cyclophosphamide and anthracycline chemotherapy was only 0.1% with the median followup of 5 years. However, women seem to have a higher risk for therapy-related MDS/AML in the National Surgical Adjuvant Breast and Bowel Project (NSABP) protocols B-22 and B-25, in which a higher dose of cyclophosphamide as well as doxorubicin were used.[237] Of potential importance was the use of G-CSF in these regimens. In one retrospective study of patients with breast cancer, use of G-CSF was associated with doubling of the risk of therapy-related MDS/AML.[232]

A history of autologous bone marrow transplantation has been associated with a substantial risk of developing therapy-related MDS and AML.[240,242–249] The cumulative probability of developing therapy-related MDS/AML after autologous SCT ranges from 4% to 14%, depending on the series. A retrospective study by Friedberg et al.[250] reported a 19.8% actuarial risk of developing MDS by 10 years. All of the 552 patients analyzed in this study were treated with cyclophosphamide and total body irradiation. The patients who developed MDS had on average a lower number of cells reinfused per kilogram at autologous bone marrow transplantation (BMT). The increased incidence of therapy-related MDS/AML has been associated with use of radiation therapy as part of the conditioning regimen, but other risk factors include advanced stage, number and type of prior courses of chemotherapy. and exposure to radiation therapy before transplantation. The prognosis of patients with therapy-related MDS or AML remains extremely poor.

Therapy-related MDS and AML are characterized by three distinct groups of cytogenetic abnormalities.[89,108] The first is an unbalanced aberration along chromosome 5 or 7. Patients typically have loss of the whole chromosome 5 or 7 or loss of various parts, specifically the long arm of chromosome 5 or 7. Another frequently observed abnormality is the gain of a whole chromosome 8 (trisomy 8).[39] Abnormalities of chromosomes 5, 7, and 8 are seen in 15% to 25% of cases in de novo MDS but compose approximately 50% to 70% of cases with therapy-related MDS. Similarly, they occur in 15% to 25% of cases of de novo AML but in 40% to 50% of therapy-related AML. A second cytogenetic subgroup comprises recurrent balance translocations involving the MLL gene on chromosome 11q23.[251,252] Patients with this abnormality typically present with AML without a myelodysplastic prodrome. From 15% to 20% of patients with therapy-related AML have rearrangements of the MLL gene, whereas this abnormality typically is not seen in patients with therapy-related MDS. In fact, the WHO has redefined patients with MLL gene rearrangements or patients with t(8;21) or t(16;16) or inv(16) as having AML regardless of the absolute blast count.[20,158] The final group of patients with therapy-related MDS consists of patients with a normal karyotype or other chromosomal aberrations. This group comprises 50% to 60% of de novo MDS but only 5% to 10% of therapy-related MDS and 10% to 15% of therapy-related AML.

With respect to specific molecular abnormalities, the most common specific gene mutation involves the MLL gene on 11q23, but other abnormalities have been identified, namely, AML1 on 21q22, the RARA locus on chromosome 17q21, and CBFB on chromosome 16q22.[93,94,97,105,107,252–254] Rearrangements of these genes lead to a dominant loss of function of the transcription factor, which results in impairment of differentiation. It is thought that by interfering with myeloid differentiation, leukemia will result. In addition, other abnormalities have been identified, including mutations of the nucleophosmin gene NPM1, which has been designated a class II mutation in leukemogenesis.[255] The critical genetic consequences of unbalanced chromosome aberrations in MDS and AML are unclear. Deletions of chromosome 17p13 or loss of whole chromosome 17 were thought to involve the p53 gene.[206,256–259] In addition, data have suggested that monosomy 5 or loss of the long arm of chromosome 5 is related to haploinsufficiency of the EGR1 gene.[260] However, a study from the Look laboratory at the Dana Farber Cancer Institute has implicated haploinsufficiency and promoter methylation of *CTNNA1*, the gene encoding α-catenin.[76] How either of these genetic defects relates to the haploinsufficiency of the ribosomal protein encoding RPS14 remains unclear.[218]

RARS with Thrombocytosis

Some patients with MDS present with marked thrombocytosis. Most patients have RARS, but with markedly elevated platelet count, and therefore have been reclassified as RARS-T (see Fig. 67–6C).[167,261–264] Bone marrow aspirate and biopsy show features consistent with a myeloproliferative and myelodysplastic overlap syndrome. Importantly, the megakaryocytes resemble those seen in essential thrombocythemia. Patients with RARS-T often have evolved from a low-grade MDS category, such as RA or RARS, but have acquired a JAK2 V617F mutation. This mutation is relatively uncommon in other patients with MDS; therefore, RARS-T represents another JAK2 mutation-associated chronic myeloproliferative disorder.[265–267]

According to the WHO, patients with RARS-T are classified under the provisional MDS/MPD category and listed as unclassifiable.[268] Given the rarity of this syndrome, definitive estimates of overall survival and time to leukemic transformation are unclear. However, a retrospective analysis of 23 patients with RARS-T revealed a 5-year survival of 86% compared to 62% in patients with RARS who did not have a JAK2 V617F mutation.

3q21-q26 Syndrome

Patients with MDS who contain a 3q21-q26 cytogenetic abnormality often have profound trilineage dysplasia, especially of the megakaryocytes.[269] Patients can present with either MDS or AML and typically have a normal or increased platelet count. Cytogenetic analysis at the time of diagnosis often reveals at t(1;3), inv(3), or t(3;3) abnormality. Patients with these cytogenetic abnormalities have an extremely poor

response to chemotherapy and, as a result, a poor overall prognosis. The peripheral blood smear often reveals giant platelets or even circulating megakaryocytic fragments. In addition, hypogranular megakaryocytic forms and micromegakaryocytes may be present in the bone marrow aspirate. These morphologic abnormalities involving the megakaryocytes are accompanied clinically with an increased risk of bleeding despite either a normal or increased absolute platelet count. Platelet aggregation studies show decreased platelet aggregation to collagen and epinephrine and may explain the increased risk of bleeding seen in these patients.[38,171]

TREATMENT

General Principles

Treatment of patients with MDS remains challenging for several reasons. First, patients with this disorder are likely to be elderly, so comorbid disease and performance status are critical components in deciding on specific therapy. Second, the disease is heterogeneous, making therapies for one type of MDS less optimal than those for others. Given the lack of precise pathophysiologic understanding of more than a few MDS subtypes, designing truly targeted therapies is impossible. We are left with agents that deal with abnormalities generally thought to play a role in MDS, such as underactive or overactive apoptosis, failure to express silenced genes required for hematopoietic cell differentiation, or overabundant angiogenic signaling. Finally, there is no widely accepted standard of care in that very few, if any, modalities have been definitively proven to change the natural history of this disease. Until recently,[270] response criteria for MDS were not standard, making for difficult interpretation of the multiple phase II trials that included trial-specific response criteria.

The primary goal of most therapeutic strategies in neoplastic diseases is improvement in overall survival. Although this remains the desired result for treatment of patients with MDS, less formidable achievements also might be useful. Such benefits might include delay in time to transformation to leukemia, response rate (rigorously defined), decrease in transfusions, decreased infection, hematologic improvement, and improved quality of life. The only modality historically associated with an appreciable degree of long-term disease-free survival is allogeneic bone marrow transplantation.[270,271] This modality is resource intense, potentially highly toxic, and heretofore available only to a minority of patients with MDS due to age and performance status requirements. On the other hand, analysis of the role of the myriad other valuable medical therapies is complicated (see box on Treatment).

Management Guidelines for a Newly Diagnosed Patient with Myelodysplasia

The only known curative modality for patients with myelodysplastic syndrome (MDS) is stem cell transplantation (SCT). Therefore, all appropriate candidates should be considered for SCT. They include patients younger than 70 years (age 75 years at some centers), with a reasonable performance status and no significant comorbidity. Retrospective data from the International Bone Marrow Transplant Registry suggest that patients with low-risk disease (International Prognostic Scoring System [IPSS] low or intermediate-1) should undergo SCT only at the time of disease progression (see text and Table 67–10). Disease progression includes progressive clinically significant cytopenias such as progressive red blood cell (RBC) and/or platelet transfusion dependency or transformation to a high-risk disease. Transformation to high-risk MDS typically is manifested by an increase in the number of bone marrow blasts but also could represent accumulation of additional cytogenetic abnormalities.

Patients with low-risk disease should be carefully analyzed for the presence of a deletion of the long arm of chromosome 5. Patients with a deletion of 5q or those who have the 5q syndrome should start taking lenalidomide at the time they become RBC transfusion dependent. For patients with hypoplastic MDS who are younger than 6 years, have a low transfusion requirement, and have no increase in marrow myeloblasts, immunosuppressive therapy should be considered with antithymocyte globulin and a calcineurin inhibitor. In all other patients with low-risk MDS, the addition of an erythropoietin-stimulating agent (ESA) should be considered, but only in patients with a serum erythropoietin (Epo) level less that 500 mU/mL. For patients who do not respond to initial ESAs, addition of a myeloid growth factor (granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor) should be considered. In patients who do not respond or those with an elevated Epo level, aggressive supportive care should continue. The addition of a hypomethylating agent, such as azacytidine or decitabine, may improve the hematologic parameters, but the overall experience of hypomethylating agents in patients with low-risk MDS is limited. The addition of lenalidomide is another option for patients who have isolated anemia, but lenalidomide has no impact on the myeloid or megakaryocytic lineages in patients without the 5q abnormality. Although controversial, iron chelation therapy can be considered for patients with low-risk MDS and a serum ferritin level greater than 1000 mcq/L.

All patients with high-risk MDS classified by an IPSS score of intermediate-2 or higher or patients with more than 10% bone marrow blasts should be seen at a transplant center for consideration of SCT if they are appropriate candidates. For patients who are not eligible for transplantation, a hypomethylating agent should be initiated at the time of presentation. Hypomethylating agents such as azacytidine and decitabine are associated with a small but reproducible complete remission rate, and evidence from Europe has demonstrated that azacytidine may improve median overall survival. In addition, regardless of the IPSS risk category, all patients should be considered for clinical trial participation. Novel strategies hopefully will make an impact not only on patient quality of life but also improve the median survival of patients with MDS.

Role of Iron Chelation in the Management of Patients with Myelodysplasia

The development of secondary hemochromatosis is associated with significant morbidity in chronic hemoglobinopathies such as thalassemia major, Blackfan-Diamond syndrome, and sickle cell anemia. Iron chelation therapy has been shown to improve the outcome in patients with these disorders. However, the same cannot be said for patients with MDS. The majority of patients with MDS become RBC transfusion dependent because since they are exposed to a significant amount of intravenous iron. Each unit of packed RBCs has approximately 200 to 250 mg of elemental iron. More than 75% of patients with MDS who receive chronic RBC transfusions will develop evidence of secondary hemochromatosis documented by a serum ferritin level of 1000 mg/mL or higher. This typically occurs after patients have received a total lifetime of 40 units of packed RBCs. Nevertheless, it remains difficult to document true organ failure as a result of iron overload in most patients with MDS. In patients with MDS, a serum ferritin level of 1000 mg/mL or higher is associated with a reduced median overall survival. What has not been demonstrated in a prospective fashion is whether the addition of iron chelation therapy can improve survival.

Patients with high-risk MDS have a shortened overall survival as a result of progressive cytopenias resulting in infection, bleeding diatheses, or transformation to acute myelogenous leukemia. In these

Role of Iron Chelation in the Management of Patients with Myelodysplasia—cont'd

patients, the role of iron chelation therapy is unlikely to improve the median survival. However, in patients with low-risk MDS, the natural history of the disease is markedly different. Many patients have an indolent course, with a median overall survival greater than 3 years. In addition, use of disease-modifying agents, such as, lenalidomide in patients with the 5q syndrome may alter the natural history of the disease.

Two studies have demonstrated that iron chelation therapy is associated with improved median survival in patients with low-risk MDS. Both studies have limitations. In the Canadian study, which was a retrospective analysis of 178 patients, only 18 patients received iron chelation therapy. The other study from the French MDS group was a nonrandomized prospective analysis of 165 patients of whom 46% received iron chelation therapy. In this latter study, various regimens of iron chelation were used, and but no formal assessment of individual iron stores was made. Thus, the role of iron chelation therapy for patients with MDS is unclear. If it has a role, it should be reserved for patients with low-risk MDS because they are expected to have a prolonged median survival, especially patients who are benefiting from their therapy.

MDS in Young Patients

Although MDS typically occurs in patients older than 60 years (median age 70 years), younger individuals also can be affected. Data on the treatment of young patients with MDS who have an indolent or low-risk presentation are unclear. When the IPSS was developed, few patients were younger than 60 years, but it was clear that young patients within the low and intermediate-1 risk groups had significantly better survival than did older patients within the same IPSS risk group. Because the outcome from SCT is related to patient age, the best approach for young patients with MDS who have a low to intermediate-1 IPSS score remains debated.

Cutler et al. demonstrated a superior outcome when patients in low or intermediate-1 IPSS risk groups were transplanted at the time of disease progression as opposed to the time of their initial diagnosis. Furthermore, data from the German registry revealed that 86% of patients younger than 50 years with low-risk disease were alive at 20 years, and patients with an intermediate-1 IPSS score had a median survival of 176 months. Therefore, patients with low or intermediate-1 risk MDS who are younger than 50 years should be observed, and SCT should be delayed until disease progression. Disease progression includes the development of significant transfusion requirements, progressive cytopenias, or transformation to a higher IPSS subgroup.

Erythropoietin-Stimulating Agents in Patients with MDS

The safety of ESAs, recombinant human erythropoietin (rh-Epo; Epogen or Procrit) and darbepoetin (Aranesp), has come into question, specifically in patients with chemotherapy-induced anemia and chronic renal failure. ESAs can increase hemoglobin and ameliorate the symptoms from anemia that develop in patients with cancer who are undergoing chemotherapy and those with chronic renal failure. However, treatment also increases the risk of thromboembolic complications. Increased risk of tumor recurrences also has been noted.

For patients with chronic renal failure, two trials have demonstrated that patients assigned to a high targeted hemoglobin experience significantly more adverse events, including death, chronic heart failure, myocardial infarction, and stroke than do patients assigned to lower targeted hemoglobin. Use of ESAs for treatment of anemia in patients with MDS has remained a standard approach used by most physicians. Interestingly, most physicians are unaware that this remains an off-label use, as regulatory authorities have not approved ESAs for use in patients with MDS. The efficacy of ESAs in MDS has been difficult to tabulate given the changing definition of response. Now with most authors using the International Working Group (IWG) criteria for response, we have a better appreciation for the low but reproducible responses seen with use of ESAs in patients with MDS. The hemoglobin response from an ESA in patients with MDS ranges from 20% to 40%. It is important to note that a major hemoglobin response includes the development of transfusion independence as well as an increase in hemoglobin of at least 2 g/dL from baseline measurements.

There have been many concerns regarding the safety of ESAs in patients with MDS. Importantly, no significant adverse events, including thromboembolic complications, have been noted in multiple studies. Mounting evidence indicates that a lower baseline serum Epo level is associated with a higher response rate; therefore, all patients should have a baseline Epo level measured before initiation of an ESA (see text and Table 67–9). Patients with a serum Epo level greater than 500 mU/mL have such a low response rate to ESAs that alternative strategies should be considered first. ESA treatment requires a long duration to see maximum benefit, and, because of increased iron utilization, concurrent iron administration may be required to achieve a maximum response. In addition, use of ESAs did not appear to be associated with higher rates of progression to AML. More importantly, it appears that amelioration of chronic anemia in patients with MDS not only may improve their quality of life but also may change the natural history of the disease (see text).

Supportive Care

If there is standard therapy for patients with MDS (other than relatively rare young patients who may be bone marrow transplant candidates), it is supportive care. Supportive care generally consists of administration of blood products and antibiotics when needed. Most also would consider use of iron chelation therapy and hematopoietic growth factors as reasonable supportive care adjuncts.

The development of hematopoietic growth factor therapy held both promise and peril as a therapeutic strategy in the treatment of patients with MDS. Certainly if platelet count, hematocrit, and neutrophil count are low, use of an agent that could stimulate growth of the appropriate precursor cell might prove beneficial in ameliorating symptoms and complications associated with the given cytopenia. On the other hand, it was recognized early on that, in most cases, the pathophysiology of MDS had nothing to do with the failure of growth factor availability. For example, levels of Epo, the renally elaborated protein that regulates red cell production,[272] usually are elevated in anemic patients with MDS[273]; however, the intrinsically diseased bone marrow cannot respond. Moreover, it has been recognized for some time that leukemic cells, the neoplastic counterparts of normal bone marrow stem cells, harbor growth factor receptors and can be induced to proliferate in vitro in response to these

agents.[274] As such, it was feared that particularly the myeloid growth factors might be leukemogenic in patients with MDS. Although clinical studies have failed to confirm a major deleterious leukemogenic effect, they also have shown that these treatments do not prevent infection or prolong life expectancy. Nonetheless, when used selectively, hematopoietic growth factors may be useful in the management of certain patients with MDS.

Management of RBC Transfusion Dependence

Because most patients with MDS are anemic, which is a major factor in fatigue and poor quality of life, the issue of primary management of this finding is critical. Transfusion of packed RBCs, generally when the patient is symptomatic or when the hemoglobin falls below 8 to 9 mg/dL, is the usual approach. RBCs should be irradiated to prevent transfusion-associated graft-versus-host disease.[275] Whether routine depletion of white cells to reduce alloimmunization is required is controversial.[276] Despite the caveat about high Epo levels in MDS patients, patients can respond meaningfully to this agent, perhaps because a blunted response curve[277] allows pharmacologic doses of recombinant Epo to stimulate erythropoiesis in MDS. The potential for exogenous Epo to raise the hematocrit, decrease transfusion requirements, and possibly improve the quality of life in patients with MDS spurred the generation of many phase II and III trials with various doses and schedules of Epo. Although the initial trials generally used three times per week dosing (based on the successful use of this drug in patients with renal failure),[278] the impracticability of this approach (based on third-party payment rules requiring patients receive drug administration in a doctor's office) have generated weekly dosing schedules. Moreover, the availability of long-acting Epo[279] has furthered the use of more intermittent schedules.

Selected phase II trials[280–283] using recombinant human erythropoietin (rh-Epo) in patients with MDS report response rates in the 25% range. However, definitions of response are highly variable, most trials were conducted before common use of the International Working Group (IWG) criteria,[270] and the clinical benefit of such responses can be quite heterogeneous. For example, an increase in hemoglobin of 1 to 2 mg/dL could have biologic but very little clinical significance unless the patient becomes transfusion independent. Older patients with MDS who have clinical or subclinical impairment of renal function leading to a relatively lower level of serum Epo for a given degree of anemia might be good candidates for a therapeutic trial with this agent.

Although most patients with MDS have abundant supplies of iron due to prior transfusion or high gut absorption, a small subset of patients may be iron deficient. Therefore, it is important to review iron stores at the time of diagnostic bone marrow examination and, if absent, to provide supplemental iron because Epo responsiveness requires an iron-replete state. Since response to Epo in MDS may be delayed, the drug should be continued for at least 8 weeks before therapeutic failure is declared. Although the drug is well tolerated, keeping severely anemic and/or heavily transfusion-dependent patients on Epo for long periods makes little sense and is costly. Several studies have suggested that adding the myeloid growth factor G-CSF at low doses to erythropoietin can enhance the erythropoietic response.[284–286] Using the combination of Epo plus G-CSF initially or adding G-CSF after the effect of Epo is stable or waning may lead to response rates in the 40% range, which appear to be higher than with Epo alone. Nonetheless, the lack of a true prospective randomized trial of Epo with/without G-CSF has limited the wide acceptance of this strategy.

For patients with low-risk MDS, rh-Epo remains the most commonly used initial therapeutic approach for treatment of patients with MDS who are transfusion dependent to RBCs. In patients with MDS, only 15% to 30% will experience an erythroid response to rh-Epo. There are good predictive features for an observed response. Predictors for response to Epo are unclear. A decision model was developed by Hellstrom-Lindberg[286] (Table 67–9). Patients with MDS who had an Epo level less than 500 mU/mL, low RBC transfusion requirements, and bone marrow blasts less than 10% had a favorable chance of responding to rh-Epo. Interestingly, the presence of a deletion 5q with or without additional cytogenetic abnormalities did not affect the response rate but did shorten the response duration.[287] In addition, patients who do not have RARS[288,289] have a higher and more durable response. The Nordic MDS group suggested that patients with multilineage dysplasia have a poorer response to rh-Epo compared to patients with unilineage erythroid dysplasia (75% vs 9%; $P = 0.003$).[290] However, this has not been uniformly observed. The addition of a granulocyte colony-stimulating factors (G-CSF or GM-CSF) to single-agent rh-Epo can increase response rates by 20% to 40%.[60,284,286,291–293] Darbepoetin, a hypersialated ESA, has a longer half-life than rh-Epo and has yielded similar response rates when administered at intervals of every 1 to 3 weeks.[293] Response durations to either ESA agent range from 1 to 2 years, with longer responses associated with lower blast percentage as well as a low-to-intermediate IPSS score.

Table 67–9 Algorithm for Predicting Response to Erythropoietin and Granulocyte Colony-Stimulating Factor in Lower-Risk Myelodysplastic Syndrome

Parameter	Value of Parameter	Score
Serum erythropoietin	<100 mU/mL	+2
	100–500 mU/mL	+1
	>500 mU/mL	–3
RBC transfusions	<2 units/month	+2
	≥2 units/month	–2

Score	Response
Score >+1	Good response = 74%
Score –1 to +1	Intermediate response = 23%
Score <–1	Poor response = 7%

Response definitions:
Complete = Stable hemoglobin >11.5 g/dL.
Partial = Increase in hemoglobin with >1.5 g/dL or cessation of red blood cell (RBC) transfusion.
Adapted from Hellstrom-Lindberg E, Ahlgren T, Bequin Y, et al: Treatment of anemia in myelodysplastic syndromes with granulocyte colony-stimulating factor plus erythropoietin: Results from a randomized phase II study and long-term follow-up of 71 patients. Blood 92:68, 1998.

Few data regarding the safety of ESA use in patients with MDS are available. Use of ESAs for treatment of chemotherapy-induced anemia and chronic renal insufficiency has been associated with increased morbidity and mortality in many but not all randomized trials. In patients with chronic renal insufficiency, a hemoglobin target of 10 to 12 g/dL was often targeted in a randomized trial in which patients assigned to a targeted hemoglobin of 13.5 g/dL experienced significantly more adverse events, including death, chronic heart failure, myocardial infarction, and stroke compared to patients assigned to a lower targeted hemoglobin.[294] These findings have been supported by a more recent meta-analysis of nine randomized studies comparing different hemoglobin targets suggesting that patients with higher hemoglobin concentration display significantly higher rates of all-cause mortality, including complications from arteriovenous (AV) access thrombosis as well as from poorly controlled hypertension.[295]

As for patients with MDS, amelioration of anemia is thought to improve quality of life, specifically in responding patients. In addition, decreasing the need for transfusion support may have a dramatic impact on RBC supplies as well as decrease the risk of secondary hemochromatosis. More important is the observation that transfusion dependency has a negative impact on the natural history of patients with MDS.[191] A retrospective case-matched study of patients with MDS treated with supportive care compared to rh-Epo demonstrated that patients with a low RBC transfusion requirement (<2 units of RBCs per month) had a significant survival advantage with

the addition of rh-Epo (hazard ratio = 0.56; $P = 0.015$).[296] Of major importance is the fact that administration of rh-Epo had no significant adverse effect on leukemic evolution. In fact, there was a suggestion that responding patients had a lower risk of AML progression compared to patients who did not respond. These findings were corroborated by another study of 419 patients with MDS who were treated with an ESA.[287] Patients were compared with case-matched controls with MDS managed by supportive care without use of rh-Epo. Similarly, a survival advantage was observed in the responding patients. Finally, a phase III prospective cooperative group trial also demonstrated a survival advantage in patients with MDS treated with rh-Epo with or without use of the myeloid growth factor G-CSF.[291] This was compared to best supportive care. The median survival in patients responding to treatment was 53 months compared to 23 months in nonresponding patients. These data importantly suggest that decreasing RBC transfusion requirements and resolution of severe anemia in patients with MDS may improve not only overall survival in low-risk patients but also decrease the risk for AML progression.

Management of Neutropenia

Due to the quantitative and qualitative defects in neutrophils, infections are common in patients with MDS and are a source of considerable morbidity and occasional mortality.[21] No data support the routine use of prophylactic granulocyte transfusions or antibiotics in MDS. Once fears about the ability of the myeloid growth factors G-CSF and GM-CSF to stimulate clinically meaningful blast cell proliferation were diminished, studies conducted in the late 1980s and early 1990s documented the efficacy of these agents in routinely increasing the number of normal white blood cells.[297–300] However, the few randomized studies performed did not demonstrate a decrease in the infection rate or an improvement in life expectancy despite achieving blood count improvement.[301] Such a discrepancy may reflect the maturation of dysfunctional or hypofunctional neutrophils that, although increased in number, cannot provide significant host defense benefit. Moreover, the mortality rate from infectious causes in MDS before conversion to AML probably is low. Although selected patients with recurrent suppurative infections might be candidates for myeloid growth factors, these agents should not be routinely used in MDS.

Management of Thrombocytopenia

Patients with MDS, particularly with more advanced subtypes, may have severe chronic thrombocytopenia with associated mucosal bleeding. Thrombocytopenia, defined as platelet count less than 100×10^9/L, occurs in 40% to 65% of patients with MDS. This problem may become life threatening if a significant bleed occurs in the brain or gastrointestinal tract. The reported incidence of hemorrhagic complications ranged from 3% to 53%, and the frequency of death as a result of hemorrhage was 14% to 24% of such cases.[165] Nonetheless, platelet transfusions should be used judiciously in MDS because overuse may result in alloimmunization and failure to respond to subsequent transfusions, even if leuko-poor products are used.[276] As in the case of RBC transfusions, platelets should be irradiated prior to use.[275] Therefore, rather than giving transfusions below a certain threshold, as is routinely done after chemotherapeutic administration,[302] it makes more sense to use clinical bleeding as the trigger. Use of the antifibrinolytic agent ε-aminocaproic acid can be considered for the thrombocytopenic patient who is bleeding but is not responding to transfusional therapy.[303]

Levels of thrombopoietin, the homeostatic hormone responsible for maintaining normal platelet counts, are elevated in thrombocytopenic patients with MDS,[304] making response to pharmacologic doses of the recombinant protein unlikely. However, neither native thrombopoietin nor its pegylated derivative megakaryocyte growth and development factor (MGDF) has been tested in patients with MDS. MGDF underwent limited testing as a supportive agent in patients with AML after induction chemotherapy.[305,306] Not only was MGDF not associated with a decrease in bleeding or need for platelet transfusions in AML, but its development was discontinued due to development of antiplatelet antibodies and thrombocytopenia in normal volunteers. IL-11, a cytokine with pleiotropic effects, is approved for use as a supportive agent for prophylaxis against severe thrombocytopenia after myelointense chemotherapy for solid tumor patients.[307] Limited testing of this agent alone in MDS patients[308] or after myelosuppressive therapy with the antibody–toxin conjugate gemtuzumab ozogamicin demonstrated side effects (e.g., fluid retention) and limited efficacy.

AMG531 (romiplostim) is a thrombopoiesis-stimulating Fc-peptide fusion protein (peptibody) that is being investigated in patients with idiopathic thrombocytopenic purpura.[309] AMG531 binds and activates the thrombopoietin receptor Mpl. Phase II studies have demonstrated durable platelet responses in patients with idiopathic thrombocytopenic purpura and the ability of these patients to subsequently discontinue corticosteroid therapy. AMG531 also is being developed in patients with chemotherapy-induced thrombocytopenia as well as in patients with MDS. A phase I/II study of AMG531 in patients with low-risk MDS who also were thrombocytopenic has been completed. Durable platelet responses were seen in 54% of patients with a decreased need for transfusions and a lower number of severe hemorrhagic events in responding patients.[310] Future studies will further explore the response rates of AMG531 in patients with MDS-related thrombocytopenia as well as patients currently undergoing hypomethylating therapy who develop thrombocytopenia as a complication of therapy.

Eltrombopag (SB-497115) is an oral nonpeptide thrombopoietin receptor agonist that binds to the transmembrane domain of the Mpl receptor, thereby inducing proliferation and differentiation of megakaryocytes.[311] Eltrombopag increased platelet production in patients with thrombocytopenia secondary to hepatitis C virus infection and in adult patients with relapsed or refractory chronic idiopathic thrombocytopenic purpura. Its use in patients with MDS has not been reported.

Management of Iron Overload

In patients with MDS, particularly those with indolent histologic subtypes and/or good prognoses based on the IPSS schema, administration of well over 100 units of packed RBCs is not unusual. The high iron load associated with such transfusion requirements may be harmful to the liver, pancreas, heart, and central nervous system.[312] Chelation therapy with either desferoxamine by continuous subcutaneous administration or the oral agent deferasirox (ICL670) can be administered to such patients, usually after they have received at least 25 to 30 units of blood.[313,314] Side effects of desferoxamine include cataract formation and chronic skin irritation from the subcutaneous injections. Chronic administration of desferoxamine is cumbersome,[315] is not well tolerated, and chelates only approximately 25 mg of iron per day, which compares unfavorably with the 250 mg given in a single unit of blood. Although beneficial in children with thalassemia who receive frequent transfusions,[316] the role of desferoxamine is limited in patients with MDS.

Deferasirox initially is administered at a dose of 20 mg/kg once per day and escalated to 30 or 40 mg/kg/day depending on the response. Typical side effects include development of gastrointestinal toxicity principally manifested as abdominal pain, nausea, vomiting, and diarrhea. Unfortunately, these side effects make dose escalation difficult in some patients. Deferasirox typically is used in patients with low-risk MDS and has been associated with decreases in serum ferritin levels. Prospective randomized trials using this agent in patients with low-risk MDS are warranted before its use can be universally recommended.

The development of secondary iron overload is difficult to define.[209] Secondary iron overload often is defined in patients with serum ferritin level greater than 1000 mg/mL. Patients who have an

elevated serum ferritin level greater than 1000 mg/mL have decreased overall survival.[191,317] Whether poorer clinical outcomes are related to increased number of transfusions, a consequence of iron overload, or are due to progressive marrow dysfunction and failure that results in lower hemoglobin levels is unclear. Although these data are provocative, further evaluation and independent validation are needed, especially because few patients live long enough to develop definitive complications of iron overload.

Agents with Limited Efficacy

In the past, virtually every patient with MDS was given pyridoxine (vitamin B_6), probably because of its safety and the fact that rare children with congenital dysmyelopoiesis may respond.[318] However, reports of adults who actually benefit are rare. Androgen therapy, formerly a mainstay in the treatment of patients with bone marrow failure due to aplastic anemia or myelodysplasia, is rarely used today because of the lack of supporting data and its untoward side effects.[319] Danazol is a weak androgen and possibly has immunosuppressive properties. Although danazol therapy occasionally improves anemia and thrombocytopenia,[320] the rarity of such responses and the associated side effects have lead to abandonment of its typical use.

Immunosuppressive Therapy

For many years, patients with MDS were treated with steroids. Response rates in the 20% range were noted, but the increased use of prednisone in patients with myelodysplasia clearly led to more complications than benefit.[321] Nonetheless, several pieces of evidence have caused resurgence in enthusiasm for immunosuppressive therapy for MDS. First, autoimmune phenomena, often polyarthritis,[174] can be associated with MDS. Treatment with steroids in such cases may ameliorate the autoimmune manifestations and improve blood counts.[181] Patients with MDS have aberrant autoimmune hematopoietic inhibitory activity. In a subset of patients, clonal amplification of T lymphocytes has been demonstrated. The implication of this T-cell repertoire is that it suppresses hematopoiesis through a $CD8^+$ cytotoxic T-lymphocyte–mediated pathway.

Hypoplastic MDS bears morphologic similarity to aplastic anemia. Some patients with aplastic anemia who initially respond to immunosuppressive therapy may progress to MDS,[322] which suggests that these two entities share a common pathophysiology, that of T-cell–mediated suppression of a primitive bone marrow stem cell. Indeed, antithymocyte globulin (ATG), the mainstay of nontransplant therapy for aplastic anemia,[323] has a role in certain patients with MDS. A report from the National Cancer Institute suggests that patients with MDS who are young and have low platelet counts may benefit from a trial of ATG, with response rates as high as 50%.[324] The pretreatment variables associated with a higher response to immunosuppressive therapy include younger age (<60 years) and short duration of RBC transfusion dependency (<6 months). Interestingly, findings have shown the presence of a PNH clone or the presence of human leukocyte antigen (HLA) DR15 phenotype is another predictor for response to ATG in MDS.[325] It was originally thought that only those patients with hypoplastic MDS would respond, but now it seems clear that bone marrow hypoplasia is not a requirement for response, that rabbit or horse ATG can be used, and that patients with excess blasts rarely respond.[326]

Although no randomized trials have confirmed a survival benefit in patients treated with immunosuppressive therapy, a comparison of more than 800 patients in the IMRAW managed for prognostic variables showed that immunosuppressive therapy was associated with an improved overall survival (8.1 vs 5.2 years; $P < 0.001$).[116] Immunosuppressive therapy also was associated with a decreased risk of leukemic transformation ($P = 0.001$). The benefit in overall survival due to decreased leukemic transformation was seen in patients with low and intermediate-1 IPSS who were younger than 60 years. In addition, investigators from Prague have shown that approximately 40% of patients with indolent subtype MDS may respond to cyclosporine A.[327] Although a large randomized trial testing the usefulness of ATG in MDS is ongoing, young patients with MDS who do not have excess marrow blasts should be considered for a trial of immunosuppression.

Manipulating the Microenvironment

The pathophysiology of MDS is complex. However, it is increasingly recognized that the bone marrow microenvironment, including endothelial cells, fibroblasts, and other stromal cells, as well as immune effector cells and certain elaborated cytokines may have critical roles in maintenance of the neoplastic MDS clone. For example, microvessel density is increased in the marrows of patients with AML and MDSm[199] and proangiogenic substances such as vascular endothelial growth factor may be required for growth of neoplastic stem cells.[200] Second, at least in the indolent MDS subtypes, peripheral cytopenias in the presence of hypercellular bone marrow have suggested overabundant apoptosis, perhaps due to stromal cell secretion of proapoptotic substances such as TNF.[62] Attempts to modify TNF availability with use of phosphodiesterase inhibitors such as pentoxyphylline in combination with the steroids and ciprofloxacin (pentoxyphylline, ciprofloxacin, and dexamethasone [PCD] therapy)[328] or with the direct anti-TNF molecule etanercept (Enbrel),[329] as used in rheumatoid arthritis,[61] have led to transient and low-level responses in MDS. Amifostine, a thiol-containing compound approved for use as a chemoprotectant and radioprotectant,[330] alone[331] or in combination with PCD,[332] has limited biologic activity, with clinical responses that are too rare to justify the routine use of any of these strategies without an ability to predict which patients will respond.

The proangiogeneic and proapoptotic cytokine milieu of MDS may be counteracted by agents such as thalidomide, which has been effective in treatment of patients with refractory myeloma.[294] Studies suggest that thalidomide can lead to significant improvement in the need for transfusions in approximately 20% of patients with low-grade MDS subtypes.[333,334] However, many in the typical older patient population are poorly tolerant of the constipation, somnolence, and neuropathy typically associated with thalidomide use. The potent and better-tolerated thalidomide analogue lenalidomide (Revimid), which has activity in patients with advanced multiple myeloma,[219,220,335] may well be a real advance in "microenvironment-directed" therapy in MDS. Arsenic trioxide, which is approved for use in relapsed acute promyelocytic leukemia[336] and may modify the cytokine and angiogenic milieu in MDS, has shown only limited clinical activity.[337,338]

Lenalidomide

Lenalidomide is a thalidomide derivative (CC5013) that has more potent inhibition of TNF-α and other inflammatory cytokines compared to the parent compound. In addition, lenalidomide has greater capacity to promote T-cell activation and suppress angiogenesis. Importantly, lenalidomide lacks much of the neurotoxicity of thalidomide but still has myelosuppressive properties. A phase I study (MDS-001) was performed in patients with MDS who had symptomatic anemia and did not respond to treatment with ESAs.[220] Patients received doses of lenalidomide at 25 mg daily, 10 mg daily, or 10 mg daily for 21 days of a 28-day cycle, and 56% of patients experienced a durable erythroid response per the International Working Group (IWG). Twenty of 32 patients who previously were RBC transfusion dependent became independent of transfusion. Importantly, erythroid response rates were dependent on the presence of deletion of chromosome 5q, with 10 of 12 patients responding compared to 57% of patients with a normal karyotype and 12% of patients with abnormal karyotype. For patients with a 5q abnormality, responses were durable, with median duration of major erythroid response exceeding 2 years. The dose-limiting toxicities were different

than expected from thalidomide and predominantly included myelosuppression, specifically within the first month of therapy. In fact, grade 3 or greater neutropenia occurred in 58% of patients and grade 3 or greater thrombocytopenia in 50% of patients.

Two multicenter confirmatory trials were performed in patients with MDS and a low or intermediate-1 risk IPSS score. Patients were transfusion dependent and had not responded to an ESA. The MDS-002 study was performed in patients without a 5q abnormality, and lenalidomide was started at a dose of 10 mg daily or 10 mg daily on days 1 to 21 of a 28-day cycle.[339] The overall transfusion response rate was 43,% with 26% of patients achieving transfusion independence. The median duration of response was 41 weeks. Although only a minority of patients had clonal cytogenetic abnormalities 19% experienced a cytogenetic response. The principal toxicity remained myelosuppression, with 30% and 25% of patients developing grade 3 or greater neutropenia and thrombocytopenia, respectively.

A second phase II trial (MDS-003) was performed in transfusion-dependent patients with MDS who contained a deletion of chromosome 5q using a similar dosing regimen as in the MDS-002 study.[219] A total of 148 patients were enrolled, and erythroid responses were seen in 76% of patients, with an amazing 67% of patients achieving a transfusion-independent state. In addition, complete cytogenetic responses were seen in 73% of patients and partial cytogenetic responses in 45% of patients. Development of a cytogenetic response was associated with achievement of transfusion independence. Surprisingly, the presence of additional chromosomal abnormalities was not associated with a decreased erythroid or cytogenetic response rate. Myelosuppression was extremely common in patients with chromosome 5q abnormality, and grade 3 or greater neutropenia or thrombocytopenia was reported in 55% and 44% of patients, respectively. A retrospective analysis suggested that patients who experience a 50% reduction in platelet count or grade 3 myelosuppression during the first 8 weeks of therapy had a higher incidence of response compared to patients who did not suffer myelosuppression. Exogenous use of myeloid growth factors was effective in treatment-related neutropenia.

The long-term outcome of lenalidomide use for treatment of patients with MDS who harbinger a deletion of chromosome 5q has been analyzed.[340,341] The data confirm a long median duration of response of 2.2 years, with some patients responding for more than 5 years. Higher response rates were seen by multivariate analysis for patients with the "actual" 5q syndrome, RBC transfusions of fewer than 4 units per 8 weeks, low-risk IPSS score, and age younger than 70 years. Using Kaplan-Meier estimates, responders had a 10-year overall survival estimate of 78% compared to 4% for patients who failed to respond. Unfortunately, these data are retrospective but nevertheless suggest that lenalidomide may change the natural history of patients with MDS who concurrently have a chromosome 5 abnormality.

Differentiation Therapy

Can the putative block in normal hematopoietic differentiation in patients with MDS be reversed by pharmacologic agents? Many compounds, including the vitamin A analogue retinoic acid,[342] the protein kinase C inhibitors phorbol ester[343] and brysotatin,[344] polar-planar solvents such as phenylbutyrate[345] and hexamethylene bisacetamide,[346] and nucleoside analogues such as low0dose cytarabine (ara-C)[78] can promote maturation of leukemic cells in tissue culture. One of the first clinical efforts with one of these agents suggested that low-dose cytarabine produced responses in patients with MDS without causing aplasia.[347] Initial enthusiasm for low-dose cytarabine in MDS faded because of studies suggesting a low response rate in meta-analysis and that some of the responses really occurred due to hypoplasia, much as would be expected from standard chemotherapy.[348,349] A randomized trial conducted by the Medical Research Council demonstrated a superior overall survival compared to best supportive care in elderly patients with AML or high-risk MDS.[350]

A randomized trial of retinoic acid versus observation, one of the few such efforts in MDS, failed to show any discernible benefit for patients enrolled in the experimental arm.[351] Phase II clinical trials with phenylbutyrate[352] and hexamethylene bisacetamide[353] each produced a few impressive responses, but the low frequency of efficacy and the requirement for cumbersome prolonged infusions prevented major interest. Although not a differentiating agent, melphalan, an orally available alkylating agent, has produced complete remissions in limited testing in patients with MDS.[354]

The mechanism of retinoic acid's differentiation activity in acute promyelocytic leukemia is inhibition of histone deacetylase-mediated transcriptional repression engendered by the PML-RARA fusion protein consequent to the characteristic t(15;17) chromosomal abnormality.[355] Several compounds that, unlike retinoic acid, have direct histone deacetylase inhibitory capability are in development as potential therapeutic agents for MDS. Depsipeptide has undergone phase I testing in patients with AML.[356] The drug appears to be well tolerated and inhibits histone acetylation in vivo. Other histone deacetylase inhibitors, including phenylbutyrate, suberoylanilide hydroxamic acid (Vorinostat), valproic acid, MS-275, LAQ823, LBH589 (panobinostat), and MGCD0103 are undergoing phase I testing in patients with MDS and related disorders.[357,358] Not surprisingly, attempts have already been made to combine DNA hypomethylating agents with histone deacetylase inhibitors in the form of azacytidine plus phenylbutyrate[359] or decitabine plus valproic acid.[360] Such efforts require careful consideration of optimal scheduling and ample ancillary studies to determine if the presumed targets really are affected.

Hypomethylating Agents

Progress in the field of epigenetics,[361] including thoughts concerning promoting expression of transcriptionally silent genes that might be required for the differentiated phenotype, has rekindled interest in the use of small molecules to promote hematopoietic maturation in patients with MDS. Structural barriers to transcription result from either overmethylation of DNA[73] or underacetylation of the histone DNA coat.[362] Cells from patients with MDS typically display overmethylation of genes such as p15INK4B,[363] which argues in favor of the relevance of this mechanism.

The greatest recent therapeutic advance in the management of patients with MDS was highlighted by a phase III trial, albeit with early crossovers permitted, of the putative DNA hypomethylating agent azacytidine given subcutaneously daily for 7 days every 28 days versus observation in patients with MDS conducted by the Cancer and Leukemia Group B.[364] Randomization to azacytidine was associated with a response rate of 60% (mostly hematologic improvement), delay in transformation to AML, and improved quality of life measured by several validated instruments.[365] The benefit of azacytidine was apparent in patients with both high- and low-risk MDS; a trend toward improvement in overall survival in the azacytidine arm did not reach statistical significance. The side-effect profile of the drug included mild nausea and vomiting and transient myelosuppression in some patients. Azacytidine, which now can be given intravenously, is metabolized in vivo to another hypomethylating agent decitabine.

Decitabine (5-aza-2′-deoxycytidine) has significant activity in patients with MDS based on a phase II trial performed in Europe[366] and a low-dose trial performed at the MD Anderson Cancer Center.[164] A phase III trial was performed in 170 patients with IPSS intermediate-1 or higher risk. Patients were randomized to receive either decitabine at a dose of 15 mg/m^2 given intravenously every 8 hours for 3 days or supportive care.[367] The overall response rate in patients treated with decitabine was 17%, including 9% complete remissions. Unfortunately, no effect was observed in terms of overall survival, but in a subgroup analysis, patients with intermediate-2 and high IPSS scores who received decitabine had a longer median time of progression to AML or death compared with patients who received supportive care alone (12.0 months vs 6.8 months; $P = 0.03$). One of the difficult issues with this study is that 43 patients received only

two cycles of therapy, yet more than two cycles or 3.3 months of therapy on average was required to demonstrate a clinical response. Both decitabine and azacytidine have been approved by the US Food and Drug Administration and are being tested against supportive care in multiinstitutional prospective phase III trials.

A randomized bayesian phase II trial of patients with MDS was conducted at the MD Anderson Cancer Center. Decitabine was administered in one of three schedules: 10 mg/m^2 intravenously for 10 days, 20 mg/m^2 intravenously for 5 days, or 20 mg/m^2 intravenously for 5 days.[368] All three groups of patients received the same total dose of decitabine, 100 mg/m^2. The 20 mg/m^2 intravenously for 5 days arm was preferentially enrolled, suggesting that this may be the superior regimen. The overall response rate was 48%, with 34% of patients entering a complete remission. Although these results seem to be superior to those achieved using the 3-day regimen, they must be confirmed in a multicenter trial.

Signal Transduction Inhibitors

In MDS subtypes associated with excess blasts, highly analogous to the situation in AML, the underlying biologic problem may include overproliferation and/or lack of apoptosis within the stem cell compartment. Insofar as there are patients with MDS whose disease behaves more like AML, one can think of the same therapies that are in use or in development for the more aggressive neoplasm. Moreover, older adults with AML in particular are generally presumed to have blasts that emanate from a primitive stem cell, much like MDS.[97] As such, remission induction chemotherapy is a variable therapeutic alternative for some patients with MDS.

The constitutively activated tyrosine kinases BCR-ABL in CML[124] and FLT-3 in 30% of cases of AML[102] represent important drug targets. The development of imatinib for treatment of patients with CML[369] has revolutionized the treatment of patients with gastrointestinal stromal cell tumors (GIST) based on the ability of imatinib to inhibit c-KIT,[370] idiopathic hypereosinophilic syndrome (HES) based on its ability to inhibit platelet-derived growth factor receptor α (PDGFR-α).[371] Similarly, the rare patients with the MDS subtype CMML whose cells harbor a cytogenetic abnormality, such as t(5;12), a translocation that activates PDGFR-β,[226,227] also exhibit striking responses to imatinib.[183,227] Therefore, it is important to carefully scrutinize the cytogenetic results in patients with MDS, especially those with CMML, for any translocation involving the long arm of chromosome 5, for the potential of initiating imatinib therapy.

Several drugs that can inhibit the activated version of the FLT-3 tyrosine kinase are in development, particularly for use in AML.[372,373] However, rarely, and again probably more likely in CMML, patients with MDS may have one of two activating FLT-3 mutations, either a so-called *internal tandem duplication*, a copy of between nine and 300 base pairs in the juxtamembrane region, or a mutation in the activation loop, usually a point mutation yielding a D835Y amino acid substitution.[102] As such, a few patients with primary MDS have been treated with PKC412, one of the FLT-3 inhibitors currently in clinical trials, and responses have been noted.[373] Identifying other tyrosine kinases that may be activated in MDS and the drugs that inhibit them could yield future therapeutic advances.

Another cell-signaling therapeutic target in MDS is mutationally activated RAS, a 20-kd guanine nucleotide binding protein.[374] Because a mutation in a RAS family member occurs in approximately 20% to 40% of patients with MDS and most commonly in CMML, drugs that inhibit this enzyme are in development. The so-called *farnesyltransferase inhibitors* were developed because they inhibited an enzyme that catalyzed a key step in the posttranslational modification of RAS, preventing attachment of the farnesyl group required for movement to the cell membrane and enzyme activation.[375] Phase I and II trials with farnesyltransferase inhibitors have been completed in patients with MDS and AML.[376] One of the most important conclusions from these trials, in addition to the presence of only modest clinical activity, was that responses occurred exclusively in patients whose cells did not have RAS mutations, suggesting the likelihood of alternative targets, perhaps farnesylation of some of the many other proteins undergoing this posttranslational modification step, including lamin A or RHOB.[377]

Induction Chemotherapy

Use of cytotoxic chemotherapy for treatment of patients with MDS was generally considered to be an unhelpful strategy based on the typically older age of these patients and their poor tolerance of chemotherapy. Moreover, the proximal nature of the stem cell defect in MDS suggests that patients would be resistant to chemotherapy, based on overexpression of proteins mediating pleiotropic drug resistance,[378] and would have limited normal stem reserve, making them prone to severe myelosuppression. However, Estey et al.[379] demonstrated that patients with MDS can respond as well, or as poorly, to chemotherapy as those with AML, if the key prognostic factors of age and cytogenetic status are controlled for. Complete response rates range from 40% to 50%. Unfortunately, these responses tend to be short lived, even with consolidation chemotherapy, which does support the intrinsic nature of chemotherapy resistance in MDS. Curative intensive consolidation regimens with high-dose ara-C is appropriate only for younger adults with de novo AML in first remission[380] and therefore has no role in the treatment of older patients with MDS, given that older adults with AML do not benefit from such an intensive approach.

The notion that selected patients with MDS might benefit from chemotherapy[379] was altered by the change in the definition of AML and MDS in the new WHO classification system. Patients with 20% or greater blasts, as opposed to 30% in the older FAB system, now are considered to have AML.[20] Second, patients with balanced chromosomal translocations associated with a favorable prognosis, such as inv(16), t(8;21), and t(15;17), are considered to have AML at any level of marrow or peripheral blood leukemic cell involvement.[20] Applying the new definitions of MDS, relatively few patients are obvious chemotherapy candidates.

Induction chemotherapy may be useful in the relatively younger patient with high-risk MDS, defined as greater than 10% blasts in the bone marrow or with serious cytopenias. Such patients can be considered for nonmyeloablative or reduced-intensity conditioning allogeneic transplant.[381] Chemotherapy may be useful as a cytoreductive step prior to a reduced-intensity transplant, but prospective data are lacking. Although regimens containing topotecan alone or with ara-C[382] have activity in patients with MDS, this novel agent is no better than standard anthracycline and ara-C combination regimens[383] and should not be used routinely. Similarly, gemtuzumab ozogamicin, an antibody–toxin conjugate that is associated with a 30% remission rate in relapsed AML,[382] is expensive, myelosuppressive, and not particularly efficacious in patients with MDS.[384]

Stem Cell Transplantation

Recognition that the stem cell defect in MDS is proximal and pervasive suggested that allogeneic transplant would be required to eliminate the malignant clone, thereby making cure a possibility. Numerous studies suggested that up to 60% of selected patients with low-risk MDS and 20% to 40% of patients with high-risk disease can experience long-term disease-free survival after allogeneic transplantation from a matched donor.[270,271,385–387] Albeit in a relatively young and well population, no other modality, including chemotherapy[379] or autologous BMT,[388] is associated with a similarly high success rate. Despite concern that high-dose chemotherapy with autologous marrow or peripheral blood stem cell rescue would be an unworthy approach given that neoplastic stem cells would be difficult to eliminate in MDS and would grow poorly as an autograft, European investigators reported appreciable disease-free survival when this modality is used as consolidation therapy in MDS patients achieving remission with chemotherapy.[388] However,

Table 67–10 Decision Analysis of Allogeneic Bone Marrow Transplantation for Myelodysplastic Syndrome

	Overall Survival (Years)		
International Prognostic Scoring System Category	***Immediate Transplant***	***Transplant in 2 Years***	***Transplant at Progression***
Low	6.51	6.86	7.21
Intermediate-1	4.61	4.47	5.16
Intermediate-2	4.93	3.21	2.84
High	3.20	2.75	2.75

From Cutler CS, Lee SJ, Greenberg P, et al: A decision analysis of allogeneic bone marrow transplantation for the myelodysplastic syndromes: Delayed transplantation for low-risk myelodysplasia is associated with improved outcome. Blood 104:579, 2004.[389]

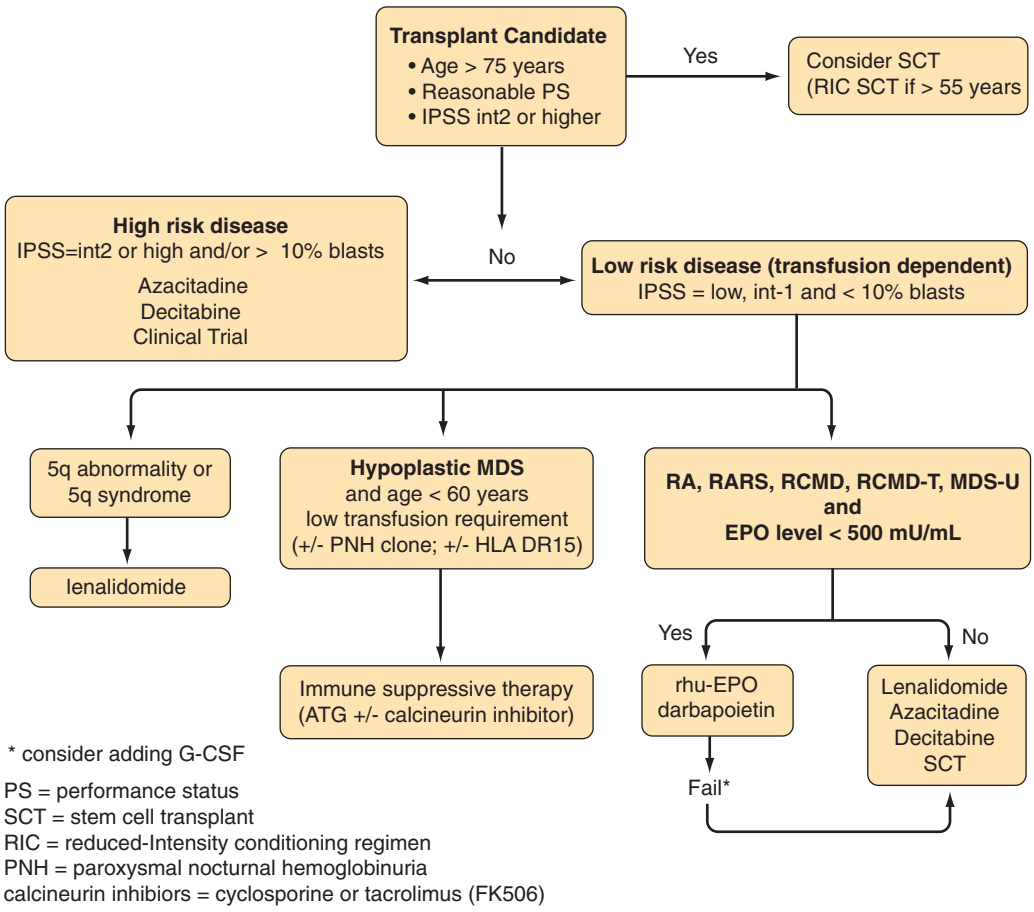

Figure 67–7 Algorithm for management of a patient with myelodysplastic syndrome.

because these patients likely would be more typical of an AML population, autologous BMT still is considered an experimental procedure for MDS.

An important treatment decision concerns the appropriate timing of transplantation, especially in low-risk disease. Upfront SCT potentially can take advantage of a relatively healthier bone marrow, with waiting until disease progression delaying transplant-related morbidity. Cutler et al.[389] analyzed a national database registry of transplant patients with MDS and their outcomes to perform a decision analysis addressing this question. They found that for low and intermediate-1 IPSS groups, delayed SCT was associated with better overall survival (Table 67–10). In contrast, for intermediate-2 and high IPSS groups, SCT at diagnosis maximized overall survival. The analysis focused only on full ablative conditioning regimens. Nevertheless, all patients with MDS who are reasonable transplant candidates based on age and comorbidity should undergo a formal consultation with transplantation specialist.

One clear advantage of allogeneic transplant in MDS, beyond the obvious benefit provided by the proffering of normal stem cells, is the powerful graft-versus-leukemia effect.[383] Evidence that neoplastic MDS cells are targets for killing by the graft emanates from data demonstrating a lower relapse after allogeneic, compared with syngeneic, transplants, the higher relapse rate after T-cell–depleted grafts, and mild graft-versus-host disease.[390] The apparent safety of unrelated matched transplants has improved recently due to the advent and routine use of molecular HLA typing.[391] Although allogeneic transplant seems an attractive option, a major problem remains the mortality associated with regimen-related toxicity and graft-versus-host disease, especially given the older age of the typical MDS patient. Use of nonmyeloablative or reduced-intensity conditioning, seeking to maximize the graft-versus-leukemia to toxicity ratio, is being used with increasing frequency.[381,392,393] Although it appears that reduced-intensity conditioning allogeneic transplantation can be accomplished with an acceptable short-term mortality rate in patients with MDS

up to age 70 to 75 years, long-term data on efficacy are lacking.[394–396] Cord blood transplants could extend the availability of allogeneic transplantation to greater numbers of patients with MDS. This technique may prove feasible in older adults, especially if it is associated with an acceptable risk of graft-versus-host disease.[397,398]

CONCLUSION

Despite recent advances in therapy for MDS, the need for improvement is great. Almost all patients with MDS should be referred for a clinical trial. Treatment recommendations involving available approaches and agents can be derived for a given patient, but generally not without prolonged discussion between the physician and the patient and his or her family (Fig. 67–7). All patients younger than 70 years with high-risk disease according to the IPSS (intermediate-2 or high) and who have a related or unrelated matched donor should be considered for allogeneic BMT if feasible. Patients older than 55 years should consider reduced-intensity conditioning SCT, but the long-term efficacy data are lacking. Use of hypomethylating agents as a form of "cytoreduction" prior to SCT is being investigated. Patients with high-risk MDS who are not considered SCT candidates should initiate treatment with a hypomethylating agent such as azacytidine or decitabine. Patients with low-risk disease have many options. Patients with a chromosome 5q deletion or the 5q− syndrome who are RBC transfusion dependent should receive lenalidomide. Patients with low-risk disease who are RBC transfusion dependent and do not have a 5q abnormality have many options. If their serum Epo level is less than 500 mU/mL, they should be started on an ESA, either rh-Epo or darbepoetin. If this treatment fails, then addition of a myeloid growth factor, such as G-CSF, should be considered. ATG should be considered for treatment of hypoplastic MDS in patients younger than 60 years who have modest transfusion requirements, a recent diagnosis, and low blast count. Nonresponding patients with low-risk disease should consider lenalidomide if the goal is only an erythroid response, or a hypomethylating agent should be considered in patients with pancytopenia. Clinical trial participation should be considered for all patients, because this is the only way that we can try and make strides in improving the survival of patients with MDS.

CHAPTER 68

THE POLYCYTHEMIAS

Ronald Hoffman, Mingjiang Xu, Guido Finazzi, and Tiziano Barbui

Under normal conditions, the red blood cell mass in humans is tightly controlled and remains relatively constant in a given individual.[1] The numbers of senescent red cells lost daily are replaced by newly formed ones by a carefully controlled network of growth factors and progenitor cells.[1–4] Erythropoiesis, which leads to a baseline production of red cells, can be augmented by a variety of stimuli that increase the delivery of oxygen to tissues. This delicate balance can be disturbed by various pathologic conditions and can result in either reduced numbers of red cells (anemia) or excessive numbers of red cells (polycythemia).[1–4] Hematocrit values over 52% in males and over 48% in females are abnormal and require further evaluation to determine the nature of a potential polycythemic disorder.[5] These polycythemic states can be caused by various disorders that can be accounted for by many different pathophysiologic mechanisms. Determination of the etiology of an individual's polycythemia is a critical step in defining the patient's appropriate prognosis and treatment plan. Primary polycythemias are the result of innate abnormalities involving hematopoietic progenitors and stem cells that lead to constitutive overproduction of red cells. By contrast, secondary polycythemias are the consequence of external factors such as erythropoietin (EPO), which act on normal progenitors to overproduce red cells.

ERYTHROPOIESIS

Red cell production can be influenced by numerous factors including nutrients, growth factors, numbers and function of marrow progenitor and precursor cells, as well as cellular receptors and transcription factors (see Chapters 21 and 25). The hematopoietic growth factor, EPO, is considered to be the physiologic regulator of the terminal phases of erythropoiesis.[1,2] Alterations in its production are followed by adjustments in the rate of formation of red blood cells.[1,2] In humans, EPO production is controlled by the relative supply of oxygen to the kidney, the major site of EPO.[1–3] In states of severe hypoxia, EPO production can be increased up to 1000-fold.[6] A large body of information is available addressing EPO physiology in patients with erythrocytosis.[1,2,7–12] Following phlebotomy of a healthy person, EPO excretion increases, and an inverse logarithmic relationship between hematocrit and EPO excretion rates is observed.[1] Patients with secondary erythrocytosis due to chronic hypoxia have either normal or increased basal values, but also have increased values following reduction of the hematocrit to normal levels by phlebotomy.[1] By contrast, EPO excretion is invariably subnormal in patients with polycythemia vera (PV), which demonstrates that this disorder is not a result of excessive EPO production.[1,8,12,13]

Different levels of EPO are required at the erythroid precursor and progenitor cell levels.[4] In addition, multipotent myeloid progenitors and primitive erythroid progenitors (burst-forming units–erythroid [BFU-E]), both of which ultimately contribute to erythropoiesis, require additional growth factors such as stem cell factor (SCF), interleukin 3 (IL-3), granulocyte–macrophage-colony stimulating factor (GM-CSF), or thrombopoietin (Tpo) to promote their proliferation and maturation (see Chapter 25).[4,14–16]

ERYTHROPOIETIN, OXYGEN SENSING, AND HYPOXIA-INDUCIBLE FACTOR

Under normal conditions, EPO production is mediated by the decreased oxygen content of hemoglobin within red cells, termed hypoxemia, which leads to decreased oxygen delivery to tissues.[4] Regulation of oxygen homeostasis is critical to survival. The acute reduction of the availability of oxygen leads to the initiation of a cascade of adaptive events occurring at the level of the organism, tissues, cells, and specific genes that sets in place compensatory events to correct the lack of oxygen supply. Low oxygen levels, hypoxia (60 mmHg), in humans result in oxygen-sensing cells within the glomus cells of the carotid body located in the carotid artery undergoing rapid membrane depolarization, leading to the production of action potentials, influx of calcium ions, and release of the neurotransmitter dopamine. These events result in an increase of the lung ventilation rate and restoration of normal oxygen tension to vital organs. Activation of the carotid body results in the sensation of breathlessness experienced by individuals at high altitudes.[17,18] The current candidates for oxygen sensors include the prolyl hydroxylase family of enzymes that require molecular oxygen for activity, the NAD(P)H oxidase family of enzymes that reduce reactive oxygen species and the electron transport systerm.[19] In response to chronic hypoxia, multiple compensatory mechanisms come into play in the kidney, the major site of EPO production.[2,20] Hypoxic stimulation results in production of hypoxia-inducible factor-1 (HIF-1), the major factor responsible for transcriptional activation of the *EPO* gene.[21] Analysis of proteins that bind to the EPO enhancer under hypoxic conditions led to the identification of HIF. The HIF transcriptional system is a master regulator of the hypoxic response controlling a large number of genes in multiple cell types. As key mediators of cellular oxygen maintenance, HIF-1 and HIF-2 facilitate body oxygen delivery and responses to oxygen deprivation by regulating the expression of gene products that are involved in cellular energy metabolism and glucose transport, angiogenesis, erythropoiesis and iron metabolism, pH regulation, apoptosis, cell proliferation, cell–cell and cell–matrix interactions. Classic HIF target genes include phosphoglycerate kinase, glucose transporter-1, vascular endothelial growth factor (VEGF) and EPO. The HIF proteins are members of the Per–ARNT–Sim family of heterodimeric basic helix–loop–helix transcription factors (Fig. 68–1).[22–32]

HIF-1α is continuously synthesized irrespective of oxygen availability. It is barely detectable in normal cells owing to rapid degradation via the ubiquitin proteasome pathway. During hypoxia, the rapid accumulation of HIF-1α is achieved by blocking its degradation, which permits an instantaneous response to hypoxia without activating the transcriptional/translational machinery.[22–32]

HIF-1 is composed of two subunits, HIF-1α and HIF-1β, that form a heterodimer (see Fig. 68–1).[32] In contrast to the constitutively expressed, HIF-1β subunits, HIF-1α is an oxygen-labile protein that becomes stabilized in response to hypoxia.[19] HIF-1α mRNA and protein levels are induced by hypoxia, and HIF-1α protein levels decay rapidly with return to normoxia. The posttranslational

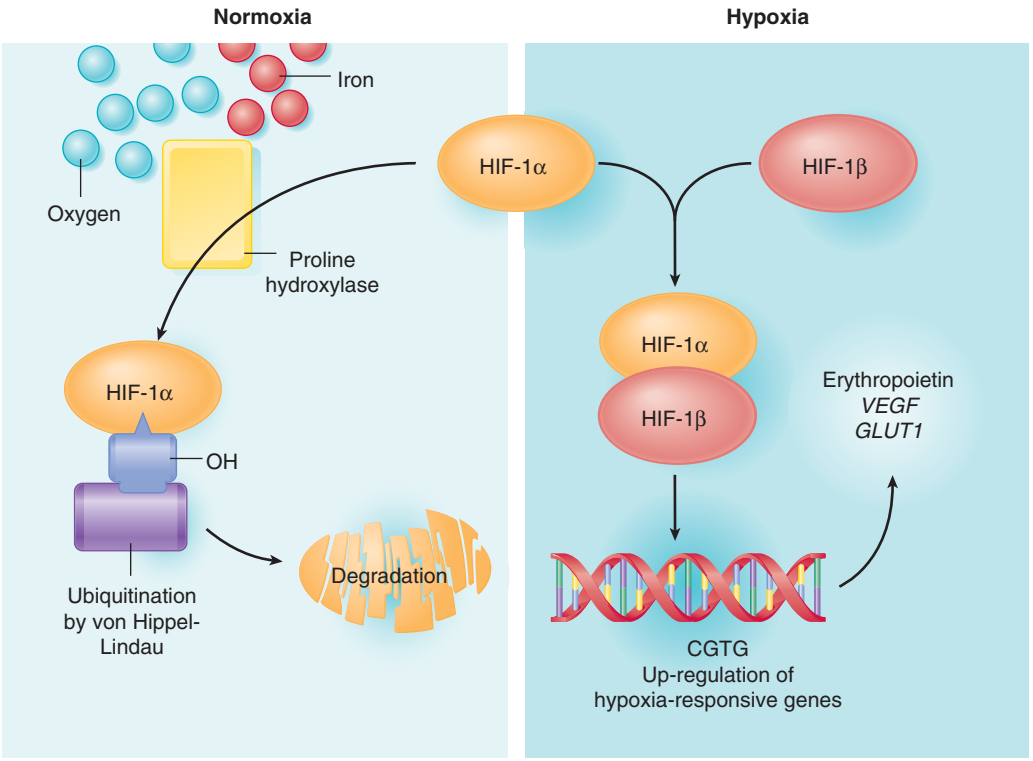

Figure 68–1. Schematic representation of the relationship between hypoxia sensing and erythropoietin production.

regulation of HIF-1α protein accounts for the majority of the regulation of this gene.[17] Normoxia-induced, ubiquitin-mediated degradation of the HIF-1α protein is the major regulator of HIF-1α levels,[33,34] thereby reducing the stimulus for additional EPO production (Fig. 68–1). The targeting and subsequent polyubiquitination of HIF-1α require the von Hippel–Lindau (VHL) protein, oxygen, and three different iron-requiring proline hydroxylase enzymes (Fig. 68–1). VHL protein targets HIF-1α for oxygen-dependent proteolysis[33–41] by a mechanism that involves the interaction of VHL protein with other proteins (Fig. 68–1). Different parts of the HIF-1α chains have different functions. The amino terminus part of HIF-1α is involved in DNA binding and dimerization while the carboxy terminus portion has regulatory functions. One domain at the carboxy terminus influences transcriptional activity without affecting HIF-1α protein levels while the other region termed the oxygen-dependent degradation domain (ODD) affects protein abundance. The ODD is divided into an amino terminus and a carboxy terminus subdomain. The ubiquitin proteasome pathway is responsible for the degradation of HIF-1α chains in the presence of oxygen.[38–41] The VHL protein physically interacts with the ODD of HIF-1α and the VHL protein is part of a multiprotein ubiquitin ligase capable of ubiquitinating HIF-1α subunits and targeting them for destruction by the proteasome. Iron-chelating drugs can also block the interaction of HIF-1α with the VHL protein, suggesting a role for iron in the degradation of HIF-1α.[38–41]

At least three prolyl hydroxylases (PHDs) have been found to hydroxylate HIF at unique proline residues and have been termed PHD-1, PHD-2, and PHD-3.[38–41] Under normoxic conditions, hydroxylation of HIF-1α at these different proline residues is essential for HIF proteolytic degradation by promoting interaction with the VHL tumor-suppressor protein through hydrogen bonding to the hydroxy proline-binding pocket in the VHL-β domain. As oxygen levels decrease, hydroxylation of HIF decreases, and HIF-1α then no longer binds VHL and becomes stabilized. The activity of PHDs depends on the availability of molecular oxygen, which qualifies these enzymes as oxygen sensors. In addition, these dioxygenases require 2-oxoglutarate as a cosubstrate and vitamin C to keep their central nonheme iron in the ferrous state. While PHD-2 appears to be the hydroxylase that is essential for HIF-1α degradation under normoxic conditions, PHD-3 is important for hydroxylation of HIF-1α during reoxygenation. Different effects of individual PHDs on HIF-1α and HIF-2α hydroxylation indicate that the stability of individual HIF-1α subunits and their target gene expression might be affected by tissue- and cell-type differences in PHD expression and activity levels. The activity of PHDs can be modulated by mitochondrial reactive oxygen species implicating mitochondria in oxygen sensing.[22]

Von Hippel–Lindau syndrome is a hereditary cancer syndrome that is associated with exaggerated responses to hypoxia due to post-translational abnormalities in HIF.[42] Von Hippel–Lindau syndrome is characterized by a propensity for developing clear cell renal carcinomas, retinal hemangioblastomas, cerebellar and spinal hemangiomas, pancreatic and renal cysts, islet cell tumors of the pancreas, and pheochromocytomas. The tumors result from somatic mutations that cause a loss of heterozygosity of the *VHL* gene.[42] VHL disease affects approximately 1 in 35,000 individuals and is transmitted in an autosomal dominant manner. Individuals with VHL disease carry one wild-type VHL allele and one inactivated VHL allele. This inactivation can occur by somatic mutation or hypermethylation. Tumor or cyst development is linked to somatic inactivation or loss of the remaining wild-type VHL allele. Approximately 20% to 37% of VHL patients have large or partial germline deletions, 23% to 27% have nonsense or frame-shift mutations, and 30% to 35% have missense mutations. More than 150 different VHL mutations linked to VHL disease have been reported. The tumors linked to VHL inactivation are often highly vascular and can produce angiogenic factors such as VEGF. In addition, renal cell carcinoma, cerebellar hemangioblastomas, and pheochromocytomas have been associated with paraneoplastic erythrocytosis due to overproduction of EPO.[42] Overproduction of HIF-inducible mRNAs is the hallmark of VHL protein defective cells. Genotype–phenotype correlates in VHL disease suggest that VHL has functions independent of HIF regulation that might play a role in tumor formation. VHL protein has other binding partners, including atypical protein kinase C and a family of deubiquitinating enzymes named VHL-interacting deubiquitinating enzymes 1 and 2. In addition, pVHL has been involved in numerous cellular processes, including regulation of extracellular matrix,

cytoskeleton stability, cell cycle control, and differentiation.[42] Although VHL disease is not associated with erythrocytosis, Richard and coworkers have recently observed the development of paradoxical polycythemia in three patients with VHL syndrome and central nervous system or retinal hemangioblastomas treated with the VEGF receptor inhibitor SU5416. The cause of these phenomena remains unknown.[43]

THE ERYTHROPOIETIN RECEPTOR

Interaction of EPO with the erythropoietin receptor (EPOR) present on the erythroid progenitor and precursor cells leads to its homodimerization, resulting in (a) stimulation of cell division, (b) differentiation by induction of erythroid-specific gene expression, and (c) prevention of erythroid progenitor and precursor cell apoptosis.[44,45] The cytoplasmic portion of the EPOR contains a positive regulatory domain that interacts with JAK2 (Fig. 68–2).[46,47] Immediately after EPO binding, JAK2 phosphorylates itself, the EPOR, and other proteins such as STAT5. This JAK2/STAT5 signaling plays an essential role in EPO/EPOR-mediated regulation of erythropoiesis.[46]

The C-terminal cytoplasmic portion of the EPOR also possesses a negative regulatory domain.[48] Hematopoietic cell phosphatase (HCP, also known as SHP-1 or PTP N6) interacts with this portion of the EPOR and downregulates signal transduction[48] by promoting dephosphorylation (see Fig. 68–2). Inactivation of the HCP-binding site leads to prolonged phosphorylation of JAK2/STAT5.[48,49] Another negative regulator of erythropoiesis, suppressor of cytokine signaling-3 (SOCS-3), binds to the cytoplasmic portion of the EPOR and suppresses EPO-dependent JAK2/STAT5 signaling.[50] Thus, deletion of the distal C-terminal cytoplasmic portion of the EPOR abolishes negative regulatory elements and results in increased proliferation of erythroid progenitor cells. Mutations in the *EPOR* gene have been observed in some patients with primary familial and congenital polycythemia (PFCP)[51–55] and are occasionally found in erythroleukemia (Fig. 68–2).[56] PV is not caused by mutations in EPOR.[57] Such secondary growth factors as insulin-like growth factor-1 (IGF-1) and the components of the renin–angiotensin system may also influence the production of red cells.

THE RENIN–ANGIOTENSIN SYSTEM AND HEMATOPOIESIS

The renin–angiotensin system (RAS) regulates fluid and electrolyte homeostasis and blood pressure[58–60] and has been hypothesized to also play a role in the regulation of erythropoiesis. The primary function of angiotensin during development is the regulation of tissue growth and differentiation.[58] Angiotensin II (AngII) is a ligand for two distinct receptors, type 1 and type 2 (AT1 and AT2). AT1 appears to play a major role in the regulation of cell proliferation.[59,60]

The RAS was first postulated to influence erythropoiesis in the 1980s after it was discovered that the use of angiotensin-converting enzyme (ACE) inhibitors to treat hypertension could result in anemia.[61] In animals, increased blood levels of renin (a major regulator of AngII synthesis) were found to result in elevated serum EPO levels and erythrocytosis.[62–64] In humans, the infusion of AngII also increases serum EPO levels.[65,66] The pathway underlying AngII-driven EPO secretion is unknown. However, some investigators have suggested that AngII modulates renal EPO production through changes in renal perfusion and sodium reabsorption.[20] This hypothesis is based on the presumption that reduced oxygen pressure in the kidneys triggers HIF-1α to induce release of EPO.[32] AngII also directly stimulates proliferation of hematopoietic progenitors in vitro,[67,68] and inhibition of this effect with ACE inhibitors induces apoptosis of erythroid progenitors in renal transplantation patients.[69] Mice with a knockout of the angiotensin-converting enzyme-1 (ACE-1) develop a normocytic anemia that can be fully reversed by infusion of AngII.[70] ACE-related anemia is most pronounced in patients with renal insufficiency or end-stage renal disease and in patients who have received a renal allograft.[71] The pathogenesis of this anemia is not clear, but reduced levels of circulating EPO are not solely responsible, suggesting that there might be other contributing factors. The AT1 receptor is present on erythroid progenitors, and its ligand, AngII, augments EPO stimulation of erythropoiesis.[72] The involvement of JAK2 kinase in AngII signaling suggests that this signal transduction pathway mediated by EPO and AngII might overlap.[73] Postrenal transplant erythrocytosis likely can be accounted by activation of the renin–angiotensin system.[72]

DEFINITION AND CLASSIFICATION OF POLYCYTHEMIA

The term *polycythemia* is a literal translation from Greek, meaning "too many cells in the blood," and refers to an increase in the red cell mass[12]; it is frequently used interchangeably with the term *erythrocytosis*. Polycythemia may be due to a myriad of causes (Table 68–1).[12,74,75] The polycythemias can be classified as relative and absolute.[12,74,75] Relative polycythemia is a disorder in which the patient characteristically has a modest elevation of the hematocrit level without an elevated red cell mass but rather due to contraction of the plasma volume, whereas the absolute polycythemias are accompanied by an actual increase in the circulating red cell mass.[74,76] Polycythemias can also be classified according to the responsiveness of their erythroid progenitor cells to growth factors or the circulating

Table 68–1 Differential Diagnosis of the Polycythemias

Relative or Spurious Polycythemia

1. Decreased plasma volume—reduced fluid intake, marked loss of body fluids (diaphoresis, vomiting, diarrhea, "third-spacing")
2. Gaisböck syndrome
3. Overfilling of blood in collection vacuum tubes

Absolute Polycythemia

1. Primary congenital and familial polycythemia
2. Secondary polycythemia
   - Acquired
     - Hypoxia
       - Pulmonary disease
       - Cyanotic congenital heart disease
       - Hypoventilation syndromes—sleep apnea, Pickwickian syndrome
     - High altitude
     - Smokers' polycythemia, carbon monoxide intoxication due to industrial exposure
     - Postrenal transplantation erythrocytosis
     - Aberrant erythropoietin production
       - Tumors—renal cell carcinoma, Wilms tumor, hepatic carcinoma, uterine leiomyomata, virilizing ovarian tumors, vascular cerebellar tumors
       - Miscellaneous renal and hepatic disorders—solitary renal cysts, polycystic kidney disease, renal artery stenosis hydronephrosis, viral hepatitis
     - Endocrine disorders—Cushing's syndrome, primary aldosteronism
     - Androgen use
     - Erythropoietin use
   - Congenital
     - Abnormal high-affinity hemoglobin variants
     - Biphosphoglycerate deficiency
     - Congenital methemoglobinemia
     - Chuvash polycythemia (von Hippel–Lindau mutations)
     - Prolyl hydroxylase mutations
3. Polycythemia vera

levels of such growth factors. Primary polycythemias are characterized by increased sensitivity of the erythroid progenitors to regulatory growth factors, as a result of acquired somatic or inherited germline mutations expressed by hematopoietic progenitor cells.[77,78] In contrast, secondary polycythemias are characterized by an increase in regulatory growth factors, primarily EPO, and normal responsiveness of their erythroid progenitors to these growth factors.[75,77,78] These conditions can usually be distinguished by in vitro assays of erythroid progenitor cells, quantitation of serum EPO levels, and detection of somatic JAK2 mutations.[79–83]

RELATIVE POLYCYTHEMIA

Individuals with a modestly increased venous hematocrit level that is not accompanied by an increased red cell mass are frequently thought to be polycythemic by imprecise yet widely accepted medical practice. Frequently these individuals are thought to be polycythemic owing to the lack of appreciation by a clinician of what constitutes the upper limit of normal values for a hematocrit (52% in males and 48% in females). Such individuals frequently prove not to have an absolute polycythemia as defined by an actual increase in the measured red cell mass. *Relative* or *spurious polycythemia* is a term used to describe an elevation of the hematocrit level due either to an acute transient state of hemoconcentration associated with intravascular fluid depletion or a chronic sustained relative polycythemia due to contraction of the plasma volume.[74–76]

Transient polycythemias may be a result of acute depletion of the plasma volume from a variety of disorders, including protracted vomiting or diarrhea, plasma loss from external burns, sudden cold exposure or protracted exercise, insensible fluid loss due to fever, sepsis, diabetic ketoacidosis, or acute ethanol intoxication.[74–76] These elevations of hematocrit can be easily corrected by appropriate replacement of intravascular fluids.

Gaisböck syndrome, first described in 1905,[84] is a benign condition observed mainly in obese, hypertensive, middle-aged, male smokers.[73–77] Alcohol, diuretics, obesity, hypoxia, psychological stress, and excess catecholamine secretion have been identified as possible causes of relative polycythemia.[85] Such individuals can have a chronic modest to moderate elevation of the hematocrit level associated with a normal red cell mass and low plasma volume, which has been attributed to reduced venous compliance,[86] or they can have a high normal red cell mass with either a normal or slightly decreased plasma volume.[74,76] The primary significance of the identification of a patient with relative polycythemia is the recognition of the increased risk of developing thrombotic vascular events likely due to excessive smoking, hypertension, and obesity associated with this disease. The optimal therapy is unknown, but treatment is generally directed at correction of the patient's underlying cardiovascular risk factors.

It is also important to emphasize that overfilling of blood collection vacuum tubes can result in pseudopolycythemia, pseudothrombocytopenia, and pseudoleukopenia as a result of inadequate sample mixing.[87] Careful attention to such a seemingly trivial detail can help avoid expensive, unnecessary diagnostic workups.

ABSOLUTE POLYCYTHEMIAS

Primary Familial and Congenital Polycythemia

PFCP is an autosomal dominant disorder.[53–57,89–95] Although PFCP is uncommon, it is more prevalent than polycythemia due to high-oxygen-affinity hemoglobin mutants or a 2,3-biphosphoglycerate deficiency.[92] Unlike patients with PV, patients with PFCP lack splenomegaly and do not progress to acute leukemia. It is not unusual for these patients to present with headaches, which resolve with normalization of the hematocrit level. An increased incidence of cardiovascular events has been reported in affected members.[89] Characteristic laboratory findings are (a) an increased red blood cell mass without increased leukocyte or platelet counts, (b) no activating mutation of JAK2, (c) a normal hemoglobin–oxygen dissociation curve, (d) low serum EPO levels, and (e) in vitro hypersensitivity of erythroid progenitors to EPO.[53–57,79–83,87–94] Even though PFCP is present at birth, many affected patients are incidentally diagnosed later in life following the performance of routine blood counts, or when evaluated in the context of multiple family members having polycythemia. It is of interest that one individual so affected was an accomplished cross-country skier who had won medals at the Olympic games.[88]

To date, 12 mutations of the EPOR associated with PFCP have been described. Nine of the 12 result in truncation of the EPOR cytoplasmic carboxyl terminal (see Fig. 68–2) and are the only mutations convincingly linked with PFCP.[44] Such abnormalities lead to a loss in the negative regulatory domain of the EPOR. Three missense EPOR mutations have also been described, but these have not been linked to PFCP or any other disease phenotype.[56]

The physiologic basis for EPO-mediated activation of erythropoiesis is as follows: EPO activates its receptor by conformational changes of its dimers, leading to initiation of an erythroid-specific cascade of events. The first signal is initiated by the binding of a tyrosine kinase to the EPOR and its phosphorylation and activation of a transcription factor, STAT5, which regulates erythroid-specific genes.[44] This "on" signal is negated by dephosphorylation of the EPOR by HCP, that is, the "off" signal.[53,54] Truncation of the EPOR leads to a loss in the negative regulatory domain of the EPOR, a binding site for HCP, leading to a gain-of-function mutation of the EPOR (see Fig. 68–2). A mouse bearing a normal human EPOR and a mutant, disease-causing human EPOR has been created by flox/cre (gene replacement) technology.[96] This mouse model, with its potential for tissue-specific deletion and augmentation of EPO signaling, should help better understand the role of EPO signaling in other tissues such

as the brain and endothelial cells. Recently an alternative explanation for the increased sensitivity of erythroid progenitors to EPO of patients with PFCP has been provided by Meyer and coworkers.[97] These investigators showed that EPOR downregulation provides another mechanism by which EPO desensitization can occur. EPOR downregulation is a complex process that involves EPOR ubiquitination and degradation by proteasomes. This degradation process removes all of the phosphorylated tyrosine residues in the intracellular domain of the receptor, thereby preventing further signal transduction. The remaining part of the EPO–EPOR complex is then internalized and degraded by lysosymes. Meyer and coworkers reported that the E3 ligase B-transducin repeat containing protein-1 (B-Trcp-1) is responsible for EPOR ubiquitination and degradation. Mutations of the B-Trcp abolish EPOR ubiquitination and degradation, making BaF3 cells expressing the EPORs hypersensitive to EPO. Each of the PFCP mutations involving the EPOR results in the loss of the binding site for B-Trcp-1. These findings suggest that the EPO hypersensitivity in PFCP might also be in some cases due to increased EPOR activity occurring as a consequence of diminished ubiquitination and degradation of the EPO–EPOR complex.[97]

The effect of a truncated EPOR is not always predictable. Some patients who inherit an EPOR mutation are not polycythemic.[98] This observation suggests that undefined environmental or genetic factors may mask the development of polycythemia. Also, the heterogeneity of the polycythemic phenotype observed in a PFCP animal model[96] appears to be strain dependent. This indicates that gene modifiers or epigenetic factors may mask the development of the full PFCP phenotype.

Mutations of genes encoding proteins other than the EPOR account for most cases of PFCP. Mutations of the EPOR were found in only 10% to 20% of subjects with PFCP.[45] Additional disease-causing genes and their mutations have yet to be identified.[99]

SECONDARY POLYCYTHEMIAS

Secondary polycythemias can be either congenital or acquired. Conditions leading to hypoxia, such as high altitude, cyanotic heart disease, or chronic lung disease, may result in physiologic polycythemia mediated by increased levels of EPO.[12,75] There are marked variations in EPO levels and the subsequent erythroid response in the face of chronic hypoxia,[78,100–103] suggesting that some of these factors may be genetically determined. The same degree of renal tissue hypoxia may induce substantially different EPO production in response to high altitude.[100–103] It is likely that these individual variations are a function of genetic differences in hypoxia sensing and the hypoxia response pathways; the exact mechanism remains to be clarified. For purposes of simplicity and clinical diagnostic usefulness, the secondary polycythemic disorders are divided into those that are acquired and those that are congenital. It should be kept in mind that this division, although useful for differential diagnosis, is artificial. Patients with inherited germline mutations, for instance, can develop an EPO-secreting pheochromocytoma or renal cell cancer, whereas a patient with PV can smoke and have chronic obstructive pulmonary disease. In other instances, polycythemia due to a germline mutation can be masked by an acquired environmental factor or another gene-modifying mutation.[98]

Acquired Secondary Polycythemias

Polycythemias of Cyanotic Heart Disease and Pulmonary Disease

Patients with cyanotic heart disease and pulmonary disease frequently suffer from arterial hypoxemia leading to increased production of EPO and polycythemia. Excessive EPO production occurs when the Pa_{O_2} is sustained below 67 mmHg as a result of severely impaired pulmonary mechanics.[75] Because patients with severe pulmonary disease and secondary erythrocytosis frequently have elevated plasma volumes, the degree of elevation of the hematocrit level may be modest. Hematocrit levels as high as 65% or rarely 75% have, however, been reported.[75]

Why some patients with pulmonary disease and congenital heart disease develop polycythemia whereas others do not is not clear. Increased oxygen-carrying capacity may improve oxygen delivery; however, it is not obvious at what hematocrit level the resultant elevation in blood viscosity impairs blood flow to the tissues, leading to a reduction in oxygen uptake. In addition, oxygen uptake to the tissues is markedly influenced by whole blood volume. Thus, whereas the optimal hematocrit level for oxygen delivery is about 45% in normovolemic subjects, it rises to over 60% in hypervolemic states,[104,105] likely as a result of engorgement of the vascular bed and a decrease in peripheral resistance. Furthermore, chronic exposure to hypoxia leads to respiratory alkalosis that, in turn, promotes the synthesis of 2,3-bisphosphoglycerate (2,3-BPG), facilitating increased oxygen delivery to tissues.[92]

The practical relevance of an elevated hematocrit level in this clinical situation is whether and at what level it is harmful or beneficial. The seminal studies of Winslow and colleagues have suggested that an extremely elevated hematocrit level might be detrimental to optimal oxygen delivery.[107] They showed that isovolemic hemodilution of the hematocrit in Andean natives led to a general improvement in symptoms, which correlated well with an increased anaerobic threshold and improved mixed venous oxygen saturation during exercise.[107] Although this careful study influenced the understanding of the relationship between an increased hemoglobin concentration and oxygen delivery, it is a single uncontrolled observation and must therefore be interpreted with caution. It is unfortunate that clinical observations regarding the optimal hematocrit level for the treatment of PV have been frequently applied to other polycythemic states. Although it is widely accepted that erythrocytotic pediatric patients with cyanotic heart disease are at an increased risk for developing cerebral vascular accidents, the literature provides conflicting data as relates to the prevalence of such events among adults. Engelfriet et al reported a 10% prevalence of stroke and transient ischemic attacks in a cohort of adult patients with cyanotic heart disease, and Anmash et al reported a 13.6% prevalence of a history of stroke in a similar adult patient population.[105,109] By contrast, Perloff followed a group of 124 patients for over 6.1 years and did not document any strokes.[110]

The major cause of the thrombotic tendency in patients with erythrocytosis and cyanotic congenital heart disease is hyperviscosity due to extreme erythrocytosis and sludging within the microcirculation.[111,112] Iron deficiency occurs in over 30% because of the total depletion of iron stores to support erythropoiesis. Microcytic iron-deficient red cells are less deformable, and therefore further elevate blood viscosity. Evidence of hyperviscosity producing cerebral perfusion abnormalities not resulting from an overt thrombosis may also lead to such symptoms as headache, sluggish mentation, dizziness, blurry vision, muscle weakness, or paresthesias caused by reduced tissue perfusion.

The treatment of hyperviscosity secondary to erythrocytosis in cyanotic heart disease is controversial. Phlebotomy among select patients has been shown to improve cerebral blood flow and neurological symptoms and increase exercise capacity. To date there are no studies that define the optimal target hematocrit level to be achieved with phlebotomy of such a patient.[111,112]

The optimal target hematocrit level is likely to vary for each patient depending on the level of shunting and cardiac output. Phlebotomy based on symptoms may presently be the only practical approach.[111] Phlebotomy must be followed by the infusion of an equal volume of fluids to maintain intravascular volume and blood flow as well as to provide a dilutional effect to reduce the hematocrit level.[111,112] Perloff et al recommended a 1:1 replacement with 0.9% normal saline whereas Rosenthal suggested replacing the volume of blood removed with 1:1 fresh frozen plasma infused over 30 to 60 minutes. Hydroxyurea therapy has been used occasionally to reduce erythropoiesis in this situation to avoid inducing iron deficiency.[110,113]

The superiority of hydroxyurea therapy versus phlebotomy therapy has not been documented.[111,112]

Large studies of patients with Eisenmenger syndrome[114] and other patients with cyanotic heart disease[114] provide little evidence for the routine use of phlebotomy for the treatment of an asymptomatic patient. These elevations in hematocrit levels cannot, however, be totally ignored. The Framingham Study demonstrated a close correlation between a hematocrit greater than 51% and the risk for stroke.[115] Furthermore, in patients with cyanotic congenital heart disease with hematocrit levels over 80%, cerebral and pulmonary thrombotic events have been shown to correlate with the degree of elevation of the hematocrit level.[110,116] It is unlikely that the degree of hematocrit level elevation is the only factor contributing to this thrombotic tendency. Shibata and colleagues have generated transgenic mice with hematocrit levels greater than 85% due to overexpression of human EPO in an oxygen-independent manner.[117] These animals did not experience thromboembolic complications in any organs at any age. Therefore, factors beyond erythrocytosis likely contribute to the biogenesis of thromboembolism in these mice as well as in humans with polycythemia. The surprising absence of thrombosis in these mice with extreme erythrocytosis has been attributed to poor clot formation due to mechanical interference by the numerous red cells present, reduction in peripheral-blood platelet counts, and reduction of the activity of both the extrinsic and intrinsic coagulation pathways.[117] Similar coagulation abnormalities have been observed in patients with cyanotic congenital heart disease and were believed to be due to hepatic dysfunction from congestive cardiac failure or a chronic disseminated coagulopathy.[118]

Chronic oxygen therapy in patients with severe chronic obstructive pulmonary disease has resulted in relief of hypoxia and a modest reduction in hematocrit levels. Phlebotomy is a more efficient method of reducing the red cell mass.[111,112,119] On the basis of these considerations and the clinical experience with polycythemic conditions of diverse causes, we recommend that only those patients with polycythemia due to cyanotic congenital heart disease or pulmonary disease who develop symptoms that might be attributed to increased whole blood hyperviscosity (difficulty concentrating, headaches, general malaise) undergo a trial of isovolemic phlebotomy. The physician should always be guided by the patient's report of or lack of subjective improvement in well-being immediately following phlebotomy. To avoid problems associated with large-volume phlebotomies, relatively small quantities of blood should be removed repeatedly and colloids or fresh frozen plasma should be infused.[111,112,119]

Obstructive Sleep Apnea-Induced Polycythemia

Obstructive sleep apnea syndrome is characterized by repetitive episodes of partial or complete obstruction of airflow during sleep. Common symptoms include loud snoring and breathing pauses observed by a bed partner, feelings of nonrefreshing sleep, and excess daytime sleeping. Although the evidence is largely anecdotal,[120] secondary polycythemia is a widely recognized complication of long-standing sleep apnea, being found in 5% to 10% of those with nocturnal apnea and hypopnea.[121] Similarly, 25% of those with unexplained polycythemia are subsequently found to have sleep apnea.[122] The mechanism by which sleep apnea causes polycythemia is unclear. McKeon and coworkers found no differences in EPO levels between normoxic and hypoxemic patients referred for suspected sleep apnea.[123] In a later study, Carlson and coworkers also were unable to find any statistically significant differences in EPO levels between sleep apnea patients with and without polycythemia and age- and gender-matched healthy controls.[121] Obstructive sleep apnea is also associated with an increased risk for developing cardiovascular diseases, including systemic hypertension, pulmonary hypertension, cardiac arrhythmias, atherosclerosis, ischemic heart disease, and stroke. Intermittent hypoxia is thought to be a major cause of cardiovascular complications. These patients undergo repeated episodes of hypoxia and normoxia. The hypoxia leads to ischemia and the reoxygenation causes a sudden increase of oxygen. This reoxygenation phase results in the production of reactive oxygen species and the promotion of oxidative stress, leading to an inflammatory response and the development of vascular complications.[124]

Conversely, PV may induce central sleep apnea by decreasing cerebral blood flow to diencephalic respiratory centers, and patients so affected can have complete resolution of their sleep disorder when appropriately phlebotomized.[125]

Pickwickian Syndrome and Polycythemia

Pickwickian syndrome or obesity-hypoventilation syndrome, seen in morbidly obese individuals, is characterized by chronic hypoxemia and hypercapnia due to alveolar hypoventilation, with a resultant increase in EPO production, polycythemia, and cor pulmonale.[75] The three principal causes are the high cost of the work of respiration in morbidly obese individuals, dysfunction of the respiratory centers, and repeated episodes of nocturnal obstructive apnea.[126] Effective treatments include surgically induced weight loss,[127] nasal continuous positive airway pressure ventilation,[128] and the respiratory stimulant medroxyprogesterone acetate.[124]

Polycythemia Due to High Altitude

Polycythemia due to the hypoxic conditions encountered by high-altitude dwellers would appear at first glance to represent a universal adaptive process to altitude. High altitude results in hyperventilation, alkalosis, and shifting of the O_2 dissociation curve to the left, which leads to the impaired release of O_2 from hemoglobin and ultimately tissue hypoxia.[75,130–132] This tissue hypoxia results in markedly increased EPO production, leading to increased plasma iron turnover, reticulocytosis, and a rising hematocrit level. Residents of the Andes Mountains who live 4200 m above sea level frequently have 30% higher hematocrit levels than individuals living at sea level.[75,130–134]

People native to high altitude (highlanders) live in a hypobaric hypoxic environment characterized by a low ambient partial pressure of oxygen. In response to this environment they develop alveolar hypoxia, hypoxemia, and polycythemia.[130–134] Healthy highlanders develop pulmonary hypertension, right ventricular hypertrophy, and an increased amount of smooth muscle cells in the distal pulmonary arterial branches, which leads to increased pulmonary vascular resistance and pulmonary artery pressure as compared to individuals living at sea level. The importance of these structural changes in the pulmonary vasculature in highlanders is confirmed by the slow decline of pulmonary artery pressure, which is normalized after living for 2 years at sea level.[130–134] Despite these adaptive changes, healthy highlanders are able to perform physical activities similar to or often even more strenuous than those living at sea level. In fact, there are differences in ventilation rates between athletes performing at sea level and those at high altitudes.[134] Ventilation rates of athletes increase normally during exercise at sea level, whereas relative hypoventilation occurs in highlanders. This relative hypoventilation is characteristic of Andean natives and has been ascribed to desensitization of the carotid bodies to the hypoxic stimulus.[134] The erythrocytosis observed in individuals who reside at high altitudes for relatively short periods of time (days) can also be attributed in part to excessive water loss and contraction of the plasma volume. Total acclimatization of an individual who moves from sea level to a high altitude may actually require years. Individuals who reside at sea level and are acutely exposed to high altitudes are at increased risks of developing deep venous thrombosis, pulmonary infarction, retinal hemorrhage, and ischemic digits due to increased blood viscosity.[75] High-altitude climbers frequently combat these problems by intravenous administration of isotonic saline, with considerable success.[75]

The chronic responses of various ethnic and racial groups to high altitudes are quite variable. Andean natives, known as the Quechua and Ayamara Indians, experience a gradual increase in their hemoglobin levels with age.[133] In addition, hemoglobin values are almost

10% higher in those living at 5500 m above sea level than in those living at 4355 m above sea level.[133] Curiously, their Tibetan and Ethiopian counterparts living at similar altitudes do not respond to the resultant chronic hypoxia by increasing their hematocrits.[136–140] It has been suggested that high levels of nitrous oxide in the exhaled breath of Tibetans may improve oxygen delivery by inducing vasodilatation and increasing blood flow to tissues, thus making the compensatory increased red cell volume unnecessary.[141] Interestingly, Tibetans and Ethiopians have lived much longer as mountain dwellers than the Quechua or Ayamara Indians, suggesting that extreme elevation of the red cell mass is a maladaptation that Tibetans and Ethiopians have avoided by adopting more physiologic compensatory mechanisms. The molecular basis of these adaptive responses is unknown. Other factors can contribute to the development of erythrocytosis in high-altitude dwellers. Many inhabitants of the mining community of Cerro de Pasco (altitude 4280 m) with excessive erythrocytosis (mean hematocrit 76%, range 66%–91%) have been shown to have toxic serum cobalt levels,[142] suggesting that other EPO-promoting factors such as cobalt might augment the hypoxia-inducing effect on EPO causing the extreme polycythemias.

This individual variability of elevation of serum EPO levels in high-altitude dwellers and the resultant increase in red cell mass appears widespread. For example, acclimatization to moderately high altitudes when combined with low-altitude training (so-called living high, training low) improves sea-level performance in endurance athletes, in part because of the erythropoietic effects of altitude exposure.[102,139,146] This substantial individual variability in response to all forms of altitude training correlates with improved athletic performance and with elevation of EPO levels.[101,143,144] A large component of this individual variability appears to be related to differences in the peak and rate of decay of the increase in EPO in response to altitude exposure.[86] These observations suggest that there are genetically determined variables accounting for individual responses to hypoxia that are different from the EPO-mediated increase of red cell mass.[87] Polymorphisms of candidate genes involved in oxygen sensing and erythropoiesis were examined to detect the genetic variants of response to hypoxia. No evidence of an association between the candidate genes and severe polycythemia were, however, observed.[145]

Chronic mountain sickness (CMS) is a pathological loss of adaptation to altitude by highlanders. CMS is a clinical syndrome that occurs in native or lifelong residents living above 2500 m.[137–140] Anecdotal reports of particularly susceptible families or people to CMS are frequently cited as evidence that certain individuals have an innate susceptibility to develop CMS.[103] It is characterized by excessive erythrocytosis (females, Hb > 19 g/dL; males, Hb > 21 g/dL), severe hypoxemia, and in some cases moderate or severe pulmonary hypertension that may lead to the development of cor pulmonale and congestive heart failure. The clinical picture of CMS gradually disappears after descending to lower altitudes and reappears after returning to high altitude.[75,130–132] The prevalence of CMS is higher in men than women and increases with altitude, aging, associated lung disease, history of smoking, and air pollution. CMS is a public health problem in populations of mountainous regions of the world living above 2500 m.[75,130–132] In China alone, 80 million people live above that altitude, whereas in South America, 35 million people live above 2500 m. CMS is a common problem in these areas. Bolivian investigators have reported a prevalence of CMS in 6% to 8% of males in La Paz (3600 m) and a hospital frequency of 28%.[130–132] Chinese investigators have reported an overall prevalence of 5.6% in Chinese Han immigrants and 1.2% in Tibetan natives living in the Qinghai Tibetan plateau. The major mechanism underlying the development of CMS is relative alveolar hypoventilation.[130–132] Healthy highlanders characteristically hyperventilate. A gradual decline in the rate of alveolar ventilation in these individuals leads to progressive loss of adaptation to chronic hypoxia and the development of CMS.[146] The main components of this syndrome include (a) alveolar hypoventilation leading to relative hypercapnia and increasing hypoxemia; (b) excessive polycythemia leading to increased blood viscosity and expansion of the total lung blood volume; (c) pulmonary hypertension and right ventricular hypertrophy that may evolve to hypoxic cor pulmonale and heart failure; and (d) neuropsychiatric symptoms, including sleep disorders, headache, dizziness, and mental fatigue.[146] Physical examination reveals cyanosis of the nail beds, ears, and lips in contrast to the ruddy color that is characteristic of a healthy highlander. In some cases the face is almost black and the mucosa and conjunctiva are dark red. The fingers are frequently clubbed and auscultation of the heart reveals an increased pulmonary second sound.[130–132,140] The patients are frequently hypertensive and have evidence of heart failure. Chest x-ray and electrocardiographic findings are characteristic of right atrial and right ventricular hypertrophy. The cardiac hemodynamic values of patients with CMS and healthy highlanders and those living at sea level are shown in Table 68–2.[130] Criteria for the diagnosis of CMS have been recently published and are useful in identifying CMS patients as well as monitoring their response to treatment.[131]

The definitive treatment for CMS is descent to lower altitudes or sea level. The degree of polycythemia decreases after a few weeks or months and eventually the hematocrit level returns to sea-level values. Pulmonary hypertension and right ventricular hypertrophy gradually resolve and disappear after 1 to 2 years of living at sea level.[130–132] Phlebotomy or isovolemic hemodilution can reduce the excessive erythrocytosis and hyperviscosity. A variety of drugs has also been evaluated for the treatment of patients with CMS. Ten weeks of the respiratory stimulant medroxyprogesterone acetate at doses of 60 mg/d led to a reduction of the hematocrit level from 60% to 52% and an increase in arterial oxygen saturation from 84% to 90% in 17 highlanders with excess erythrocytes.[147,148] Medroxyprogesterone use however was associated with a loss of libido in males and therefore is infrequently used in this population.[147,148] Therapy with almitrine, a respiratory stimulant, or enalaprial, an ACE inhibitor (10 mg/d for 30 days), has resulted in even more modest reductions of hematocrit levels.[149] Acetazolamide therapy has been evaluated in a small double-blind, placebo-controlled, randomized clinical trial of patients with CMS.[150] Acetazolamide is an inhibitor of carbonic anhydrase and stimulates ventilation by promoting the development of metabolic acidosis. Furthermore, acetazolamide reduces renal EPO production. Patients with CMS were randomized to receive placebo or acetazolamide therapy at a dose of 250 or 500 mg/d for 21 days. Drug therapy at both doses of acetazolamide resulted in reduction of hematocrit levels by 7% ($P < 0.001$) and serum EPO levels by 50% to 67% ($P < 0.1$), with an increase in nocturnal oxygen saturation levels of 5% ($P < 0.01$).[150] According to this small study, 250 mg of acetazolamide daily appears to be an inexpensive, nontoxic, effective therapy for CMS.[150] Whether this conclusion can be validated by larger clinical trials and can be implemented successfully in large populations of patients with CMS has yet to be determined.

Smokers' Polycythemia or Carbon Monoxide-Induced Polycythemia

Smoking is the most common cause of secondary polycythemia.[75,151–154] Those affected have a carboxyhemoglobin-induced increase in red cell mass or decrease in plasma volume,[122–124] either of which is reversible with smoking cessation. Excessive carbon monoxide exposure can also be attributed to exposure to industrial emissions and automobile exhaust.[75] Carbon monoxide binds to hemoglobin with a more than 200 times greater affinity than oxygen, resulting in not only occupation of one of the heme groups of hemoglobin but also an increase in the O_2 affinity by the remaining heme group.[75] Individuals smoking even one pack of cigarettes a day frequently have elevated hematocrit levels.[75] These patients characteristically have normal blood gases and elevation of carboxyhemoglobin levels, resulting in a reduction in $P_{50}O_2$.[75] The elevation of the hematocrit level is reversed with the interruption of the smoking behavior. Increased hematocrit levels have been observed in 3% to 5% of heavy smokers. Although these patients are not immune to thrombotic complications, the number of thromboembolic events is lower than in patients with PV.[153–156] A

Table 68–2 Hemodynamic Values in Chronic Mountain Sickness in Comparison With Healthy Highlanders and Sea Level Subjects

	Sea Level Controls (n = 25; age 17–23 y)	Healthy Highlander Controls (n = 12; Age 19–38 y)	CMS Subjects (n = 10; Age 22–51 y)	P, CMS vs Healthy Highlanders
Hb, g/dL	14.7 ± 0.88	20.1 ± 1.69	24.7 ± 2.36	<0.001
Hct, %	44.1 ± 2.59	59.4 ± 5.4	79.3 ± 4.2	<0.001
Sa_{O_2}, %	95.7 ± 2.07	81.1 ± 4.61	69.6 ± 4.92	<0.001
RAP, mmHg	2.6 ± 1.31	2.9 ± 1.4	3.9 ± 1.8	NS
PPA, mmHg	12 ± 2.2	23 ± 5.1	47 ± 17.7	<0.001
PWP, mmHg	6.2 ± 1.71	6.9 ± 1.4	5.7 ± 2.3	NS
PVR, dynes cm^{-5}	69 ± 25.3	197 ± 57.6	527 ± 218.1	<0.001
CI, L min^{-1} M^{-2}	3.9 ± 0.97	3.8 ± 0.62	4.0 ± 0.93	NS

CI, cardiac index; CMS, PVR, pulmonary vasculan resistance; chronic mountain sickness; Hb, hemoglobin; Hct, hematocrit; NS, nonsignificant; PWP, pulmonary wedge pressure; RAP, right atrial pressure.
Values are mean ± SD.

Data derived from Penaloza D, Arias-Stella J. The heart and pulmonary circulation at high altitudes: Healthy highlanders and chronic mountain sickness. Circulation 115(9):1132, 2007. [review]

retrospective review of patients with either PV or smokers' polycythemia found that 60% of those with PV suffered thromboses, whereas only 41% of those with smokers' polycythemia were so affected ($P < 0.05$).[154]

Postrenal Transplantation Erythrocytosis

Postrenal transplantation erythrocytosis (PTE) is defined as a persistently elevated hematocrit level greater than 51% after renal transplantation without an elevation of the white blood cell count or platelet count. PTE is a potentially dangerous condition found in approximately 10% to 15% of renal allograft recipients.[156,157] PTE usually develops within 8 to 24 months following a successful renal transplantation and resolves spontaneously within 2 years in about 25% of patients, despite persistently good renal allograft function.[72,158] PTE is more common in males and may recur in the same patient after a second successful renal transplantation.[159] Factors that increase the likelihood of its development are a lack of EPO therapy before transplantation, a history of smoking, diabetes mellitus, transplant-related renal artery stenosis, retention of the native kidney, low serum ferritin levels, and normal or high pretransplantation EPO levels. PTE is also more frequent in patients who do not suffer rejection. At higher hematocrit levels (usually >60%), thrombotic events may complicate the clinical course of patients with PTE.[72,157,159]

Approximately 60% of patients with PTE experience malaise, headache, plethora, lethargy, and dizziness. In addition, from 10% to 20% develop thromboembolic complications involving either arteries or veins. Retention of the native kidney is essential for the development of PTE in most cases. Although the transplanted kidney produces EPO under normal regulatory mechanisms, the native kidney overproduces EPO in spite of the development of erythrocytosis. Frequently the PTE resolves with removal of the native kidney.[72] Plasma EPO levels are higher (10-fold) in patients with PTE as compared to nonerythrocytotic renal transplant recipients. In addition, erythroid progenitor cells isolated from patients with PTE are hypersensitive to EPO.[72]

The molecular basis of PTE remains unclear; AngII is believed, however, to play an important role in its pathogenesis by sustaining the secretion of EPO.[158] There is growing evidence that increased AT1R expression makes erythroid progenitor cells hypersensitive to AngII.[160,161] Furthermore, AngII can modulate release of erythropoietic stimulatory factors including EPO and IGF-1.[55,162] Because men comprise almost all of the transplant recipients who develop PTE, androgens are thought to play a role in the development of the syndrome. Androgens can directly affect erythroid progenitor cells or stimulate EPO production or actually the RAS system.[72] Treatment of patients with PTE includes intermittent phlebotomy or administration of drugs.[72] The ACE inhibitor enalapril suppresses the renin–angiotensin pathway and virtually eliminates the need for therapeutic phlebotomy in these patients.[162] Maximal reduction of hemoglobin levels is evident 6 months after starting therapy with either ACE inhibitor or angiotensin receptor blockers. Some patients are exquisitely sensitive to these medications and may in fact become severely anemic.[163–165] The AT1R antagonist losartan has been shown to be as effective in treating PTE as any ACE inhibitors. Therapy is usually begun at hematocrit levels above 55% with the hope of maintaining hematocrit levels below 50% in order to reduce the risk of thrombosis.[72] Furthermore, the ACE inhibitor fosinopril in an open-label crossover trial with theophylline was shown to produce a dramatic reduction in hematocrits in patients with PTE (51.3%–43.7%, $P < 0.005$).[166] Low doses of ramipril, another ACE inhibitor, normalized the hematocrit level in 26 of 27 patients with PTE after a mean of 127 days of therapy.[167]

Polycythemia Accompanying Kidney and Liver Diseases and Neoplastic Disorders

Polycythemia has been reported in association with kidney diseases such as renal cell carcinoma, renal artery stenosis, hydronephrosis, Wilms tumor, and polycystic kidney disease.[75] Renal tumors account for approximately one-third of cases of tumor-associated polycythemias. The tumor tissue has been demonstrated to produce excessive amounts of EPO, and the erythrocytosis resolves with surgical resections of the tumor. The mechanisms underlying the activation of EPO gene has been related to somatic mutation of the VHL gene in clear cell renal carcinomas. Wiesener et al reported that clear cell carcinoma associated with erythrocytosis and high serum EPO levels strongly expressed EPO mRNA and HIF-1α and HIF-2α.[168] These abnormalities were related to a point mutation in the VHL gene that impaired the bindings of HIF-1α to VHL leading to its accumulation and increased production of EPO.[168] Polycythemia is also a well-described paraneoplastic manifestation of hepatocellular carcinoma in 2.5% to 10% of patients and is again due to the production of EPO by the tumor.[169,170] Polycythemia in hepatoma patients is strongly related to tumor burden and elevated α-fetoprotein levels.[170,171] Polycythemia has also been associated with cerebellar hemangioblastomas (Fig. 68–3) and very large uterine fibromas.[75,172] In tumor-associated erythrocytosis, EPO production has been shown to be autonomous of hypoxic stimuli.[75]

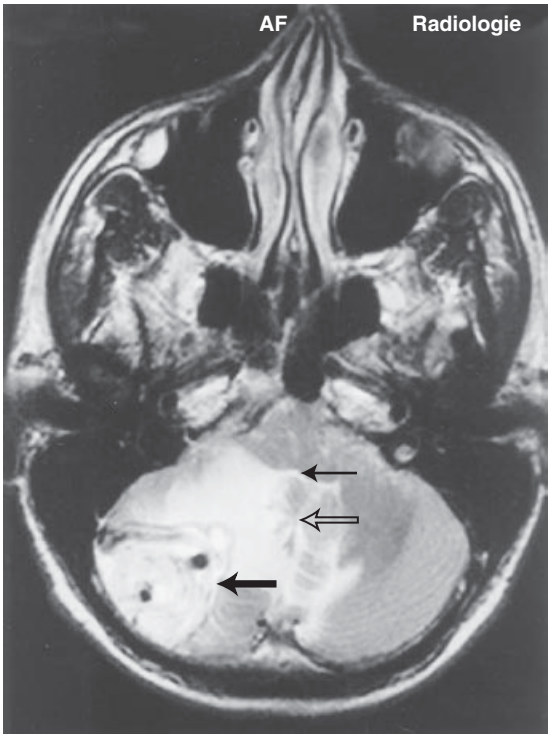

Figure 68–3. This MRI scan discloses a tumor measuring 3 × 4 cm in diameter in the right cerebellar hemisphere (black arrow) with perifocal edema and midline shift (white arrow), resulting in obstruction of the fourth ventricle (thin arrow). (From Kuhne M, Sidler D, Hofer S, Lugli A, Ludwig CH: Challenging manifestations of malignancies. Case 1. Polycythemia and high serum erythropoietin level as a result of hemangioblastoma. J Clin Oncol 22(17):3639, 2004.)

Polycythemia in Endocrine Disorders

Polycythemia is also associated with Cushing syndrome[173] and primary aldosteronism.[174] Secondary polycythemia can also be seen in 24% of older hypogonadal males receiving long-term androgen replacement therapy[175] and a significant number of competitive athletes taking anabolic steroids. For instance, in a small study of professional bodybuilders, 67% of those examined had hematocrit levels above 50%.[176] The effectiveness of drug screening in athletic competitions is demonstrated by the very low rate of positive tests for androgens (<2% of 170,000 tests) on random testing at the Olympic games and other international events.[177] In spite of previous assertions regarding increased EPO excretion following androgen therapy,[178] none of the athletes examined had elevated levels of EPO.[179] Recombinant human EPO has also been abused by athletes competing in endurance sports and can be detected by analyzing the individual's hematocrit level, reticulocyte count, percentage of macrocytic red blood cells, serum EPO level, serum transferrin receptor level, and the electrophoretic mobility of the EPO molecule (recombinant EPO is less negatively charged than endogenous EPO).[143]

Congenital Secondary Polycythemias

High-Oxygen-Affinity Hemoglobins and Biphosphoglycerate Deficiency

There are more than 100 mutations of hemoglobin that lead to increased oxygen affinity, and thus decreased oxygen delivery and compensatory polycythemia (see Chapter 44).[75,180] These mutations involve either the α- or β-chain globin chains. Such polycythemias are usually well tolerated in young patients but may lead to thrombotic complications in older patients.[180] High-oxygen-affinity hemoglobin variants are transmitted as autosomal dominants.[180] Phlebotomy therapy of such patients has been reported to be of no beneficial value, and have been shown to decrease exercise tolerance and anaerobic threshold. The best test to detect a high-oxygen affinity hemoglobin relies on the determination of hemoglobin dissociation kinetics and P_{50} (partial pressure of O_2 at which hemoglobin is 50% oxygenated). If co-oximetry is not available, the P_{50} can be mathematically estimated from a venous blood gas measurement[181] by using the following formula:

$$\text{AS REC } P_{50}\text{std} = \frac{\text{antilog}(\log 1/k)}{n}$$

$$\text{Where } 1/k = \text{Antilog}(n \log Po_{2(7.4)}) \times \frac{100 - So_2}{So_2}$$

A Hill constant (n) for hemoglobin A of 2.7 is used in all calculations. The Po_2 in venous blood measured at 37°C is converted to Po_2 at pH 7.4 with the formula

$$\log Po_{2(7.4)} = \log Po_2 - 0.5(7.40 - \text{pH}),$$

where pH represents the value in the antecubital venous blood. An example of a calculation provided by Lichtman and colleagues[144] follows. The Po_2 = 25 mmHg, So_2 = 44%, Sco = 2.0%, and pH = 7.37.

$$\begin{aligned}\log Po_{2(7.4)} &= \log Po_2 - 0.5(7.40 - \text{pH})\\ &= \log 25 - 0.5(7.40 - 7.37)\\ &= 1.3979 - 0.0150\\ &= 1.3829.\end{aligned}$$

$$1/k = \text{antilog}(2.7 \log Po_{2(7.4)}) \times \frac{100 - So_2}{So_2}$$

$$= \text{antilog}(2.7 \times 1.3829) \times \frac{100 - So_2}{So_2}$$

$$= \text{antilog}(3.7338) \times \frac{100 - 44}{44}$$

$$= 5417.5134 \times 1.2727$$

$$= 6894.8693$$

$$\text{AS REC } P_{50} \text{ std} = \text{antilog } \frac{\log 1/k}{2.7}$$

$$= \text{antilog } \frac{\log 6894.8693}{2.7}$$

$$= \text{antilog}(3.8385/2.7)$$

$$= \text{antilog } 1.4216$$

$$= 26.4$$

A $P_{50}O_2$ below 17 mmHg is indicative of a mutant hemoglobin with high oxygen affinity, whereas a level above 35 is strongly suggestive of a mutant hemoglobin with a low oxygen affinity.[75,181] Hemoglobin electrophoresis is not a reliable screen to rule out hemoglobin mutations as only about one half of these mutants are electrophoretically distinguishable. A hemoglobin electrophoresis will reveal the presence of an abnormal hemoglobin only if the mutation leads to a change in electrical charge. In 30 hemoglobin variants, such a charge differential was not present and more complex studies including isoelectric focusing and high-performance liquid chromatography were required to make the diagnosis.[180]

A rare cause of congenital polycythemia is 2,3-BPG (previously known as 2,3-DPG) deficiency (see Chapter 44). 2,3-BPG is synthesized in red cells and binds to hemoglobin, thereby reducing its affinity for oxygen.[75,106] An absence of 2,3-BPG therefore leads to increased affinity of hemoglobin for oxygen resulting in a lifelong hypoxic stimulus and erythrocytosis.

Congenital methemoglobinemias, whether due to cytochrome b5 reductase mutations or globin mutations, may be associated with mild polycythemia (see Chapter 44). When hemoglobin is oxidized to methemoglobin all of the four subunits of the tetramer may be affected, eliminating the oxygen transport capacity of hemoglobin.[180]

Chuvash Polycythemia

Chuvash polycythemia (CP) is an autosomal recessive disorder associated with germline mutations of VHL and erythrocytosis.[182,183] CP was first described in the mid-1970s and is endemic in the Chuvash population of the Russian republic.[182–187] It has been alleged that there may be thousands of affected individuals among the 1 million Chuvash people.[184–186] The serum EPO concentration in affected individuals is elevated compared with healthy first-degree family members, although some patients may have normal serum EPO levels.[184,185] The erythroid progenitors of patients with CP are also hypersensitive to EPO; thus, CP has characteristics of both primary and secondary polycythemias.[183] A missense mutation in the VHL gene, VHL598C→T mutation, has been identified in CP patients.[186,187] The disorder is characterized by a high hemoglobin level, increased plasma, EPO level, varicose veins, vertebral hemangiomas, low blood pressure, and an elevated concentration of VEGF. The defective VHL gene product is not capable of promoting the ubiquitin-mediated degradation of HIF-1α, thereby leading to increased elaboration of EPO. CP is associated with a high mortality rate due to thrombotic and hemorrhagic vascular complications.[183–187] Cerebral vascular events are especially common causes of death. The median age of death from a cerebral vascular event is 42 years. Estimated survival to age 65 is 29% for individuals with CP and 64% for age-matched community members. There is a perfect genotype–phenotypic correlation, with all patients with CP being homozygotes for the mutation. Interestingly, heterozygous carriers do not develop erythrocytosis but do have lower blood pressures and do not seem to be at increased risk for tumors, which contrasts with patients with VHL syndrome.[187]

Germline mutations of VHL alleles have been reported in several patients with apparent congenital polycythemia that had no evidence of developing a tumor[187–189]; some of these subjects had germline mutations of both VHL alleles. Other subjects with congenital polycythemia of various ethnicities, including Pakistanis, Punjabis, African Americans, and Caucasians, harboring homozygosity for the CP VHL mutation or double heterozygosity for CP and other VHL mutations, have been found.[187–189] The VHL598C→T mutation, has been shown to originate in a single haplotype in the Chuvash patients, as well as in Caucasians, Asian Indians, and one African American individual.[182,187–189] This mutation appears to be the most common genetic defect leading to congenital polycythemia. The mutation originated from a single founder 12,000 to 51,000 years ago.[187] This suggests that such wide dissemination from the original founder may be associated with some survival advantage for heterozygotes carrying this mutation. Such an advantage might be related to a subtle improvement of iron metabolism, erythropoiesis, embryonic development, energy metabolism, or some other yet unknown effect.

Rapidly accumulating data suggest that VHL mutations might be the most common cause of congenital polycythemias, greatly exceeding the number of patients with hemoglobin chain mutations. In point of fact, in one study of over 200 unrelated subjects with apparently congenital polycythemia, none had a 2,3-BPG deficiency, 2 had a globin mutation (Hgb Vanderbilt, and Hemoglobin San Diego), and 12 had EPOR mutations to account for their polycythemia.[183] By contrast, when 50 patients were examined for the VHL mutation, 22 had VHL mutations, most of these being the CP VHL mutation, occurring either homozygously or in combination with another VHL mutation.[187] The failure of patients with CP to develop VHL syndrome tumors is consistent with the concept that deregulation of H1F-1α and VEGF are not sufficient to cause tumors. Recently a cluster of patients with clinical features identical to patients with CP has been documented on the island of Ischia in the Bay of Naples, Italy.[190] All of these patients also had the VHL598C→T mutation. Twelve of the 14 patients were homozygotes and 2 were heterozygotes. The homozygotes have symptoms identical to patients in Chuvashia with this mutation. Unlike heterozygotes in Chuvashia, the two heterozygotes from Ischia developed erythrocytosis associated with high EPO levels, which raises the possibility that genetic alterations of certain components of the oxygen-sensing pathway other than VHL may contribute to the development of erythrocytosis in the Italian patients. The disorder in Ischia has a gene frequency even higher than that in Chuvashia, with 14% of the population estimated to be heterozygotes, which has led Prchal and Gordeuk to suggest that heterozygotes have a survival advantage.[191]

The Chuvash mutation has also been shown to have a profound effect on the cardiopulmonary system. Smith and coworkers have reported that patients with Chuvash polycythemia have significant abnormalities of cardiopulmonary physiology, including elevated basal ventilation rates and increased pulmonary vascular tone, with extremely high ventilatory rates and heightened pulmonary vasoconstriction and heart rates in response to acute hypoxia.[192] These observations indicate that the VHL–HIF pathway might also play a central role in calibrating the pulmonary system to hypoxic challenges. Such undesirable exaggerated hypoxic responses and the resulting elevated pulmonary vascular hypertension may contribute to the morbidity and mortality associated with CP.[192] Increased expression of endothelin 1 has been documented in patients with CP.[193] Endothelin 1 has been associated with the development of hypoxia-related pulmonary hypertension. Endothelin 1 receptor inhibitors might therefore be useful in reversing the associated pulmonary hypertension in these patients. Treatment strategies for patients with CP have included phlebotomy, aspirin, and occasionally chemotherapy. It is unknown whether such therapeutic strategies alter the natural history of this disorder. A variety of HIF-1 inhibitors being currently evaluated for the treatment of tumor patients might potentially also be useful for the treatment of patients with CP.

An additional genetic abnormality of oxygen sensing has been reported that leads to familial polycythemia. A heterozygous C-to-G change at base 950 of the coding sequence of PHD2 (P317R mutation) was detected in all three affected family members with this syndrome. Hydroxylation of HIF-1 by PHD2 facilitates its interaction with VHL, thereby favoring its ubiquitination and degradation by the proteosome.[194] The failure of PHD2 P317R to bind the HIF-1 and HIF-2α and promote HIF hydroxylase activity ultimately leads to increased HIF-l and erythropoietin levels, resulting in the development of erythrocytosis. Mutations involving other PHD isoforms might potentially play a role in the development of erythrocytosis in other cases of familial polycythemia.[40] The PHD2 P317R mutation is inherited as an autosomal dominant trait, in contrast to the Chuvash polycythemia defect, which is an autosomal recessive disorder.[194] Polycythemic patients with PHD2 P317R do not have any evidence of tumors characteristic of the VHL syndrome.[194]

Neonatal Polycythemia

Because of the high oxygen affinity of fetal hemoglobin, many neonates have markedly elevated hematocrit levels. Babies with hematocrit levels over 65% have more neurologic and functional impairments and are more likely to be born to diabetic mothers. Although phlebotomy has been recommended,[195] there is little evidence that it has been beneficial for these babies.

POLYCYTHEMIA VERA

PV is a clonal, chronic, progressive myeloproliferative disorder (MPD) often of insidious onset, characterized by an absolute increase in red cell mass and also usually by leukocytosis, thrombocytosis, and splenomegaly.[4,196,197] PV leads to excessive proliferation of erythroid, myeloid, and megakaryocytic elements within the bone marrow. Vaquez[198] first described this clinical entity in 1892, noting the characteristic physical findings. At the turn of this century, Cabot[199] and Osler[200] independently associated the name PV with this newly described clinical disorder. Limited insight into the pathogenesis of this disorder has been gained. Studies have been performed that demonstrate the hypersensitivity of hematopoietic progenitor cells derived from the malignant clone to a number of regulatory factors.[77,78,201–204]

PV differs from many other hematologic malignancies, in that prolonged survival is enjoyed by most patients if the excessive production of red blood cells and platelets can be controlled.[12,205,206] This prolonged survival, however, is punctuated by the development of other syndromes, such as myelofibrosis and acute leukemia (Fig. 68–4).[12,207,208] Frequently, patients present asymptomatically to a physician only to find that they have splenomegaly, isolated erythrocytosis, or thrombocytosis; left untreated, these patients will become symptomatic, owing to the excessive production of red blood cells or platelets, or both.[5] After a number of years, the erythrocytotic phase of the disease frequently becomes inactive, and the patient may no longer suffer from the sequelae of excessive red cell production. Subsequently, these patients can develop so-called spent-phase or PV related myelofibrosis postpolycythemic myeloid metaplasia (PV related MF), which is frequently indistinguishable from another MPD, primary myelofibrosis (PMF).[207–209] Finally, a significant proportion of these patients will go on to develop acute myeloid leukemia. Only a limited number of patients undergo this orderly transition; many patients can transition from the polycythemic phase directly into an acute leukemia or a myelodysplastic disorder.[12]

The transition from one phase of this MPD to another is not necessarily unidirectional. A number of cases of presumed IM have been described in which chemotherapy treatment has resulted in a striking decrease in marrow fibrosis associated with the development of an elevated red cell mass and a syndrome that was virtually indistinguishable from de novo PV.[209] The constantly changing clinical picture of this malignant hematologic disorder requires careful observation and treatment to deal with the numerous problems that can be encountered.

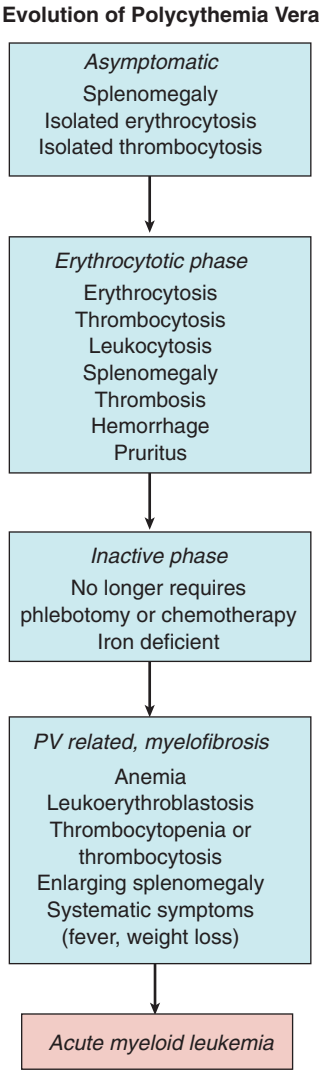

Figure 68–4. Evolution of polycythemia vera.

EPIDEMIOLOGY

PV is the most common primary polycythemia. It has been previously estimated that between 2.3 and 2.8 per 100,000 persons per year are affected.[210–215] Its incidence surpasses that of chronic myeloid leukemia, making it the most common MPD.[214] It is important to emphasize that no or very few population-based estimates of the prevalence of this disorder are presently available. Actual determination of its prevalence is a difficult process because of the need for an extensive diagnostic evaluation to differentiate this disorder from other causes of spurious or absolute erythrocytosis.[205] Ten thousand individuals between 18 and 65 years of age enrolled in the Vicenza Thrombophilia and Atherosclerosis project in Italy were screened for an elevated hematocrit level or platelet count, or both, and followed for 5 years.[5] On the basis of these studies, the prevalence of PV was shown to be 300 cases per 1 million.[5] This higher prevalence data is likely due to the previous inability to identify asymptomatic patients with PV before presentation to a physician. If confirmed, these estimates from Italy are likely conservative, as patients older than 65 years of age were not included in this project. These data indicate that, in fact, PV is not a rare disease but actually a relatively common hematologic malignancy.

The prevalence of PV has been reported by several investigators to be higher among American Jews and lower among African Americans.[210,216–218] The incidence of the disorder is greater among Ashkenazi Jews, who originate from eastern and central Europe, than among Arabs and Sephardic Jews.[218] Interestingly, extremely low occurrence rates have been reported from Japan, where the incidence was found to be 2 cases per 1 million per year.[219] These findings suggest that important environmental or genetic factors might be involved in the biogenesis of this disorder. One notable exception to the low prevalence of PV in Japan has been the higher incidence observed among populations exposed to atomic bomb explosions.[220] The possibility that radiation exposure is an etiologic factor in the generation of PV was also raised by the observation in the United States of four cases of PV 10 to 20 years after a nuclear explosion in which 3000 military observers were exposed.[221]

An epidemiologic investigation that focused on occupational exposure among petroleum refinery and chemical plant workers has revealed an increased incidence of PV relative to the general population.[222] In this study, the increased incidence of PV was linked to similar increases in the frequency of multiple myeloma and non-Hodgkin lymphoma, suggesting involvement of a putative environmental toxin that may have broad hematopoietic toxicity.[222]

The importance of genetic factors in the origin of this disease is further emphasized by case reports of PV within families.[223–232] A greater than expected prevalence has been reported in the parents of patients with this disorder.[223–232] In addition, one family of three sisters all having the disorder has been reported.[228] An additional report describes a father and son who were exposed to organic solvents and in whom PV subsequently developed.[232] These forms of familial PV must be distinguished from PFCP, which is characterized by isolated erythrocytosis and is inherited as an autosomal dominant disorder, as previously discussed in this chapter. The reports of families in which multiple members have PV have first raised the possibility that a genetic predisposition occurs in concert with several additional external insults, which might lead to the development of PV.[231] The inheritance pattern of familial PV is compatible with an autosomal dominant pattern with decreased penetrance.[231] Clinical analyses of affected family members confirmed that they have clonal hematopoiesis and that their clinical manifestations are identical to sporadic PV. Such families with multiple members with PV have been of scientific importance because they offer the possibility for genewide linkage analysis and positional cloning to identify additional genes predisposing to PV.[231]

Slightly more males than females develop PV, the male-to-female ratio being approximately 1.2 : 1.[167–171] The average age at diagnosis is 60 years,[12,210–214] and the disease is extremely rare in patients younger than 30 years of age. In several large studies, 5% of patients with PV were younger than 40 years of age, 1% were younger than 25 years at diagnosis, and 0.1% were younger than 20 years.[12,146,207,230] Small numbers of patients with PV have been reported who presented during childhood.[233] More importantly, in several of these children, hepatic vein thrombosis (Budd–Chiari syndrome) was the initial manifestation of the disease.[234]

BIOLOGICAL AND MOLECULAR ASPECTS

Considerable speculation has centered on the pathobiology of the erythrocytosis that characterizes PV.[235,236] London and colleagues[3] established that the expanded red cell mass of PV was due to a two- to threefold increase in the production of red blood cells by a hyperplastic marrow and was not attributable to prolongation of the red cell life span. Granulocyte and platelet production are also increased in this disorder. This overly exuberant production of all cellular elements of the blood suggests that the basic defect resides at the level of the hematopoietic cellular hierarchy from which each of these cells originates, the pluripotent hematopoietic stem cell.

A variety of studies have documented serum EPO levels in patients with PV, secondary erythrocytosis, and relative polycythemia, and in normal adults.[6–11] Serum EPO levels have been shown to be subnormal in patients with PV, elevated in many but not all cases of secondary erythrocytosis, and normal in patients with relative polycythemia (Fig. 68–5),[6–11] indicating that PV cannot be an abnormality of EPO production.

In 1951, Dameshek[197] postulated that chronic myeloid leukemia, PV, essential thrombocythemia, and IM were related disorders, which he called MPD. He concluded that these disorders resulted from a generalized hyperresponsiveness of marrow cells to myelostimulatory factors and speculated that these disorders were neoplastic in origin.[197]

Since the mid-1970s, much data have accumulated that conclusively demonstrate PV to be the result of a neoplastic proliferation of hematopoietic cells.[78,231,236–242] The cellular origin of the disorder was first established by the analysis of glucose-6-phosphate dehydrogenase (G6PD) isoenzymes in African American women who were heterozygous for this X-linked gene (Fig. 68–6). This approach was based on the random irreversible inactivation of one X chromosome in each female somatic cell during embryogenesis. Inactivation of the same X chromosome occurs in the progeny of these cells.[194] A normal African American female heterozygous for G6PD will therefore have approximately equal populations of marrow cells with a different G6PD isoenzyme.[60] The G6PD isoenzymes can be readily distinguished by electrophoretic methods.[237]

This approach was exploited in a seminal study by Adamson and coworkers[238] in an effort to determine the cellular origin of PV. They presumed that cells composing a tumor that arises from a single cell in a G6PD heterozygote would express a single isoenzyme type, whereas a neoplasm originating from multiple cells would express both isoenzyme types.[237] These investigators found that circulating

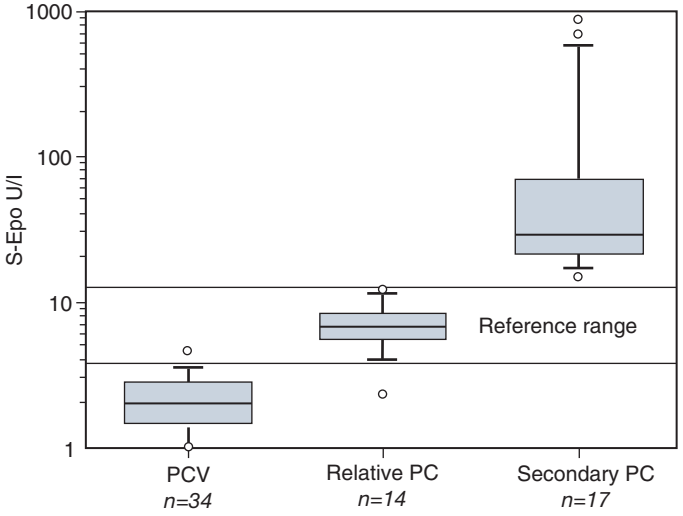

Figure 68–5. Serum erythropoietin levels in polycythemia vera, relative to secondary polycythemia. The middle bar represents the median; the boxes, quartiles, and the end bars, the 95% range. The open circles represent individual values outside the 95% range. (From Birgegaard G, Miller O, Caro J, Erslev A: Serum erythropoietin levels by radioimmunoassay in polycythaemia. Scand J Haematol 29:161, 1982.)

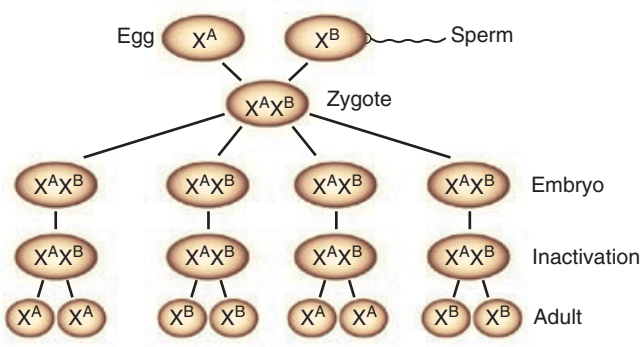

Figure 68–6. Schematic presentation of X chromosome inactivation in an embryo heterozygous at the *G6PD* locus (Gd^b/Gd^a). In this diagram, the maternal X chromosome bears an A gene for G6PD(X^A) and the paternal X chromosome a B gene (X^B). During embryogenesis, one X chromosome in each somatic cell is randomly inactivated, so that half the somatic cells will have an active X^A and the other half an active X^B. Inactivation is fixed for a particular cell and its progeny. All progeny of an active X^A gene will express X^A. Female G6PD heterozygotes are mosaics, with some cells active X^A and others X^B. A tumor with clonal origin will consist entirely of either X^A or X^B cells and therefore will contain only G6PD type A or B but not both. Tumors with multicellular origin will contain X^A and X^B cells and, therefore, both G6PD types. (Adapted from Fialkow PJ: Clonal origin of human tumors. Annu Rev Med 30:135, 1979.)

Table 68–3 Relative Amounts of G6PD Isoenzymes in Various Mesenchymal Tissues in Two Patients With Polycythemia Vera

Tissue	*%A* Case 1	*%B* Case 2
Skin	55:45	55:45
Lymphocytes	85:15*	55:45
Erythrocytes	100/0	100/0
Granulocytes	100/0	100/0
Platelets	100/0	100/0

*Contaminated with erythrocytes.

red cells, granulocytes, and platelets obtained from African American females who were G6PD heterozygotes express the same isoenzyme, whereas skin and cultured marrow fibroblasts obtained from these same patients demonstrate both isoenzymes (Table 68–3).[236,238] They concluded that PV represented a clonal proliferation of neoplastic hematopoietic stem cells and was not multicellular in origin or the consequence of excessive proliferation of normal hematopoietic stem cells.[238]

The clonality of blood cell production in PV has subsequently been confirmed using restriction fragment length polymorphisms of the active X chromosome.[240–242] A monoclonal pattern of X chromosome inactivation has been defined in red cells, granulocytes, monocytes, and platelets in females with PV.[78,240–242] Such studies confirm the clonal cellular origin of the disorder.

On the basis of the knowledge that red cell production in PV is not associated with excessive EPO production, several investigators have hypothesized that the erythroid progenitor cell in this disorder is no longer subject to physiologic regulators.[205] With the development of clonal assay systems for hematopoietic progenitor cells, it became possible to analyze the effect of EPO on in vitro colony formation.

Two classes of erythroid progenitor cells, the burst-forming unit–erythroid (BFU-E) and the colony-forming unit–erythroid (CFU-E) present in the marrow and peripheral blood of patients with PV were studied. Prchal and Axelrad[77] first reported that PV bone marrow can form substantial numbers of erythroid colonies in vitro in the absence of exogenous EPO, whereas normal human bone marrow is incapable of forming such colonies without the addition of EPO. These erythroid colonies have been termed *endogenous colonies*.[243,244] When erythroid PV and normal bone marrow were subsequently assayed in the presence of EPO, PV marrow was characterized by a higher cloning efficiency.[78,243–248] Mixed-colony formation has also been shown to be enhanced in PV.[244] Mixed colonies originate from multilineage progenitor cells. Their formation by PV marrow, but not by normal marrow, also occurs in vitro in the absence of exogenous EPO.[244] These observations suggest that the altered response to EPO in PV is characteristic not only of erythroid progenitor cells but of more primitive hematopoietic progenitor cells as well. Cell-cycle analysis of PV hematopoietic progenitor cells revealed another cell progenitor abnormality[245]: A higher proportion of PV progenitor cells were in the synthetic phase of the cell cycle than was observed in normal subjects.[245]

Further insight into the cellular defects in PV was provided by the studies of Prchal and coworkers (Table 68–4).[246] These researchers cloned marrow cells from African American female G6PD heterozygotes with PV in the presence and absence of exogenous EPO and demonstrated that the erythroid colonies that formed in the absence of exogenous EPO contained the same G6PD isoenzyme type as that expressed by peripheral blood elements.[246] Thus, the so-called endogenous erythroid colonies arose from the abnormal clone that was responsible for supplying red cells, granulocytes, and platelets to the peripheral blood. When exogenous EPO was added, increasing numbers of colonies were formed containing cellular elements expressing the other G6PD isoenzymes; presumably, these colonies originated from cells not involved in the malignant process. Similarly, small numbers of granulocyte–macrophage colonies not originating from the PV clone were also observed in these assays. These data collectively indicate the existence of malignant and nonmalignant populations of hematopoietic progenitor cells in PV marrow. The relative frequency of the neoplastic clone in relation to normal progenitor cells was further examined by Adamson and coworkers,[239] who, by monitoring the proportion of neoplastic erythroid clones and their numeric relationship to normal clones over a period of several years, showed disease progression to be associated with a significant decline in the frequency of normal colony-forming cells and increasing preponderance of the neoplastic clone.[239]

The clonal assay systems first used to obtain "endogenous erythroid colonies" contained serum contaminated with trace amounts of EPO.[243] This EPO contamination led to confusion about the responsiveness of the PV cells to the actions of this hormone. Two conflicting hypotheses were entertained: one suggesting that proliferation of abnormal populations of erythroid progenitor cells is completely independent of EPO and the other was consistent with hypersensitivity of polycythemia progenitors to EPO. Using an anti-EPO antiserum to remove trace amounts of EPO present in serum, Zanjani and colleagues[243] concluded that erythroid progenitor cells from PV patients do not proliferate in the absence of EPO but are, in fact, abnormally sensitive to the actions of this hormone. This increased responsiveness allowed these cells to form colonies in the presence of serum containing small amounts of EPO. By constructing EPO dose–response curves from PV marrows and comparing them with those obtained from normal marrow cells, Eaves and Eaves[247] drew similar conclusions. Their studies showed that most PV patients possess two distinct populations of erythroid progenitor cells: a normally EPO-responsive population and a population of cells similar in proliferative and maturational behavior in vitro but requiring little or no EPO.[247] These investigators suggested that because of the exquisite EPO sensitivity of the malignant clone, the proliferation of the normal progenitor cells in vivo was at a disadvantage.[247] The EPO dependence of PV progenitor cells was further demonstrated by Casadevall and coworkers,[248] who used a serum-free culture system, which no longer was contaminated with EPO. They were unable to demonstrate endogenous erythroid colony formation by normal or PV marrow and showed that PV erythroid progenitor cells were exquisitely sensitive to EPO compared with normal progenitors.[248] These data collectively indicated that the abnormality in the erythroid progenitor cell in PV is not only quantitative but also qualitative.

Using semipurified populations of blood and bone marrow BFU-E, a number of investigators have demonstrated that the increased

responsiveness of these marrow progenitor populations extends to their responses to SCF, IL-3, GM-CSF, and insulin-like growth factor-1 (IGF-1). These studies also demonstrated that bone marrow fractions enriched for granulocyte–macrophage progenitors as well as megakaryocyte progenitors from the patients had a heightened responsiveness to IL-3 and GM-CSF.[201,202] The dogma that the hyperresponsivity of PV progenitor cells to a variety of growth factors (EPO, IL-3, GM-CSF, steel factor) is the underlying defect that leads to PV has been universally accepted.[237,236]

Many investigators have examined the possibility that the hematopoietic defect in PV could be accounted for by genetic alteration of cytokine receptors expressed by affected hematopoietic cells.[249–252] In PV, the EPOR is structurally similar to the normal EPOR, and mutations in the EPOR do not appear to be directly involved in the pathobiology of PV.[249–252] Furthermore, no significant differences in the number, dissociation constant, or internalization rate of receptors for steel factor have been detected in the erythroid progenitor cells of PV patients.[249]

The receptor for TPO (Mpl) has also been implicated in the biogenesis of PV. Mpl is expressed by the megakaryocytes, platelets, and pluripotent hematopoietic stem cells.[12,253–255] Impaired expression of Mpl in murine knockout models results in a reduction of multipotent and committed hematopoietic progenitors, and TPO increases the proliferation of primitive hematopoietic progenitor cells in vitro.[12,253] The retrovirus, MPLV, which encodes a truncated form of MPL, induces a fatal myeloproliferative disorder in mice.[254,255] Mpl expression has been shown to be abnormal in the megakaryocytes and platelets of patients with PV.[256,257] Two forms of Mpl were detected in PV platelets compared with normal platelets, where a single form is present. The two forms of Mpl in PV have been attributed to an abnormality in posttranslational glycosylation, which has been suggested to be characteristic of PV.[257] The removal of the distal extracellular domain of Mpl in mice results in independent survival of hematopoietic progenitor cells expressing this truncated receptor.[254,255] In PV platelets and megakaryocytes, this extracytoplasmic domain is not detectable by flow cytometry, and total platelet Mpl is reduced, which has recently been shown to be a consequence of JAK2-induced Mpl trafficking.[12,256,257] The abnormal expression of Mpl in PV has been used as a diagnostic tool in distinguishing the etiology of various causes of erythrocytosis. In addition, these data provide the rationale for the belief that abnormal Mpl function may play a fundamental role in the development of PV. Furthermore, the defect in Mpl expression becomes more pronounced with disease progression, suggesting that it may be a useful marker of disease activity.[12,256,257]

Several groups have suggested that the overproduction of red cells in PV is a consequence of progenitor and precursor cell accumulation rather than proliferation.[12,258] This hypothesis was first based on the observation that the antiapoptotic protein BCL-XL was overexpressed in PV progenitor cells, resulting in their resistance to apoptosis in the absence of EPO. This overexpression of such antiapoptotic proteins presumably permits erythroid progenitors to terminally differentiate in the absence of EPO. Additional proof of this pathogenetic mechanism was provided by the demonstration of increased expression of the cyclin-dependent kinase inhibitor INK4α/ARF locus in PV erythroid cells.[259] Furthermore, Pellagatti and colleagues, using cDNA microarray technology to analyze the gene expression profile in PV granulocytes, showed upregulation in PV granulocytes of several protease inhibitors that are known to possess high affinity for proteases that promote neutrophil apoptosis.[260] They have suggested that upregulation of such protease inhibitors might lead to increased survival of neutrophil precursors in PV.

Identification of JAK2V617F Mutation in PV

For more than two decades, a number of research groups have been searching for the genetic defect underlying PV. Most groups predicted that this defect involved the signaling pathways downstream of the EPOR. These pathways include the tyrosine kinase JAK2 and the transcriptional signal transducers and activators of transcription (STAT)3 and STAT5. The initial discovery of a mutation was predicated on a somewhat simplistic yet revealing set of experiments performed by Vainchenker and his colleagues in France and reported in 2005.[79,261] They observed that the inhibition of JAK2 by a small molecule (AG490) or by small interfering RNA (siRNA) reduced erythropoietin-independent colony formation by PV bone marrow mononuclear cells.[261] This observation prompted them to directly sequence JAK2 in the hematopoietic cells of PV and to discover a single recurrent point mutation.[79] A guanine-to-thymine mutation was observed that resulted in a substitution of valine to phenylalanine at codon 617 within the pseudokinase domain (JH2) of JAK2 (*JAK2V617F*) (Fig. 68–7).[79] These findings were quickly confirmed by several different groups.[79–82] Kralovics et al had previously identified a region of loss of heterozygosity (LOH) on chromosome 9p in PV, and identified a 6·2-Mbp region common to all PV patients screened.[262] As this region contained JAK2, with its known role in erythropoiesis, it was screened for mutations and the same JAK2V617F mutation identified.[81] Three other groups targeted JAK2 as part of a global sequencing screen of tyrosine kinases and phosphatases in MPDs.[80,82,263] Analysis of germline DNA demonstrated that *JAK2V617F* is an acquired somatic mutation present exclusively in hematopoietic cells.[79–82,263] All patients with PV have a population of erythroid progenitor cells which are homozygous for the mutation.[268] Using quantitative PCR, patients with a low burden of JAK2V617F in granulocytes have been termed heterozygotes (<50%), while patients with a higher burden of JAK2V617F are termed homozygotes (>50%). A subset of patients with PV are homozygous for *JAK2V617F*, which was demonstrated to be the result of mitotic recombination and duplication of the mutant allele (Fig. 68–8).[81,262] The consequence of this mitotic recombination event has been observed during the clinical course of individual patients leading to JAK2V617F heterozygote patients becoming homozygotes over time.[264] The concept of the conversion of JAK2V617F heterozygosity to homozygosity is further supported by the observation that the median duration of disease at the time of evaluation was 48 months in homozygous PV patients as compared to 23 months in heterozygotes and 15 months in patients with wild-type JAK2.[82] These observations are consistent with a multistep pathogenesis of PV. The multiple steps being the acquisition of JAK2V617F, which results in JAK2V617F heterozygosity, followed by a second step, homologous recombination, that leads to JAK2V617F homozygous progenitor cells and eventually JAK2V617F homozygous granulocytes.[82] It remains unknown at present if a lesion occurring prior to acquisition of the JAK2V617F mutation predisposes an individual to acquire JAK2V617F.

A number of groups have reported the frequency of JAK2V617F in patients with MPDs (Table 68–5).[79–82,265,266] The prevalence of the mutation in PV ranges from 65% to 97%, with an average of 82% in nearly 1000 reported cases. The differences in reported rates of positivity are likely due to at least three causes: first, the stringency of the criteria used to diagnose PV; second, the sensitivity of the method used to detect mutations; and third, the source of DNA (granulocytes, mononuclear cells, or whole blood cells). The majority of studies have used peripheral blood neutrophils as they are derived from the same clonal progenitor that is transformed in PV. Direct sequencing techniques are likely to have a lower sensitivity than techniques that employ PCR amplification of the mutant allele.[267] Approximately 50% to 60% of patients with essential thrombocytosis (ET) and IM are also *JAK2V617F*-positive. ET can be distinguished from PV by cloning erythroid progenitors and analyzing the JAK2V617F status of individual hematopoietic colonies.[268] In the overwhelming majority of cases, PV is characterized by a population of JAK2V617F homozygous colonies with some heterozygous and wild-type colonies. By contrast in ET, there are few homozygous colonies, with the majority being heterozygous or wild-type.[268] The majority of ET and IM patients who are negative for *JAK2V617F* have clonal hematopoiesis,[269] which indicates that these JAK2V617F diseases likely are the consequences of another genetic event. The *JAK2V617F* allele has also been observed in a limited number of

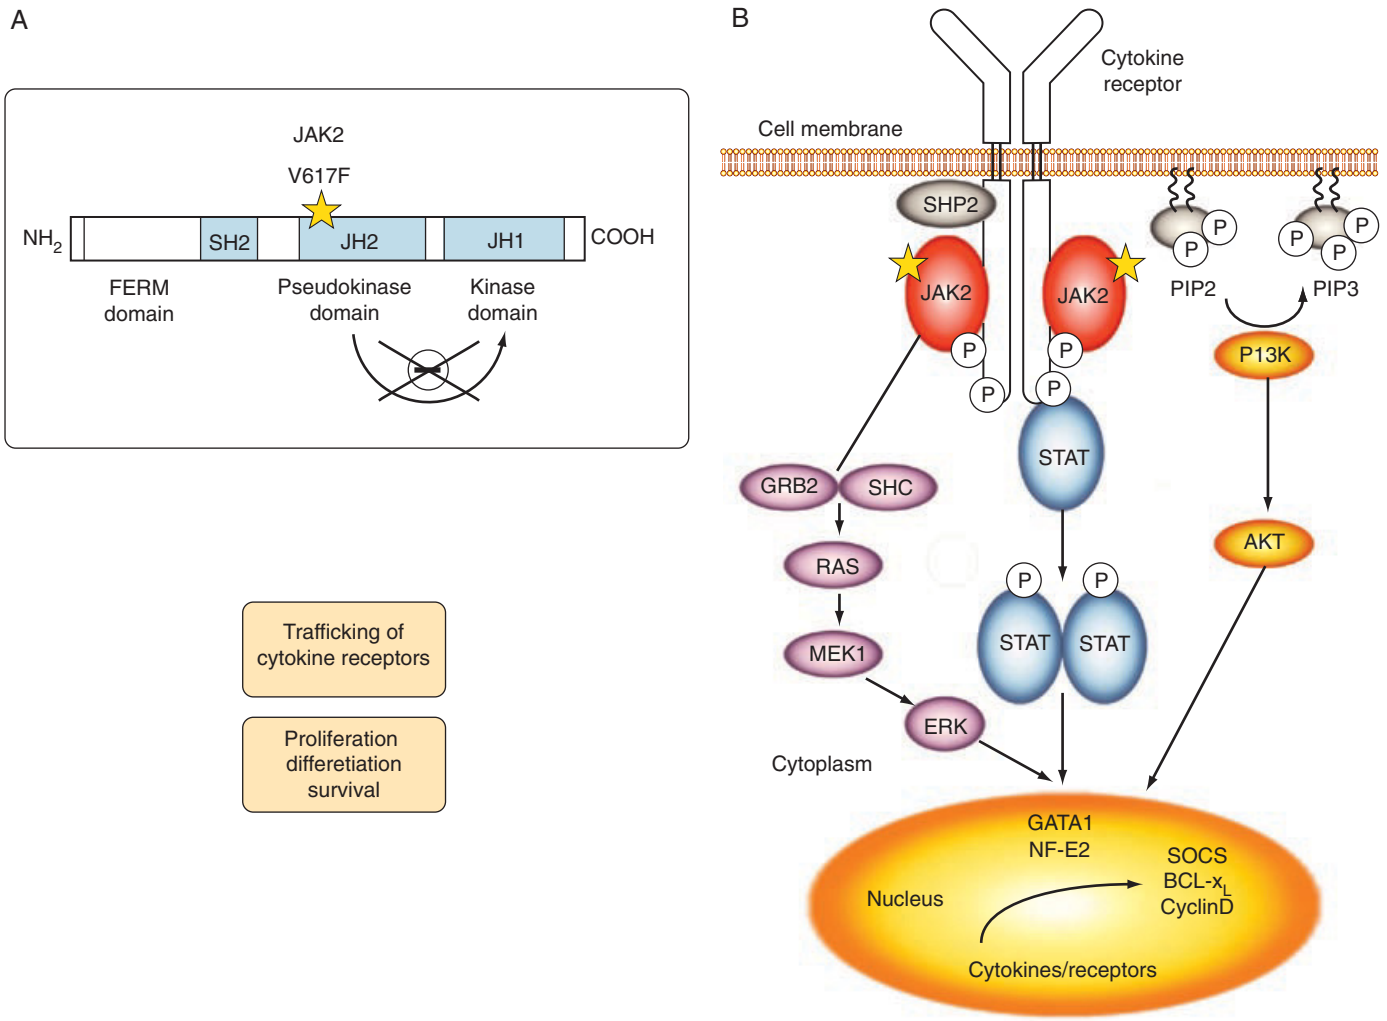

Figure 68–7. JAK2V617F signaling in myeloproliferative disorders. (*a*) Structure of JAK2 V617F: the mutation is located in pseudokinase JAK homology domain 2 (JH2) and disrupts the autoinhibition of this regulatory domain. Consequently, the tyrosine kinase corresponding to the JH1 domain is constitutively activated. (*b*) In the presence of a homodimeric cytokine receptor (eg, EPOR), the two JAK2V617F proteins bound to the intracellular domain of the receptor transphosphorylate its tyrosine residues. In turn, STAT5, PI3K, and RAS signaling pathways are activated, leading to the downstream modulation of transcription and protein levels for cell cycle, proliferation and apoptosis-related factors. P, phosphate; PIP2 and PIP3, phosphatidyl inositol bi- and triphosphate; PVR, pulmonary vascular resistance. (From Delhommeau F et al: Cell Mol Life Sci 63, 2006.)

Table 68–5 Frequency of JAK2V617F Mutations in PV, ET, and IM

	JAK2V617F Detection Method	PV: JAK2V617F (Homozygous)	ET: JAK2V617F (Homozygous)	IM: JAK2V617F (Homozygous)

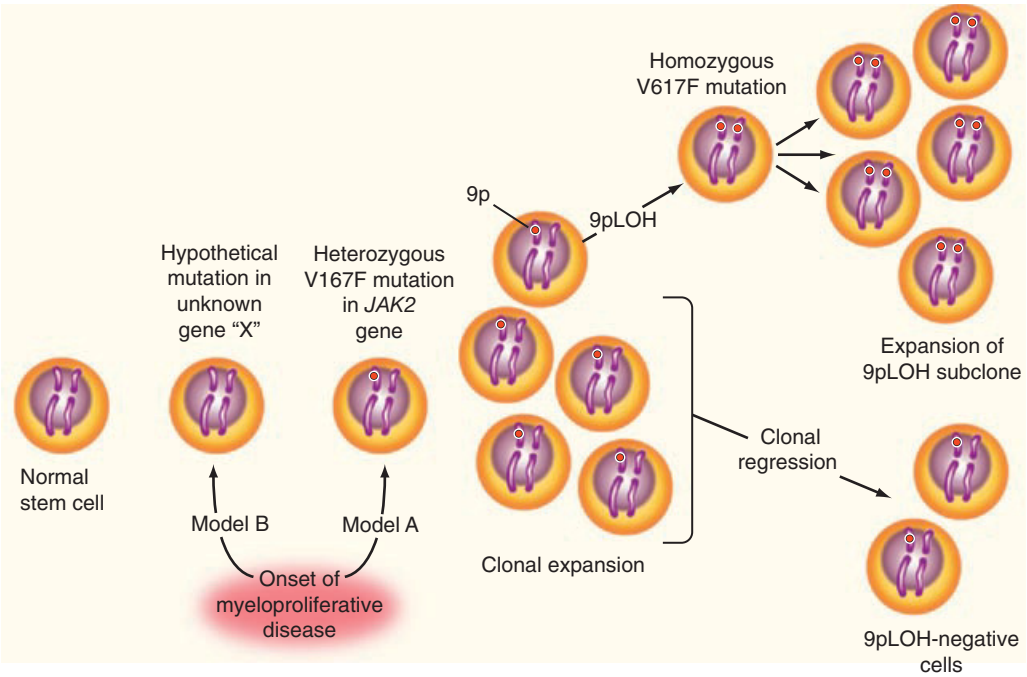

Figure 68–8. Possible role of JAK2V617F in the biology of myeloproliferative disorders. The chromosome 9 with the wild-type *JAK2* sequence (G) is depicted in white, and the chromosome 9 with the GT transversion (T) is shown in red. Circles symbolize the nuclei of the cells. Deletion of the telomeric part of wild-type chromosome 9p as a potential mechanism for 9pLOH is shown on the left. Alternatively, mitotic recombination could also result in 9pLOH, shown on the right. The events during mitosis and the resulting cell progeny after mitotic recombination of chromosome 9p are also shown. (Adapted from Kralovics R, Passamonti F, Buser AS, et al: A gain-of-function mutation of JAK2 in myeloproliferative disorders. N Engl J Med 352:1779, 2005.)

patients with chronic myelomonocytic leukemia, myelodysplastic syndromes (MDS), and acute myeloid leukemia (AML), although most *JAK2V617F* mutations in AML occur in patients with a preceding diagnosis of PV, ET, or IM.[265,266,270] JAK2V617F is an acquired somatic mutation, and does not appear in nonhematopoietic cells and has not been detected in patients with secondary erythrocytosis. Moreover, JAK2V617F has not been observed in lymphoid malignancies although another mutation, *JAK2 L611S*, was identified in one case of pre-B-ALL during a screen for *JAK2* mutations using denaturing high-performance liquid chromatography.[266] Using high-sensitivity allele-specific PCR, JAK2V617F has been detected in small numbers of normal individuals or hospitalized patients who do not have MPD.[271] At this time, it remains unknown whether this observation is a consequence of oversensitivity of the assay utilized or the presence of the mutation in patients with preclinical forms of MPDs. Long-term follow-up of such individuals would be required to determine the clinical significance of such an observation.

The JAK2V617F Mutation Is Present in Hematopoietic Stem Cells in PV

Previous studies had demonstrated that the majority of patients with PV had clonal involvement of multiple lineages, including myeloid, erythroid, and lymphoid cells.[238,240,272,273] These results suggested that PV originates in hematopoietic progenitors with the ability to differentiate into multiple lineages. In addition, loss of heterozygosity at 9p24, now known to correspond to homozygous *JAK2V617F* mutations, can be identified in both myeloid and lymphoid cells in some patients with PV, further suggesting that the underlying mutations occur in progenitor cells with the ability to differentiate into multiple hematopoietic lineages.[262]

The JAK2V617F mutation has been detected in hematopoietic colony-forming cells and more mature progeny, such as neutrophils and platelets.[79–82,274] Jamieson et al have recently isolated, according to phenotypic populations of cells enriched for HSCs, common myeloid progenitors (CMPs), granulocyte–macrophage progenitors (GMPs), and megakaryocytic–erythroid progenitors (MEPs) from patients with PV and analyzed for the presence of the *JAK2V617F* mutation in these progenitor populations.[275] They detected *JAK2V617F* in HSCs, CMPs, GMPs, and MEPs from patients with PV supporting that PV is a disorder that arises in HSCs and involves the myeloid, erythroid, and megakaryocytic lineages.[275] These data are in agreement with a recent report by Ishii et al claiming that *JAK2V617F* can be detected in different hematopoietic lineages in patients with PV,[276] although the mutation could only be detected in lymphoid cells in a minority of patients. Delhommeau et al and Larsen et al have also provided data indicating the JAK2V617F mutation in PV originates in lymphomyeloid progenitor cells.[277,278]

Structural and Functional Aspects of JAK2V617F-Mediated Transformation

The JAK2V617F mutation occurs within the JH2 domain of JAK2, which has significant homology to the kinase domain of JAK2 (JH1) but lacks catalytic activity (see Fig. 68–7). The JH2 domain exerts an inhibitory effect on JAK2 kinase activity and the *V617F* mutation is predicted to disrupt this inhibition.[279] In vitro kinase assays with JAK2V617F and wild-type JAK2 have revealed that JAK2V617F has greatly increased kinase activity, as assessed by autophosphorylation and by substrate phosphorylation.[263] Ectopic expression of JAK2 V617F in either epithelial or hemopoietic cell lines results in autophosphorylation of mutant JAK2, but not the wild-type (WT) JAK2, and activation of downstream signaling events.[79–82,263] BAF3 or FDCP cell lines expressing the EPOR and engineered to stably express JAK2 V617F are largely independent of the addition of exogenous growth

factors and are hypersensitive to EPO.[79–82] Lu et al have shown that coexpression of JAK2 V617F and a homodimeric type 1 cytokine receptor (EPOR, TPOR, or G-CSFR) facilitates the transformation of cells to growth-factor independence, suggesting that the mutant JAK2 requires a receptor scaffold in order to be active.[280] This contrasts with the effects of the TEL-JAK2 fusion gene, which can readily transform cells on its own, presumably because of the strong homodimerization effects of the TEL moiety.[281] Ectopic expression of JAK2 V617F can also sensitize cells to the effects of IGF1, a characteristic feature of PV progenitors.[282]

Expression of JAK2V617F in hematopoietic cells activates intracellular signaling pathways downstream of the EPOR including STAT5, STAT3, the MAP kinase pathway, and the PI3K–Akt pathway.[79–82,263] STAT5 is normally phosphorylated by the cytokine receptor–JAK2 complex, and phosphorylated STAT5 then translocates to the nucleus and activates the transcription of target genes. The target genes of STAT5 include Bcl-X_L, an important antiapoptotic protein known to be expressed in increased levels in PV proerythroblasts.[258] The possibility that STAT5-mediated activation of Bcl-X_L is important in the pathogenesis of PV was suggested by a recent report that demonstrated that expression of either constitutively active STAT-5 or Bcl-X_L resulted in spontaneous erythroid colony formation. In addition, cells expressing JAK2V617F display constitutive activation of the MAP kinase pathway (as assessed by phosphorylation of ERK), and of the PI3K pathway (as assessed by phosphorylation of AKT). Furthermore, JAK2 has been shown to play a role in cellular mpl trafficking.[284] The JAK2V617F might also lead to the decreased expression of mpl by platelets observed in PV patients.[284] It is important to note that many other oncogenic tyrosine kinases activate the same signal transduction pathways, and the role and requirement for each of these signaling pathways in the transformation of hematopoietic cells by JAK2V617F remains unknown.

Many PV patients have a low burden of *JAK2V617F* as assessed by DNA sequencing, suggesting that there is either a subpopulation of cells that are homozygous for *JAK2V617F* mixed with wild-type cells or a clonal population of cells with one wild-type copy of *JAK2* and one mutant copy of *JAK2*. In PV, data from clonality/quantitative *JAK2V617F* assessment and from colony assays suggest that most PV patients have a subpopulation of cells homozygous for *JAK2V617F*, whereas in ET clonal progenitor cells are heterozygous for *JAK2V617F*.[268,269] It is therefore important to determine whether the wild-type allele can interfere with the ability of JAK2V617F to constitutively signal in the heterozygous state and whether there is an effect of gene dosage on the activation of signal transduction pathways. Transient coexpression of wild-type JAK2 does not interfere with the ability of JAK2V617F to autophosphorylate, even when wild-type JAK2 is expressed at higher levels than the mutant kinase.[79] This suggests that JAK2V617F kinase activity is unaffected by coexpression of wild-type JAK2. In contrast, when JAK2V617F and wild-type JAK2 were coexpressed in Ba/F3 cells, cytokine-independent growth was attenuated, suggesting in this cellular context that wild-type JAK2 is able to interfere with JAK2V617F-mediated transformation.[79] Suppressors of cytokine signaling (SOCS) proteins bind to the JH1 catalytic loop and target JAK2 for degradation. SOCS1 and SOC3 bind to the catalytic groove belonging to JAK2 and inhibit its catalytic activity. SOCS3 binds to the EPOR and JAK2 to inhibit EPOR signaling. SOCS proteins inhibit JAK2 by functioning as E3 ubiquitin ligases. Hookham and coworkers recently reported that although SOCS1, SOCS2, and SOCS3 inhibit phosphorylation of wild-type JAK2, they are incapable of blocking phosphorylation of JAK2V617F.[285] On the basis of their findings, SOCS3 appears to be unable to inactivate JAK2V617, and SOCS3 itself is not degraded but accumulates and actually promotes the further phosphorylation of JAK2V617F.[285] Such dysregulation likely enhances JAK2V617F-induced cell proliferation and prolongs signaling. These data have been suggested by Hookham to provide an explanation why JAK2V617F hematopoiesis predominates in PV heterozygotes. Low levels of JAK2V617F signaling in JAK2V617F heterozygotes likely induce SOCS3, which would downregulate JAK2 wild-type signaling and enhance signaling by JAK2V617F, permitting the malignant clone to predominate.[285]

Murine Models of JAK2V617F-Mediated Disease

Significant insight regarding the biological consequences of JAK2V617F has been gained by genetic modification of murine bone marrow, allowing them to express JAK2V617F. James et al first reported that the transplantation of marrow cells into lethally irradiated mice that expressed JAK2V617F but not wild-type JAK2 led to the development of marked erythrocytosis and splenomegaly without elevation of granulocyte or platelet counts 28 days after transplantation.[79] This report suggests that JAK2V617F is sufficient for the development of erythrocytosis in PV. Subsequent reports have provided additional insights into the in vivo effects of JAK2V617F.[79,286–289]

Wernig et al have shown that JAK2 V617F expression by marrow cells produces an increased hematocrit and splenomegaly in both C57Bl/6 and Balb/c recipient mice, but marked leukocytosis and bone marrow reticulin fibrosis were only observed in Balb/c mice.[226] Although the bone marrow was characterized by megakaryocyte hyperplasia, recipient mice did not develop thrombocytosis as a result of defects in megakaryocytic maturation and platelet production. These data suggest that there are host modifiers that affect the phenotype induced by JAK2V617F expression. Activation of JAK2 and STAT5 was observed in JAK2V617F-expressing cells but not in cells expressing wild-type JAK2, demonstrating activation of these signal transduction pathways by JAK2V617F in vivo.[286] In addition, erythroid colonies were cloned from marrow cells isolated from mice transduced with JAK2V617F in the absence of EPO and further increased in number in the presence of low levels of EPO. These results suggest that the presence of the JAK2 V617F may be sufficient to induce PV but that the disease phenotype may be affected by other unknown genetic modifiers.

Using a similar approach, Lacout et al also assessed the effects of JAK2V617F on C57Bl/6 mice and followed these mice for 6 months after transplantation.[287] Mice expressing JAK2V617F developed polycythemia and leukocytosis, peaking 3 months after transplant, followed by a progressive reduction in cell counts that was associated with progressive marrow fibrosis and increasing splenomegaly. The degree of bone marrow fibrosis was variable, and interestingly, mice with high-grade fibrosis developed anemia, thrombocytopenia, and neutrophilia consistent with post-PV IM. Again, elevated platelet counts were not observed in mice transduced with JAK2V617F, suggesting that JAK2V617F may not be sufficient for the development of thrombocytosis in patients with PV. One group of secondarily transplanted animals where there was a relatively low level of JAK2 V617F expression was associated with a transient period of thrombocytosis. It has been suggested that this is a situation analogous to that seen in clinical ET where JAK2 V617F homozygosity is rare and may suggest that the lower doses of JAK2V617 lead to thrombocytosis while higher allele frequency results in polycythemia and leukocytosis. These data have also been confirmed by Bumm et al and Zaleskas et al.[288,289]

Data generated from these bone marrow transplant models of JAK2V617F-mediated disease suggest that JAK2V617F is sufficient for the development of PV. Although mice transduced with JAK2V617F display certain features of IM (reticulin fibrosis) and ET (megakaryocytic hyperplasia), the phenotype of these mice more closely resemble that in PV. The dominant erythroid phenotype of JAK2V617F may reflect differences in the pathogenesis of the different MPD. It is possible that PV may result from acquisition and subsequent homozygosity of *JAK2V617F*. Gene dosage or level of expression of JAK2V617F might dictate the phenotype of a particular MPD. This hypothesis is supported by the observation that patients with PV, but not ET, frequently have homozygous *JAK2V617F* mutations and that some patients with ET have monoclonal granulopoiesis even when a minority of cells are *JAK2V617F*-positive.[268] However, the consequences of the expression of JAK2V617F in the

heterozygous and homozygous state cannot be assessed using these models, and the genetic basis of the strain-specific differences in phenotype remains unknown. Despite these limitations, these models provide a powerful tool to study a human PV-like illness and provide an in vivo platform for preclinical testing of therapeutic agents that inhibit JAK2V617F.

Other JAK2 Mutations in PV

Other mutations of JAK2 associated with erythrocytosis, however, can also constitutively activate JAK2 kinase activity. Grunebach et al have identified a new mutation in JAK2 that leads to a change of the amino acid aspartate for glutamate at position 620 (JAK2 D620E) in a 27-year-old patient with PV.[290] Scott et al have recently identified four somatic gain-of-function mutations affecting *JAK2* exon 12 in 10 JAK2V617F-negative patients. Those with a *JAK2* exon 12 mutation presented with an isolated erythrocytosis and distinctive bone marrow morphology and had reduced serum EPO levels. Erythroid colonies could be grown from their blood samples in the absence of exogenous EPO.[83] All such erythroid colonies were heterozygous for the mutation, whereas colonies homozygous for the mutation occur in most PV patients with JAK2V617F. BaF3 cells expressing the murine EPOR and also carrying exon 12 mutations can proliferate without added interleukin-3. They also exhibited increased phosphorylation of JAK2 and ERKs, as compared with cells transduced by wild-type JAK2 or V617F JAK2.[83] Three of the exon 12 mutations involved a substitution of leucine for lysine at position 539 of JAK2. This mutation resulted in a myeloproliferative disorder phenotype, including erythrocytosis, in retroviral murine bone marrow transplantation model.[83] *JAK2* exon 12 mutations, therefore, might define a distinctive myeloproliferative syndrome that affects patients who currently carry a diagnosis of idiopathic erythrocytosis. Additional genetic lesions are currently being sought in patients who meet clinical criteria for PV but are JAK2V617F negative.

Familial and Congenital PV—Additional Genetic Events in the Pathogenesis of PV

Despite in vivo data suggesting that *JAK2V617F* might be sufficient for the development of PV, there is evidence that additional genetic events might contribute to the pathogenesis of PV, ET, and/or IM. The fact that the identical *JAK2* mutation is identified in patients with three phenotypically related but clinically distinct MPD suggests that additional genetic and/or epigenetic events likely contribute to the phenotypic divergence of these disorders. Furthermore, Kralovics and coworkers have reported using either restricted fragment length polymorphism analysis or the presence of the cytogenetic abnormality $20q^-$ in patients with MPDs that the percentage of granulocytes and platelets that were JAK2V617F positive was often lower than the percentage of granulocytes belonging to the malignant clone.[291] These findings suggest that the acquisition of JAK2V617F is a relatively late event that is preceded by a genetic event that leads to clonal hematopoiesis. The acquisition of the JAK2V617F apparently occurs in this background of clonal hematopoiesis.

Several investigators have reported families where multiple members have an MPD and have analyzed the JAK2V617F status of family members.[292–295] In a study by Bellane-Chantelot et al, the members of 72 families with multiple members with MPD were analyzed for *JAK2V617F* mutational status.[292] Somatic *JAK2V617F* mutations were identified in some, but not all family members with MPDs. Interestingly, in some families both *JAK2V617F*-positive and *JAK2V617F*-negative members with MPD were observed. A small number of relatives who were JAJ2V617F negative and did not have a diagnosis of PV, ET, or PMF had hematopoietic cells that formed endogenous erythroid colonies in vitro. These results suggest that an as yet unidentified genetic event might contribute to the pathogenesis of PV, ET, and PMF, regardless of *JAK2* mutational status, and that there may be "initiating events" that precede the acquisition of *JAK2V617F* in these disorders. It is anticipated that the recent development of whole genome mapping technologies will permit researchers to identify the disease allele that predisposes these family members to develop an MPD.[292–295]

ETIOLOGY AND PATHOGENESIS

The most frequent cause of mortality in PV patients is vascular thrombosis.[206,207,296,297] This increased thrombotic tendency is believed primarily to be a direct consequence of the expanded red cell mass that characterizes this disorder.[298] However, the thrombotic tendency in PV may be multifactorial in origin, with quantitative defects of platelets and neutrophils contributing to its development.[299–306]

In the European Collaboration on Low-Dose Aspirin in Polycythemia Vera (ECLAP) study,[307] the incidence of cardiovascular complications was higher in patients older than 65 years (5.0% of patients per year; hazard ratio 2.0; confidence interval (CI) 1.22–3.29; $P < 0.006$) or with a history of thrombosis (4.93% of patients per year; hazard ratio 1.96; 95% CI 1.29–2.97; $P = 0.0017$).[307] Patients both with a history of thrombosis and older than 65 years had the highest risk of developing additional cardiovascular events (10.9% of patients per year; hazard ratio 4.35; 95% CI 2.95–6.41; $P < 0.0001$). These data confirm previous findings that increasing age and history of thrombosis are the two most important prognostic factors for the development of vascular complications.[307]

This information does not negate the increased incidence of thrombotic incidents also observed in younger patients with this disorder.[308] In a series of 58 PV patients younger than 40 years, a disturbingly high incidence of life-threatening thrombotic events was observed. In fact, 7 of the 10 patients in this series who died during the period of observation died from thrombotic events: four from Budd–Chiari syndrome, one from a pulmonary embolism, and two from cerebral thrombosis.[244] Therefore, although a significant factor, preexisting atherosclerotic disease is not the sole etiologic factor in the genesis of thrombosis in PV. Some have suggested an important role for smoking as a secondary factor leading to the increased incidence of thrombotic events in this patient population.[309,310]

The principal hemorrheologic abnormality in PV is an elevated whole blood viscosity.[311–313] The blood viscosity in PV is higher than that of normal controls at all shear rates.[311–313] In a retrospective analysis of the records of 69 PV patients with histories of vascular thrombosis, Pearson and Wetherley-Mein,[298] in a seminal report, demonstrated a strong correlation in univariate analysis between hematocrit level and the development of thrombotic episodes, including many cerebrovascular occlusions (Fig. 68–9). Thomas and coworkers showed that cerebral blood flow is reduced in patients with PV in whom the hematocrit level is 53% to 62%.[298] These abnormalities were observed even in patients with hematocrits at the lower levels of normal, that is, 46% to 52%.[298] Reductions in cerebral blood flow were correctable with phlebotomy. Reduction of the hematocrit by relatively small amounts frequently led to substantial improvements in whole blood viscosity and cerebral blood flow. Some PV patients apparently still maintain a higher than normal whole blood viscosity despite the normalization of the hematocrit, suggesting that an increase in hematocrit may not be the only factor responsible for increased blood viscosity.[312]

A number of possible explanations have been suggested for the observed relationship between hematocrit and the development of thrombotic events in PV patients. Turrito and Weiss[313] presented evidence indicating that platelet adhesion and thrombus formation on the vascular subendothelium are determined in part by the rate at which platelets are transported to the vascular surface. In a polycythemic condition in which increased numbers of red cells are present, a greater number of intercellular collisions between red cells and platelets occur. These collisions could lead to increased platelet movement in a direction perpendicular to blood flow. This facilitation of platelet transport to the vessel wall may be an important factor in the development of thrombosis.[313] An alternative explanation for

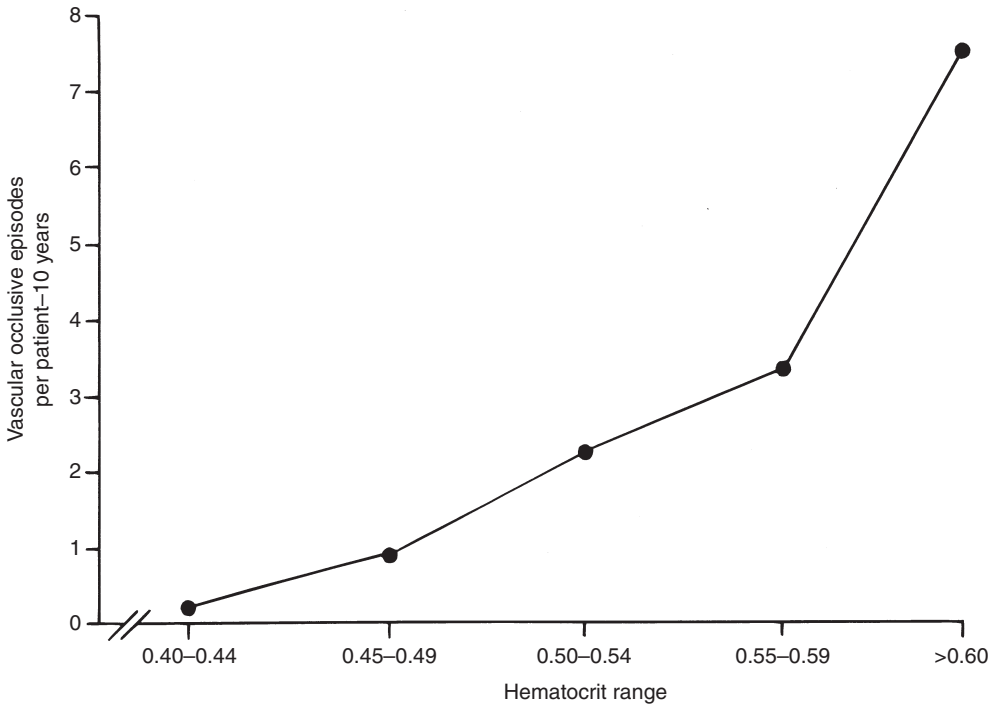

Figure 68–9. Relation of hematocrit to number of vascular occlusive episodes per 10 years in patients with polycythemia vera. (Data from Pearson TC, Wetherley-Mein G: Vascular occlusive episodes and venous haematocrit in primary proliferative polycythemia. Lancet 2:1219, 1978.)

the association between hematocrit level and the risk of thrombosis is based on the knowledge that blood viscosity is particularly sensitive to hematocrit levels.[12,309,310] Increased hematocrits lead to increased blood viscosity, in turn leading to increased peripheral vascular resistance and an actual reduction in blood flow to a variety of organs, predisposing them to the development of thrombosis.[309,310] The issue of hematocrit and thrombosis in PV has been prospectively investigated in a recent analysis of 1638 patients enrolled in the ECLAP study.[314] In this prospective study, in spite of recommendations of maintaining hematocrit levels less than 45%, only 50% of patients achieved this target during the follow-up and 10% had hematocrit levels above 50%.[314] These different hematocrit values were not associated with different thrombotic outcomes as assessed using univariate and multivariable analysis. The clinical significance of this finding appears to be relevant for the construction of future therapeutic guidelines and deserves to be validated in prospective randomized clinical trials. Additional factors have been implicated in the development of thrombosis in PV patients. Almost all patients with PV are iron deficient.[315] Decreased red cell deformability has been said to accompany iron deficiency, leading to increased blood viscosity and a decreased ability of red cells to pass through small-bore polycarbonate filters.[316–320] Such abnormalities have been shown by Tillman and Schröter[320] and Yip and colleagues[252] to be due to increased membrane stiffness rather than to reduced surface–volume ratio, as has been suggested by others. This increased membrane stiffness, however, might be counterbalanced by the effect of a reduced red blood cell size on the adherence of blood platelets to arteriolar subendothelium. Aarts and coworkers[319] have shown that red cell size is a major determinant of platelet adherence, with larger red blood cells leading to increased platelet adherence and smaller red cells to decreased platelet adherence. Whether the increased membrane stiffness associated with iron deficiency is counterbalanced by the decreased platelet adherence associated with smaller red blood cells is yet to be determined.

Studies of patients with hemoglobinopathies due to abnormal oxygen binding who have secondary erythrocytosis provide further support to the belief that hematocrit elevations are not the sole cause of the thrombotic tendency in PV. A survey of patients with these types of hemoglobinopathies has not demonstrated a higher incidence of myocardial ischemia or any other form of thrombosis, even though the red cell mass is frequently as elevated as that in patients with PV.[321] Furthermore, Shibata and colleagues studied the risk of thrombosis in a transgenic mouse model with extreme erythrocytosis due to overexpression of EPO and did not observe an increased incidence of thrombosis.[117]

Thrombocytosis and qualitative platelet abnormalities occur frequently and are likely to be important contributory factors to the development of thrombosis.[206,304,305,322–332] Dawson and Ogston[324] have implicated uncontrolled thrombocytosis as a cause of thrombosis in these patients, but this relation has not been confirmed by Kessler and colleagues[322] or Berk and colleagues.[296] Increased plasma and urinary thromboxane production has been linked to increased platelet activation in these patients.[323] A low-dose aspirin regimen selective for inhibition of platelet cyclooxygenase has been found to suppress increased thromboxane production in vivo and to clinically benefit patients with PV.[302,303,325,326] Furthermore, elevated levels of serum vascular endothelial growth factor and plasma TPO have been observed in PV patients.[301] These growth factors have been shown to lead to platelet activation.[301]

Despite conflicting data, no clear clinical relationship between platelet number or function and the incidence of hemorrhage or thrombosis in PV patients has been delineated.[297,298,314,322–327] An argument in favor of a role of elevated platelet numbers in the genesis of thrombosis in PV and ET is the observation in patients with ET that a reduction of excessive platelet numbers with the use of hydroxyurea is associated with a reduction in the risk of developing thrombotic events.[327] However, this should not be taken as evidence that the reduction in developing additional vascular events was due to platelet count normalization alone; very likely, it may be related to the suppression by hydroxyurea of each of three myeloid lineages. In line with this interpretation are the results of a randomized study performed by the Medical Research Council in the United Kingdom (PT-01) in which patients with ET were randomized to receive either hydroxyurea or anagrelide therapy.[333] This study showed that hydroxyurea therapy rather than anagrelide, a selective platelet number-reducing drug, was associated with a reduction in the number of arterial thrombotic events, especially in JAK2V617F patients.[333] In a recently reported analysis of the ECLAP study, the rate of thrombosis in PV patients during follow-up did not vary according to different platelet numbers.[314] Select patients with PV have, however, been afforded prompt resolution of vascular complications such as erythromelalgia or transient ischemic attacks following institution of platelet antiaggregating agents or cytoreduction.[259,260,262] It is important to emphasize that erythromelalgia does not resolve in PV patients with phlebotomy alone or with anticoagu-

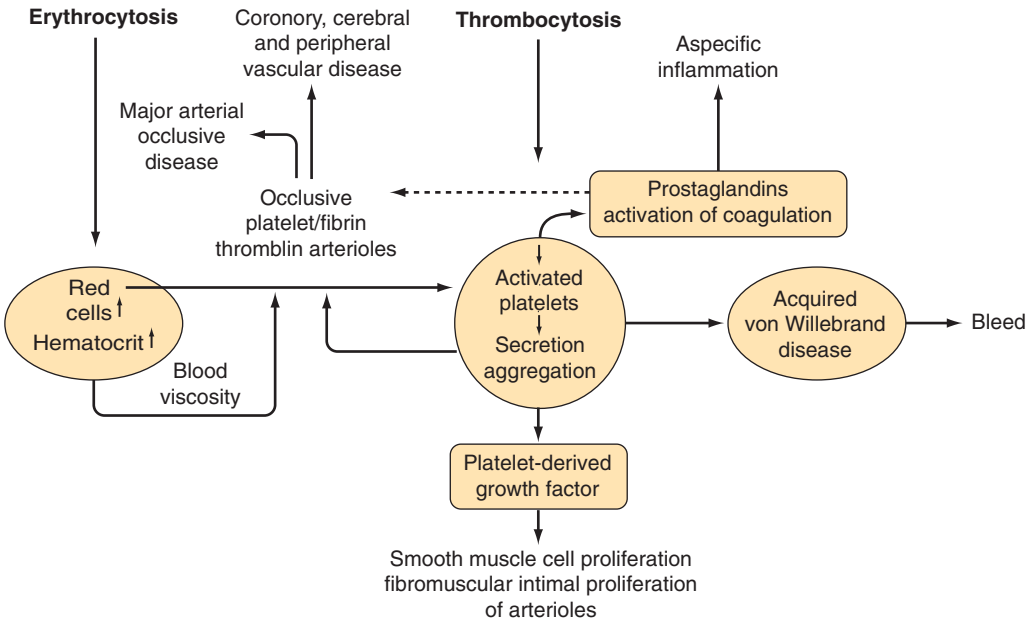

Figure 68–10. Pathophysiology of arteriolar and arterial thrombosis and inflammation, as well as hemorrhage, as a multicellular process in polycythemia vera. (Modified from Michiels JJ, Leenknegt H, Michiels JJ, Budde U: Acquired von Willebrand disease in myeloproliferative disorders. Leuk Lymph 22(Suppl 1):79, 1996.)

lation but requires the use of platelet antiaggregating agents or reduction of platelet numbers.[328] What distinguishes the clinical courses of these patients from those of others is unknown. These reports coupled with the knowledge of abnormal thromboxane metabolism of platelets in PV provide substance to the belief that platelets contribute to the generation of the thrombotic and hemorrhagic tendencies observed in PV (Fig. 68–10).[323–328] Although a number of clinical assessments of platelet function have been used to identify patients who are potentially at a high risk of developing a life-threatening hemorrhagic or thrombotic event, the results of these studies to date have been very disappointing.[323–328] It appears that the etiology of thrombosis and hemorrhage in PV is multifactorial and that the available tools are inadequate to identify those patients at highest risk.[303]

An elevation of white cell number occurs in 50% to 60% of PV patients that may also have a detrimental effect on the rheology of the microcirculation in PV.[299,300,334] A recent analysis of the ECLAP database showed that baseline white blood cell count above 15,000 $\times$ 106 L^{-1} was associated with the development of major arterial events, mainly myocardial infarction.[334] Similar results were shown also in two additional studies in patients with ET.[335,336] Activated leukocytes may release proteases and oxygen radicals that alter endothelial cells and platelets so as to favor the development of a prothrombotic state.[299,300] Falanga and coworkers have shown that a series of markers of leukocyte activation, including expression of membrane CD11b and leukocyte alkaline phosphatase antigen, cellular elastase content, plasma elastase levels, and myeloperoxidase levels are elevated in patients with PV.[300] Limited and conflicting data are available as to whether or not there is a correlation between the presence of platelet-leukocyte interactions and thrombotic events. Moreover, the association between these functional abnormalities and the presence of JAK2V617F is unclear.[337] Overall these results would indicate that an increased release of neutrophil proteases may provide a mechanism by which the hemostatic pathway is activated in PV, which ultimately would contribute to the establishment of a prethrombotic state.[300]

PV patients are also at an increased risk of developing life-threatening hemorrhagic complications.[305,329–332] Abnormalities in platelet function and number have been implicated as the cause of this hemorrhagic tendency.[305,306,322–332] Qualitative platelet abnormalities frequently found in these patients include platelet hypofunction as demonstrated by defective in vitro platelet aggregation, acquired storage pool disease, platelet membrane defects, increased platelet reactivity as demonstrated by enhanced platelet aggregation, increased plasma β-thromboglobulin levels, and shortened platelet survival.[323–325,330] With platelet counts greater than 1000 $\times$ 10^9 L^{-1}, the development of acquired von Willebrand syndrome has been reported and is associated with life-threatening hemorrhagic episodes.[329,330]

A major cause of morbidity and mortality in PV results from the transition from the polycythemic phase of the disease to PV related MF and to acute leukemia. PPMM is characterized by cytopenias, myelofibrosis, and extramedullary hematopoiesis.[338–340] In a variety of MPDs, the fibroblastic component of the bone marrow has been shown not to be directly involved in the malignant process but to be a reactive event to the neoplastic clone.[341,342] Several investigators have suggested that the release of growth factors, particularly platelet-derived growth factor (PDGF), fibroblast growth factor, and transforming growth factor-β from megakaryocytes or platelets, which are present in abundance in patients with MPDs, might be responsible for this fibroblastic proliferation.[341] Whether the use of any particular therapeutic agents for treatment of PV accelerates the development of PV related MF remains hotly debated. Some have suggested that the use of radioactive phosphorus (^{32}P) favors such a transition, although others have not noted any relation between the treatment modality used and more rapid progression to PV related MF.[271–275] Najean and associates have reported a long-term follow-up of PV patients and noted a high incidence of myelofibrosis in patients treated by phlebotomy alone.[276] In this study, myelofibrosis was rarely observed before the 10th year of follow-up, but occurred in 20% of patients surviving after 15 years and 50% surviving after 20 years.[276] Messinezy and Pearson have reported that of 20 patients known to have survived 15 years with PV, 25% developed myelofibrosis.[277] Surprisingly, in the Italian Natural History Study with a follow-up of 20 years, myelofibrosis was a rare cause of death.[235] After treatment with alkylating agents or irradiation during the proliferative phase, patients with PV related MF have been reported to be more likely to transform to acute leukemia.[166] No randomized studies have been powered to assess the relative risk of malignant transformation in patients given HU. The bulk of evidence does not support a clear leukemogenic role for this drug that is currently considered the standard therapy in high-risk PV patients. Nevertheless, as a cautionary principle, it is wise to consider carefully the use of this agent in very young subjects and in those carrying cytogenetic abnormalities, and to avoid it in pregnant women and in patients previously exposed to radiophosphorus or alkylating agents.[348]

CLINICAL MANIFESTATIONS

The principal clinical manifestations of PV are direct consequences of the excessive proliferation of cellular elements of the various hematopoietic cellular lineages involved in the neoplastic process. With the current widespread use of laboratory screening tests during routine patient examination, increasing numbers of people are being diagnosed with PV before the development of symptoms related to this neoplastic process. Symptomatic patients with PV may present to a physician with a myriad of nonspecific complaints, including headaches, weakness, pruritus, dizziness, excessive sweating, visual disturbances, paresthesias, joint symptoms, epigastric distress, and weight loss.[196,206–208] Thrombosis is a frequent presenting event.[297] In one series, two-thirds of such thrombotic events occurred either at presentation or before diagnosis and the remainder during follow-up.[297] At diagnosis, one-third of patients have already lost 10% of their body weight, presumably secondary to the hypermetabolism associated with this disorder.[206] Arthropathies that are frequently observed in these patients are largely due to the clinical manifestations of gout. The hyperproliferative bone marrow state characteristic of PV and the increased nucleoprotein degradation are contributing factors in the development of hyperuricemia.

The principal findings on physical examination of a patient with PV include ruddy cyanosis, conjunctival plethora, hepatomegaly, splenomegaly, and hypertension.[196,206,208,297]

Untreated patients are at particularly high risk for thrombotic and hemorrhagic events.[285,307,331,332] In several large series of patients with PV, thrombosis was the cause of death in 30% to 40% of patients (Table 68–6).[206–208,285,329–333] Arterial thrombotic events account for two-thirds of such events, with venous thrombotic events representing the remainder. Ischemic stroke, myocardial infarction, and transient ischemic attacks are the most common arterial thrombotic events. Patients may also present with deep venous thrombosis in the lower extremities, pulmonary embolism, or peripheral vascular occlusions.[296–298] It is not unusual for patients with PV to develop thromboses at unusual anatomic sites; in particular, thromboses are relatively frequent in the splenic, hepatic, portal, and mesenteric vessels.[206–208,285,307] A meta-analysis on 120 patients from seven studies indicated that the estimated prevalence of an underlying MPD was 49% for patients with idiopathic hepatic vein thrombosis and 23% for patients with portal vein thrombosis.[350]

Table 68–6 Fatal and Nonfatal Thrombotic Events (n = 254) During Follow-Ups in 1213 Patients With Polycythemia Vera

	Type of Complication	
	Nonfatal Event n (%)	Fatal Event n (%)
Arterial thrombosis	101 (50.5)	44 (81.5)
Myocardial infarction	28 (14.0)	27 (50.0)
Ischemic stroke	19 (9.5)	17 (31.5)
Transient ischemic attack	39 (19.5)	—
Peripheral arterial thrombosis	15 (7.5)	—
Venous thrombosis or embolism	77 (38.5)	10 (18.5)
Deep venous thrombosis	35 (17.5)	—
Superficial thrombophlebitis	37 (18.5)	—
Unknown	5 (2.5)	—
Unknown	22 (11.0)	—
Total	200 (100)	54 (100)

Reisner and coworkers have demonstrated by echocardiography that cardiac valvular abnormalities are common in patients with myeloproliferative disorders.[351] In fact, aortic or mitral valve lesions were found in 77% of patients with PV. The most common echocardiography lesion was leaflet thickening, found in 40% of patients, and vegetation, which occurred in 16%. The presence of such lesions was closely associated with the occurrence of arterial or venous thrombosis or embolism. Such vascular abnormalities may account for a significant number of thrombotic events in this patient population.[351]

A particularly serious thrombotic event associated with PV is Budd–Chiari syndrome,[352–359] which results from hepatic venous or inferior vena caval thrombosis and obstruction. These events lead to hepatic venous outflow obstruction, increased hepatic sinusoidal pressure, and portal hypertension. Portal venous perfusion of the liver is frequently reduced, leading to portal venous thrombosis and hypoxic damage of liver parenchymal cells. This cascade of events results in centrilobular hepatic necrosis, centrilobular fibrosis, and nodular regenerative fibrosis, which culminates in the development of cirrhosis of the liver.[356] The cause of Budd–Chiari syndrome can be identified in 75% of cases, including hereditary and acquired prothrombotic disorders; trauma and infection PV account for 10% to 40% of all cases of Budd–Chiari syndrome.[352–359] Paroxysmal nocturnal hemoglobinuria is also a frequent cause of Budd–Chiari syndrome. Because marrow cells from 87% of patients with idiopathic Budd–Chiari syndrome form erythroid colonies in the absence of EPO, such patients are believed to be suffering from a forme fruste of an MPD.[356–358] The identification of these latent MPDs, without elevated blood counts, may be facilitated by screening for the JAK2 mutation. Primignani et al reported that JAK2V617F mutation occurred in 35% of 73 patients with extrahepatic portal vein thrombosis and in 40% of 20 patients with the Budd–Chiari syndrome while Patel and coworkers demonstrated that 58% of patients with idiopathic Budd–Chiari syndrome were JAK2V617F positive.[360] An MPD developed in over 90% of the JAK2V617F-positive patients after a median of 49 months from the diagnosis of Budd–Chiari syndrome.[361] Detection of the JAK2V617F mutation in 38% to 42.8% of patients with splanchnic vein thrombosis and normal/low blood cell counts has been reported.[362] Furthermore, JAK2V617F has been detected in 18% to 37% of patients with portal vein thrombosis.[363,364] The diagnostic value of low serum erythropoietin level in Budd–Chiari syndrome has been questioned since elevated levels have been attributed in JAK2V617F-positive patients to necrotic liver tissue.[365]

There are fulminant, acute, subacute, or chronic forms of Budd–Chiari syndrome.[356] These clinical manifestations are dependent on the extent and rapidity of hepatic vein occlusion and the development of venous collaterals to decompress the venous sinusoids. One should always consider a diagnosis of Budd–Chiari syndrome in any patient with an MPD with ascites, upper abdominal pain, and liver function abnormalities.[344–356] This syndrome is characterized by hepatosplenomegaly, ascites, edema of the peripheral extremities, and distention of superficial abdominal veins due to resultant portal hypertension.[356] Routine biochemical determinations of hepatocellular function and injury are frequently of little diagnostic value in patients with suspected Budd–Chiari syndrome.[356] Doppler ultrasonography is the best tool for screening patients for Budd–Chiari syndrome. This test has a sensitivity and specificity of 85%.[356,359] Characteristic findings include an absence of flow in the hepatic veins or nonvisualization of the hepatic vein. Contrast-enhanced computed tomographic scanning and magnetic resonance imaging are useful in better defining the hepatic venous anatomy.[356,359] Hepatic venous and inferior vena caval catheterization are key diagnostic procedures that indicate the sites of venous obstruction.[356–359] The diagnosis can be definitively made by a spider web pattern on hepatic venography. Transjugular liver biopsy specimens usually reveal intense congestion and cellular atrophy.[356,359]

It has been emphasized that patients with PV can present with portal or hepatic vein thrombosis with normal hemoglobin or hematocrit values. Such patients have leukocytosis, thrombocytosis, or splenomegaly.[355,359] The diagnosis of "inapparent PV" in this patient population can only be made after red cell volume measurements are performed.[355] Screening for the JAK2 mutation should be systematically carried out in such situations, and may substitute for red cell volume measurements.[362] Gastrointestinal bleeding or an increase in plasma volume that is a consequence of splenomegaly often accounts for the normal blood counts in such patients with Budd–Chiari syndrome. The factors operational in the PV patient that lead to the development of hepatic vein thrombosis are believed to be multiple. Splenomegaly causes increased portal blood flow whereas extramedullary hematopoiesis within the hepatic sinusoids frequently obstructs hepatic blood flow.[355] These processes are surely important contributory factors, in addition to the other previously discussed risk factors that lead to the development of thrombosis in this patient population.[355–359]

Neurologic abnormalities occur in almost 60% to 80% of untreated or poorly controlled PV patients and include transient ischemic attacks, cerebral infarction, cerebral hemorrhage, fluctuating dementia, confusional states, and choreic syndromes.[296,298,351,366–372] In addition, complaints of dizziness, paresthesias, visual disturbances, tinnitus, and headaches have been attributed to the increased blood viscosity[296,298,351,366–372] and reduced cerebral blood flow caused by erythrocytosis. The transient neurologic symptoms can also be the consequence of small infarcts in the region of the basal ganglia, which can be detected by computed tomography.[367] These small infarcts are known as lacunae and result from the occlusion of small penetrating arteries, which are particularly susceptible to thrombosis.[367] Cerebrovascular thrombosis occurs more often in PV patients than in the general population.[331,370,366–369] Symptoms due to intermittent carotid or vertebral basilar artery insufficiency (or both) occur so frequently in PV that Millikan and colleagues[369] suggest that every patient with focal cerebrovascular insufficiency should at least have a complete blood count test to rule out an underlying MPD.

Cavernous sinus thrombosis is usually associated with a primary infectious etiology involving a focus in the face, throat, mouth, ear, or sinuses.[371–374] Aseptic cavernous sinus thrombosis is an extremely rare phenomenon that has been reported in patients with PV.[371–379] These patients present with monocular blindness and the characteristic features of ipsilateral cavernous sinus thrombosis, and only retrospectively is the diagnosis of PV made.[374] Therefore, patients found to have this symptom complex who have no known infectious predisposing causes should be carefully evaluated to rule out this diagnosis. The most sensitive diagnostic technique is MRI in combination with magnetic resonance venography. If MRI is not readily available, CT scanning is useful as the initial examination to rule out other acute neurological disorders. In some cases cerebral angiography may be indicated.[375]

Thrombosis of large-caliber arteries is a relatively rare event in PV patients, but there have been case reports of thromboses within the chambers of the heart, leading to refractory congestive heart failure and acute aortic occlusion.[295,296] Such catastrophic thrombotic events in the heart or large vessels would suggest that cardiac catheterization be performed with some caution.[296]

PV frequently manifests with symptoms due to peripheral vascular disease.[254,255,297–299] In these cases, patients may first be seen by surgeons or dermatologists.[298] Intense redness or cyanosis of the digits with or without burning, classic erythromelalgia, digital ischemia with palpable pulses, or thrombophlebitis without other known cause may be the presenting symptoms.[327,380–384]

Erythromelalgia is characterized by burning pain in the digits, an objective sensation of increased temperature, and relief by cooling.[328,380–384] PV is the most common cause of erythromelalgia and is one of the few disorders in which digital ischemia with or without ulceration may exist in the presence of palpable pulses.[384] Other disorders that can lead to this abnormality include embolism, trauma, cutaneous infarction, neuritis, infection, and various types of arteritis.[384] Painful and ulcerating toes and fingers have frequently been observed to be presenting symptoms in patients with PV.[380–384] The likelihood that arterial insufficiency is the cause of such ulceration is quite small in patients who have a palpable dorsalis pedis and posterior tibialis pulses; in this situation, the possibility of an underlying hematologic disorder such as PV should be entertained. Foot pain at rest is a distressing but not widely recognized symptom of PV. In patients with this complaint, peripheral pulses are of normal character and cutaneous circulation appears to be adequate.[328,380–384] The pain is most severe at night, is dull in nature, and occurs primarily in the feet or legs. These symptoms have been shown to be the results of platelet activation and aggregation in vivo, which preferentially occur in arterioles.[261] If untreated, erythromelalgia can progress to ischemic acrocyanosis or gangrene. Phlebotomy alone in PV does not improve erythromelalgia.[328,380–384] These symptoms can be abolished by reducing the platelet counts to normal levels and can be rapidly reversed after the institution of antiplatelet aggregation therapy. Therefore, the cause of erythromelalgia appears to be closely linked to abnormal arachidonic acid metabolism that occurs within platelets in this disorder.[328]

Retrospective reviews have revealed a higher than expected number of patients with PV and pulmonary hypertension.[385–387] Proposed etiologies include direct obstruction of pulmonary arteries by circulating megakaryocytes, extramedullary hematopoiesis in the pulmonary parenchyma, smooth muscle hyperplasia induced by release of platelet-derived growth factor from activated platelets, chronic disseminated intravascular coagulation, and unrecognized recurrent thrombotic events.[387] Endothelin-1 has been associated with development of hypoxia-related pulmonary hypertension and VEGF with protection from this complication. The diagnosis of pulmonary hypertension is made, on average, 9.5 years after the diagnosis of the underlying MPD disorder and is associated with a poor prognosis, with death usually occurring as a result of congestive heart failure or pneumonia.[380] Although anecdotal reports have claimed improvements in patients' pulmonary artery pressure with control of the underlying disease,[386,387] Dingli and coworkers at the Mayo Clinic did not find any change in serial measurements of 11 patients' pulmonary arterial pressures despite good disease control.[386]

As many as 30% to 40% of patients with PV experience some sort of hemorrhagic event,* which can be relatively trivial, such as epistaxis or gingival hemorrhage, or can be life-threatening, such as gastrointestinal hemorrhage or hematomas involving vital organs.[329–331,388] The gastrointestinal tract is a frequent site of hemorrhagic complications, as patients with PV are predisposed to portal vein thrombosis and resultant variceal bleeding and pepticular disease. Gastroduodenal erosions and ulcers and *Helicobacter pylori* infection are all significantly more common in PV patients than in control patients with dyspepsia.[391] This may be due in part to altered mucosal blood flow as a result of increased plasma viscosity or increased histamine release due to peripheral blood basophilia.[391] Cerebral hemorrhage is a common cause of morbidity and mortality.[367] Bleeding events frequently occur with the use of antiinflammatory agents[332]; an association between the hemorrhage and the use of high doses of these platelet-paralyzing drugs has been made in almost one-third of such instances.[389,390] Low-dose aspirin therapy has, however, been recently shown not to lead to an increased incidence of life-threatening hemorrhagic events.[302,303] Spontaneous bleeding in patients with PV is relatively rare,[304,308] although spontaneous retropharyngeal hematomas leading to acute upper-airway obstruction or hematomas in the groin have been reported.[392]

The PV patient who undergoes a surgical procedure is at a very high risk of developing postoperative complications.[393–395] In one series of 62 major operations on 54 patients with PV, postoperative complications occurred in 47% of patients[393]; 52% of complications were due to hemorrhage, 18% to thrombosis, and 14% to hemorrhage and thrombosis.[315] The postoperative mortality rate in this patient population was 18%.[393] In another series of 15 patients, 5

*References 12, 331, 332, 336, and 388–390.

suffered serious complications secondary to thrombosis and hemorrhage.[394,395] A recent study by an Italian group evaluated retrospectively 311 surgical interventions in 105 patients with PV and 150 with ET[394]: 24 arterial or venous thrombosis (7.7%), 23 major hemorrhages (7.3%), and 5 surgery-related deaths (1.6%) were observed within 3 months of the procedure. PV patients with uncontrolled erythrocytosis prior to surgery have been shown to have the highest complication rate. Patients with inadequately controlled disease had a 79% incidence of complications, whereas in those who enjoyed adequate hematologic control before surgery the rate of perioperative and postoperative complications was reduced to 28%.[396] In addition, duration of disease control was an important factor in decreasing surgical risk[393–396]; a prolonged period of effective disease control before surgery reduced the complication rate to 5%.[396] Complication rates following surgery can therefore be dramatically reduced by appropriate therapeutic interventions with normalization of blood counts. The chief deterrent to such an approach has been the failure by physicians to recognize the risk associated with PV in the surgical setting.

Generalized pruritus occurs in approximately 50% of cases of PV.[196,397–400] Water contact, such as during showers or bathing, induces attacks of intolerable pruritus.[398] There appears to be no clear relation between the degree of the pruritus and severity of the disease,[400] and 20% of patients continue to experience itching despite reduction of their red blood cell masses to the normal range.[397–400] Aquagenic pruritus is significantly more common among JAK2V617F homozygous patients than heterozygotes or WT patients.[401,402] The degree of pruritus is so severe in some patients that they are unable to tolerate bathing at all and find it necessary to substitute gentle skin swabbing or to simply not bathe. The etiology of the pruritus in PV remains uncertain. Several groups have attempted to implicate elevated blood and urine histamine levels in its pathobiology.[397,400] Steinman and colleagues[398] have presented data suggesting that water exposure in patients with PV actually leads to elevated histamine levels, which would provide an explanation for the exacerbation of the pruritus frequently observed with water contact. Jackson and associates[399] have been able to establish a strong correlation between skin mast cell numbers and the severity of itching. However, the failure of the pruritus to respond to antihistamine therapy in many patients suggests that abnormally high histamine levels probably do not constitute the sole factor in its development.

Iron deficiency has also been implicated as a factor contributing to pruritus in PV patients who are almost invariably iron deficient.[403] Iron substitution therapy has resulted in symptomatic improvement,[403] but this approach is less than optimal because it frequently results in uncontrollable erythrocytosis.

Several investigators have suggested that patients suffer from serious nonhematologic symptoms secondary to iron deficiency.[404–406] Rector and colleagues[406] evaluated these sequelae in patients with PV who were uniformly iron deficient and followed these patients for more than 25 years. Their data are unique in that they indicate that the quantitative evaluation of symptoms fails to provide convincing evidence that undue fatigue occurs as a result of iron deficiency.[406] In fact, treadmill performances by six patients were equivalent to those observed among normal subjects.[323] None of the patients experienced dysphagia or the esophageal changes associated with chronic iron deficiency.[323] The one symptom that was observed to occur regularly, particularly in women, was picophagia, a pica consisting of compulsive ice eating.[323] This symptom can be resolved with ingestion of extremely small amounts of oral iron.

PV related MF occurs in 5% to 50% of patients with PV.[†] The transition to this stage of the disease occurs, on average, 10 years after the initial diagnosis, but in individual cases it can occur after either shorter or longer intervals. Two extremes of opinion exist on the frequency of this complication. Najean and coworkers have reported that 15 years or more after the initial diagnosis, this complication is a major clinical problem affecting almost 50% of patients.[338] Spivak has, however, questioned the true frequencies of anemia, myelofibrosis, and extramedullary hematopoiesis in the absence of cytotoxic therapy for PV patients.[12] He has suggested that in individuals treated only with phlebotomy PV related MF is a rare event. In the ECLAP study, the development of PV related MF was associated with long duration of disease and was not influenced by patient age or the use of cytoreductive drugs. For patients with disease duration greater than 10 years, hazard ratio was 15.24 (95% CI 4.22–55.06, $P < 0.0001$).[307] PV related MF is characterized by (a) increasing splenomegaly, (b) teardrop red blood cell morphology, (c) extensive bone marrow fibrosis, (d) a leukoerythroblastic blood picture, and (e) a normal or decreasing red blood cell mass. The patients may be entirely asymptomatic but often complain of fatigue, dizziness, weight loss, and anorexia.[338–390] Splenomegaly can lead to abdominal pain due to repeated splenic infarcts and to early satiety due to mechanical obstruction of the upper gastrointestinal tract.

The anemia that characterizes the spent phase is primarily a result of splenic pooling, ineffective erythropoiesis, and extramedullary production of red blood cells with a shortened red cell survival. Patients positive for JAK2V617F are less likely to require blood transfusion but have a poorer survival.[408] Occasionally, the anemia is exacerbated by a folate or iron deficiency.[309] Before assuming that a patient has entered the spent phase, it is prudent to assess bone marrow iron stores. Replacement therapy with iron may lead to the resurgence of erythropoiesis and prevent the faulty categorization of disease progression.

Bleeding abnormalities due to thrombocytopenia or qualitative platelet abnormalities are especially common during this phase of the disease. Frequent instances of epistaxis or ecchymoses occur,[338–340] and gastrointestinal hemorrhage due to esophageal varices arising from portal hypertension is a recurrent problem.[338–340] The majority of hemorrhagic events are minor in nature. Frequently, patients suffer from generalized wasting characterized by progressive asthenia and weight loss. Severe hyperuricemia, leading to secondary gout or uric acid nephropathy, may also complicate the clinical course.

Patients with PV related MF are at a high risk for the development of acute leukemia.[12,233,340–348,410–422] Of those patients who enter the spent phase of PV, 20% to 50% will eventually undergo leukemic transformation.[339,340] Approximately 70% of patients who enter the spent phase will be dead 3 years after this transition; however, the other 30% of these patients will have much longer survival times averaging 6.5 years.[338–340]

The leukemic transformation of PV has been extensively described.[315,410–424] The possibility that a relation exists between the therapeutic modality used during the erythrocytotic phase and the frequency of development of acute leukemia has been a point of heated discussion.[12,410,411] Some of the controversy surrounding this question was formerly due to a lack of understanding of the basic origins of PV.[12] Clinical hematologists in the 1950s and 1960s frequently thought of PV as a benign hematologic abnormality and believed that therapeutic interventions either with alkylating agents or radiotherapy were solely responsible for the development of acute leukemia. That concept has proved erroneous, and PV, like the other MPDs, has been shown to be a clonal malignant hematologic disorder.[78,336,337] The evolution to acute leukemia can therefore be thought of as a natural consequence of this malignant disorder, which can be accentuated by the therapeutic interventions discussed above.

Further insight into the relation between acute leukemia and PV has been best provided by the results of the PV Study Group (PVSG), which described a randomized trial comparing the use of phlebotomy, chlorambucil, and ^{32}P for the treatment of this disorder.[333] The incidence of acute leukemia was approximately 1.5% in patients treated with phlebotomy alone, 17.5% in patients treated with chlorambucil, and 10.9% in patients treated with ^{32}P after over 15 years of follow-up.[418–421] The incidence of acute leukemia in the patients treated with phlebotomy alone is therefore much higher than that expected in a normal age-matched control group, again indicating that leukemia is a natural evolutionary event in the clinical course of an individual with PV. The incidence of acute leukemia can be

[†]References 206–208, 307, 338–340, 349, 407, and 408.

increased, however, by institution of therapy with either alkylating agents or ^{32}P.[418–421] The time course for the development of acute leukemia appears to be dependent on the treatment used to control the polycythemia. The development of acute leukemia in patients treated with phlebotomy in the PVSG trial was limited to the first 5 years of treatment, suggesting that the development of acute leukemia is not due solely to the prolongation of survival. In contrast, analysis of the hazard function was virtually flat for patients treated with chlorambucil from years 2 to 7 after randomization; however, the risk for acute leukemia became alarmingly high after 10 years of study, suggesting that the risk of acute leukemia increases with time, even after the drug has been stopped.[412–421] One half of the cases of acute leukemia in the chlorambucil arm occurred in the first 5 years, with the remainder equally split between the second and third 5-year periods. In contrast, 60% of the cases of acute leukemia in the group treated with radioactive phosphorus occurred 6 to 10 years after randomization. Of particular concern is the high incidence of leukemia recently reported in patients who were initially treated with radioactive phosphorous or busulphan and then switched to maintenance therapy with hydroxyurea, previously believed to be a nonleukemogenic agent.[418,419] These findings suggest that a combination of radiotherapy (^{32}P) or an alkylating agent, busulphan, and another chemotherapeutic agent (hydroxyurea) may particularly increase the risk of leukemia.[418,419] In the ECLAP study, independent variables associated with increased risk to transform to AML/MDS were older age, exposure to ^{32}P, busulphan and pipobroman but not hydroxyurea when used alone. The effects of overall disease duration on the development of AML failed to reach statistical significance.[425] Approximately 30% to 50% of patients with PV who develop acute leukemia have previously entered the spent phase.[410–420] In contrast, approximately 50% of patients progress directly from the erythrocytotic phase to acute leukemia.[12] The phenotype of the leukemia cells that characterize the leukemic phase is overwhelmingly myeloid.[419,424] Unusual cases of lymphoblastic transformation of PV have, however, been reported, as have rare cases of biphenotypic leukemias.[423,424] Another adverse effect solely associated with the use of chlorambucil has been the development of large-cell lymphoma in 3.5% of patients.[418–421]

The development of leukemia sometimes can be abrupt, however. In some instances, a preleukemic phase characterized by refractory anemia with excess blasts has been described.[12,421] In fact, one half of such cases of acute leukemia in one series were preceded by a myelodysplastic disorder.[421]

In addition, the incidence of nonhematologic malignancies has been shown to be increased in patients treated with either chlorambucil or radioactive phosphorous but not with phlebotomy therapy.[418–420] The rates of nonhematologic cancers were highest in sites in the skin and gastrointestinal tract. These malignancies are presumed to be treatment related.

A surprising finding that provides some insight into the origins of acute leukemia occurring in PV patients has been provided from studies of the JAk2V617F status of the leukemia blast cells of such patients.[266,426–428] Surprisingly, in only about 50% of these patients, the leukemic cells were JAK2V617F negative even though in excess of 90% of the PV patients and JAK2V617F positive.[428] Furthermore, Theocharides and coworkers showed that 53% of patients with JAK2V617F-positive MPD had JAK2V617F-negative blasts at the time they developed AML. Patients with JAK2V617F-positive MPD who developed JAK2V617F-negative leukemias had a shorter time between the diagnosis of the original MPD and the leukemic transformation (3 + 2 vs 10 + 7 years) than patients with JAK2V617F-positive leukemias.[428] The possible origins of JAK2V617F-negative leukemias from JAK2V617F-positive MPDs are diagrammatically presented in Fig. 68–11.[68] The AML could potentially originate in the normal stem cell pool that persists in MPD patients or it could originate in a malignant clone that has not acquired the JAK2V617F mutation. The other possibility remains that the chronic MPD and the AML represent two subclones originating from a common ancestor, and that the leukemic transformation results in loss of JAK2V617F.

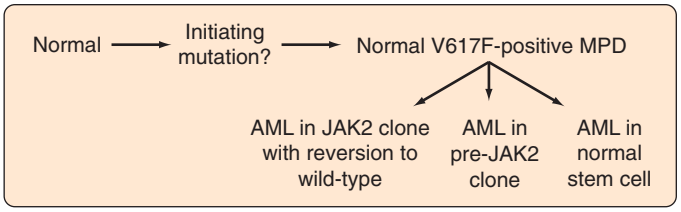

Figure 68–11. Models for the development of JAK2V617F-negative acute myeloid leukemia from JAK2V617F-positive myeloproliferative disorder. Three possible models are shown, in which $V617F^-$ acute myeloid leukemia could develop from (1) a $V617F^+$ cell that subsequently reverts to $V617F^-$; (2) a cell that had some other initiating mutation prior to *JAK2*; or (3) a normal stem cell. (From Campbell PJ, Baxter EJ, Beer PA, et al: Mutation of JAK2 in the myeloproliferative disorders: Timing, clonality studies, cytogenetic associations, and role in leukemic transformation. Blood 108(10):3548, 2006.)

LABORATORY EVALUATION

Laboratory evaluation of the patient with erythrocytosis involves the careful use of a broad range of diagnostic studies. These studies must be employed in a rational manner, or the evaluation can become extremely costly. Because PV is a panmyelosis, the overwhelming number of patients has elevated hematocrits, white blood cell counts, and platelet counts.[196] The diagnosis of PV has been greatly simplified by the discovery of the JAK2V617F mutation, which is present in over 90% of PV patients. Hematocrit values greater than 52% in males and greater than 48% in females are abnormal and require further evaluation.[5] To document the absolute increase in red cell mass, the performance of a blood volume study with direct quantitation of the red cell mass and plasma volume is frequently necessary.[12,429–432] A hematocrit value greater than 60% in men or greater than 55% in women is almost always associated with an absolute erythrocytosis.[12,429–432] In such cases, it is frequently unnecessary to order blood volume studies. In men suspected of polycythemia with a hematocrit level below 60% and women with a hematocrit level below 55%, blood volume measurement if available is suggested to be required for determining whether the elevated hematocrit level is actually due to an expanded red cell mass.[12,429–432] Occasionally, an elevated red cell mass can actually be present in the face of a normal hematocrit. In cases of splenomegaly due to portal hypertension, an expanded plasma volume may mask an elevated red cell mass.[355] In addition, iron deficiency can also lead to a fall in hematocrit in PV, making the diagnosis difficult.[12] PV is associated with a 20% to 30% frequency of gastric ulcers and gastritis, which can be associated with blood loss.[311] In this situation, thrombocytosis may be exacerbated as a consequence of the iron deficiency. Iron supplementation and correction of the bleeding lesion may permit the diagnosis to be established. Administration of iron to such patients must be performed carefully to avoid a rapid increase in red cell mass, which can be associated with a high risk of thrombosis. Lamy and associates have recommended that increased hematocrit and hemoglobin levels do not constitute the only criteria for proceeding with a red cell mass determination to make a diagnosis of PV.[355] They suggest that red cell mass determinations be performed in patients with normal hemoglobin and hematocrit values with portal or hepatic vein thrombosis, splenomegaly, leukocytosis, or thrombocytosis. Performance of JAK2V617F mutational analysis may represent a more direct means of identifying an underlying MPD.[360–365] In such patients, the use of red cell measurements in these settings is intended to aid in the diagnosis of so-called inapparent PV.[12,282,429–432] Indirect calculations of the red cell mass from plasma volume measurements assume a normal body venous hematocrit ratio. Unfortunately, this ratio may be abnormal in patients with spurious PV, and calculations derived from venous-packed red cell volumes may overestimate the red cell mass.[429–432] It is regrettable that red cell mass determinations are no longer available at many institutions.[432] To be assured of the presence

of an absolute erythrocytosis in appropriate patients, clinicians should refer individuals to institutions where these analyses are performed. In a world where it is easier to obtain an analysis for a JAK2V617F mutation than a red cell mass, the reality is that the molecular analysis is and will become the more widely used diagnostic tool.

The criteria for establishing a red cell mass has previously been based on values expressed as mL/kg of total body weight. Because adipose tissue is considerably less vascular than lean tissue, it may not contribute equally to the red cell mass.[429–431] Red cell mass measurements, therefore, based solely on body weight can be misleading. Red cell mass measurements more closely correlate with lean body mass than total body weight. Measured red cell mass values in obese subjects are regularly lower when expressed as mL/kg of total body weight than those observed in lean individuals.[429–431] To overcome this difficulty, the International Council for Standardization in Haematology has presented formulas to calculate normal red cell mass values, based on lean body mass, surface area, height, and weight.[429] Implementation of this approach is suggested due to the high incidence of obesity in our society.[429] Modification of the PVSG's criteria for definition of elevation of the red cell mass has been suggested. An elevated red cell mass is now defined as being 25% greater than the mean predicted value of a red cell mass for that individual rather than basing evaluations on the volume per kg of total body weight.[431]

Leukocytosis is present in approximately two-thirds of cases and seems to be proportional to the burden of JAK2V617F.[433] Thrombocytosis is observed in 50% of cases.[196] Abnormalities of red blood cell, white blood cell, and platelet morphology are frequently observed. The morphologic red blood cell changes observed during the erythrocytotic phases are characteristic of iron deficiency and include microcytosis, hypochromia, and frequently polychromatophilia.[12,315] Some anisocytosis and poikilocytosis can be seen as well. Fetal hemoglobin levels and the number of red cells containing fetal hemoglobin, known as F cells, may be increased.[434] The white blood cells are characterized by normal morphology, although the numbers of basophils, eosinophils, and immature myeloid forms can be increased.[196] Platelet morphology is also quite striking in PV. Frequently, megathrombocytes (platelets the sizes of red blood cells) are seen on the peripheral blood smear. Patients frequently have platelet counts of less than 1×10^6 mm^{-3}, but it is not unusual to observe a patient with a platelet count higher than this value. PV related myelofibrosis is characterized by a leukoerythroblastic blood picture, with the appearance in the peripheral blood of dacryocytes or teardrop red blood cells, myelocytes, metamyelocytes, and, rarely, blasts and promyelocytes in addition to nucleated red blood cells in the peripheral blood.[338–340]

Platelet aggregation studies and bleeding times are frequently abnormal in patients with PV, but do not correlate frequently with the risk of bleeding episodes. The most common abnormalities are decreased primary and secondary aggregation to either or both epinephrine and ADP and decreased response to collagen with generally a normal response to arachidonic acid. Abnormal platelet storage pool disease is a characteristic feature and due to abnormal platelet activation.[305,330–332] Prothrombin times (PT) and partial thromboplastin times (aPTT), as well as fibrinogen levels, are usually normal.[435,436] Profound abnormalities of the PT and aPTT are, however, frequently reported. This is largely a laboratory artifact caused by the extreme erythrocytosis, which results in a relatively smaller volume of plasma being present in the whole blood sample. Coagulation assays are performed on blood anticoagulated with sodium citrate, and the citrate concentration in the anticoagulant is calibrated to chelate the plasma calcium and inhibit coagulation reactions. All coagulation assays include the addition of calcium chloride to neutralize the excess citrate and provide free calcium to mediate coagulation reactions. In patients with extreme erythrocytosis, the ratio of citrate in the collection tube to the volume of plasma is too high; therefore, excess citrate is present, and the standard amount of calcium chloride added during the performance of the PT and aPTT is insufficient to neutralize the excessive citrate and the coagulation assays are frequently and factually prolonged. To avoid this problem, the clinician should calculate the relative amount of plasma compared with the normal amount and remove the corresponding volume of sodium citrate from the blood collection tube. Normal values can then be confidently anticipated in patients with erythrocytosis. Tytgat and colleagues[435] have detected a shortened fibrinogen half-life in some PV patients and a significantly increased fractional catabolic rate of the plasma fibrinogen pool per day. Boughton and Dallinger[436] have confirmed these findings. In addition, elevated platelet β-thromboglobulin and plasma β-thromboglobulin levels are observed. The constellation of findings is indicative of increased platelet turnover rates. Furthermore, Falanga and colleagues have shown that prothrombin fragments F1 and 2, thrombin–antithrombin complex, and D dimer levels were elevated in PV patients.[300] These are enzyme–inhibitor complexes or by-products of active thrombosis that serve as a biochemical signature of the hypercoagulable state that characterizes PV.[300]

An acquired von Willebrand syndrome occurs frequently in patients with PV and ET who have extreme elevations of platelet numbers.[329,437,438] This syndrome is characterized by a normal or prolonged bleeding time, a normal factor VIII level and normal von Willebrand factor (vWF) antigen level but abnormal vWF ristocetin cofactor actively associated with a decrease or absence of large vWF multimers.[329,437,438] This acquired defect resembles type II vWF disease. Because the molecular size of vWF is a major determinant of its adhesive function and the larger multimers are most active in achieving hemostasis, the deficiency of large vWF multimers is associated with a bleeding tendency. The decrease in the frequency of large vWF multimers occurs in patients with platelet counts over 1000×10^9 L^{-1}.[329,437,438] This abnormality has been reported not only with patients with severe thrombocytosis due to myeloproliferative disorders but also in patients with reactive thrombocytosis.[329,437,438] An inverse correlation between the proportion of large vWF multimers and platelet numbers has been observed.[263,264,346,347] In addition, normalization of the platelet count is accompanied by restoration of a normal vWF multimer pattern.[329] These findings suggest that thrombocytosis of any etiology may favor the adsorption of larger forms of vWF multimers onto platelet membranes, resulting in their removal from the circulation and subsequent degradation by platelet-associated proteases.[329] Although patients with MPD frequently have bleeding tendencies, this is not the case in secondary thrombocytosis, possibly because of the limited periods of extreme thrombocytosis observed in such patients.[329] Patients with PV with clinical courses punctuated by hemorrhagic events, extreme thrombocytosis, and acquired von Willebrand syndrome should not receive aspirin therapy if they are suffering from a thrombotic episode, but should be phlebotomized and platelet reduction therapy should be initiated.[329] Patients with PV and acquired von Willebrand syndrome suffer from recurrent bleeding from mucous membranes and the digestive tract and easy bruisability. These symptoms frequently resolve with normalization of the platelet count.

Deficiencies of one or more natural anticoagulants as well as the antiphospholid antibody syndrome have been observed in patients with PV and thrombosis.[439–441] These studies indicate that either familial or acquired antithrombin III deficiency, protein C or S deficiency, the factor V Leiden mutation, or the prothrombin G gene mutation may contribute to the hypercoagulable state observed in PV.[439–441] Of note, although hyperhomocyteinemia due to deficiency of cobolamin or folate can be found in 32% to 56% of PV patients, there is no agreement as to its role in the genesis of thrombotic episodes.[442,443] Such inherited disorders associated with the erythrocytosis of PV provide a scenario that frequently favors thrombosis in affected individuals. In attempting to determine if a patient with PV and an active thrombosis suffers from such an inherited predisposition, it is important to be aware that proteins C and S as well as antithrombin III levels can be low in patients with an ongoing acute thrombosis or liver cirrhosis. Normal prothrombin and factor VII levels in such a patient eliminate liver cirrhosis as a cause of the reduction of these circulating anticoagulants in patients with cirrhosis. Individuals with inherited prethrombotic conditions frequently have levels of specific proteins below 10% to 20% of normal during periods of active thrombosis.[439–441]

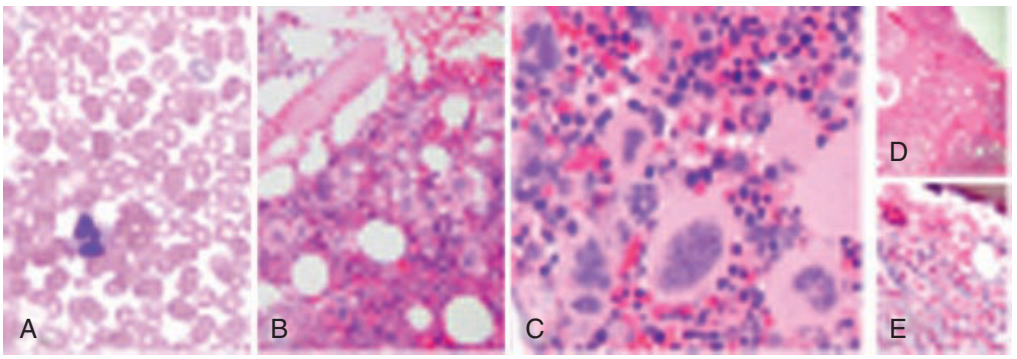

Figure 68–12. Photomicrograph of bone marrow biopsy obtained from a polycythemia vera patient in myelofibrotic phase demonstrating hypercellularity and increased number of megakaryocytes (×160).

The leukocyte alkaline phosphatase activity level is elevated in 70% of patients.[196] Moreover, recent data indicate an increase of neutrophil elastase levels in granulocytes and in plasma that correlates with JAK2 mutational status.[444] Serum B_{12} concentrations have been found to be elevated in 40% of patients, whereas serum B_{12}-binding proteins are elevated in 70% of cases.[196] Hyperuricemia occurs in an overwhelming number of patients, and elevated histamine levels are also frequently observed.[445] Bone marrow aspirates and biopsies obtained at the time of diagnosis of patients with PV are hypercellular and display characteristic erythroid, granulocytic, and megakaryocytic hyperplasia.[310,346,446,447] The cellular elements (Fig. 68–12) are frequently morphologically normal. Iron stores are almost uniformly absent in pretreatment biopsy specimens.[310,346,446,447] Significant increases in bone marrow reticulin may be present in biopsies obtained early in the course but also may develop during the erythrocytotic phase and may be present for long periods before the onset of the myelofibrotic phase.[12,243,275,354,355] It is important to emphasize that individuals may have considerable marrow fibrosis, which occurs as a consequence of the underlying MPD. The presence of such marrow fibrosis should not be considered a harbinger of the development of PV related myelofibrosis. In those patients who enter the spent phase of the disease, a moderate to marked increase in reticulin fiber is observed, either simultaneously with or within 1 year of this clinical transformation.[310,340,343,446,447]

Several investigators have attempted to use bone marrow biopsy morphology as a differential diagnostic tool to differentiate between PV and secondary forms of erythrocytosis. The marked hypercellularity and megakaryocytic hyperplasia that are the hallmarks of myeloproliferative disorders are useful parameters for identifying such individuals (see Fig. 68–12).[310,343,446,447] It is imperative to use the bone marrow biopsy rather than the aspirate specimens for this purpose.[310,343]

The pathologic appearance of the spleen in PV depends on the stage of the disease at which that organ is examined.[448] Spleens from patients in the erythrocytotic phase of the disease are characterized by striking congestion with mature erythrocytes.[448] Small numbers of hematopoietic precursor cells are frequently present. By contrast, spleens examined during the PV-related myelofibrosis phase are characterized by prominent numbers of foci of extramedullary hematopoiesis, with representation of all marrow precursor elements.[448]

The proliferative capacity of PV hematopoietic progenitor cells has been shown to be a useful laboratory adjunctive study.[77,78,449–451] Lemoine and coworkers[449] prospectively used the formation of endogenous erythroid colonies as a diagnostic tool to confirm the diagnosis of PV in the evaluation of a group of patients with isolated erythrocytosis (Table 68–7). In this study, the clinical courses of those patients with marrow cells that formed endogenous colonies were very similar to those of patients who met standard criteria for the diagnosis of PV.[449] Slightly greater than 70% of these patients developed difficulties that eventually required treatment. Conversely, those patients whose marrow cells did not form colonies in the absence of EPO enjoyed benign clinical courses not requiring therapeutic intervention. The usefulness of such assays has also been emphasized by Shih and Lee, who studied patients with idiopathic thrombocytosis who did not meet the diagnostic criteria for PV.[432] Shih and Lee reported that a high proportion of patients with normal or reduced hematocrit levels associated with marked isolated thrombocytosis ($>1 \times 10^6$ mm^{-3}) who had marrow cells that formed endogenous erythroid colonies eventually developed PV within a median period of 24 months.[452] These findings require confirmation because other laboratories have reported endogenous erythroid colonies in 50% of patients with ET.[451,453] It is important to emphasize that although the presence of endogenous colonies in the blood is indicative of PV, the inability to detect these colonies does not entirely eliminate the diagnosis.[12] Assays of bone marrow cells are indicated when endogenous colonies are not detectable in the peripheral blood.[12] Because of the lack of quality assurance in the performance of such clonal erythroid progenitor cell assays in some laboratories, some reservations concerning their widespread use as diagnostic tools have been expressed.[359] The formation of EEC by marrow mononuclear cells can be an important diagnostic tool in those rare patients who are JAK2V617F negative.

Allele-specific polymerase chain reaction methods can be used to detect the JAK2V617 mutation in approximately 95% of patients with polycythemia vera.[454,455] The very high frequency of JAK2V617F in PV has dramatically improved our ability to diagnose this disease.

Table 68–7 Study of Diagnostic Usefulness of Marrow Erythroid Progenitor Cell Cultures in Patients Suspected of Polycythemia Vera Based on Standard Clinical Criteria

Diagnosis	Standard Criteria*	Endogenous Erythroid Colonies†
Group A‡		
Polycythemia vera	46	43 (93%)
Secondary polycythemia	12	0
Unclassifiable polycythemia	29	18
Total	87	61 (70%)
Group B‡		
Secondary polycythemia	5	0
Unclassifiable polycythemia	16	4 (25%)
Total	21	4 (20%)

‡Group A is defined to include male patients having a red cell mass of >36 mL/kg and female patients with a red cell mass of >32 mL/kg. Group B is defined as male patients having a red cell mass of 30 to 36 mL/kg and female patients with a red cell mass of 25 to 32 mL/kg.

Data from Lemoine F, Najman A, Baillou C, et al: A prospective study of the value of bone marrow erythroid progenitor cultures in polycythemia. Blood 63:996, 1986.

Recently Scott et al have identified somatic gain of function mutations affecting JAK2 exon 12 in 10 JAK2V617F negative patients.[83] Each of these patients had isolated erythrocytosis associated with normal neutrophil and platelet counts but low serum EPO levels and the formation of erythroid colonies by peripheral blood mononuclear cells in the absence of EPO in vitro. Bone marrow biopsies from these patients were slightly hypercellular with isolated erythroid hyperplasia.[83] Megakaryocytes were morphologically normal and not clustered. The exon 12 mutations were frequently present at low levels in granulocyte DNA but were readily identifiable in endogenous erythroid colonies generated in vitro. Since granulocyte involvement with JAK2 exon 12 mutations is low, it is important to sequence DNA from bone marrow cells or from endogenous erythroid colonies generated in vitro in order to make this diagnosis.[83] At diagnosis, serum EPO levels in PV are either reduced or at the lower limits of normal. Even following normalization of the hematocrit, the serum EPO level in PV remains low in two thirds of patients.[8–12]

The occurrence of nonrandom cytogenetic abnormalities in PV is not unexpected, as this is a feature of most hematologic malignancies.[456–464] Such abnormalities have been observed, with no single characteristic chromosome abnormality defined; the most frequent abnormalities are the gain of chromosome 9/9p, deletion of chromosome 20q, trisomy 8, deletion of chromosome 13, and gain of the long arm of chromosome 1.[461,462] Interphase fluorescence in situ hybridization (I-FISH) has been used to detect cryptic chromosome 9 rearrangements. FISH uncovered chromosome 9 rearrangements in 53% of patients with abnormal FISH patterns indicating that gain of 9p is the most frequent genomic alteration PV.[370,371] Swolin and coworkers had previously reported that trisomy for 9p was the most frequent finding at initial cytogenetic examination of patients with PV.[456] The association between the trisomy of 9p and PV was one of the keys to the identification of the JAK2V617F mutation.[262] Kralovics and coworkers identified loss of heterozygosity by genomewide screening on the long arm of chromosome 9.[262] Cytogenetic studies of 9p loss of heterozygosity did not indicate any terminal losses or deletions along the entire short arm of chromosome 9, indicating that the loss of heterozygosity was due to mitotic recombination. According to the physical map of the short arm of chromosome 9, 85 genes were present in this arm, one of them being JAK2.[262] Subsequently, the JAK2V617F mutation was identified and homologous recombination was shown to be the event by which PV patients transitioned from being heterozygous to homozygous for JAK2V617F.

At diagnosis, approximately 25% of patients have a recurrent clonal chromosome marker whereas the remainder are cytogenetically normal, as categorized according to the phase of disease (onset, erythrocytotic, or spent phase).[443–464] Certain cytogenetic abnormalities are clearly a result of treatment-induced mutation, associated with the use of ^{32}P or alkylating agents.[461,462] The frequency of detection of cytogenetic abnormalities in PV is a cumulative function, with clonal cytogenetic abnormalities being observed in 8% to 25% at diagnosis, in 35% to 55% following a number of years of treatment, and in greater than 80% in those patients in whom acute leukemia eventually develops.[443–464] Therefore, clonal progression from a normal to abnormal karyotype, especially acquisition of abnormalities involving chromosomes 5 and 7, is an important adverse prognostic parameter.[443–464] It is important to emphasize, however, that patients with del(20q) have been observed without further karyotypic instability for over 10 years.[464] These abnormalities are not predictive of poor outcome unless other chromosome rearrangements or genetic alterations occur. Occasionally, patients lose their cytogenetic abnormality as a result of chemotherapy. This is a very rare event and of unknown clinical significance.[464]

$20q^-$ (q11) has been shown to be the second most common cytogenetic abnormality.[465–469] $20q^-$ is recognized as a genomic constitutive fragile site subject to mutagenic insult in vitro.[470] This cytogenetic defect is not diagnostic of PV. The $20q^-$ (q11) deletion is due to an interstitial deletion.[465–468] To date, an extensive search for a putative tumor suppressor gene at the site of the $20q^-$ deletion that might play a role in the biogenesis of PV has been unrewarding.[465–468]

Serial cytogenetic evaluation of previously karyotypically normal patients indicate that other abnormalities most often acquired with progression of the disease are $13q^-$, $12q^-$, and $1q^-$.[456–462] These particular abnormalities do not necessarily herald transition to acute leukemia, but leukemia or myelofibrosis was observed in 8 of 12 patients with the $1q^-$ abnormality in one study.[461] Deletion of the long arm of chromosome 13 has been observed during the myelofibrotic phase of PV, but this abnormality has been detected also during the erythrocytotic phase. It does not appear, therefore, that a chromosome $13q^-$ abnormality heralds disease transition. PV related myelofibrosis occurring after the use of chemotherapy is often accompanied by additional karyotypic abnormalities, with chromosomes 5 and 7 being the most frequently involved.[458]

One can conclude that chromosome abnormalities such as +8,+9, and $20q^-$ might be related to the biogenesis of the disease rather than to the treatment employed.[462,463] In addition, it appears that, at best, in some patients, an abnormal clone (abnormalities of chromosome 5 or 7) and hypodiploidy develop as a consequence of therapy with chemotherapeutic agents.[456–462] Diez-Martin and colleagues have also suggested that patients with a cytogenetic abnormality at diagnosis have a statistically significantly poorer survival rate than those in whom a normal karyotype is observed.[461] This influence of cytogenetics on prognosis has not been confirmed by others.[459–463]

DIFFERENTIAL DIAGNOSIS OF THE POLYCYTHEMIAS

In most patients, establishing the cause leading to erythrocytosis is not difficult. Initially, it is critical to be certain that one is dealing with a patient with an absolute erythrocytosis. For this purpose, a direct determination of red cell mass is not always necessary.[8–12,429–431] Unfortunately, this test is not presently available at many institutions.[432] Many patients with a raised hematocrit level, however, will require blood volume studies to document an elevated red cell mass.[12,429–431] A hematocrit level greater than 60% on several occasions in men or greater than 55% in women, however, is associated with an elevated red cell mass in virtually every case.[12,429–431] In those situations, it would be reasonable not to proceed with blood volume studies. If the hematocrit is below 60% in men or below 55% in women, blood volume studies are recommended. It has become increasingly apparent that an elevated hematocrit level should not be the only criterion for proceeding with a red cell mass determination.[429] Splenomegaly can lead to an expanded plasma volume, which can mask the diagnosis of polycythemia.[429–431] It is suggested that red cell mass determinations be performed in patients with normal hemoglobin or hematocrit determinations in the context of hepatic or portal vein thrombosis, isolated leukocytosis, or splenomegaly.[355,357] Testing for JAK2V617F can be extremely useful in diagnosing PV and is viewed by some as an alternative to blood volume measurements if they are not available. The presence of splenomegaly is an important finding on clinical examination, and adjunctive laboratory findings include normal arterial oxygen saturation, elevated leukocyte alkaline phosphatase activity, and JAK2V617F assays.[196,78–82] Splenic sizing by ultrasound can be useful in documenting splenic enlargement when the spleen is not palpable by physical examination.[471]

It is initially important to differentiate PV from the large number of other causes of secondary erythrocytosis. Characteristically, the patient with PV will present with erythrocytosis, leukocytosis, and thrombocytosis, and splenomegaly and are positive for JAK2V617F.[78–82] The bone marrow biopsy shows hypercellularity with trilineage hyperplasia. In individuals with less pronounced disease, it is important to determine the Sao_2 using an arterial blood gas, the carboxyhemoglobin level, and the $P_{50}O_2$ in patients with other family members with erythrocytosis to exclude obvious causes of secondary erythrocytosis. Because smokers' polycythemia is the most frequent cause of erythrocytosis, it is wise to measure carboxyhemoglobin levels early on in the investigation. In addition, a Pao_2 greater than 67 mmHg or an O_2 saturation greater than 95%, as quantitated on an arterial blood gas, will be helpful in ruling out hypoxic conditions that lead

to erythrocytosis. In patients with intermittent hypoxia, such as sleep apnea syndrome or alveolar hypoventilation due to obesity, such blood gas determinations can be normal. A low $P_{50}O_2$ will be indicative of a hemoglobin mutant with high O_2 affinity leading to tissue hypoxia and erythrocytosis. These patients will often have multiple other family members with erythrocytosis. Tests that can be especially useful for this purpose are the serum EPO level, the ability of bone marrow cells to form erythroid colonies in the absence of exogenous EPO and a JAK2V617F determination.[8–12,78–82,265] Numerous studies have indicated that classification of 90% of patients with erythrocytosis can be achieved by quantitating serum EPO.[8–12] These studies have indicated that patients with PV most frequently exhibit serum EPO levels below the 95% confidence intervals for the range observed in normal controls.[8–12] The subnormal serum EPO levels are maintained even after several phlebotomies have been performed that normalize the serum hemoglobin concentration in PV patients.[8–12]

Spivak has, however, expressed some caution about overreliance on the use of serum EPO levels to define the etiology of erythrocytosis in an individual patient.[12] He has pointed out that although the lowest EPO levels occur in PV, it is not unusual to have a normal EPO level in some patients with hypoxic causes of secondary erythrocytosis unless the hypoxia exists over an extended period of time. Spivak concludes that a normal EPO level cannot be used to exclude a hypoxic cause of erythrocytosis.[12] EPO measurements do, however, remain an important diagnostic tool. Elevation of EPO levels in the face of erythrocytosis are indicative of a hypoxic cause of secondary erythrocytosis, whereas extremely low levels of EPO (<4 mIU/mL) are virtually diagnostic of PV.[8–12] It is the patient with erythrocytosis and a normal EPO level where additional adjunctive diagnostic tests are required to define the cause of erythrocytosis. The availability of newly defined genetic markers such as JAK2V617 or JAK2 exon 12 mutations clearly expedite the diagnosis.[8–12,78–82,265]

Incorporating a mutational screen into the algorithm for investigating a case of suspected polycythemia will help to streamline the diagnosis of PV, although the presence of a JAK2 mutation alone does not distinguish PV from IM or ET. James et al have investigated 88 patients with erythrocytosis, the JAK2 V617F mutation was found in 57 of 61 cases diagnosed as PV and 0 of 11 with idiopathic erythrocytosis.[454] These data and data by others have suggested that mutational analysis can be used to help screen individuals and that this may reduce the need for investigations such as red cell mass determination and bone marrow biopsies. JAK2 analysis has broader applicability than clonality assays, which are restricted to females and are also not evaluable in older women because of the phenomenon of age-related skewing. Of course, it has to be remembered that patients without a JAK2 mutation can still have a primary MPD.

The ability of bone marrow cells to form endogenous erythroid colonies also been used to analyze etiologic factors in the development of Budd–Chiari syndrome.[78,449–453] Valla and associates[357] studied the marrow proliferative capacities of 20 patients with this syndrome and observed endogenous erythroid colony formation in 16 cases. In 2 of these 16 patients, it was quite obvious that an MPD was the underlying etiologic factor in the development of hepatic vein thrombosis. This abnormality in the other 14 patients suggests that the development of Budd–Chiari syndrome may represent, in some cases, a forme fruste of an MPD.[355,357] Furthermore, marrow cells from patients with other MPDs, ET, CML, and IM also frequently form endogenous erythroid colonies. As has been previously discussed, the JAK2V617F mutation can be detected in 20% to 40% of patients with Budd–Chiari syndrome, portal vein thrombosis, or mesenteric vein thrombosis and normal hematological values.[360–365] Clearly, JAK2V617F assays should be performed in such patients to diagnose an early form of an MPD.

Clinical criteria for the diagnosis of PV have been defined by the PVSG and the World Health Organization and have been used successfully to obtain a uniform patient population with PV for evaluation of therapeutic modalities.[12,196,431,472] It is important, however, for the clinician to realize that some patients undoubtedly have a MPD disorder resembling PV but do not fulfill all the diagnostic criteria of the PVSG or the World Health Organization.[12] The criteria for the diagnosis of PV including the use of the JAK2V617 assay have recently been revised by the World Health Organization and are now provided in Table 68–8.[472] These criteria are the consensus of many experts working in this field and represent an advance in this field. There will always be unusual cases with clinical characteristics that cannot be pigeonholed into a particular diagnostic category. If asymptomatic; these patients should be followed carefully until the disorder evolves into a more recognizable entity. This would appear prudent to avoid unnecessary therapeutic interventions. If these patients have serious symptoms, the individual physician must make treatment decisions on the basis of the risk-benefit ratio for that patient.

Table 68–8 Proposed Revised World Health Organization Criteria for Polycythemia Vera

Diagnosis Requires the Presence of Both Major Criteria and One Minor Criterion OR the Presence of the First Major Criterion Together With Two Minor Criteria.

Major Criteria

1. Hemoglobin >18.5 g/dL in men and 16.5 g/dL in women or another evidence of increased red cell volume*
2. Presence of *JAK2*V617F or other functionally similar mutation such as *JAK2* exon 12 mutation

Minor Criteria

1. Bone marrow biopsy showing hypercellularity with trilineage hyperplasia (panmyelosis) with prominent erythroid, granulocytic, and megakaryocytic proliferation
2. Low serum erythropoietin level
3. Endogenous erythroid colony formation *in vitro*

** Hemoglobin or hematocrit >99th percentile of method-specific reference range for age, sex, altitude of residence, or Hemoglobin >17 g/dL in men and 15 g/dL in women if associated with a documented and sustained increase of at least 2 g/dL from an individual's baseline value that cannot be attributed to correction of iron deficiency, or Elevated red cell mass >25% above mean normal predicted value.*

Data from Tefferi et al. Proposals for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: From an ad hoc international expert panel. Blood 2007, 110:1092–1097.

A particularly difficult dilemma occurs when evaluating patients with isolated pure erythrocytosis.[473–476] These patients have elevated red blood cell masses, normal white blood cell counts, normal platelet counts, no evidence of splenomegaly, and no evidence of any recognizable cause of secondary erythrocytosis. Clearly, some of these patients have JAK2V617F-positive PV or mutations of exon 12 JAK2 leading to isolated erythrocytosis. The familial congenital form of polycythemia due to truncation of the EPOR, characterized by increased sensitivity of erythroid progenitor cells to EPO, can be easily distinguished from PV. These patients frequently present in childhood, and this disorder is characterized by isolated erythrocytosis that is associated with an increased risk of thrombotic events.[88–94] There is a strong family history of polycythemia.[77–83] In contrast to PV, the marrow progenitor cells are hypersensitive to EPO, yet no colonies form in the absence of EPO.[88–94] In addition, patients with other cases of familial polycythemia due to mutations of VHL or PHD should be excluded.[182–190,194]

PV must also be differentiated from the other MPDs, such as CML, ET, and PMF.[477] Such classification has major prognostic implications and influences important therapeutic decisions, including the use of tyrosine kinase inhibitors such as imatinib, dasatinib, or holotinib. With the distinctive cytogenetic abnormalities and molecular genetic abnormalities that are unique to CML (Philadelphia chromosome, *BCR–ABL* gene fusion), these two disorders should not be difficult to differentiate.[196] A less complex test, the leukocyte alkaline phosphatase activity, may also be of assistance. The leukocyte alkaline phosphatase score is elevated in PV but is decreased

in patients with CML.[196,309] In addition, the incidence of elevated red cell masses in patients with CML is low.

Patients with PMF can present with abnormalities that are virtually indistinguishable from those of patients with PV related MF.[338–340] Almost 50% of PMF are JAK2V617F positive while over 90% of patients with PPMM are JAK2V617F positive.[78–82] The survival of patients with the latter disorder is much shorter than that of patients with the former condition.[338–340] Some patients with presumed PMF may actually develop PV after the institution of chemotherapy.[209]

A preceding history of PV permits differentiation between these two situations. ET and PV with marked thrombocytosis can easily be confused. When the red blood cell mass is used as a definitive diagnostic test, a distinction between ET and the erythrocytotic phase of PV is usually readily apparent.[457,476] This measurement, however, can be normal or actually low in the patient with PV who is iron deficient because of bleeding or excessive phlebotomy.[12] Campbell and coworkers have recently used sensitive PCR-based methods to assess the JAK2 mutational states in 806 patients with ET.[478] The mutation was present in over 50% of patients with ET. JAK2V617F-positive ET patients were characterized by multiple features that resembled those of patients with PV, including higher Hgb levels, higher white blood cell counts, more prominent marrow erythroid and granulocytic hypoplasia, a higher incidence of venous but not arterial thrombosis, low serum EPO levels, and lower serum ferritin levels.[478] Surprisingly, JAK2V617F-negative patients had higher platelet counts. Furthermore, JAK2V617F-positive ET patients had a higher probability of developing PV with longer follow-up. Acquisition of homozygosity for the JAK2V617 due to homologous recombination is likely the critical event in the development of PV in JAK2V617F ET patients.[81,262] Homozygosity for JAK2V617F occurs in at least 30% of patients with PV, but is extremely rare in ET.[478]

An elevated expression of polycythemia rubra vera 1 (PRV-1) mRNA in granulocytes has been suggested to be diagnostic of PV.[12,78,479–481] PRV-1 is a novel member of the urokinase type plasminogen activator receptor (uPAR) super family.[479] Use of a quantitative reverse transcription–polymerase chain reaction (RT-PCR) assay for the measurement of PRV-1 mRNA expression in PV granulocytes has been useful in distinguishing PV from secondary erythrocytosis.[481] Expression analysis has revealed that PRV-1 is constitutively expressed in the bone marrow of patients with a variety of hematologic disorders and that its usefulness as a diagnostic tool for the MPD is restricted to peripheral blood granulocytes. In PV, PRV-1 is not downregulated in granulocytes within the marrow.[482] Furthermore, the specificity of overexpression of PRV-1 mRNA in granulocytes has been questioned as increased PRV-1 mRNA has also been documented in the granulocytes of patients with ET, idiopathic myelofibrosis, normal patients receiving granulocyte-colony stimulating factor, patients recovering from trauma or surgery, occasional patients with hereditary forms of thrombocythemia due to higher TPO levels, as well as occasional patients with secondary or spurious polycythemia.[483,484] The overexpression of PRV-1 in PV does not involve structural genetic changes.[485] Impaired expression of Mpl by PV platelets has also been examined as a universal marker of PV. Some investigators have reported that this abnormality, however, was observed only in a subset of patients with PV and IM. Both PRV-1 overexpression and impaired expression of Mpl likely represent downstream events of the JAK2V617F mutation.[486]

THERAPY

Dramatic prolongation of survival over that expected from the natural history of patients with untreated PV has been achieved with several therapeutic strategies.[196,207,296,297,302,303] Historic evidence of a median survival period of approximately 18 months of untreated patients from the time of diagnosis is derived from descriptive accounts, but more recent data of the clinical course of untreated patients are not available. It is clear that many patients remain asymptomatic for years before diagnosis.[5] A cumulative median duration of survival for PV patients treated with modern strategies of more than 15 years has been reported.[12,297,302] However, in spite of modern therapies, an excess of mortality in comparison with a matched normal population has been reported.[307] Men have a higher mortality rate than women in each age group of patients with PV.[12,297,302] At present, the therapeutic goals are to reduce the risk of thrombosis by normalizing the hematocrit levels to 45% or lower in males and 42% or lower in females.[12]

A series of studies performed over a 17-year period (1967–1984) by the PVSG has answered several very important questions regarding the efficacy and associated complications of particular therapeutic modalities.[296,418–421] These investigations have aided in the identification of optimal therapy for individual patients, which must be selected on the basis of age and comorbid disease status to minimize treatment-related complications.[12,296,418–421,487]

The first PVSG randomized trial (01 trial) evaluated three treatment strategies: (a) phlebotomy alone, to maintain the hematocrit level at less than 45%; (b) intravenous ^{32}P, 2.3 mCi/m^2 repeated every 12 weeks if needed (maximum 5mCi per dose), supplemented by phlebotomy to maintain the hematocrit level at less than 45%; and (c) myelosuppression with chlorambucil 10 mg per day PO for 6 weeks, then daily on alternate months, with necessary dose reductions

General Principles of Therapy

1. Etiology of erythrocytosis must be correctly categorized to be certain the patient has polycythemia vera (PV). This will avoid inappropriate exposure of patients with nonmalignant disorders to potential leukemogenic agents. To this end, a major contribution will be played by incorporating a JAK2V617F determination in the diagnostic workup, and in this way, early phases of PV can be recognized as well.
2. Therapy should be individualized.
3. Initially, the blood volume should be reduced to normal as rapidly as possible. The speed of phlebotomy will depend on patients' general medical conditions (250–500 mL every other day). Elderly patients with compromised cardiovascular or pulmonary systems should be more carefully phlebotomized (twice a week), or smaller volumes of blood should be removed.
4. Hematocrit levels should be maintained at 42% for females and 45% for males.
5. Excessive doses of chemotherapeutic agents should be avoided. Supplementary phlebotomy rather than potentially toxic doses of chemotherapeutic agents should be used to avoid excessive marrow and systemic toxicity.
6. Hyperuricemia is treated with allopurinol (100–300 mg/d).
7. Pruritus is treated with cyproheptadine 4 to 16 mg/d; if unsuccessful, interferon-α therapy 3.0×10^6 units subcutaneously three times a week. A role for serotonin-uptake inhibitors (paroxetine 20 mg/d or fluoxetine 10 mg/d) has been proposed.
8. Elective surgery or dental procedures should be delayed until red cell mass and platelet counts have been normalized for more than 2 months. Aspirin should be withdrawn at least 1 week before surgery. If emergency surgery is contemplated, phlebotomy and cytopheresis should be pursued.
9. Women and men who are contemplating having children should be treated by phlebotomy plus low-dose aspirin therapy (81 mg/d or with interferon-α) to avoid teratogenic effects of chemotherapy. Such avoidance will also prevent deleterious effects on fertility. During pregnancy, therapy is frequently not necessary; if it is, phlebotomy plus low-dose aspirin should be exclusively used. If phlebotomy control is inadequate, treatment with interferon-α should be pursued.

Algorithm for Management of Patients with PV

Low-risk young patients (<60 years) and no prior history of thrombosis, platelet count lower than 1.5×10^6 mm^{-3}

Phlebotomy + low-dose aspirin (81 mg/d) to maintain hematocrit lower than 45% in males and lower than 42% in females. Aspirin should not be used in patients with histories of a hemorrhagic episode or with extreme thrombocytosis (>1.5×10^6 mm^{-3}) or acquired von Willebrand syndrome.

↓

Thrombosis or hemorrhage
Systemic symptoms
Severe pruritus refractory to histamine antagonists
Painful splenomegaly

↓

Pegylated interferon 90 to 180 μg/week or Interferon α (3×10^6 units three times a week; alter dose depending on response and toxicity). Consider the use of pegylated interferon, which can be administered once weekly

↓

If platelet control is inadequate or patient cannot tolerate interferon, one option could be the use of anagrelide. However, the use of this drug is controversial. In this case, supplemental phlebotomy is required to maintain hematocrit lower than 45% in males and lower than 42% in females and the use of hydroxyurea should be considered, especially if patient continues to have thrombotic episodes.

↓

If the patient has increasing splenomegaly, systemic symptoms, or repeated thromboses, in spite of adequate dose of hydroxyurea (2–3 g daily) start busulphan: 4 to 6 mg/d PO for 4 to 8 weeks. It should be mentioned that the sequential use of hydroxyurea and busulphan may be associated with an increased risk of leukemia. Supplemental phlebotomy may be required.

↓

Painful splenomegaly
Splenectomy + continued systemic therapy

↓

High-risk patients (>60 years), previous thrombosis, platelet count higher than 1.5×10^6 mm^{-3}

Phlebotomy to hematocrit of 42% in females and 45% in males
Aspirin (81 mg/d) to be given only in patients with platelet counts lower than 1.5×10^6 mm^{-2}
Myelosuppressive therapy with hydroxyurea 30 mg/kg PO for 1 week

↓

Then 15 to 20 mg/kg
If patient continues to have thrombotic episodes and has extreme thrombocytosis or cannot tolerate hydroxyurea.
Consider pegylated interferon 90 to 180 μg/wk or add busulphan 4–6 mg/d PO for 4 to 8 weeks.
Stop when blood counts are normalized or platelet count is lower than 300,000 mm^{-3}.
Occasional supplemental phlebotomy if hematocrit is greater than 42% in females and greater than 45% in males; when patient relapses (patient is symptomatic), initiate busulphan therapy again at same dose.

↓

If patient is poorly compliant, consider ^{32}P: 2.3 mCi/m^2 IV every 12 weeks as needed (limit 5 mCi per dose).
Increase dose by 25% if no response

Patient age more than 70 years

Phlebotomy + low-dose aspirin + hydroxyurea

↓

No response or poor compliance
Busulphan 4 to 6 mg/d PO for 4 to 8 weeks. Stop when blood counts are normalized or platelet count is lower than 300,000 mm^{-3}.

↓

No response
^{32}P

and supplemental phlebotomy.[418–421] More than 400 patients were randomly assigned to this protocol. Median survival duration from entry into the study until death was 9.1 years for patients treated with chlorambucil, 10.9 years for those treated with ^{32}P, and 12.6 years for the phlebotomy group.[418–421] Long-term survival was inferior for patients treated with chlorambucil when compared with those treated with ^{32}P or phlebotomy.[418–421] An early finding was the appearance during the first 5 years of a significant excess of deaths from acute leukemia in the chlorambucil arm, which reached 17% after 15 years of follow-up.[418–421] As a result, the chlorambucil arm was discontinued, and patients were assigned randomly to one of the other two arms. Even though no statistical difference in overall survival between ^{32}P and phlebotomy alone was apparent through the first 10 years, the morbidity and mortality associated with each type of therapy were attributable to distinctly different causes.[418–421] Thrombosis as a cause of death was much more frequent in the phlebotomy-only group during the first 5 to 7 years of follow-up.[418–421] Analyses of factors associated with thrombosis revealed that the performance of phlebotomy, the rate of phlebotomy, advancing age, and history of previous thrombosis were statistically significant factors predictive of this outcome.[420] In contrast, the use of ^{32}P led to a lower rate of thrombosis during the first 5 years, but the incidences of leukemias, lymphomas, and nonhematologic malignancies increased during the next 5 years to nearly 10%.[417–421] Following a 15-year period of observation, the incidences of leukemia and lymphoma in the chlorambucil group had risen to 17%.[417–421] A statistically significant increase in skin and gastrointestinal cancers occurred in the ^{32}P- and chlorambucil-treated cohorts, compared with the group treated with phlebotomy alone.[417–421]

Given the paradox of equal 10-year survivals but demise due to distinct causes in comparable populations of patients treated by phlebotomy alone or by phlebotomy plus ^{32}P, the PVSG pursued strategies to reduce the thrombotic risk in the phlebotomy-only group. One study attempted reduction of the thrombotic risk by combination antiplatelet therapy. It appeared possible that therapy directed toward altering platelet function might reduce the frequency of thrombosis.[331] Therefore, a randomized trial was performed in which phlebotomy, supplemented with the platelet antiaggregating agents aspirin and dipyridamole, was compared with ^{32}P (PVSG trial 05). The outcome for the group treated with phlebotomy, aspirin, and dipyridamole was disappointingly inferior to the ^{32}P results.[389] In fact, more thromboses occurred in the former than in the latter group, but surprisingly there was also a significantly greater incidence of severe gastrointestinal hemorrhages.[389]

Renewed impetus for the use of nonchemotherapeutic agents for the treatment of PV was provided by an extensive natural history study of 1213 patients reported by the Gruppo Italiano Studio Policitemia.[297] They showed that the age- and gender-standardized mortality rate of patients with PV was 1.7 times greater than the mortality rate of controls in the general Italian population.[297] In addition, four times as many patients who had previously received ^{32}P, alkylating agents, or hydroxyurea died of cancer compared with patients treated with phlebotomy alone.[297] When this group combined the total number of deaths and the number of nonfatal myocardial infarctions

and strokes, they found an unsatisfactory risk-benefit profile in patients treated with chemotherapeutic agents and suggested that antithrombotic strategies, such as low-dose aspirin, be carefully evaluated for use in the care of PV patients.[297]

In light of more recent knowledge of the dose requirements for selective antiplatelet therapy with aspirin, it appears that the PVSG study of platelet antiaggregating agents might have failed due to the use of excessive aspirin dosages (900 mg/d). Such aspirin doses appear to diminish vascular endothelial production of the platelet antiaggregatory factor, prostacyclin I_2 (PGI_2).[326,331]

PV platelets are known to have a generalized abnormality of arachidonate metabolism that is characterized by enhanced synthesis of thromboxane A_2, which likely reflects stimuli to platelet activation.[326,331] The exact mechanism responsible for enhanced platelet synthesis of thromboxane A_2 in PV remains unknown and requires further investigation. A low-dose aspirin regimen (50 mg/d for 7–14 days) has been shown to suppress more than 80% of the excretion of the metabolites of thromboxane A_2.[325] A pilot study was performed in which the toxicity of low-dose aspirin therapy in PV patients was evaluated.[325] A very-low-dose aspirin regimen (40 mg/d) was chosen to prevent thrombosis yet minimize the risk of bleeding. After follow-up of the low-dose aspirin treatment group and control group, low-dose therapy was shown not to be associated with an increased incidence of bleeding complications. Aspirin therapy was well tolerated and was associated with complete inhibition of platelet cyclooxygenase activity.[325] A large, randomized, placebo-controlled clinical trial testing the risk–benefit ratio of low-dose aspirin therapy in preventing thrombotic episodes in PV has been recently completed.[302] Treatment with low-dose aspirin (100 mg/d) compared with placebo reduced the risk of the combined endpoint of nonfatal myocardial infarction, nonfatal stroke, pulmonary embolism, major venous thrombosis, or death from cardiovascular courses. Overall mortality and cardiovascular mortality, however, was not reduced significantly by aspirin therapy. Importantly, the incidence of major bleeding episodes was not significantly increased in the aspirin group.[302] It is important to emphasize that patients require aggressive phlebotomy therapy to the appropriate target hematocrit levels as well as the appropriate use of myelosuppressive agents as primary therapy, with the addition of aspirin serving as an adjunct to this strategy. Spivak has questioned the conclusions of this study, as many of the patients had hematocrit levels above the acceptable therapeutic range and were receiving myelosuppressive agents to normalize platelet numbers.[303] However, in the recently reported analysis by ECLAP investigators, multivariate analysis did not show any differences in the rate of thrombosis associated with different hematocrit levels during follow-up. High hematocrit levels were not found to be significant predictors of death, development of thrombotic events, or hematological progression.[314] We can conclude that aspirin therapy appears to be a relatively innocuous therapy but should be avoided in patients with extremely high platelet counts. Surely, in young (<60 years of age), low-risk patients (no prior history of thrombosis, platelet count $>1 \times 10^6$ mm^{-3}), phlebotomy with low-dose aspirin (81 mg/d) therapy is an attractive approach.

It is interesting to compare the results of the PVSG study with those of a randomized trial of ^{32}P versus busulphan for the treatment of PV conducted by the European Organization for Research and Treatment of Cancer (EORTC).[488,489] The two studies were comparable in size, design, and duration of follow-up. In the EORTC trial, induction courses of busulphan 4 to 6 mg/d for 4 to 8 weeks were compared with ^{32}P treatment.[392] Patients treated with busulphan enjoyed a survival advantage over ^{32}P-treated patients.[392,393] This difference was due primarily to a threefold greater incidence of fatal thrombotic events in the ^{32}P group. Interestingly, the incidence of leukemia in both groups was very low (<2%), with an overall malignancy rate of less than 10% (involving mostly solid tumors).[488,489]

It is reasonable to conclude from this trial that busulphan is a myelosuppressive agent with limited leukemogenic potential when used on an intermittent schedule.[488,489] A retrospective study of patients in England treated with phlebotomy and intermittent busulphan supports these same conclusions.[480]

After the disappointing results experienced with the alkylating agent chlorambucil, the PVSG began a nonrandomized phase II investigation of hydroxyurea, an S-phase-specific ribonucleotide reductase inhibitor.[421,490,491] The hope was that this agent would be nonleukemogenic. Of 53 patients with PV treated with hydroxyurea who had never received other forms of myelosuppression, after follow-up for a median period of 8.6 years and a maximum follow-up of 795 weeks, 5.4% developed acute leukemia compared with 1.5% of patients treated with phlebotomy alone on the original PVSG randomized study.[421]

In a comparable trial reported by Sharon and coworkers, 71 patients were treated with hydroxyurea for a mean duration of 7.3 years.[492] Remarkably, the incidence of thrombosis was only 6%, indicating the impressive potential of hydroxyurea to lower the incidence of thrombosis in patients with PV, confirming an observation previously made by Kaplan and colleagues.[491] The incidence of leukemia in the Israeli trial was 5.6%.[492,493] Several other reports are also available reporting the incidence of acute leukemia in PV patients treated with hydroxyurea.[416,490–498] The incidence varies from 10.5% in the 30 patients treated by Weinfeld and associates, to 6.2% in the 65 patients treated by Lovfenberg and colleagues, and 10% in the 150 cases treated by Najean and colleagues.[494,495] Furthermore, in a randomized trial including 296 patients comparing the efficacy of hydroxyurea with piprobroman, an alkylating agent, for the treatment of PV, the incidence of leukemia was similar in both treatment arms. The incidence of PPMM was, however, statistically greater in the patients treated with hydroxyurea.[494] Piprobroman is not available in the United States. In a more recent retrospective series, the incidence of acute leukemia and myelodysplasia in patients with PV treatment hydroxyurea alone was 6.9%.[498] These patients received a greater dose of hydroxyurea than patients who did not develop leukemia. The leukemia associated with hydroxyurea therapy developed over 6.3 years after treatment with hydroxyurea was initiated. In patients treated first with busulphan and then hydroxyurea, the rate of acute leukemia/myelodysplasia was even higher, 13.8%. Finazzi et al examined 22 cases with AML/MDS reported in the ECLAP study that enrolled 1638 patients. AML/MDS were diagnosed after a median of 8.4 years from the diagnosis of PV and variables associated with progression were older age, whereas overall disease duration (more than 10 years) failed to reach statistical significance.[425] Exposure to P32, busulphan, and pipobroman but not hydroxyurea alone had an independent role in producing an excess risk for progression to AML/MDS as compared with treatment with phlebotomy or interferon.[425] However, the documented ability of hydroxyurea to lower the incidence of thrombotic events, even in the face of a possible increasing documentation of its leukemogenic potential, makes this drug a very useful chemotherapeutic agent in older, high-risk patients with disease that cannot be controlled with phlebotomy alone. Excessive myelosuppression, macrocytosis, hypersegmentation of polyps, stomatitis, leg ulcers, creatinine elevations, and jaundice have been attributed to the use of hydroxyurea.[490–498] Aphthous and leg ulcers occur in 20% of patients, usually after 5 years of hydroxyurea maintenance therapy.[490–498] In addition, the use of hydroxyurea requires patient compliance and careful monitoring of blood counts to avoid the sequelae of excessive myelosuppression.

Some clinical investigators have suggested that a program of phlebotomy alone would be the most appropriate for younger patients, who have not experienced a cerebrovascular or cardiovascular event. Strong consideration should be given to the use of phlebotomy therapy in conjunction with low-dose aspirin therapy in addition to the use of such apparently nonleukemogenic drugs as interferon-α in this younger patient population.[12,302,303,497–505]

Anagrelide, a selective inhibitor of platelet production, has been used to treat thrombocytosis in PV patients with thrombotic or hemorrhagic complications.[497] This agent appears to be nonleukemogenic and acts by impairing megakaryocyte maturation.[500,501,505] Its use leads to a selective reduction in platelet numbers, and it has been effective in patients refractory to hydroxyurea and interferon.[497–500,503] This drug does not effectively control the erythrocytosis and leuko-

cytosis or systemic symptoms associated with PV and therefore was suggested to be used as a supplement to phlebotomy therapy.

Pettit and colleagues have reported that anagrelide use in polycythemia resulted in a complete resolution of thrombocytosis as defined as a platelet count of less than 600,000 or a 50% reduction of pretreatment levels in 66% of 113 patients with PV.[503] In nearly all responders, platelet reduction was observed within a week. The time to complete response generally ranged between 17 and 25 days.[503] The dose of anagrelide required to control thrombocytosis remained constant over time in most patients. When anagrelide is discontinued, platelet counts returned to pretreatment levels within 5 to 7 days. The average daily dose required to control thrombocytosis in PV patients was 2.4 mg.[503] After the recent publication of the PT-O1 randomized clinical trial comparing hydroxyurea and anagrelide therapy for ET patients, many physicians are cautious about the use of this drug in preventing vascular events. In fact, major arterial thrombosis was more frequent in the anagrelide arm as compared with the hydroxyurea arm, in spite of a similar normalization of elevated platelet counts.[333] Moreover, the association of anagrelide and low-dose aspirin led to a significant increase of bleeding manifestations. Clinicians presume that the effects of anagrelide observed in ET patients will be relevant to patients with PV. This assumption has not been tested in a randomized clinical trial. Anagrelide should not be used in pregnant patients because it can easily cross the placenta, leading to adverse effects on the platelet count of the fetus.[497]

Approximately 15% to 20% of patients treated with anagrelide discontinued the medication due to nonmyelosuppressive side effects.[497–499,503–505] The spectrum of adverse effects involved neurologic (headaches and dizziness), cardiac (vasodilatation, fluid retention, congestive heart failure, palpitations, and tachycardia), and gastrointestinal (nausea) toxicities. These toxicities reflect the novel mechanism of action of anagrelide as a cyclic nucleotide phosphodiesterase inhibitor. Anagrelide should be used with caution in patients with known or suspected cardiac disease because of its ability to promote fluid retention.[497–499,503] Because many of the patients with PV are elderly, careful attention to fluid status should be maintained to avoid slipping into congestive heart failure following the initiation of anagrelide.

Another potential approach to controlling the erythrocytosis and thrombocytosis in PV involves the use of interferon-α.[506–518] Interferon-α has global effects on hematopoiesis.[518] It inhibits in vitro erythropoiesis and thrombopoiesis and antagonizes the action of PDGF, which likely plays a major role in the pathobiology of myelofibrosis.[518] Silver has suggested that treatment with interferon potentially might alter the natural history of polycythemia by interrupting the development of PPMM and myelofibrosis.[514] Reports of small groups of patients treated with interferon indicate that the erythrocytosis can be controlled in 6 to 12 months, virtually eliminating the need for phlebotomy in approximately 70% of cases.[497,506–513] In addition, interferon is capable of eliminating or reducing the degrees of splenomegaly, leukocytosis, and thrombocytosis in the majority of PV patients.[497,506–513] More importantly, interferon treatment has been shown to be capable of diminishing the severity of pruritus in 80% of patients.[515–517] Occasionally the effect on pruritus can occur in days.[515–517] The mechanism by which interferon eliminates pruritus remains unknown. The usual dose of interferon used to control polycythemia varies between 1.9 to 25×10^6 units weekly with a median maintenance dose and 10.5×10^6 units weekly administered subcutaneously in divided doses three times a week.[497,506–513] A loss of biologic effect can be attributed to the development of interferon-α-neutralizing antibodies, which may be overcome by retreatment with lymphoblastoid interferon-α N3.[497,506–513] Disease control persists in most patients only as long as interferon-α therapy is continued. Rare patients have, however, enjoyed sustained remissions after discontinuation of interferon.[413,419] Silver updated his experience on the long-term use (median 13 years) of interferon-α in 55 patients with PV.[519] Complete responses, defined by absence of the need to phlebotomize patients to maintain a normal hematocrit level less than 45% and platelet counts below 600,000 μL^{-1}, were reached in the great majority of cases after 1 to 2 years of treatment and the maintenance dose could be decreased in half of the patients. Noteworthy is the absence of thrombohemorrhagic events during this long period of follow-up.[519] Although these results are promising, treatment of larger numbers of patients for longer periods of time is required before the results of long-term interferon therapy in the treatment of PV can be appropriately evaluated. Although one would anticipate that this form of therapy would be nonleukemogenic, insufficient data are available to justify this conclusion. In addition, although interferon-α has a profound effect on PDGF and megakaryocytopoiesis, no data are available to suggest that its use delays or prevents the development of PPMM. Interferon-α has, however, been reported to be capable of suppressing the abnormal clone in PV, similar to its ability to induce cytogenetic remissions in chronic myeloid leukemia.[78,515] In these patients clonal hematopoiesis reverts to a normal polyclonal pattern.[78] Intolerance to therapy with interferon-α leads to drug withdrawal in 14% of patients.[497,505–513] Initially, all patients suffer flu-like symptoms, which are controllable with acetaminophen or aspirin. Such symptoms usually resolve spontaneously after several months of therapy. More serious side effects, including high fevers, severe asthenia, and reversible lower extremity bilateral neuritis, may require cessation of interferon-α therapy. It is anticipated that further evaluation of interferon-α therapy will be pursued in the future. A pegylated form of interferon has been recently used to treat a variety of MPDs with great success.[512] This form of interferon can be administered once weekly and its use is associated with a more favorable toxicity profile.[512] Interestingly, in a multicenter phase II trial of pegylated interferon-α2a in 27 patients, Kiladjian et al reported a decrease in JAK2V617F allele frequency in 24 patients (89%), and in one patient the mutant JAK2 was no longer detectable after 12 months of therapy.[520] Ishii and coworkers have demonstrated the elimination of JAK2V617F-positive cells following pegylated interferon therapy, which was associated with the restoration of polyclonal hematopoiesis.[521] The role of pegylated interferon therapy versus the present standard of care will be defined only after the performance of a randomized phase III trial.

Imatinib mesylate (Gleevec) therapy has also been shown to be effective in reducing phlebotomy requirements, in lowering abnormal platelet counts, and reducing spleen size in PV patients.[522] Imatinib is a potent inhibitor of the BCR–ABL tyrosine kinase and is approved for the treatment of chronic myeloid leukemia. Imatinib also inhibits other tyrosine kinases encoded by protooncogenes such as *KIT* (formerly designated c-kit) and *PDGF-R*.[522] Oehler and colleagues have shown that in vitro Imatinib treatment blocks EPO-independent colony formation by PV marrow cells.[523] The amount of suppression was dose dependent and occurred at drug concentrations that are achieved in patients receiving imatinib therapy for chronic myeloid leukemia PV. Patients undergoing imatinib therapy who achieved a complete hematological remission enjoyed an approximately two- to threefold reduction in the frequency of JAK2V617F.[524]

Symptomatic management of the PV patient may be complicated by the occurrence of intractable pruritus.[196,398–403] Normally, the pruritus occurs on exposure to sudden body cooling, especially after a warm bath[196,398–403] and is experienced by as many as 40% to 60% of patients treated with phlebotomy.[398–403] The frequency of pruritus appears to be somewhat lower in patients treated with myelosuppressive agents.[196] This observation is related to the probable relation between pruritus and degranulation of tissue mast cells and circulating basophils.[397] Some uncontrolled studies have attributed pruritus to hyperhistaminemia or severe iron deficiency, with relief associated with the use of histamine antagonists or ferrous sulfate.[403] Iron replacement is frequently not possible because it can lead to dangerous elevations of the red cell mass. In a number of instances, however, iron replacement has been possible with disease control with interferon-α.[12] The association between pruritus and tissue infiltration by mast cells would appear to explain the response of occasional patients to photochemotherapy with psoralens and ultraviolet irradiation.[522,523] At present, interferon therapy for pruritus appears to be extremely useful.[516] Taylor reported that significant pruritus control occurred in 83% of patients treated with appropriate doses of interferon-α.[394]

This use of interferon-α represents a significant advance in the treatment of a frequently disabling symptom in this patient population. In addition, 80% of patients with pruritus have been reported to respond to paroxetine or fluoxetine, selective serotonin uptake inhibitors.[525–527] Other effective options include psoralen photochemotherapy and narrowband ultraviolet B phototherapy.[528]

Budd–Chiari syndrome is a catastrophic illness that can lead to significant morbidity and mortality in a patient with PV.[352–359] Patients with MPD are at a high risk of developing this syndrome.[196,352–359] Independently, the use of oral contraceptive pills and congenital and acquired thrombophilic factors are involved in its development.[529] A number of cases of hepatic vein thrombosis have been reported in nonpolycythemic women taking oral contraceptives.[356,530] Although no data are available, one must be concerned about the use of oral contraceptives in women with PV.

The optimal approach to the problem of Budd–Chiari syndrome is obviously preventive and involves maintenance of normal blood values in the patient with PV.[356,359,531] Once the Budd–Chiari syndrome develops, the prognosis without treatment is dismal. The goals of therapy are to prevent further propagation of thrombus, relieve the intense hepatic congestion, and manage the severe ascites that often plague these patients.[356,359] If untreated, these patients often have a slowly progressive course, with deterioration and death occurring within 3.5 years.[356] Spontaneous resolution of the hepatic vein occlusion rarely occurs. Diuretics may be of value in the treatment of the ascites but do not affect the long-term outcome.[356] Thrombolytic therapy within 24 hours of onset of diagnosis with urokinase (240,000 units per hour for 2 hours, followed by 60,000 units per hour) or tissue plasminogen activator (0.5–1.0 mg/h) directly infused into the thrombosed hepatic vein for 24 hours results occasionally in success.[356,359] Even if therapy is delayed for 2 to 3 weeks, a favorable outcome can be achieved in some instances with thrombolytic therapy. Such therapy is not innocuous since bleeding can complicate the course of therapy. Angioplasty of localized segments of the hepatic vein can result in the relief of symptoms in the majority of patients but the risk of restenosis is high.[356] Anticoagulant therapy may have a role in the prevention of further clot formation, but there has been no definitive evidence that such therapy promotes resolution of established thromboses.[356]

The clinical deterioration of patients with Budd–Chiari syndrome results from damage to the hepatocytes from necrosis associated with marked elevation in sinusoidal pressure, coupled with ischemia from reduced hepatic arteriole perfusion.[356] The only rational therapeutic intervention therefore involves some sort of portal vein decompression to achieve an effective reduction of sinusoidal pressure.[356,359,531] A variety of surgical procedures resulting in portal-splenic decompression have been shown to be of value in patients with Budd–Chiari syndrome.[356,359] Transjugular intrahepatic portosystemic shunt placement has been used as a bridge to liver transplantation.[356,359,531,532] Surgical portosystemic shunts may reverse hepatic necrosis and prevent cirrhosis.[356] The 5-year survival rate after surgical shunts ranges from 75% to 94%.[356] Liver transplantation is a potential option for treatment of those patients with continued hepatic decompensation.[356,532,533] The indications for liver transplantation are cirrhosis, fulminant hepatic failure, and failure of a portosystemic shunt.[356,359] The overall actuarial survival at 1 year is 76% and was 68% at 10 years.[534] Since PV is a slowly progressive disease, transplantation should not be withheld from these patients.[534] Pretransplant predictors of mortality based on a multivariable analysis were impaired renal function and a history of a shunt.[534] The hematologic consequences of polycythemia must be aggressively treated in the posttransplantation setting, the hepatic vein occlusion may reoccur in the transplanted liver.[356,359,535]

Therapy of cerebral vein thrombosis and sinuses includes anticoagulation with heparin to arrest the thrombotic process and to prevent pulmonary embolism. Low-molecular-weight heparin should be started as soon as the diagnosis is confirmed, even in the presence of hemorrhagic infarcts.[534] After the acute phase, vitamin K antagonists are given for 6 months after a first episode or longer if the MPD disease is not well controlled.[537] There is currently no available evidence from randomized clinical trials regarding the efficay or safety of thrombolytic therapy.

The performance of any surgical procedures on patients with PV is, as previously discussed, accompanied by excessively high morbidity and mortality.[393–397] Elective surgery should not be contemplated unless the patient's hematologic values have been normalized for several months.[393–397] The longer the hematologic control has been in effect, the lower the incidence of postoperative complications. If emergency surgery is required, the patient should be phlebotomized rapidly until a normal hematocrit is reached, and platelets should be available in case excessive perioperative or postoperative bleeding occurs.[393–397] Following emergency or elective surgery, the patient should be mobilized as soon as possible and strong consideration should be given to anticoagulation with low-molecular-weight heparin, unless the patient has some contraindication. Dental extractions can also result in excessive hemorrhage and should not be performed unless the patient is under strict hematologic control.[393–397]

Perhaps the most difficult and frustrating period encountered during the clinical course of a patient with PV is the development of PV related MF.[339,340] These patients are frequently symptomatic, as a result of the sequelae of anemia, infection, bleeding, and splenic enlargement.[339,340] Because few of these patients have been treated in a uniform, controlled fashion, it is difficult to make strict therapeutic recommendations. In a study by Dingli and coworkers, an unfavorable marrow karyotype (other than $13q^-$ or $20q^-$) in patients with PV- and ET-related myelofibrosis was associated with a poor prognosis (median survival of 12 months).[407] Causes of death include transformation into acute myeloid leukemia, sepsis, hemorrhage, thrombotic events, and multiorgan failure.[407]

The anemia that characterizes the spent phase is usually multifactorial in origin. An important factor is splenic pooling of red cells and expansion of the plasma volume, which occurs as a consequence of splenomegaly.[538] It can therefore be useful in these patients to obtain red blood cell mass measurements and to quantitate the degree of anemia directly to detect those patients who have a low hematocrit level but normal red cell mass.[12,409] Folate or iron deficiency may be important in anemic patients and should be corrected.[12] Almost 20% of patients with PV related MF develop overt hemolytic anemia.[338–340] Some of these patients respond to prednisone therapy, but most require splenectomy. By far the most common cause of anemia is ineffective erythropoiesis,[539] and these patients often require transfusion therapy. Androgen therapy (danazol 400–800 mg/d) may be effective in stimulating effective hematopoiesis and diminishing transfusion requirements.[540] Low-dose thalidomide and a short course of prednisone may also be effective in eliminating the red cell transfusion requirement.[541] Iron overload syndrome secondary to ineffective erythropoiesis or transfusion therapy is a dangerous possibility. In this situation, some consideration should be given to chronic oral iron chelation therapy.

The clinical courses of these patients are frequently punctuated by pressure symptoms secondary to splenic enlargement and repeated splenic infarcts.[338–340] Treatment must be directed toward decreasing the expansion of a rapidly enlarging spleen. Small doses of busulphan, hydroxyurea, or melphalan, or occasionally interferon-α therapy, may result in the relief of such symptoms.[338–340,542–544] Radiotherapy in small doses is also sometimes helpful.[541,542] Unfortunately, its effect is frequently transient.[543,545] The chemotherapy or radiation dose must be carefully determined, because overzealous use may lead to granulocytopenia and thrombocytopenia. Often, as a last resort, splenectomy is the only reasonable therapeutic maneuver. This procedure in advanced disease is associated with an operative mortality rate of 25% and should be performed by only the most experienced of surgeons.[545–550] Surgical intervention should not be inappropriately delayed.[546–550] Splenectomy in such patients is frequently complicated by excessive hemorrhage and infected hematomas.[546–550]

Thrombocytopenia may lead to life-threatening hemorrhages in PV related mMF myelofibrosis patients.[338] Its development is due to ineffective thrombopoiesis and platelet sequestration by an enlarged spleen, and patients may rarely respond to splenectomy.[546–550] Bleeding due to qualitative platelet abnormalities has been noted in these

patients; when it is severe, platelet transfusions are often required, although because of marked splenomegaly such transfusions frequently do not increase platelet numbers. The clinician therefore must follow the extent of hemorrhage as a means of determining the effectiveness of such transfusions. In patients with refractory bleeding, a trial of epsilon aminocaproic acid or Factor VIIa infusions is suggested.[12] Disseminated intravascular coagulopathy occasionally complicates PV related myelofibrosis and can lead to life-threatening hemorrhage.[546] After careful laboratory documentation, replacement therapy with fresh frozen plasma should be pursued. Some mention should also be made of the use of biologic response modifiers for the treatment of PV related myelofibrosis. A number of investigators have suggested that interferon might be useful in the treatment of PMF and might be successful in reducing spleen size, but in reality responses are rare.[550]

Limited information is available concerning the treatment of those patients who develop acute leukemia following PV.[419,423,424,551–556] The overwhelming majority of such cases involve myeloid leukemias, but a small number of patients have a lymphoblastic phenotype.[419,423,424,551–556] The optimal treatment of such patients is unknown. In the elderly, the choice not to institute chemotherapy is a reasonable option, because results with treatment are so poor.

Rare prolonged remissions of acute leukemia following PV have been reported in the literature.[553] These patients are frequently elderly, and poor results with standard regimens have been reported. Alternative approaches to standard therapy should be entertained in these elderly patients with secondary leukemias. In a recent retrospective analysis on 23 patients with leukemic transformation of PV, the median patient age was 68 and leukemia developed a median of 12.8 years from the diagnosis of PV.[557] Twelve of the 14 patients in which cytogenetic analyses were performed had complex cytogenetic abnormalities associated with high-risk leukemias.[557] Fifteen patients were treated with palliative measures and had a median survival of 2.5 months. Of the eight patients treated with standard induction therapy, one obtained a complete remission and seven died without obtaining a response.[557] The median survival of these chemotherapy-treated patients was 5.6 months. The median survival of the entire cohort of 23 patients was 2.9 months.[559] This poor outcome is likely the result of clinical and biological features of the acute leukemia, advanced patient age, unfavorable cytogenetics, and patient comorbidities associated with advanced age.[557] Allogeneic stem cell transplantation is poorly tolerated in these patients. In Seattle, many of the transplanted patients with acute leukemia that developed following PV or ET died of transplant-related complications.[558] Selected patients are likely to tolerate and to have a favorable outcome with allogeneic stem cell transplantation and reduced intensity condition. Because of these poor outcomes, patients with PV-related acute leukemia should be considered candidates for experimental therapeutic strategies. Arsenic trioxide has recently been shown to induce apoptosis of AML cells and to downregulate activated STAT proteins by targeting JAK2.[559] A trial of low-dose cytosine arabinoside and arsenic trioxide chemotherapy in elderly patients has recently been reported with promising results.[560] Such regimens should be explored in patients with MPD-related acute leukemias.

PV occurs infrequently during the childbearing years.[554–562] When it does, it has been reported to lead to an increased incidence of fetal wastage, with 30% of pregnancies in PV patients terminating in spontaneous abortions.[554–562] In addition, preeclampsia occurs more frequently in these women.[554–562] Pregnancy in PV patients is frequently associated with a gradual normalization of blood values, and it is not unusual for a woman who has required extensive therapy for control of her disease to no longer require phlebotomies during pregnancy.[561–565] Delivery appears not to be complicated by excessive hemorrhage or by an increased risk of venous thrombosis.[561–565]

The normalization of the hematocrit level during pregnancy in PV has been associated with lowering of the red cell mass into the normal range in the few patients in whom these measurements have been performed. Although some degree of hematocrit level normalization can be explained by expansion of the plasma volume or by nutritional deficiencies that occur during pregnancy, it is unlikely that these factors can be solely responsible. It seems more reasonable to assume that the high estrogen levels characteristic of pregnancy suppress erythropoiesis. In the few male patients with PV who have been treated with estrogen, suppression of red cell production has been noted. After termination of the pregnancies, the patients' hematologic values slowly drift back to their previously elevated values in parallel with the return to normal estrogen levels. Because pregnancy is usually associated with spontaneous control of the polycythemic state, no specific therapy is required, except for careful observation. If needed, therapy should be limited to phlebotomy and low-dose aspirin therapy because of the mutagenic effects of chemotherapeutic agents.[240] If this management strategy therapy is unsuccessful, interferon therapy is suggested because it is not known to be leukemogenic or teratogenic and does not cross the placenta.[499] In the puerperium, thromboprophylaxis with 6 weeks of low-molecular-weight heparin therapy is recommended.[562] Aggressive intervention with hematocrit level control and aspirin therapy with low-molecular-weight heparin is associated with a feasible outcare for the pregnancy.[562]

Because PV is ultimately a stem cell disorder, it should be possible to achieve cure with stem cell transplantation.[558,566–568] Thus far, the majority of patients undergoing allogeneic stem cell transplantation have been relatively young (<50 years of age), and have been transplanted either in the "myelofibrotic" or after transformation to acute leukemia.[563–565] In the largest study reported thus far, 36 of 56 patients (64%) with myelofibrosis of various etiologies (including 5 with antecedent PV) are alive for a median of 2.8 years following transplantation.[566] Acute graft-versus-host disease occurred in 68% of patients, and chronic graft-versus-host disease in 59%. Transplantation-related mortality rates were low among patients with marrow fibrosis, but substantial among patients with leukemic transformation, due perhaps to either the biology of the disease itself or to the induction chemotherapy required pretransplantation.[566] Recent promising studies suggest that reduced-intensity conditioning may be better tolerated by older patients who progress to PV related MF before transformation to acute leukemia.[567–569] Transplantation during the polycythemia phase of the disease is rarely appropriate.

Development of JAK2 Inhibitors and Their Implications for the Treatment of PV

The identification of *JAK* mutations in PV has raised the exciting prospect of developing specific JAK2V617F inhibitors to treat PV patients. Given the remarkable clinical success of imatinib therapy for the treatment of *BCR–ABL*-positive CML,[570] *FIP1L1–PDGFR*-positive hypereosinophilic syndrome,[571] and chronic myelomonocytic leukemia associated with *PDGFR*β rearrangements,[572] and the rapid development of second-generation BCR–ABL inhibitors for imatinib-refractory CML,[573,574] the expectations that discovery of *JAK2V617F* will facilitate the development of a molecularly targeted therapy for PV have been heightened.

Although JAK kinase inhibitors with specific activity against JAK2 have been previously identified and characterized,[575] most of these compounds do not have sufficient potency (eg, cellular IC_{50} < 1–2 μM) to be used for preclinical and clinical testing. An enormous amount of effort is currently being expended to identify a specific inhibitor of JAK2V617F. Recently two tyrosine kinase inhibitors currently used clinically, erlotinib[576] and Cephalon-701 (CEP-701),[577] have been identified that inhibit JAK2V617F. Erlotinib (Tarceva) is a kinase inhibitor that inhibits epidermal growth factor receptor-related tyrosine kinase activity. Erlotinib has been used in the treatment of non-small-cell lung cancer and pancreatic cancer associated with mutations of epidermal growth factor receptor.[578] Recently, Li et al have shown that erlotinib also is a potent inhibitor of JAK2V617F activity.[576] In vitro colony assays revealed that erlotinib at micromolar concentrations effectively suppressed the proliferation of PV erythroid progenitor cells while having little effect on normal cells.[576] CEP-701 is an orally active inhibitor of the receptor tyrosine kinase Flt-3 and is currently in phase III clinical trials in

patients with AML associated with Flt-3 mutations.[579] Dobrzanski et al recently reported the ability of CEP-701 to inhibit JAK2V617F and to suppress the growth of cells from patients with MPD.[577] A hundred nanomoles of CEP-701 inhibited the growth of over 50% of $CD34^+$ cells isolated from patients with MPD, but did not affect the proliferation of normal cells.[577] Multiple academic groups and pharmaceutical companies are actively working on additional novel JAK2 inhibitors with even more favorable pharmacokinetic and pharmacodynamic properties.

There are several issues that need to be addressed before JAK2 inhibitors can be used for the treatment of chronic MPDs: (a) It has been shown that loss-of-function mutations involving JAK3 and the tyrosine kinase Tyk2 are associated with inherited forms of severe combined immunodeficiency and that JAK3-specific inhibitors are effective immunosuppressive agents.[580] It is, therefore, critical for a candidate JAK2 inhibitor to have minimal inhibitory activity against Tyk2 and JAK3. JAK2 inhibitors with significant inhibitory activity against JAK3 and Tyk2 at pharmacologic doses might suppress cell-mediated immunity, leading to an unacceptable incidence of opportunistic infection. (b) The JAK2 inhibitors should have preferential activity against mutant rather than WT *JAK2* to avoid significant hematological toxicity. Wild-type JAK2 function is indispensable for definitive hematopoiesis, and specifically for erythropoiesis.[581] Thus an agent that inhibits JAK2 might cause dose-dependent cytopenias, particularly anemia. (c) Since the management of many patients with PV with conventional therapies, including venesection, aspirin, and hydroxyurea are associated with a reasonable outcome at relatively modest costs, a cost–benefit analysis of the use of a potentially expensive long-term targeted therapy will be required. (d) The role of JAK2V617F as the initiating event in PV pathophysiology is not as yet clear, and the potential impact of JAK2-directed therapy is uncertain. (e) It has been shown that the blast cells of patients with acute leukemia that develop after an MPD are in about 50% of cases negative for JAK2V617F even if the patient was JAK2V617F positive prior to the malignant transformation.[425–428] It is possible that the use of JAK2V617F inhibitors would promote the proliferation of clones responsible for leukemic transformation by eliminating the JAK2V617F-positive clone. (f) Given the important role of JAK2 signaling in prolactin- and growth hormone-mediated signal transduction, it is possible that endocrine side effects might occur in patients treated with JAK2 inhibitors.[486]

Allele-specific assays such as allele-specific PCR,[82] pyrosequencing,[80] and quantitative real-time PCR[276] can precisely quantitate *JAK2V617F* mutational burden. Such quantitative assessments of *JAK2V617F* mutational burden has clearly been used to demonstrate that the *JAK2V617F* mutant clone persists in PV patients treated with imatinib and interferon-α.[582] Given the need to assess response to therapy with molecular targeted agents, quantitative assays for *JAK2V617F* should be used to follow tumor burden in trials of JAK2 inhibitors. It is imperative that these assays be validated as surrogate assays predictive of long-term survival or reduction of complications associated with PV.

PROGNOSIS

The prognosis of a patient with PV depends on the nature and severity of the complications that occur during the clinical course of that particular patient's disorder.[12,296,297,417–420,531] In addition, an individual patient's prognosis depends on the duration of the erythrocytotic phase or the time for transition to PPMM or acute leukemia.[12,153] Survival is also influenced by whether appropriate treatment is instituted during the erythrocytotic phase of the illness. Patients who have uncontrolled erythrocytosis are at an extremely high risk for the development of thromboses.[12,296,297,417–420,531] The median survival from onset of symptoms may be as short as 1.5 years in untreated patients.[207] Determination of the optimal management of patients with PV has been a difficult task, as the disease, when treated, is associated with a survival period of 10 to 15 years.[12] Studies of new potential therapeutic interventions therefore require prospective studies with prolonged follow-ups before meaningful results can be generated.[302,303]

Table 68–9 Risk Stratification in Polycythemia Vera Based on Thrombotic Risk

Risk Category	Age >60 y or History of Thrombo\sis	Cardiovascular Risk Factors*
Low	No	No
Intermediate	No	Yes
High	Yes	

*Hypertension, hypercholesterolemia, diabetes, smoking (see text). Extreme thrombocytosis (platelet count >1500 × 10^9 L^{-1}) is a risk factor for bleeding. Its role as a risk factor for thrombosis is uncertain. Increasing leukocyte count has been identified as a novel risk factor for thrombosis, but confirmation is required.

Data from Finazzi G, Barbui T: How we treat patients with polycythemia vera. Blood 2007 Jan 30 [Epub ahead of print].

Increasing age and history of vascular events have consistently proven to be independent predictors of developing additional thromboses in patients with PV. In the ECLAP trial, the incidence of cardiovascular complications was higher in patients older than 69, patients with a prior history of thrombosis, and patients with a WBC higher than 15,000 × 109 L^{-1}. Conventional cardiovascular risk factors including hypertension, hyperlipidemia, diabetes, and smoking are assumed to be associated with the same relative risk of developing thrombosis in PV patients as that observed in the general population. Although practicing hematologists are frequently concerned about elevated platelet counts in PV patients, both the PVSG 01 trial and the ECLAP trial failed to show any association between platelet count and thrombotic events, suggesting that therapies in PV targeting reduction of platelet numbers are ill conceived.

These data have led to stratification of therapy in patients with PV based on clearly identifiable risk factors (Table 68–9).[349] The development of acute leukemia was a relatively rare event in PV occurring in 22 of 1638 patients in the ECLAP observational study after a median of 8.4 years from the time of diagnosis.[425] Older age as well as treatment with P32, busulphan, and pipobroman was associated with a four- to eightfold increased risk of developing acute myeloid leukemia of a myelodysplastic syndrome, as compared to patients treated with phlebotomy alone, hydroxyurea, or interferon. For reasons not presently understood, patients presenting with PV and a low blood cholesterol are at an especially high risk for developing acute leukemia.[425]

Recently, the effect of JAK2V617F allele frequency on the prognosis of PV patients has been examined.[401,402] Over 95% of patients with PV are JAK2V617F positive and their mutational load can be determined by allele-specific PCR.[402] Approximately 30% of PV patients have a high JAK2V617F burden (>50%) and the remainder have a lower burden (<50%), with the small numbers being wild-type. Two groups have recently reported that high burdens of JAK2V617F in PV patients is associated with larger splenic volumes, more frequent aquagenic pruritus, and a higher rate of evolution into myelofibrosis.[401,402] A high burden of JAK2V617F, although associated with higher hematocrit levels and white cell counts, were not associated with a higher incidence of thrombosis or a shorter survival.

FUTURE DIRECTIONS

The discovery of JAK2V617F mutations has led to a more comprehensive understanding of the pathophysiology of this clonal neoplastic disorder. The use of JAK2V617F assays as diagnostic tools has dramatically changed the manner in which PV is diagnosed. The use of JAK2V617 and a variety of other biomarkers including PRV-1, cMPL, and cytogenetic abnormalities may prove useful in better identifying patients at risk of developing fatal thrombotic

events. Furthermore, JAK2V617F is being pursued as a target for the rational identification of small molecule therapies for the treatment of PV. Furthermore, JAK2V617F allele chimerism is being used as a means of quantitating tumor burden in patients treated with JAK2V617F inhibitors or pegylated forms of interferon-α. The relationship between JAK2V617F burden and disease outcome must be carefully validated before it can be used as a surrogate biomarker for more rapid approval of drug therapies for PV. Randomized clinical trials of such novel agents comparing these outcomes with the standard of care are clearly required in order to be certain that they represent significant advances in the treatment of PV patients.

CHAPTER 69

CHRONIC MYELOID LEUKEMIA

Ravi Bhatia and Jerald P. Radich

BACKGROUND

Chronic myeloid leukemia (CML) is a hematopoietic malignancy originating from transformation of a primitive hematopoietic cell. Without treatment, CML progresses from an initial chronic phase (CP) characterized by marrow hyperplasia and increased numbers of circulating differentiated myeloid cells followed by advanced phases of disease (accelerated phase [AP] and blast crisis [BC]) marked by a block in differentiation, an accumulation of blasts, and a depletion of normal hematopoietic cells, especially white blood cells and platelets. CML was the first malignant disease found to be consistently associated with a specific cytogenetic abnormality, the Philadelphia chromosome (Ph), resulting in the formation of the *BCR–ABL* fusion oncogene. Study of *BCR–ABL* has led to sensitive methods to detect residual disease and predict outcome and to "targeted" therapy aimed at inhibiting abnormal tyrosine kinase activity resulting from the *BCR–ABL* fusion oncogene. In addition, CML was one of the first diseases demonstrated to be curable by hematopoietic cell transplantation (HCT). Thus, CML has become the model for "tailored" therapy, where various treatments can be escalated on the basis of molecular response.

ETIOLOGY/EPIDEMIOLOGY/GENETICS

Chronic myelogenous leukemia was recognized as a distinct entity, associated with massive splenomegaly and leukocytosis without other explanations, in the mid-1800s. The modern history of CML was initiated by Nowell and Hungerford in 1960. They used newly developed techniques to detect a small chromosome in metaphase preparations of marrow cells from CML patients.[1] This abnormal chromosome was the first consistent chromosomal abnormality in human malignancies and was termed the Philadelphia chromosome after the city of its discovery. Rowley showed that the Philadelphia chromosome resulted from a translocation between chromosomes 9 and 22 [t(9; 22)(q34;q11)].[2] The genes involved in this translocation were cloned in the 1980s, and the t(9:22) translocation was shown to result from the fusion of the BCR (breakpoint cluster region) gene on chromosome 22 to the *ABL* (Abelson leukemia virus) gene on chromosome 9, with formation of the *BCR–ABL* fusion oncogene.[3] This oncogene codes for a constitutively active cytoplasmic tyrosine kinase, which is now believed to be the principal cause of the chronic phase of CML. Until the 1970s, CML was regarded as an incurable and inevitably lethal disorder. It was then recognized that selected patients can be cured, by allogeneic HCT. However, transplantation therapy for CML is limited by donor availability and the risk of life-threatening toxicity. More recently, imatinib mesylate, a tyrosine kinase inhibitor that specifically blocks the enzymatic action of the abnormal tyrosine kinase coded by the fusion oncogene, has resulted in a high rate of remission and improved survival in CML patients.

Chronic myelogenous leukemia is the most common of the myeloproliferative diseases and represents 15% to 20% of all new leukemia cases.[4] The annual incidence of CML is 1 to 1.5 cases per 100,000 population per year. The median age at diagnosis is 67 years and the incidence sharply rises with age. The disease occurs slightly more often in men than in women. Chronic myelogenous leukemia may occur in children but only approximately 10% of cases occur in subjects between 5 and 20 years of age, and represent only 3% of all childhood leukemias. Concordance of disease is not observed between identical twins.[4] Radiation may play a role in some cases, because persons exposed to high-dose irradiation, including survivors of the atomic bomb, have a significantly increased risk of leukemia, and high-dose irradiation of myeloid cell lines in vitro induces the expression of BCR–ABL transcripts indistinguishable from those that characterize CML.[5] The BCR–ABL gene has been reported to be detectable at very low levels in a high proportion of healthy individuals using a very sensitive PCR assay.[6] These findings suggest that fusion genes may develop relatively frequently in hematopoietic cells, but only infrequently lead to development of leukemia. The mechanism by which the Ph chromosome is first formed and the time required for progression to overt disease are unknown.

PATHOPHYSIOLOGY

CML is generally believed to develop from transformation of a primitive hematopoietic stem cell (HSC) by the *BCR–ABL* fusion gene.[7] The progeny of transformed HSC have a proliferative advantage over normal hematopoietic cells, thus allowing the Ph-positive clone gradually to displace residual normal hematopoiesis. The translocation is found in cells of myeloid, erythroid, megakaryocytic and B-lymphoid origin, consistent with a hematopoietic stem cell origin of the disease.[8–10] Hematopoietic expansion in patients with chronic-phase disease primarily involves an increase in myeloid cell mass, which is related to an expansion of mature cells as well as increased numbers of precursor and progenitor cells. In chronic phase, the leukemic cells are minimally invasive and are primarily located in hematopoietic tissues including blood, bone marrow, spleen, and liver. The proliferative advantage of the malignant clone may be related to enhanced responsiveness to hematopoietic growth factors and/or reduced response to inhibitory factors.[11–14] Chronic myelogenous leukemia progenitors also demonstrate defective adhesion to marrow stromal cells and extracellular matrix.[15] Altered microenvironmental interactions may contribute to another feature of CML, which is abnormal progenitor trafficking with increased numbers of circulating progenitors and extramedullary hematopoiesis. Several observations indicate that although the Ph-positive clone displaces normal hematopoiesis, it does not destroy residual normal stem cells. For example, Ph-negative progenitors can be seen after cultures of CML cells in vitro,[16,17] can be selected on the basis of cell surface phenotype,[18] and can be identified in the blood after high-dose chemotherapy.[19] As described later in the Therapy section, treatment with agents such as interferon (IFN) or imatinib mesylate can result in restoration of Ph-negative hematopoiesis in CML patients.

The *BCR–ABL* gene that characterizes CML results from a chromosomal translocation that results in the fusion of the *ABL* gene on chromosome 9 and the *BCR* gene on chromosome 22 (Fig. 69–1). The translocation is related to a break in *ABL* upstream of exon a2, and in the major breakpoint cluster region of the *BCR* gene. This leads to juxtaposition of a 5′ portion of *BCR* and a 3′ portion of *ABL* on a shortened chromosome 22 (the derivative 22q-, or Ph).[3,20–22] The resulting messenger RNA (mRNA) usually contain one of two *BCR–ABL* junctions, designated e13a2 (formerly b2a2) and e14a2 (or b3a2).[23] Both *BCR–ABL* mRNA molecules are translated into a

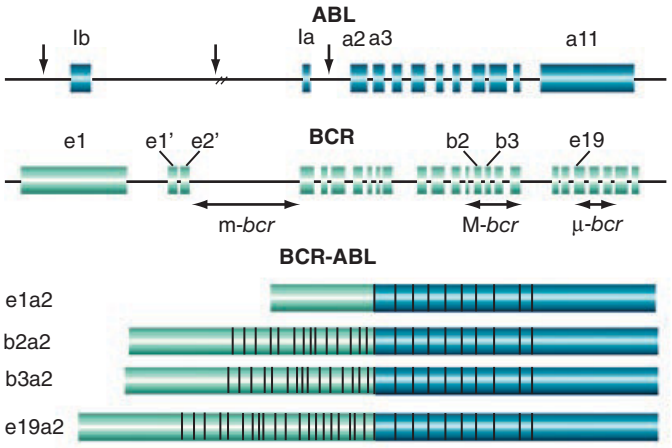

Figure 69–1 Locations of the breakpoints in the *ABL* and *BCR* genes and structure of the chimeric mRNAs derived from the various breaks. (Adapted from Deininger MW, Goldman JM, Melo JV (eds) The Molecular Biology of Chronic Myeloid Leukemia. Blood 96 (10): 3343, 2000.)

210-kd fusion protein, referred to as p210*BCR–ABL*. Rarely, other variant breakpoints and fusions can give rise to full-length, functionally oncogenic *BCR–ABL* proteins, notably p190*BCR–ABL* (associated with an e1a2 mRNA junction) and p230*BCR–ABL* (associated with an e19a2 mRNA junction).[24] Of patients with CML who have a normal-appearing karyotype, one-third have a cytogenetically occult *BCR–ABL* gene, usually located on a normal-appearing chromosome 22 but occasionally on chromosome 9. In the remaining patients with Ph-negative, *BCR–ABL*-negative disease, the molecular basis of leukemia is not known.

Some studies have suggested that pathogenesis of CML may be multistep, with development of clonal hematopoiesis preceding the t(9;22) translocation.[8,25] However there is substantial evidence to suggest that the generation of a classic *BCR–ABL* fusion gene in a hematopoietic stem cell is sufficient to initiate CML. Expression of *BCR–ABL* has been shown to transform mouse fibroblast cell lines, growth factor-dependent hematopoietic cell lines, and primary murine bone marrow cells.[26] Expression of *BCR–ABL* in human $CD34^+$ cells also causes increased proliferation, reduced apoptosis and altered adhesion and migration mimicking alterations seen in progenitor cells from CML patients.[27] Transplantation of murine bone marrow cells made to ectopically express the *BCR–ABL* gene by retroviral transduction induces a myeloproliferative disorder (MPD) that closely resembles human CML with increased numbers of peripheral-blood cells (with a predominance of granulocytes), splenomegaly, and extramedullary hematopoiesis, although the disease is much more fulminant than human CML.[28,29] Initial development of transgenic and knockin mouse models of CML was problematic. It appears to be crucial to express this oncogene in the proper cell type. Expression of BCR–ABL in B-cell lymphocytic and megakaryocytic precursors resulted in the development of B-acute lymphocytic leukemia (B-ALL) and megakaryocytic myeloproliferative syndrome.[30–32] Specific expression of the oncogene in hematopoietic stem cells through a stem cell leukemia (SCL) enhancer to regulate expression induces development of a CML-like disease.[33] Together, these studies indicate that *BCR–ABL* expression alone is sufficient to induce chronic-phase CML-like disease in mice.

The *ABL* gene encodes a nonreceptor tyrosine kinase that is expressed in most tissues (Fig. 69–2). Mice with homozygous disruption of the *ABL* gene demonstrate increased perinatal mortality, lymphopenia, and osteoporosis and are smaller, with abnormal head and eye development.[34] The *BCR* gene also encodes a signaling protein that contains multiple modular domains (Fig. 69–2). Although *BCR*-deficient mice develop normally, their neutrophils produce excess levels of oxygen metabolites following activation.[32,35] The normally regulated tyrosine kinase activity of the *ABL* protein is constitutively activated by the juxtaposition of N-terminal *BCR* sequences. *BCR* acts by promoting protein dimerization, leading to phosphorylation of tyrosine residues in the kinase-activation loops and leading to constitutive activation of kinase activity. The fusion of *BCR* sequences to *ABL* also adds new regulatory domains/motifs to *ABL*, such as the growth factor receptor-bound protein 2 (GRB2) SH2-binding site. The uncontrolled kinase activity of *BCR–ABL* and enhanced interaction with a variety of effector proteins leads to deregulation of cell signaling mechanisms that regulate proliferation. The *ABL* protein is found in both the nucleus and the cytoplasm and shuttles between these two compartments, whereas the *BCR–ABL* is exclusively cytoplasmic and localizes to the cytoskeleton where it appears to contribute to adhesion and migration abnormalities.[36]

The structure of the *BCR–ABL* protein and the biochemical pathways affected have been extensively studied (see Fig. 69–2).[36] However, most such interactions have been studied only in cell lines and conditions of forced overexpression. Their existence in primary leukemia cells and relevance to CML pathogenesis is not certain. The murine transduction–transplantation CML model has been helpful in studying the role of *BCR–ABL* domains and signaling interaction in primary hematopoietic cells. However, the murine CML model is not fully representative of human CML, and the role of different domains in development of disease in CML patients still needs to be confirmed. The *ABL* tyrosine kinase is crucial for oncogenic transformation. Mice that express a form of *BCR–ABL* with a point mutation in the ATP-binding site of *ABL* that inhibits its kinase activity do not develop leukemia. This suggests that the *ABL* kinase activity is essential for *BCR–ABL* leukemogenesis in vivo. The success of kinase inhibitor therapy for CML provides further proof of the importance of kinase activity in maintenance of human disease. Other important domains in *BCR–ABL* have also been shown to regulate the kinase activity of *ABL* or connect to other downstream signaling pathways. The amino-terminal coiled-coil (CC) oligomerization domain of *BCR* is an important activator of *ABL* kinase activity, and also promotes the association of *BCR–ABL* with F-actin fibers.[37,38] Phosphorylation of *BCR* at tyrosine 177 generates a GRB2-binding site, which is important for *RAS* activation. Mutation of the tyrosine-177 residue of *BCR–ABL* to phenylalanine (Y177F) largely abolishes its ability to bind GRB2, without affecting the kinase activity of ABL. The Y177F mutant has a greatly reduced ability to induce MPD in mice.[39] A tyrosine phosphorylation site in the activation loop of the *ABL* kinase domain and the SH2 domain of *ABL* also contribute to *RAS* activation. Mutations in the SH2 domain of *ABL* and a Y1294F point mutation reduce the ability of *BCR–ABL* to induce a CML-like MPD in mice.[40] The carboxy-terminal region of *ABL* is required for the proper function of normal *ABL*. However, deletion of the *ABL* actin-binding domain was reported to not affect the ability of *BCR–ABL* to induce CML-like MPD in mice, suggesting that this domain may be dispensable for *BCR–ABL*-mediated leukemogenesis.[41] Certain *BCR–ABL* domains may have complementary or overlapping functions.

Many signaling proteins become phosphorylated in *BCR–ABL*-expressing cells and/or to interact with *BCR–ABL* through various functional domains. These interactions may in turn activate signaling through mechanisms including *RAS*, *PI3K*, *AKT*, *JNK*, and *SRC* family kinases, protein phosphatase, STATs, nuclear factor-B and *MYC*. *BCR–ABL* also induces expression of cytokines such as interleukin-3 (IL-3), granulocyte colony-stimulating factor (G-CSF), and granulocyte–macrophage colony-stimulating factor (GM-CSF).[36] A CML-like MPD was still induced following expression of *BCR–ABL* in bone marrow cells from *Stat5a*$^{-/-}$*Stat5b*$^{-/-}$, *Cbl*$^{-/-}$, and *Il-3*$^{-/-}$*GM-CSF*$^{-/-}$ mice, indicating that these proteins may not be required for *BCR–ABL*-mediated leukemogenesis.[42,43] *BCR–ABL* expression induced CML-like MPD but failed to induce B-ALL in mice that lacked the *SRC* family kinases LYN, HCK, and FGR, indicating the potential importance of the kinases in lymphoid blast crisis or ALL but not for MPD.[28,44] Disruption of the gene encoding IFN consensus sequence-binding protein (*ICSBP*) results in the development of a CML-like disease in mice. Forced expression of *ICSBP* inhibits *BCR–ABL*-induced CML-like disease.[45] Downregulation of *ICSBP* transcripts was also found in patients with CML, and this reduction

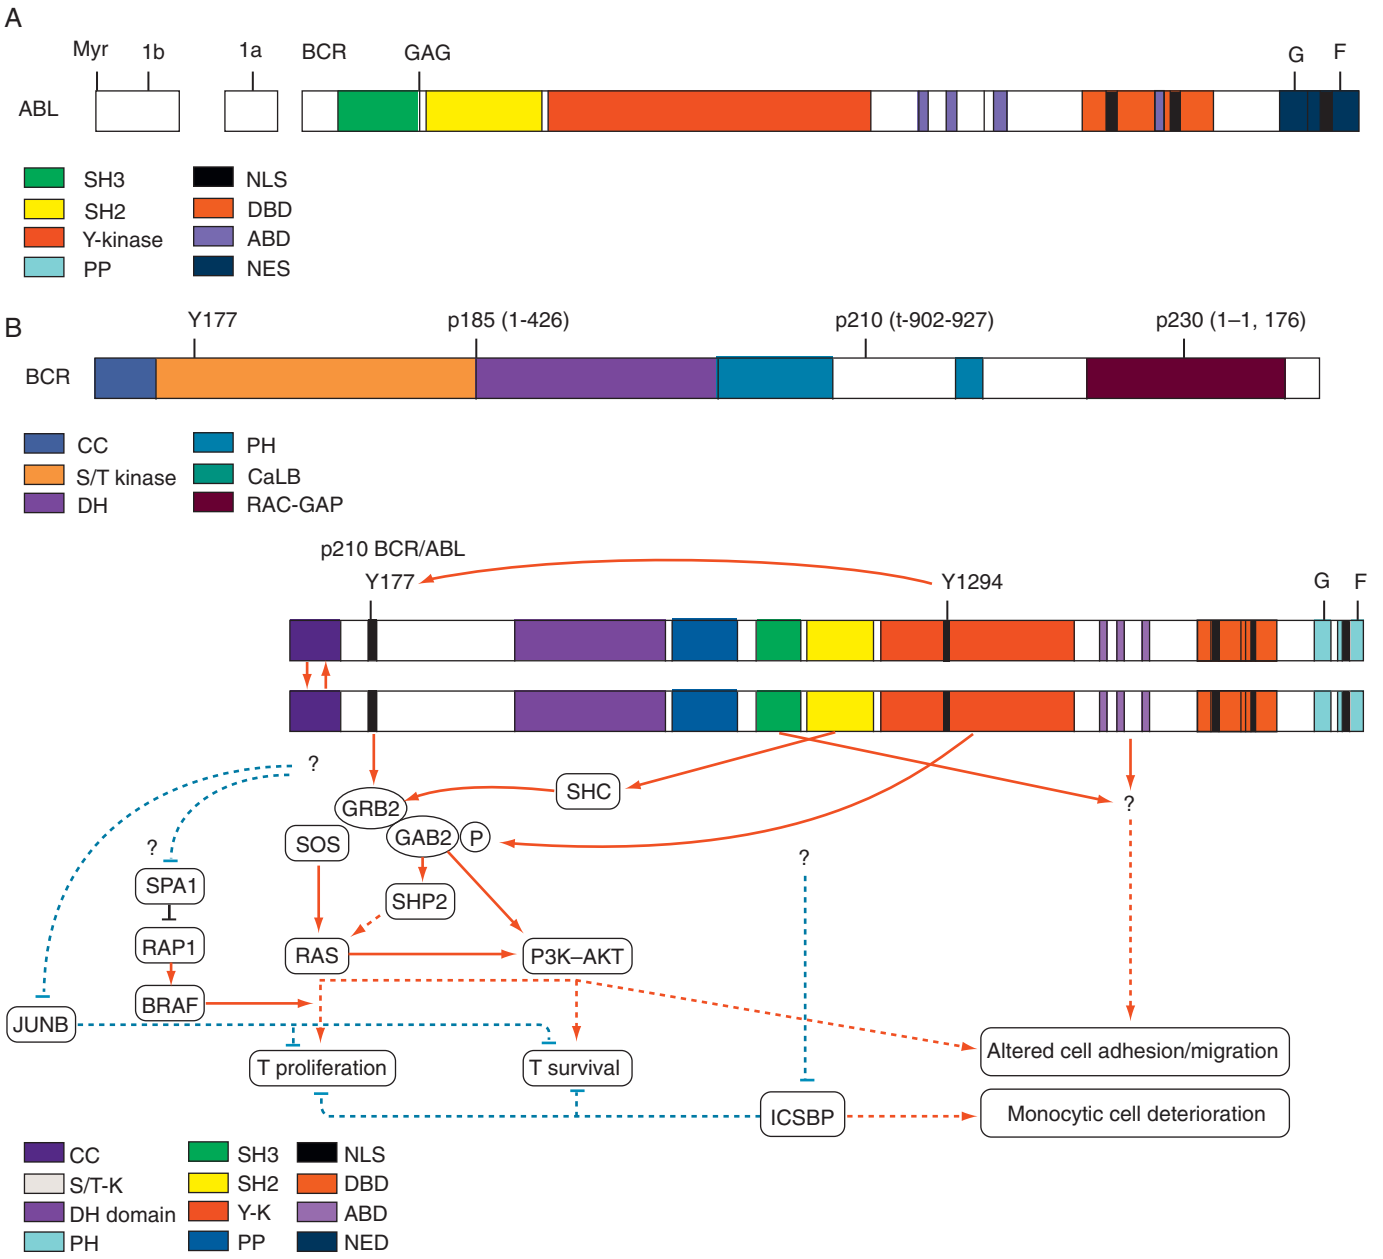

Figure 69–2 **A**, The *ABL* and *BCR* proteins. Several important domains make up the *ABL* and *BCR* proteins. Two isoforms of *ABL* (human types 1a and 1b) are generated by alternative splicing of the first exon, one of them (1b) contains a myristoylation modification site (Myr). The amino-terminal half of ABL contains tandem SRC homology 3 (SH3), SH2, and the tyrosine-kinase (Y-kinase) domains. These domains can assemble into an autoinhibitory structure, in which the SH3 and SH2 domains hold the kinase in the "off" state. In its carboxy-terminal region, *ABL* contains four proline-rich SH3-binding sites (PPs), three nuclear localization signals (NLSs), one nuclear exporting signal (NES), a DNA-binding domain (DBD), and an actin-binding domain (ABD). The actin-binding domain contains binding sites for both monomeric (G) and filamentous (F) forms of actin. The points in ABL that fuses with BCR and GAG (for v-Abl) are indicated. **b |** *BCR* contains a coiled-coil (CC) oligomerization domain, a serine/threonine (S/T) kinase domain, a Dbl/CDC24 guanine-nucleotide exchange factor homology (DH) domain and a pleckstrin homology (PH) domain, a putative calcium-dependent lipid-binding site (CaLB), and an RAC guanosine triphosphatase-activating protein (RAC-GAP) domain. *BCR* also contains binding sites for growth factor receptor-bound protein 2 (GRB2) at tyrosine 177 (Y177), as well as for the GRB10, 14–3-3, and the *ABL* proteins, through its SH2 domain. p185, p210, and p230 indicate the points at which *BCR* most commonly fuses to *ABL*. These forms are associated with acute lymphoblastic leukemia, chronic myelogenous leukemia (CML) and a milder form of CML, respectively. The number of amino acids in each form are indicated in parentheses. **B**, Leukemogenic signaling of BCR–ABL. The BCR–ABL proteins can form dimers or tetramers through their CC domains, and trans-autophosphorylate. Phosphorylation at Y177 generates a high-affinity binding site for growth factor receptor-bound protein 2 (GRB2). GRB2 binds to *BCR–ABL* through its SH2 domain and binds to SOS and GRB2-associated binding protein 2 (GAB2) through its SH3 domains. SOS in turn activates *RAS*. Following phosphorylation (P) by *BCR–ABL*, GAB2 recruits phosphatidylinositol 3-kinase (PI3K) and SHP2 proteins. The SH2 domain of ABL can bind SHC, which following phosphorylation can also recruit GRB2. The *ABL* SH3 domain and the SH3-binding sites in the carboxy-terminal region can bind several proteins that involve regulations of cell adhesion/migration. *BCR–ABL* can promote cell proliferation and survival partly by activating the *RAS, SHP2 and PI3K-AKT* signaling pathways. It can also downregulate transcription of *ICSBP* and *JUNB* and might also inhibit *SIPA1*. Red arrows indicate direct interactions and/or activations. Black arrows indicate negative regulations. Broken arrows indicate multiple steps. (From Ren R: Mechanisms of *BCR–ABL* in the pathogenesis of chronic myelogenous leukaemia. Nat Rev Cancer 5(3):172, 2005.)

could be reversed by treatment with IFN-α. These data suggest that downregulation of *ICSBP* is important for the pathogenesis of CML.

Progression to accelerated phase and blast crisis is associated with increase in immature blast cells that may be located within hematopoietic tissues or may infiltrate a number of extramedullary sites, including lymph nodes, skin, soft tissue, and the central nervous system. A variety of molecular mechanisms, rather than a single gene defect, is likely to underlie the arrest of maturation, enhanced proliferation and survival, and increased tissue invasiveness that characterize blast crisis CML.[46] Increased level of *BCR–ABL* expression is a common feature and appears to be a key factor in the development of features of blast crisis, through effects on cell signaling and on transcription and translation of important regulatory genes. Disease progression is believed to be related to increased susceptibility of the *BCR–ABL*-expressing clone to additional molecular changes, and additional cytogenetic and molecular changes are frequently found in patients with CML during the progression of the disease from chronic to blast phase. Genetic instability in CML appears to be related to several factors, including increased oxidative stress, reduced DNA repair, or reduced DNA damage checkpoint signaling response. Genetic changes observed in leukemic cells from blast-phase CML patients include nonrandom cytogenetic changes, including +8, +Ph, +19, and I(17)q, identified in 60% to 80% of patients with disease; point mutations in genes, including in *TP53*, *RB*, and *CDKN2A* (*p16*^{INK4A}); and overexpression of genes such as *EVI1* and *MYC*. Additional chromosome translocations are also observed, such as t(3;21)(q26;q22), which generates *AML1–EVI1*. Other CML-associated fusion genes include *AML1–ETO*, which results from the t(8;21)(q22;q22) translocation; *NUP98–HOXA9*, which results from the t(7;11)(p15;p15) translocation; and *CBF*β*–SMMHC*, which results from inv(16)(p13;q22). These observations suggest that the block in myeloid differentiation in blast crisis may involve cooperation between *BCR–ABL* and defects in hematopoietic transcriptional regulators. Gene expression analyses suggest that the progression of CML from CP to advanced phase may be a two-step rather than a three-step process, with new gene expression changes occurring early in accelerated phase before the accumulation of increased numbers of leukemia blast cells. Especially noteworthy and potentially significant in the progression program were the deregulation of the *WNT*/beta-catenin pathway, the decreased expression of *JUN B* and *FOS*, and alternative kinase deregulation. Other studies suggest that the granulocyte/macrophage progenitor (GMP) pool is expanded in patients with blast-phase CML, and that these cells have increased levels of *BCR–ABL* expression and increased *WNT* signaling activity that may lead to increased self-renewal capacity. It is suggested that GMP cells might be transformed into leukemic stem cells during blast-phase CML, although these findings and the role of *WNT* signaling need to be confirmed.[47,48]

CLINICAL FEATURES

History

Most (>90%) CML patients present in chronic phase (CP). CML is often diagnosed incidentally during routine examination or examination for another illness. Symptoms usually include fatigue, weight loss, bone pain, sweating, and abdominal discomfort and early satiety related to splenomegaly. Symptoms are generally gradual in onset over weeks to months. Uncommon presenting symptoms include those related to leukostasis, acute abdominal pain related to splenic infraction, priapism, and hypermetabolism, hyperuricemia, and gouty arthritis.

Physical Examination

Physical examination may detect pallor and splenomegaly. The incidence of splenomegaly used to be greater than 90% at diagnosis but has been decreasing in frequency as the disease is diagnosed earlier.

Laboratory Findings

Laboratory findings at presentation generally include leukocytosis, thrombocytosis, and anemia (Fig. 69–3). The total leukocyte count is always elevated at the time of diagnosis and is usually over 25×10^9/L. The WBC count rises progressively if patients are left untreated. Striking cyclic variations in WBC counts have been described in rare patients. Differential counts reveal granulocytes at all stages of differentiation in peripheral blood cells. Circulating granulocytes are usually normal in appearance. The blast percentage is between 0.5% and 10%. Neutrophil alkaline phosphatase activity is low or absent in more than 90% of patients. However, activity can increase in response to infection, inflammation, and reduction of counts by treatment. Functional abnormalities of neutrophils are mild and are not associated with predisposition to infection. Although the proportion of eosinophils is usually not increased, the absolute eosinophil count is usually increased. The absolute basophil count is almost always increased in CML. The proportion of basophils is usually less than 15% in chronic-phase patients, but may rarely be higher. In contrast to mastocytosis, hyperhistaminemia is uncommon. The absolute lymphocyte count is increased as a result of an increase in T but not B cells.

The platelet count is elevated in 50% of patients at the time of diagnosis. The platelet count may increase during the course of chronic phase. Platelet dysfunction may occur but disorders of thrombosis and hemorrhage are rare. Thrombocytopenia is rare at diagnosis and usually is a sign of progression toward accelerated phase. A deficiency in the second wave of aggregation to epinephrine is the most common abnormality, and is associated with deficiency of adenine nucleotides in the storage pool. The hematocrit is decreased in most patients at diagnosis. Red cells tend to show only mild alterations with increased variability of size and shape. Small numbers of nucleated red blood cells and mild reticulocytosis may be seen.

Chemical abnormalities seen in patients with untreated CML include hyperuricemia and hyperuricosuria. The formation of urate stones is common and patients with underlying susceptibility may develop acute gouty arthritis or urate nephropathy. Patients have increased serum level of Vitamin B12 binding capacity related to release of Transcobalamin I and II from mature neutrophils. The serum B12 level in CML is an average of 10-fold higher than normal. Serum LDH is elevated in CML. Pseudohyperkalemia may be seen related to release of potassium from WBC during clotting. Spurious hypoglycemia or hypoxemia may result from consumption by neutrophils after a sample is drawn.

Examination of the marrow usually reveals a very hypercellular marrow, with 75% to 90% marrow cellularity (see Fig. 69–3B–F). The granulocytic/erythroid ratio is increased to 10:1 to 30:1, with increased granulopoiesis and reduced erythropoiesis. Eosinophils and basophils may be increased. Blasts usually represent less than 5% of cells. Presence of more than 10% blasts indicates transformation to accelerated phase. Megakaryocytes are typically smaller than usual and may have hypolobated nuclei. Megakaryocyte numbers may be normal or slightly decreased, but 40% to 50% of patients show moderate to extensive proliferation of megakaryocytes. Collagen type III detected by silver staining is typically increased (Fig. 69–3H). Approximately half the patients demonstrate increased reticulin fibrosis which may be associated with increased megakaryocytes in marrow. Increased fibrosis may be associated with larger spleen size, anemia, and increased blasts in blood and marrow. Pseudo-Gaucher cells and sea blue histiocytes, secondary to increased marrow cell turnover, may be seen in 30% of specimens (see H5eC69, Fig. 69–3G). The spleen shows enlargement related to infiltration of the cords of the red pulp with granulocytes at different stages of maturation. The liver may show infiltration with granulocytic cells in the portal areas and hepatic sinusoids.

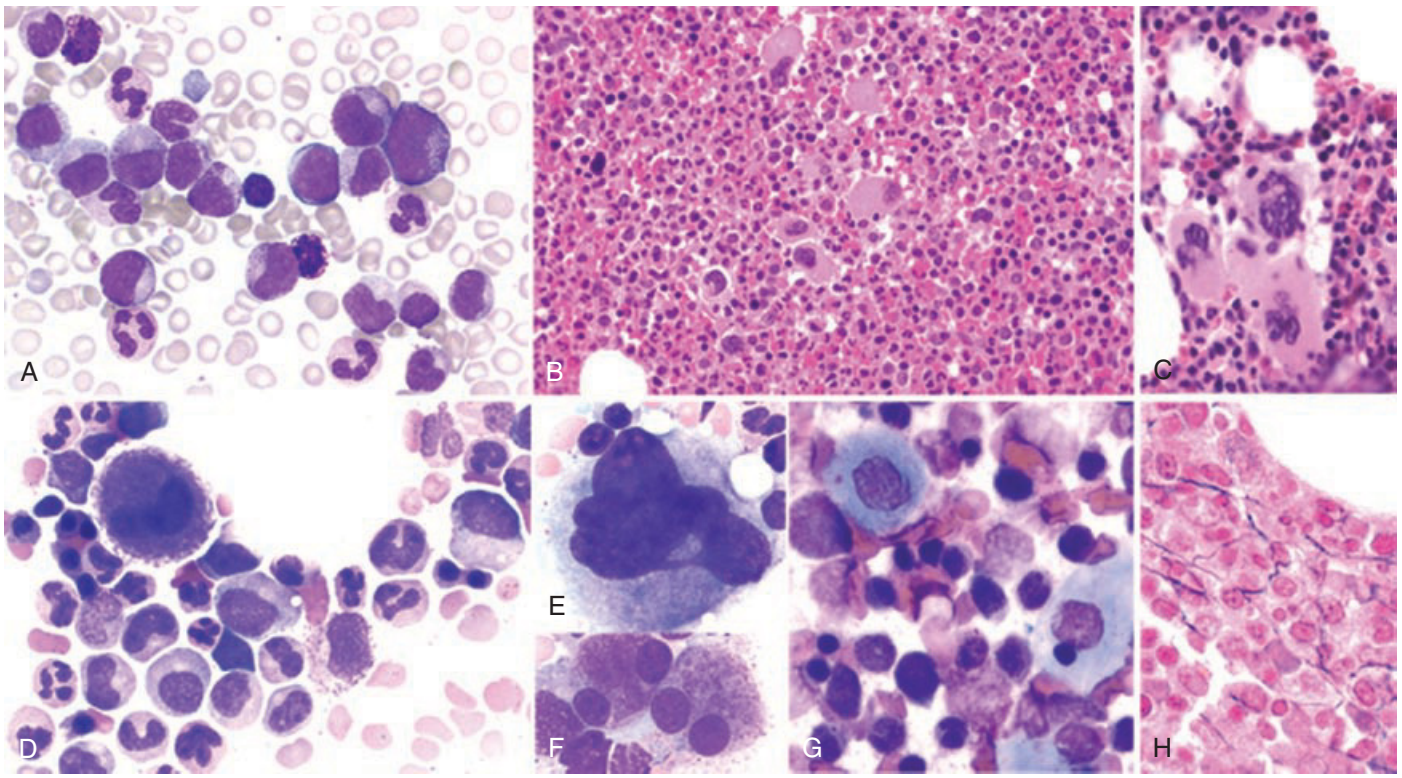

Figure 69–3 Chronic myelogenous leukemia, chronic phase: **A**–**H**. Peripheral smear (**A**) showing marked leukocytosis due to a granulocytic proliferation of all stages with particularly increased myelocytes and absolute basophilia. Bone core biopsy (**B**) illustrating markedly hypercellular marrow due to granulocytic proliferation and increased small hypolobated megakaryocytes. Compare with large megakaryocytes (**C**) from a myeloproliferative disorder other than CML. Bone marrow aspirate (**D**) showing granulocytic proliferation and small, "dwarf" megakaryocyte, compared with large-sized megakaryocyte (**E**) and micro-megakaryocytes (**F**) typical of MDS. Pseudo-Gaucher cells (**G**) and mild fibrosis (**H**) as seen on reticulin stain.

Cytogenetic examination shows t(9;22)(q34;q11) and Ph chromosome in more than 90% of patients. Additional chromosomal abnormalities besides the Philadelphia chromosome are seen at diagnosis in 20% of patients including –Y and +8, and have not been shown to affect disease course. Variant Ph chromosomes are seen in 5% of patients, with complex rearrangement involving exchange of material with an additional chromosome besides chromosomes 9 and 22. In a small proportion of patients cryptic or complex translocations can be detected by fluorescence in situ hybridization (FISH) or polymerase chain reaction (PCR) assays. The methodology used for identifying *BCR–ABL* transcripts has evolved over the years. Initially it was possible only to identify the presence or absence of *BCR–ABL* transcripts by either single-step amplification or a two-step "nested" amplification with internal primers to increase the sensitivity. Real-time quantitative polymerase chain reaction (RQ-PCR) provides an accurate measure of the total leukemia cell mass, and the degree to which *BCR–ABL* transcripts are reduced by therapy correlates with progression-free survival. A consensus meeting at the National Institutes of Health (NIH) in October 2005 made suggestions for (a) harmonizing the different methodologies for measuring *BCR–ABL* transcripts in patients with CML undergoing treatment and using a conversion factor whereby individual laboratories can express *BCR–ABL* transcript levels on an internationally agreed scale; (b) using serial RQ-PCR results rather than bone marrow cytogenetics or FISH for the *BCR–ABL* gene to monitor individual patients responding to treatment; and (c) detecting and reporting Philadelphia (Ph) chromosome-positive subpopulations bearing *BCR–ABL* kinase domain mutations.

In any new patient whose blood count suggests the diagnosis of a chronic myeloproliferative disorder, the detection of *BCR–ABL* transcripts in a blood specimen is probably the best way to confirm the diagnosis of CML. Current guidelines suggest that circulating *BCR–ABL* transcript numbers be measured, and marrow cytogenetics studied in every new patient with CML before initiation of treatment.[49] Marrow cytogenetics is essential to identify any unusual translocations or additional cytogenetic abnormalities, and RQ-PCR for *BCR–ABL* at diagnosis will identify whether the commonly observed e13a2 (b2a2) or e14a2 (b3a2) transcripts are present, or one of the less common fusion transcripts that are not amplified by the standard primer sets. This can prevent confusion if a patient on therapy has undetectable *BCR–ABL* transcripts because their transcripts were not amplified in the standard assay. If collection of marrow cells is not feasible, FISH on a blood specimen using dual probes for the *BCR* and *ABL* genes is another method of confirming the diagnosis. FISH may also detect cytogenetically "silent" *BCR–ABL* rearrangements and also deletions in the derivative 9q+, which have prognostic significance, and may therefore be performed in conjunction with marrow cytogenetics and RQ-PCR for *BCR–ABL* transcripts.

Natural History

The natural history of CML, determined more than 75 years ago, suggests a median survival from diagnosis of approximately 3 years. Without therapy, CML evolves from a chronic to an accelerated phase (AP) and eventually to blast crisis (BC). In approximately 25% of patients, there is no intervening AP between CP and BC (Table 69–1). Median survival times have been significantly prolonged with therapy (discussed below in the Therapy Section).

Accelerated Phase

In general, accelerated phase is characterized by symptoms of fever, night sweats, weight loss and bone pain, difficulty in controlling

counts using conventional therapy, increased numbers of blasts and early myeloid cells in marrow and peripheral blood, and evidence of karyotypic evolution (Fig. 69–4A–C). The WHO classification defines accelerated phase of CML as one or more of the following changes: (a) 10% to 19% myeloblasts in peripheral blood or bone marrow; (b) peripheral blood basophils higher than 20%; (c) persistent thrombocytopenia, less than 100×10^9/L; (d) persistent thrombocytosis, more than 1000×10^9/L unrelated to therapy; (e) increasing WBC count and increasing spleen size unresponsive to therapy; and/or (f) evidence of clonal evolution.[50] The most common cytogenetic changes associated with disease evolution are an additional Ph chromosome, trisomy 8, isochrome I(17q), and trisomy 19.

Table 69–1 WHO Criteria for Accelerated and Blast Phases of Chronic Myeloid Leukemia (CML)

Accelerated phase	Diagnosis can be made if one or more of the following is present: Blasts 10% to 19% of peripheral blood white cells or bone marrow cells Peripheral blood basophils at least 20% Persistent thrombocytopenia (<100×10^9/L) unrelated to therapy, or persistent thrombocytosis (>1000×10^9/L) unresponsive to therapy Increasing spleen size and increasing WBC count unresponsive to therapy Cytogenetic evidence of clonal evolution (ie, the appearance of an additional genetic abnormality that was not present in the initial specimen at the time of diagnosis of chronic-phase CML) Megakaryocytic proliferation in sizable sheets and clusters, associated with marked reticulin or collagen fibrosis, and/or severe granulocytic dysplasia, should be considered as suggestive of CML-AP. (These findings have not yet been analyzed in large clinical studies, however, so it is not clear if they are independent criteria for accelerated phase. They often occur simultaneously with one or more of the other features listed.)
Blast crisis	Diagnosis can be made if one or more of following is present: Blasts 20% or more of peripheral blood white cells or bone marrow cells Extramedullary blast proliferation Large foci or clusters of blasts in bone marrow biopsy

Blast Crisis

The blast phase of CML resembles acute leukemia. Blast crisis is defined as having more than 20% blasts in the bone marrow or peripheral blood, the presence of large aggregates and clusters of blasts in the bone marrow biopsy, or the development of extramedullary blastic infiltrates. In approximately two-thirds of patients, the blasts have a myeloid or undifferentiated-like phenotype whereas in the remaining third the blasts appear more lymphoid-like. Immunophenotypic analysis is recommended to characterize the nature of the blasts (Fig. 69–5A–C). Extramedullary blast crisis most commonly affects the skin, lymph nodes, spleen, bone, or central nervous system, but may occur elsewhere, and may be of myeloid or lymphoid lineage.

PROGNOSIS

A number of prognostic scoring systems have been developed with the goal of predicting the length of chronic phase in individual patients. The best known and widely used index was developed by Sokal et al. An algorithm using spleen size, percentage of circulating blasts, platelet count, and age were identified as prognostic factors for chronic-phase patients.[51] However, the Sokal scale was based on therapies available at that time (busulfan, splenectomy), and newer systems for patients treated with IFN resulted in newer prognostic scoring systems.[52] These scales, however, may have limited predictive value in the age of tyrosine kinase inhibitors.

Approximately 20% of patients with CML have deletions of chromosomal material of varying size on the derivative 9q+.[53] These deletions presumably occur at the same time as the formation of the Philadelphia chromosome, and are thus not considered to be additional clonal changes as would be suggestive of accelerated-phase disease. Patients with der 9q+ have a worse prognosis if they receive IFN therapy; it is unclear whether or not such deletions have a poor prognosis in patients receiving imatinib therapy.[54,55]

THERAPY

Definitions of Response to Treatment

Hematologic, cytogenetic, and molecular response to treatment in CML have been defined (Table 69–2). A complete hematologic remission is defined as the achievement of normal WBC and platelet counts and normal differential, and disappearance of all symptoms

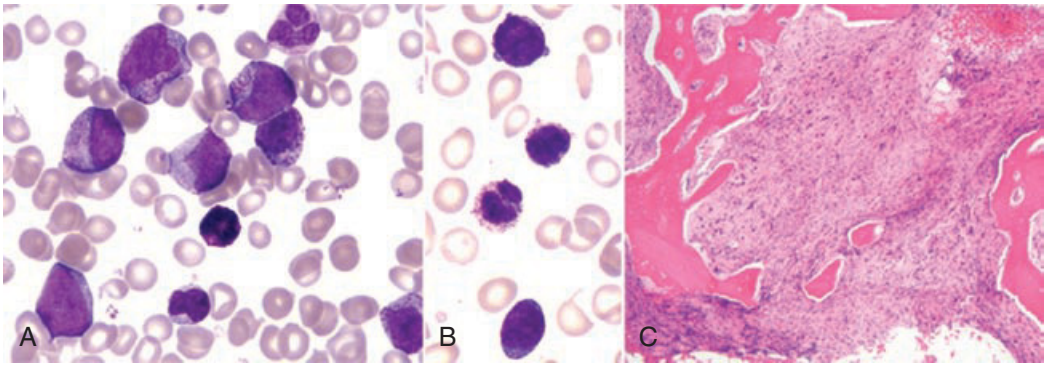

Figure 69–4 Chronic myelogenous leukemia, accelerated phase: **A–C**. Peripheral smear (**A**) showing increased immaturity in a case in which blasts were more than 10% of circulating leukocytes. Peripheral smear (**B**), illustrating increased basophils, in a case in which basophils were more than 20% of circulating leukocytes. Bone core biopsy (**C**) showing increased fibrosis and small dysplastic megakaryocyte. These findings are suggestive of accelerated phase.

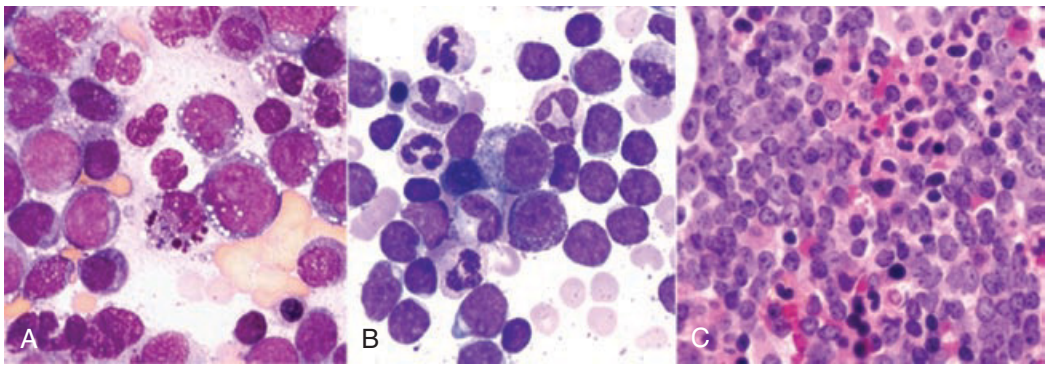

Figure 69–5 Chronic myelogenous leukemia, blast phase: **A–C**. Bone marrow aspirate (**A**) showing myeloid blast phase associated with t(9;22) and inv(16). Note abnormal eosinophil (center). Bone marrow aspirate (**B**) showing lymphoid blast phase in the background of residual CML. Bone core biopsy (**C**) illustrating focal blast phase.

Table 69–2 Response Definition and Monitoring

Hematologic Response	Cytogenetic Response	Molecular Response
Complete: Platelet count <450 × 10^9/L; WBC count <10 × 10^9/L; differential without immature granulocytes and with less than 5% basophils; nonpalpable spleen	Complete: Ph-negative = 0% Major: Ph-positive = 1% to 35% Minor: Ph-positive = 36% to 65% Minimal: Ph-positive = 66% to 95% None: Ph-positive < 95%	Complete: *BCR–ABL* transcripts nonquantifiable and nondetectable Major: *BCR–ABL* transcripts ≤0.10%

To control *BCR–ABL/ABL* gene ratio according to the proposed international scale for measuring molecular response, with a standardized "baseline," as established in the IRIS trial, taken to represent 100% on the international scale and a 3-log reduction from the standardized baseline (MMR) is fixed at 0.10%.

and signs of CML.[49] A partial hematologic response is defined as a decrease in the WBC count to less than 50% of the pretreatment level, or the normalization of the WBC count accompanied by persistent splenomegaly or immature cells in the peripheral blood. A complete cytogenetic response is defined as the absence of Ph-positive metaphases in marrow cells, and partial cytogenetic response as 1% to 34% Ph-positive metaphases. Major cytogenetic remission combines the percentages of complete and partial response. A reduction of *BCR–ABL* mRNA by 3-log or more, compared with a standardized baseline, has been designated a major molecular response (MMR), whereas consistent lack of detection of *BCR–ABL* mRNA is referred to as a complete molecular response (CMR).

Chemotherapy

Busulfan (BU) chemotherapy for CML was introduced in the 1950s. Busulfan was administered in doses of 4 to 6 mg/day and then held when the WBC count fell to 30 × 10^9/L. The drug effect could persist for weeks, and the counts could fall further after therapy was discontinued. Busulfan therapy was associated with serious adverse effects, including prolonged aplasia, pulmonary fibrosis, and a syndrome simulating adrenal insufficiency.

Treatment with hydroxyurea (HU) was started as an alternative to busulfan. Hydroxyurea therapy is usually initiated at doses of 1 to 6 g/day in an attempt to lower counts. Hydroxyurea administered at doses of 1 to 2 g/day is then used to maintain blood counts in the normal range. Hydroxyurea is less toxic than busulfan. Its major adverse effect is reversible marrow suppression. In randomized trials, hydroxyurea was shown to prolong survival of patients with chronic-phase CML when compared to busulfan therapy. Median survival of hydroxyurea-treated patients was 5 years compared with 3.75-year median survival of busulfan-treated patients. Because neither drug results in significant selective suppression of the Ph-positive clone, the aim of therapy with these agents is to control disease and symptoms. Hydroxyurea is now commonly used to achieve control of counts simultaneous with or prior to initiation of treatment with imatinib or other disease-specific therapies.

Several other chemotherapeutic agents can be used to reduce the white cell counts in CML. Low-dose cytosine arabinoside can be used either as an intermittent bolus or as a daily infusion to control disease where hydroxyurea or busulfan are not proving useful. Cytosine arabinoside has also been used in combination with other agents including IFN and imatinib in an attempt to enhance response.

Hyperuricemia and hyperuricosuria are frequently encountered problems in newly diagnosed and relapsed CML patients. Allopurinol, given at a dose of 300 mg daily and adequate hydration should be started prior to initiating treatment. Allopurinol should be discontinued after the WBC count has been controlled.

Interferon

Pioneering observational studies initiated in the 1980s by investigators at the MD Anderson Cancer Center provided evidence for efficacy of IFN in CML and indicated a 70% to 80% probability of complete hematologic remission in selected CML patients.[56–58] Initial research involved the use of human leukocyte IFN, but subsequent clinical studies used recombinant human interferon-α (rIFN-α). Recombinant interferon gamma (rIFN-γ) has been shown to be relatively ineffective for CML. The potential mechanisms by which IFN works in CML are not understood, but may include inhibition of increased proliferation, correction of the adhesion defect of the malignant progenitor in CML, or stimulating an immune response to CML. Rates for complete and partial cytogenetic remissions range from 0% to 38%.[59] Evidence exists for a dose–response relationship, with IFN doses of 4 to 5 million units/m^2/d more likely to achieve remission (and toxicity) than lower doses. Durable remissions are more common in young patients, those treated soon after diagnosis, with less advanced stage disease, and with favorable prognostic stage. Hematologic remissions usually occur within 1 to 3 months after starting IFN. The median time to complete cytogenetic remissions is 9 to 18 months, but may occur after 4 years of therapy. Durable cytogenetic responses, some lasting as long as 10 years, are more common in patients who achieve a complete cytogenetic remission compared with partial cytogenetic remission.

Virtually all patients receiving IFN experience some constitutional adverse effects, and discontinuation of treatment as a result of toxicity is necessary for 4% to 18% of patients compared with 1% of those receiving hydroxyurea. Acute adverse effects are generally mild to moderate and include flu-like symptoms such as fever, chills, and malaise. A constellation of other more severe acute reactions and chronic complications can occur. Overall, the mechanisms underlying the toxic effects are not well understood, but the incidence of adverse effects is usually dose- and duration-dependent.[59]

Randomized studies show an improvement in survival rates in patients receiving IFN compared with patients receiving busulfan or hydroxyurea. The Italian multicenter study randomly assigned 218 patients to receive IFN and 104 patients to receive HU or BU (the control group).[60] Cytogenetic remissions were significantly more common in the IFN group. After a median follow-up of 68 months, the observed 6-year survival rate was 50% for IFN-treated patients and 29% for controls, with median survivals of 72 and 52 months, respectively. The time for progression from chronic phase to accelerated or blast phase was lengthened from 45 months to more than 72 months. In a German multicenter study, 622 patients were randomized to receive IFN, BU, or HU. The 5-year survival rate in the IFN group (59%) exceeded that of the BU group (32%), but was not significantly higher than that of the HU group (44%).[61] Much of the discrepancy between the Italian and German findings can be explained by differences in case mix and treatment regimens. Two other randomized trials also showed benefit for IFN treatment compared with chemotherapy. The UK Medical Research Council randomly assigned 293 patients to receive IFN and 294 patients to receive HU or BU.[62] The 5-year survival rate was 52% for the IFN group and 34% for the control group. A Japanese randomized control trial compared IFN (80 patients) with BU (79 patients).[63] Hematologic and cytogenetic remission rates did not differ significantly. After a median follow-up of 50 months, the predicted 5-year survival rate was 54% for patients receiving IFN and 32% for those receiving BU.

The added value of combining IFN with cytosine arabinoside was shown in a French multicenter trial, wherein 360 patients were randomly assigned to receive IFN combined with cytosine arabinoside (20 mg/M^2/day for 10 days) and 361 patients to receive only IFN.[64] After 3 years, the survival rate was 86% with IFN and cytosine arabinoside and 79% with IFN alone. The rate of hematologic response was higher in the IFN-cytosine arabinoside group than in the IFN group. Major cytogenetic responses were observed 12 months after randomization in 41% patients treated with IFN-cytosine arabinoside and in 24% patients treated with IFN only.

Thus, the accumulated evidence from randomized trials suggests that IFN improves survival in chronic-phase patients with favorable features compared with BU and HU. Meta-analysis suggests that the pooled 5-year survival rate is 57% (50%–59%) for IFN and 42% (29%–44%) for chemotherapy, which results from a delay in the onset of blast crisis.[65] The controlled trials suggest that IFN increases life expectancy by a median of approximately 20 months compared with BU and HU. There is no direct evidence that IFN has a greater impact on survival than HU for patients who are in the later stages of chronic phase or who are sicker (eg, more than 1 year from diagnosis, or more than 10% to 30% blasts in peripheral blood). Adding cytosine arabinoside to IFN appears to add further survival benefit but also increases toxicity. Although IFN clearly is beneficial in patients with CML patients, benefit is limited by low levels of cytogenetic response and considerable toxicity. As discussed below, the use of IFN in the modern treatment of CML patients has been replaced by use of imatinib and other tyrosine kinase inhibitors.

Imatinib Mesylate and Targeted Therapies

Because the tyrosine kinase activity of *BCR–ABL* plays a critical role in cellular transformation, it is an attractive target for inhibition. Imatinib is a small, 2-phenylaminopyrimidine molecule that inhibits the kinase activity of all proteins that contain *ABL*, *ABL*-related gene (ARG) protein, or platelet-derived growth factor receptor, as well as the KIT receptor, at micromole concentrations.[66,67] Imatinib is a competitive inhibitor that acts at the ATP-binding site in the kinase domain to inhibit the normal binding of ATP and blocks the ability of *BCR–ABL* to phosphorylate tyrosine residues on its substrates (Fig. 69–6A–F).

Initial phase 1 and phase 2 trials established that imatinib was well tolerated and induced hematologic as well as cytogenetic response in the majority of chronic-phase CML patients who had failed other treatments.[68] Subsequently the International Randomized Interferon and STI571 (IRIS) study compared imatinib at 400 mg daily with IFN-α plus cytosine arabinoside in 1106 newly diagnosed patients in first chronic phase. This study was closed with the conclusion that imatinib is the initial nontransplant treatment of choice for patients with newly diagnosed chronic-phase CML. This conclusion was based primarily on a higher rate of disease progression in the patient group receiving IFN plus cytosine arabinoside. In the initial report from this study, after a median follow-up of 19 months, the estimated rate of an MCR at 18 months was 87.1% (95% CI, 84.1–90.0) in the imatinib group and 34.7% (95% CI, 29.3–40.0) in the IFN plus cytosine arabinoside group ($P < 0.001$).[69] The estimated rates of CCR were 76.2% (95% CI, 72.5–79.9) and 14.5% (95% CI, 10.5–18.5), respectively ($P < 0.001$). At 18 months, the estimated rate of freedom from progression to accelerated-phase or blast-crisis CML was 96.7% in the imatinib group and 91.5% in the IFN group ($P < 0.001$). Imatinib was better tolerated than combination therapy. In a subsequent 60-month follow-up report for this study, the estimated cumulative incidence rate of CHR, MCR, and CCR for patients on first-line imatinib was 98%, 92%, and 87% at 60 months (Fig. 69–7).[70] Only 7% of patients progressed to advanced phase, and the estimated overall survival was 89%. Crossover between arms was permitted for treatment failure, and 382 (69%) of 553 patients originally allocated to the IFN/cytarabine arm crossed over to the imatinib arm at a median of 60 months from start of treatment. The main reason for crossover from IFN to imatinib was intolerance of treatment, but reasons also included disease progression and failure to achieve hematologic or cytogenetic response.

Pretreatment risk factors have been found to predict the likelihood of achieving and maintaining response to imatinib. At 60 months, the estimated risk of disease progression was significantly higher for patients with a higher pretreatment Sokal score (estimated rates for high-risk, intermediate-risk, and low-risk groups of 17%, 8%, and 3%, respectively; $P = 0.002$). The achievement of certain milestones of response has also been found to predict prognosis. For example, patients who fail to achieve a complete hematologic response by 3 months of treatment, any cytogenetic response by 6 months or a major cytogenetic response by 12 months do poorly in comparison with patients achieving these milestones. Reduction of *BCR–ABL* levels observed with cytogenetic and quantitative PCR monitoring is also predictive of prognosis (Fig. 69–8). A landmark analysis indicated that at 60 months, 97% of the patients (95% CI, 94 to 99) who had achieved CCR at 12 months after the initiation of imatinib treatment ($n = 350$) had not progressed to accelerated phase or blast crisis (Fig. 69–9). For patients who did not have an MCR within 12 months ($n = 73$), the estimate was 81% (95% CI, 70–92; $P < 0.001$). Interestingly, the Sokal score was not predictive of risk of disease progression in patients who had a complete cytogenetic response (95%, 95%, and 99% in the high-risk, intermediate-risk, and low-risk groups, respectively; $P = 0.20$). The molecular responses at 12 and 18 months was predictive of long-term outcome. Patients who had a more than 3-log reduction in *BCR–ABL* transcript numbers at 18 months had 100% progression-free survival at 5 years, whereas patients who had failed to achieve CCR had 83% progression-free survival ($P < 0.001$).

A dose of 400 mg of imatinib daily is currently considered to be the standard dose for initiating therapy in newly diagnosed chronic-phase patients. Nonrandomized studies performed at the MD Anderson Cancer Center suggest that patients receiving initial therapy with 800 mg imatinib daily will achieve CCR more rapidly than patients receiving standard 400-mg daily doses.[71] However, it is not clear that the overall frequency of response will differ between the two groups,

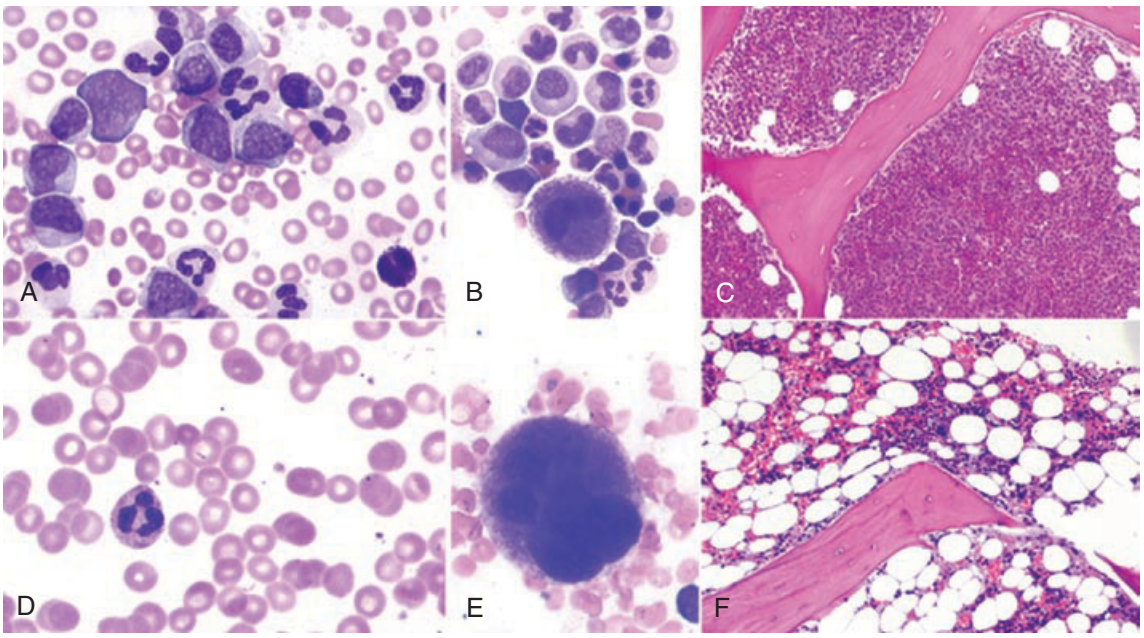

Figure 69–6 Chronic myelogenous leukemia, before and 3 months after imatinib therapy (**A**–**F**). Chronic-phase CML, as seen in the peripheral blood (**A**), aspirate (**B**), and biopsy (**C**), and after 3 months of imatinib therapy (**D**, **E**, **F**). Note normalization of white cell count (**D**), megakaryocyte size (**E**) and marrow cellularity (**F**).

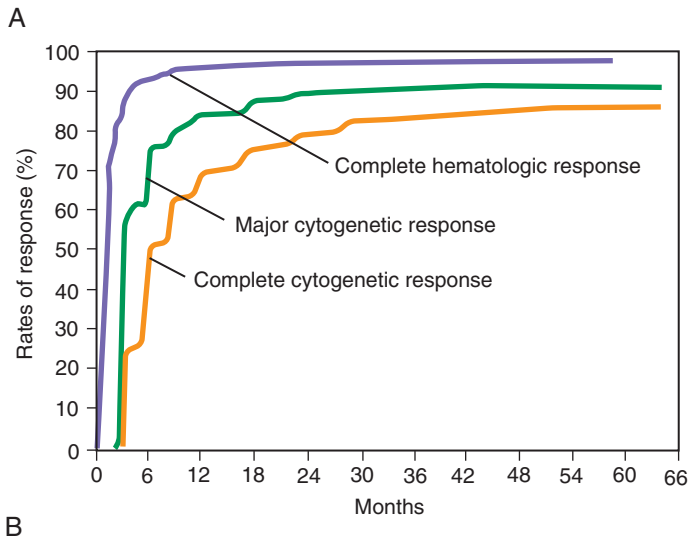
and overall survival and progression-free survival are excellent with standard-dose imatinib (Fig. 69–10). Randomized trails examining the question of optimal imatinib dosing are ongoing.

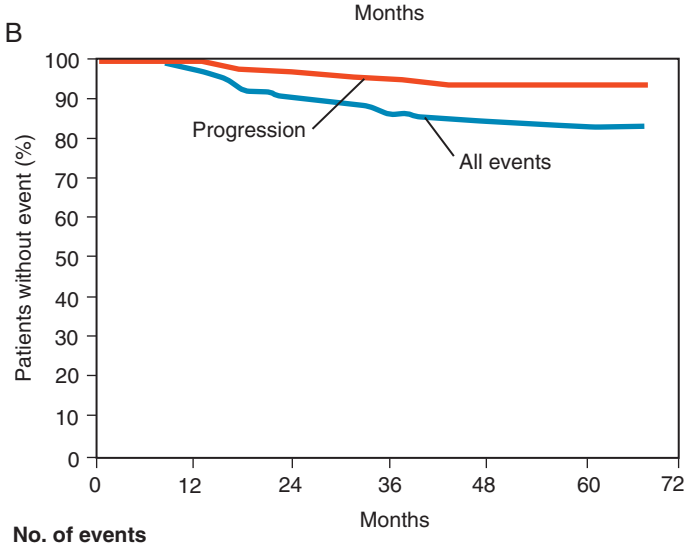
Results of Treatment of Patients Failing Interferon

In a phase II study, 532 chronic-phase patients who were refractory to or intolerant of IFN-α were treated with imatinib at a dose of 400 mg daily. A CHR was achieved in 95% of patients, MCR in 60% of patients, and CCR in 41% of patients. With a median follow-up of 18 months, the estimated progression-free survival was 89%. Only 2% of patients discontinued therapy because of adverse events. Baseline features that predicted a high rate of MCR included the absence of blasts in the peripheral blood, a hemoglobin level greater than 12 g/dL, less than 5% blasts in the marrow, CML disease duration of less than 1 year, and a prior cytogenetic response to IFN.[72]

Results of Treatment in Accelerated Phase



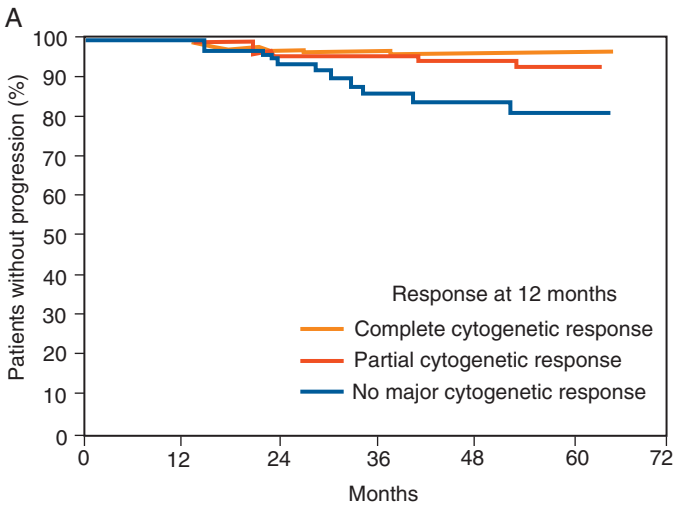
A phase II study in accelerated-phase patients enrolled 235 patients. Some hematologic response was seen in 82% of patients, with 34% of patients achieving a CHR. A major cytogenetic response occurred in 24% of patients, with 17% complete responses. Estimated 12-month progression-free and overall survival rates were 59% and 74%, respectively.[73]



Results of Treatment in Blast Crisis

A phase II study of 260 myeloid blast crisis patients treated with imatinib showed an overall response rate of 52%, with sustained hematologic responses lasting at least 4 weeks in 31% of patients. Eight percent of patients achieved a complete remission with peripheral blood recovery. Another 4% of patients cleared their marrows to less than 5% blasts but did not meet the criteria for CR because of persistent cytopenias. Eighteen percent of patients either "returned" to chronic phase or had partial responses. Major cytogenetic responses were seen in 16% of patients, with 7% having complete cytogenetic responses. The median survival was 7 months. These results compare favorably with historical controls treated with chemotherapy for myeloid blast crisis in which the median survival is approximately 3 months. In patients with Ph-positive ALL, 29/48 (60%) responded to a single agent, imatinib. However, the duration of response was relatively short, with a median estimated time to disease progression of only 2 months.[74]

Toxicity



Myelosuppression is particularly common in CML patients treated with imatinib and is more common in patients with advanced disease. In the phase III randomized trial of newly diagnosed patients in the chronic phase, grade 3 neutropenia (ANC < 1000/mm^3) was experienced by 11% of patients, grade 4 neutropenia (ANC < 500/mm^3) occurred in 2% of patients, grade 3 thrombocytopenia (platelets <50,000/mm^3) occurred in 6.9% of patients, and grade 4 thrombocytopenia (platelets <10,000/mm^3) occurred in less than 1% of patients. Myelosuppression can occur at any time during imatinib therapy, but it usually begins within the first 2 to 4 weeks of starting therapy for blast crisis, with a slightly later onset in patients in accelerated or chronic phase. Although grade 3 and 4 neutropenia is frequent, particularly in advanced phases, infectious complications are relatively rare, possibly related to the lack of mucous membrane damage in patients on imatinib. Central nervous system and gastrointestinal hemorrhages may occur, most frequently in patients in blast crisis with platelet counts less than 20,000 and with uncontrolled leukemia. The primary goal in treating otherwise healthy patients in chronic phase is to avoid the risk of potentially dangerous neutropenia and platelet transfusion dependence. For patients with blast crisis or high-risk accelerated-phase disease (>15% blasts), a suggested approach is to balance risks and benefits, and support patients with a platelet count under 10,000/mm^3 or under 50,000/mm^3 with clinically evident bleeding with platelet transfusions. In the event of clinically significant bleeding, imatinib should be held immediately, until the bleeding is controlled. In patients whose absolute neutrophil count is less than 500/mm^3, imatinib is continued if the marrow is

hypercellular or if there are more than 30% blasts. In cases where the marrow is hypocellular and the ANC is less than 500/mm^3 for 2 to 4 weeks, imatinib may be held, the dose reduced or myeloid growth factors can be used.[75] Concurrent administration of growth factors and imatinib is well tolerated and patients have not experienced a greater rate of relapse.[76]

The most common nonhematologic adverse events related to imatinib were nausea, muscle cramps, fluid retention, diarrhea, musculoskeletal pain, fatigue, and skin rashes. Only a minority of patients experienced grade 3 or 4 toxicity, and there was a low rate of discontinuance of therapy because of toxicity of 5%, 3%, and 2% in the phase II studies for blast crisis, accelerated phase, and chronic phase, respectively. The higher rate of severe toxicity in patients with advanced-phase disease may relate to the higher doses administered, or the poorer underlying health of patients. Most adverse effects can be managed successfully with supportive measures. Some toxicities (eg, mild skin rashes, mild elevations of transaminases, bone pain, and arthralgias) may improve spontaneously despite continued therapy at the same dosage.

Imatinib Resistance

Both de novo and acquired resistance have been observed in imatinib-treated CML patients. The two most commonly described mechanisms associated with resistance are point mutations in the *BCR–ABL* gene that prevent imatinib from inhibiting kinase activity and *BCR–ABL* gene amplification. The Sawyers group, in an original study of nine patients who relapsed on imatinib treatment, detected *BCR–ABL* gene amplification in three patients and kinase domain mutations in six.[77] Relapse was associated with reactivation of *BCR–ABL* kinase activity. This group subsequently reported results of sequencing analysis of *BCR–ABL* kinase domain mutations in 32 patients whose disease relapsed after an initial response to imatinib. Twenty-nine of 32 patients had *BCR–ABL* kinase mutations, with 15 different amino acid substitutions affecting 13 residues in the kinase domain.[78] The different mutations conferred varying degrees of

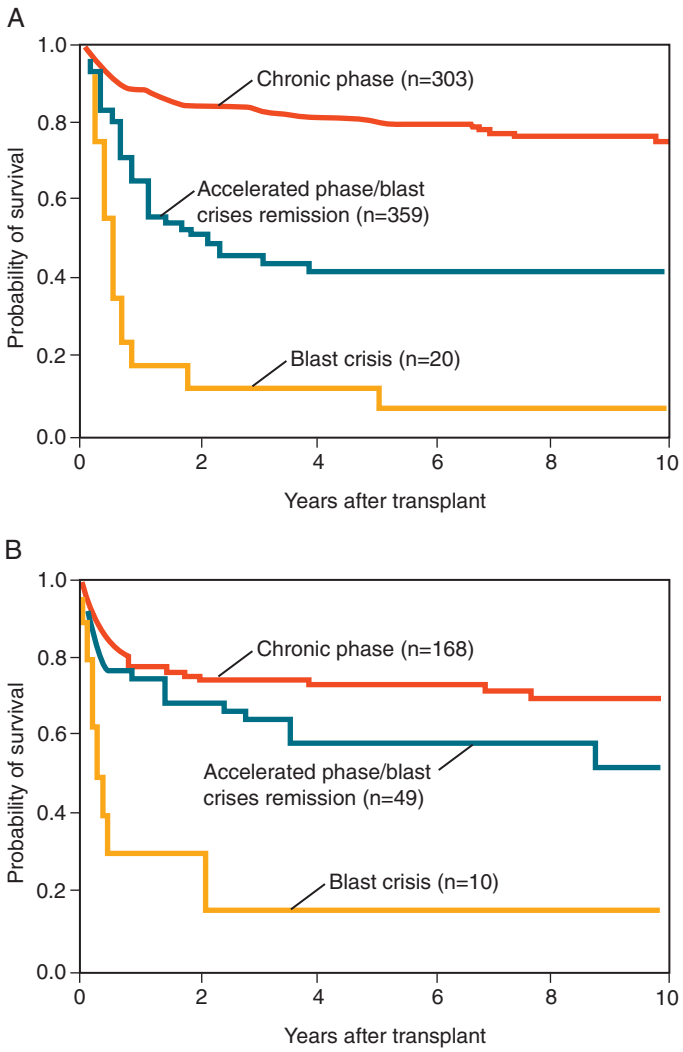

Figure 69–9 Probability of survival following (**A**) related donor transplantation, and (**B**) unrelated donor transplantation for chronic myelogenous leukemia (CML), chronic phase (CP), accelerated phase (AP), and blast crisis (BC), performed after 1992, at the FHCRC, Seattle.

imatinib resistance. In patients with stable chronic-phase disease, detection of mutations correlated with subsequent disease progression. Multiple independent mutant clones were seen in some patients. Subsequent studies have identified mutations in more than 40 different amino acids.[79] Mutations have been found in some patients prior to start of treatment supporting a model in which preexisting *BCR–ABL* mutations that confer imatinib resistance acquire a selective clonal growth advantage during imatinib treatment. There is some evidence that *BCR–ABL*-independent mechanisms may also play a role in imatinib resistance in some patients. Activation of the *SRC* family kinases, *LYN*, has been demonstrated in cell derived from patients with acquired imatinib resistance.[80]

The structure of the *ABL* kinase domain in complex with imatinib has been solved. This information sheds light on the mechanisms by which kinase domain mutations confer drug resistance.[81] Mutations may affect residues that directly contact imatinib such as a mutation resulting in substitution of isoleucine for threonine in the T315 position (T315I). The P-loop of the *ABL* kinase domain undergoes extensive downward displacement upon imatinib binding. Mutations in the P-loop prevent conformational changes required for imatinib binding. Imatinib captures and stabilizes the *ABL* kinase in its inactive conformation, but is sterically excluded from the active conformation. The M351T mutation and mutations in the activation loop result in the kinase remaining in the active conformation rather than the inactive conformation required for imatinib binding.[78]

Because the active conformations of *ABL* and *SRC* bear a high degree of structural similarity, compounds with *SRC* kinase inhibitory activity have been evaluated against native and mutant *BCR–ABL*. BMS-354825 (dasatinib, Sprycel) is a dual *SRC-ABL* kinase inhibitor that exhibits approximately 300-fold higher potency against native *BCR–ABL*.[78] Dasatinib can effectively inhibit most clinically detected *BCR–ABL* kinase domain mutants at low nanomolar concentrations, with the notable exception of T315I. Dasatinib entered clinical trials in late 2003 and has recently been approved by the Federal Drug Administration for the treatment of patients who failed imatinib.[82] Another compound, AMN107 (nilotinib) was generated by rational modification of Imatinib to enhance *BCR–ABL* kinase binding activity. Nilotinib binds *ABL* but with significantly increased avidity and can overcome resistance of most kinase domain mutants, with the exception of T315I. This drug is currently in clinical trials. It is evident however that both agents have significant activity in imatinib-resistant CML. Interestingly, responses occurred in patients with and without *BCR–ABL* kinase domain mutations at trial entry, with the exception of patients with the T315I mutation. Responses in chronic phase and, to a lesser extent, in accelerated phase have been stable. In contrast, many patients with myeloid, and all patients with lymphoid, blast crisis or Ph-positive ALL have relapsed.[83] These data are similar to the results of the initial studies with imatinib and indicate that once the disease has progressed beyond the chronic

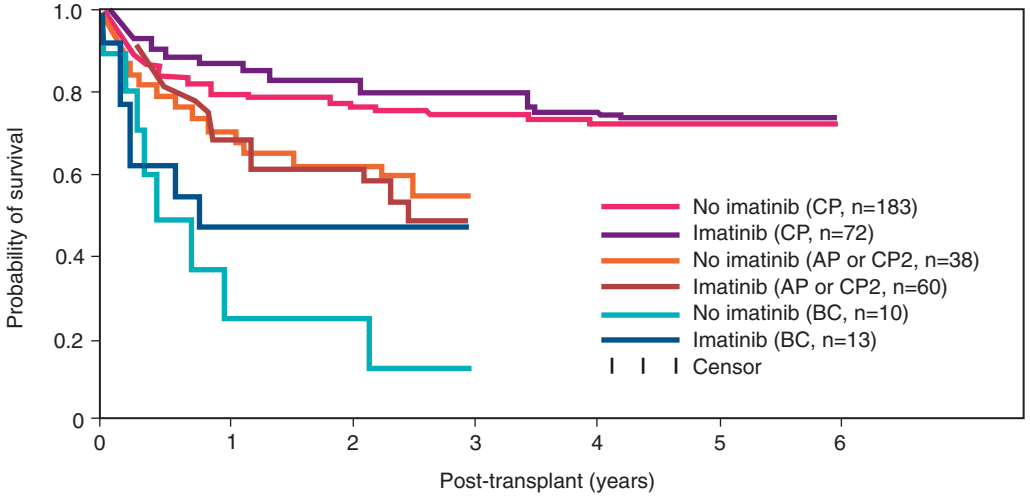

Figure 69–10 Effect of prior treatment with imatinib on overall survival after transplantation. CP2 = a return to chronic phase after treatment for accelerated phase or blast crisis disease. (Data from Oehler VG, Gooley T, Snyder DS, et al: The effects of imatinib mesylate treatment before allogeneic transplantation for chronic myeloid leukemia. Blood 109(4):1782, 2007.)

phase, tyrosine kinase inhibitor-based monotherapy is not sufficient to induce lasting responses.[84]

The fact that the T315I mutant is not responsive to either dasatinib or nilotinib and that this mutant has been detected in some patients with acquired resistance to dasatinib underscores the need to develop a T315I inhibitor. One compound termed VX-680, initially designed as an inhibitor of aurora kinases, is in Phase 1 trials, and several others are in preclinical development.[81,85]

Residual Disease

Currently, the reverse-transcriptase polymerase chain reaction (RT-PCR) is the most sensitive method for detecting low numbers of *BCR–ABL* transcripts in a patient after apparently successful hematopoietic cell transplantation. Most patients who have been treated with imatinib and have responded well continue to demonstrate evidence of residual disease using sensitive PCR assays. Recent updates of clinical trials of imatinib in CP CML patients indicate that an increasing proportion of patients appear to enter a molecular remission over time, including some patients achieving a PCR-undetectable status.[70] However, even patients with negative PCR (so-called complete molecular response) may still have significant numbers of residual malignant cells. Persistence of small populations of leukemia cells raises the concern that they could be a potential source of relapse. It is unclear whether the drug can be stopped in patients with MMR or CMR. Anecdotal observations of patients who discontinued therapy in CCR or CMR for various reasons, indicate that most such individuals experienced disease recurrence.[86–89] Patients who maintain response tend to be individuals who have received imatinib for relapse after allogeneic transplantation or who had been treated with IFN-α before they commenced imatinib.[90,91] Together, these data suggest that imatinib alone may not be capable of eradicating the leukemic cell clone.

Allogeneic Hematopoietic Cell Transplantation

The Seattle team reported initial results of HLA-matched sibling donor hematopoietic cell transplants performed as therapy for 10 CML patients in 1982, and subsequently published a larger study on 167 patients transplanted from matched siblings through 1983.[92,93] Long-term follow-up demonstrates that approximately 40% of patients transplanted in chronic phase nearly 20 years ago are surviving. Hematopoietic cell transplant became the first curative treatment in CML. Data from 4267 recipients of matched-sibling transplants reported to the IBMTR between 1994 and 1999 show a probability of survival of 69% ± 2% for 2876 patients transplanted within the first year from diagnosis, and 57% ± 3% for 1391 patients transplanted more than 1 year from diagnosis.[94] Contemporary results from selected single institutions continue to demonstrate excellent outcomes with HCT, in part due to advances in preparative regimens, supportive care, and HLA typing for unrelated donors. For example, the Seattle group has recently reported on their most recent trial using a preparative regimen of targeted busulfan (BU) plus cyclophosphamide (CY) in 131 consecutive chronic-phase CML patients. Survival 3 years posttransplant was 86%, and 87% of surviving patients were molecularly negative for *BCR–ABL*.[91,95]

The outcome of allogeneic HCT in CML is influenced by many factors, most importantly the phase of disease. Other important variables include the type of donor used (related or unrelated), the source of the stem cell product (marrow or peripheral blood), and the age of the patient. Outcomes are superior for HCT in chronic phase compared to advanced phases of disease.[96,97] In a Seattle analysis of 58 patients with accelerated-phase CML transplanted from HLA-identical siblings, the 4-year probabilities of survival and event-free survival were 49 and 43%, and the probability of relapse was 12%.[98] The outcome of transplantation for patients in blast crisis is uniformly poor, both from a high rate of disease recurrence and transplant-related deaths with event-free survivals of 43%, 18%, and 11% at 100 days, 1 year, and 3 years, respectively.[93,99,100] Prior to the development of imatinib, only a small proportion of patients with blast-phase CML (generally patients with lymphoid blast crisis) could achieve a hematologic remission with chemotherapy. Transplantation for patients with CML in remission after a previous blast phase results in cure rates somewhat worse than those seen in chronic-phase patients. Response rates of patients with CML in blast phase to imatinib are considerably higher than those seen with conventional chemotherapy. These responses tend to be short, particularly in the setting of lymphoid blast crisis. There are limited data on the outcome of transplantation for patients with previous blast crisis who are back in remission following treatment with imatinib, but these few patients seem to have a progression-free survival at 3 years of over 50%.[101]

Preparative regimens have improved incrementally. The majority of patients treated in the early 1980s received a preparative regimen of 120 mg/kg CY, followed by total body irradiation (TBI).[93] Tutschka et al later described the use of 16 mg/kg BU administered over 4 days combined with 60 mg/kg CY on each of 2 successive days, in myeloid malignancies.[102] In 1988 a randomized trial of BU/CY versus CY/12 Gy TBI in myeloid malignancies showed no differences between the CY/TBI and BU/CY treatment groups in survival at 3 years (80%), relapse (13%), or event-free survival (68% for CY/TBI and 71% for BU/CY).[103] An update of this study shows overall survival of 78% at 10 years with BU/CY versus 64% with CY/TBI.[104] The absorption and metabolism of busulfan varies considerably from patient to patient, and busulfan assays were incorporated into transplant trials. Patients with a steady-state busulfan concentration less than the median value (<917 ng/mL) of the cohort had a significantly higher risk for disease recurrence and worse overall survival than those with levels greater than 917 ng/mL.[105] A subsequent report of 131 consecutive CML chronic-phase patients transplanted with HLA-identical relatives showed a 3-year survival of 86%, a relapse rate of only 8%, and a nonrelapse mortality rate of 14%.[106] Surprisingly, there were no significant differences in outcome related to patient age up to age 65.

Only approximately one-third of patients have HLA-matched family members to serve as donors. Although early results with matched unrelated donor transplantation in CML showed results somewhat poorer than those seen with matched siblings, advances in donor selection, GVHD prophylaxis, and supportive care have resulted in continued improvements in outcome.[107–110] Thus, in many institutions results following unrelated transplants are almost equivalent to those seen with matched siblings (with a caveat that unrelated donor transplants have a lower-age patient exclusion), and registry data of multiple centers report 65% survival at 5 years among younger patients transplanted within a year of diagnosis.

Marrow was used as the stem cell source in all initial transplant studies. Two large randomized trials involving a variety of hematologic malignancies have shown that use of filgrastim [granulocyte-colony stimulating factor (G-CSF)] mobilized peripheral blood hematopoietic cells leads to more rapid myeloid and platelet recovery when compared to marrow, with no significant difference in acute or chronic GVHD and an overall survival advantage.[111,112] Although there was a trend toward improved survival in CML patients with the use of peripheral blood, it should be noted that these studies were not prospectively designed to address the role of peripheral blood versus marrow for individual disease states. Lastly, the results of a randomized study of chronic-phase CML showed no statistically significant differences in outcome between the marrow and peripheral blood groups, though relapse rates were lower in the peripheral blood group and chronic GVHD higher compared with patients transplanted with marrow.

Several studies have shown that an increased interval from diagnosis to transplant is associated with a worse transplant outcome, for patients treated in chronic phase.[113,114] No single cause of failure is markedly increased with delay; rather there is a modest effect of delay on relapse rate and nonrelapse mortality. Thus the delay effect may be due in part to the advancing disease over time and/or the effect of the cumulative toxicity of prior therapy. An IBMTR report suggested that exposure to low-dose busulfan led to a worse outcome

with subsequent transplantation.[114] Reports have suggested that exposure to IFN might worsen the outcome of unrelated donor transplant, but data on the effect of IFN on matched sibling transplantation were less clear. In a recent German report, the 5-year survival rate from transplant was 46% for the 50 patients who received IFN within the last 90 days before transplant and 71% for the 36 who did not.[115] These observations suggest that IFN should be avoided, if possible, in the months immediately preceding allogeneic hematopoietic cell transplantation.

There have been several studies on the effect of prior imatinib and transplant outcomes. Early reports warned of an increase in regimen-related toxicity and mortality, especially from hepatic causes.[116] Larger studies have failed to show a deleterious effect of pretransplant imatinib.[117,118] A study of only CML patients showed no difference in regimen-related mortality, survival, or relapse between 140 patients who received imatinib versus 200 historical controls.[101] Curiously, in a few studies, chronic GVHD has been significantly less in patients receiving imatinib before transplant. The biology underlying this effect is unknown.

The form of GVHD prophylaxis used in the treatment regimens also influences the outcome of transplantation for CML, especially in chronic phase. Prevention of GHVD by removing T cells from the donor marrow was explored in a number of transplant studies in the 1980s. Although successful in reducing the incidence of GVHD, T-cell depletion in CML was associated with high rates of graft failure and relapse, leading to poorer disease-free and overall survival.[100] These findings illustrated the critical role of the graft versus leukemia (GVL) effect in eradicating CML following allogeneic transplantation. Because of these observations, T-cell depletion was largely abandoned as a method to control GVHD in CML transplants. However, there has been renewed interest in the possibility of preventing GVHD without loss of a GVL effect by combining T-cell depletion with an intensified conditioning regimen and delayed reinfusion of viable donor lymphocytes.[119]

Graft Versus Leukemia Effect in Chronic Myeloid Leukemia

Although evidence for a GVL effect can be found in many settings, nowhere is it as strong as in the setting of allogeneic HCT therapy for CML. Evidence in support of such an effect includes the following[120]: the higher rates of relapse following syngeneic and T cell-depleted transplants compared to unmodified allogeneic transplants[100,121]; the close association between the development of acute and chronic GVHD and freedom from relapse following non–T cell-depleted transplants[122–124]; the high response rate to donor lymphocyte infusions to treat posttransplant relapse (range from 50% to 100%), which is higher than in any other malignancy.[125,126] The markedly increased relapse rates seen with T-cell depletion indicate a role for T cells in GVL. T cell targets might include minor histocompatibility antigens shared by most cells in the body, thus accounting for the association of GVL with GVHD. Alternatively, there may be polymorphic minor histocompatibility antigens, with expression limited to hematopoietic tissue.[127,128] A third possible category of targets for the GVL effect in CML is the overexpression of protein targets in CML cells.[129] Understanding the cells and their targets responsible for the potent GVL effect seen in CML will be critical to the development of more effective, less toxic transplant-based therapies in the future.

Reduced Intensity Conditioning

Investigators have begun to study reduced intensity conditioning (RIC) or nonablative transplant approaches in an attempt to avoid the toxicities of high-dose preparative regimens while retaining the potentially powerful GVL effects. These approaches are of particular relevance for patients with CML because their median age at diagnosis is 67 years. Although the results of these studies are still in the early stages, some of the early observations are intriguing. For example, using a preparative regimen consisting only of 200-cGy TBI, and GVHD prophylaxis using cyclosporine (CSP) and mycophenolate mofetil (MMF), McSweeney et al reported complete molecular responses in five of nine patients transplanted for CML in chronic phase ($n = 6$) or accelerated phase ($n = 3$). The other four patients rejected their grafts. By adding 30 mg/m^2 fludarabine pretransplant, graft rejection has been eliminated as a problem following matched sibling transplantation.[130] Or et al recently reported similar encouraging results using a preparative regimen of fludarabine, low-dose busulfan, and antithymocyte globulin.[131] Thus, nonablative allogeneic hematopoietic cell transplantation may offer a safe and effective way to treat CML in the chronic phase.

Residual Disease Posttransplantation

The detection of *BCR–ABL* transcripts posttransplant is a strong predictor of relapse following transplantation. In a study of 346 patients after transplantation, 40% of patients were positive for *BCR–ABL* residual disease at 3 months posttransplant but this finding was not predictive of outcome, suggesting that eradication of the CML clone posttransplant takes an extended period of time.[132] In contrast, at 6 or 12 months posttransplant, 27% of patients were *BCR–ABL*-positive and at this time the assay was a powerful predictor of outcome, as only 3% of PCR-negative patients eventually relapsed compared with 42% of PCR-positive patients. The predictive power of PCR detection of *BCR–ABL* among longer-term survivors is somewhat weaker. At 18 months posttransplant, 1% of 289 *BCR–ABL*-negative patients subsequently relapsed compared with 14% of 90 *BCR–ABL*-positive patients. The advent of reliable quantitative PCR testing further refined risk prediction of *BCR–ABL* detection. Olavarria et al studied 138 transplant patients at 3 to 5 months posttransplant, and were able to define patients as having a low risk of relapse (16%), an intermediate risk (43%), or a high risk (86%) based on *BCR–ABL* quantification.[133] Further studies have confirmed the importance of quantitative *BCR–ABL* monitoring of minimal residual disease after transplantation for CML, which offers an obvious opportunity for early intervention for patients with residual or recurring disease.[134]

Treatment of Posttransplant Relapse

The pace of disease progression after posttransplant relapse is variable; some patients remain low-level PCR-positive for *BCR–ABL* for years without relapsing and some relapse with low levels of Ph-positive metaphases and remain stable for many years. The EBMT retrospectively studied 130 patients who relapsed after transplant before 1990 and noted that postrelapse survival (without DLI or imatinib therapy) was significantly better for recipients of matched sibling grafts for chronic-phase disease, with a short interval from diagnosis to transplant but a long interval from transplant, with a likelihood of being alive 10 years after posttransplant relapse of 42%.[135,136] An appreciation of the likely tempo of progression is thus important when considering treatment intervention options.

An increasing number of potential interventions are available for relapsing disease. IFN can produce both clinical and cytogenetic remissions in patients who have relapsed after transplantation.[137,138] Results with IFN appear better if treatment is initiated at the time of cytogenetic relapse instead of waiting until hematologic relapse, as IFN induces molecular remissions in some individuals treated early.[95] There are now a large number of studies demonstrating cytogenetic complete response rates of 50% to 100% in patients treated with DLI for clinically relapsed chronic-phase CML.[125] Response rates tend to be higher for patients treated earlier at the time of cytogenetic relapse and lower for patients in accelerated phase. The two major complications of DLI are transient marrow failure and the development of GVHD. Marrow failure only occurs in patients treated in hemato-

logic relapse and likely reflects clearance of host hematopoiesis before donor hematopoiesis recovers, and thus is of particular concern for patients in full-blown hematologic relapse with no evidence of residual donor hematopoiesis.[139] Treatment earlier in the course of relapse can avoid this complication. The overall incidence of GVHD following DLI is approximately 50% in most series. Most early studies of DLI involved a single infusion of a relatively large number of donor T cells. It has since been reported that large numbers of T cells are tolerated with less GVHD if administered in a fractionated fashion rather than as a single bulk dose.[106] A recent report from the EBMT provides further support for starting at lower doses of lymphocytes and escalating dosage as required.[140]

More recently, imatinib mesylate has been shown to be active as posttransplant therapy. In a recent report of 28 patients who were treated with imatinib for posttransplant relapse, an overall response rate of 79% was seen, with CHR seen in 100% of patients in chronic phase, 83% in accelerated phase, and 43% in blast crisis.[72] CCR was seen in 29% of patients. Recurrence of GVHD disease was seen in 18% and granulocytopenia requiring dose adjustments of imatinib developed in 43% of patients. Because imatinib has only recently become available, almost all of the reported cases treated with imatinib for posttransplant relapse had never been treated with the drug previously. However, imatinib appears to be tolerated given early after transplantation to prevent relapse in high-risk Ph+ cases.[141] Twenty-two patients with Ph+ ALL or advanced-phase CML received imatinib at a median of 28 days postengraftment. Seventeen of 19 adults and all 3 children tolerated imatinib at the targeted dose (400 mg/day for adults, 260 mg/m^2/day for children), and 19 completed the planned course of 1 year of imatinib therapy. At a median follow-up of approximately 1$^1/_2$ years, 12 of 15 of the Ph+ ALL and 5 of 7 of the CML patients were in molecular remission.

Autologous Transplantation

The rationale for autologous transplantation in CML has been experimental and clinical evidence for persistence of polyclonal Ph-negative progenitors capable of reconstituting hematopoiesis in CML patients. This is most dramatically demonstrated by the high rate of complete cytogenetic response seen in CML patients treated with imatinib. Furthermore, it has been shown that transplantation of autologous cells may allow restoration of Ph-hematopoiesis.[142–149] Initial studies carried out using unmanipulated autologous marrow or blood cells indicated that autologous transplantation could reestablish CP in patients with advanced disease and induce cytogenetic responses in a small proportion of CML CP patients.[150–155] Subsequent studies indicated that depletion of Ph-positive progenitors by ex vivo graft manipulation was possible and associated with cytogenetic remission posttransplant.[156–159] Another approach to depleting malignant cells from the graft was to treat patients before harvesting marrow or peripheral blood for transplantation, also called in vivo purging.[142,160–173] However, remissions following autologous transplantation were usually of short duration, indicating either ineffective purging or relapse posttransplantation secondary to residual leukemic cells in the patient. In addition, the procedure was often associated with significant toxicity and delayed recovery. Although the compiled results of 200 autologous transplants at eight different centers in Europe and North America indicated a possibility of improved survival,[174,175] it is not possible to make any definite conclusions in the absence of controlled clinical trials. A meta-analysis of six trials in which patients were randomly allocated to receive autologous HCT or an IFN-based regimen did not show an advantage for HCT.[176]

Any trials of autologous HCT now need to be considered in the context of the excellent results of imatinib treatment, and the availability of second-generation kinase inhibitors with significant activity in imatinib-resistant CML patients. Pilot studies to collect PBSC from patients who have received imatinib mesylate and achieved CCR, for use for autologous HCT in case of later progression, have been reported.[177–181] The PBSC collection process is well tolerated and Ph-negative collections are more consistently achieved than with previous strategies. Although the target numbers of CD34$^+$ cells is usually attained, a subset of patients fails to reach this target. Furthermore, many patients mobilize suboptimally and require multiple collections, possibly as a result of the effects of imatinib on normal hematopoiesis and the mobilization process.[67] Collections are usually Ph-negative, but molecular evidence of disease can be found in most patients. Collection of PBSC from patients responsive to imatinib may form the framework of future attempts to perform autologous transplantation in CML; however, additional strategies are required to further deplete cells containing the *BCR–ABL* from PBSC collections as well as improve therapy for residual disease posttransplant.[182] At this point, autologous HCT for CML should probably be limited to investigational clinical trials for patients who fail kinase inhibitor studies therapy and lack allogeneic donors.

CAN TYROSINE KINASE INHIBITOR TREATMENT CURE CHRONIC MYELOID LEUKEMIA?

A fraction of CML patients treated with imatinib may not have detectable levels of the *BCR–ABL* gene even with sensitive PCR assays. This raises the question as to whether patients can actually be cured with tyrosine inhibitor treatment. Patients with negative PCR may still have significant numbers of residual malignant cells. The definition of a "cure" remains controversial. Although cure might theoretically require the total eradication of all leukemia cells, it can be argued that patients may be considered cured if low numbers of leukemia cells persisted but could not reestablish clinical disease. Such a situation may occur in CML post allogeneic transplantation where a graft-versus-leukemia effect may help maintain remission. In AML associated with the t(8;21), many long-term survivors continue to demonstrate molecular evidence of this translocation. On the other hand, late relapses can be observed in patients with childhood ALL more than 10 years after remission, with molecular evidence that the relapse originated from the same clone that caused the disease originally.

Therefore, it is important to consider whether *BCR–ABL*-expressing cells that escape elimination with imatinib include cells with leukemogenic potential. Mathematical modeling of the effect of imatinib on different hematopoietic cell compartments in CML suggests that leukemia stem cells are resistant to elimination by this drug.[89] This is supported by evidence that *BCR–ABL* -positive stem and progenitor cells are retained in patients in CCR on imatinib treatment.[183] In vitro treatment with imatinib and dasatinib effectively inhibits proliferation of CML primitive progenitors but only modestly increases progenitor cell apoptosis.[184–186] Similarly, treatment with imatinib and dasatinib failed to eradicate primitive leukemia cells in a mouse model of CML.[44] These observations suggest that at least short-term treatment with imatinib or dasatinib does not eliminate primitive leukemogenic cells, implying that "cure" of CML is likely to remain elusive with treatment with these agents alone. This is supported by observations of disease recurrence in patients who were *BCR–ABL* negative by PCR and stopped treatment for various reasons.[86–89] Intriguingly, some patients have been reported to have maintained a *BCR–ABL*-negative status for more than 1 year following discontinuation of imatinib treatment, but the long-term durability and frequency of such responses, or factors that predict for such responses, are not clear at present.[86]

The mechanisms underlying "primary resistance" leading to the incomplete elimination of a subset of malignant cells in imatinib-responsive patients are not well understood. Point mutations in the *BCR–ABL* kinase domain and *BCR–ABL* gene amplification are associated with acquired resistance to imatinib and are detectable in patients with a stable CCR.[187] However mutations are not consistently seen, occur in only a small percentage of cells, and do not consistently predict for subsequent relapse. Imatinib resistance could also be related to increased drug efflux and reduced intracellular drug levels in primitive progenitors, which may also express higher levels

of *BCR–ABL* than more mature cells.[188] It has been shown that nondividing primitive CML hematopoietic cells are especially insensitive to imatinib-induced apoptosis.[185,189] Microenvironmental interactions through maintenance of dormancy or by inducing antiapoptotic signals may help preserve viability of CML hematopoietic cells treated with imatinib. In the future, a better understanding of the mechanisms underlying persistence of leukemogenic cells may allow development of improved strategies to effect "cures" in CML patients with tyrosine kinase inhibitor treatment.

MANAGEMENT OF THE NEWLY DIAGNOSED CHRONIC MYELOID LEUKEMIA PATIENT IN THE IMATINIB ERA

What should be the initial management for CML patients? After years of clinical research, we know (a) imatinib is remarkably effective for patients treated in chronic phase, as greater than 85% of patients obtain a complete cytogenetic remission (CCyR).[70] In the IRIS trial, approximately 70% of cases remain in CCyR at 5 years of follow-up. Treatment of advanced phase (accelerated or blast disease) is associated with much poorer outcomes[73,74]: (b) allogeneic transplantation is generally associated with 10-year survival rates of 70% or better for younger patients in early chronic phase, but survival likewise falls in accelerated- or blast-phase disease[104]; and (c) relapse occurs for chronic-phase patients treated with imatinib, but outcome can be effectively monitored by sensitive RT-PCR assays.[190]

Imatinib has become the initial treatment of choice for patients with CML. For patients diagnosed in accelerated phase or blast crisis, initial treatment with imatinib results in better responses than seen with other nontransplant therapies, but these responses in general tend to be short-lived, and therefore advanced-phase patients should consider transplantation as soon as possible. For patients diagnosed during chronic phase, imatinib is a reasonable first choice of therapy. Current recommendations from advisory panels, such as the European Leukemia Net and the National Cancer Care Alliance, state that all chronic-phase patients should start on imatinib therapy, but allow for consideration of transplantation based on the patient's age, preference, and response to initial imatinib.

However, there are also questions that make the decision on how early to transplant problematic. For example, given that tyrosine kinase inhibitors such as imatinib do not appear to kill the CML stem cell, is relapse inevitable? Many relapses stemming from *ABL* point mutations act aggressively. Will these patients be especially hard to cure with transplantation? And although short-term tyrosine kinase inhibitor therapy does not seem to adversely affect transplant results, what will happen with long-term exposure to these agents?

For patients with chronic-phase disease, imatinib can be initiated with simultaneous workup of family donors and unrelated donors. Criteria for imatinib failure or suboptimal response are in evolution. Certainly, failure to achieve a complete hematologic response at 3 months of treatment is an indication to switch therapy. At 6 months of therapy, patients should have some cytogenetic response, and by 12 months, patients should achieve a major cytogenetic response, with the elimination of two-thirds of their Ph on cytogenetic exam. By a conservative approach, patients should achieve a complete cytogenetic remission by 18 months of therapy. Patients who relapse after a CCR, especially those with *ABL* point mutations, should consider alternative therapy, including transplant.

CHAPTER 70

PRIMARY MYELOFIBROSIS

Ronald Hoffman, Mingjiang Xu, and Giovanni Barosi

Primary myelofibrosis (PMF) is a chronic, malignant hematologic disorder characterized by splenomegaly, leukoerythroblastosis, teardrop poikilocytosis (ie, dacryocytes), some degree of marrow fibrosis, increased marrow microvessel density, and extramedullary hematopoiesis.[1–12] In PMF, there is a profound hyperplasia of morphologically abnormal megakaryocytes and clonal populations of monocytes that may be responsible for the marrow fibrosis due to the local release of fibrogenic growth factors.[7] This disorder was first described in 1879 by Heuck,[13] who reported the presence of marrow fibrosis and extramedullary hematopoiesis in the liver and spleen of two patients. PMF has also been referred to by a variety of other terms, including agnogenic myeloid metaplasia, myelosclerosis, idiopathic myeloid metaplasia, osteosclerosis and idiopathic myelofibrosis.[1–12] Fibrosis of the bone marrow is not unique to PMF and may accompany many other disorders (Table 70–1).[6,7] The designation PMF rather than idiopathic myelofibrosis was recently chosen by an international group of hematologists and hematopathologists to reflect our greater understanding of the origins of this disorder.[14,15] Furthermore, this same group created the terms post polycythemia vera (PV) myelofibrosis (post-PV MF) and post essential thrombocythemia (ET) myelofibrosis (post-ET MF) to identify myelofibrosis which is preceded by a history of PV or ET.[14,15] In PMF, the marrow fibrosis is believed to occur in response to the progeny of a clonal proliferation of hematopoietic stem cells.[16] This syndrome frequently leads to progressive marrow failure. In 1951, Dameshek[17] included PMF among the myeloproliferative disorders (MPD). This hypothesis was largely based on clinical observations of patients with PV, chronic myeloid leukemia (CML), and ET who developed marrow fibrosis and a clinical picture resembling PMF. Dameshek[17] also noticed that each of these MPDs frequently terminates in a leukemic phase.

EPIDEMIOLOGY

Few epidemiologic studies are available to estimate the incidence of PMF. Since the chronic MPDs have not been considered in the past to be malignancies, case registries have limited data on the incidence of such chronic MPD as PMF. The yearly incidence of PMF in Goteborg, Sweden, during a study period of 1983 to 1992 was calculated to be 0.4 cases per 100,000 persons.[18] Review of previously published reports indicated an annual incidence rate in European, Australian, and North American localities ranging from 0.5 to 1.3 cases per 100,000 persons.[18–23] The annual incidence rate of PMF in Olmstead County, Minnesota, was determined to be 1.33 cases per 100,000 persons, and in southeast England, the annual incidence has recently been reported to be 0.37 per 100,000 persons.[19] In Japan, PMF is considered a rare disorder, with only 84 cases per 100,000 persons determined at autopsy.[24,25] This figure was obtained by monitoring autopsy protocols from all Japanese medical schools, universities, general hospitals, and research institutes over a 10-year period.[24] The incidence of myelofibrosis among survivors who were 10,000 meters or less from the hypocenter of the atomic bomb explosion at Hiroshima was 18 times the incidence reported from the remainder of Japan.[26] These patients became symptomatic an average of 6 years after the bomb blast.[26] Such data indicate a strong link between excessive radiation exposure and development of PMF, which is further substantiated by the high incidence of myelofibrosis in patients who have received the contrast material Thorotrast (which contains 232Th, a radioactive element with a half-life of 1.41×10^{10} years).[27] Thorotrast is taken up and retained indefinitely by cells of the reticuloendothelial system, which results in continuous irradiation of the liver, spleen, lymph nodes, and bone marrow. Chronic exposure to several industrial solvents, including benzene and toluene, has also been associated with development of PMF.[28–31] PMF has been reported as a complication of chronic benzene poisoning since the chemical was first used in the leather and shoe industries during the 1930s and 1940s.[29,31] The average age at diagnosis of PMF is approximately 65 years, and most patients are diagnosed between 50 and 69 years of age.[1–12,23] In several series, men have been affected more frequently than women, but others have failed to confirm this male predominance.[1–12,23] Rarely, PMF has been reported in the pediatric age group.[32,33] In several children, PMF manifested in early childhood, and in one family, twins were affected.[32,33] Evidence of genetic transmission exists: a higher incidence has been reported in Ashkenazi Jews than in Arabs who both live in Northern Israel.[22]

BIOLOGIC AND MOLECULAR ASPECTS

Ward and Block[4] originally proposed that PMF represented a response of an intrinsically normal stem cell to an unidentified stimulus, but Dameshek[17] conjectured that the abnormal fibroblastic proliferation in PMF was not an integral part of the primary disorder. These conflicting hypotheses were first tested in studies using a variety of genetic markers to define the cellular origin of PMF. Jacobson and colleagues[16] demonstrated in an African American female PMF patient who was heterozygous for isoenzymes of glucose-6-phosphate dehydrogenase (G6PD) that circulating hematopoietic cells were derived from a common hematopoietic stem cell and that the bone marrow fibroblasts were nonclonal in origin. Using X chromosome gene probes, Lucas and coworkers[34] confirmed the clonal origin of hematopoiesis in PMF. Using a similar molecular biologic approach, Anger and associates[35] reported that in each of three cases of PMF suitable for clonal analysis, a clear-cut monoclonal X-inactivation pattern was observed. Greenberg and colleagues[36] studied the cytogenetic composition of bone marrow fibroblasts of a PMF patient who had a clonal cytogenetic abnormality in unstimulated peripheral blood cells, which was absent in the marrow fibroblasts. Fully developed fibrosis of the bone marrow in PMF is frequently preceded by a hypercellular phase of variable duration. The diagnosis depends on the demonstration of atypical megakaryocytes and an increased fibrosis within marrow biopsies and the exclusion of other MPDs.[8,37] Kriepe and coworkers[38] used an analysis of X-linked restriction fragment length polymorphisms of blood cells of patients at various stages of PMF to demonstrate clonality of hematopoiesis in advanced stages of PMF and in the prefibrotic phase. An *NRAS* mutation present in the hematopoietic cells of a PMF patient indicated that T and B cells were also involved in the malignant process in some patients, perhaps providing some explanation for the immunologic abnormalities associated with PMF.[39] Similarly, fluorescence in situ hybridization techniques have been used to detect clonal cytogenetic abnormalities in myeloid and in purified B- and T-cell lymphocytes in patients with PMF.[40] These studies indicate that PMF is a clonal hematologic malignancy originating in primitive hematopoietic cells capable of

Non-Hodgkin lymphoma
Carcinomas: breast, lung, prostate, stomach

producing lymphoid and myeloid cells and that the marrow fibrosis represents a secondary reaction of marrow stromal cells not involved by the process.[34–41] If marrow fibrosis is truly an epiphenomenon of the neoplastic hematopoietic cell proliferation, it may be expected to disappear if this cell population is eradicated. Reversal of myelofibrosis has been observed after allogeneic stem cell transplantation and infrequently seen after long-term administration of chemotherapy or interferon.[42–44] Such findings indicate that the bone marrow fibrosis in PMF is not irreversible and is clearly a consequence of the neoplastic cellular proliferation.

Erythroid and megakaryocyte colony formation occurs in vitro in the absence of added exogenous cytokines in PMF, a finding common to other MPDs.[45–48] LeBousse-Kerdiles and associates reported that such autonomous colony formation was observed only when the mononuclear cell fractions isolated from peripheral blood of PMF patients were assayed but not when purified CD34+ cells were similarly assayed. These findings indicated that the reported autonomous colony formation in PMF was caused by paracrine stimulation by cytokines secreted in culture by ancillary cell populations.[49] In contrast, Taksin and coworkers[50] provided convincing data indicative of true autonomous megakaryocyte colony formation by PMF progenitor cells. The autonomous megakaryocyte proliferation could not be attributed to a mutation in the cell receptor for thrombopoietin or by autocrine production of thrombopoietin by PMF progenitor cells. To gain insight into the molecular basis for this dysregulation of hematopoietic progenitors, a differential gene expression approach was employed to analyze autonomously proliferating megakaryocytes from PMF patients from their normal counterparts. These studies demonstrated that the gene for the immunophilin, *FKBP59* (also designated *FKBP4*), was overexpressed in 8 of 10 patients with PMF.[51] Their data suggest that FKBP[51] may exert an antiapoptotic effect mediated by inhibition of calcineurin activity.[51] Such a phenomenon may provide a potential biologic basis for increased cell survival signal in hematopoietic cells in PMF that may manifest as autonomous progenitor cell proliferation in vitro. Although a population of autonomous proliferating megakaryocyte progenitor cells may exist, a second and more common population remains dependent on the addition of exogenous growth factors. The hypothesis that marrow fibrosis in PMF is a secondary process has been further explained by the work of Castro-Malaspina and colleagues,[52] Wang,[53] and Hirata and coworkers.[54] These groups found that fibroblasts derived from marrow explants obtained from PMF patients displayed the same physical and proliferative characteristics as normal marrow fibroblasts. PMF and normal marrow fibroblasts exhibited anchorage and serum dependence, contact inhibition of growth, and similar production of hematopoietic colony stimulating activities. These data suggest that marrow fibroblasts and their precursor cells in PMF patients do not differ from those of normal subjects.

Many of the peripheral blood abnormalities associated with PMF may be attributed to the extramedullary hematopoiesis that is characteristic of this disorder. Extramedullary hematopoiesis had previously been attributed to the reactivation of quiescent hematopoietic stem cells, which are retained at sites of prior embryonic hematopoiesis, especially in the spleen.[4] This hypothesis has been questioned, because of the observation that the spleen is not a prominent site of fetal hematopoiesis in humans and by the observation that extramedullary hematopoiesis occurs in a wide variety of sites in PMF that cannot be accounted for by the fetal reversion hypothesis.[55–57] CD34+ cells in PMF exit from the bone marrow; because of abnormal trafficking patterns, they are filtered out by the spleen, accumulate progressively, and continue to proliferate.[56] Ultimately, there is an unequal distribution of CD34+ cells, with a twofold greater number being present in the spleen than the marrow. The myeloid metaplasia of the spleen is characterized by disturbances of splenic architecture, including an increased presence of megakaryocytes and their progenitor cells.[56] Intravascular hematopoiesis within the sinusoids of the bone marrow is a conspicuous finding in PMF.[58] It is likely that this finding is the result of marrow fibrosis distorting the marrow sinuses and allowing entrance of hematopoietic precursors or progenitor or stem cells into the sinusoids and access to the circulation.[58–60] The characteristic changes of the marrow vascular architecture consist of increased quantities of collagen type IV deposits associated with endothelial cell proliferation.[61,62] Moreover, sinusoidal hyperplasia and hypervascularity occur, resulting in increased blood flow.[62] The excessively dilated marrow sinusoids in PMF contain prominent intraluminal foci of hematopoiesis.[62,63] Thiele and associates[61] pursued a morphometric analysis of marrow vascular structures and collagen type IV deposits in PMF. Compared with normal controls and patients with PV, a significant increase in the numbers of marrow sinusoids and subendothelial collagen type IV was observed in cases of PMF.[61] Evolution of the fibroosteosclerotic changes in PMF was accompanied by a striking accumulation of collagen IV and a marked luminal expansion and irregularity. The formation of a network of blood vessels has been shown to be triggered by a broad variety of tumor cells as a consequence of the production and release of angiogenic factors and is therefore not specific to PMF.[63] This increase in marrow vasculature in PMF has been confirmed using immunohistochemical methods and has been shown to correlate with increased spleen size and to be an independent risk factor for overall survival.[64] Vessels from patients with PMF are frequently markedly abnormal and appear as localized vascular nests consisting of numerous short vessels that are highly branched and tortuous.[64,65] Thiele and colleagues[61] hypothesized that the increased marrow microvessel density in PMF was probably mediated by megakaryocyte α-granule constituents. Transforming growth factor β (TGF-β) and vascular endothelial growth factor (VEGF), for instance, has a profound effect on angiogenesis.[65–68] The evolution of the fibroosteosclerotic process in PMF appears to be a coordinated process closely related to the vascular proliferation and also modulated by growth factors present within abnormal megakaryocytes.

Chagraoui and coworkers have reported that the osteosclerosis in mice with MPD due to thrombopoietin overexpression occurs predominantly due to upregulation of osteoprotegerin production by

marrow stromal cells.[69] Osteoprotegerin is a secreted molecule that binds to the ligand for the RANK receptor (receptor activator of NF-κB) expressed on osteoblast progenitor cells. The RANK ligand binds to the RANK receptor and promotes osteoblasts differentiation.[70] TGF-β is also a negative regulator of osteoclastogenesis through direct stimulation of transcriptional secretion of osteoprotegerin and downregulation of RANK ligand.[71,72] In patients with PMF, it remains unknown if the degree of osteosclerosis can be corrected with increased levels of osteoprotegerin. By contrast, Garimella and coworkers have also provided evidence that the osteosclerosis observed in GATA1 low mice and myelofibrosis is due to the elaboration of bone morphogenetic proteins by megakaryocytes.[73] Bone morphogenetic proteins cause abnormal stimulation of marrow osteoprogenitor cells resulting in overgrowth of cancellous bone and osteosclerosis.

A number of angiogenic growth factors, including basic fibroblast growth factor (bFGF) and vascular endothelial cell growth factor, have been implicated as causative factors of the increased marrow microvessel density in PMF.[49,66–68] Elevated serum VEGF levels have been reported in PMF, and increased expression of bFGF has been reported in PMF megakaryocytes and platelets.[47,59,60] These angiogenic cytokines are the products of the abnormal megakaryocytes present in PMF marrow and the increased marrow microvessel density observed is ultimately a consequence of a cytokine release characteristic of PMF megakaryocytes. It is yet to be proved that the endothelial cell proliferation in PMF is not part of the malignant clone leading to this disease process. A cell called a *hemangioblast*, which is capable of giving rise to myeloid and endothelial cells, may be the site of the oncogenic event leading to PMF.[75] Groopman[75] first hypothesized that growth factors released from neoplastic hematopoietic cells in PMF were capable of stimulating marrow fibroblast proliferation and suggested that the megakaryocyte was the primary source of such proliferation factors. The role of megakaryocytes in the development of fibrosis in PMF is further supported by the megakaryocytic hyperplasia with dysplastic or necrotic megakaryocytes that characterizes this disorder, by the increased circulating megakaryocytes and megakaryocyte progenitors that are present in PMF, by the association of marrow fibrosis and acute megakaryocytic leukemia, and by the presence of myelofibrosis in gray platelet syndrome, an inherited disorder of platelet α-granules.[76–78] Castro-Malaspina and coworkers[79] subsequently showed that megakaryocyte-enriched marrow cell homogenates and platelet homogenates induced DNA synthesis by human marrow fibroblasts. This group hypothesized that ineffective megakaryocytopoiesis in PMF results in liberation of excessive amounts of such growth factors, leading to marrow fibroblast proliferation and collagen synthesis.[79] Platelet-derived growth factor (PDGF), TGF-β, and epidermal growth factor (EGF), each of which are contained within platelet and megakaryocyte α-granules, stimulate marrow fibroblast proliferation.[81–83] TGF-β enhances type I and type III procollagen and fibronectin synthesis by marrow fibroblasts.[81] Kimura and associates[83,84] presented data to suggest that MPD fibroblasts are more sensitive to human serum mitogens than normal marrow fibroblasts. The PDGF content of platelets from PMF patients is decreased, indicating that a release or leakage of such growth factors by marrow megakaryocytes may occur.[49,85] Their studies indicated that if α-granule constituents were important in the development of marrow fibrosis, their release or leakage would likely occur within the marrow cavity. Such local effects could result in fibrosis without leading to increased concentrations of α-granule constituents in the general circulation. Martyré and colleagues[49,85] further examined the possibility that platelet α-granule constituents may account for marrow fibrosis in PMF. In these studies, PMF platelet PDGF and TGF-β levels were found to be 2.0- to 3.0-fold and 1.5- to 3.0-fold higher, respectively, in PMF than in normal controls, whereas EGF levels in PMF were similar to those of control platelets.[85] The roles of PDGF and TGF-β in the biogenesis of PMF probably are not restricted to promoting fibroblastic proliferation but are also related to the effect of these two growth factors on synthesis, secretion, and degradation of extracellular matrix components.[80,82] Martyré and coworkers[49,85] provided additional data that strengthens the hypothesis that TGF-β plays a pivotal role in the development of progressive fibrosis in PMF. This group documented the increased expression of TGF-β mRNA in peripheral blood mononuclear cells isolated from PMF patients and localized this to peripheral blood megakaryocytes of PMF patients.[85] They have recently reported that the overexpression of PMF megakaryocyte TGF-β is a consequence of NF-κB activation.[86] These data strongly implicate TGF-β as a major player in the biogenesis of fibrosis in PMF.[49,76,85]

TGF-β enhances fibronectin and collagens types I, III, and IV as well as chondroitin or dermatan sulphate and proteoglycan gene expression.[87,88] TGF-β decreases the synthesis of various collagenase-like enzymes that degrade extracellular matrices while at the same time stimulating the synthesis of protease inhibitors such as plasminogen activator inhibitor 1.[89,90] The net effect of these complex interactions is the accumulation of extracellular matrix, which probably contributes to further progression of fibrosis. Additional growth factors probably are involved in the development of progressive fibrosis in PMF. Circulating megakaryocytic cells and platelets from PMF patients have been shown to possess high levels of bFGF.[91] Because bFGF is devoid of a secretion peptide signal, bFGF is not present in media conditioned by megakaryocytic cells from PMF patients.[92] bFGF is a potent angiogenic factor and is a mitogen for human bone marrow stromal cells.[91] Elevated platelet, megakaryocyte, and serum bFGF levels have been reported in PMF patients with progressive fibrosis.[91,93] BFGF may be released or leaked from dysplastic and necrotic PMF megakaryocytes or platelets. These findings suggest that bFGF may also contribute to the progressive fibrosis and pronounced angiogenesis frequently observed in PMF.[91,93]

The roles of the megakaryocytes and platelets in the development of marrow fibrosis were further clarified by the transplantation of marrow cells genetically modified to overexpress thrombopoietin into normal mice.[94,95] These animals possessed increased numbers of platelets and megakaryocytes and developed a syndrome characterized by marrow myelofibrosis, osteosclerosis, extramedullary hematopoiesis, and elevated numbers of circulating hematopoietic precursors within a period of 3 months.[94,95] In these mice, TGF-β and PDGF levels in platelet-poor plasma were elevated twofold to threefold higher than those in normal control mice.[94,95] Retransplantation of these mice with normal marrow cells resulted after 12 to 15 weeks in reduction of platelet and megakaryocyte numbers and reversal of the marrow myelofibrosis and osteosclerosis.[95] These data dramatically demonstrate the roles of megakaryocytes and platelets and their intracellular growth factors in the generation of marrow fibrosis. Remarkably, transgenic mice overexpressing thrombopoietin in the liver but not the marrow have similar degrees of megakaryocytic hyperplasia and thrombocytosis but do not develop marrow fibrosis.[96] The discrepancy between these two animal models emphasizes the unique consequences that marrow thrombopoietin generation may play in the generation of marrow fibrosis. Ozaki and associates[97] reported that thrombopoietin was capable of enhancing the production of megakaryocyte PDGF, PF-4, and TGF-β.

In a number of reports, elevated thrombopoietin levels have been reported in patients with PMF.[98–100] This unanticipated elevation of plasma thrombopoietin levels was not caused by enhanced production of thrombopoietin mRNA by marrow fibroblasts or marrow cells but was probably caused by the reduced expression of the thrombopoietin receptor by the platelets and megakaryocytes of PMF patients, leading to decreased clearance of thrombopoietin.[100,101] Vannucchi and colleagues[102] used another rodent model to determine the relationship between marrow megakaryocytic hyperplasia and marrow fibrosis. They studied mutant mice with reduced expression of the transcription factor GATA1. These mice frequently develop anemia and die during gestation or after birth. The few animals that survive to adulthood recover from the anemia but remain thrombocytopenic throughout life because of a block in megakaryocyte maturation into proplatelets that results in megakaryocyte hyperplasia in the marrow and the spleen and increased production of TGF-β.[103] These animals develop a clinical picture after 15 months that closely resembles PMF, including anemia, teardrop red blood cells, fibrosis of the marrow

and spleen, extramedullary hematopoiesis in the liver, and progenitor cell mobilization into the peripheral blood.[102] Unlike PMF in humans, the myelofibrosis in the GATA1 low mice is not the consequence of a clonal disorder and does not progress to acute leukemia. Mutations in the GATA1 functional pathway in human PMF have not been described.[104] However, at the protein level, a large number of the megakaryocytes in the bone marrow of PMF patients are GATA1 negative, suggesting that whatever the genetic defect leading to PMF is, it involves the pathway which affects the posttranscriptional and/or posttranslational regulation of GATA1 in megakaryocytes.[105] Interesting, this study identified that the presence of GATA1 negative megakaryocytes, and not the Jak2V617F mutation, is a marker that distinguishes PMF from other MPDs. Given the central role played by GATA1 in megakaryopoiesis, it is not surprising that megakaryocytes with low GATA1 content are all characterized by common morphological abnormalities. These abnormalities include: lack of proper organization of the α-granules, abnormal P-selectin localization on the demarcation membrane system, increased emperipolesis of neutrophils through the demarcation membrane system and increased levels of para-apoptosis, a TUNEL negative process of cell death mediated by neutrophils and macrophages.[104] It is conceivable that at least some of these megakaryocytes alterations may play a central role in the pathobiology of PMF. The two rodent models of myelofibrosis, GATA1 low mice and mice that overexpress thrombopoietin eventually develop myelofibrosis, but the rate of progression to marrow fibrosis is remarkably different. The thrombopoietin-overexpressing mice develop myelofibrosis in 3 months, whereas the GATA1 animals require 15 months to achieve a similar state. Although both animal models have been shown to have increased levels of the fibrogenic cytokines TGF-β1, PDGF, and VEGF within their femurs compared with normal littermates, the levels of these cytokines in the GATA1 low mice were reduced compared with the animals that overexpressed thrombopoietin.[102,103] The less pronounced elevation in these cytokines probably explains the greater period required to develop marrow fibrosis in the GATA1 low mice.

To further assess directly the role of TGF-β in the development of myelofibrosis, marrow stem cells from homozygous TGF-β1null mice (TGF-$\beta1^{-/-}$) and wild-type mice were isolated and genetically modified with a retroviral vector encoding the murine thrombopoietin gene and transplanted into lethally irradiated wild-type hosts.[106]

Although thrombopoietin levels and platelet levels were increased in both groups of animals, only animals receiving the wild-type grafts but not the stem grafts from TGF-β1null mice developed myelofibrosis. These studies provide further evidence for the critical role that TGF-β1 plays in the biogenesis of myelofibrosis and provides rationale for the potential use of TGF-β as a drug target in future treatments for this disease. The mechanism by which the pathologic release of growth factors from megakaryocytes occurs in PMF remains unknown. Schmitt and coworkers[107] suggested that megakaryocyte emperipolesis might lead to this liberation of fibrogenic cytokines. *Emperipolesis* is defined as the random entry of hematopoietic cells into the cytoplasm of megakaryocytes. This group documented increased emperipolesis of neutrophils and eosinophils in PMF and the liberation of myeloperoxidase-positive granules by the engulfed neutrophils.[107] They correlated the degree of emperipolesis in PMF marrow biopsies with the degree of marrow fibrosis. They suggested the abnormal P-selectin distribution in megakaryocytes accounted for the selective sequestration of granulocytes by PMF megakaryocytes.[107]

Megakaryocytes are not the only cells capable of releasing cytokines that promote marrow fibrosis. Levels of macrophage colony stimulating factor, a cytokine that regulates macrophage development and proliferation, are elevated in the serum of PMF patients.[108] Monocytes/macrophages from patients with PMF can produce greater quantities of TGF-β and interleukin-1 (IL-1) than normal controls.[109] IL-1 and TGF-β are fibroblast mitogens that induce extracellular matrix protein production. Rameshwar and coworkers[109] showed that monocyte adhesion to extracellular matrix proteins led to the overproduction of IL-1 and TGF-β by PMF monocytes. The monocyte adhesion molecule CD44 appears to be involved in the induction of fibrogenic cytokines by mediating the interaction between monocytes and accumulated extracellular matrix protein deposits.[109] Rameshwar and associates[110] showed that the pro-inflammatory transcriptional factor NF-κB plays a pivotal role in the elaboration of IL-1 and TGF-β in the activation of NF-κB monocytes and that of PMF patients. These investigators suggest that NF-κB stimulates TGF-β production by influencing intracellular IL-1 levels and may serve as another potential therapeutic target for the treatment of PMF. The role of monocytes in the biogenesis of marrow fibrosis was further supported by the report of Frey and colleagues.[111] They showed that although immune-deficient mice that were treated with an adenoviral vector expressing the human thrombopoietin gene developed megakaryocyte hyperplasia, osteomyelofibrosis, and extramedullary hematopoiesis, similarly treated nonobese diabetes (NOD) and severe combined immune deficiency (SCID) mice with similar elevations of thrombopoietin levels did not develop fibrosis of the marrow. NOD/SCID mice possess functionally defective monocytes and macrophages in terms of IL-1β secretion, cytokine receptor expression, and protein kinase C levels. These investigators hypothesized that normal monocytes and macrophages that were present in SCID mice but not NOD/SCID mice were necessary for the development of osteomyelofibrosis.[111] Recently, however, Wagner-Ballon and coworkers have performed similar studies resulting in conflicting data, which suggest that completely functional monocytes are not required to develop myelofibrosis.[112] They showed that thrombopoietin and TGF-β levels in the plasma of NOD/SCID mice engrafted with thrombopoietin overexpressing hematopoietic cells reach levels similar to the levels achieved in immunocompetent mice and that both types of animals develop an MPD characterized by marrow fibrosis. The discrepancies between the studies of Fey et al and Wagner-Ballon et al might be due to the levels of thrombopoietin achieved using two different gene delivery system.[111,112] Frey et al used an adenoviral construct with a human thrombopoietin cDNA, while Wagner-Ballon et al used a retroviral vehicle encoding a murine thrombopoietin DNA to overexpress thrombopoietin in NOD/SCID, SCID, and wild-type mice.[111,112] Wagner-Ballon et al were able to achieve higher levels of thrombopoietin and TGF-β1 than Frey and coworkers.[112] These data lead one to question if monocytes/macrophages play a crucial role in the development of myelofibrosis promoted by thrombopoietin.

Recently, greater insight into the molecular origins of the MPD has been gained following the discovery of a gain of function mutation of an auto-inhibitory domain of the Janus kinase family of protein tyrosine kinases, which is involved in cytokine receptor signaling. The Jak2V617F mutation results from a valine to phenylalanine mutation at amino acid Jak2V617F which leads to ongoing phosphorylation activity which then can bind to a cytokine receptor and promote STAT recruitment.[113,114] This mutation is the likely cause of the hypersensitivity to cytokines that characterizes hematopoietic progenitors from each of the MPD.[113,114] In a mouse marrow transplant model, marrow cells transduced with Jak2V617F results in a clinical phenotype which closely resembles PV including erythrocytosis, extramedullary hematopoiesis, and marrow fibrosis.[115] Although 90% of patients with PV are Jak2V617F positive, approximately 50% of PMF patients harbor this mutation.[14,15,113–116] The Jak2V617F mutation is homozygous in 13% of patients with PMF but 30% of patients with PV.[14,15] Homozygosity has been attributed to homologous recombination. Homozygosity of Jak2V617F in PMF patients is associated with a more frequent occurrence of unfavorable cytogenetic abnormalities.[117] There is conflicting data as to whether the clinical course of patients with Jak2V617F positive and Jak2V617F negative PMF differ.[118,119] Additional somatic mutations have been identified in patients with PMF which likely play a role in the biogenesis of PMF. A mutation in the transmembrane domain of the thrombopoietin receptor (cMPL) has been documented in 9% of patients with Jak2V617F negative PMF (MPLW515L or MPLW515K).[120,121] Pardanani and coworkers have provided data to support the coexistence of MPL515L, MPL515K, and MPL wild-

type (WT) alleles in the same patient.[121] Furthermore, 30% of PMF patients with mutations of cMPL also have the Jak2V617F mutation.[121] By studying archival material, the burden of MPL515L and MPK515K and Jak2V617 in PMF patients has been shown to remain constant throughout the clinical course of patients with PMF.[122] In a murine bone marrow transplant assay, expression of MPLW515L but not wild-type MPL resulted in a rapidly progressive, fully penetrable, lethal MPD (18 days) characterized by marked thrombocytosis, leukocytosis, splenomegaly, hepatomegaly, marrow megakaryocytic hyperplasia, and marrow fibrosis, but not erythrocytosis.[120] These data have suggested that the MPL mutation favors the development of thrombocytosis while the Jak2V617F mutation favors the development of erythrocytosis. Guglielmelli and coworkers have recently reported that PMF patients with MPL515L/K mutations as compared with MPL wild-type PMF were older, presented with more severe anemia and were more likely to require transfusional support.[123] Although 50% of patients with PMF have clonal hematopoiesis and lack mutations of either Jak2 or cMPL, they have a similar clinical phenotype to patients with the recently identified somatic mutations.[124] It is, therefore, difficult to attribute to either of these mutations as the sole cause of PMF. It appears, however, that the genetic origins of PMF represent the culmination of multiple genetic and possibly epigenetic events. Additional genetic events which might play a role in this process are being sought by a number of laboratories.[125–127] Comparative genomic hybridization has shown that gains of cytogenetic material occur in over 50% of PMF patients and most commonly involve gains of 9p, 2q, 3p, chromosome 4, 12q, and 13q.[127] Furthermore, Dingli et al have identified an unbalanced translocation between chromosomes 1 and 6 with specific breakpoints (t1,6) that they believe to be highly specific to PMF. These chromosomal sites may harbor additional genes that play a role in the origins of PMF.[125]

Further insight into the phenotypic heterogeneity of Jak2V617F positive and negative MPDs has recently been provided. Teofili and coworkers using immunohistochemical approaches of bone marrow reported that PV is characterized by increased expression of phosphorylated STAT3 and STAT5 protein, whereas PMF is characterized by reduced expression of STAT3 and STAT5.[128] This expression pattern was independent of Jak2V617F status. Such observations suggest that additional or alternative molecular events occur in PMF and PV that might play a role in the development of their distinctive clinical phenotypes.

A number of investigators have shown that myeloid cells (red cells, white cells, and megakaryocytes/platelets) are clonal in this disorder and that they harbor the Jak2V617F or MPL515L/K mutations.[129–131] Furthermore B, T, and natural killer cells isolated from PMF patients have been shown in selected cases to be Jak2V617F or MPL515 L/K positive.[131] These studies indicate that Jak2V617F and MPL mutational events originate in a cell capable of generating both myeloid and lymphoid cells such as the pluripotent hematopoietic stem cell. The ability of primitive human hematopoietic cells to engraft sublethally irradiated immunodeficient mice is the standard surrogate in vivo assay for human hematopoietic stem cells. Xu et al have demonstrated that PMF $CD34^+$ cells are capable of engrafting NOD/SCID mice and generating myeloid and B cells that are clonal, Jak2V617F positive and carry a patient-specific marker chromosomal abnormality.[132] The differentiation program of PMF $CD34^+$ cells following transplant into NOD/SCID mice was also remarkably different from that of normal $CD34^+$ cells, producing greater numbers of $CD34^+$, $CD33^+$, and $CD41^+$ cells but fewer $CD19^+$ cells.[132] This predisposition to produce greater numbers of megakaryocytes was further explored by incubating PMF, PV, and $CD34^+$ cells in vitro in the presence of stem cell factor and thrombopoietin. PMF $CD34^+$ cells displayed a far greater proliferative capacity and produced greater numbers of megakaryocytes which were characterized by a resistance to undergo apoptosis in vitro due to overexpression of the antiapoptotic factor Bcl-XL.[133] The megakaryocyte hyperplasia in PMF, therefore, could be accounted by two factors, an increased ability of $CD34^+$ cells to generate megakaryocytes and the accumulation of megakaryocytes due to Bcl-xL overexpression.[133] Although Bcl-xL overexpression has been linked to Jak2V617F, PMF megakaryocyte Bcl-xL overexpression also occurred to a similar degree in megakaryocytes generated from $CD34^+$ cells isolated from individuals with both Jak2V617F positive and negative disease.[133]

Marrow megakaryocytes PMF have been shown by Ciurea et al to produce greater amounts of TGF-β than MKs generated in vitro from normal volunteers or patients with PV.[133] Komura and coworkers have previously reported that an immunophilin FK506 binding protein 51 (FKB51) is overexpressed in PMF megakaryocytes and that FKB51 overexpression leads to activation of NF-κB in PMF MKs.[86] Cells with activated NF-κB produce greater amounts of TGF-β. This effect of NF-κB is likely indirect since NF-κB cannot directly increase transcription of TGF-β since its promoter does not have NF-κB binding sites. These studies suggest that NF-κB or TGF-β inhibitors might be useful in preventing the progression of marrow fibrosis in PMF.

The number of unilineage and multilineage hematopoietic progenitor cells constitutively mobilized into the blood of PMF patients is dramatically increased.[45–48] The number of CD34+ cells present in the peripheral blood in PMF is 360 times greater than in normal controls and 18 to 30 times higher than in patients with polycythemia vera or essential thrombocythemia.[55] These findings are so striking that some investigators have suggested that the quantitation of CD34+ cells in the peripheral blood might serve as a means of discriminating PMF from other MPDs. A level of 15×10^6/L of $CD34^+$ cells in peripheral blood allows differentiation of PMF from PV and ET.[55] Barosi and coworkers[55] reported that the numbers of circulating $CD34^+$ cells tend to increase as the disease progresses and that there is a close correlation between patients presenting with more than 300×10^6 $CD34^+$ cells/L of peripheral blood and imminent evolution to leukemia. These findings suggest that PMF $CD34^+$ cells trafficking abnormality due to the inability of these cells to be retained within the marrow or their premature release into the peripheral blood.

PMF is characterized not only by the constitutive mobilization of $CD34^+$ hematopoietic cells but also endothelial progenitor cells into the peripheral blood. Endothelial progenitor cell mobilization predominates during the prefibrotic phase of PMF while hematopoietic stem/progenitor cell mobilization occurs characteristically in more clinically advanced phases of the disease.[134,135] This dysregulation of stem cell trafficking likely ultimately leads to the seeding of extramedullary sites with primitive hematopoietic and endothelial cells which results in production of extramedullary hematopoiesis within the liver and spleen as well as a variety of other organs. Several proteolytic pathways have been documented to play a role in cytokine mediated stem cell mobilization. Proteins released by activated neutrophils cleave vascular adhesion molecule-1 (VCAM-1) expressed by stromal cells leading to the disruption of a key adhesive interaction between VCAM-1 and very late antigen-4 (VLA-4) expressed by hematopoietic stem cells and progenitor cells.[136] The interaction between stromal cell-, endothelial cell and osteoblasts derived stromal cell derived factor-1 (SDF-1) and the CXC chemokine receptor-4 (CXCR-4) expressed by hematopoietic stem cells and progenitor cells is also believed to determine patterns of stem cell trafficking. Proteases including neutrophil elastase, soluble matrix metalloproteinase-9 (MMP-9) and cell-bound MMP-9 have been shown to play a role in the constitutive mobilization of $CD34^+$ cells that occurs in PMF patients. The concentrations of soluble VCAM-1, a degradation product of VCAM-1 is elevated in the plasma of PMF patients and these levels correlate with the absolute numbers of $CD34^+$ cells in the peripheral blood. Furthermore, CXCR-4 expression by PMF $CD34^+$ cells is downregulated which may account for altered SDF-1/CXCR-4 interactions participating in $CD34^+$ cell mobilization.[136,137] This down regulation of CXCR4 expression can be reversed in vitro by treatment with chromatin modifying agents which suggest that this event might be due to epigenetic events.[138] Furthermore the expression levels of CXCR4 were significantly lower in patients with a high burden of Jak2V617F (allele frequency 75%) as compared to patients with low burden Jak2V617F, suggesting the dependence of gene expression on the frequency of the mutated allele.[139] Similar degrees

of CD34+ cell mobilization are observed in post-ET and post-PV MF as occurs in PMF.[135,136] In PV patients, Passamonti and coworkers have demonstrated a relationship between Jak2V617F gene dosage and the degree of constitutive mobilization of CD34+ cells suggesting that such mobilization may be a consequence of the transition from Jak2V617F heterozygosity to homozygosity which is accompanied by granulocyte activation.[140] Drugs which target the proteases responsible for constitutive CD34+ cell mobilization may present an intriguing strategy to prevent the establishment of or to eliminate extramedullary sites of hematopoiesis in patients with PMF.

ETIOLOGY AND PATHOGENESIS

Exposure of a variety of animal models to chemical agents, industrial solvents, hormones, viruses, immunologic stimuli, and ionizing radiation have led to the development of marrow fibrosis.[3] A model of PMF has been established in the rabbit,[141–147] in which saponin administered intravenously induces extramedullary hematopoiesis and myelofibrosis over a period of weeks.[142] Mice and rats fail to respond to the same doses of saponin.[141] Hoshi and Weiss provided ultrastructural evidence to suggest that saponin causes damage to the endothelium of marrow vascular cells, rendering them incompetent.[141] A series of hemorrhagic events appears to occur, leading to release of normoblasts into the peripheral blood, marrow hypoplasia, fibrosis, and regeneration.[141] This effect is accompanied by the appearance of increased numbers of hematopoietic progenitor cells in the blood and spleen and a simultaneous depletion of such cells in the marrow.[141] Such marrow vascular injury may be a common link leading to the development of myelofibrosis.

Reticulin fibrosis of the marrow represents an exaggeration of the fibrous pattern of normal marrow. In contrast, collagen fibrosis occurs in primary and secondary PMF and results in the disruption and obliteration of the sinusoidal architecture of the bone marrow. The marrow stroma in PMF is composed of an increased deposition of extracellular matrix proteins, including collagen types I, III, V and VI; hyaluronic acid; the noncollagenous glycoproteins; fibronectin; vitronectin; tenascin; and the basement membrane components collagen type IV and laminin.[7] Bone marrow reticulin is composed of types I and III collagen and fibronectin.[144–146] Charron and coworkers[147] documented a progressive increase in marrow collagen content during the course of PMF. The increment in collagen was highest in patients in whom the disease was of longest duration.[147] The degree of collagen fibrosis can be best estimated by silver impregnation or by the use of a trichrome stain of a marrow biopsy specimen.[7] The silver stain stains reticulin, the glycoprotein coating of stromal cells, black (Fig. 70–1), and trichrome stains collagen bluish green. Compared with collagen extracts from normal individuals, PMF extracts showed a moderate increase in neutral soluble collagen and a larger increase in polymeric collagen.[147] Charron and associates[147] also observed changes in the pattern of marrow collagen deposition during the course of PMF. Early in the course, there is a higher percentage of newly synthesized fibers, and later, more polymeric collagen is present, presumably as a result of progressive cross-linking and insolubilization. Charron and colleagues[147] and Gay and coworkers[145] claim that type III collagen preferentially increases in the early stages of the disease but that it is subsequently replaced by type I collagen. The serum level of procollagen N-terminal peptide III (PC III), which is cleared extracellularly during collagen biosynthesis, is increased in most PMF patients.[148] This finding supports the concept that type III collagen synthesis is increased in PMF.[149–151] Some investigators have suggested that PC III levels do not reflect the extent of marrow fibrosis in PMF,[149,150] but PC III elevation in a longitudinal study of patients with PMF was found to be a sensitive marker of disease activity.[151,152] PC III levels were observed to fall in patients responding to chemotherapy and to rise 1 to 2 weeks before elevations in white blood cell and blast cell counts in patients unresponsive to chemotherapy.[152] Bone marrow fibrosis appears to depend on the accumulation of collagen and on the establishment of an equilibrium

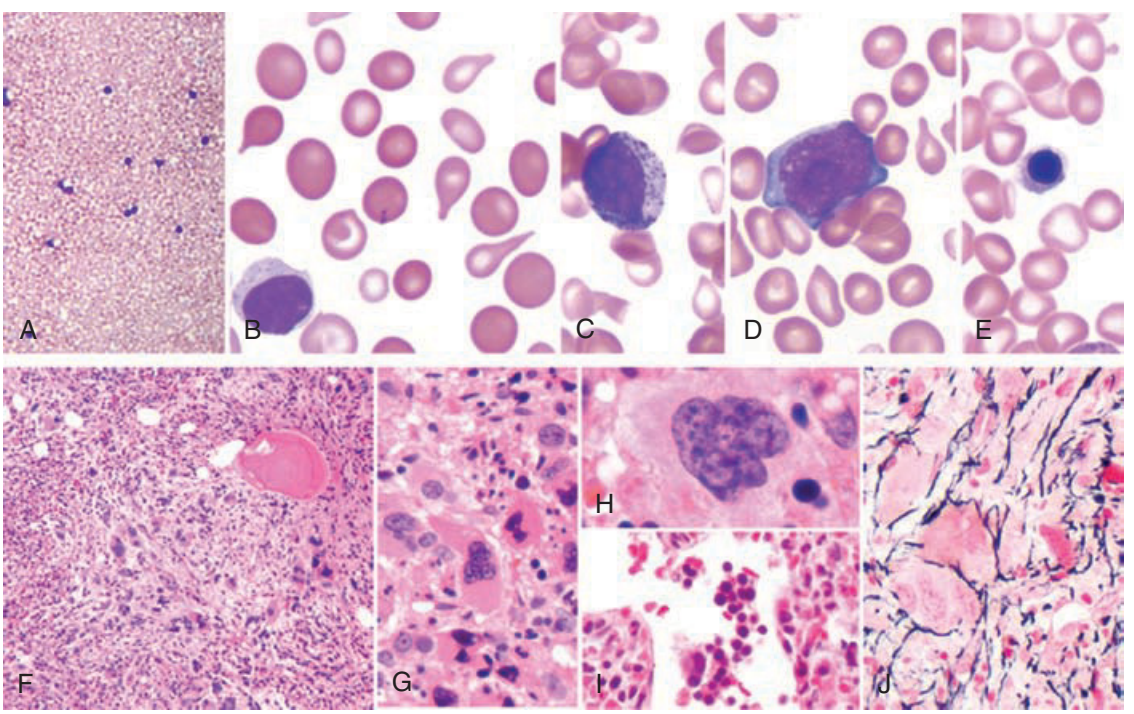

Figure 70–1 PRIMARY MYELOFIBROSIS. Peripheral Blood **A–E,** and Bone Marrow Biopsy **F–J.** The leukocyte count can vary in PMF from leukopenia to marked leukocytosis. In the case illustrated, the count was normal (**A**). However, the smear showed numerous dacryocytes, or teardrop forms (**B**), and a leukoerythroblastic picture (**C, D, E**), ie, the presence leukoblasts, or immature granulocytic precursors (**C**), including blasts (**D**), and circulating nucleated red blood cells or erythroblasts (**E**). The bone marrow biopsy is frequently hypercellular (**F**) and comprised of an atypical megakaryocytic and granulocytic proliferation (**G**), in which some of the megakaryocytes have atypical and pyknotic nuclei. Other megakaryocytes (**H**) are considered to have nuclei that are "cloud-like." The marrow biopsy frequently shows sinusoidal hematopoiesis (**I**) and significant fibrosis as illustrated by a reticulin stain (**J**).

between collagen production and destruction. PC III levels would therefore be expected to reflect collagen synthesis more closely than total marrow collagen content. Extensive deposition of collagen type VI in PMF has been documented.[78] This structural component forms a linkage between individual collagen type I or collagen type III fibers, or both. Advanced marrow fibrosis is associated with increased deposition of fibronectin, tenascin, and vitronectin. In normal bone marrow, collagen type IV and laminin are limited to discontinuous sinusoidal membranes, and myelofibrotic stroma possess continuous sheets of both proteins resulting from increased marrow microvessel density and endothelial cell proliferation. The accumulation of matrix depends on a balance between the synthesis and degradation of matrix components. Extracellular matrix can be degraded by a variety of proteases, including matrix metalloproteinases (MMPs). MMP activity can be inhibited by tissue inhibitors of matrix metalloproteinases (TIMPs). Wang and associates[153] explored whether the marrow fibrosis in MMP could be caused by an imbalance between MMPs and TIMPs. They documented decreased plasma levels of MMP-3 and an elevation of TIMP-1, but normal levels of MMP-1, MMP-2, and MMP-9 in PMF patients and suggested that these enzymes might play a role in the degree of marrow fibrosis of individual patients.[153] Jensen and colleagues[154] reported that plasma levels of soluble plasminogen activator receptor levels were increased in PMF patients. The binding of this single-chain proenzyme of urokinase-type plasminogen activator to its cell bound receptor (CD87) results in the generation of plasmin.[154] Plasmin-mediated activation of MMPs in concert with plasmin can lead to the degradation of a variety of matrix proteins. The elevation of plasma levels of the soluble plasminogen activator receptor is likely an indication of ongoing stromal cell activity and constant tissue remodeling within the marrow of PMF patients.

The kinetics of engraftment of normal stem cells following allogeneic stem cell transplantation in PMF patients and the slow regression of fibrosis after transplant leads one to question if the distorted marrow architecture associated with fibrosis in PMF actually disrupts the functions of the marrow microenvironment.[155–157] In PMF patients, normal stem cells engraft following transplant and hematopoietic cell recovery occurs before the marrow fibrosis has resolved.[155–157] These observations raise some questions concerning the prospects for success with strategies for the treatment of patients with PMF that are directed solely toward reversing the marrow fibrosis rather than eliminating the malignant clone and its progeny. Furthermore in mouse models of myelofibrosis, inhibition of TGF-B1 was capable of preventing the development of marrow fibrosis but did not rescue animals from a fatal MPD.[158]

CLINICAL MANIFESTATIONS

Table 70–2 lists the symptoms and physical findings of patients with PMF at presentation.

Approximately 25% of patients are entirely asymptomatic and come to medical attention because of an enlarged spleen detected during routine physical examination or because of an abnormal blood cell count or peripheral blood smear. The most common symptom in PMF is fatigue, which in the majority of patients affects the quality of daily life and social activities. Fatigue may be the result of anemia, which leads to the associated complaints of weakness, dyspnea on exertion, and palpitations. But when patients were questioned with the aid of specific questionnaires, fatigue was found to be a significant burden even in patients who were not anemic.[159] The presence of anemia, splenomegaly, and other features associated with advanced disease favored the development of higher levels of fatigue. Other nonspecific constitutional symptoms, including fever, night sweats, pruritus, bone pain, and weight loss are present at diagnosis in 20% to 50% of patients with PMF[159] and are more frequent in older patients.[160]

With enlargement of the spleen, various syndromes characterized by abdominal discomfort emerge.[161] Pressure of the spleen on the stomach may lead to delayed gastric emptying and early satiety.[161]

Table 70–2 Summary of Symptoms and Physical Findings of Patients with Primary Myelofibrosis Detected at Diagnosis

	Incidence (%)		
Symptom or Finding	**Varki et al.[5]**	**Silverstein[3]**	**Visani et al[377]**
Asymptomatic	21	30	16
Fatigue	71	58	47
Fever	5	10	5
Weight loss	39	15	7
Night sweats	21	6	NR
Symptoms due to enlarged spleen	11	23	48
Bleeding	20	17	5
Gout/renal stones	13	6	NR
Pallor	NR	60	NR
Petechiae/ecchymoses	20	15	NR
Splenomegaly	89	90	99
Hepatomegaly	64	70	39
Peripheral edema	13	NR	NR
Evidence of portal hypertension	2	6	2
Lymphadenopathy	2	10	1
Jaundice	0	4	NR

NR, not reported.

Patients may merely complain of a dull, heavy sensation in the left upper quadrant. Pain of extreme severity, simulating an acute abdominal emergency, is produced by splenic infarction. Pressure of the spleen on the colon or small bowel may be responsible of severe, disabling diarrhea.

Thrombotic episodes may rarely be the presenting feature of the disease or may occur during its course with a probability of 9.6% at 5 years, a rate higher than in the control general population.[162] Thrombosis may be venous (cerebral venous sinus thrombosis, splanchnic vein thrombosis, deep vein thrombosis, pulmonary thromboembolism) or arterial (stroke, transient ischemic attacks, retinal artery occlusion, myocardial infarction, angina pectoris, and peripheral arterial disease). The cellular phase of PMF with thrombocytosis and presence of cardiovascular risk factors such as hypertension, smoking, hypercholesterolemia, and diabetes are the independent predictors of thrombosis.[162] After splenectomy, the rate of thrombosis increases and is associated with the development of thrombocytosis following the procedure.[162]

Bleeding problems may complicate the clinical course of PMF patients. Bleeding may be trivial, as manifested by petechiae and ecchymoses, or it may be life-threatening as a result of uncontrollable esophageal bleeding.[1–3,7,9] It may result from thrombocytopenia or poor platelet function.[1–3,7,9] Bleeding may be only initially encountered during a surgical procedure such as splenectomy; in this case, the bleeding diathesis may result from inapparent disseminated intravascular coagulopathy (DIC) and has the potential for catastrophic consequences.[6]

Occurrence of isolated sites of ectopic sites of myeloid metaplasia has been reported, particularly in the pulmonary, gastrointestinal, central nervous, and genitourinary systems.[1–3,7,9] Extramedullary hematopoiesis can rarely occur in the skin, manifesting as nontender, occasionally pruritic red, pink, or violaceous plaques, papules, or hemangioma-like nodules. These dermal infiltrates, when biopsied, are composed of combinations of myeloid, erythroid, and mega-

karyocytic cells.[163–165] Patients with nonsplenic ectopic myeloid metaplasia present with cough and "large lung tumors," headache, or paralysis resulting from "brain tumors or spinal cord tumors," small-bowel obstruction, or intractable ascites from ectopic implants of hematopoietic tissue in the gut or peritoneum.[1–3,7,9,166–170] Myeloid metaplasia of the renal pelvis, ureters, and bladder, and renal parenchymal infiltration have been observed.[170] Expansion of hematopoietic tissue at the urethral meatus may be confused with a urethral carbuncle.[170] Such strategically localized sites of extramedullary hematopoiesis may lead to renal failure or obstruction of both kidneys and bladder dysfunction.[170] Ascites occurring in a patient with PMF may result from peritoneal or mesenteric implants of extramedullary hematopoietic tissue or from portal hypertension.[171,172] If the ascites result from peritoneal implants, the fluid is always exudative and sterile and frequently contains myeloid, erythroid, and megakaryocytic elements.[171,172] Such cytologic studies should routinely be performed on ascitic or pleural fluid obtained from patients with PMF. Unusual sites of extramedullary hematopoiesis have been reported in the gallbladder and lacrimal fossae.[173,174]

Table 70–2 lists the prominent physical findings in patients with PMF.[2,5] Splenomegaly serves as the hallmark of the disease. Its extent may vary, but massive splenomegaly, with the organ occupying the entire left side of the abdomen and extending into the pelvis, may occur in 35% of patients. Hepatomegaly occurs in almost 70% of cases,[1–3,7,9] and lymphadenopathy is observed in 10% to 20%, but the degree of nodal enlargement is frequently only moderate.[2,5] Other important physical findings include pallor, peripheral edema, jaundice, and bony tenderness. Acute monoarticular inflammation caused by secondary gout is seen in 6% of patients.[3]

Portal hypertension may occur and is a result of massive increases in hepatic blood flow and intrahepatic obstruction.[1–3,7,9,161,175,176] Clinical features of portal hypertension, such as ascites or esophageal varices, occur in 9% to 18% of patients with PMF.[161,175,176] Occasionally, cirrhosis or evidence of thrombosis of the portal or hepatic veins has been reported.[171,172] Wanless and coworkers,[175] analyzed a large series of patients with polycythemia vera and PMF at autopsy. In patients with portal hypertension, thrombotic lesions in small- or medium-sized portal veins and in extrahepatic portal veins were observed. Nodular regenerative liver hyperplasia occurred in 14.6% of cases and correlated closely with the presence of portal vein lesions. They concluded that thrombosis is the most likely cause of portal venous obliteration and portal hypertension in PMF and that clinically significant thrombosis confined to small intrahepatic veins or large hepatic veins should be considered in any patient with PMF. In this autopsy series, portal and hepatic venous disease occurred even in the absence of signs of portal hypertension. Such a finding is consistent with subclinical thrombosis with recanalization occurring fairly commonly in this patient group.[175,176]

Rarely, the development of PMF can be preceded by the appearance of multiple cutaneous edematous plaques and nodules characteristic of the Sweet syndrome, a cutaneous process occurring in response to a number of hematologic malignancies.[177] Pyoderma gangrenosum has been reported to be associated with PMF,[178] and atypical pyoderma gangrenosum is reported to be a complication at splenectomy incision.[179]

PMF may be associated with the development of pulmonary hypertension.[180–185] These patients present with progressive dyspnea, signs of biventricular heart failure, and rapidly increasing hepatosplenomegaly. An elevation in pulmonary artery pressure can be documented by transthoracic Doppler echocardiography and right heart catherization.[180,182] Many of these patients succumb to cardiopulmonary complications within 18 months of the documentation of pulmonary artery hypertension.[180–185] The development of pulmonary artery hypertension can be attributed to thromboembolic disease, extramedullary hematopoiesis diffusely involving the lung, or pulmonary fibrosis due to the elaboration of fibrogenic cytokines from dysfunctional circulating megakaryocytes and platelets.[180–185] Marrow fibrosis also occurs in patients with primary pulmonary hypertension and can be associated with anemia and thrombocytopenia. These patients can be distinguished from patients with PMF by their lack of high levels of circulating $CD34^+$ cells, teardrop red cells, hematopoietic cell clonality, and their Jak2V617F negativity.[185]

Nephrotic syndrome associated with PMF has been reported in few cases.[186,187] Renal extramedullary hematopoiesis is a constant finding in these cases, but renal biopsy may reveal also a picture of mesangioproliferative glomerulopathy,[186] or membranous glomerulonephritis.[187] Immunocomplexes deposition with subepithelial electron dense deposits caused by immuno dysfunction of PMF has been proposed as the pathogenetic explanation for this association.[187]

PMF may be associated with a preexisting or simultaneously appearing autoimmune disease, such as systemic lupus erythematosus, scleroderma, primary biliary cirrhosis, ulcerative colitis, polyarteritis nodosa, or juvenile rheumatoid arthritis.[188–191] In addition, autoimmune forms of myelofibrosis have been described distinct from PMF and are most commonly associated with systemic lupus erythematosus. These patients characteristically have cytopenia and marrow fibrosis, but have limited degree of splenomegaly and only mild numbers of teardrop red cell and immature myeloid cells in the peripheral blood. Patients with autoimmune myelofibrosis frequently have a positive direct antiglobulin test and antinuclear antibodies but are Jak2V617F negative.

LABORATORY EVALUATION

Careful examination of the peripheral blood smear (Fig. 70–1) and bone marrow (Fig. 70–1) permits ready diagnosis of PMF. Leukoerythroblastosis with teardrop red cells strongly suggests this diagnosis. The leukoerythroblastic condition is characterized by the presence of nucleated red blood cells and immature myeloid elements in 96% of cases.[1–3,7,9] Megathrombocytes and megakaryocytic fragments are frequent findings. The number of teardrop erythrocytes (ie, dacryocytes) decreases after splenectomy or institution of chemotherapy,[192,193] which has led some to suggest that splenic fibrosis causes the development of these red cell changes.[193,193] In approximately 60% of patients, hemoglobin levels drop to less than 10 g/dL.[1–3,7,9] The degree of anemia is not infrequently difficult to estimate by hemoglobin or hematocrit determinations, because individuals with large spleens often have expanded plasma volumes and apparent anemia, which is largely dilutional in nature. Of the patients with decreased red cell mass, 95% have normochromic normocytic red cell indices.[194] The anemia may be aregenerative or may be caused by ineffective red cell production and shortened red blood cell survival.[195–197] Morphometric analysis of bone marrow biopsies has demonstrated that erythroid hypoplasia is more common than previously appreciated,[198] and ferrokinetic studies have demonstrated that 30% of patients have erythroid failure.[199] Ineffective red cell production in PMF can be demonstrated with ferrokinetic studies by increased plasma iron turnover but decreased incorporation of radioactive iron into circulating red blood cells.[195–197] Ineffective iron incorporation in red blood cells occurs in 90% of patients with PMF.[3] Fifteen percent of patients have major hemolytic episodes during the clinical course of the disease.[3] The cause of the hemolytic anemia is usually multifactorial, with contributions from hypersplenism, a defect in red blood cells resembling paroxysmal nocturnal hemoglobinuria, and antierythrocyte autoantibodies.[1–3,7,9,199]

Hypochromic microcytic anemia resulting from iron deficiency secondary to blood loss may develop in 5% of PMF patients. Blood loss may be caused by leaking esophageal varices, duodenal ulceration, gastritis, or intravascular hemolysis. Occasionally, a patient with PMF may develop an occult malignancy or a site of extramedullary hematopoiesis within the gastrointestinal tract, which may serve as a bleeding source.[161] Unexplained microcytosis (MCV < 80 fL) has been reported as a laboratory feature in PMF and in general not has been shown to have prognostic relevance.[200] Macrocytic anemia may complicate PMF.[201] Folic acid absorption is normal in these patients, and the folic acid deficiency probably results from increased use.[201]

Leukopenia can occur in 13% to 25% of patients, and leukocytosis is seen in one third.[1–3,7,9] Occasional blast cells and granulocytes

with the pseudo-Pelger-Huët anomaly are frequent findings.[1–3,7,9] The leukocyte alkaline phosphatase score was studied in 78 patients by Silverstein and Elveback,[202] and was high in 41 patients (>100), normal in 17 patients (30 to 100), and low in 20 patients (<30). In the Mayo Clinic series of 169 patients in the myelofibrotic phase of the disease, platelet counts of less than 100,000/mm^3 were observed in 31% of patients, and platelet counts of more than 800,000/mm^3 were observed in 12%.[3] In the prefibrotic phase of the disease, almost 90% of patients had platelet counts greater than 500,000/mm.[3,37] Defective platelet aggregation is common, and platelets frequently do not respond to collagen or epinephrine.[3] A variety of qualitative platelet anomalies have been documented by abnormal in vitro aggregation patterns.[203,204] In 15% of patients, abnormalities suggestive of ongoing DIC are found, including decreased platelet numbers, decreased levels of factor V and VIII, and increased fibrin-split products.[3] Usually, when DIC occurs in PMF, it produces no symptoms and unfortunately may only become clinically apparent after surgical intervention. Associated liver dysfunction may also be a contributory factor to prolongation of the prothrombin time.

Additional laboratory abnormalities are quite common. In one series, lactic acid levels were elevated in 95% of patients, bilirubin levels in 40%, uric acid in 60%, and alkaline phosphate and serum glutamic oxaloacetic transaminase levels in 50%.[5] Patients with PMF have decreased levels of total cholesterol.[205,206] The ratio of high-density lipoprotein cholesterol to low-density lipoprotein cholesterol is diminished.[205,206]

A variety of immunologic abnormalities have been reported in PMF, including the presence of antinuclear antibodies, elevated rheumatoid factor titers, direct Coombs test positivity, lupus-type circulating anticoagulants, hypocomplementemia, marrow lymphoid nodules, and increased circulating immune complexes.[207–211] In one series of 50 patients with PMF, increased quantities of circulating immune complexes were detected in 39% and found to be associated with increased disease activity as manifested by increased transfusion requirements, bone pain, and fever.[207] Some investigators have suggested that abnormalities of the complement system may be important in the disease progression of PMF,[210] and others have hypothesized that low levels of C3 may predispose these patients to develop serious bacterial infections.[207] A remarkably high incidence of monoclonal gammopathies has been reported in PMF, with such benign gammopathies occurring in 8% to 10% of patients in some series.[212,213] Ten cases of the simultaneous occurrence of a plasma cell dyscrasia and PMF have been reported.[3,212,213]

Successful bone marrow aspiration is unusual, accomplished in only 6 of 48 cases in one series, with the tap completely dry in 50% of cases.[5] A bone marrow biopsy is necessary in all cases for the diagnosis and monitoring of the disease. The amount of residual hematopoietic cellular tissue and the degree of marrow fibrosis are the key elements that should be assessed. Table 70–3 summarizes the appearance of bone marrow biopsies in the series of Varki and associates.[5] Some caution should be taken in using repeated bone marrow biopsy specimens to diagnose PMF. Cases in which a marrow biopsy was performed at the site of a previous bone injury during the healing process frequently results in confusion because of primary callus formation at that site.[214] Most marrow biopsies in PMF are hypercellular and are remarkable for increased numbers of megakaryocytes. Bone marrow fibrosis and osteosclerosis were seen in 67% and 54% of cases, respectively.[5,8] The characteristic morphologic features include patchiness of the hematopoietic cellularity and the reticulin fibrosis, some microscopic fields being cellular and others depleted of hematopoietic cells. The amount of neticulin may vary from field to field. The megakaryocytes are increased in numbers and often are arranged around and within the sinuses and not always clustered in groups. They are large with irregular, roundish, cloud-like nuclei[8] and distended marrow sinusoids frequently containing intravascular hematopoiesis.[8,47,215,216] The marrow biopsies reveal a substantial increase in vascularity. The marrow microvessels are more tortuous and branched than observed in normal controls. The increased microvessel density is correlated with increased VEGF expression by megakaryocytes. A rare histological variant of PMF is the so-called myelofibrosis with fatty bone marrow,[7–9] in which the bone marrow is characterized by myeloid hypoplasia associated with fairly complete fatty substitution, mimicking bone marrow of aplastic anemia. These patients frequently have areas of clusters of densely aggregated hematopoietic elements exhibiting the histopathological characteristics of PMF and large numbers of hematopoietic progenitors circulating in their peripheral blood.[9] This variant of PMF is likely due to the abnormal trafficking of hematopoietic cells from the bone marrow to extramedullary sites. Consistent with the osteosclerosis observed in patients with PMF, increased thickness of some bone units with new lamellae and focal areas of woven bone. There is a net decrease in osteoclast number and conversion of trabecular pillars into plates.[217]

In Wolf and Neiman's series, morphologic evidence of progression of fibrosis was present in only 1 of 21 cases in which sequential biopsies were obtained.[218] No connection was observed between bone marrow cellularity, fibrosis, and splenic size.[218] In contrast, Lohmann and Beckman[219] observed progressive fibrosis in 18 of 20 patients who did not have maximal myelofibrosis at the time of the initial biopsy.[219] Thiele and colleagues[215] presented data to indicate an early prefibrotic subtype of PMF with no or minimal marrow reticulin and another phase with conspicuous fibrosis and osteosclerotic changes of the marrow. Based on a careful histomorphometric evaluation of the bone marrow they concluded that in a subset of patients there was a progressive fibroosteosclerotic process during the evolution of the disease that was paralleled by an increase in numbers of small megakaryocytes with irregular perimeters and megakaryocytes with naked nuclei.[8,215] The clinical and morphologic findings of patients with the prefibrotic stage of PMF have been further characterized[8,37,220–225] (Tables 70–4 and 70–5). Although a steady progression to marrow fibrosis has been demonstrated in patients with the

Table 70–5 Morphologic Findings in Patients with the Prefibrotic Phase of Primary Myelofibrosis

Blood
No or mild leukoerythroblastosis
No or minimal red blood cell poikilocytosis; few or no dacryocytes
Bone marrow
Hypercellularity
Neutrophilic proliferation
Megakaryocytic proliferation and atypia (eg, clustering of megakaryocytes, abnormally lobulated megakaryocytic nuclei, naked megakaryocytic nuclei)
Minimal or absent reticulin fibrosis

Adapted from Thiele J, Pierre R, Imbert M, et al: Chronic idiopathic myelofibrosis. In Jaffe ES, Harris N, Stein H, Vardiman JW (eds): World Health Organization's Tumors of Hematopoietic and Lymphoid Tissues. Washington, DC, IARC Press, 2001, p 35.

Table 70–6 Grading of Myelofibrosis according to the European Consensus Criteria

Grading	Description*
MF-0	Scattered linear reticulin with no intersections (cross-overs) corresponding to normal bone marrow
MF-1	Loose network of reticulin with many intersections, especially in perivascular areas
MF-2	Diffuse and dense increase in reticulin with extensive intersections, occasionally with focal bundles of collagen and/or focal osteosclerosis
MF-3	Diffuse and dense increase in reticulin with extensive intersections and coarse bundles of collagen, often associated with osteosclerosis

*The quality of the reticulin stain should be assessed by detection of normal staining in vessel walls as internal control. The degree of myelofibrosis should be assessed by disregarding lymphoid nodules and vessels and disregarding fibers framing adipocytes. Areas of prominent scleredema and/or scarring should be included in the overall grading of myelofibrosis. Fiber density should be assessed in hematopoietic areas.
Data from: Thiele J, Kvasnicka HM, Facchetti F, Franco V, van der Walt J, Orazi A: European consensus on grading bone marrow fibrosis and assessment of cellularity. Haematologica 90:1128, 2005

prefibrotic phase,[8,37,220–225] fibrosis may remain static or diminish in the more advanced stages of PMF.[225]

Different scoring systems for pathologically grading the marrow cellularity and fibrosis have been employed with the aim of staging and documenting progression of the disease.[222] In a recent European consensus conference, the importance of age-dependent decrease in cellularity was recognized.[226] Grading of myelofibrosis was simplified by using four easily reproducible categories including differentiation between reticulin and collagen. A consensus was reached that the density of fibers must be assessed in relation to the hematopoietic tissue. This feature is especially important in order to avoid a false impression of a reduced fiber content in fatty and/or edematous bone marrow samples after treatment[226] (Table 70–6). Bock and coworkers have shown that progression of marrow fibrosis in PMF is accompanied by expression of subsets of collagenases which is independent of the Jak2V617F status.[227]

Morphologic examination of the spleen reveals foci of extramedullary hematopoiesis in the sinusoids of the red pulp, where megakaryocytes, myeloid elements, and nucleated erythroid elements are seen.[8,175,218,228] Follicular atrophy in the white pulp frequently occurs.[218] The extramedullary hematopoietic cells belonging to each of the myeloid lineages can be distributed in the spleen diffusely or be limited to macronodules. The predominance of immature granulocytic forms is associated with an especially poor prognosis.[8,228]

Pathologic examination of the liver reveals hematopoietic cellular elements within the sinusoids. Sinusoidal dilatation is a common finding, as well as prominent intrahepatocyte and Kupffer cell hemosiderin deposition. A marked increase in the hepatic reticulin network has also been observed.[175]

Approximately 30% to 75% of patients with PMF have karyotypic abnormalities at diagnosis.[229–233] It is important to perform cytogenetic analysis on this patient population to discriminate PMF from CML.[233] Detection of a Philadelphia chromosome or *BCR-ABL* fusion gene indicates that the marrow fibrosis results from CML. In cases that are Philadelphia chromosome negative, it is prudent to perform polymerase chain reaction (PCR) analysis for *BCR-ABL* to exclude the diagnosis of CML. Chromosomal abnormalities in PMF have been reported to involve chromosomes 1, 2, 5 to 13, 15, 17, 18, 20, 21, and the Y chromosome.[125–127,229–233] Reilly and associates[232] reported that three cytogenetic patterns (ie, 13q–, 20q–, and partial trisomy 1q) were seen in 65% of all cases with an abnormal karyotype. In a series from Mayo Clinic,[233] 20q–, 13q–, and trisomy 8 were the most frequent individual abnormalities in PMF, whereas abnormalities of chromosomes 1, 5, 7, and 9 were almost universally associated with coexisting abnormalities.[233] The presence of clones with trisomy 8 or 12p– as well as chromosome 7 deletions have been associated with an adverse prognosis.[233–235] A correlation between the presence of multiple chromosomal deletions and poor survival has been reported.[235] The deletions of chromosome 13 have been shown to include the region of the retinoblastoma gene *(RB1)*, which is a putative tumor suppressor gene.[236] Translocations involving 12q have also been described. Rearrangement of the HMGA2 gene in two PMF patients with 12q aberrations has been described, and overexpression of HMGA2 was observed in these patients as well as in 10 of 10 patients with PMF without 12q abnormalities.[237] Since HMGA2 is known to play a major role in fetal growth and development, HMGA2 activation has been proposed to play an important role in the pathogenesis of PMF.[237] Partial or complete losses of chromosomes, particularly chromosomes 5 and 7, appear to be associated with the use of chemotherapeutic agents for the treatment of PMF.[230–233] An association between erythroid hypoplasia in PMF and a defect on chromosome 11 has been reported.[238] It is not unusual for a leukemic transformation of PMF to be preceded by additional cytogenetic abnormalities, a finding consistent with a multistep process leading to a leukemic transformation.[239] An unbalanced translocation between chromosomes 1 and 6 with specific breakpoints, der(6)t(1;6)(q21–23;p21.3), was described in patients with typical

PMF by Dingli and associates, suggesting that this translocation is a highly specific cytogenetic anomaly for PMF.[125] Since the marrow is almost uniformly unable to be aspirated in PMF, cytogenetic analysis are frequently performed on peripheral blood cells leading to a high proportion of failed studies. Cytogenetic abnormalities can however be detectable by fluorescence in situ hybridization (FISH) on deparaffinized sections of bone marrow biopsy specimens. FISH analysis can also be more sensitive than conventional cytogenetics for detecting specific aberrations such as 20q- and 13q-.[127]

Investigation of PMF by a comparative genomic hybridization technique suggests that genomic aberrations are much more common than has been previously indicated by conventional cytogenetic analysis and occur in the majority of cases.[127] Gains of 9p were the most frequent finding, occurring in 50% of patients, suggesting that genes on 9p may play a crucial role in the pathogenesis of PMF.[185] This observation, together with the observation that loss of heterozygosity at 9p was a frequent stem cell defect in polycythemia vera, served as a foundation for the discovery of normal *V617F* mutation in MPD.[240]

In PMF the proportion of patients with normal V617F mutation in granulocytes has been reported to range from 35% to 95%.[113,114,241,242] The detection rate for Jak2V617F is much higher for patients with post-PV MF (91%) than PMF (45%) or post-ET MF (39%).[119] In PV a high burden of Jak2V617F allele has been associated with an increased rate of evolution to myelofibrosis.[119,243] Such wide differences in the mutational frequencies can be attributed to the different sensitivity of the techniques used to detect the mutation and to differences in the case-mix of the reported series, ie, proportion of idiopathic and secondary PMF cases. Tefferi and coworkers[119] have reported that the Jak2 mutation in PMF is associated with an older patient age at diagnosis and a history of thrombosis or pruritus. The clinical utility of performing normal mutation in patients with PMF is yet to be defined. The quasi-perfect specificity of the mutation for a Philadelphia-negative MPD may be used in the process of diagnosing patients in whom the cause of bone marrow fibrosis cannot be immediately attributed to PMF. Moreover, since the proportion of *Jak2* mutated alleles in granulocytes has been reported to reflect the progression of the disease,[140] this measurement may be also used for monitoring the response to therapeutic agents during cytoreductive therapies.

Gain-of-function mutations of the thrombopoietin receptor, MPLW515L and MPLW515K, are present in patients with PMF at a frequency of approximately 5%, 1% of patients with ET, but not patients with PV.[120,121] MPL mutations may occur concurrently with the normal V617F mutation, suggesting that these alleles may have functional complementation in MPD.[121] In all cases the MPLW515K/L mutant allele is present in excess of the Jak2V617F allele.[120] In contrast to acute myeloid leukemia, mutations in the receptor tyrosine kinases KIT, FMS, FLT3 have not been documented in PMF.[244,245]

The number of circulating cells expressing the CD34 antigen, a phenotypic marker of hematopoietic stem and progenitor cells, in patients with PMF has been reported to be more than 300 times higher than in normal volunteers and 18 to 30 times higher than in patients with PV or ET.[55–57] The clinical utility of the cytofluorimetric measurement of CD34+ cells as a diagnostic marker of PMF is hampered by the fact that a small number of subjects with PMF exhibit a normal number of $CD34^+$ cells in the peripheral blood. Arora and coworkers[246] found that 14% of patients with PMF and post-ET and post-PV MF had peripheral blood CD34 positive cell numbers that did not exceed the upper limit of the normal reference range (5×10^6/L). Cases with a very mild disease phenotype, absent or slight reticulin BM fibrosis account for the majority of these patients. CD34+ cell numbers may be otherwise used for monitoring the disease course, and the response to therapies. High values of CD34+ cells (>200 $\times 10^6$/L) indicate an accelerated phase of the disease.[55]

Other biomarkers of a myeloproliferative process, such as decreased expression of the receptor for thrombopoietin (c-MPL) by platelets,[247] or overexpression of the polycythemia rubra vera-1 gene (*PRV-1*),[247–249] have been reported in variable proportions of patients with PMF, but their assessment seems to not have clinical utility in practice.

On radiographic examination, the characteristic features of PMF are a diffuse increase in bone density and increased prominence of the bony trabeculae. This increased bone density may be patchy and can produce a mottled appearance. Such abnormalities have been reported in 25% to 66% of patients with PMF.[3]

Noninvasive imaging of bone marrow is a promising means of evaluating the bone marrow cellularity and distribution in PMF. Magnetic resonance imaging (MRI) can portray the conversion or reconversion of fatty to cellular marrow.[250,251] Fibrotic marrow is easily distinguished from cellular marrow by its strikingly low signal intensity with all pulse signals.[250] Kaplan and colleagues[250] reported that marrow patterns in the proximal femurs of PMF patients correlated with the clinical severity of the disease and that might be useful in staging and evaluating the progression of the disease process.[251] Marrow MRI has been used to differentiate PMF from ET, where the marrow adipose tissue is preserved, while in PMF, the adiposity of the marrow is reduced.[252]

The specificity of ^{18}F-FLT (3′–^{18}F-fluoro-3′-deoxy-L-thymidine) uptake for cycling cells and the high resolution of PET (positron emission tomography) have brought to use ^{18}F-FLT PET to visualize the proliferative activities of bone marrow in PMF.[253] Displacement of tracer uptake in bones of the long extremity, spleen and liver but reduced in the iliac crest and spine was a typical imaging pattern in PMF that might have a diagnostic and staging relevance.[253]

DIFFERENTIAL DIAGNOSIS

A patient with hepatosplenomegaly, peripheral cytopenias, teardrop poikilocytosis, leukoerythroblastosis, and marrow fibrosis probably has PMF, but other disorders may lead to this clinical picture (see Table 70–1 and Fig. 70–2).[9,10] Two sets of criteria for the diagnosis of PMF have been previously created (Tables 70–7 and 70–8).[10,220] The Cologne Criteria are particularly useful because they provide a tool with which to diagnose the prefibrotic phase of the disease.[220]

Table 70–7 The Cologne Criteria for the Diagnosis and Staging of Primary Myelofibrosis

A. No preceding or allied other subtype of myeloproliferative disorders or MDS
B. Splenomegaly (on palpation or >11 cm on ultrasound).
C. Thrombocythemia (platelet count ≥500 $\times 10^9$/L)
D. Anemia (Hb < 12 g/dL)
E. Definite leukoerythroblastic blood picture
F. Histopathology: granulocytic plus megakaryocytic myeloproliferation with large, multilobulated nuclei containing megakaryocytes that show abnormal clustering and definitive maturation defects and
1. No reticulin fibrosis
2. Slight reticulin fibrosis
3. Marked increase (density) in reticulin fibers or collagen fibrosis
4. Osteosclerosis (endophytic bone formation)

Diagnosis and classification of PMF are acceptable if the following combinations are present:

Stage 1 A + B + C + F1 is consistent with a hypercellular (prefibrotic) stage clinically simulating ET.

Stage 2 A + B + C + D + F2 is consistent with early PMF. Stage 3 A + B + D + F3 is consistent with manifest IMF. Stage 4 A + B + D + E + F3 + 4 is consistent with advanced IMF complicated by osteosclerosis (osteomyelosclerosis).

ET, essential thrombocythemia (ET); Hb, hemoglobin; PMF, primary myelofibrosis; MDS, myelodysplastic syndrome

Data from Thiele J, Kvasnicka HM, Diehl V, et al: Clinicopathological diagnosis and differential criteria of thrombocythemias in various myeloproliferative disorders by histopathology, histochemistry and immunostaining by the bone marrow. Leuk Lymphoma 33:207, 1999.

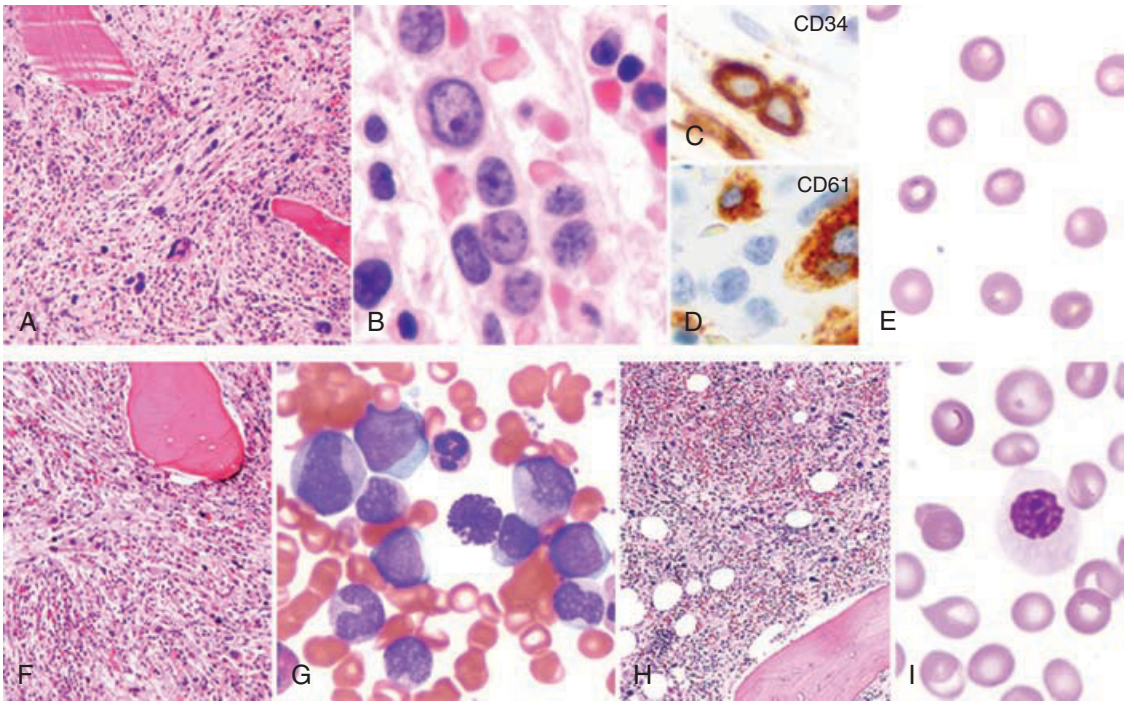

Figure 70–2 DIFFERENTIAL DIAGNOSTIC CONSIDERATIONS IN PMF. Acute panmyelosis with myelofibrosis (APMF) **A-E**; Chronic Myelogenous Leukemia (CML) in advances phase with fibrosis **F,G;** Myelodysplastic Syndrome (MDS) with fibrosis **H, I.** The bone marrow biopsy of APMF, CML in advanced phase with fibrosis, and MDS with fibrosis can all look similar to PMF at low power (**A, F, H**). In APMF the distinction from PMF is made in part by seeing increased immature cells on the biopsy (**B**) interspersed with other hematopoietic precursors. These are usually $CD34^+$ (**C**), but in contrast to acute megakaryoblastic leukemia are usually CD61 negative (**D**). Also the peripheral blood usually shows pancytopenia with neither teardrop red blood cells nor a leukoerythroblastosis (**E**). Although the biopsy of CML presenting in advanced phase can resemble PMF, the peripheral blood usually shows a classic granulocytosis with left shift and basophilia. In the case illustrated, the 30-year-old female patient had a fibrotic bone marrow (**F**), but presented with a WBC of 148K/μL showing a full spectrum of granulocytes, increased blasts (22%) and basophilia. P210 BCR/ABL was demonstrated.

Table 70–8 The Italian Criteria for the Diagnosis of Primary Myelofibrosis

Necessary criteria
A. Diffuse bone marrow fibrosis
B. Absence of Philadelphia chromosome or *BCR-ABL* rearrangement in peripheral blood cells
Optional criteria
A. Splenomegaly of any grade
B. Anisopoikilocytosis with teardrop erythrocytes
C. Presence of circulating immature myeloid cells
D. Presence of circulating erythroblasts
E. Presence of clusters of megakaryoblasts and anomalous megakaryocytes in bone marrow sections
F. Myeloid metaplasia
Diagnosis of PMF is acceptable if the following combinations are present:
• The two necessary criteria plus any other two optional criteria when splenomegaly is present, or
• The two necessary criteria plus any other four optional criteria when splenomegaly is absent

Data from Barosi G, Ambrosetti A, Finelli C, et al: The Italian Consensus Conference on Diagnostic Criteria for Myelofibrosis with Myeloid Metaplasia. Br J Haematol 104:730, 1999.

Recently the World Health Organization (WHO) diagnostic criteria were revised, incorporating testing for Jak2V617F and activating MPL mutations (Table 70–9).[14,15] The WHO criteria are based upon the recognition of a prefibrotic form of PMF without reticulin fibrosis and that the primary diagnostic features of PMF are increased megakaryocyte numbers, megakaryocyte morphology and abnormalities of granulocyte mutation.[14,15] Secondary myelofibrosis frequently occurs in patients with lymphoma or metastatic carcinoma of the stomach, prostate, lung, and breast.[6,254–257] The clinician should be extremely careful in making the diagnosis of PMF in a patient who has a previous history of a primary neoplasm. Demonstration of carcinoma cells in the marrow establishes that metastatic carcinoma is the cause of the marrow fibrosis. Careful breast examination and mammography are indicated in all women suspected of having PMF to exclude the possibility of metastatic breast cancer. The finding of blastic or lytic bone lesions in patients with myelofibrosis suggests the presence of an underlying carcinoma. Disseminated tuberculosis and histoplasmosis have been associated with the development of secondary myelofibrosis.[3,258] Caseating or noncaseating granulomas observed on bone marrow biopsy suggest the presence of these infectious disorders. Identification of the causative organisms by culture techniques should be pursued.

A number of other primary hematologic disorders can also be accompanied by marrow fibrosis. The peripheral blood and marrow findings that allow differentiation of these disorders were reviewed by Dickstein and Vardiman (Table 70–9) and can be enhanced by Jak2V617F and MPLW515L/K mutational analysis.[60] A variant myelodysplastic syndrome with myelofibrosis has been described by Pagliuca and coworkers.[259] These patients frequently present with cytopenias and have dysplastic cellular abnormalities indistinguishable from those of other patients with myelodysplasia. Their marrows, however, are characterized by the presence of marrow fibrosis and a striking megakaryocytic hyperplasia, with a predominance of small hypolobulated forms, in some cases surrounding fibrosis. Reticulocytopenia is characteristic of these patients, as are teardrop red blood cells and a clinical picture of leukoerythroblastosis.[259] Unlike patients with PMF, patients with myelodysplasia and marrow fibrosis do not have hepatic or splenic enlargement extending more than 3 cm below the costal margin.[259] The overall survival time of patients with this

Table 70–9 Proposed Revised World Health Organization Criteria for Primary Myelofibrosis

Major criteria

1. Presence of megakaryocyte proliferation and atypia,* usually accompanied by either reticulin and/or collagen fibrosis, or, in the absence of significant reticulin fibrosis, the megakaryocyte changes must be accompanied by an increased bone marrow cellularity characterized by granulocytic proliferation and often decreased erythropoiesis (ie, prefibrotic cellular-phase disease)
2. Not meeting WHO criteria for PV†, CML‡, MDS§, or other myeloid neoplasm
3. Demonstration of *Jak2*617V > F or other clonal marker (eg, *MPL*515W > L/K), or in the absence of a clonal marker, no evidence of bone marrow fibrosis due to underlying inflammatory or other neoplastic diseases¶

Minor criteria

1. Leukoerythroblastosis‖
2. Increase in serum lactate dehydrogenase level‖
3. Anemia‖
4. Palpable splenomegaly‖

Diagnosis requires meeting all 3 major criteria and 2 minor criteria.
*Small to large megakaryocytes with an aberrant nuclear/cytoplasmic ratio and hyperchromatic, bulbous, or irregularly folded nuclei and dense clustering.
†Requires the failure of iron replacement therapy to increase hemoglobin level to the polycythemia vera range in the presence of decreased serum ferritin. Exclusion of polycythemia vera is based on hemoglobin and hematocrit levels. Red cell mass measurement is not required.
‡Requires the absence of *BCR-ABL*.
§Requires the absence of dyserythropoiesis and dysgranulopoiesis.
¶Secondary to infection, autoimmune disorder or other chronic inflammatory condition, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies. It should be noted that patients with conditions associated with reactive myelofibrosis are not immune to primary myelofibrosis and the diagnosis should be considered in such cases if other criteria are met,
‖Degree of abnormality could be borderline or marked.
Data from Tefferi A, Thiele J, Orazi A, et al: Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. Blood 110:1092, 2007.

variant of myelodysplasia has been reported to be 30 months, with death resulting from the effects of cytopenias or transformation to acute leukemia. Two additional studies indicated that the presence of myelofibrosis in patients with myelodysplasia was associated with a particularly short survival time (9.6 months) compared with patients with myelodysplasia without fibrosis (17.4 months).[260,261]

Hairy cell leukemia can also be confused with PMF.[5] In one study, 5 of 61 patients who had originally been diagnosed as having PMF were shown retrospectively to have had hairy cell leukemia.[5] Hairy cell leukemia can present as pancytopenia with splenomegaly and is associated with a dry marrow tap. In one series, marrow reticulin content was increased in 26 of 29 patients with hairy cell leukemia.[262] The presence of hairy mononuclear cells possessing tartrate-resistant acid phosphatase or the appropriate phenotype in the peripheral blood or marrow should facilitate differentiation of PMF from hairy cell leukemia[8] (see Chapter 84). This exercise is important because of the different modalities of treatment that can be successfully employed for hairy cell leukemia.

Marrow fibrosis can occur in patients with other MPDs, especially PV and CML, and less frequently with ET.[263] In CML, progressive marrow fibrosis may herald the onset of accelerated disease or blast crisis. Myelofibrosis in CML occurs in two distinct patterns, one in which patients present with CML and significant associated marrow fibrosis and a second in which the myelofibrosis develops late in the course of the CML.[264] The myelofibrosis in the latter group appears at a mean of 36 months after the diagnosis of CML, is associated with a mean survival time of 4.9 months from the detection of myelofibrosis, and therefore represents an ominous prognostic sign.[264]

Post-PV MF occurs in 5% to 15% of patients with PV.[263] This transition occurs, on average, 10 years after the initial diagnosis of PV is made, but in individual cases, it may appear after shorter or longer intervals.[263] PMF is clinically indistinguishable from post-PV MF except for the previous history of erythrocytosis in the latter group. Of patients with post-PV MF, 25% to 50% will develop leukemia, and 70% will be dead within 3 years of this transition.[263] Post-PV MF represents a transitional myeloproliferative syndrome with relatively grave prognostic implications. Myelofibrosis has also been reported after ET.[223] In a series of 195 patients with ET followed at a single institution, Cervantes and coworkers[223] observed 13 patients who developed myelofibrosis after a median follow-up of 7.2 years. The investigators claimed that these patients did not represent individuals with prefibrotic stages of PMF, but rather evolution of ET. They estimated the probability of developing such a complication to be 3% 5 years after diagnosis, 8% at 10 years, and 15% at 15 years, and considered this evolution to marrow fibrosis a major long-term complication of ET.[223] This evolution of ET was reported not to be associated with or prevented by the use of cytotoxic agents.[223] Thiele and associates,[224] however, suggested that most individuals with a presumptive diagnosis of ET whose disease evolved into post-ET MF suffered from prefibrotic PMF if strict diagnostic criteria were used. They have conjectured that a considerable number of patients who carry a diagnosis of ET already are actually in a prefibrotic phase of PMF.[224] Careful prospective natural history studies using strict histopathologic criteria will be required to resolve this controversy.

Acute panmyelosis with myelofibrosis (APMF) represents a clinical entity distinct from PMF.[265–267] This disorder has been termed also acute myelofibrosis, acute myelosclerosis, acute megakaryocytic myelofibrosis, and acute myelodysplasia with myelofibrosis. APMF is exceedingly rare and corresponds to less than 1% of the cases of acute myeloid leukemias (AML). Patients characteristically present with pancytopenia, fever, absence of clinically significant splenomegaly, minimal or absent teardrop poikilocytosis, and fibrotic bone marrow.[265–267] The bone marrow is characterized by the appearance of immature myeloid cells and the blast cells, which frequently express megakaryocytic phenotypic properties.[265] Survival ranges from 1 to 9 months after diagnosis. Its distinction from PMF is important, because aggressive chemotherapy and possibly stem cell transplantation are the treatments of choice. Even though some authors consider APMF a form of acute megakaryoblastic leukemia,[268] the WHO criteria for diagnosing APMF are somewhat distinct from those for acute megakaryoblastic leukemia (AMKL).[269] The main requirement for the diagnosis of AMKL is a minimum of 20% marrow blasts, a percentage that is significantly higher than observed in APMF. In addition, the blasts in all cases of AMKL stain strongly for CD61 and CD41 and are negative for myeloperoxidase. In contrast, APMF is characterized by a lower percentage of blasts within a polymorphic cellular background, which includes erythroblasts, megakaryocytes, and maturing myeloid elements with variability in their relative proportions from case to case. The blasts in APMF did not express significant reactivity to megakaryocytic phenotypic markers, but are identifiable by their strong reactivity with CD34 and occasional reactivity with myeloperoxidase. These results emphasized the panmyelotic nature of APMF.[265] In PMF, the peculiar cytologic characteristics of the megakaryocytes, which include anisocytosis with a predominance of large size forms arranged into tight cellular clusters, the abnormal chromatin clumping with hyperchromatic nuclei and clumped (cloud shape) nuclear lobulation as well as the characteristic stromal changes that include the presence of intrasinusoidal hematopoiesis allow for a distinction from these more acute disorders.

Pacquette and colleagues[270] reported that up to 12% of patients who present with myelofibrosis might suffer from an underlying autoimmune disorder such as systemic lupus erythematosus. Pullarkat and coworkers[271] suggested that primary autoimmune myelofibrosis (primary AIMF), represent a distinct clinicopathologic syndrome unrelated to other well-defined autoimmune disorders.

They described eight diagnostic criteria for AIMF, including grade 3 or 4 reticulin fibrosis in the marrow, lack of clustered or atypical megakaryocytes, lack of dysplasia or eosinophilia or basophilia, lymphoid infiltration of the marrow, lack of osteosclerosis, absent or mild splenomegaly, presence of autoantibodies, and absence of disorders associated with myelofibrosis. They described seven patients fulfilling most of these criteria, six of whom responded to therapy with steroids.[271] The appearance of the marrow in AIMF is indistinguishable from that of PMF. Autoimmune myelofibrosis occurs predominantly in females with a broad clinical spectrum. Patients may present with myelofibrosis in the setting of established systemic lupus or in patients with minimal manifestations of an autoimmune disorder as in primary AIMF.[269–272] The presence of teardrop erythrocytes or leukoerythroblastosis in a patient with lupus suggests autoimmune myelofibrosis. Such patients universally have a positive antinuclear antibody (ANA) test result or an elevated anti-DNA titer.[269–272] According to these authors, since the physical manifestations of an autoimmune disease may not be evident, all patients with myelofibrosis should have an ANA test to exclude an autoimmune etiology. Moreover, a diagnosis of AIMF is important because the cytopenias and marrow fibrosis in this disorder may partially resolve with steroid or methotrexate therapy.[269–272] However, it must be pointed out that the place of primary AIMF in the classification of fibrotic disorders needs a more precise definition. This is particularly true since in none of the reported cases categorized as primary AIMF was PMF excluded with the use of markers including hematopoietic cell clonality or presence of Jak2V617F or MPLW515L and MPLW515K.

TREATMENT AND COMPLICATIONS

Therapy

The optimal forms of treatment for PMF have not yet been defined, but reports of non-myeloablative allogeneic stem cell transplantation provide hope for cure of a subpopulation of these patients. A conservative approach to management is generally accepted, with observation of asymptomatic patients and therapeutic intervention reserved for patients with symptoms.[7,9,273] An alternative approach proposed by Pegrum and coworkers[274] provides for the institution of single-agent chemotherapy early in the course of the disease. Traditional chemotherapeutic or biologic response modifier regimens used have included busulfan (2–4 mg/day), 6-thioguanine (20–40 mg/day), and a combination of chlorambucil (15 mg/day) and prednisone (30 mg/day), administered intermittently for a course of 3 to 4 weeks with a 2-week rest interval between courses, interferon-α, or low-dose melphalan therapy.[7,9,274–285] Such an approach may be associated with reduction in spleen size, and some investigators have claimed reversal of marrow fibrosis with reduction in the number of teardrop red cells, poikilocytosis, and leukoerythroblastosis.[276–285] Hydroxyurea appears to be a useful agent for the treatment of PMF. Its use has been associated with significantly reduced platelet numbers and a reduction of megakaryocytic abnormalities, as well as a significant reduction of myelofibrosis.[107,280,281] Some investigators have hypothesized that hydroxyurea-induced suppression of megakaryocytopoiesis causes a reduction in the levels of platelet-derived fibrogenic cytokines, resulting in reduced fibroblast proliferation and deposition of reticulin.[280] Manoharan[281] has shown that moderate doses (20–30 mg/kg) of hydroxyurea given twice or three times weekly are effective and safe in PMF patients requiring treatment. Similar reports have appeared after the use of busulfan; Chang and Gross[282] have reported three patients with PMF who responded to daily busulfan therapy with the achievement of hematologic remission and reversal of myelofibrosis. Not only did hematologic parameters, including the hemoglobin and hematocrit levels, improve, but a reduction of the number of teardrop erythrocytes and the degree of leukoerythroblastosis occurred. Most importantly, the quality of life of these individuals improved.[282] Judicious use of busulfan is recommended in this setting, however, because of its potential for producing delayed marrow suppression. Petti and colleagues[284] reported the use of melphalan administered at low doses (2.5 mg given 3 times/week) in 99 evaluable patients with PMF. Melphalan was well tolerated and produced less hematologic toxicity than busulphan. Among 16 patients with severe anemia requiring transfusion therapy, 38% became transfusion independent, and 20% experienced a 50% reduction in their transfusion requirement. Approximately 54% of patients with symptomatic splenomegaly experienced a clinically significant reduction in spleen size.[284] The median duration of the response to melphalan therapy was somewhat longer than 2 years. The disease of more than 20% of the patients receiving melphalan evolved into the leukemic phase. It is impossible to determine whether melphalan therapy played a role in this evolution or if this rate of blastic transformation was a consequence of the advanced stage of the disease at the time of treatment. The use of this agent was associated with acceptable toxicity, with only 13% of patients stopping their therapy because of the development of cytopenias and 17% requiring a dose reduction because of hematologic toxicity.[284] Whether low-dose melphalan therapy is superior to other chemotherapeutic agents or biologic response modifiers and has a significant effect on long-term survival will require further study.

Interferon-α has been suggested as a biologic response modifier that might alter the course of PMF.[285] It can be useful in suppressing thrombocytosis and inhibiting the activity of PDGF, which stimulates the proliferation of fibroblasts. Bourantos and coworkers[286] reported the use of the combination of interferon, granulocyte- macrophage colony-stimulating factor (GM-CSF), and erythropoietin in seven patients with PMF. Each of these patients had an aspirable marrow with megakaryocytic hyperplasia but only mild to moderate deposition of reticulin fibers.[286] Six of seven patients enjoyed marked reductions in spleen size.[286] Each of these patients had an increase of 1 g/dL or more in the hemoglobin concentration. In one patient, the degree of marrow fibrosis was diminished. These investigators suggested that interferon might decrease the rate of fibrosis if administered chronically during the early course of this disease.[286] Tefferi and associates[287] treated 11 patients with PMF with interferon-α (3 million international units given three times each week for the first 3 months). If no unacceptable side effects were experienced, the dose was increased to 15 million international units weekly. Only four patients were able to complete 1 year of therapy; the other seven patients discontinued the drug because of unacceptable toxicity or the development of severe cytopenias. No clinically significant improvement was observed in any of these patients. Interferon therapy did not appear to alter the degree of bone marrow fibrosis, osteosclerosis, or angiogenesis.[287] The clinician probably should expect only modest benefits to be derived from interferon-α therapy for PMF after patients have entered the more advanced phases of the disease. Whether interferon-α may be more effective during the prefibrotic phase of PMF requires careful study in a large randomized trial.

Therapy is indicated for PMF patients with the following conditions: symptoms attributable to anemia, pressure symptoms related to splenomegaly, bleeding problems, or life-threatening thrombocytopenia, significant hyperuricemia bone pain, systemic symptoms (fevers, night sweats and weight loss), and portal hypertension and life-threatening gastrointestinal bleeding.[3,7,11,12,288] Hyperuricemia should be aggressively treated in all patients with PMF. Hydration and chronic administration of allopurinol (300 mg/day) are suggested.[3]

Anemia is a common problem in patients with PMF. It is usually multifactorial in origin; contributing factors are folate deficiency, iron deficiency, ineffective erythropoiesis, erythroid hypoplasia, and hemolysis.[194–196] Patients with documented nutritional deficiencies should receive folate or iron supplementation, or both. Transfusion therapy with packed red blood cells is clearly indicated in patients who are symptomatic from their anemia. Chronic transfusion therapy is frequently required, and the clinician should try to attain a hemoglobin level at which symptoms resolve. Long-term transfusion therapy potentially may lead to the development of iron overload

syndrome. Thus, serious consideration should be given to early institution of iron chelation therapy. For a handful of patients, transfusion requirements have been reported to be reduced after desferrioxamine or deferasirox therapy.[289] Since an oral effective iron chelator, deferasirox, is now available; therapy should be initiated early in the course of the disease when repeated cell transfusion therapy is required.[289] The remainder of approaches to the anemic patient deals with therapeutic interventions designed to avoid or diminish the number of transfusions administered.

Low-dose dexamethasone has been reported to be useful in the treatment of patients with transfusion-dependent PMF.[290] Whether these cases represent steroid responses of autoimmune-induced myelofibrosis and not classic PMF remains unknown. Low-dose melphalan therapy has been successfully used to reduce the transfusion requirements of a reasonable number of PMF patients.[284] Corticosteroids (eg, prednisone 1 mg/kg/day taken orally) have also been successfully employed for treatment of the hemolytic anemia associated with PMF.[1–3,7,9,291] Silverstein[3] reported a 2-gram increase in hemoglobin in 29% of men and 52% of women. Folate should be simultaneously administered to all such patients. Bouroncle and Doan[291] reported even more encouraging results with simultaneous administration of busulfan and corticosteroids, with clinical responses lasting 6 to 12 months. After patients have reached a peak response, tapering of prednisone should be initiated to determine an acceptable maintenance dose. The hemolytic process frequently recurs after such tapering. It is important to be aware that the hemolytic anemia in patients with PMF may also be a consequence of a coexisting secondary form of paroxysmal nocturnal hemoglobinuria.[292] In addition, a case of paroxysmal cold hemoglobinuria associated with a Donath-Landsteiner antibody has also been described.[293] Furthermore, patients with PMF who receive multiple transfusions are candidates for developing delayed hemolytic transfusion reactions which occasionally may be severe and persistent.[294] The direct antiglobulin test is usually positive in this setting. It is generally believed that additional transfusions in these patients with delayed hemolytic transfusion reactions should be avoided if possible. Other therapeutic options include steroids, intravenous immunoglobulins, and recombinant human erythropoietin-α (rHuEPO).[294]

Erythroid failure and ineffective erythropoiesis in PMF may respond to anabolic steroids.[1–3,7,9,295–298] Gardner and Nathan[295] have recommended that all patients with PMF and anemia should receive a trial of androgens. A number of preparations have been suggested, including testosterone enanthate (600 mg/week IM), stanozolol (12 mg/day taken orally), nandrolone (3 mg/kg/week IM), fluoxymesterone (10 mg taken orally 3 times daily), and oxymetholone (50 mg taken orally 4 times daily). A good response, as defined by a decrease or total avoidance of transfusion therapy, occurs in about 50% of patients. A course of 3 to 6 months of androgen therapy is indicated to identify responsive patients,[295] but the development of hepatic dysfunction or virilizing side effects may limit long-term androgen administration. Besa and colleagues[298] indicated that patients with associated chromosomal abnormalities were less likely to respond to androgen therapy. Danazol, a synthetic attenuated androgen, has been useful in reducing the requirement for red blood cell transfusion support and correction of thrombocytopenia.[299] Danazol appears to be a potentially effective therapy for PMF, which is mainly characterized by marrow failure.[299] Cervantes and colleagues[300] reported 33 patients with PMF who were either transfusion dependent or had hemoglobin levels below 10 g/dL who received an initial dose of 600 mg/day of danazol. Of the 30 evaluable patients, a favorable response was seen in 11 (37%), with 27% having a complete response. The median time to response was 5 months (range 1–9 months). Variables associated with response were lack of transfusion requirement and higher Hb levels. In 8 out of 30 patients (27%) a moderate increase of liver enzyme levels was reported. It is unknown whether any of the anabolic steroids preparations are superior to the others, or whether they are superior to danazol in improving anemia of PMF.

Early reports of rHuEPO therapy have suggested that rHuEPO alone does not improve the anemia associated with PMF.[301,302] However, the experience with the use of rHuEPO in PMF has been recently reviewed by Cervantes and colleagues in a total of 51 patients,[303] documenting that 28 (55%) of these patients responded to rHuEPO treatment including 16 complete and 12 partial responses. Endogenous serum levels inappropriately low for the degree of anemia is predictive of a favorable response to rHuEPO. Serum Epo levels less than 125 U/L were found to be associated with a favorable response to rHuEPO therapy. Lower number of responders were reported in a small trial, in which only 4 (16%) of 25 patients responded and in which the variables associated with response were favorable cytogenetic abnormalities (13q− or 20q−) and absence of a higher burden of the normal V617F mutation.[304] Responses are also associated with a limited enlargement of the spleen, and a small red cell transfusion requirement.

The use of darbepoetin, a novel hyperglycosylated erythropoiesis-stimulating protein, has been reported in 20 PMF patients.[305] With an initial weekly dose of 150 μg, increased to 300 μg, when no response was observed after 4 to 8 weeks, eight patients (40%) responded to treatment, including six complete and two partial responses, and five maintained their response after a median follow-up of 12 months (range 4–22 months). The median time to response was 2 months. Univariate analysis indicated that older age was the only factor associated with a favorable response to treatment ($P = 0.006$). None of the patients with elevated serum erythropoietin levels responded. Treatment was usually well tolerated and patients can be successfully switched from rHuEPO to darbepoetin.

Multiple trials have explored the use of thalidomide in the treatment of anemia in PMF, based on this drug's antiangiogenic, immunomodulatory, and antiinflammatory actions.[306–311] A pooled analysis of five small phase II studies published from 2000 to 2002 have indicated that 29% percent of patients with moderate to severe anemia can experience an increase in hemoglobin or reduction/elimination of blood transfusion requirements, with thalidomide therapy at a standard dose of 200 to 800 mg a day.[312] Nevertheless, most of the patients treated with these doses suffered from adverse effects that resulted in an attrition rate of greater than 50% after 3 months. Moreover, increases of white blood cell numbers and/or platelet counts were frequently reported to be associated with such serious adverse events as pericardial effusions secondary to myeloid metaplasia. Using a dose-escalation design and starting with a low dose of thalidomide (50 mg per day), Marchetti and colleagues[313] reported that 31% of patients with transfusion-dependent anemia experienced a response after treatment. Combining low-dose thalidomide (50 mg/day) with prednisone, Mesa and colleagues[314] reported that the regimen was better tolerated and equally or more effective than standard dose treatment.[314] Although the size of the patient population was limited, with this regimen 40% of patients with a red blood cell transfusion requirement became transfusion independent, and 95% of the patients were able to complete the 3-month course of therapy with acceptable toxicity.[314] The median hemoglobin level was reported to increase by 1.8 g/dL after low-dose thalidomide and prednisone therapy. This regimen also had a significant effect on the degree of thrombocytopenia and resulted in a reduction in the degree of splenomegaly in almost 10% of the patients.[314] These responses were frequently maintained after therapy was halted.[315] More recent reports provided further evidence that higher doses of thalidomide were not more effective than lower doses. Abgrall and colleagues[316] reported a prospective phase II B, randomized double-blind multicenter trial comparing therapy with 200 to 400 mg thalidomide with placebo, and documented that in the thalidomide group, in which only 10 of 26 patients completed 6 months of treatment, no difference was observed between the thalidomide and placebo groups as regards improvement of hemoglobin levels or reduction of the number of red blood cell transfusion required.[316] Thomas and coworkers reported the experience with thalidomide therapy in a two-stage phase II dose-escalation trial in 44 patients with advanced PMF.[317] Starting at 200 mg daily and increasing to 800 mg as tolerated, the median tolerated dose was 400 mg for a median duration of 3 months; and 20% of the patients experienced improvement in their degree of anemia (21% became transfusion independent).[317] Recently a more potent

thalidomide analog, lenalidomide, has been evaluated in 68 symptomatic patients with PMF at two institutions.[318] Oral lenalidomide was administered at a dose of 10 mg/day if the platelet count was ≥100,000/mm^3 or at a dose of 5 mg/day if the platelet count was <100,000/mm^3 for 3 to 4 months. The overall response rates were 22% for patients with anemia, 33% for patients with splenomegaly and 50% for thrombocytopenia. Several patients normalized their hemoglobin levels or became red blood cell transfusion independent. The most common associated toxicities were grade 3 and 4 neutropenia and thrombocytopenia which occurred in approximately 30% of patients but resolved with discontinuation of therapy. In several patients with del(5)(q31) associated PMF or post-PV MF, lenalidomide therapy was associated with reduction of the numbers of cells with a marker chromosome as assayed by FISH and reduction of the Jak2V617F burden.[319] Lenalidomide therapy in combination with prednisone therapy in PMF is currently being evaluated in a cooperative group setting.

Pressure symptoms caused by splenic enlargement can be treated initially with cytotoxic chemotherapy. Busulfan, chlorambucil and prednisone, 6-thioguanine, radioactive phosphorus, melphalan and hydroxyurea (15–20 mg/kg 3 times each week) have each been used for this purpose.[1–3,9,284] In the Mayo Clinic series, a significant reduction in spleen size with relief of pressure symptoms occurred in 70% of patients receiving chemotherapy.[3] Responses are unfortunately short lived, lasting a median of only 4.5 months.[3] Only 16% of patients with long-term maintenance therapy enjoyed sustained relief of symptoms.[3] Hematologic toxicity often necessitates cessation of therapy.

Splenic irradiation frequently has been used for treatment of the painful, large spleen syndrome.[3,4,320–323] Irradiation in fractions of 0.15 to 1 Gy administered daily or by an intermittent fractionation schedule (ie, 2–3 times/week) to a total dose per treatment course of 2.5 to 6.5 Gy may be effective.[3,4,320–323] Responses are transient, lasting an average of 3.5 months, and hematopoietic toxicity is frequently significant. Wagner and associates[322] recommended simultaneous treatment with splenic irradiation and oral hydroxyurea and have obtained some promising results. Silverstein[3] reported that splenic irradiation was especially useful for treatment of splenic pain of sudden onset and for treatment of ascites due to implants of hematopoietic tissue. Radiation therapy should be considered as a temporary measure to be employed in patients who are too ill to tolerate splenectomy or chemotherapy. In one series, the median duration of response to irradiation was 6 months, and the median survival after irradiation was 20 months.[320] Splenic irradiation is limited by myelosuppression with significant prolonged cytopenias,[320] which is not predictable and is not correlated with the doses of radiation administered. Splenectomy after irradiation can be associated with increased complications, and irradiation should probably be administered only to patients who are not candidates for surgery.[3,7]

Radiotherapy offers a viable treatment option and sometimes may be the therapy of choice for the treatment of symptomatic hepatomegaly, peritoneal and pleural implants or pulmonary infiltration leading to ascites or pleural effusions, and extramedullary hematopoiesis in vital organs leading to organ dysfunction.[324] Because of the inherent sensitivity of myeloid tissue to radiation and profound marrow suppression that may occur after irradiation, therapy is usually initiated at low doses (20–25 cGy/day), with modification of the dose as the clinical situation dictates.[324] An alternative approach using intraperitoneal administration of cytosine arabinoside has been used to treat ascites in PMF.[325] Therapy is initiated at 0.77 mg/kg/day to achieve a concentration of 30 mg per 2 L of peritoneal fluid. The dosage is advanced so that the patient eventually receives 1 g or 13.5 mg/kg/day. Abdominal pain is the most common adverse effect associated with this approach.[325] Low-dose, single-fraction, whole-lung radiotherapy has also been useful in treating pulmonary artery hypertension associated with PMF.[182]

Splenectomy is indicated in patients with hemolysis, thrombocytopenia, painful splenomegaly, recurrent splenic infarction, and portal hypertension refractory to other therapeutic modalities.[3,7] Benbassat and colleagues[326] reviewed the role of splenectomy in PMF by evaluating 321 patients undergoing splenectomy and concluded that this procedure should be considered only in select individuals for specific indications. Splenectomy in patients with PMF is associated with a postoperative morbidity rate of 15% to 30% and a mortality rate of almost 10%. These events largely result from episodes of bleeding, infection, and thrombosis.[326–332] Following splenectomy 77%, 50%, 40%, and 30% of patients, respectively, have been reported to experience long-term improvement in symptomatic splenomegaly, anemia, portal hypertension, and severe thrombocytopenia.[332] Bleeding and thrombotic complications, however, complicated the course of 25% of patients with PMF, and 6.7%% of patients died during the perioperative period.[332] Postoperatively, the major long term complications include leukocytosis, thrombocytosis, and accelerated hepatic enlargement. Such adverse events can frequently be controlled with the immediate institution of hydroxyurea therapy during the postoperative period or if unsuccessful treatment with 2-chlorodeoxyadenosine therapy. The appropriate implementation of splenectomy can result in the improved quality of life of PMF patients who frequently do not have other therapeutic options available. Since splenectomy is associated with significant morbidity and mortality, the physician should only resort to this strategy if thrombocytopenia, anemia or symptomatic splenomegaly is unresponsive to less invasive approaches. Patients should only be considered for this procedure if their performance status allows one to anticipate a favorable surgical outcome with some certainty. Excessive delay of the decision to undergo splenectomy may result in a missed window of opportunity because the patient may become increasingly debilitated, no longer making them a viable surgical candidate. Histopathologic and cytogenetic features of the patient's marrow did not predict the likelihood of response for the cytopenias to splenectomy. Progressive hepatomegaly and marked thrombocytosis occurred, respectively, in 16% and 22% of patients after splenectomy.[332] The latter was associated with increased risk of thrombosis and decreased postoperative survival duration. In this report and several others, an extraordinarily high rate of leukemic transformation was observed after splenectomy.[328–331] Whether this was a function of the absence of the spleen or more likely the consequence of the natural history of the disease is unknown. Barosi and colleagues[331] suggested that splenectomy was an independent risk factor for leukemic transformation, stemming from a disruption of the host-tumor relationship. Porcu and associates,[330] however, argued for the possibility that patients with late-stage PMF who required splenectomy might be undergoing leukemic transformation in areas of splenic extramedullary hematopoiesis without overt marrow transformation. This population may be destined to develop leukemic transformation, and the need for splenectomy may only serve to identify this group of patients before such an event. Ferrokinetic measures of total erythropoiesis and of plasma volume, previously claimed to be useful guides for the choice of splenectomy, have little value for predicting outcome.[333] Compensatory hepatic myeloid metaplasia may accelerate after splenectomy, leading to rapid enlargement of the liver.[7,9,327,334,335] Occasionally, this massive myeloid metaplasia and sinusoidal dilation can result in liver failure and death.[334] This complication can, however, frequently be treated with a variety of agents including low radiation, low-dose melphalan, hydroxyurea, or 2-chlorodeoxyadenosine.[284,336–340] 2-chlorodeoxyadenosine therapy can be a particularly useful agent for patients with increased hepatomegaly, rapidly rising white blast cell counts, a extreme degree of thrombocytosis following splenectomy, or patients with these same clinical features who have not undergone splenectomy.[341] The drug can be administered every four4 weeks according to one of two dosing schedules (0.1 mg/kg/day IV by continuous infusion for 7 days, or 5 mg/m^2/day for 2 hours IV for 5 consecutive days). Responses occur usually by the second cycle and the medium duration of response is 6 months. 2-chlorodeoxyadenosine can be extremely useful in controlling the excessive myeloproliferation in patients awaiting an allogeneic stem cell transplant.

Excessive bleeding in patients with PMF can be a result of thrombocytopenia, qualitative platelet defects, or DIC.[3] Based on his clinical observations, Silverstein and coworkers[3,339] suggested that splenectomy was contraindicated in patients with DIC. Actively bleeding patients with consumption coagulopathy should receive platelet and plasma replacement therapy. Low-dose heparinization has resulted in improvement in some patients.[3] Platelet transfusions are suggested in bleeding patients who are thrombocytopenic or have normal platelet counts but who are known to have qualitative platelet abnormalities. Factor VII infusions should be considered in patients with bleeding refractory to platelet transfusion.

Allogeneic stem cell transplantation is a potentially curative option in patients with PMF who have an appropriate donor available.[155,156,342–351] Successful transplantation is associated with gradual resolution of marrow fibrosis and normalization of hematopoiesis.

Most of the knowledge of allogeneic SCT with conventional conditioning regimens comes from two series of transplants, with more than 50 patients each.[342,343] The first was published by Guardiola and coworkers in 1999, and reported the collected results of European and American transplant centers.[342] The second was published by Deeg and coworkers, and reported the results of the Fred Hutchinson Cancer Center in Seattle.[343] The Seattle experience has been recently updated.[351] In the two cohorts of 55 and 56 PMF patients, the median age of transplanted patients was 42 and 43 years, treatment-related mortality (TRM) was 27% and 33%, and 5-year survival 47% and 58%, respectively. The 5-year probability of treatment failure due to relapse or persistent disease after transplantation was 36% (28% for patients receiving an unmanipulated HLA matched related transplant) in the series of Guardiola and coworkers,[342] whereas in the series of Deeg and colleagues,[343] failure of sustained engraftment was 10.7%, and occurred solely in patients receiving transplants from alternative donors. A hemoglobin level of 10 g/dL or less and osteomyelosclerosis before transplantation adversely affected the outcome. The probability of grade III or IV acute graft-versus-host disease (GVHD) was 33%, with 16 of 45 patients developing extensive chronic GVHD. In a follow-up of the report of Guardiola and colleagues with inclusion of 11 new patients, multivariate analysis demonstrated the influence of age on 5-year survival (14% for patients 45 years or older compared with 62% for those younger than 45 years).[344] In an recent update from the Seattle group, the experience of 95 PMF patients who received busulfan, a total body irradiation conditioning reagent, was provided.[351] The 7-year actual survival was 61%. Although 10% of patients died of recurred a persistent disease and nonrelapse related mortality at 5 years was 34%.[351] An even higher 1-year cumulative nonrelapse mortality of 48% was successively reported from two Canadian centres in 25 patients.[345] Furthermore, Ditschkowski and colleagues[346] reported the experience of the University Hospital of Essen, Germany, in 20 patients. The median age of the patients was 45 years with a range from 23 to 59 years. The estimated TRM was 20%, while overall survival was 38.5%. Three of 20 (15%) died from relapse. By using low hemoglobin level, severe bone marrow fibrosis, and the presence of peripheral blasts prior to allogeneic SCT as predictors for decreased posttransplant survival, the mortality was 33% in the low-risk group and 73% in the high-risk group. Among low-risk patients, the 3-year relapse-free survival was 51%, whereas it was 17% among high-risk patients. From these experiences, myeloablative allo-HSCT in PMF has provided evidence that engraftment can be obtained, and that a complete and durable remission of the disease can be achieved in approximately 50% of patients. However, owing to the poor transplant outcomes in older patients, enrollment to this procedure represents a major therapeutic dilemma in PMF patients who are primarily diagnosed older than 60 years of age.

The advent of nonmyeloablative, reduced-intensity conditioning (RIC) regimens for allogeneic SCT has expanded the use of to procedure to older patients. As a result of diminished transplantation-related toxicity, it has been possible to investigate the usefulness of allo-SCT in patients with PMF previously believed to be unsuitable candidates due to advanced age. The use of RIC regimens were first reported in PMF patients by Devine and colleagues[155] and by Hessling and colleagues,[347] indicating that the use of RIC regimens in older patients with PMF resulted in lower TRM and achievement of histo-hematological responses. The experience from 10 European Centers from the EBMT was successively reported by Hertenstein and coworkers.[348] In 20 patients with a median age at transplantation of 50 years (range 39–65 years) and treated with conditioning regimens containing fludarabine or total body irradiation (TBI) and including antithymocyte globulin (ATG) or antilymphocyte globulin (ALG) in 9 cases, the 1-year TRM was 37% and 1-year overall survival was 54%. Since the cohort of cases included 5 patients who had acute transformation before HSCT, this report should be read with the understanding that a high proportion of high-risk patients are in the study cohort. Indeed, when patients were transplanted before acute transformation, 1-year TRM was 18%.

In recent years, two studies have enrolled over 40 patients in a retrospective registry study, including European and American institutions of the MPD Consortium, Rondelli and coworkers[156] reported 21 patients with a median age of 54 years and a range from 27 to 68 years. All patients had an intermediate or high severity score taking into account hemoglobin and WBC count values. However, no patient had undergone leukemic transformation. Different conditioning regimens, most of whom containing fludarabine, resulted in a TRM of 10% and 2-year overall survival rates of 87%. Eighteen patients were alive 12 to 122 months (median, 31 months) after transplant, and 17 were in remission (1 after a second transplant), with a relapse rate of 14%. Thirty-three percent of the patients developed acute GVHD grades II to IV, and 72% developed chronic GVHD. Posttransplant chimerism analysis showed more than 95% donor cells in 18 patients, and two patients achieved complete donor chimerism after donor lymphocyte infusion (DLI). In a prospective study of 21 patients with a median age of 53 years (range 32–67 years), Kröger and coworkers[349] reported remarkably similar data. The conditioning regimen consisted of busulphan and in vivo T-cell depletion with ATG. TRM was 16% at 1 year. Hematological response was seen in 100%; complete histopathological remission was observed in 75% of the patients, and 25% of the patients showed partial histopathological remission with a continuing decline in the grade of fibrosis. No instance of primary graft failure was observed and only one case of secondary graft failure was documented. After a median follow-up of 22 months (range, 4–59), the 3-year estimated overall and disease-free survival was 84%. These studies, and other successive reports,[350] suggest that RIC regimen followed by related or unrelated allo-HSCT, may reduce TRM and achieve long-term control of the disease in a high proportion of patients. Grafting with an unrelated donor is associated with greater TRM, although not significantly. Although longer-term follow-up data and larger studies are desirable, nonmyeloablative transplantation appears to be a promising therapeutic option in older patients with PMF before leukemic transformation.

Many unresolved issues remain to be clarified concerning the optimal strategy for allo-SCT in PMF. The need for splenectomy prior to allo-SCT remains a major issue. Splenectomy prior to allo-HSCT in PMF results in faster hematopoietic recovery.[342,343] Li and coworkers specifically analyzed the impact of pretransplant splenectomy on posttransplant outcome in 26 patients transplanted for PMF.[352] Posttransplant granulocyte recovery was faster among splenectomized patients: 14 to 51 days (median 18 days) to reach 0.5×10^9/L, compared with 19 to 85 days (median 23) among patients with intact spleen ($P = 0.04$); and the need for both red blood cell and platelet transfusions was greater among patients with intact spleens (mean 9.8 vs 6.1 units for red blood cells, and 21.7 vs 16 units for platelets). The 3-year probability of disease-free survival was 73% for splenectomized patients and 64% for patients without splenectomy; however, this difference was not statistically significant. At this time transplant centers have different policies regarding patients with extensive splenomegaly. The role of splenectomy prior to HSCT should be evaluated in prospective studies. Our initial observations in patients who were prepared with fludarabine and melphalan and then received an allogeneic HSCT, suggest that even severe splenomegaly (>30 cm longitudinal size by CT scan) can be reduced in a

relatively short period of time after transplant (Ciurea S, Hoffman R, and Rondelli D, submitted).

The establishment of valid complete remission criteria of PMF after allogeneic SCT remains a major issue because the conventional criteria for response after allo-SCT are often influenced by GVHD, infections, or poor graft function and cannot be used. Conversely, normal blood counts and disappearance of disease-related symptoms do not exclude residual disease. Molecular markers of minimal residual disease monitoring have been evaluated as a biomarker for long-term disease-free survival. A highly sensitive method to monitor and quantify normal V617F positive cells in normal mutation positive patients with PMF after SCT allowed detecting minimal residual disease. This method has proven useful as a parameter for complete remission assessment and as a guide for instituting adoptive immunotherapy.[353] Autologous transplantation has also been investigated based on the premise that bone marrow fibrosis and extramedullary hematopoiesis are related to the bulk of the neoplastic clone, and therefore successful debulking using high-dose chemotherapy may interrupt the disease process and improve the disease manifestations at least until the reestablishment of the abnormal clone in the marrow by the "contaminated" autologous graft is achieved. This hypothesis was tested in a study in 21 patients with PMF.[354] The median patient age was 59 years. The conditioning regimen consisted of oral busulfan (16 mg/kg). The median times to neutrophil and platelet recovery were 21 days and 21 days, respectively. Five patients required backup stem cell infusions because of delayed engraftment. The 2-year actuarial survival rate was 61%. Six patients died of nonrelapse related causes (n = 3) or disease progression (n = 3). Transfusion independence was achieved in 10 of 17 anemic patients, and 4 of 8 patients with platelet counts of less than 100×10^9/L responded with durable counts of more than 100×10^9/L.[354] Although this study clearly demonstrates the feasibility of this procedure, the role of autologous transplantation in PMF remains uncertain.

With increased understanding of the biology of PMF, a number of phase I and II studies have examined more rational therapy for PMF. Imatinib mesylate is a tyrosine kinase inhibitor with specific inhibition of a number of kinases, including BCR-ABL, KIT, and PDGFR.[355] Tefferi and colleagues administered imatinib mesylate at a daily dose of 400 mg to 23 patients with PMF. They reported significant side effects, including neutropenia, musculoskeletal pain, thrombocytosis, edema, diarrhea, and hyperbilirubinemia, but found no significant clinical benefit. Zarnestra, a farnesyl transferase inhibitor interfering with RAS signaling pathways, was evaluated in eight patients with PMF and reported to be effective in the reduction of splenomegaly and attainment of transfusion independence.[356] Etanercept, a soluble tumor necrosis factor (TNF) receptor, has been effectively used to alleviate the constitutional symptoms in a pilot study of 22 patients with PMF.[357] Sixty percent of the patients who were able to be evaluated patients experienced an improvement in their symptoms, and 20% had an objective response with improvement in their cytopenias or splenomegaly.[357]

Small molecule tyrosine kinase receptor inhibitors has been shown to have modest activity in patients with PMF.[358,359] Giles and coworkers administered PTK787/ZK222584 to 20 patients with PMF at dose of 500 or 750 mg twice daily. Twenty percent of patients achieved a response indicating that therapies which target VEGF or its receptor might be active alone or in combination with other chemotherapeutic agents.[359] Several pilot trials of bisphosphonates for bone pain in PMF patients have reported with occasional success.[360] Shi et al recently presented data, which suggest that chromatin modifying agents such as hypomethylating agents and histone deacetylase inhibitors might be candidate agents for the treatment of PMF.[138] Inoue et al have reported the successful treatment of a single patient with PMF with severe anemia and thrombocytopenia with the histone deacetylase inhibitor valproic acid.[361] This class of agents leads to accumulation of acetylated histones which in turn leads to increased gene expression. The therapeutic potential for the use of chromatin modifying agents for the treatment of PMF patients requires careful evaluation.

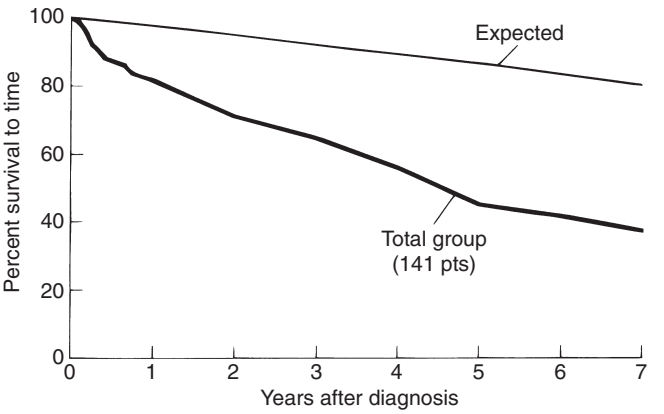

Figure 70–3 Overall survival from time of diagnosis of 141 patients with primary myelofibrosis. *(Data from Silverstein MN: Agnogenic Myeloid Metaplasia. Acton, MA, Publishing Sciences Group, 1975, p 197.)*

PROGNOSIS

The median overall survival period from the time of diagnosis of PMF varies from series to series but is approximately 5 years[1,3,7,9,362] (Fig. 70–3). Individual survival times have been reported to range from 1 year to more than 30 years.[1–8] In one series of 106 cases of PMF, the primary causes of death were determined in 53 cases and included infection (16 cases), leukemic transformation (9 cases), heart failure (9 cases), bleeding (7 cases), hepatic failure due to massive myeloid metaplasia of the liver (5 cases), portal hypertension (4 cases), and renal failure, pulmonary embolism, and post-transplantation GVHD (1 case each).[363] The incidence of acute leukemia as a terminal event ranges from 5% to 22% (Fig. 70–4), depending on the series cited.[1,3,7,9,362–365] Approximately one half of the patients who develop acute leukemia have not received previous treatment with alkylating agents or radiotherapy, suggesting that the evolution into acute leukemia may be part of the natural history of PMF.[362–365] The actuarial cumulative risk of death from leukemic transformation at 1 and 5 years after diagnosis has been reported to be 2% and 16%, respectively.[329,365–368] Immunologic and morphologic characterization of the blast phenotypes comprising these leukemias reveals that a typical myeloid phenotype is most commonly detected; other cell lineages, such as megakaryocytic, erythroid, lymphoid, and even stem cell phenotype, may also be involved, leading to the existence of mixed myeloid and hybrid transformations.[365–375] Megakaryoblastic transformations have been detected in one third of cases in one series, an incidence higher than that found in de novo acute myeloid leukemia.[374] Survival after blast transformation is limited, a phenomenon that is probably a result of patient age and the aggressive biology of these leukemias. In a series of 91 patients the leukemic transformation of PMF was fatal in 98% after a median of 2.6 months.[375] Successful leukemia remission induction therapy in these patients is an extremely rare event.[375] Patients should be sent for transplant prior to leukemic transformation.

Several clinical and biologic parameters that are characteristic of patients at diagnosis have been used to identify subgroups of patients with different outcomes.[9,232,363,369,376–381] Some investigators have suggested that there are two subpopulations of patients in PMF: short-lived and long-lived subpopulations of patients.[363] Such efforts at developing prognostic parameters have met with conflicting results, with the exception that anemia at presentation is consistently associated with short survival.[363] Dupriez and associates[369] developed an extremely simple scoring system, the Lille scoring system, based on two adverse prognostic factors—hemoglobin level less than 10 g/dL and white blood cell count less than 4,000 or more than 30,000/mm^3 and were able to stratify patients into three groups (Table 70–10). The low-risk (0 factors), intermediate-risk (1 factor), and high-risk (2 factors) groups were associated with median survival

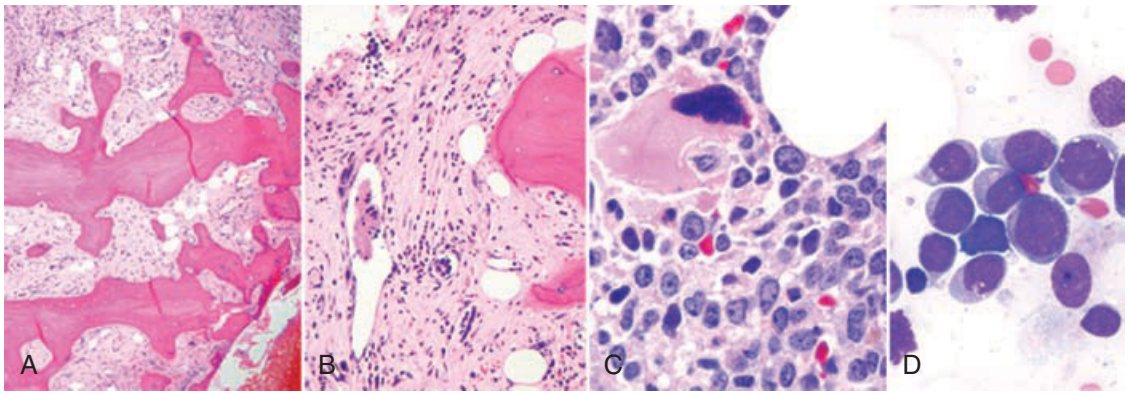

Figure 70–4 DISEASE PROGRESSION IN PRIMARY MYELOFIBROSIS. Marked osteosclerosis **A, B,** and acute leukemia **C, D**. PMF progresses in some patients to severe osteosclerosis in which there is markedly thickened and irregular bone formation (**A**) and a marrow space that is fibrotic and nearly depleted of hematopoietic elements (**B**). A terminal transformation to acute leukemia (**C, D**) occurs in 5% to 22% of cases.

Table 70–10 Distinguishing Features of Myeloid Malignancies Presenting with Marrow Fibrosis

Disorder	Splenomegaly	WBC	Teardrop poikilocytosis	Marrow Fibrosis	% Marrow Blasts	Bilineage or Trilineage Dysplasia	Jak2V617F, MPLW515L/K
MDS with fibrosis	No or mild	Decreased, normal or increased	No or few	+	<20	+	Negative
Acute panmyelosis with myelofibrosis (APMF)	No or mild	Decreased or normal	No	++	<20	+++	Negative
Acute megakaryoblastic leukemia (AMKL)	No or mild	Decreased, normal or increased	No or few	++	>20	++	Negative
PMF	Increased	Decreased, normal or increased	Present	++	<20	+	Positive in 50% of cases
CML, chronic phase	Increased	Increased	No or few	0-+	<20	–	Negative
CML accelerated phase	Increased	Increased	No	0-+	<20	0-+	Negative

CML, chronic myeloid leukemia; MDS, myelodysplastic syndrome; PMF, primary myelofibrosis.

Am J Clin Pathol 99:513, 1993; and (b) Orazi A, O'Malley DP, Jiang J et al: Acute panmyelosis with myelofibrosis: an entity distinct from acute megakaryoblastic leukemia. Mod Pathol 18:603, 2005.

times of 93, 26, and 13 months, respectively.[369] Other scoring systems that use simple clinical hematological parameters have been subsequently proposed. In a large Japanese study of 336 patients,[379] the presence of a hemoglobin level of 10 g/dL or higher, a platelet count of at least 100×10^9/L, and less than 3% circulating blasts predicted a median survival of approximately 15 years compared with less than five years in the remaining patients.

In 106 patients with PMF with successful marrow karyotypic analysis, Reilly[232] demonstrated that 35% percent of cases exhibited clonal abnormalities. A Kaplan-Meier analysis defined age ($P < 0.01$), hemoglobin ($P < 0.001$), white blood cell count ($P < 0.06$), platelet count ($P < 0.0001$), and abnormal karyotype ($P < 0.001$) as adverse prognostic parameters.[232] From these results, a prognostic schema was defined (Table 70–11). Median survival times varied from 180 months for the low-risk group (age <68 years, hemoglobin level >10 g/dL, normal karyotype) to 16 months for high-risk group (age >68 years, hemoglobin level ≤10 g/dL, abnormal karyotype).[232] Tefferi and colleagues[215] restricted the negative influence of chromosome changes to the presence of trisomy 8 and deletion of 12p, while deletions of 13q and 20q did not involve a shorter survival.

The impact of cases with a prefibrotic myelofibrosis in staging the disease is difficult to examine since these patients have been rarely considered for inclusion in the published prognostic schemas, thus possibly producing a selection bias against the very early, indolent cases. Kvasnicka and colleagues[380] analyzed a large series of patients, including a high proportion of cases with prefibrotic stage of the disease. Even though the degree of bone marrow fibrosis had prognostic significance after univariate analysis, the authors were able to distinguish three classes of patients on the basis of hemoglobin (Hb) level, white blood cells (WBC), percentage of circulating blasts, and age. What most significantly emerged from this series was the identification of a subset of young patients who were not anemic and who had a normal number of WBC at diagnosis who had a very long duration of disease, ie, median survival of approximately 20 years.

Table 70–11 Lille Scoring System for Predicting Survival in Primary Myelofibrosis

Adverse Prognostic Factors
Hb < 10 g/dL
WBC < 4 or >30 $\times 10^9$/L
The scoring system (number of adverse prognostic factors)

Factor No.	Risk Group	Cases (%)	Median Survival (mo)
0	Low	47	93
1	Intermediate	45	26
2	High	8	13

Prognostic scoring systems have been developed for use at the time of referral of a young patient for stem cell transplantation. Cervantes and colleagues documented that in patients younger than 55 years of age, the factors associated with poor prognosis are anemia (Hb value <10 g/dL), constitutional symptoms and presence of blast cells in peripheral blood.[160] Based on the above mentioned three variables, two prognostic groups could be clearly identified among these younger patients: a "low-risk" group, including patients with none or one of the bad prognostic factors, and a "high-risk" group, defined by patients with two or three unfavorable factors. The "low-risk" group encompassed three quarters of the patients overall and median survival approached 15 years, whereas the "high-risk" group included a quarter of the patients, with a median survival of less than three years. In a cohort of 160 patients with PMF younger than 60 years of age and an overall survival of 78 months, Dingli and coworkers[381] identified a hemoglobin level of <10 g/dL, white blood cell count of either <4 or >30 × 10^9/L, platelet count of <100 × 10^9/L, an absolute monocyte count ≥ 1×10^9/L, the presence of constitutional symptoms, and hepatomegaly as independent predictors of inferior survival. By combining four parameters including hemoglobin level of <10 g/dL, white blood cell count of either <4 or >30 × 10^9/L, platelet count of <100 × 10^9/L, an absolute monocyte count at least 1 × 10^9/L, Tefferi et al was able to predict the course of three subpopulations of 334 PMF patients irrespective of age.[382] Almost 47% of patients were in the low-risk group and had a median survival of 134 months; 30% were in an intermediate-risk group and had a median survival of 58 months, and 23% were in the high-risk group with a median survival of 28 months. It is important to note that these laboratory values were obtained at the time of diagnosis or within six months of diagnosis, but prior to therapeutic intervention.[382] Clearly whatever the prognostic scoring system utilized, patients in the high risk group have a grave prognosis and be considered as candidates for stem cell allogeneic transplantation. Patients in a low-risk group should be observed, and patients in an intermediate-risk group should be considered as candidates for experimental therapeutic agents which are increasingly becoming available. If such agents are effective, they might serve as a viable alternative to stem cell transplantation in the future.

The prognosis of post-ET or PV MF has not been as well defined as PMF. Dingli and coworkers have recently reported that Hb levels <10 g/dL, older age and unfavorable cytogenetic abnormalities (clones other than 13q- and 20q- were predictive of a poor survival).[383] Post-ET and PV MF does not appear to be associated with a significantly proorer prognosis than PMF. The median survival for an entire cohort of such patients in one study was 90 months.[383] Patients with unfavorable cytogenetic abnormalities had a median survival approximately only 30 months.[383]

FUTURE DIRECTIONS

A major challenge with PMF remains the definition of the clinical boundaries of the PMF syndrome which will reconcile the disease definition with its clinical features, histological features, and patient prognosis. The scientific community must employ uniformly applicable diagnostic criteria not only for clinical trial enrollment purposes but also for better communication with patients, the development of better prognostic tool for stratification of therapy, and more accurate interpretation of results from molecular testing or targeted therapy. More rationale therapy for PMF should evolve from a better understanding of the basic cellular and molecular biologic abnormalities underlying PMF. Targeting tyrosine-kinases that are specifically activated in PMF, like normal mutated protein, or signalling pathways that are disrupted by disease specific mechanisms, like the TGF-β pathway, may provide promising therapeutic options. Until new drugs are available, allogeneic stem cell transplantation with reduced-intensity conditioning and peripheral blood stem cell grafts remains the only potentially curative therapy available for patients younger than 65 years with a good performance status. Although there is a reluctance to expose such patients to the risks of allogeneic stem cell transplantation, if their underlying disorder is associated with a poor prognosis, this risk appears to be warranted. The decision requires a detailed discussion of the risks and benefits of such a high risk but potentially effective procedure. The establishment of a multi-institutional cooperative group to evaluate therapies and treatment strategies for PMF patients must be a goal for the future. No single institution has sufficient numbers of patients to perform the phase III trials that have been sorely needed in this area. Only with the implementation of a rigorous evaluation of individual therapeutic strategies will we be able to determine the value of a growing number of potentially active agents. Each new therapy must be evaluated using a number of clinical endpoints as well as surrogate biomarkers and the immediate and long-term toxicities associated their use deter-

Approach to Treatment and Complications

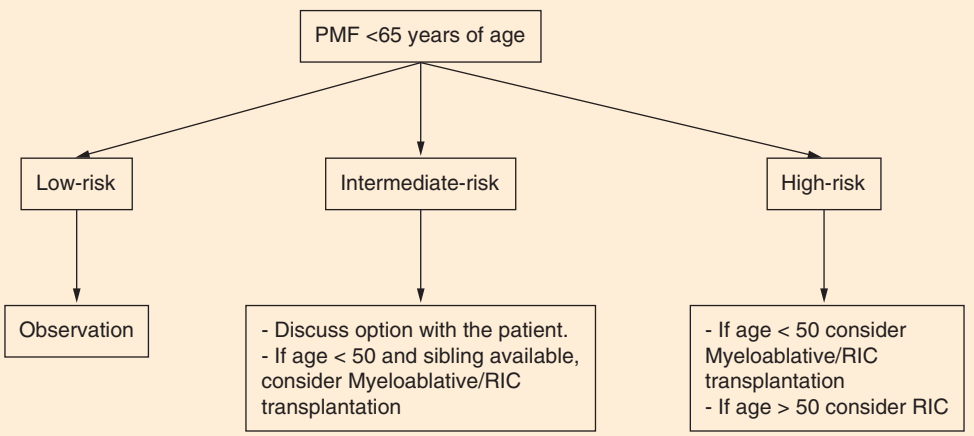
When initially encountering a patient with presumed PMF, the physician must be certain that this process is not secondary to carcinoma invading the marrow or involvement of the marrow with lymphoma, an infectious disease such as tuberculosis or an autoimmune process. After a careful history and physical examination, appropriate cultures, chemistries, and radiographic studies should be performed to exclude these secondary forms of myelofibrosis. An ANA screen should be performed on patients with myelofibrosis and signs of immunoreactive process, like fever, high erythrocyte sedimentation rate, arthralgias to avoid missing an immune-mediated myelofibrosis that is treatable with steroids.

The treatment of PMF depends on the major manifestations of the disease in an individual patient. The clinician must consider treatment of anemic patients, patients with symptoms resulting from splenomegaly, those with bleeding abnormalities, those with portal hypertension, and those with ascites, bone pain, or symptoms due to hypermetabolism. Because most patients with the prefibrotic phase of PMF are largely asymptomatic, an approach to the treatment of this newly defined entity remains unknown. Prospective clinical trials will be needed to evaluate treatments to delay or prevent transition to the myelofibrotic phase. Nutritional deficiencies of iron or folate are easily diagnosed and treated. From the analysis of the results of the three most effective drugs in the treatment of the anemia associated with PMF, androgen therapy seems to be the first therapeutic option due to the safety and efficacy of the treatment. Screening for prostate cancer is recommended before using androgen therapy in males.

No evidence exists to determine if any of the anabolic steroids, such as testosterone enanthate, oxymetholone, or danazol are superior. Many centers now prefer danazol because of its better tolerability and absence of virilizing side effects. In the case of a lack of response, thalidomide or rHuEPO should be considered. RHuEPO therapy should be restricted to those patients with serum erythropoietin levels that are inappropriately low in relation to the degree of anemia, especially those without marked anemia and without a high burden of the normal V617F mutation (>50%).

In patients with symptoms resulting from splenomegaly, or with progressing splenomegaly, chemotherapy in the form of hydroxyurea, busulphan, interferon-α, or low-dose melphalan therapy is able to achieve some reduction of spleen size in approximately two thirds of patients; in some cases the response is sustained.

Individuals with acute splenic infarction who do not respond to administration of analgesics may gain pain relief from local irradiation over the spleen at doses of 0.25 to 0.50 Gy/day for 4 to 5 days. Radiotherapy may be also beneficial in those with huge, painful spleens in whom splenectomy is too risky. Patients with symptoms resulting from a profoundly enlarged spleen are best treated with splenectomy. Whenever a patient is considered a candidate for splenectomy, an extensive preoperative evaluation must be pursued. All patients must have an extensive preoperative evaluation of the coagulation system, which should include assays for coagulation factors V and VIII, fibrin-split products, platelet count, and bleeding times. Patients with qualitative platelet abnormalities remain candidates for splenectomy, but successful surgical intervention may require the use of adrenal steroids before surgery and platelet transfusions at the time of surgery. In patients with subclinical DIC, surgery is definitely contraindicated. The operation itself must be considered a major procedure. Morbidity after splenectomy can be minimized by careful selection of patients with respect to cardiac and renal status, improved surgical technique, aggressive blood bank support with platelet transfusions, and early postoperative mobilization of the patient. Only a senior staff surgeon who has performed this type of surgery many times should attempt such an operation. Immunization against pneumococcus, *Haemophilus influenzae* and meningococcal vaccines should be given at least 2 weeks prior to splenectomy. Since thrombocytosis prior to splenectomy is a risk factor for development of thrombosis after surgery, patients at splenectomy should have a platelet counts reduced to 200 $\times$ 10^9/L and, if necessary, this should be achieved with hydroxyurea or short courses of cytosine arabinosine at standard doses (100 mg/day for 5–6 days). Since the occurrence of thrombosis of the portal system is a potentially life-threatening complication after splenectomy in PMF,[384] thrombosis prophylaxis with low-molecular-weight heparins is mandatory. Doppler ultrasonography monitoring of the portal vein system (at least at the first weeks after intervention) is recommended. At the documentation of new thrombosis of the portal system, anticoagulation therapy must be established. Platelet transfusions should be administered to the bleeding patient after splenectomy, even if the platelet count is normal, because PMF is frequently associated with qualitative platelet abnormalities.



Thrombocytopenia and nonapparent DIC may lead to a hemorrhagic diathesis. In patients who have qualitatively abnormal platelet function, platelet transfusions are suggested for serious bleeding or when preparing a patient for surgery. Patients with thrombocytopenia resulting from marrow failure and hypersplenism can often be managed by administering danazol (600 mg/day). For patients with life-threatening thrombocytopenia who do not respond to danazol, splenectomy should be seriously considered.

Portal hypertension in PMF may be caused by increased blood flow from the spleen to the liver (ie, forward-flow portal hypertension) or by an intrahepatic block due to postnecrotic cirrhosis or intrahepatic extramedullary hematopoiesis. Forward-flow portal hypertension is correctable by splenectomy, whereas portal hypertension due to an intrahepatic defect may require a portosystemic shunt procedure. The indications for portosystemic decompression include upper gastrointestinal bleeding and refractory ascites. Some patients can be decompressed with a transjugular intrahepatic portosystemic shunt.[385,386] Limited survival of patients treated medically with variceal bleeding has been observed, but prolonged survival (>3 years) of patients treated surgically has been reported.

Patients with ascites, bone pain, or hypermetabolism present unique problems. If the ascites is caused by portal hypertension, management should be directed at relieving the hypertension. Development of ascites in PMF may also result from seeding of the peritoneal cavity with extramedullary hematopoiesis. In all patients with myelofibrosis who develop ascites, paracentesis should be performed and careful study of the ascitic fluid pursued. If megakaryocytes are found in the samples of ascitic fluid, the ascites probably results from peritoneal implants of myeloid tissue. These implants are treated by intraperitoneal instillation of cytosine arabinoside, initially at a dose of 0.77 mg/kg/day, which can be advanced to 13.5 mg/kg/day, or by abdominal irradiation. Administration of fractionated doses of radiation at 0.25 Gy/day with rotation into the four quadrants of the abdomen is also extremely effective. Radiation therapy to a total dose of 5 to 10 Gy may be very rewarding. Patients with myelofibrosis who develop severe bone pain have an extremely guarded prognosis. Treatment with etidronate at a dose of 6 mg/kg daily on alternating months has resulted in complete recovery from bone symptoms in a few patients.[387] This complication frequently serves as a prodrome of leukemic transformation. In these patients, biopsies at sites of pain may reveal pure populations of leukemic blasts. The pain appears to be the result of invasion of the periosteum by blast cells. Bone pain may also be treated with local irradiation for several days. Symptoms resulting from hypermetabolism, such as weight loss, sweating, and asthenia are not unusual. Such patients may benefit from low-dose hydroxyurea or etanercept. Patients with excessive myeloid proliferation, extensive hepatomegaly or extramedullary hematopoiesis involving the lung may benefit from therapy with 2-chlorodeoxyadenosine.

Approach to Treatment and Complications—cont'd

All patients younger than 65 years with symptomatic PMF should be evaluated for allogeneic stem cell transplantation. Identification of an appropriate donor and rapid referral to an expert stem cell transplantation unit should be expedited. Patients with a poor prognosis (high-risk group) as determined by the Lille scoring system or the system proposed by Dingli should be referred for transplant. If patients enjoy a good performance status, they should be encouraged to consider allogeneic SCT or enter a clinical trial evaluating such procedure. For patients with low-risk disease, allogeneic SCT is not recommended because of the prolonged survival of these patients. Allogeneic transplantation should be considered in intermediate-risk patients. The optimal conditioning regimen for RIC allogeneic SCT for PMF remains unknown. As far as splenectomy before allo-SCT, the recommendation is to consider splenectomy in patients who have significant symptomatic splenomegaly, refractory hemolytic anemia, or complications of portal hypertension refractory to medical management

Above, algorithm for selection of PMF patients for allogeneic stem cell transplantation stratified according to clinical characteristics of patients. High-risk patients are those with two of the following abnormalities in the hemopoietic cell lineage: Hb < 10 g/dL, WBC >30 or <4 × 10^9/L and platelet <100 × 10^9/L.[321] Intermediate-risk patients are those with one of these; low-risk patients are those with none of these.

mined. The European Myelofibrosis Network (EUMET) and the International Working Group for Myelofibrosis Research and Treatment (IWG) have independently developed objective criteria by which responses to experimental therapeutic agents might be judged.[388,389] Since it is likely that a large number of such agents will be evaluated in patients with PMF during the next few years, it is recommended that either of these two means of evaluating a response to a therapeutic agent be implemented so that their relative efficacy can be more easily judged.

CHAPTER 71

ESSENTIAL THROMBOCYTHEMIA

Guido Finazzi, Mingjiang Xu, Tiziano Barbui, and Ronald Hoffman

Essential thrombocythemia (ET) is a chronic myeloproliferative disorder (MPD) characterized by a sustained proliferation of megakaryocytes, which leads to increased numbers of circulating platelets.[1–20] In addition to platelet counts in excess of 450×10^9/L, this disorder typically is characterized by profound marrow megakaryocyte hyperplasia, splenomegaly, and a clinical course punctuated by hemorrhagic or thrombotic episodes or both.[1–20] ET is a clinically heterogeneous disorder with up to two-thirds of patients who meet the criteria for diagnosis being asymptomatic at presentation. ET was first reported in 1934 by Epstein and Goedel,[21] who described a patient with an elevated platelet count who suffered from repeated hemorrhagic episodes.[21] This disease entity has been referred to by a variety of names, including primary thrombocythemia, idiopathic thrombocythemia, primary thrombophilia, and essential thrombocytosis.

Originally, many clinical investigators questioned whether ET represented a distinct clinical entity.[22] However, extensive descriptions of larger series of patients have provided information to dispute this initial skepticism.[1–20] Dameshek[23] in 1951 speculated that ET may represent one of the MPD. Laboratory investigations have confirmed this concept and clearly demonstrated that the disorder is typically a clonal hematologic malignancy.[24–28] Many patients, however, meet the criteria for the diagnosis of ET but have polyclonal hematopoiesis.[11–20,29–31]

In 2005 a breakthrough in our understanding of the pathogenesis and management of ET was made with the discovery of the Jak2V617F mutation in the majority of patients with chronic MPD, especially polycythemia vera (PV).[32–37] This finding has had a major impact on the classification of and diagnostic approaches to these disorders as well as creating drug development strategies based upon molecular pathogenesis.

EPIDEMIOLOGY

The true incidence of ET is unknown because extensive epidemiologic studies are not available. Although many investigators have indicated that this disorder is very rare, information from several institutions suggests that it occurs considerably more frequently than originally believed.[1–20] Following the incorporation of a platelet channel in automated complete blood cell counts, extreme thrombocytosis has been shown to be a relatively common occurrence in a general hospital setting.[38,39] Thus, 94 cases of newly diagnosed ET were identified from 1961 to 1982 at the Saint Louis Hospital in France, whereas 61 patients with this disorder were discovered from 1974 through 1987 at the Medizinische Poliklinik in Munich.[13,14] The incidence of ET has been reported to be approximately 1.5 to 2.4 patients/100,000 population annually.[40–42] Interestingly, a significant increase in the annual incidence rate of ET from 0.69 to 4.35 patients/100,000 inhabitants through the years 1983 to 1999 has been observed in the city of Goteborg, Sweden.[42] This trend was not observed for PV and is most likely due to the more frequent use of automated platelet counters in recent years. These figures are in keeping with the findings of an epidemiological cross-sectional study carried out in the city of Vicenza, Italy reporting a prevalence of ET of 400 per million inhabitants.[43] ET and PV appear to have approximately a 1:1 relative incidence,[42] although this incidence may be influenced by institutional affiliations and geographic differences.

The disorder appears to affect primarily middle-aged people, with an average age at diagnosis of 50 to 60 years.[1–20] In most series, there appears to be no gender predilection; although in several reports, a higher prevalence in females has been noted.[1–20,44,45] This discrepancy might be due to an equal frequency in older patients of both sexes but to a second peak frequency at around 30 years of age for women.[13] This predisposition of young women to develop ET has been reported previously.[45–47]

An abnormality of thrombopoietin production or of the thrombopoietin receptor has been suggested as the basis of inherited disorders leading to thrombocytosis.[48] A Dutch family with 11 family members and a Japanese family with 8 family members were reported with a hereditary form of thrombocytosis that was inherited in an autosomal dominant fashion.[49] The thrombopoietin receptor in the Dutch family was normal, yet there was a G to C transversion in the splice donor site of intron 3 of the thrombopoietin gene.[49] All of the affected members of both the Japanese and Dutch families were shown to have elevated thrombopoietin levels. In each family, a point mutation in the thrombopoietin gene was believed to lead to systemic overproduction of thrombopoietin, leading to a familial form of thrombocytosis.[48,49] The patients with autosomal dominant familial thrombocytosis have a benign course, which is not complicated by thrombotic or hemorrhagic events or transformation to myelofibrosis or acute leukemia. In addition, such patients frequently have lower platelet counts than pediatric patients with ET and a lower incidence of hepatosplenomegaly.[48–52] Recently another form of familial thrombocytosis has been defined. Ding have described a Japanese pedigree of familial thrombocythemia which is inherited as an autosomal dominant.[53] This disorder has been attributed to a dominant-positive activating mutation of the cellular receptor of thrombopoietin (MPL).[53] A unique mutation, serine 505 to asparagine 505 ($MPL^{Ser505Asp}$) has been identified in the transmembrane domain of MPL. These patients all have polyclonal hematopoiesis. Thrombopoietin and MPL mutations do not account for all cases of autosomal dominant familial thrombocythemia-indicating some degree of genetic heterogeneity.[49–53]

Moliterno and coworkers have also described a polymorphism of the thrombopoietin receptor (MPL Baltimore) which is accompanied by thrombocytosis. This polymorphism is due to a single nucleotide substitution that results in a lysine to asparagine (K39N) substitution in the ligand binding domain of MPL.[54] The polymorphism is associated with reduced expression of platelet MPL and the development of thrombocytosis. The polymorphism occurs exclusively in African American and appears to have an autosomal dominant pattern of inheritance with incomplete penetrance. Approximately 7% of African Americans are heterozygous for K39N.[54]

Several cases of ET have been reported in patients in the pediatric age group, but this is an extremely unusual occurrence.[55–63] A review of the literature cannot accurately determine the risk of thrombosis or bleeding of ET in childhood, but the clinical course is not entirely benign. The incidence of ET in childhood has been reported to be approximately 1 per 10^7 population, 60 times lower than that in adults. Approximately 30% of children with this disorder experience thrombotic or hemorrhagic complications at diagnosis or later in their course and 50% have splenomegaly.[61] Interestingly, in a recent study only 20% of pediatric patients with ET, as compared to 45% of adult ET patients, had clonal hematopoiesis, and 20% were Jak2V617F positive as compared to 60% of adult patients.[63]

Several families with multiple members having ET have been described.[64–66] The prevalence of the Jak2V617F mutation in familial cases of MPD has been recently analyzed in 72 families including 174 patients (68 with ET).[67] The Jak2 mutation was found in half of patients with ET, a similar proportion as observed in sporadic, non familial cases. Among 46 families with at least 2 cases of PV, ET, or primary myelofibrosis (PMF) the Jak2 mutation was absent in 6 families, heterogeneously distributed in 18 and present in all patients with MPD in 22. Thus, the Jak2 mutation does not seem to be required for the development of ET or other MPD.

ETIOLOGY

Greater insights into the mechanisms leading to thrombocytosis in ET have been gained. Patients with ET have normal or near-normal platelet survival.[68,69] The thrombocytosis is due to increased platelet production by megakaryocytes. Effective platelet production is increased as much as 10-fold and is associated with an increase in megakaryocyte clustering, volume, nuclear lobe number, and nuclear ploidy.[68,69]

Analysis of circulating blood cells of females with ET who were heterozygotes for isoenzymes of glucose-6-phosphate dehydrogenase has revealed that platelets, erythrocytes, and neutrophils express a single isoenzyme type.[24–28,30,31] In addition, Raskind and colleagues[27] have presented data to indicate that B cells can also be involved in this neoplastic process. Such findings indicate that ET is typically a clonal hematopoietic disorder originating at the level of the pluripotent hematopoietic stem cell. The clonal origin of ET has subsequently been confirmed using restriction fragment-length polymorphisms of X chromosome genes.[28,30,31,70]

Such clonal analyses have revealed that a significant proportion of nonclonally derived leukocytes exist in addition to the clonally derived population of leukocytes in patients with ET.[28,30,70] In one study of 42 patients with ET, 31 patients exhibited clonality of at least one hematopoietic lineage, whereas the remaining 11 patients had polyclonal origin of all lineages studied.[30] The biogenesis of polyclonal ET remains ill defined. It is possible that small numbers of normal hematopoietic stem cells persist to account for this admixture of nonclonal populations. It has been reported by several groups that ET patients with polyclonal hematopoiesis have fewer thrombotic complications.[11,18,29,30,70]

In one patient, Anger and coworkers[70] determined that although the total leukocyte fraction was clonally derived, the T-lymphocyte population was nonclonal in origin. In fact, most studies indicate that T lymphocytes are of polyclonal origin in ET patients.[28] Interestingly, in some patients, monoclonality of hematopoiesis is restricted to platelets, despite the polyclonal origin of the other lineages. Other studies, however, have indicated a common origin of granulocytes, platelets, and B lymphocytes in this disorder.[26] Such studies raise the possibility that the malignant transformation leading to ET occurs at a number of cellular stages along the hematopoietic cellular hierarchy.[56]

The biologic behavior of megakaryocyte progenitor cells present either in the marrow or in the peripheral blood of patients with ET has been extensively studied.[72–85] In each of these studies, the use of serum-containing culture systems has led to the detection of increased numbers of assayable progenitors. These data support the concept that the principal abnormality is an expansion of the progenitor cell pool. In addition, colonies were noted to appear in the absence of exogenous cytokines.[72–85] A second subpopulation of colony-forming unit-megakaryocyte (CFU-MK) assayed from patients with ET was also shown to remain responsive to the addition of cytokines, suggesting the presence of both a MPD clone not requiring exogenous cytokines and a more physiologic clone that does.[72–85]

Several laboratories have demonstrated that megakaryocyte progenitor cells isolated from ET patients are hypersensitive to the action of several cytokines including IL-3, IL-6, and thrombopoietin, but not GM-CSF.[82–85] Investigators have explored the possibility that the defect in ET might actually be due to resistance to inhibitors of megakaryocytopoiesis.[86] Zauli and associates have shown that the ET CFU-MK has a significantly lower sensitivity to the inhibitory effects of low doses of TGF-β and a limited response to the inhibitory effects of high concentrations of autologous platelet lysates.[86] TGF-β was shown to be primarily responsible for the inhibitory activity present in such platelet lysates.[86] Some combination of increased sensitivity to growth factors that promotes platelet production and disrupted sensitivity to negative regulators of thrombopoiesis at the level of the megakaryocyte progenitor cell might account for the thrombocytosis that is characteristic of ET.

Using serum-free cultures, a number of laboratories have reported conflicting data about spontaneous megakaryocyte colony formation by CFU-MK from patients with ET in the absence of the addition of exogenous cytokines.[77–85] Several groups have attempted to use this in vitro characteristic as a diagnostic tool to discriminate ET from reactive thrombocytosis.[84,85] Because there is some degree of spontaneous megakaryocyte colony formation by normal marrow in such serum-free culture systems, these findings remain difficult to interpret.[87] No evidence of an autocrine regulatory defect involving IL-3, IL-6, GM-CSF, or thrombopoietin has been detected to account for the expansion of the megakaryocyte progenitor cell pool in ET.[82,88,89]

Erythroid progenitor cells in ET can also proliferate in response to the small amount of cytokines present in serum alone. Erythroid colony formation in the absence of exogenous erythropoietin is a hallmark of the proliferative defect that characterizes PV.[90] Burst-forming unit-erythroid can be assayed from both marrow and peripheral blood of patients with ET and form erythroid colonies in the absence of exogenous erythropoietin.[91–94] Such an abnormality in these nonpolycythemic patients probably indicates an underlying defect shared by progenitor cells in many MPD.[91–94]

Thrombopoietin is the primary physiologic regulator of megakaryocytopoiesis and platelet production. This growth factor acts by binding to its cell surface receptor, Mpl.[95] The thrombopoietin receptor is expressed by $CD34^+$ hematopoietic progenitor cells, megakaryocytes, and platelets.[95] Normal or slightly elevated thrombopoietin levels have been observed in patients with ET.[96–100] Furthermore, expression of the thrombopoietin receptor and its mRNA have been shown to be dramatically reduced in the platelets of patients with ET.[97–102] Investigators have reported that in PV there is overexpression of the polycythemia rubra vera (PRV-1) gene in leukocytes; however PRV-1 overexpression is found less frequently in patients with ET.[103] Interestingly, decreased Mpl expression and elevated granulocyte PRV-1 expression have been observed in patients with autosomal dominant familial thrombocythemia who carry a mutation in the thrombopoietin gene.[49] These studies question the specificity of c-mpl and PRV-1 expression in identifying patients with MPD.[49]

The Jak2V617F mutation is present in 40% to 60% of patients with ET while gain of function mutations involving the thrombopoietin receptor, MPLW515L and MPL515K are present in approximately 1% of patients with ET.[32–37,104–110] Jak2 is a cytoplasmic tyrosine kinase which plays a key role in mediating intracellular signaling from a variety of growth factors including IL-3, erythropoietin, GM-CSF, G-CSF, and thrombopoietin, Lu et al have shown that coexpression of Jak2V617F with a homodimeric type 1 cytokine receptor (including erythropoietin, thrombopoietin, or G-CSF) is necessary for hormone activation of Jak-STAT signaling pathways and for hematopoietic cell proliferation to become growth factor independent.[111] The Jak2V617F mutation is present in ET patients with both clonal and polyclonal hematopoiesis.[101–110] Patients with clonal hematopoiesis have a higher Jak2V617F mutational burden (26%) than patients with polyclonal hematopoiesis (16%).[112] Gale et al have presented data in ET patients which indicates that the relative size of the Jak2V617F clone is often small and that it remains stable over time in patients with both clonal or polyclonal hematopoiesis.[113] Although an allele burden higher than 50% Jak2V617F indicating the presence of granulocytes homozygous for Jak2V617F has been

found in 70% of PV patients, it was observed in only 2% of ET patients.[114] Scott and coworkers examined the Jak2V617F status of hematopoietic colonies cloned from 22 PV patients with either a high or low burden of Jak2V617F.[115] All PV patients had assayable erythropoietic bursts that were homozygous for Jak2V617F and concluded that even in PV patients with low a burden of Jak2V617F that Jak2V617F homozygous progenitors were present.[115] By contrast hematopoietic colonies cloned from ET patients were virtually never Jak2V617F homozygous.[115] The transition from Jak2 heterozygous to homozygous progenitors is a consequence of homologous recombination. These studies suggest that such an event is characteristic of PV, but rarely occurs in ET.[34] If such event occurred in ET, it would likely lead to a transition from an ET phenotype to a PV phenotype.[110] Some investigators, but not all, have reported a higher allelic burden of Jak2V617F in platelets as compared to granulocytes in patients with ET, while the allelic burden in PV and PMF is higher in granulocytes than platelets.[107–110,116–121] Jak2V617F is observed only in platelets in rare patients with ET.[117] Jak2V617F can be detected, not only in granulocytes and platelets of ET patients but also erythroblasts.[122] In PV Jak2V617F produces an increased phosphorylation of signal transducer activator of transcription (STAT).[123] In PV uniformly increased phosphorylated STAT3 and STAT5 expression in bone marrow cells was observed while in ET normal or increased phosphorylated STAT3 but reduced phosphorylated STAT5 has been noted.[123] STAT3 is a pivotal regulator of megakaryocytopoiesis which might provide an explanation for its exclusive upregulation in ET.[123]

The methodology used to detect Jak2V617F influences the proportion of ET patients documented to be positive for the mutation.[124] The frequency of Jak2V617F positive ET tends to be higher if real time PCR is utilized (72%) than if DNA resequencing (23%–32%) or allelic specific PCR (57%) is utilized to detect the mutation.[124] This still leaves a subset (22%) of patients with ET who are Jak2V617F negative, indicating that alternative pathways are likely responsible for the ET phenotype in these patients.[124] Discordance between the percentage of clonal granulocytes and the percent of Jak2V617F positive granulocytes have led some investigators to speculate that the development of a clonal form of ET may precede the acquisition of the Jak2V617F mutation.[112]

The clinical phenotype of patients with Jak2V617F positive and negative ET appears to be different.[107–110,116–121] At diagnosis, patients with the mutation tend to be older and to have a higher hemoglobin level, a higher neutrophil count, but a lower platelet count than patients with Jak2V617F negative ET. Patients with Jak2V617F positive ET, have marrows which are more hypercellular and are characterized by greater degrees of erythroid and granulocytic hyperplasia.[110] Serum erythropoietin levels are lower in Jak2V617F positive patients, and they have lower serum ferritin levels. In addition the rate of thrombosis has been suggested by some, but not all investigators to be higher in Jak2V617F positive ET patients.[110] Furthermore, a greater number of ET patients who have the mutation eventually go on to develop PV.[110] Jak2V617F positive patients have been reported to require smaller doses of hydroxyurea to lower their platelet counts.[110] Campbell and coworkers have hypothesized that since Jak2V617F positive ET shares many phenotypic similarities with PV and that these two disorders should be considered as a continuum rather than being categorized as two separate diseases.[110]

Most clinical sequelae of ET are related to hemorrhagic and thrombotic episodes, which frequently punctuate the clinical course of individual patients.[1–20,125,126] Thrombotic complications occur most frequently in older patients and patients with a previous history of a thrombotic event, whereas hemorrhagic events occur almost exclusively in individuals with extremely high platelet counts (>1000 $\times$ 10^9/L).[1–20,127,128] A subset of young patients who are asymptomatic and remarkably free of such complications has also been described.[49,56,128,129] Unfortunately, catastrophic thrombotic complications can be seen in both the young and the elderly.[130,131] The age-related differences in the frequency of these events have been attributed to the coexistence of vascular disease in older patients.[130,132] This hypothesis remains controversial because other studies have described younger patients with a significant incidence of vascular thrombosis, sometimes in usual sites, such as the portal or superior sagittal sinus veins.[13,133] Microvascular thrombosis causing digital or central nervous system ischemia leads to a variety of clinical syndromes closely associated with ET.[9,125–127,130–138]

Past studies have concluded that the degree of elevation of the platelet count in ET is an important determinant of the frequency of thrombotic and hemorrhagic events.[1,4,5] These conclusions were, however, based on observations of a limited number of patients. Many other studies have failed to define a relationship between the frequency of thrombotic complications and platelet numbers.[13,14,137,138]

Some progress has been made in further defining the relationship between platelet numbers and the risks for thrombotic and hemorrhagic events in ET.[125,128,139–142] Cortelazzo has reported in a randomized trial of patients at a high risk of developing a thrombotic event (>60 years of age and/or a previous history of a thrombotic episode) that reduction of platelet numbers was highly effective in preventing additional thrombotic events.[139] Furthermore, Cortelazzo and colleagues have shown that the incidence of thrombotic events was closely correlated with the duration of thrombocytosis.[127] Several groups have now confirmed that the degree and duration of bleeding in this patient population is correlated with the platelet count.[97,134–136] Bleeding events appear to occur exclusively when the platelet counts are excessively high and are reduced in number when the platelet count returns to normal.[96–102,128,140–143] The clinical spectrum of bleeding in ET patients closely resembles that observed in von Willebrand disease.[140–143] Several groups have now shown that high platelet counts (>1000 $\times$ 10^9/L) are associated with an acquired form of von Willebrand syndrome and that reduction of platelet numbers is associated with correction of the von Willebrand syndrome like abnormalities and cessation of bleeding episodes.[140–143] The mean platelet count in patients with ET and acquired von Willebrand disease is 2050 $\pm$ 1107 $\times$ 10^9/L.[144,145] An increase in the number of circulating platelets appears to favor the adsorption of larger von Willebrand multimers onto platelet membranes, resulting in their removal from the circulation and their subsequent degradation.[141,145]

Platelets with patients with ET have been known for a considerable time to be qualitatively abnormal.[4,7,125–128,140,142–145] Although both increased and decreased platelet reactivity has been described, these findings have not been definitively associated with thrombohemorrhagic complications with two noteworthy exceptions; erythromelalgia, where the prompt relief of symptoms by cyclooxygenase inhibitors provides direct evidence that prostaglandins play a role in the development of vascular occlusion, and acquired von Willebrand syndrome, which is a major cause of bleeding in patients with ET.[4,7,126,134–145] Prolongation of the bleeding time has been reported in 7% to 19% of newly diagnosed patients with ET.[128]

A close correlation between prolongation of the bleeding time and the occurrence of hemorrhage in ET patients does not always exist. This is in contrast to correction of the bleeding time in those patients with ET, extreme thrombocytosis, and an acquired von Willebrand syndrome following reduction of platelet numbers to the normal range.[126,142,145] It is important to emphasize that aspirin prolongs the bleeding time of patients with ET to a greater degree than that of normal controls.[128,130,145] Abnormal platelet aggregation has been reported in 35% to 100% of patients with ET.[128] The majority of such studies have used conventional platelet aggregation studies performed on platelet-rich plasma. In one study, the simultaneous measurement of platelet aggregation and ATP dense granule release by whole blood platelet lumi-aggregometry was used to identify ET patients at a risk of developing thrombosis. This observation has not been confirmed and a prospective analysis of larger cohorts of patients is required to confirm the utility of such assays.[146]

Abnormal aggregation studies are not related to prolongation of the bleeding time or to the incidence of episodes of hemorrhage or thrombosis. In ET, platelet aggregation is classically defective in response to epinephrine, adenosine diphosphate (ADP), and collagen, but is usually normal with arachidonic acid and ristocetin.[128,147]

Characteristically, in ET, the first wave of aggregation is diminished and the second wave of aggregation is absent in response to epinephrine.[128,147] Interestingly, preincubation of ET platelets with thrombopoietin corrects, in part, the impaired aggregation in response to epinephrine, ADP, and collagen.[148] Usuki and coworkers have proposed that circulating thrombopoietin levels in this disorder might regulate platelet function and responses to agonists in vivo.[148] An acquired form of platelet storage pool disease occurs frequently in ET. Platelet α-granule content and the release of the content of granules are abnormal resulting in elevated plasma levels of platelet factor-4 and β-thromboglobulin.[128]

Because the content of α-granule constituents has been reported to be normal in ET megakaryocytes, the synthesis of these molecules is not believed to be abnormal, but rather, the release of α-granule constituents is believed to be a consequence of platelet activation.[128] The finding of an acquired storage pool defect again does not correlate with platelet numbers or with the occurrence of clinical symptoms. Numerous individual functional platelet abnormalities have been demonstrated.[149–157] A defect in the metabolism of arachidonic acid by lipoxygenase has been documented, as have decreased numbers of platelet receptors for prostaglandin D_2 and adrenergic receptors for epinephrine.[128,154,155] Platelets from patients with thrombotic episodes have been found to be capable of increased generation of thromboxane B_2 and to have an increased affinity for fibrinogen.[156,158] Elevations in β-thromboglobulin and serum thromboxane B_2 levels in ET patients are suggestive of the presence of enhanced in vivo platelet activation and possibly thrombin generation.[158] These same abnormalities are not detected in patients with secondary thrombocytosis and may provide some explanation for the high incidence of thrombosis associated with ET.

The survival of platelets in ET patients with erythromelalgia and thrombosis has been shown to be reduced to 4.2 ± 0.2 days as compared with normal platelet survival in asymptomatic ET patients (6.6 ± 0.3 days) and patients with reactive thrombocytosis (8.0 ± 0.4 days).[159] Thrombosis in this setting is associated with an increased platelet turnover, which can be quantitated cytometrically by measuring the number of platelets most recently released into the circulation (reticulated platelets).[160] Treatment of erythromelalgia with aspirin increased mean platelet survival from 4.0 ± 0.3 days to 6.9 ± 0.4 days and was associated with a significant elevation of platelet numbers.[143,159] These findings suggest that erythromelalgia results from platelet-mediated thrombosis of the arterial microvasculature of the extremities (Fig. 71–1).[126,143,159] Complete correction of this ischemic circulatory defect is associated with the use of platelet cyclooxygenase inhibitors, such as aspirin and indomethacin.[135] Agents that do not inhibit platelet cyclooxygenase, such as coumadin, sodium salicylate, dipyridamole, sulfinpyrazone, and ticlopidine are not active in the treatment of this disorder. Dazoxiben is capable of inhibiting platelet malondialdehyde and thromboxane B_2 synthesis but does not correct the symptoms of erythromelalgia.[126,143,159] These findings suggest that prostaglandin endoperoxides play a role in the generation of platelet-associated thrombosis in ET (Fig. 71–1).[126]

Abnormalities of platelet membrane constituents have also been demonstrated in ET. Most commonly, decreased concentrations of glycoprotein (GP) Ib and also reduced concentrations of GPIIb and GPIIIa have been reported.[128] A remarkable patient with ET with a prolonged bleeding time was shown to have an acquired deficiency of glycoprotein Ia-IIa, the putative collagen receptor. Collagen-induced platelet aggregation was totally absent.[150] The mechanisms underlying these acquired membrane defects, as well as their clinical significance, remain unclear.

One intriguing explanation for the increased risk of thrombosis in patients with ET has been proposed by Lee and Baglin.[151] These investigators demonstrated that the total amount of thrombin generated on the platelet surfaces of patients with ET was markedly greater than that generated on the platelet surfaces of normal controls or patients with reactive thrombocytosis.[151] The molecular basis of this abnormality has not been defined, but it remains possible that an abnormal membrane structure of ET platelets may account for the enhanced thrombin potential that may lead to a relatively high thrombotic risk. Villmow and coworkers have documented increased numbers of platelet microparticles, as well as increased platelet-neutrophil and platelet-monocyte completes, in patients with ET.[161] Platelet microparticles support thrombin generation and leukocyte activation.[161] Increased numbers of platelet microparticles have been associated with the development of vascular thrombosis.[161]

Recently, in vivo leukocyte activation has been shown to occur in ET and to be associated with signs of activation of both the coagulation cascade and endothelial cells. Falanga and associates have speculated that platelet and leukocyte activation may play a role in the generation of the prethrombotic state that characterizes ET.[162–164] Interestingly, the presence of the Jak2 mutation is associated with a greater degree of platelet and leukocyte activation in these patients.[165] Activated neutrophils are able to bind platelets which triggers the expression of tissue factor as well as endothelial cell activation and damage. From a clinical point of view, two recent studies have demonstrated that an increased leukocyte count in patients with ET is an independent risk factor for developing thrombosis and is associated with an inferior survival.[166–168] Therefore, an important role for leukocytes in the pathogenesis of thrombosis in ET is becoming more evident.

CLINICAL MANIFESTATIONS

The presenting symptoms of patients with ET are quite variable. Many patients (12% to 67%) reach medical attention fortuitously, as a result of the extreme degree of thrombocytosis detected when obtaining a routine blood cell count.[1–20] In two series, in fact, 76% to 84% of cases were asymptomatic, and the diagnosis was made incidentally.[127,169] Most patients present with symptoms related to small- or large-vessel thrombosis or minor bleeding.[1–20] In general arterial events predominate over venous events. Presentation with a major bleeding episode is unusual.[170] After thrombocytosis has been detected, 13% to 37% of patients relate symptoms resulting from hemorrhagic events, whereas 22% to 84% of patients report thromboembolic complications.[1–20,127,171] Table 71–1 lists the thrombotic symptoms at diagnosis and subsequently reported from one large series of patients.[127] The thrombotic events primarily involved the microvasculature, with thrombosis of large vessels also occurring. Neurologic complications are common.[1–12,133–136,171–174] Table 71–2 lists representative neurologic complaints,[134] of which headache was

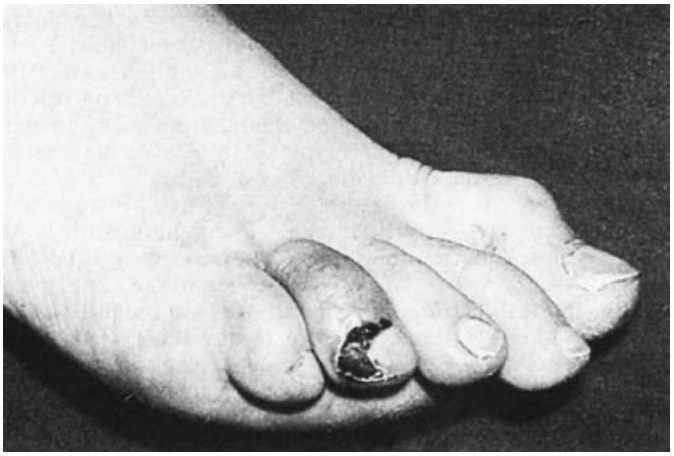

Figure 71–2. Gangrene of the toe in a patient with essential thrombocythemia.

the most common, with paresthesias of the extremities a close second. There was an extremely high incidence of transient ischemic attacks involving both the anterior and posterior cerebral circulation.[172–174] These attacks have a sudden onset, last for a few moments, and are frequently associated with a pulsatile headache.[172–174] The various symptoms occur sequentially rather than simultaneously and can be preceded or followed by erythromelalgia. Transient neurologic symptoms include unsteadiness, dysarthria, dysphoria, motor hemiparesis, scintillating scotomas, amaurosis fugax, vertigo, dizziness, migraine-like symptoms, syncope, and seizures.[172] The syndrome is caused by platelet-mediated ischemia and thrombosis in end-arterial microvasculature. It is not unusual for these symptoms to eventually progress to definitive cerebral infarcts.[173]

Microvascular circulatory insufficiency involving the toes and fingers is frequent.[125–127] Such events can lead to digital pain, enhanced by warmth; distal extremity gangrene (Fig. 71–2), and classic erythromelalgia.[9,125–127,135,136,175,176] The term *erythromelalgia* refers to a syndrome of redness and burning pain in the extremities.[176] Venous thrombosis is not typically observed in these patients. Erythromelalgia, which is characterized by a burning pain and a dusky congestion of swollen extremities, is usually preceded by paresthesias.[96] Cold provides relief to these symptoms, and heat intensifies the symptoms. Patients prefer to wear shoes or slippers without socks and elevate their feet.[126,175] These symptoms may progress in intensity and lead to peeling of the skin in affected appendages or affected toes or fingers, which then may become cold and ischemic with a dark purplish tinge. Erythromelalgia symptoms are asymmetric in the majority of cases.[126] Symptoms related to coronary artery disease or transient ischemic attacks may precede or accompany the onset of erythromelalgia.[126] Occasionally, hemorrhagic episodes may occur in patients experiencing erythromelalgia.[126] Platelet counts in patients with

erythromelalgia are frequently below 1000×10^9/L, except in those patients with concomitant occurrence of erythromelalgia and hemorrhage.[126,135,136,175] The relief of such pain for several days after a single dose of aspirin is diagnostic of erythromelalgia.[126,135,136] The specific microvascular syndrome of erythromelalgia is readily explained by platelet-mediated arteriolar inflammation and occlusive thrombosis leading to acrocyanosis and even gangrene.[126,135,136] Skin biopsies from affected sites reveal arteriolar lesions without involvement of venules, capillaries, or nerves.[135] The arteriolar endothelial cells are swollen and the vessel walls thickened by cellular swelling and deposition of intracellular material.[135] Compared with atherosclerotic circulatory obstruction, arterial pulses in patients with erythromelalgia remain normal.[135,136]

Although thrombosis of the microvasculature is generally more frequent, thrombosis of large veins and arteries in patients with ET still occurs commonly.[13,14,177] In one series, 51% of patients had symptoms related to large-vessel thrombosis, mostly in the arteries of the legs (30%), the coronary arteries (18%), and the renal arteries (10%).[14] Involvement of the carotid, mesenteric, and subclavian arteries is not unusual. In the same series, 7% of patients suffered from venous thrombosis involving either the splenic vein, hepatic veins, or veins of the legs and pelvis.[14] Unexplained thrombosis of the hepatic veins leads to Budd-Chiari syndrome, whereas thrombosis of the renal vein can result in the development of the nephrotic syndrome.[178–181] Abdominal venous thromboses occur predominantly in young females with ET. Patients with this complication are at a high risk of having a poor survival due to hepatic failure or transformation to myelofibrosis (MF) or acute leukemia.[180] It is worth noting that abdominal venous thrombosis may occur in patients with normal or near-normal blood counts but as an occult MPD. In these cases, an extensive diagnostic work-up, including a bone marrow biopsy and a search for the Jak2V617F mutation, is recommended.[179–181] In one study of 41 patients presenting with the Budd-Chiari syndrome who had a mean hemoglobin concentration (12.4 g/dL, SD 2.8) and a mean platelet count (289×10^9/L, SD 192) not previously suggestive of a MPD, 58% were positive for the Jak2V617F.[181] Priapism is a rare complication of ET, presumably caused by platelet sludging in the corpus cavernosum.[172,182] In addition, myocardial ischemia or infarction, or both, associated with normal coronary angiograms has been reported in patients with ET, as has a high incidence of anginal symptoms.[183–185] A high incidence of aortic and mitral valvular lesions has been reported in patients with MPD, including ET.[185] These valvular lesions resemble previous descriptions of nonbacterial thrombotic endocarditis and may be the origin of the peripheral arterial emboli observed in these patients.[185] In addition, acute renal failure has been observed after thrombosis of renal arteries and veins in one patient with ET.[186] Pulmonary hypertension secondary to alveolar capillary plugging by platelets and megakaryocytes has also been reported in patients with ET.[187–189]

Hemorrhagic problems plague many patients with ET;[1–20] the primary site of bleeding is the gastrointestinal tract.[5,125,126,130,142,190] Other sites of bleeding may be the skin, eyes, urinary tract, gums, tooth sockets (following extraction), joints, or brain.[1–20] Bleeding most often is not severe but occasionally may require red cell transfusion support.[1,8,13] The postoperative period appears to be an extremely precarious time, with a high incidence of bleeding episodes following surgical insult,[18,183,191] likely caused by postsurgical thrombocytosis and the development of acquired von Willebrand syndrome. The syndrome of hemorrhagic thrombocythemia is closely correlated with a significant increase of platelet counts in excess of 1000×10^9/L and is associated with pseudohyperkalemia.[126]

In one large study, in which 97 ET patients were followed for an average of 7 years, 26 had some type of hemorrhage, mostly of gastrointestinal or mucosal origin, few of which were life threatening; 44 of the 97 patients had some form of thrombosis, mainly in the peripheral arteries. Risk factors for atherosclerotic disease, especially cigarette smoking, increased the risk of thrombosis.[132,192,193] It is important to emphasize that individual patients can suffer from both thrombotic and hemorrhagic episodes and that patients are not necessarily consistent "bleeders" or "clotters."[125,126,130,190]

A controversy revolves around the understanding the risk of thrombohemorrhagic events in asymptomatic patients with ET who are less than 40 years of age.[40,45,47,56,129,194–196] This group represents 25% of the patients studied in a 13-year period at one institution and 34% of those studied at another institution.[56] In one series of 57 such adults with a mean follow-up period of 4.7 years (range from 5 months to 20 years) 43% remained asymptomatic, whereas thrombotic complications developed in another 43%.[56] Hemorrhagic complications occurred in 11% of the patients and 4% suffered a spontaneous abortion (2 of the 16 pregnancies).[56] The thrombotic complications were life-threatening in only 5% of the patients, all of whom recovered. The two deaths that occurred were not attributable to ET.[56] The most common thrombotic complications were migraine headache in 20% of the patients and erythromelalgia in 5% of the patients. None of the hemorrhagic episodes were life threatening.[56] In this series, young patients enjoyed a low incidence of life-threatening complications and a favorable long-term prognosis, findings confirmed by other large series.[56,129,134,194] However, in another study of 44 patients younger than the age of 45, serious thrombotic or hemorrhagic complications occurred in 23% of patients and 4% died as a consequence of thrombotic events.[130] Carobbio and coworkers have shown that an association between leukocytosis and the development of additional thrombotic events was most evident in such untreated low risk ET patients.[166]

In a retrospective study Cortelazzo and colleagues demonstrated that patients older than 60 years of age who had a previous thrombotic event had a major risk of developing additional thrombotic events.[127] By contrast, the incidence of thrombotic and hemorrhagic complications in asymptomatic patients with ET less than 60 years of age who had a platelet count of less than 1500×10^9/L has been shown to be comparable with a normal control population.[194] Ruggeri and associates have emphasized the importance of the concurrent absence of both of the formerly mentioned clinical characteristics to define a low-risk profile in young patients with ET.[194] Gender and smoking have been shown to be independent risk factors for developing arterial thrombotic complications in ET. Men have a significantly higher risk of such complications and smoking increases markedly the risk of arterial thrombosis in women but not men.[193] Investigators continue to search for other acquired or congenital defects of hemostatic mechanisms, such as the factor V Leiden mutation, prothrombin G 20210A gene mutation, and so on, to better understand why many patients remain asymptomatic, whereas others experience a serious thrombosis. Screening of patients for such thrombophilic states may identify patients at an even higher risk for both arterial or venous thrombotic events.[11,197]

The identification of the Jak2V617F mutation in about 50% of patients with ET raised the question of whether patients with or without the mutation differ in terms of thrombotic risk.[107–110] In a large study of 806 patients, Campbell and coworkers suggested that the Jak2 mutation was associated with a high risk of developing venous but not arterial thrombotic events.[110] An increased risk of thrombosis in Jak2 mutated patients with ET has also been reported by other investigators.[109,198] However, the rate of vascular complications was reported not to be affected by the presence of the mutation in two other relatively large studies, including 150 and 130 patients, respectively.[108,117] Regardless, it is conceivable that the significantly higher age distribution, hematocrit and leukocyte levels in mutation-positive patients might contribute to the apparent association between Jak2V617F and thrombosis reported in some studies.[108–110,117,198] Vannucchi et al have reported that the rare ET patients with a high Jak2V617F burden are at a particularly higher risk of developing cardiovascular events.[114]

Pregnancy is not contraindicated in patients with ET. The outcome of pregnancy in patients with ET has recently been the subject of intense investigation.[199–209] In a systematic review of the literature, Barbui and coworkers pooled data from 461 pregnancies reported by retrospective and prospective cohort studies.[209] The rate of spontaneous abortions was 44%, which is approximately twofold higher than in the general population. Loss of the fetus late in the pregnancy was also more common in ET than in normals (5%–9.6%

versus 0.5%). Placental infarction was reported in 18 cases: which was often responsible for intrauterine fetal growth retardation (11 cases). Abruptio placenta was reported in 9 cases (3.6%), a rate which is higher than that observed in the general population (1%). Postpartum thrombotic episodes were reported in 13 patients, occurring in 5.2% of the pregnancies.[209] This rate is higher than in the overall population of pregnant women.[210] The average platelet count at the beginning of pregnancy in patients with successful pregnancies was $1{,}010 \times 10^9$/L, and it was 977×10^9/L among those with an unsuccessful outcome; thus, the baseline platelet count was not predictive of pregnancy outcome. ET patients with the Jak2V617F mutation have been reported to be at a higher risk of developing complications with pregnancy.[211] During the second trimester, a spontaneous decline in platelet counts was reported, reaching a nadir of 599×10^9/L.[209] This decrease in platelet counts seems larger than the reduction observed in normal pregnancies, which is attributed to an increase in plasma volume. The mechanism for this reduction in platelet numbers is not known, but could involve placental or fetal production of a factor that downregulates platelet production. In the postpartum period the platelet counts are elevated to their earlier levels and rebound thrombocytosis may occur in some patients. This increases the probability of vascular complications during this period of high thrombotic risk to a level similar to that observed in other conditions of thrombophilia.

In the large majority of cases, the fetal losses in pregnant ET women occur during the first trimester.[201–208] In one series, 65% of the miscarriages occurred in 17% of women.[202] Thus, a previous history of spontaneous abortion may be the greatest risk factor for the development of subsequent spontaneous abortions.[201–208] Excessive bleeding during delivery appeared to be an extremely rare event.[199–209] Maternal complications are rare. Minor thromboses usually occur in the post-partum period, but such major events as deep venous thrombosis, transient ischemic attacks and superior sagittal sinus thrombosis have been reported. Hemorrhage is usually minor and occurs in 4% to 9% of cases. Major hemorrhagic episodes are restricted to patients with acute von Willebrand syndrome.

Physical examination is relatively unremarkable in patients with ET. Most patients are not severely ill at diagnosis, a median Karnofsky score of 90% being reported in one series.[1–20] Splenomegaly is detectable in 40% to 50% of patients, and approximately 20% have hepatomegaly.[1–20] During the course of the disorder, a further increase in the degree of hepatosplenomegaly is reported to not typically occur, but it may be observed.[1–20]

LABORATORY EVALUATION

The hallmark of ET is a sustained and unexplained elevation of the platelet count ($\geq 450 \times 10^9$/L). The level of thrombocytosis required for the diagnosis is arbitrarily determined; the range being 450 to greater than 1000×10^9/L, depending on the series cited (Table 71–3).[1–20,212–214] Table 71–3 lists the laboratory findings reported in one large series of patients with typical ET.[13] Accompanying leukocytosis was a common finding in this series, as in others reported in the literature.[1–20] A leukoerythroblastic blood picture, as well as teardrop-shaped red blood cells are not features of ET.[1–20,212] Mild eosinophilia (>400/mm^3) and basophilia (>100/mm^3) have been reported in more than one third of patients.[7,8]

The most common morphologic abnormalities are variations in red blood cell size and shape and the presence of megathrombocytes (see Fig. 71–3).[1–20] Enlargement of megakaryocytes with hyperlobulated nuclei and their tendency to cluster in small groups along sinuses are the hallmarks of ET.[212,215] The megakaryocytes are characterized by abundant, mature, cytoplasm and hyperlobulated nuclei with smooth nuclear contours (see Fig. 71–3). Granulopoiesis and erythropoiesis are not remarkable except for increased cell numbers. Reticulin content was increased in 25% of patients, but collagen fibrosis was not evident.[7,12] Significant reticulin fibrosis or any collagen fibrosis argues against a diagnosis of ET.[212] In 70% to 80% of patients, iron stores were present in the marrow, albeit at reduced levels.[213] Almost all patients have normal serum ferritin levels.[215] Cervantes and colleagues[218] have suggested that the absence of iron stores in 30% of patients may merely be an epiphenomenon of a chronic MPD, and not truly reflective of an iron deficiency state. By contrast patients with a prefibrotic form of PMF have marrows with dense clusters of megakaryocytes with maturation defects and bulbous nuclei. Bleeding times are prolonged in 10% to 20% of patients.[13,128] Platelet aggregation studies are frequently abnormal, most often demonstrating impaired aggregation in response to epinephrine, ADP, and collagen but not to arachidonic acid and ristocetin.[128] Spontaneous platelet aggregation has been reported to occur frequently in such patients, but this has not been a universal finding.[128]

Approximately 25% of patients with ET have been reported to have elevated uric acid levels at diagnosis.[10,12,14] The average value of the serum potassium at diagnosis is usually within the normal range, although 23% of patients have been reported to have pseudohyperkalemia and falsely elevated phosphorus concentrations.[219] The laboratory features of acquired von Willebrand syndrome associated with an excessively high platelet count and a bleeding tendency have been previously described in detail.[143] This syndrome in patients with ET is associated almost uniformly with a platelet count greater than 1500×10^9/L, a prolonged bleeding time, a normal factor VIII coagulant activity, and a von Willebrand antigen level but a decreased von Willebrand factor-ristocetin cofactor activity and collagen binding activity, as well as a decrease or absence of large von Willebrand factor multimers simulating a type II von Willebrand disorder.[140–143] The enhanced thrombotic risk of ET patients has been associated with a reduction in the concentration of one of the natural anticoagulants including protein S, antithrombin III protein C, and resistance to activated protein C.[197,220] These studies indicate that such a genetic deficiency of one of the natural anticoagulants might further contribute to the thrombotic tendency of patients with ET. Pseudohypoxemia has also been observed in ET patients with extreme degrees of

Data from Bellucci S, Janvier M, Tobelem G, et al: Essential thrombocythemias: Clinical, evolutionary and biological data. Cancer 58:2440, 1986.

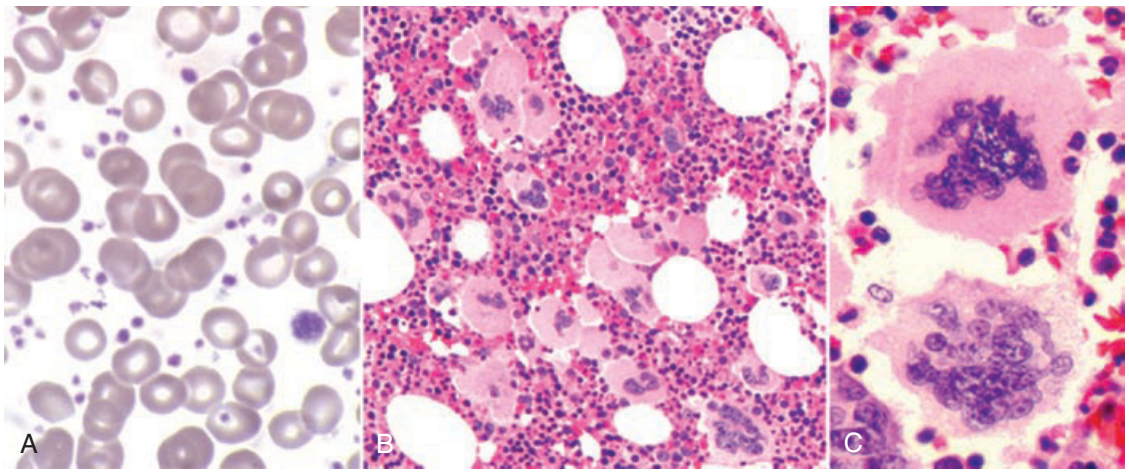

Figure 71–3. Essential thrombocythemia: peripheral blood smear and bone marrow biopsy (**A-C**). The peripheral blood smear in ET shows a marked thrombocytosis with anisocytosis (varying sizes) of the platelets (**A**). The bone marrow (**B**) is hypercellular and exhibits a marked proliferation of large and giant megakaryocytes in loose clusters with other hematopoietic elements in the background. The large megakaryocytes (**C**) tend to be extensively lobulated.

thrombocytosis.[221] The serum B_{12} level can be increased in 25% of cases.[7,12,13]

In ET, marrow karyotypes are characteristically normal.[7–14,222,223] The absence of the Philadelphia chromosome and the BCR/ABL rearrangement excludes the diagnosis of chronic myeloid leukemia (CML).[224–227] The Philadelphia chromosome or the BCR/ABL rearrangement that is seen in patients with CML must be searched for in patients who present with a high platelet count due to the observation that thrombocytosis may be the initial laboratory abnormality in patients with CML.[228] Because the prognosis and management for ET and CML are very different, it is important to rule out chronic myeloid leukemia as the cause of the elevation in platelet numbers. Aneuploidy is seen in the minority of cases. In fact, analysis of 170 cases of ET revealed a definite chromosomal abnormality in only 5.3% of cases. Marker chromosomal abnormalities, such as $1q^+$, $20q^+$, $21q^+$, or $1q^+$, have been reported, but no consistent chromosomal abnormality has been identified.[222,230–233] As has been previously mentioned, approximately 50% of ET patients are Jak2V617F positive with only 4% having a high allele burden.[114] Approximately 1% of patients have the activating MPL mutations.[105]

DIFFERENTIAL DIAGNOSIS

In the pre-Jak2V617F era, the diagnosis of ET was one of exclusion. The discovery of Jak2V617F has provided a definitive diagnostic tool with which to diagnose ET. This mutation, however, can be found only in about half of the patients and the technology required to detect it is based on the polymerase chain reaction (PCR) assays.[234] Hence, it is reasonable to consider Jak2V617F analysis for the evaluation of patients with otherwise unexplained thrombocytosis in order to streamline further investigations. Accordingly, a positive test indicates an underlying MPD. However, further investigations, including a bone marrow biopsy (Table 71–4) and cytogenetic analysis, are still required to differentiate ET from the other chronic MPD as well as from myelodysplastic syndromes presenting with thrombocytosis, such as the 5q– syndrome and refractory anemia with ringed sideroblasts associated with thrombocytosis (RARS-T) (Table 71–5) and prefibrotic forms of PMF.[235–239]

For those patients who present with thrombocytosis and are Jak2 negative, the first step in determining the cause of thrombocytosis is to exclude reactive forms of thrombocytosis. The causes of secondary or reactive forms of thrombocytosis are numerous. In a hospital population, patients with extreme thrombocytosis (>1000 × 10^9/L) are not particularly rare in adult or pediatric patient populations.[38,39,236,240–243] Examination of the blood smear is important to avoid confusion with so-called pseudothrombocytosis. This occurs in a number of conditions in which platelet-sized particles that are red or white cell fragments (CLL, TTP, Hgb-H disease, and microspherocytosis) are erroneously enumerated as platelets by automatic particle counters.[243] Confirmation of increased numbers of platelets by examination of the peripheral smear will avoid misdiagnosis and unnecessary clinical evaluation.

Table 71–4. Bone Marrow Biopsy Findings in Essential Thrombocythemia

Data from Iland HJ, Laszlo J, Peterson P, et al: Essential thrombocythemia: Clinical and laboratory characteristics at presentation. Trans Assoc Am Physicians 96:165, 1983.

In one series of 280 patients with extreme thrombocytosis encountered over a 5-year period at a university hospital, reactive thrombocytosis accounted for 82% of cases of extreme thrombocytosis, whereas thrombocytosis due to an MPD accounted for only 14% of cases.[241] In fact, of the patients with MPD, ET accounted for only 29% of the cases. Reactive thrombocytosis was more common in all age groups except those in the eighth decade and older. The causes of extreme thrombocytosis outlined in this series are listed in Table 71–5.[241] Importantly, in this series, the mean peak platelet counts for patients with reactive thrombocytosis (1195 × 10^9/L) was significantly lower than those of patients with thrombocytosis secondary to an MPD (1,808 × 10^9/L).[241] This shows, however, that a significant number of patients with reactive thrombocytosis have platelet counts greater than 1000 × 10^9/L and that it is impossible to distinguish between reactive thrombocytosis and thrombocytosis caused by an MPD, based solely on the degree of thrombocytosis.[31,39,236,240–243] Thrombotic and hemorrhagic events infrequently occur in patients with reactive thrombocytosis.[31,39,236,240–243] These findings are in contrast to the enhanced risk of these two complications in patients with ET. This relatively high frequency of extreme thrombocytosis in an acute care hospital emphasizes the need for caution in making a

Table 71–5. Etiologic Conditions Associated with Extreme Thrombocytosis

BM, bone marrow; ET, essential thrombocythemia; RT, reactive thrombocytosis.

Modified from Tefferi A, Hoagland HC: Issues in the diagnosis and management of primary thrombocythemia. Mayo Clin Proc 69:651, 1994.

Table 71–7. Proposed Revised WHO Criteria for Essential Thrombocythemia (ET)

1. Sustained platelet count ≥450 × 10^9/L*
2. Bone marrow biopsy specimen showing proliferation mainly of the megakaryocytic lineage with increased numbers of enlarged, mature megakaryocytes; no significant increase or left-shift of neutrophil granulopoiesis or erythropoiesis
3. Not meeting WHO criteria for PV†, PMF‡, CML§, MDS¶, or other myeloid neoplasm
4. Demonstration of Jak2V617F or other clonal marker, or in the absence of a clonal marker, no evidence for reactive thrombocytosis

Diagnosis requires meeting all 4 criteria.

During the work-up period.

††Requires the failure of iron replacement therapy to increase hemoglobin level to the PV range in the presence of decreased serum ferritin. Exclusion of PV is based on hemoglobin and hematocrit levels, and red cell mass measurement is not required.

‡Requires the absence of relevant reticulin fibrosis, collagen fibrosis, peripheral blood leukoerythroblastosis, or markedly hypercellular marrow for age accompanied by megakaryocyte morphology that is typical for PMF—small to large with an aberrant nuclear/cytoplasmic ratio and hyperchromatic, bulbous or irregularly folded nuclei and dense clustering.

§Requires the absence of *BCR-ABL*.

¶Requires absence of dyserythropoiesis and dysgranulopoiesis.

‖Causes of reactive thrombocytosis include iron deficiency, splenectomy, surgery, infection, inflammation, connective tissue disease, metastatic cancer, and lymphoproliferative disorders. However, the presence of a condition associated with reactive thrombocytosis does not exclude the possibility of ET if the first three criteria are met.

From: Tefferi A, Thiele J, Orazi A, et al: Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. Blood 110:1092, 2007.

diagnosis ET. A number of groups have shown that reactive thrombocytosis may be a consequence of the elaboration of known cytokines in response to the underlying inflammatory or neoplastic disorder.[244–250] Elevated levels of IL-1, IL-6, GM-CSF, G-CSF, and thrombopoietin have been detected in such patient populations and not infrequently in individuals with thrombocytosis caused by an underlying MPD.[97,98,250–252] Elevation of thrombopoietin levels has not only been found in patients with reactive thrombocytosis but also in patients with ET.[98] IL-6-induced thrombocytosis is mediated in part by secondary thrombopoietin production by the liver in inflammatory disorders and malignant diseases.[247,252] Thus, as opposed to the determination of the erythropoietin levels in patients with erythrocytosis being helpful to differentiate primary from secondary causes, the level of thrombopoietin cannot be used to differentiate ET from secondary causes of thrombocytosis.[98] C-reactive protein is an acute phase reactant, the hepatic synthesis of which is mediated by IL-6.[244] C-reactive protein levels are high in patients with high levels of IL-6.[244] In one series, 81% of patients with reactive thrombocytosis had elevated IL-6 or C-reactive protein levels, whereas patients with uncomplicated thrombocytosis secondary to an MPD had undetectable IL-6 levels.[244] Low levels of both IL-6 and C-reactive protein are strongly indicative of the thrombocytosis being the consequence of an underlying MPD.[244]

A number of investigators have constructed lists of diagnostic criteria useful in identifying individuals with ET.[7,13,45,46,253–258] No such list is infallible. Table 71–6 list useful tests in distinguishing reactive thrombocytosis from ET. Table 71–7 outlines the recently updated WHO criteria for the diagnosis of ET which incorporates Jak2V7617F testing.[259] Although useful in diagnosing adults with ET, the utility of these criteria in diagnosing children with ET has recently been questioned.[260] Red cell mass and plasma volume studies are sometimes necessary to differentiate ET from PV. In males with thrombocytosis and a hematocrit of less than 60% or in a female with a hematocrit of less than 55%, it has been suggested that such studies be performed.[261] Hematocrit values greater than these are associated with an elevated red cell mass, and radioisotope studies are unnecessary to document the presence of an elevated red cell mass.[261] Bone marrow karyotypic analysis or studies for the *BCR-ABL* fusion gene are imperative in every patient to exclude the diagnosis of CML[224–227] or to detect another clonal hematological malignancy.[223] This step is necessary because the natural history of these disorders is very different and early therapeutic intervention with specific medical therapy for CML, such as with imatinib, dasatinib, nilotinib, or stem cell

transplantation for appropriate patients is potentially curative.[225,262] In one series, six women presented with the clinical picture of ET without anemia, marked splenomegaly, or extreme leukocytosis characteristic of CML.[225] Each of these patients was shown to have a Philadelphia chromosome on karyotypic analysis, and five of the six entered the accelerated phase or blast crisis within 5 to 7 years of diagnosis.[225]

A highly instructive case was reported by Morris and colleagues.[224] The patient was a 23-year-old woman who presented with a syndrome indistinguishable from ET.[224] Although no Philadelphia chromosome was detected, the patient did develop blast crisis after 4 years of follow-up. By Southern blot analysis, she was shown to have the *BCR-ABL* fusion gene, suggesting that she actually suffered from CML and not from ET.[224] This case emphasizes the importance of molecular studies when evaluating patients suspected of having ET.[224]

Occasionally, ET might be distinguished from acquired sideroblastic anemia associated with thrombocytosis, which has been recognized by the WHO classification of hematologic malignancies.[212,263] These patients present with thrombocytosis that is associated with a moderate-to-severe anemia and frequently splenomegaly. Their marrows are characterized by the morphologic features of ET and the presence of more than 15% ringed sideroblasts.[212,263] This entity likely represents a heterogeneous, poorly defined disorder that includes a spectrum of conditions sharing features of MPD and myelodysplastic disorders. Interestingly, most patients (6 of 9 patients) with acquired sideroblastic anemia associated with thrombocytosis (RARS-T) carry the Jak2V617F mutation.[237–239] In addition, ET clearly needs to be distinguished from the prefibrotic phase of PMF.[212] In the prefibrotic phase of PMF, nucleated red blood cells, teardrop-shaped red cells, immature myeloid cells, and megathrombocytes are observed in the peripheral blood.[212,264,265] In the marrow biopsy the megakaryocytes are markedly abnormal, a morphologic finding that is helpful in distinguishing this entity from ET. In prefibrotic PMF, the megakaryocytes often appear in clusters adjacent to the sinusoids; deviations in the nuclear cytoplasmic ratio in the megakaryocytes are observed with abnormal patterns of chromatin clumping and plump cloud like balloon shaped lobulation of the nuclei are observed associated with minimal fibrosis or even absent reticulin fibrosis during this stage of PMF.[212,263,264]

The presence of clonal hematopoiesis, at least in one lineage, quickly establishes the diagnosis of ET.[11,24–31] Unfortunately, techniques to study clonality are currently not widely available and are restricted to the evaluation of females. Such studies may be particularly useful in young females with thrombocytosis, Probes for a variety of genes on the X chromosome can be informative for clonal analysis of blood cell production in greater than 72% of American females.[28,31] In such patients, analysis of restriction fragment length polymorphisms can be used to establish a pattern of clonal hematopoiesis, which is indicative of a hematologic malignancy and establishes the diagnosis of ET in a young female with thrombocytosis who is Jak2V617F negative.[27] Polyclonal hematopoiesis is found in all cases of reactive thrombocytosis. Polyclonal hematopoiesis, however, does not exclude the diagnosis of ET because in several series, almost one third of patients who met the clinical criteria for ET had polyclonal hematopoiesis in all studied lineages.[28–31] The biogenesis of this polyclonal form of ET is poorly understood. Initial studies, however, have suggested that women with polyclonal hematopoiesis my have fewer thrombotic complications than those with clonal hematopoiesis.[29,30] Further follow-up will be required to confirm these observations.

A number of diagnostic tests, including splenic volume estimates using ultrasound evaluations and assays of bone marrow progenitor cells (erythroid or megakaryocyte), have been suggested as useful means of differentiating reactive thrombocytosis from ET.[11,82,85,91,266] Insufficient numbers of patients, as well as a lack of long-term follow-up, make it impossible to assess the clinical value of such tests. Studies such as PRV-1 gene overexpression in leukocytes, or decreased expression of platelet MPL are not useful in aiding clinicians in differentiating ET from other MPDs.[103] As outlined above, the most important step in improving the diagnosis of ET has been the identification of the Jak2V617F mutation in about 50% of patients with ET.[32–37] The current availability of this relatively simple molecular test makes it easier to establish the diagnosis of a ET, although the utility of the test is limited by suboptimal negative predictive value and lack of diagnostic specificity.

As has been previously discussed, the lack of quality control in many laboratories in the performance of clonal assays for hematopoietic progenitor cells is of concern and limits the usefulness of such information gained by their performance.[77–86] The presence of endogenous erythroid colonies or megakaryocyte progenitors with increased sensitivity to hematopoietic growth factors is, however, helpful in distinguishing reactive thrombocytosis from thrombocytosis due to an MPD.[77–82] Such assays are of limited use in distinguishing ET from the other MPD.[82]

At times it is impossible to define the cause of an individual patient's thrombocytosis. In an asymptomatic patient, the resolution of this problem is easy: one should simply provide follow-up and determine whether the degree of thrombocytosis increases. If additional clues to the cause of the thrombocytosis are subsequently revealed, a diagnosis will become apparent. In a patient with thrombohemorrhagic difficulties, one must make a presumptive diagnosis of the cause of the thrombocytosis and then, after weighing the benefits versus the risks of various treatment plans, determine whether reduction of platelet numbers or simple observation is indicated. Some reassurance is provided by the report of Schilling, who followed a large cohort of patients, each with platelet counts of greater than 1000×10^9/L, for 18 months. None of the patients with reactive thrombocytosis developed a cerebrovascular accident, thrombophlebitis, or peripheral arterial thrombosis.[236] These findings are consistent with the conclusions of Buss and coworkers that thrombohemorrhagic complications are rare in patients with secondary thrombocytosis.[138,241]

THERAPY

The challenge in treating patients with ET is to prevent thrombotic and hemorrhagic events without increasing the risk of transformation to post-ET MF and/or acute myeloid leukemia. Both age (>60 years of age) and a history of a previous thrombosis are predictors of a patient developing additional thrombotic events during follow-up (Table 71–8).[267] Other predictors of cardiovascular morbidity include a history of smoking, diabetes mellitus and congestive heart failure.[267] The use of these parameters have allowed investigators to stratify ET patients according to their risk to develop additional thrombotic events (Table 71–9).[267]

The treatment of asymptomatic low risk patients with ET is controversial and remains largely problematic, yet greater insight into the

Table 71–8. Risk Factors for Thrombosis in 100 Patients with Essential Thrombocythemia

Risk Factor	Incidence of Thrombosis (% Pt-Yr)	Relative Risk (95% Confidence Interval)	*P*

Risk Category	Age >60 Years Or History Of Thrombosis	Cardiovascular Risk Factors
Low	NO	NO
Intermediate	NO	YES
High	YES	

Cardiovascular risk factors: hypertension, hypercholesterolemia, diabetes, smoking, congestive heart failure. Extreme thrombocytosis (platelet count >1500×10⁹/L) is a risk factor for bleeding. Its role as a risk factor for thrombosis in ET is uncertain.

Data from: Finazzi G, Barbui T. Risk-adapted therapy in essential thrombocythemia and polycythemia vera. Blood Rev 19:243, 2005.

management of such patients has recently been gained.[9–20,46,131,194,209,254] Management of ET patients with life-threatening hemorrhagic or thrombotic episodes is more straightforward. One approach is platelet pheresis in combination with the institution of myelosuppressive therapy.[268–272] Rapid platelet pheresis using continuous or discontinuous flow centrifugation devices has proved effective in preventing additional morbidity in patients with ET in the setting of a potential life-threatening thrombotic event.[268–272] In this situation, immediate physical removal of large numbers of platelets is preferred. Because chemotherapeutic agents generally require 18 to 20 days before platelet counts can be reduced to normal levels, Taft and colleagues[268] have recommended reducing the platelet count to 500,000/mm^3 by each platelet pheresis and suggest that achievement of such a goal requires the passage of two blood volumes over a 3-hour to 4-hour period.

Such a therapeutic approach has been employed to treat acutely ill patients with problems, such as cerebrovascular accidents, myocardial infarction, transient ischemic attacks, or life-threatening gastrointestinal hemorrhage.[268–272] Long-term platelet pheresis has proved an ineffective means of controlling thrombocytosis, presumably because of the rapid rate of production of platelets.[269] Therefore, most clinicians begin by administering a chemotherapeutic agent that has a rapid onset of action, such as hydroxyurea, simultaneously with the institution of platelet pheresis.[271]

In those patients found to have ET and who are clearly symptomatic and fall into the high risk group, little controversy exists as to the need for lowering the platelet number. The large number of thrombotic complications that occur in patients with ET who smoke, points to the urgent need for these patients to stop smoking immediately.[132,193] Most investigators try to normalize the platelet count or to reach a platelet count at which the symptoms of the high-risk patient resolve. Although major bleeding episodes requiring hospitalization are rare, those patients with extreme thrombocytosis (>1500 × 10^9/L), acquired von Willebrand syndrome, and history of hemorrhagic episode are clearly at risk for developing additional bleeding complications.[140–145] These patients require reduction of the increased platelet numbers to the normal range with use of a variety of agents, including hydroxyurea, anagrelide, or interferon-α. According to some authors, such patients should avoid exposure to aspirin, even if they are suffering hemorrhagic complications and thrombotic episodes simultaneously.[140–145] Thrombotic complications are more frequent, especially when thrombocytosis is less marked, and are the major causes of morbidity and mortality. Symptoms of functional ischemia are the most common clinical presentation, although the majority of patients are asymptomatic at diagnosis (Table 71–1).[1–20,47,127] Many investigators have attempted to identify factors associated with an increased risk of thrombotic complications.[1–20,47,127,197,266] Patients older than 60 years of age or with a history of a vascular occlusive episode have a significantly greater risk of developing additional thrombotic episodes.[90] Such patients define a high-risk population who merit therapeutic intervention (Table 71–9).[127] Cortelazzo and associates, in a randomized trial of high-risk patients, reported that cytoreductive therapy with hydroxyurea which reduced the platelet count to 600 × 10^9/L was effective in preventing additional thrombotic episodes in high-risk patients.[139] The use of anagrelide, with good control of the platelet numbers, has also been shown to minimize thrombotic complications.[273] The target platelet count to be achieved with any of these therapeutic interventions to avoid additional thrombotic events has not been well established.

Another situation that requires treatment is discomfort due to erythromelalgia or progression of erythromelalgia to frank gangrene.[126] Such patients respond within days to low-dose aspirin therapy or platelet reduction therapy.[126]

The therapeutic strategy to be employed with asymptomatic patients younger than 60 years of age remains controversial.[10,11,131,194,254] The risk of the development of thrombotic events, the leukemogenic potential of chemotherapeutic agents used to treat thrombocytosis, and the ability of cytoreductive therapy or a platelet antiaggregating therapy to reduce the incidence of thrombotic events must be considered before embarking on treatment of an asymptomatic younger (<60 years) patient with ET.[194] The Italian treatment guidelines do not recommend the use of chemotherapeutic drugs in these patients.[209]

In the past, groups of ET patients have been successfully treated with a variety of chemotherapeutic agents, including busulfan, melphalan, chlorambucil, pipobroman, thiotepa, radioactive phosphorus P^{32}, hydroxyurea, nitrogen mustard, uracil mustard, and CCNU (lomustine).[1–7,38,39,45,46,274–285] Many of these agents have been used to treat a variety of MPD and solid tumors, and their use has been associated with an increased risk of developing leukemia.[46,222,274–285] Very few phase III studies comparing the efficacy of such agents for the treatment of ET in high-risk patients have been completed.[139,286] In a study of a small group of patients, the response to either melphalan or radioactive phosphorus therapy was studied during the first year of therapy.[277] The only conclusion that could be drawn from this study was that the time to response as defined by platelet count reduction was considerably shorter for patients receiving melphalan than for those receiving radioactive phosphorus.[277] Intermittent use of busulfan (4 mg/day, until the platelet count fell to 400,000/mm^3, followed by a series of 2-week courses when the platelet count rose to >400,000/mm^3) has proved to be another relatively nontoxic and effective regimen.[274,283] These conclusions were based on a lengthy examination of the courses of 37 patients.[274,280]

During the 1980s and 1990s, hydroxyurea became the drug of choice for the treatment of ET.[46,99,139,280,285–289] The impetus for this practice was based on the capacity of ^{32}P and alkylating agents such as melphalan and busulfan to induce acute leukemia.[46] The popularity of the ribonucleoside reductase inhibitor, hydroxyurea, for the management of ET was due to the belief in the early 1970s that it was nonleukemogenic.[46,282] Hydroxyurea can be administered at a dose of 15 mg/kg initially, with adjustment of the dose to maintain a platelet count (at the least) below 600 × 10^9/L[46] without inducing significant neutropenia. Once the agent is started, frequent monitoring of blood counts is mandatory to avoid the development of neutropenia, and until the maintenance dose is determined.[139,285] The use of this drug in a high-risk group of patients with reduction of platelet numbers to less than 600 × 10^9/L has resulted in reduction of thrombotic events when compared with a control population.[139] The reduction of platelet numbers to this level did not entirely eliminate the occurrence of additional thrombotic episodes. One center has suggested that platelet reduction to less than 400 × 10^9/L might be needed to minimize the residual risk of thrombosis during therapy.[290] These findings require confirmation in a large, well-controlled randomized clinical trial.

Hydroxyurea use is associated with some toxicity, including dose-related neutropenia, nausea, stomatitis, hair loss, nail discoloration, and lower extremity and oral ulcerations.[284,285,289] Each of these problems resolves with withdrawal of the drug or dose reduction. Hydroxyurea is also not universally successful in controlling the thrombocytosis. Resistance to hydroxyurea has been reported in 11% to 17% of cases.[285] The criteria for defining resistance or intolerance to hydroxyurea have been recently established by an International Working Group.[291] They include: platelet count greater than 600 × 10^9/L after

Table 71–10. Effects of Essential Thrombocythemia Treatment Options on the Development of Acute Leukemia

*$P < 0.006$ (Fisher exact test) for B, C, E, versus D.
AA, alkylating agent; HU, hydroxyurea.
Data from Murphy S, Peterson P, Iland H, Laszlo J: Experience of the Polycythemia Vera Study Group with essential thrombocythemia: A final report on diagnostic criteria, survival and leukemic transition by treatment. Semin Hematol 34:29, 1997.

three months of at least two g/day of HU (2.5 g/day in patients with a body weight >80 kg); platelet count greater than 400×10^9/L and WBC less than 2,500/mm^3 or hemoglobin less than 10 g/dL at any dose of HU; presence of leg ulcers or other unacceptable mucocutaneous manifestations at any dose of HU; HU-related fever. In such situations, hydroxyurea can be substituted for (or combined with) other platelet-lowering agents, such as anagrelide or interferon-α.[291]

The risk of evolving to acute leukemia is extremely low in untreated ET patients.[1–20,44,46,292] Unfortunately, hydroxyurea has not been proved to be entirely nonleukemogenic.[280,285–289,292,293] In fact, some of the strongest evidence for the leukemogenic potential for hydroxyurea has been provided by the PV Study Group, which had previously been an advocate of hydroxyurea therapy for the treatment of ET.[44,46] A cohort of 29 patients with ET were treated with hydroxyurea between 1977 and 1982.[46] These patients met the diagnostic criteria for this disorder as established by this cooperative group.[44,46] Although five patients were lost to follow-up, the median follow-up time for the remaining patients was 7.3 years (Table 71–10). Disturbingly, 6 of the 24 patients developed acute leukemia. One patient developed acute leukemia 2.4 years after treatment, whereas other cases occurred after 6.7 to 9.7 years of follow-up. One of these patients was treated with hydroxyurea alone, whereas five others were switched from hydroxyurea to either P^{32} or an alkylating agent.[46] Another group of 62 patients was treated by this group initially with P^{32} or melphalan. Of these patients, 21 were later switched to hydroxyurea therapy. After the analysis of patients in all of these groups, the predicted probability of developing acute leukemia was determined to be 21.6% at 10 years with the greatest likelihood being between 5 and 10 years after diagnosis.[46] With careful analysis of this data, the subgroup of patients who were initially treated with hydroxyurea, but subsequently switched to an alkylating agent or p^{32} had a high incidence of acute leukemia (Table 71–10).[34,46] By contrast, those patients initially treated with P^{32} or melphalan, whether or not they were eventually treated with hydroxyurea, had a lower incidence of leukemia (Table 71–10).[34,46] More recent, prospective studies both in ET and PV have confirmed that hydroxyurea therapy was associated with a very low incidence of leukemic transformation when used alone (lower than 5%), with long-term follow-up (up to 14 years). However, the leukemic risk increased significantly when the drug was used before or after treatment with alkylating agents, particularly busulphan.[294–296] One can conclude from these studies and those of others that hydroxyurea therapy alone is less leukemogenic than alkylating agents or P^{32} alone but that some enhanced risk for the development of leukemia secondary to its use can not be completely excluded.[44,46,280,284,288,292] In those patients who cannot tolerate hydroxyurea or who cannot be controlled with its continued use, according to the consensus criteria cited above,[291] anagrelide or interferon-a therapy appears to be an alternate choice.[1–20] Recently, data on the use of anagrelide in ET suggest that it is nonleukemogenic when used in patients with ET; however, further follow-up will be required to confirm this initial observation.[297] When considering the risk-benefit ratio, one can conclude that hydroxyurea therapy is first-line therapy for ET patients at a high risk of developing an additional thrombosis, including those older than 60 years of age or with a history of a thrombotic episode or with significant other cardiovascular risk factors.[139,286,298] Such nonleukemogenic drugs as interferon-α, anagrelide, or pegylated interferon, appear to be good choices in symptomatic patients younger than 40 years of age.[209,291–310] A high proportion of the acute myeloid leukemias and myelodysplastic disorders occurring in ET patients treated with hydroxyurea alone have morphologic, cytogenetic, and molecular characteristics of the 17p deletion syndrome.[223,288] These patients are reported to have a typical form of dysgranulopoiesis characterized by hypolobulated polymorphonuclear leukocytes with small vacuoles in polys, and p53 mutations.[284,288]

Interferon-a has been employed to treat the thrombocytosis associated with MPD with increasing frequency since the 1990s.[299–310] Interferon-α acts by directly inhibiting megakaryocyte colony formation and secondarily by inhibiting the expression of thrombopoietic stimulating cytokines, such as GM-CSF, G-CSF, IL-3, and IL-11 and by stimulating the production of negative regulators of megakaryocytopoiesis, such as IL-1ra (receptor agonist) and MIP-1a.[311] Interferon-a ?inhibits thrombopoiesis by suppressing thrombopoietin-induced phosphorylation of the Jak2 substrates, Mpl and STAT5.[244] Furthermore, interferon-α also induces the production of suppressor of cytokine signalling-1 (SOCS-1), which inhibits thrombopoietin-mediated cell proliferation.[312] In a total of 212 patients treated with interferon-α in a total of 11 different clinical trials, a response rate of approximately 90% has been reported.[306] Therapy was administered to outpatients, most frequently at an initial dose of 3 million units daily, and usually produced a rapid decrease in platelets within 2 months.[306] The mean time to complete response with a daily dose of 3 million units daily was about 3 months.[306] Interferon-α was effective in patients who had received other chemotherapeutic agents and in patients resistant to conventional cytotoxic drugs.[299–310] In the majority of patients, the interferon dose required to maintain a normal platelet count during maintenance therapy was lower than the induction dose.[299–310] In one study, 61% of patients required 3 million units 3 times a week, 15% once a week, and 24% daily.[306] In addition, sustained remissions that persisted for 3 to 36 months were achieved with interferon-α therapy in 9% to 16% of patients. Interferon-α is reported to be nonmutagenic and to not cross the placenta, making it a useful drug for the treatment of the symptomatic pregnant patient with ET.[18,209,299–310] Reduction in platelet numbers with interferon results in a marked improvement in clinical symptoms. Toxicity, especially in older patients, the need for parenteral administration, and cost, limit the usefulness of interferon-α.[299–310] Side effects include flu-like symptoms during induction therapy, such as fever, bone and muscle pain, fatigue, lethargy, and depression. Symptoms are frequently controlled with acetaminophen.[299–310] Long-term administration of interferon-α can result in mild weight loss, alopecia, and late development of autoimmune conditions, including thyroiditis leading to hypothyroidism and autoimmune hemolytic anemia.[299–310] Patients may develop neutralizing antibodies to recombinant interferon, leading to a concomitant rise in platelet numbers.[313] In such a situation, use of leukocyte interferon-a results in an excellent response.[313] In one review, it was reported that 25% of 273 patients failed to continue to receive interferon therapy either because of poor compliance or side effects.[307] To gain a more comprehensive evaluation of the clinical usefulness of interferon-α a prospective clinical trial comparing interferon-α with hydroxyurea in patients with ET is required. Until the results of this trial are available, interferon-α or

anagrelide should be considered as reasonable alternatives to hydroxyurea in a patient younger than 40 years of age who has suffered a previous thrombotic episode.[1–20,209]

Recently a semisynthetic protein polymer conjugate of interferon-α 2b, pegylated interferon (PEG-IFNa2b), which was anticipated to be superior to unmodified interferon as related to its adverse event profile and efficacy has been used to treat ET.[308–310] This formulation of interferon provides prolonged activity which permits once weekly dosing. Normalization of blood counts occurred after a median time of 2 to 3 months; 12% of patients discontinued therapy because of inability to tolerate the drug, and 17% did not achieve normalization of their platelet counts. The majority of side effects were WHO grade 1 or 2, although some had grade 3 toxicity, primarily fatigue and flu-like symptoms.[310] More importantly, no thromboembolic or hemorrhagic complications occurred during the period of treatment, although 12 thrombotic events occurred in 42 patients (24%) in the 24 months prior to the institution of therapy.[310] This form of interferon, however, appears to lead to a similar frequency and severity of side effects during long term use as experienced with conventional interferons. Interestingly, the use of another pegylated form of interferon (peg-IFNa-2a) in patients with PV was able to decrease the percentage of mutated Jak2 allele in 24 of 27 treated patients from a mean of 49% to a mean of 27%.[314] The use of this form of interferon appeared to be associated with less side effects then standard forms of interferon or peg-IFNa-2b. A less pronounced effect on the Jak2 mutational burden has been reported following the administration of peg-IFNa-2b in patients with ET.[315]

The use of platelet anti-aggregating agents remains an important area of investigation. Patients with ET have an increased predisposition to hemorrhage, which is likely potentiated by the use of drugs that affect platelet function.[1–20,126,141–145,290] Transient ischemic attacks and erythromelalgia associated with ET have been reported to respond rapidly to aspirin alone, to aspirin and dipyridamole in combination, or to indomethacin alone.[135,136] In erythromelalgia, symptoms disappear for 2 to 4 days after administration of a single dose of aspirin.[135] Although these agents surely have a role in the treatment of these specific complications, their use should be pursued with extreme caution because of the increased risk of hemorrhage. Kessler and colleagues have, in fact, determined that 32% of bleeding episodes in patients with extreme thrombocytosis and MPD occurred concurrently with the use of antiinflammatory agents.[137] By contrast, Hehlmann and coworkers[14] have reported the treatment of 46 patients with ET with 250 mg/day of aspirin without any bleeding complications.

Aspirin, particularly in lower doses, 81 to 100 mg/day has been shown to be useful in preventing thrombotic episodes in patients with ET.[290] Risk for bleeding associated with aspirin can be minimized if it is administered solely to patients with platelet counts of less than 1000×10^9/L or the absence of a bleeding history.[290] Van Genderen and associates have retrospectively analyzed a group of 57 patients receiving aspirin alone or in combination with a chemotherapeutic agent (Table 71–11).[290] Their data suggest that low-dose aspirin, 100 to 500 mg/day, is not only effective in the treatment of erythromelalgia and transient ischemic attacks but also reduces the recurrence of other thrombotic events in symptomatic patients.[290] Impressively, in this admittedly small population of high-risk patients with a mean follow-up of only 6.2 years, myelosuppressive therapy, plus low-dose aspirin therapy totally eliminated the incidence of thrombotic complications.[290] These findings are encouraging and are supportive of the judicious use of aspirin in patients with a history of a thrombotic episode. Low-dose aspirin therapy must be restricted to patients with a platelet count of less than 1000×10^9/L. The diagnosis of acquired von Willebrand syndrome should be excluded before aspirin use and considered a contraindication to the use of aspirin.[290] A large, randomized trial evaluating benefit and risk of low-dose aspirin (100 mg daily) has been carried out in 518 patients with PV. Treatment with aspirin, as compared with placebo, reduced the risk of non-fatal major thrombosis and death from cardiovascular causes without increasing significantly the incidence of major bleeding.[316] These results are reassuring in terms of benefit/risk ratio of this drug in MPD but their relevance to patients with ET is uncertain. Statin therapy has been proposed to be a useful means of reducing platelet activation in patients with MPD.[317] This strategy has not been evaluated in clinical trials as yet.

Anagrelide, has been hailed as a non leukemogenic treatment of ET.[1–20,297,318–328] Anagrelide is a member of the imidazo (2,1-b)quinazolin-2-1 series of compounds. When studied in humans, it was noted that anagrelide in small doses produced thrombocytopenia. The drug acts primarily by reducing megakaryocyte size and ploidy and decreasing megakaryocyte proliferation. Anagrelide, therefore, appears to lower platelet counts primarily by interfering with the development of megakaryocytes.[329] A major study of 577 patients treated with anagrelide has confirmed its usefulness.[273,297] Anagrelide in low doses was effective in lowering the platelet count in 93% of patients. Most importantly, it was effective, despite resistance to previous therapy. Resistance to anagrelide therapy has not been documented.[297,318–328] The recommended initial dose is 0.5 mg orally two to four times a day. The dose should be increased by 0.5 mg/week to control thrombocythemia.[318–328] The dose of anagrelide should not exceed 10 mg/day or 2 mg/dose.[318–328] Excessive use will result in predictable thrombocytopenia and increase the likelihood of side effects. The median maintenance dose in patients with ET is 2.0 mg/

Table 71–11. Incidence of Thrombotic and Bleeding Complications in 68 Patients with Essential Thrombocythemia who had Long-Term Follow-up According to Treatment Strategy

Treatment	Duration of Follow-up Events/100 (person-years)	Thrombotic Complications Events (*n*)	Events/100 (person-years)	Bleeding Complications Events (*n*)	(person-years)

day administered in divided doses.[322] Data on over 3000 patients with a variety of MPD complicated by extreme thrombocytosis are available.[322] In addition, follow-up of more than 500 patients for more than 5 years had been reported.[297] Anagrelide has been shown to be an effective drug in the treatment of ET resulting in a median time to response of 2.5 to 4 weeks. An effect on platelet numbers is usually noted in 6 to 10 days.[318–328] Anagrelide leads to a reduction in hematocrit in 36% of patients, but it has no effect on white cell numbers.[318–328] In a long-term study of 35 young patients (17–48 years) followed for a median of 10.8 years (range, 7–15.5 years) more than 3 g/dL decrease in hemoglobin level was reported in 8 cases (24%).[330] Most important, the reduction in platelet numbers attributed to anagrelide use has been reported to be associated with a decrease in symptoms attributable to the thrombocythemia.[297] Silverstein reported that anagrelide use in 1700 patients reduced the incidence of thrombohemorrhagic episodes due to thrombocytosis associated with MPD from 0.66 symptoms per patient before therapy to 0.07 symptoms per patient after 28 to 30 months of therapy.[318] However, in the study of Storen and Tefferi, 7 of 35 (20%) young patients given anagrelide for more than 7 years experienced a total of 10 thrombotic episodes, and a similar proportion experienced major hemorrhagic events.[330]

The most common side effects of anagrelide resulted from its vasodilatory and positive inotropic actions. These effects resulted in complaints of headache, dizziness, fluid retention, palpitations and high output cardiac failure.[318–328] The vasodilatory effect leads to reduced renal blood flow resulting in fluid retention. In addition, gastrointestinal complications, such as nausea, abdominal pain, and diarrhea are prominent. These side effects usually develop within 2 weeks of initiation of therapy and frequently diminish in severity or resolve within 2 weeks of continued therapy. Because of its ability to promote fluid retention and the development of tachyarrhythmias, anagrelide therapy should be avoided in patients with cardiac disease and should be administered carefully to elderly patients.[318–332] If congestive heart failure or arrhythmias other than tachycardia develop, anagrelide therapy should be discontinued.[331,332] Jurgens and coworkers have reported that prolonged anagrelide therapy may be associated with a potentially irreversible drug induced cardiomyopathy which is reminiscent of tachycardia induced cardiomyopathy.[331] Dose reduction can be used to lessen the degree of tachycardia or fluid retention. Acetaminophen may be useful for treatment of the headaches. The carrier for the anagrelide is lactose, and Silverstein reported that patients with nausea, diarrhea, and abdominal pain are usually lactase-deficient and that the use of LactAid results in resolution of such symptoms.[321] Although most adverse effects are mild or moderate, in one series therapy was discontinued in 16% of patients because of intolerable side effects—especially headache, nausea, fluid retention, and, rarely, frank congestive heart failure.[318] Anagrelide has no mutagenic activity but its use is not currently advised during pregnancy. Because of its small molecular weight, it is believed to be capable of crossing the placenta and, thus, may lead to fetal thrombocytopenia.[286,297,318–321] Anagrelide does not appear to be leukemogenic because no cases of leukemic transformation have been attributed to its use.[286,297,318] Anagrelide, therefore, appears to be suitable drug for the treatment of young, symptomatic patients with ET and for those who are resistant or refractory to first-line treatment with hydroxyurea.[209,291] Anagrelide has also been successfully used to treat children with ET.[59,319,326]

Hydroxyurea and anagrelide have been compared head-to head in a large randomized trial of 809 high-risk patients with ET, all treated also with low-dose aspirin (75 mg daily).[286] Overall patients randomized to anagrelide (and aspirin) were more likely to reach the composite primary end point of major thrombosis (arterial or venous), major hemorrhage or death from a vascular causes ($P = 0.03$). When individual end points were assessed arterial thrombosis, major hemorrhage and the development of myelofibrosis were all significantly more frequent in patients treated with anagrelide ($P = 0.004$, 0.008, and 0.01 respectively).[286] Anagrelide and aspirin seemed to offer at least partial protection from thrombosis as the prevalence of thrombotic events (8% at 2 years) was significantly less than that observed in the control arm of a previous study (28%).[286] Intriguingly the number of venous thromboses was less frequent in patients treated with anagrelide ($P = 0.006$).[298] Based on this large randomized study hydroxyurea is presently considered first line therapy for patients with high risk ET. Although equivalent control of the platelet count was achieved with both agents, hydroxyurea proved superior, perhaps due to its ability to reduce not only platelet numbers but also leukocyte numbers which have been associated with thrombosis in ET patients. In addition, the combination of anagrelide and low-dose aspirin was associated with a higher incidence of hemorrhagic episodes, indicating that this combination should be avoided.[286]

A continuing clinical controversy revolves around the question of whether any treatment is indicated in patients with ET in whom the platelet count elevation is initially detected fortuitously and who remain largely asymptomatic.[131,194] Such a decision is particularly important because the use of most chemotherapeutic agents is associated with an increased risk of the development of leukemia, and the use of platelet anti-aggregating agents is not without risk.[136,289,290] The need for such treatment can be questioned, because in several studies a relationship between frequency of thrombotic episodes and degree of platelet elevation has not been established.[13,128,138] One should not lapse into a false sense of security in deferring therapy, however, because the course of ET can include infrequent but dangerous thromboembolic complications, and patients may function normally for long periods of time without experiencing a life-threatening event.[1–20] In a retrospective study of 99 consecutive low risk ET patients (age <60 years) who presented with extreme thrombocytosis (platelet count $>1000 \times 10^9$/L) but without a previous history of thrombohemorrhagic complications, the incidence of major thrombosis and hemorrhagic events was shown to be similar during follow up between those who were treated with prophylactic cytoreductive therapy and those who did not receive such therapy.[196] The clinical course of these patients with a median age of 43 years was, however, not benign since 21% experienced a major thrombotic episode, and 7% a major hemorrhage after a medium follow-up of 147 months.[196] If the clinician feels compelled to use some therapeutic intervention in the young, asymptomatic patient, low-dose aspirin (100 mg/day) appears to be effective in the treatment of microvascular complications and its use is associated with limited toxicity.[246] Still, it would seem reasonable to withhold therapy in younger, asymptomatic patients until the development of a clinically significant thrombotic or hemorrhagic event. The older patient (>60 years) with other significant risk factors for cardiovascular complications is probably best served by immediate institution of therapy.[139] In addition, platelet reduction therapy is indicated in a patient with excessive thrombocytosis (platelet count $>1500 \times 10^9$/L) and a documented acquired von Willebrand syndrome.[140–144] Such an individual is at a very high risk of suffering a serious hemorrhagic episode.

The management of a pregnant patient with ET remains problematic.[201–208] The major goal of any therapeutic intervention in a pregnant patient with ET should be the prevention of the vasoocclusive events that lead to placental infarction, intrauterine fetal growth retardation, and, in some cases, fetal death. Patients with Jak2V617F positive ET have a higher risk of developing such complications.[211] In one large series, there was no significant relationship between the fetal outcome and the degree of maternal thrombocytosis or presence of disease complications.[202] In this series, there were no instances of excessive bleeding or other related complications during delivery.[202] This group did not recommend the use of therapeutic platelet pheresis and, in fact, claimed that specific therapy (aspirin, heparin, or platelet pheresis) did not alter the clinical course.[202] However, of the many patients reported in the literature who did not receive any therapy, a significant number experienced either spontaneous abortion or intrauterine deaths.[201–208] Low-dose aspirin (100 mg/day), because of its profound effect on events involving the microcirculation, such as erythromelalgia and transient ischemic events, has been used with increasing frequency in pregnant patients during the first and second trimesters.[201,206–208,290] Low dose aspirin

therapy is safe in pregnant women. It is recommended that aspirin be discontinued at least 1 week before delivery to avoid bleeding complications such as an epidural hematoma during delivery or during the postpartum period.[201] Because of the high risk of bleeding in patients with platelet counts greater than 1000×10^9/L with acquired von Willebrand syndrome, aspirin therapy is contraindicated.[139–145] There is limited experience reported in the literature with aspirin therapy alone and although the results are promising, the sample size is too small to confirm a beneficial effect.[201–208] The observed true birth rate, however, was 75% in those receiving aspirin compared with 43% in the group in the literature who received no therapy.[201,209] Aspirin therapy has, however, recently been found to be ineffective in preventing complications in Jak2V617F positive pregnant ET patients.[211] Chemotherapeutic drugs are to be avoided during the period of conception and especially during the first trimester.[201] Both hydroxyurea and busulfan are known teratogens in animal models.[153] In addition, busulfan and hydroxyurea reduce fertility in males.[201] Because the greatest risk of thrombosis is postpartum, thrombosis prophylaxis should be initiated in the form of low molecular weight heparin and low-dose aspirin following delivery unless there is hemorrhage or evidence of bleeding. These measures should be continued for 6 weeks. Mothers receiving interferon, anagrelide or hydroxyurea should refrain from breast feeding.

With the availability of interferon to treat ET, it is difficult to justify the use of chemotherapeutic agents during the time of conception or during the first two trimesters of gestation. Interferon-α therapy is not known to be leukemogenic or teratogenic, and because it does not cross the placenta, its use may be considered during pregnancy.[306] The manufacturers of interferon-α still advise that interferon-α not be used during pregnancy because adverse effects on the fetus cannot be ruled out.[306] The effect of interferon-α on male fertility remains uncertain. Anagrelide therapy should be avoided in the pregnant patient because of its potential to lead to fetal thrombocytopenia.[313–323]

Because none of the strategies described earlier has been tested in large clinical trials, one must develop a therapeutic strategy for an individual pregnant patient.[18] In the patient who has no history of spontaneous abortions and who is totally asymptomatic but is found to be pregnant, no therapy is presently indicated, although low-dose aspirin therapy (100mg/day) can be initiated without appreciable risk and can be continued throughout the pregnancy. Its use should be discontinued 1 week before delivery. Aspirin therapy is contraindicated in patients with platelet counts greater than 1500×10^9/L or patients with acquired von Willebrand syndrome. If a patient is symptomatic from a thrombohemorrhagic episode or if the platelet count is rising to levels above 1500×10^9/L, therapy with a platelet-reducing agent is indicated. Platelet pheresis therapy can be attempted in selected patients but if incomplete control is obtained, interferon-α therapy is, at this point, the best option. Several successful pregnancies have been reported with interferon-α therapy.[201–208] The patient with a history of a previous spontaneous abortion appears to be at a particularly high risk of developing subsequent spontaneous abortions if left untreated.[201–208] At the minimum, low-dose aspirin therapy in this patient population is a reasonable therapeutic approach.

Hormone replacement therapy including oral contraceptives and estrogen replacement hormone therapy remains controversial in patients with ET. Each of these agents in the normal population is associated with an increased incidence of arterial and venous thrombosis. Intuitively it would seem wise to avoid such agents in patients with ET who are already at an increased risk of developing thrombosis. Gangat and coworkers retrospectively reviewed the consequences of such hormonal interventions in 305 women.[333] Oral contraceptive therapy was associated with a high incidence of venous thrombosis occurring within the abdominal cavity, while estrogen replacement hormone therapy in menopausal women did not appear to be associated with an increase incidence of thrombosis.[333] This observation is surprising and might be a consequence of the limited numbers of patients included within this study.

PROGNOSIS

The probability that a patient with ET will survive 10 years ranges from 64% to 80%.[1–20] In a large study from Spain with extensive follow-up, there was no substantial difference between the probability of survival of patients with ET and that of the control population.[334] However, a more recent cohort study of 322 consecutive patients seen at the Mayo Clinic and followed for a median follow-up of 13.6 years showed a different pattern.[167] Survival of patients with ET was similar to that of the control population during the first decade of disease whereas the survival became significantly worse thereafter.[167] Multivariable analysis identified an age at diagnosis of 60 years or older, leukocytosis, tobacco use and diabetes mellitus as independent predictors of poor survival. The risk of developing leukemia or myelofibrosis was low in the first 10 years (1.4% and 3.8%, respectively) but increased substantially in the second (8.1% and 19.9%, respectively) and third (24.0% and 28.9%, respectively) decades of the disease.[167,335] The presence of the Jak2V617F mutation did not influence either survival or the rate of leukemic transformation.[335] The rate of leukemic transformation was however higher in patients with platelet count 1000×10^9/L and abnormal hemoglobin levels.[335]

Table 71–12 presents the outcome and causes of death in one series of 435 patients with ET.[8] Death predominantly resulted from thrombotic complications.[8] Transformation to acute myeloid leukemia has been reported with increasing frequency in patients with ET and is an important cause of mortality.[46,285,289–293] The rate of leukemic transformation ranges from 3% to 10%.[1–20] The phenotype of the blast cell can be either myeloid, myelomonocytic, megakaryocytic, of mixed lineage, or even lymphoblastic.[285,289–293,336–341] A limited number of patients have been reported who have developed acute leukemia and who had not been previously treated with any

chemotherapeutic agents.[289–293,335,340] Most investigators have concluded that the transformation of ET into acute leukemia is a rare event that can be accelerated by the administration of chemotherapeutic agents.[1–20]

The development of acute leukemia is associated with a deletion of the short arm of chromosome 17, which is most frequently deleted in hydroxyurea-treated patients, whereas a trisomy of the long-arm of chromosome 1 and monosomy 7q have been observed in patients treated with piprobroman.[289] These cytogenetic abnormalities are believed to be induced by the use of these chemotherapeutic agents.[288] The median survival after the development of myelodysplasia and/or leukemic transformation is 4 months.[335] Acute leukemia, which develops after ET, is frequently refractory to combination chemotherapy, but stem cell transplantation can be curative.[342,343]

Transformation of ET to a clinical stage that resembles PMF has been well documented.[1–20,46,264,265] In fact, 6% of the patients documented unequivocally as having ET by the criteria of the PV Study Group went on to develop myelofibrosis.[46] Three additional patients who met these diagnostic criteria went on to develop PV.[44,46] These studies emphasize the potential of ET to eventually evolve into a clinical picture that resembles one of the other MPD. In a series of 195 patients with ET evolution into myelofibrosis occurred in 13 cases after a mean of 8 years from the time of diagnosis.[265] After 10 years, the actuarial probability of developing myelofibrosis was 8% in one study and 9.7% in another. The development of myelofibrosis was heralded by the appearance of immature myeloid precursors and dacryocytes in the blood smear and increased serum lactate dehydrogenase levels followed by a reduction in platelet numbers and progressive splenomegaly.[265] This does not represent an instance of misdiagnosis but rather the natural evolution of the underlying hematologic malignancy. In addition, some patients, especially women who are iron deficient, may have their erythrocytosis masked and, thus, may truly have PV although, with the finding of an elevated platelet count, a diagnosis of ET may have been made. According to the data mentioned earlier, the risk of patients with ET transforming into acute leukemia is greater than that of normal individuals.[1–20] This is a phenomenon shared with the other MPD. The risk of developing acute leukemia following treatment with hydroxyurea alone increases only slightly (3%–4%), but the sequential use of hydroxyurea with other cytotoxic agents, such as busulfan or piposbroman significantly increases the risk of developing a secondary leukemia.[285,288,289,294,295]

FUTURE DIRECTIONS

ET is a hematological malignancy with its own distinct clinical manifestations and associated complications.[1–20] Better means of identifying patients at risk for developing fatal thrombotic or hemorrhagic complications are necessary to provide the basis with which to develop the optimal care of such patients. The ability to reduce the incidence of thrombohemorrhagic episodes with cytoreductive therapy in high-risk patients is now well established.

Multi-institutional studies comparing the efficacy of such promising agents as interferon-α or pegylated interferon, for the treatment of high-risk patients compared with hydroxyurea are needed. The use of low-dose aspirin therapy to reduce the number of episodes of erythromelalgia and transient ischemic attacks is now well-established.[88] Another pressing question that requires resolution is the degree of platelet reduction that is required for optimal management to be achieved. Whether reduction of platelet numbers below 400×10^9/L rather than using 600×10^9/L as a therapeutic target will further reduce the rate of thrombotic events will require further study.[290]

Finally, the discovery of the Jak2 V617F and MPL mutations have already had a major impact on disease classification during routine clinical practice. Diagnostic strategies have now incorporated screening for the Jak2 and MPL mutations, although their prognostic significance remains to be clearly established. This new understanding of the molecular pathogenesis of MPD lays the foundation for the development of novel targeted therapies. The use of specific Jak2 inhibitors for Ph negative MPD will clearly be the subject of current investigation.

Personal Approach to Therapy of ET

The optimal therapy for patients with ET remains uncertain. Certain concepts, however, apply to all patients. One is that all patients with ET should stop smoking to minimize the risk factors associated with atherosclerotic disease. Indiscriminant use of high doses of nonsteroidal anti-inflammatory drugs, including clopidogrel, should be avoided because this practice can lead to an increased risk of hemorrhage. Use of such agents is particularly frequent in the elderly in whom ET is common.

In a randomized trial of high-risk patients, cytoreductive therapy has been shown to lessen the chance of developing additional thrombotic events. High-risk patients include patients older than 60 years of age and patients with a history of a previous thrombotic episode, including erythromelalgia, transient ischemic attacks, or large vessel thrombosis. At present, no therapy is indicated in asymptomatic patients younger than 60 years of age. If a patient has a platelet count greater than or equal to 1500×10^9/L and acquired von Willebrand syndrome with bleeding symptoms, platelet reduction therapy is indicated to avoid the high risk of hemorrhage. Patients with acquired von Willebrand syndrome should clearly avoid the use of aspirin.

In those patients requiring platelet reduction therapy, the choice between the use of anagrelide, interferon-α, pegylated interferon, or hydroxyurea therapy is based on patient age, ease of administration, and drug-related toxicity. In patients older than 40 years, hydroxyurea therapy is the treatment of choice, whereas in younger patients, we prefer to initiate therapy with interferon-α. If the patient cannot tolerate interferon-α or fails to respond, we feel comfortable treating the symptomatic patient younger than 40 years of age with hydroxyurea. Although we remain concerned about the leukemogenic potential of hydroxyurea, this potential danger is far less than that associated with the use of the alkylating agents or P^{32}.

Those patients who initially receive hydroxyurea and no longer respond to this agent or suffer toxicity and require another agent should not receive long-term P^{32} or an alkylating agent. This sequence of administration is associated with an extremely high risk of leukemic transformation. Those patients who have had a trial of hydroxyurea and require further treatment should receive either anagrelide, interferon-α, ?or pegylated interferon. Doses of each of these agents required for disease control will, of course, be dependent on the target platelet level that one hopes to achieve. Strict control to a platelet count of less than or equal to 400×10^9/L may lead to greater protection from thrombosis than merely reduction to a level of less than or equal to 600×10^9/L., but there are no randomized trials to support this practice. The success in achieving this goal is obviously dependent on the ability of the patient to tolerate the agents used. In the younger patient, if such strict control is not achievable due to poor compliance or toxicity associated with anagrelide or interferon-α therapy, we are satisfied with continuing therapy and maintaining platelet counts of less than or equal to 600×10^9/L. In these patients, the addition of low-dose aspirin (100 mg/day) should be considered; it is less clear to us if those patients who achieve better platelet control with cytoreductive therapy should also be so treated. However, in studies from Europe addressing this question in PV, the approach of combining aspirin with cytoreduction therapy appears to minimize

Personal Approach to Therapy of ET—cont'd

thrombotic complications. The use of anagrelide and aspirin in combination should be avoided due to the high risk of a hemorrhagic episode. In patients who suffer from thrombotic episodes, especially episodes involving the microcirculation or large vessels, we administer low-dose aspirin (100 mg/day). This dose of aspirin does increase the number of bleeding episodes to a modest degree but is effective in the treatment of thrombotic events. This low-dose aspirin therapy is given in addition to an agent, which reduces platelet numbers.

Hydroxyurea can be started at a dose of 1g/day and then adjusted to achieve the target platelet count ($<400 \times 10^9$/L) without developing leukopenia. Anagrelide is initiated at 0.5 mg twice daily and increased by 0.5 mg/day every 5 to 7 days if platelet counts do not begin to drop. The usual dose to achieve platelet number control is 2.0 to 2.5 mg/day. There are patients who do not tolerate either hydroxyurea or anagrelide. In this patient group, interferon-α therapy is initiated at 3 million units 3 times per week subcutaneously or consideration to therapy with a pegylated form of interferon (peg-IFNa-2a) should be given. Another choice is busulfan at 4mg/day for 2-week courses every time the platelet count rises above the normal range. Busulfan therapy is reserved for patients older than 60 years.

In general, we do not routinely treat patients younger than 40 years of age, unless they have already have had a thrombohemorrhagic event or have significant risk factors for atherosclerotic disease. Complications even in young, otherwise healthy, patients with platelet counts greater than 2000×10^9/L are unusual. However, these marked elevations of platelet numbers can be anxiety-provoking situations for the patient and the clinician.

In certain situations, in young, low-risk patients, treatment should be instituted. Surgery can increase the risk of thrombosis, and the use of antiinflammatory agents can increase the risk of bleeding postoperatively. Under these circumstances, the platelet count should be lowered to the normal range. In pregnant patients with ET, low-dose aspirin therapy is the first treatment option. If the patient develops symptoms as a result of thrombosis, platelet reduction therapy is necessary and interferon-α therapy is the treatment of choice. Since interferon does not cross the placenta, it likely will not be teratogenic. Both hydroxyurea and busulfan have been successfully used to treat MPD during pregnancy, but they are probably teratogenic if used during the first trimester. If such agents are needed, they should be instituted after the first trimester.

In a patient with ET and a serious acute hemorrhagic event, the site of bleeding should be determined immediately, and any antiplatelet aggregating agents should be stopped. Although the platelet count may be high, these platelets should be considered to be qualitatively abnormal, leading to defective hemostasis. The patient may be suffering from acquired von Willebrand syndrome. In patients with acquired von Willebrand syndrome, DDAVP or factor VIII concentrates containing von Willebrand factor can be used immediately at the same time chemotherapy is being administered. If acquired von Willebrand syndrome is not present, the transfusion of normal platelets is suggested. In those patients with persistent hemorrhage, immediate reduction of the platelet count can be achieved by platelet pheresis. Hydroxyurea at 2 to 4 g/day for 3 to 5 days should be administered immediately, then reduced to 1 g/day. Any patient receiving hydroxyurea should be monitored for the onset of granulocytopenia or thrombocytopenia. Reduction of platelet counts is usually observed within 3 to 5 days of hydroxyurea treatment.

In contrast, patients with acute arterial thrombosis require immediate institution of platelet antiaggregating agents. Aspirin at a dose of 100 mg/day is suggested. Patients with erythromelalgia or transient ischemic attacks will have a rapid cessation of symptoms following the use of low-dose aspirin. In a patient with a life-threatening arterial thrombosis, the platelet count should be lowered with either a combination of apheresis and hydroxyurea or with hydroxyurea alone, depending on the severity of the event. If the arterial thrombosis involves the microcirculation and is not life threatening (transient ischemic attacks or erythromelalgia), immediate low-dose aspirin therapy is indicated and platelet reduction therapy (hydroxyurea, anagrelide, or interferon-α) can be initiated using a standard dose and schedule.

CHAPTER 72

EOSINOPHILIA, EOSINOPHIL-ASSOCIATED DISEASES, CHRONIC EOSINOPHIL LEUKEMIA, AND THE HYPEREOSINOPHILIC SYNDROMES

Steven J. Ackerman and Joseph H. Butterfield

HISTORICAL BACKGROUND, ETIOLOGY, AND PATHOPHYSIOLOGY OF HYPEREOSINOPHILIA

In the 100 years following the initial identification of the eosinophilic granulocyte (Fig. 72–1) by Paul Ehrlich in 1879, an extensive list of diseases and conditions characterized by blood or tissue eosinophilia, or both (Table 72–1), was developed. However, the specific functional roles of eosinophils in host defense, allergic reactions and other inflammatory responses, tissue injury, and fibrosis have only begun to be fully delineated and appreciated during the past 25 years. Recent research has now served to characterize the unique cellular characteristics of activated tissue and peripheral blood eosinophils, their preformed granule protein constituents and inducible lipid, oxidative, and cytokine products, focusing on the eosinophil's proinflammatory and cytotoxic potential in the pathogenesis of allergic, parasitic, neoplastic, and a variety of other idiopathic disease processes.[1] Recognition of the eosinophil as a proinflammatory effector cell in bronchial asthma has in part fueled the surge in interest in this granulocyte in asthma and other respiratory diseases,[2] and the prior epidemic of eosinophil myalgia syndrome related to ingestion of tainted L-tryptophan,[3] and recent increase in cases of eosinophilic esophagitis have served to markedly increase public interest and awareness of the eosinophil.

Studies of the biochemistry, biologic activities, and in particular, the localization in tissues of the distinctive enzymatic and nonenzymatic cationic protein constituents of the eosinophil's secondary or specific granule provided the first convincing evidence for the role of this granulocyte in the pathogenesis of inflammation and tissue damage in eosinophil-associated diseases.[1] In addition, identification of eosinophil-specific granule constituents in tissues by a variety of sensitive and specific immunochemical methods provided additional evidence for the participation of this leukocyte in diseases not normally associated with tissue or blood eosinophilia, for example, certain skin diseases.[4] Investigations over the past 10 to 15 years of the biochemistry, functions, and localization in tissues of these unique enzymatic and nonenzymatic cationic proteins have now provided compelling evidence supporting a pathologic effector role for the eosinophil in directly inducing tissue damage.[5] These distinctive cationic granule protein constituents include the two major basic proteins (MBP-1, MBP-2), the eosinophil peroxidase and the ribonucleases eosinophil cationic protein (ECP), and eosinophil-derived neurotoxin (EDN). Eosinophils have also been shown to have the capacity to express a variety of toxic oxidative intermediates,[6] eicosanoid and other lipid mediators of inflammation,[7] and most recently, inflammatory and hematopoietic cytokines that are integral to the normal and pathologic role of this granulocyte in health and disease.[8] This chapter will provide an overview of current knowledge and understanding of the inflammatory and pathologic activities of this granulocyte in human disease, focusing principally on the consequences of hypereosinophilia in the idiopathic hypereosinophilic syndrome (HES).

Patients presenting with hypereosinophilia provide an often daunting diagnostic challenge to physicians who must navigate multiple medical subspecialties in order to wade through the long and diverse list of potential causes (Table 72–1). This process, an often frustrating experience for both physician and patient, may nevertheless result in an indeterminate diagnosis of hypereosinophilia of unknown etiology. The hypereosinophilic syndrome (HES) comprises a group of myeloproliferative disorders of unknown etiology that are marked by sustained overproduction of eosinophils and tissue infiltration. In addition to the striking and sometimes profound eosinophilia associated with the syndrome, idiopathic HES is characterized by a predilection for end-organ damage most commonly involving the heart, with the development of eosinophilic endomyocardial fibrosis and related cardiac pathologies. However, as heart disease can also develop with eosinophilias due to other known etiologies, for example, tropical eosinophilia and certain cancers,[9,10] the cardiac manifestations of idiopathic HES are not unique to this syndrome. The currently defined criteria for HES as originally presented by Chusid and colleagues[11] and which serve to distinguish HES patients from those with identifiable (reactive) causes for their eosinophilia include (a) persistent eosinophilia of greater than 1500 eosinophils/mm^3 for more than 6 months; (b) exclusion of other potential etiologies for the eosinophilia including parasitic, allergic, or other causes; and (c) presumptive signs and symptoms of organ system dysfunction or involvement that appears related to the eosinophilia that is otherwise unexplained in the clinical presentation. Of interest, the more recent identification of subgroups of patients with profound idiopathic eosinophilia characteristic of HES but who do not go on to develop end-organ damage characteristic of HES (eg, patients with episodic angioedema with eosinophilia[12,13]) complicates the diagnosis, treatment, and management of patients with profound eosinophilia of unknown etiology. This chapter provides a review of the distinguishing, as well as more variable, hematologic and clinical features of HES that should assist the physician in separating this syndrome from more common (reactive) eosinophilias of known etiology. This will include a discussion of the current understanding of HES etiology and pathogenesis, as well as therapeutic approaches and strategies for managing this complex syndrome.

EOSINOPHIL MORPHOLOGY

Eosinophils contain three distinct membrane-bound granule populations that are produced during their differentiation from hematopoietic progenitors in the bone marrow (Fig. 72–2). These include (a) round, uniformly electron-dense primary granules, present mainly at the eosinophilic promyelocyte/myelocyte stages; (b) specific or secondary granules, containing an electron-dense crystalloid core surrounded by a less dense granular matrix (>95% of granules in mature eosinophils and the morphologic hallmark of this granulocyte); and (c) less well characterized small granules, which are sites for hydrolytic

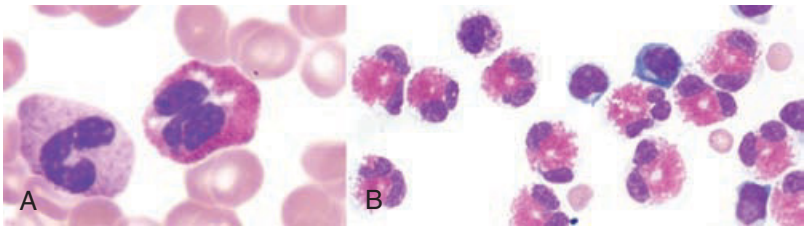

Figure 72–1 Eosinophil and Eosinophilia (**A**, **B**). Eosinophil in a standard peripheral blood smear (**A**) (center) compared to a neutrophilic granulocyte (left). The eosinophil usually has a bilobed nucleus and heavily condensed chromatin usually with two lobes. The granules are considerably larger than those of a neutrophil, and are spherical red-orange and refractile. They fill the cytoplasm and frequently overlie the nucleus. An eosinophilia is illustrated in a CSF specimen (**B**) from a patient with hydrocephalus and a V-P shunt; apparently the eosinophilia is due to an allergic response.

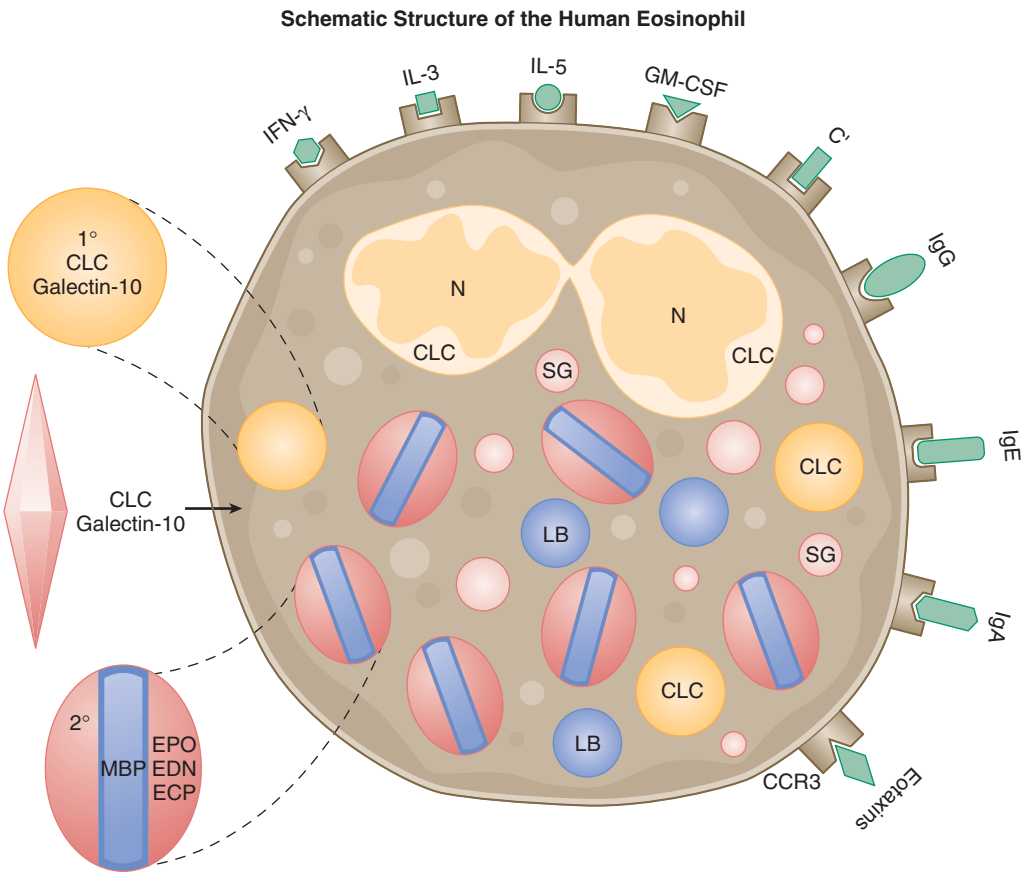

Figure 72–2 Schematic structure of the mature human eosinophil. Primary (1°) and secondary (2°) granules, small granules (SG), and non-membrane-bound lipid bodies (LB) are shown, as are the major cell surface cytokine, chemokine, immunoglobulin, and complement receptors. The subcellular localizations of the eosinophil granule cationic proteins major basic protein (MBP), eosinophil peroxidase (EPO), eosinophil cationic protein (ECP), and eosinophil-derived neurotoxin (EDN) in the secondary granule and the Charcot–Leyden crystal (CLC) protein (galectin-10) in the coreless primary granule, and the nucleus and cytosolic space beneath the plasma membrane are also indicated. (Redrawn from Gleich GJ, Adolphson CR, Leiferman KM: The biology of the eosinophilic leukocyte. Annu Rev Med 44:85, 1993.)

enzymes such as acid phosphatase and arylsulfatase, may contain catalase, and may be functionally analogous to lysosomes and peroxisomes of other cells. The large specific granule is the major repository for the eosinophil's cytotoxic and proinflammatory cationic proteins, which also confer the unique and characteristic tinctorial (eosinophilic) properties of this cell as originally identified by Paul Erlich in 1879. Eosinophils also contain lipid bodies, non-membrane-bound lipid-rich organelles often confused with granules and present in many types of leukocytes and other cells.[7] Normal blood eosinophils contain greater numbers of lipid bodies than do neutrophils, and the numbers of lipid bodies increase during eosinophil activation in vitro and engagement in inflammatory reactions in vivo.[14] Although the functions of lipid bodies are incompletely understood, they incorporate fatty acids such as arachidonate and likely serve as intracellular depots for its storage and metabolism, as suggested by the lipid body localization of all the principal eosinophil eicosanoiden-forming enzymes including 5-lipoxygenase, leukotriene C4 synthase, and cyclooxygenase.[15] As reviewed in detail elsewhere,[16] these four organelles, along with vesiculotubular structures and small vesicles involved in transport and secretion in the activated cell, serve as the major subcellular sites for the eosinophils' armamentarium of preformed cytotoxic and inflammatory mediators.

Table 72–1 Diseases, Syndromes, and Conditions Commonly Associated With Peripheral Blood Eosinophilia and/or Tissue Eosinophilia

Infectious Agents

Parasitic

Tropical eosinophilia
Visceral larval migrans (VLM, Toxocariasis)
Helminth infections
Filariasis (*Wuchereria bancrofti, Brugia malayi*)
Onchocerciasis
Schistosomiasis
Fascioliasis
Paragonimiasis
Strongyloidiasis
Trichinosis
Hookworm
Ascariasis
Echinococcosis/hydatid disease
Nonparasitic
Coccidioidomycosis
Chlamydial pneumonia of infancy
Scarlet fever and pneumococcal pneumonia (convalescent phase)
Cat scratch disease
Cryptococcosis (CSF eosinophilia) in HIV

Allergic Diseases

Asthma (atopic and intrinsic, nasal polyps, aspirin intolerance syndromes)
Bronchopulmonary aspergillosis
Allergic rhinitis
Urticarias (acute allergic and chronic idiopathic)
Atopic dermatitis
Acute drug (hypersensitivity) reactions (interstitial nephritis, cholestatic hepatitis, exfoliative dermatitis)

Respiratory Tract Disorders

Hypersensitivity pneumonitis (rare)
Allergic bronchopulmonary aspergillosis
Eosinophilic pneumonia
Transient pulmonary infiltrates (Löeffler syndrome)
Prolonged pulmonary infiltrates with eosinophilia (PIE syndromes)
Tropical pulmonary eosinophilia (TPE)
Bronchiectasis
Cystic fibrosis

Endocrinologic Disorders

Addison disease

Gastrointestinal Diseases

Inflammatory bowel disease (IBD)
Eosinophilic gastroenteritis, eosinophilic esophagitis (EE)
Allergic gastroenteritis (young children)
Celiac disease (when associated with EE)

Toxic Reactions to Ingested Agents

Eosinophil myalgia syndrome (L-tryptophan)
Toxic oil syndrome

Reactions to Cytokine Therapies

IL-2 and IL-2 plus lymphokine activated killer (LAK) cells
GM-CSF for chemotherapy-induced neutropenia

Cutaneous Disorders

Atopic dermatitis
Immunologic skin diseases
Scabies
Eosinophilic cellulitis (Wells syndrome)
Episodic angioedema with eosinophilia
Chronic idiopathic urticaria
Bullous pemphigoid
Herpes gestationis

Immunodeficiency Syndromes

Wiskott–Aldrich syndrome
Selective IgA deficiency with atopy
Hyper-IgE recurrent infection syndrome (Job syndrome)
Swiss-type and sex-linked combined immunodeficiency
Nezelof syndrome
Graft-versus-host-disease (GVHD)

Connective Tissue Diseases

Vasculitis/Collagen Vascular Disorders
Hypersensitivity vasculitis
Allergic granulomatosis with angiitis (Churg–Strauss syndrome)
Serum sickness
Eosinophilic fasciitis
Sjögren syndrome
Rheumatoid arthritis (severe)

Neoplastic and Myeloproliferative Diseases and Syndromes

Neoplastic
  Ovarian carcinoma
  Solid tumors (mucin secreting, epithelial cell origin)
Eosinophil leukemia
Idiopathic hypereosinophilic syndrome (HES)
Systemic mastocytosis
Lymphomas (T cell, Hodgkin)
Chronic myelogenous leukemia, acute myelogenous leukemia, MDS (myelodysplastic syndrome)
T-cell lymphocytic leukemia
Myelomonocytic leukemia with bone marrow eosinophilia (M4Eo, inversion 16)
Angioimmunoblastic lymphadenopathy
Angioblastic lymphoid hyperplasia (Kimura disease)

Rare Causes

Chronic active hepatitis
Chronic dialysis
Acute pancreatitis
Postirradiation
Hypopituitarism

Modified and updated from Mahanty S, Nutman, TB: Eosinophilia and eosinophil-related disorders. In Middleton EJ, Reed CE, Ellis EF, et al (eds.): Allergy: Principles and Practice, 4th ed. St. Louis, Mosby-Year Book, 1993, p 1077.

EOSINOPHIL DEVELOPMENT, RECRUITMENT, AND ACTIVATION

Eosinophilopoiesis

Eosinophils are derived in the bone marrow from $CD34^+$ multipotential myeloid progenitors in response to a number of T cell-derived eosinophilopoietic cytokines and growth factors including IL-3, GM-CSF, and IL-5. These cytokines affect the eosinophil lineage at three different levels, including the (a) commitment, proliferation, and differentiation of hematopoietic progenitors in the bone marrow; (b) priming and activation in the blood and tissues for enhanced functional activities; and (c) recruitment and tissue localization (discussed later). Although activated T cells are likely the primary source for IL-3, IL-5, and GM-CSF pertinent to eosinophil differentiation and the development of reactive eosinophilia in disease, other cell types including mast cells, macrophages, natural killer cells, endothelial cells, and stromal cells such as fibroblasts are also producers of GM-CSF. IL-5, produced primarily by activated T_{H2} type helper T cells[17] and mast cells,[8,18] stimulates the proliferation and differentiation of

murine activated B cells and regulates the production of eosinophils in vitro and in vivo.[19–21] Both IL-3 and GM-CSF have activities on other hematopoietic lineages, whereas IL-5 is more eosinophil-specific and plays a crucial role in regulating the terminal differentiation and postmitotic activation of eosinophils.[22] IL-5 is therefore a late-acting cytokine that demonstrates maximum activity on an eosinophil progenitor pool that is first expanded by the earlier-acting, multipotential cytokines such as IL-3 or GM-CSF.[22] Although IL-3 and GM-CSF participate in the proliferation and commitment of progenitors to the eosinophil lineage, IL-5 is both necessary and sufficient for eosinophil development to proceed in vivo.[22,23] In humans, IL-5 does not appear to have any effect on B cells or other lymphoid lineages, and its activity, high-affinity receptor, and functions are restricted to eosinophils and hematopoietically related basophils.[22] The expression of the high-affinity receptor for IL-5 is an important prerequisite and very early lineage-specific event in the hematopoietic program for these granuloctyes. Overexpression of IL-5 is observed in many eosinophil-associated diseases[24–26] and IL-5 transgenic mice develop profound eosinophilia,[27,28] indicating that IL-5 plays important roles in promoting the production and function of eosinophils in vivo. These general observations have recently been confirmed and expanded in studies of IL-5 deficient (gene knockout) mice,[29,30] which produce basal levels of normal eosinophils in the bone marrow, but do not develop blood and tissue eosinophilia, airway hyperreactivity, or lung damage in the murine ovalbumin allergic asthma model,[30] nor eosinophilic responses to helminth parasites.[29] For these reasons, IL-5 and its receptor may be excellent targets for therapeutic intervention in eosinophil-associated inflammatory diseases.

Mobilization and Migration of Eosinophils to Sites of Inflammation

In the normal individual, eosinophils produced in the bone marrow reside only briefly in the peripheral circulation in transit to extravascular sites. They tend to localize preferentially in certain tissues and organs exposed to the external environment, principally in the submucous membrane and loose connective tissue of skin, gastrointestinal tract, genital tract, and the lungs.[31] In contrast, the acute and chronic inflammatory recruitment of eosinophils into tissues occurs primarily in response to the early- and late-phase components of immediate hypersensitivity reactions, but also in association with a number of other immunologically mediated reactions, diseases, and idiopathic syndromes to be outlined or discussed in detail later. In addition, diurnal variations in the eosinophil intravascular compartment are well documented, with minimum numbers of blood eosinophils early in the morning and highest numbers late at night, mirroring circadian rhythms in circulating adrenal corticosteroids. Likewise, diurnal variations have also been documented to occur in the mobilization, recruitment, and activation state of eosinophils in tissues, for example, in diseases such as nocturnal asthma.[32,33]

Although eosinophils may represent only part of an inflammatory infiltrate composed of neutrophils, monocytes, and/or lymphocytes, the mechanisms by which they are selectively recruited in large numbers in certain reactions are currently under investigation.[34] The mobilization of eosinophils, as for other leukocytes, from the vasculature involves their rolling and adherence to vascular endothelium via L-selectin, followed by interactions with intercellular adhesion molecule-1 (ICAM-1) through CD18/CD11a,b-dependent mechanisms, and migration in response to specific cytokines or chemoattractants. Adherence via CD18-independent mechanisms involves binding to cytokine-activated endothelial cells utilizing either E-selectin, also known as endothelial leukocyte adhesion molecule-1 (ELAM) or vascular cell adhesion molecule-1 (VCAM). Selective recruitment of eosinophils likely involves adhesion to VCAM via the β_1 integrin very late activation antigen-4 (VLA-4), which is expressed by eosinophils but not by neutrophils.[35] Because no single chemotactic agent identified thus far is uniquely specific for eosinophils, selective eosinophil recruitment likely involves the complex interaction of multiple adhesion pathways and chemotactic gradients. The inflammatory mediators identified to function as potent eosinophil chemoattractants include the complement fragment C5a and platelet activating factor (PAF), along with a number of the eosinophil-active cytokines, including IL-3, IL-5, and GM-CSF, which also prime eosinophils for enhanced migratory responses to agents such as PAF, fMLP, LTB_4, and IL-8. Other potent eosinophil chemoattractants identified thus far are active in the 10^{-12} to 10^{-11} M range, are approximately 1000-fold more active than PAF and C5a, and include both IL-2 and the $CD8^+$ T cell-derived lymphocyte chemoattractant factor (LCF) that utilizes CD4 expressed on the activated eosinophil as its receptor.[36] The chemokine RANTES, which is chemotactic for certain T-cell subsets and monocytes, but not for neutrophils, is likewise a potent stimulus for eosinophil migration[37]; its production by the $CD4^+$ T-cell component of cutaneous and pulmonary allergen-induced late-phase reactions may contribute to the eosinophil infiltration characteristic of these responses. The most potent and eosinophil-selective chemoattractants identified to date are the family of eotaxins (eotaxin-1, 2, 3), chemokines that bind and signal through the CCR3 receptor expressed on eosinophils.[38–41] Recent studies have characterized the selective signals that regulate eosinophil accumulation in tissues in eosinophil-associated diseases. Two interrelated mechanisms for the tissue accumulation of eosinophils have recently been identified and shown to be linked to eosinophil-associated pathophysiology.[42] Interleukin-5 was shown to play a critical role in expanding and terminally differentiating eosinophil progenitor pools in the bone marrow in response to allergenic or other stimuli in peripheral tissues. T_{H2} T cell-derived cytokines such as IL-4 and IL-13 operate within tissues to regulate the transmigration of eosinophils from the vascular bed, a process that exclusively promotes tissue accumulation of eosinophils over other leukocytes, probably by activating eosinophil-specific adhesion pathways on endothelial cells and by regulating the production of IL-5 and eotaxin expression in the target tissue compartment. IL-5 and eotaxin likely cooperate locally to selectively and synergistically promote eosinophilia, the former working both systemically and within tissues to promote the local eosinophil chemotactic signals provided by the latter. The regulation of IL-5 and eotaxin levels within tissues by cytokines that include IL-4 and IL-13, allows T_{H2} cells to coordinate both tissue and peripheral blood eosinophilia. These observations highlight the importance of targeting both IL-5 and eotaxin/CCR3 signaling systems to block eosinophil-associated inflammation and tissue pathology.[42–45]

Eosinophil Activation in Disease: Eosinophil Heterogeneity

Eosinophils secrete their preformed granule constituents and newly synthesized lipid, and cytokine and peptide mediators of inflammation on stimulation (Fig. 72–3). It has become increasingly clear that peripheral blood eosinophils from patients with eosinophilia and eosinophils from the inflammatory tissue microenvironment are heterogeneous with regard to their capacity for stimulation and secretion of the described mediators. Eosinophils from blood and tissues of patients with eosinophilia differ from their normal counterparts by a variety of morphologic, biochemical, and functional characteristics,[46] some of which appear to be linked to a significant decrease in cell density as measured by separation over density gradients of cell separation media such as Percoll. A distinction is now made between the populations of "normodense" (normal density) and "hypodense" (light density) eosinophil phenotypes isolated from the peripheral blood and tissues. The blood of normal individuals contains less than 10% of eosinophils with densities less than 1.082 g/mL, whereas patients with eosinophilia can have markedly increased numbers of the hypodense cells.[25,47,48] Hypodense eosinophils possess a variety of properties consistent with their being primed, activated in vivo, or both, by analogy with classic macrophage activation. On a morphologic level, activated hypodense eosinophils show increased vacuolization, decreased granule size (and content of granule cationic proteins

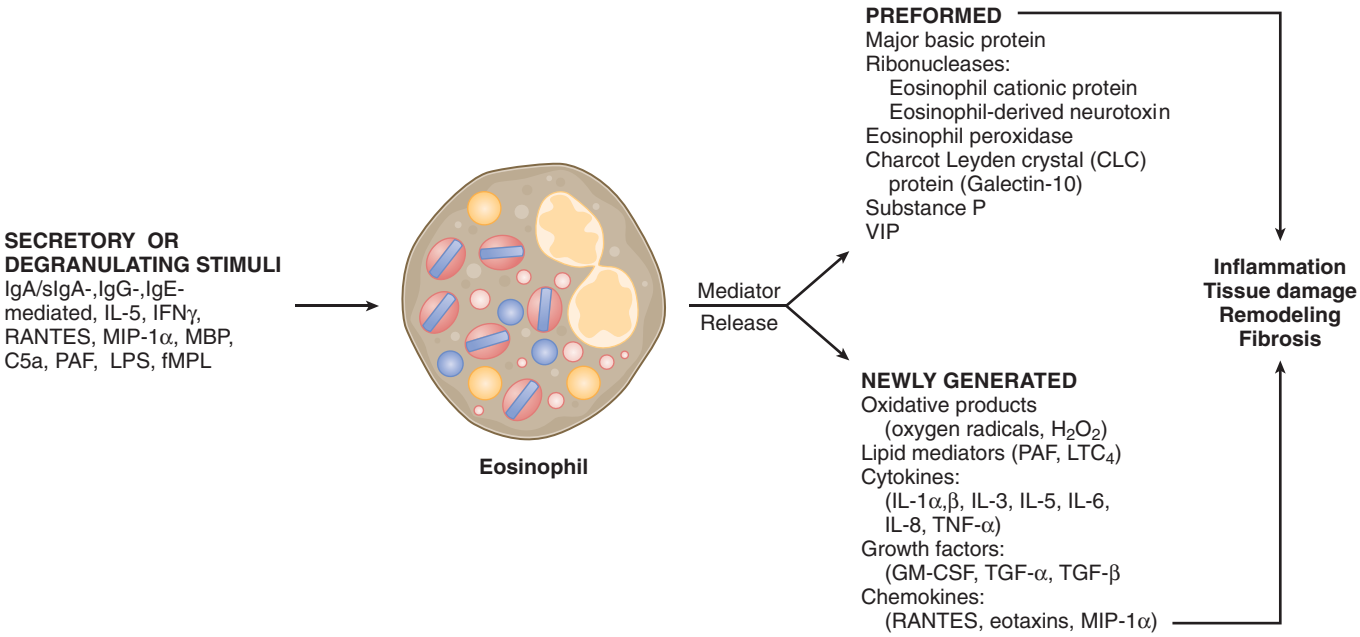

Figure 72–3 Eosinophil secretory/degranulating stimuli and eosinophil-derived inflammatory mediators. The listed factors have been shown to stimulate the secretion of inflammatory mediators from the eosinophil. These mediators may be either preformed, such as the eosinophil granule-derived cationic proteins, or newly generated mediators such as oxidative products, lipid mediators (eg, LTC_4), inflammatory or hematopoietic cytokines, chemokines, and growth factors. Release of these mediators leads to tissue inflammation, damage, remodeling, and fibrosis. (Redrawn from Furuta GT, Ackerman SJ, Wershil BK: The role of the eosinophil in gastrointestinal diseases. Curr Opin Gastroenterol 11:541, 1995.)

such as MBP[48]), and increased numbers of cytoplasmic lipid bodies.[15] The numbers of surface receptors for a variety of eosinophil-active agonists, including complement cleavage fragments of C3 (CR1 and CR3), immunoglobulins (IgE, IgA), cytokines, and PAF, are increased on hypodense eosinophils from eosinophilic patients, as are a variety of membrane surface antigens such as CD4.[36] Functionally, hypodense eosinophils show increased metabolic activity, oxygen consumption, and generation of superoxide anion as well as an increased capacity for the synthesis and secretion of LTC_4 and certain cytokines, enhanced chemotaxis, and augmented cytotoxicity for antibody-coated targets.

The mechanism by which eosinophils develop the morphologic, biochemical, and functional characteristics of activated cells in vivo has been largely defined through the in vitro analysis of factors capable of prolonging eosinophil survival and inducing the development of the hypodense phenotype. Culture of normal peripheral blood eosinophils with growth factors (GM-CSF), hematopoietic cytokines (IL-3, IL-5), and interferons (IFN-α and IFN-γ), either alone or in coculture with endothelial cells or fibroblasts, induces the development of the hypodense activated phenotype characteristic of eosinophils isolated from patients with hypereosinophilic disorders. In addition, the eosinophilopoietic cytokines (IL-3, IL-5, and GM-CSF) also prolong the survival of mature normodense and hypodense eosinophils in vitro (and possibly in vivo in the tissue microenvironment), likely through the prevention of programmed cell death (apoptosis).[49,50] Of interest, culture of eosinophils with the previously mentioned factors in vitro does not precisely recapitulate all the functional characteristics of the in vivo activated, tissue-derived cell, suggesting a requirement for additional, as yet undefined, factors that may include interaction of adhesion receptors with their ligands during eosinophil recruitment and migration into the tissue or stromal cell-derived factors.

The diagnostic and therapeutic significance of eosinophil heterogeneity has not been fully evaluated. Although the percentage of hypodense eosinophils in the blood may correlate with the degree of peripheral blood eosinophilia,[47] precise relationships between the percentage of hypodense eosinophils and the clinical status of an eosinophilic disorder have not been clearly defined. Rough correlations have been reported between disease severity and numbers of hypodense eosinophils in circulation for particular hypersensitivity disorders such as allergic asthma and allergic rhinitis. However, there is a significant overlap in the percentage of hypodense peripheral blood eosinophils in hypereosinophilic disorders of greatly varying severity, such as bronchial asthma, the hypereosinophilic syndrome, and certain helminth infections. As eosinophils reside primarily in the tissue microenvironment for the majority of their lifespan, it is not surprising that their heterogeneity in the peripheral circulation is at best a crude reflection of disease severity. In vitro models of eosinophil heterogeneity suggest a number of pathways for the development of eosinophil subpopulations, including acute exposure to mediators generated in immediate-type hypersensitivity reactions (eg, PAF, eosinophil-active cytokines such as GM-CSF, IL-3, IL-5, IFN, or TNF) or more chronic exposure to eosinophil-active cytokines in combination with as yet undefined factors in the tissue microenvironment as discussed earlier. Regardless of the specific mechanisms or mediators involved in eosinophil priming or activation, the development of eosinophil heterogeneity as a reflection of the functional, proinflammatory capacity of the cell in vivo suggests the possibility that these processes could be manipulated in a therapeutic manner. For example, in disorders such as HES where excessive levels of IL-5 have been demonstrated in the peripheral circulation (see below),[24] therapies aimed at modulating IL-5 levels to normalize the eosinophil phenotype and attenuate the eosinophilia may be appropriate. One such example has been the use of cyclosporin A to produce a clinical remission in a patient with steroid-resistant HES in which cyclosporin A was shown in vitro to inhibit IL-5 production from T-cell clones derived from the patient.[51] In contrast, because eosinophil infiltration of certain types of malignancies, including colon cancers or lung adenocarcinomas, may be associated with improved prognosis,[52,53] it may be advantageous to induce the development of tissue eosinophilia and enhanced cytotoxicity as demonstrated in response to local production of IL-4.[54] Studies suggest novel roles for the eosinophil in tumor immune surveillance and antitumor effector cell responses in animal models.[55]

EOSINOPHILIA AND EOSINOPHIL-ASSOCIATED DISEASES, SYNDROMES, AND INFLAMMATORY REACTIONS

Assessment of Eosinophilia

Identification and Quantitation

Eosinophils, so named for their unique granular staining with acidic fluorone dyes such as eosin, were first identified by Paul Ehrlich in 1879. Subsequently, histochemical staining with eosin-based stains became the standard for eosinophil identification in both blood and tissues (hematoxylin and eosin) (see Fig. 72–1). Other histochemical dyes such as chromotrope 2R are more definitive in tissues, and Fast Green or Luxol Fast Blue can be utilized in blood smears or cytocentrifuge slides to specifically distinguish the mature eosinophil from polymorphonuclear leukocytes and basophils, whose granules are not stained. The chemical characteristics of the fluid medium or tissue in which the eosinophil is analyzed, and most importantly the eosinophil's degree of maturity, activation, secretion, and/or degranulation, can induce significant variability in histochemical characteristics for the Romanovsky-type metachromatic stains used most widely for detection of eosinophils in blood and bone marrow specimens. For example, eosinophils in urine, as found in eosinophilic cystitis or interstitial nephritis, are best detected by Hansel stain.[56] As a result, it is now appreciated that the definitive identification of the eosinophil's participation in a particular inflammatory response or disease may require immunochemical localization using specific monoclonal or polyclonal antibodies to eosinophil-specific granule proteins such as MBP, eosinophil peroxidase, or ECP, all of which have been used to identify eosinophil infiltration and secretion or degranulation in tissues where they have been missed by more classic histochemical techniques.[4,57] For peripheral blood, absolute eosinophil counts done manually or using automated counting systems provide a much more reliable estimation of eosinophil numbers than does microscopic differential counting of blood smears combined with total leukocyte counts, especially in situations where there is an absolute leukocytosis or leukopenia for another lymphoid or myeloid lineage. Circulating eosinophils are generally present in low numbers in normal healthy individuals with consensus absolute counts ranging from 35 to 350 eosinophils/mm^3 (mean 125 for adults; 225 for children under 12 years). The broad range of variability in normal blood eosinophil levels reflects the multiple sources of both subtle and more obvious physiologic effects due to diurnal variation in endogenous glucocorticoid levels (discussed earlier), degree of atopy in the general population, and other factors that can include exercise, emotional stress, and hormonal influences of the menstrual cycle.

Clinical Assessment of Eosinophilia: Peripheral Blood Versus Tissue Eosinophils

The low numbers of eosinophils in the blood compared to neutrophils and lymphocytes, coupled with their principal localization in tissues, makes accurate quantitation and interpretation of blood eosinophil counts more difficult than that of other cellular elements. As noted earlier, cell differential counts of 100 to 200 are fraught with the problems inherent in sampling error when eosinophils constitute less than 3% to 5% of total peripheral blood leukocytes. Further, automated cell counters may not accurately enumerate eosinophils unless they are present in sufficiently high numbers, and can miss eosinophil peroxidase-deficient cells. A manual differential or absolute cell count should be performed if low-to-moderate eosinophilia is suspected in the clinical evaluation of a patient. The number of circulating eosinophils in the blood reflects a complex interplay of factors, including rates of development and transit from the bone marrow, margination, and subsequent emigration into tissues through postcapillary venules. Because the eosinophil is primarily a tissue dwelling cell, is present in extravascular sites at levels several 100-fold more than in peripheral blood, and blood levels may vary significantly as noted earlier, circulating cells reflect only those in traffic between the marrow and their final functional destination. Normal adult bone marrow contains approximately 3% to 5% eosinophils, with approximately 40% mature cells, and migration of eosinophils from the marrow into the blood takes approximately 3.5 days. The half-life of the eosinophil in the peripheral circulation of normal individuals is approximately 18 hours, with an average blood transit time of approximately 26 hours, similar to that of neutrophils. Daily mean turnover is approximately 0.2×10^9/kg, and the bone marrow has a postmitotic reserve of approximately 0.1×10^9 eosinophils/kg. Under ideal steady-state conditions, one would anticipate that peripheral blood eosinophil levels are proportional to levels in normal tissue compartments. In contrast, under the dynamic conditions of certain acute inflammatory or immune responses, temporal lags have been observed to occur between infiltration into reactive tissue sites and the induction of eosinophil development and emigration from the marrow resulting in the development of eosinopenia or delayed blood eosinophilia, or both.[58–60] Moreover, in the pathology of more chronic eosinophil-associated inflammatory conditions, tissue eosinophilia may be prominent in the absence of any peripheral blood eosinophilia, for example, in certain skin diseases.[4] Thus, the clinical assessment of peripheral blood eosinophilia, although diagnostically important, must be interpreted with these caveats in mind.

The list of diseases, syndromes, and inflammatory processes associated with peripheral blood (>300 eosinophils/mm^3) or tissue eosinophilia, or both, is quite extensive (see Table 72–1). Of course, the most common associations are infections with parasitic helminths and allergic diseases and their related inflammatory reactions. Effective clinical assessment of patients with eosinophilia requires a careful and detailed history, including travel information; where the patient has lived; drug use, including intravenous drugs, L-tryptophan, vitamin supplements, and other over-the-counter nonprescription medications; diet; and allergic symptomatology. In addition, the systemic nature of many of the nonallergic/noninfectious conditions involving eosinophilia dictates that a careful history of fever, weight loss, myalgias, arthralgias, rashes, lymphadenopathy, and so on should be obtained as well. Symptomatic or asymptomatic eosinophilia in patients taking drugs associated with known eosinophil responses and eosinophil-related drug reactions strongly dictates that their use be discontinued and that follow-up evaluation confirms that the eosinophilia and related symptoms have resolved. Patients with eosinophilia who have resided in or visited areas endemic for helminth or other parasites should be examined for intestinal and blood-borne infections, with additional serologic evaluation as necessary to identify the causative agent. Once the more common and obvious causes of eosinophilia have been excluded, that is, drug reactions, parasitic infections, and various allergic conditions, the differential diagnosis of eosinophilia becomes more difficult because of the complexity and number of potential organ systems and conditions involved (see Table 72–1).

Monitoring of Eosinophil Activity

An appreciation of the importance of both numbers of tissue eosinophils and their functional status, as well as differences in functional status between circulating eosinophils and those that have been recruited into and exposed to cytokines and other factors in the tissue microenvironment, has resulted in the development and more routine use of methods to monitor eosinophil activity in situ. Tissue biopsies have become more routinely employed for both the clinical and experimental evaluation of eosinophil function in diseases involving the skin,[4,58,61] lungs,[33,62,63] lymph nodes,[64] heart,[65] and other tissues, greatly contributing to the current understanding of the eosinophil's proinflammatory role in disease pathogenesis. The difficulties, tediousness, and sampling errors inherent in accurately quantitating the numbers of eosinophils, let alone their functional status in tissue biopsy specimens, even using antibodies that recognize specific cell

surface activation markers or secretion products and modern morphometric techniques, makes routine clinical evaluation of tissue eosinophils by these methods somewhat impractical. Alternatives such as analysis of tissue secretions from affected organs, for example, bronchoalveolar lavage of the lung, have been used with great success in the clinical and experimental evaluation of eosinophil function in diseases such as asthma.[32,66,67] In addition to the more routine histochemical identification and enumeration of eosinophils, and immunochemical localization of secreted eosinophil granule cationic proteins in tissue biopsies, two additional methods have been extensively used to monitor eosinophil activation, secretion, and involvement in disease pathogenesis. These include the identification of activated eosinophils by staining with a monoclonal anti-ECP antibody EG2 that recognizes a secreted, deglycosylated form of the protein,[68–70] and measurement of the eosinophil granule cationic proteins such as MBP, ECP, and EDN by radioimmunoassay[71–73] in various body fluids including serum, plasma, urine, sputum, nasal lavage, and BAL fluid.[74] Under controlled sampling conditions, measurements of these eosinophil granule products have served as excellent indicators of eosinophil secretory activity in vivo and eosinophil involvement in a variety of allergic, parasitic, and certain inflammatory and skin diseases not normally associated with blood or tissue eosinophilia. Examples include assays of MBP and ECP in bronchoalveolar lavage[75] and nasal lavage[76] in asthma and allergic rhinitis,[74] in serum and plasma in lymphatic filariasis,[58,77] and in skin diseases such as chronic idiopathic urticaria.[78] Such measurements likely reflect in vivo secretion in tissues or secretory activity of eosinophils in the fluid sampled,[74] or both, and have provided compelling evidence for relationships between eosinophil secretory activity and disease severity.[75,79,80]

IDIOPATHIC HYPEREOSINOPHILIC SYNDROME

The hypereosinophilic syndrome (HES) comprises a group of myeloproliferative disorders of unknown etiology that are marked by a sustained overproduction of eosinophils. In addition to the striking and sometimes profound eosinophilia associated with the syndrome, HES is characterized by a predilection for end-organ damage, most commonly involving the heart, with the development of eosinophilic endomyocardial fibrosis and related cardiac pathologies. The currently defined criteria for HES as originally presented by Chusid et al[11] are listed in Table 72–2 and include (a) persistent eosinophilia of greater than 1500 eosinophils/mm^3 for more than 6 months; (b) exclusion of other potential etiologies for the eosinophilia including parasitic, allergic, or other causes; and (c) signs and symptoms of organ system dysfunction or involvement that appears related to the eosinophilia or is of unknown cause in the clinical presentation. Total leukocyte counts are often less than 25,000/mm^3 with 30% to 70% eosinophils. However, extremely high leukocyte counts (>90,000/mm^3) may be associated with poor prognosis in some patients. These three primary features of the syndrome, including sustained eosinophilia of unknown etiology or disease association, along with evidence of organ involvement (see Table 72–2), comprise the defining characteristics of HES. The clinical features of patients diagnosed with HES, as summarized by Spry[81] and most recently reviewed by Weller and Bubley,[82] Brito-Babapulle,[83] and one of us,[84] are shown in Table 72–3 as well as their frequency at presentation. The most commonly encountered features in approximately 50% to 75% of patients studied in detail to date[85–87] include the cardiovascular manifestations, especially endomyocardial disease (discussed later) and its associated thromboembolic complications, the major causes of morbidity (and mortality) in the HES.

Table 72–2 Criteria for the Diagnosis of the Idiopathic Hypereosinophilic Syndrome

Eosinophils >1500/mm^3 for at least 6 months
Reactive causes of eosinophilia excluded
Known eosinophilic disease entities excluded
Evidence of eosinophilic end-organ damage
Clonal eosinophilic disorders excluded
Factors Favoring a Diagnosis of HES
Elevated serum immunoglobulins
Elevated levels of tumor necrosis factor or interleukins (IL-5)
Elevated serum IgE levels
Good therapeutic response to corticosteroids

DIFFERENTIAL DIAGNOSIS OF HYPEREOSINOPHILIC SYNDROME

As shown in Table 72–1, a large number of diseases have been identified that are associated with reactive, secondary eosinophilia and hypereosinophilia. Their clinical presentations vary significantly and must be clearly distinguished from HES. In particular, there are a number of eosinophilic diseases and syndromes of questionable or unknown etiology that must be differentiated from HES according to both clinical and pathologic parameters. The pathology of a number of these eosinophilic syndromes is generally restricted to specific organs; for example, eosinophilic gastroenteritis and eosinophilic pneumonia lack the multiplicity of end-organ damage generally seen in HES, and for this reason they can usually be distin-

guished from HES. In many of these disorders such as eosinophilic gastroenteritis, eosinophilic esophagitis, and eosinophilic cystitis, localized tissue eosinophilia may not be accompanied by eosinophilia in the peripheral blood. For reasons that remain unclear, these syndromes lack the propensity to evolve toward secondary eosinophil-mediated cardiac disease. Because some patients with HES exhibit evidence of vasculitic disease, and the major eosinophil-associated vasculitis is the Churg–Strauss syndrome, this syndrome likewise needs to be ruled out. The Churg–Strauss syndrome is characterized by a history of blood eosinophilia greater than 10%, asthma, pulmonary infiltrates (nonfixed), abnormalities in the paranasal sinuses, mononeuropathy or polyneuropathy, and extravascular eosinophilic infiltrates in biopsied blood vessels.[88] Necrotizing vasculitis of small arteries and veins and extravascular granulomas are characteristic findings in biopsies from most, but not all Churg–Strauss patients.[89,90] Asthma, peak eosinophil counts of greater than 1500/mm^3, and systemic vasculitis involving two or more extrapulmonary organs are generally the identifying characteristics of these patients.[90] Although neurologic, pulmonary, and possibly paranasal findings may accompany HES,[85] asthma is characteristically absent.[91] Nevertheless, it may be difficult to make a clear-cut distinction between HES and Churg–Strauss syndrome in some patients, especially as responses to high-dose corticosteroids would be identical for both at the outset.

Eosinophilic syndromes with cutaneous involvement can generally be distinguished from HES by the histopathology of biopsied skin lesions. These syndromes include Kimura's disease (angiolymphoid hyperplasia with eosinophilia), Wells syndrome (eosinophilic cellulitis), eosinophilic fasciitis, and eosinophilic pustular folliculitis. The syndrome of episodic angioedema with eosinophilia, characterized by a clinical course of periodic recurring episodes of angioedema, urticaria, fever, and marked blood eosinophilia, is not associated with end-organ cardiac damage and has thus been distinguished from HES.[12,13] The eosinophil myalgia syndrome, induced by ingestion of tainted L-tryptophan, is relegated to mainly historic interest, since there have not been any new cases following removal of the "tainted" L-tryptophan from the market.

A differential diagnosis of HES requires the exclusion of all identifiable eosinophilias of reactive, secondary etiologies (see Tables 72–1 and 72–4). These especially include eosinophilias due to parasitic infections caused predominantly by helminthic parasites, but also by two enteric protozoans, *Dientamoeba fragilis* and *Isospora belli*. In adults, filarial infections and strongyloidiasis are most likely to elicit pronounced and prolonged eosinophilias, in contrast to *Trichinella spiralis* infections, which cause an acute eosinophilia that does not persist without reinfection.[92] Infections with *Strongyloides stercoralis*, which have the capacity to induce marked hypereosinophilia that mimics HES,[85,93] are particularly important to exclude, especially because HES has been misdiagnosed in patients with unsuspected strongyloidiasis, and treatment of these patients with immunosuppressive glucocorticoids can lead to disseminated, often fatal disease.[94] Serial stool examinations and, in particular, assays for *Strongyloides* infection should be performed, e.g. strongyloides agar plate culture, since serologic ELISA assays may cross-react with other helminth infections such as Filariasis, Ascaris lumbricoides and Schistosomiasis. Parasitic helminth infections not amenable to or detectable by routine stool examinations, including tissue or blood-dwelling helminths causing filariasis, trichinosis, or visceral larval migrans[95] (*Toxocara canis* infections in children), should be evaluated by diagnostic examinations of blood, tissue biopsies, or specific serologic tests (ELISAs) that are now available.

Table 72–4 Causes of "Reactive" Eosinophilias

Allergic/Hypersensitivity Diseases
Asthma, rhinitis, drug reactions, allergic bronchopulmonary aspergillosis, allergic gastroenteritis
Infections
Parasitic Strongyloidiasis, *Toxocara canis*, *Trichinella spiralis*, visceral larva migrans, filariasis, Schistosomiasis, *Ancylostoma duodenale*, *Fasciola hepatica*, *Echinococcus*, *Toxoplasma*, other parasitic diseases Bacterial/Mycobacterial (mainly pulmonary TB) Fungal (Coccidioidomycosis, *Cryptococcus*) Viral (HIV, HSV, HTLV-II) Rickettsial
Connective Tissue Diseases
Churg–Strauss syndrome, Wegener's granulomatosis, rheumatoid arthritis, polyarteritis nodosa, systemic lupus erythematosus, scleroderma, eosinophilic fasciitis/myositis
Pulmonary Diseases
Bronchiectasis, cystic fibrosis, Löffler syndrome, eosinophilic granuloma of the lung
Cardiac Diseases
Tropical endocardial fibrosis, eosinophilic endomyocardial fibrosis or myocarditis
Skin Diseases
Atopic dermatitis, urticaria, eczema, bullous pemphigoid, dermatitis herpetiformis, episodic angioedema with eosinophilia (Gleich syndrome)
Gastrointestinal Diseases
Eosinophilic gastroenteritis, eosinophilic esophagitis (EE), celiac disease (in association with EE)
Malignancies
Hodgkin and non-Hodgkin lymphomas, acute lymphoblastic leukemia, Langerhans cell histiocytosis, angiolymphoid hyperplasia with eosinophilia (Kimura disease), angioimmunoblastic lymphadenopathy, solid tumors (eg, renal, lung, breast, vascular neoplasms, female genital tract cancers)
Immune System Diseases/Abnormalities
Wiskott–Aldrich syndrome, hyper-IgE (Job's) syndrome, hyper-IgM syndrome, IgA deficiency
Metabolic Abnormalities
Adrenal insufficiency
Other
IL-2 therapy, L-tryptophan ingestion (eosinophil myalgia syndrome), toxic oil syndrome, renal graft rejection

CLINICAL MANIFESTATIONS OF HYPEREOSINOPHILIC SYNDROME

Hematologic Findings

The definitive hematologic manifestation of HES is sustained eosinophilia of 30% to 70%, with total leukocyte counts ranging from 10,000/mm^3 to 30,000/mm^3 (see Fig. 72–4). However, extremely high leukocyte counts of greater than 90,000/mm^3 are not uncommon in some patients with HES, but are often associated with a poorer prognosis.[96] Blood smears from patients with HES generally show more or less normal, mature eosinophil morphology, including typical bilobed nuclei and granule-rich cytoplasm. However, eosinophilic myeloid precursors may also be noted, though less commonly, and eosinophils may also exhibit morphologic abnormalities including nuclear hypersegmentation, decreased size and/or numbers of secondary granules, and cytoplasmic vacuolization when viewed at the light microscope level.[11,97] The presence of myeloblasts and/or

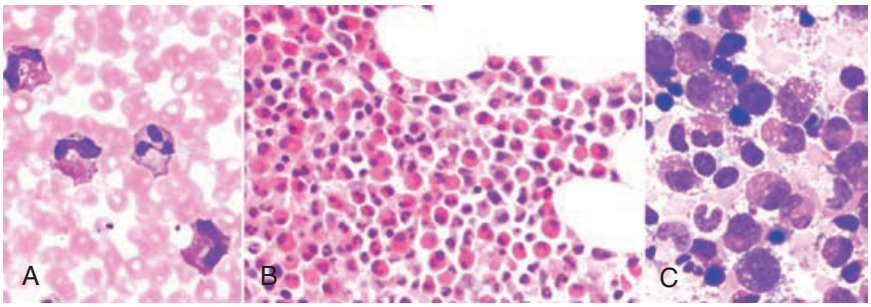

Figure 72–4 Hypereosinophilic Syndrome (**A**–**C**). The illustration is from the case of a 38-year-old woman who was found to have a marked eosinophilia when she presented with headaches, nausea and vomiting. The WBC was 16,900/uL, with 36% eosinophils (A). The bone marrow was hypercellular and showed sheets of eosinophils (B). On the aspirated material (C) eosinophils and eosinophilic precursors accounted for more than 70% of the cells. The patient had no obvious infectious process and no allergies. There was no malignancy associated with eosinophilia such as T-cell lymphoma, Hodgkin lymphoma, or other myeloid disease. Peripheral blood lymphocyte phenotyping showed no abnormal T-cell subset. Cytogenetic analysis showed a normal female karyocyte, and FISH analysis for del 4q12 showed no deletion of *CHIC2*.

dysplastic findings in the peripheral blood may suggest an alternative, clonal etiology such as AML or a myelodysplastic syndrome (Table 72–5).[83] Ultrastructurally, HES eosinophils may show a selective loss of secondary granule components (crystalloid MBP-containing core or granular matrix, or both), decreased numbers and/or size of granules, and increased numbers of cytoplasmic lipid bodies and tubulovesicular structures of unknown function.[14,48,98,99]

In addition to their hypereosinophilia, patients with HES may also present with an absolute neutrophilia, further contributing to their overall increased leukocyte counts. This may include band forms, less mature precursors, and alterations in neutrophil nuclear segmentation and cytoplasmic granules.[100] Basophilia, when seen in some HES patients, is usually minimal. Levels of leukocyte alkaline phosphatase may be abnormally elevated or decreased in HES patients,[11] and vitamin B_{12} and B_{12}-binding proteins in serum can be normal or elevated.[101,102] In the NIH series, platelet counts were found to be decreased or increased in 31% and 16% of patients, respectively.[100] Approximately 50% of HES patients may be anemic, with nucleated erythrocytes being present in the peripheral blood. The bone marrow in these patients is hypercellular with significant increases in the percentage of eosinophils (generally from 25% to 75% of marrow elements), with a clear left shift in eosinophil maturation.[100] Myeloblasts are generally normal in number, and myelofibrosis is rare, being observed in only a minority of patients in the NIH series.[100] Splenomegaly has been reported in approximately 43% of HES patients (see Table 72–3). Hypersplenism in these individuals may contribute to the development of both thrombocytopenia and anemia. Splenic pain induced by capsular distention or infarction is a frequent complication of splenic involvement in these individuals.[103] The progressive leukocytosis with hypereosinophilia in these patients, along with the hypercellular bone marrow and lack of increased numbers of myeloblasts, can make it difficult to distinguish HES from other myeloproliferative syndromes.

Cardiovascular Findings

The cardiac manifestations of HES can be frequent and considerable (approximately 50%–60% of patients) (see Table 72–3). Prior to the advent of early diagnosis, improved management, and newer therapies, cardiac disease was the leading cause of morbidity and mortality in HES patients. The cardiac and thromboembolic manifestations of HES are likely eosinophil-mediated. However, the risks of developing cardiac disease are not necessarily related to the extent or duration of the eosinophilia,[104,105] as patients who ultimately develop cardiac involvement are more likely to be males with an HLA-Bw44 phenotype, develop splenomegaly and thrombocytopenia, have elevated vitamin B_{12} levels, and have abnormal hypogranular and vacuolated blood eosinophils and circulating early myeloid progenitors.[104] In contrast, those HES patients who do not develop heart disease tend to be females with angioedema, hypergammaglobulinemia, and increased serum IgE levels and immune complexes.[104] The cardiac damage seen in HES, progressing from early necrotic changes through thrombosis and fibrosis, is identical to that seen in patients with hypereosinophilias of diverse etiologies. These include tropical eosinophilias caused by loiasis or other filarial infections and parasitic infections such as trichinosis and visceral larval migrans,[106] drug reactions or administration of GM-CSF,[107] and eosinophilias of neoplastic origin including eosinophil leukemia, various carcinomas,[108] and Hodgkin or non-Hodgkin lymphomas.[109] Because identical forms of cardiac pathology can develop in patients with hypereosinophilias of diverse etiologies, and some patients never go on to develop cardiac involvement, the pathogenesis of eosinophil-associated cardiac disease likely involves both eosinophils and as yet undefined factors required for the recruitment, activation, and secretion of these eosinophilic constituents in the heart and associated cardiovascular tissues.

Eosinophilic endomyocardial fibrosis, as first described by Löffler,[110] is pathologically similar to that of tropical endomyocardial fibrosis,[111,112] save for the frequent absence of eosinophilia in the latter disorder.[110] However, the general absence of hypereosinophilia in patients with tropical endomyocardial fibrosis is thought to be a function of the late stage of helminthic disease in which the heart disease develops. The histopathology of cardiac involvement in HES is well characterized and can evolve through three sequentially defined stages for which eosinophils and secretion of eosinophil-derived mediators may be directly involved in the pathogenesis. These include (a) an initial acute necrotic stage of short duration (5 weeks) involving active endomyocarditis, (b) a later thrombotic stage (10 months) with

mural thrombus formation over endocardial lesions, and (c) a late fibrotic stage (after approximately 2 years of illness) with development of endomyocardial fibrosis.[113] The early necrotic stage with damage to the endocardium, involves marked eosinophil and lymphocyte infiltration of the myocardium with myocardial necrosis, formation of eosinophilic microabscesses, and eosinophil degranulation. However, this early necrotic stage of cardiac disease is usually not recognized clinically. Echocardiography and angiography may fail to detect abnormalities in this early stage of the disease because ventricular thickening has not yet occurred, and endomyocardial biopsies, generally from the right ventricle, are required to make the diagnosis of cardiac involvement.[86] Treatment of HES patients with corticosteroids during this acute necrotic stage may avert or control the subsequent development of myocardial fibrosis. However, patients often present at the later stages of the cardiac involvement. In the second stage, thrombi form over the damaged endocardium in either of the ventricles or the atrium, generally with sparing of the aortic and pulmonary valves.[114] Progressive scarring at sites of mural thrombus formation ultimately leads to the late fibrotic stage, with endomyocardial fibrosis resulting in a restrictive cardiomyopathy and mitral or tricuspid valve regurgitation, or both. The more common clinical manifestations in the later progressive stages of endomyocardial fibrosis include dyspnea, chest pain, signs of left or right ventricular congestive heart failure, or both, murmurs from mitral valve regurgitation, cardiomegaly, and T-wave inversions.[114] Most patients who progress to this stage of HES cardiomyopathy will benefit from standard medical therapies for congestive heart failure, or mitral valve replacement where hemodynamically indicated. Two-dimensional echocardiography is the most sensitive method for detecting cardiac abnormalities in these patients, with visualization of mural thrombi and the various manifestations of fibrosis, including thickening of the mitral valve and its supporting structures. Approximately 80% of HES patients in the NIH series had echocardiographic abnormalities, with thickening of the left ventricular free wall the most common finding (68% of patients).[114] Cardiac catheterization may also be useful for demonstrating elevated right and left ventricular end diastolic pressures, and angiography may be used to visualize valvular incompetence. Although electrocardiographic changes in these patients are common, they are not specific to HES. Recently, intractable coronary artery spasm has been reported as the sole cardiovascular manifestation of HES.[115]

Histopathologic evaluation of the heart of HES patients generally shows four dominant features: (a) endocardial fibrosis and thickening, including involvement of mitral valve and supporting structures; (b) mural thrombus and granulation tissue on the endocardium with extensive infiltration by eosinophils; (c) thrombotic and fibrotic involvement of small intramural coronary vessels, including inflammatory cells and eosinophils; and (d) eosinophilic infiltration of the endocardium and, in some cases, of the myocardium. In a multicenter study of biopsy and postmortem specimens of cardiac tissue from HES patients at various stages of eosinophilic endomyocardial disease, activated eosinophils (identified by staining with the EG2 anti-ECP monoclonal antibody) and marked intracardiac extracellular deposition of eosinophil granule cationic proteins, including MBP, ECP, and EDN/EPX in the early necrotic and later thrombotic lesions, were identified mainly in areas of acute tissue damage on and beneath the endocardium, myocardial necrosis, and in the walls of small vessels.[65] The presence of activated eosinophils and toxic granule proteins in the early lesions of this disease suggests an active role for eosinophils and their products in inducing endocardial damage and myofibrillar injury, although the mechanisms involved in eosinophil recruitment into the heart have yet to be identified. In vitro studies have shown that secretion products of activated eosinophils can damage rat heart cell plasma membranes.[116] In addition, eosinophil peroxidase in the presence of hydrogen peroxide and bromide or thiocyanate ion can induce damage to the endothelium of the working isolated rat heart,[117] and eosinophil granule proteins can impair thrombomodulin activity,[118] findings that support a role for these eosinophil products in the development of endocardial injury and subsequent thrombotic events in the HES.[119] The in vitro findings that eosinophil secretion products such as EDN can induce fibroblast proliferation,[120] that ECP alters fibroblast proteoglycan synthesis,[121] and that MBP can augment IL-1 or TGF-β-induced production of inflammatory cytokines (IL-6 and IL-11) by fibroblasts,[122] further implicates the eosinophil in the development of endocardial fibrosis in later stages of the disease.

Table 72–6 Diagnosis of Chronic Eosinophilic Leukemia

Mature eosinophils in blood
Establish clonality
No dysplastic morphological features
Absence of *BCR-ABL*-positive cells
Absence of clonal lymphoproliferation
Presence of the *FIP1L1-PDGFRα* gene fusion (interstitial deletion of *CHIC2* on chromosome 4q12) **OR**
Elevated levels of serum tryptase (a surrogate marker for the *FIP1L1-PDGFRα* gene fusion)
Presence of the *ETV6-PDGRFβ* gene fusion (in patients with chronic myeloproliferative diseases with eosinophilia)

OTHER MAJOR CLINICAL MANIFESTATIONS OF HYPEREOSINOPHILIC SYNDROME

Pulmonary Findings

The overall pulmonary involvement reported for HES patients is approximately 50% (Table 72–6), with the most common respiratory problem being a chronic and persistent, usually nonproductive cough. Although the physiologic basis for pulmonary involvement in HES is not known, it may be secondary to aspects of congestive heart failure or numerous other factors, including infiltration and sequestration of eosinophils in lung tissues or pulmonary emboli originating from ventricular thrombi. Of note, although bronchospasm has been noted in some series of patients,[123] asthma is apparently quite rare in HES.[124] Transudative pleural effusions are the most common abnormality in patients with frank congestive heart failure.[11] In contrast to chronic eosinophilic pneumonia,[125] the pulmonary infiltrates seen in 14% to 28% of HES patients[11,122] were either diffuse or focal, without any preference for particular regions of the lung. Pulmonary infiltrates in HES may or may not clear with prednisone treatment, and pulmonary fibrosis can develop in patients with endomyocardial fibrosis.[85]

Neurologic Manifestations

As noted in Table 72–5, neurologic involvement is quite frequent in HES (approximately 50% of patients), encompassing three different complications.[126] The first type of neurologic involvement is caused by thromboemboli, which may originate from intracardiac thrombi in the left ventricle. These thromboembolic episodes may occur even before overt cardiac disease is visible by echocardiography. Patients with thrombotic complications may experience embolic strokes or transient ischemic episodes that may be multiple and recurrent, and these episodes may occur even though the patient is adequately anticoagulated with coumadin and antiplatelet agents.[86,126] The second type of neurologic manifestation involves primary diffuse central nervous system (CNS) dysfunction of unknown etiology. HES patients may variably exhibit changes in behavior, confusion, ataxia, and loss of memory.[126] The third neurologic dysfunction noted in HES is the development of peripheral neuropathies, which can occur

in approximately 50% of HES patients exhibiting neurologic involvement.[126] These include symmetric or asymmetric sensory polyneuropathies, including sensory deficits, painful parathesias, or mixed sensory and motor defects.[126–128] These neuropathies may improve with steroid administration or other treatments, may be stable or continue to progress despite therapy, or may improve or resolve with time. The histopathology of the involved nerves usually shows varying degrees of axonal loss, without evidence of vasculitis or direct or peripheral eosinophil infiltration.[126–128] The presence in eosinophils of two granule cationic proteins, eosinophil-derived neurotoxin (EDN)[129] and eosinophil cationic protein,[130] both equally potent in inducing a neurotoxic and paralytic syndrome known as the Gordon Phenomenon[129,131] when injected experimentally (intrathecally) into rabbits,[132] has led to speculation that these proteins might be responsible for inducing the various neuropathies commonly seen in HES. The histopathology of the cerebrocerebellar dysfunction in the brains of experimental rabbits undergoing the Gordon Phenomenon includes a spongiform degeneration of white matter and loss of Purkinje cells,[131] changes not comparable to the peripheral axonal nerve damage seen in HES. Both EDN and ECP, related approximately 16-kd cationic proteins with 70% amino acid sequence homology,[133,134] are members of the ribonuclease gene family and possess potent ribonuclease activity and cellular toxicities in vitro.[134] However, there is no direct evidence that these ribonucleases and cellular toxins have the capacity to mediate the types of neurologic damage seen in HES, nor have these proteins been visualized by immunochemical means at sites of HES neuropathology. Marked elevations in CSF levels of IL-5, MBP, and EDN have been documented in two children with raccoon roundworm infections, progressive neurologic deterioration, and deep white matter changes on magnetic resonance images of the brain. This was the first report of MBP and EDN measurements in the CSF associated with human disease.[137] Thus, the pathogenesis of the encephelopathic, CNS, and peripheral manifestations of HES-associated neuropathy remain speculative.

Cutaneous Manifestations

For reasons that remain unclear, the skin is frequently involved in HES pathology, with cutaneous manifestations present in greater than 50% of patients in most series (see Table 72–6).[11,85,135] The skin lesions associated with HES most commonly fall into three categories: (a) angioedematous and urticarial; (b) erythematous, pruritic papules, and nodules; and (c) mucosal ulcerations. As noted earlier, patients with angioedema and urticaria are more likely to have a benign disease course that is responsive to corticosteroids, without the development of cardiac or neuropathic complications.[85,103] A subgroup of HES patients with cyclic angioedema and eosinophilia are now considered to have a syndrome (episodic angioedema with eosinophilia) that is distinct from classic HES.[13] These patients have a disorder with recurrent attacks of angioedema, urticaria, fever, and bodyweight gain that can be quite pronounced. These clinical manifestations are associated with marked leukocytosis and eosinophilia during the episodes. In HES patients who develop papular or nodular lesions, these usually improve concomitantly with positive responses to systemic therapy.[136] Dermal biopsies in these patients generally show mixed cellular infiltrates including eosinophils, without signs of vasculitis.[136] Perivascular eosinophilic infiltrates are also found in these lesions.[136] The aquagenic erythematous pruritic eruptions and indurated papules and nodules in some HES patients have been found to respond to psoralen and ultraviolet light A therapy (PUVA),[138,139] and in some patients, this treatment has interestingly been accompanied by a return of eosinophil counts to normal.[137] PUVA therapy may also be effective for the cutaneous manifestations of HES associated with HIV infection (exfoliative erythroderma, linear flagellate plaques).[140] HES-associated pruritus and nodular lesions have also been controlled with the addition of Dapsone (75–150 mg/day) to prednisone.[141] Oral sodium cromoglycate (cromolyn sodium) given before meals has also been reported to be efficacious,[142] though neither of these agents had any effect on peripheral eosinophilia. Severe and sometimes incapacitating mucocutaneous ulcerations may be a prodrome to HES and indicate a subset of HES patients with a poor prognosis.[141,142] They can occur at multiple sites, including the mouth, nose, pharynx, penis, esophagus, stomach, and anus,[143,144] and lesions can flare up independent of other clinical manifestations of HES. Biopsies of the ulcerative lesions usually show mixed cellular infiltrates, without a predominance of eosinophils or any evidence of vasculitis or microthrombi.[143] These ulcers have generally been resistant to treatment with topical or systemic corticosteroids, colchicine and hydroxyurea, but have recently been shown to respond remarkably well to IFN-α with complete and durable remissions.[145,146]

Eosinophils are present in many skin diseases and, in certain conditions, may constitute part of the diagnostic histology of the lesion.[147] Although eosinophils in general may not appear prominent in many cutaneous diseases, there is now ample evidence to suggest that they may nevertheless participate in the pathogenesis of cutaneous inflammation[4,148] and contribute to edematous reactions in atopic dermatitis,[61] syndromes associated with acute[149,150] and chronic urticarias,[78] IgE-mediated late-phase reactions,[151] chronic dermatitis associated with parasitic infections such as onchocerciasis,[58] episodic angioedema with eosinophilia,[13] eosinophilic cellulitis,[151] and skin lesions associated with rIL-2 administration for advanced malignancies.[152] Indirect evidence includes the ability of the eosinophil to elaborate its granule cationic proteins, some of which are capable of inducing release of vasoactive amines from basophils and mast cells and inducing cutaneous wheal-and-flare reactions following direct injection into human skin,[148] and production of lipid mediators such as LTC_4 and PAF, both potent inducers of vasopermeability in vivo. In addition, levels of eosinophil-active IL-5 are elevated in the syndromes of episodic angioedema with eosinophilia,[12] eosinophil-associated toxicity due to IL-2 administration,[153] and in the acute inflammatory response (Mazzotti reaction) in human patients with onchocerciasis treated with diethylcarbamazine.[154]

By far, the most direct evidence to date for eosinophil participation in the etiology of the skin diseases listed earlier has been the immunochemical detection, generally by immunofluorescent staining of skin biopsies, of prominent extracellular deposits of eosinophil granule cationic proteins such as MBP, ECP, or EDN, but not neutrophil products (neutrophil elastase) in affected but not unaffected skin, and in the absence of prominent numbers of intact eosinophils in lesional infiltrates. One example is the IgE-mediated late-phase reaction that follows the wheal-and-flare response characteristic of type I, IgE-mediated hypersensitivity. This classic late-phase reaction characterized clinically by erythema, edema, pruritus, and tenderness peaking 6 to 12 hours after intradermal antigen or anti-IgE challenge, involves infiltration by mononuclear cells, neutrophils, basophils, and eosinophils presumably in response to mast cell degranulation, along with extensive extracellular deposition of eosinophil (MBP) and neutrophil (elastase) granule products.[151] The secretion and extracellular deposition of eosinophil granule constituents, shown to possess potent cytotoxic and proinflammatory activities in edematous and eczematous lesions, clearly suggests that eosinophils may contribute to the pathogenesis of both acute and chronic skin diseases, including the cutaneous lesions associated with HES.[155] However, studies elucidating the mechanisms that regulate eosinophil recruitment, activation, and secretion in the skin are still needed to more clearly understand the dynamics of eosinophil participation in these cutaneous disorders and to identify potential therapeutic approaches to selectively block their influx and function.

ETIOLOGY OF HYPEREOSINOPHILIC SYNDROME

Hypereosinophilic Syndrome Versus Eosinophil Leukemia

The hypereosinophilic syndrome has historically been confused with chronic eosinophil leukemia (CEL), especially because distinguishing between malignant versus nonmalignant causes of hypereosinophilia

Table 72–7 Published Reports of Imatinib Use in Hypereosinophilic Syndrome, Chronic Eosinophil Leukemia, and Systemic Mastocytosis With Eosinophilia

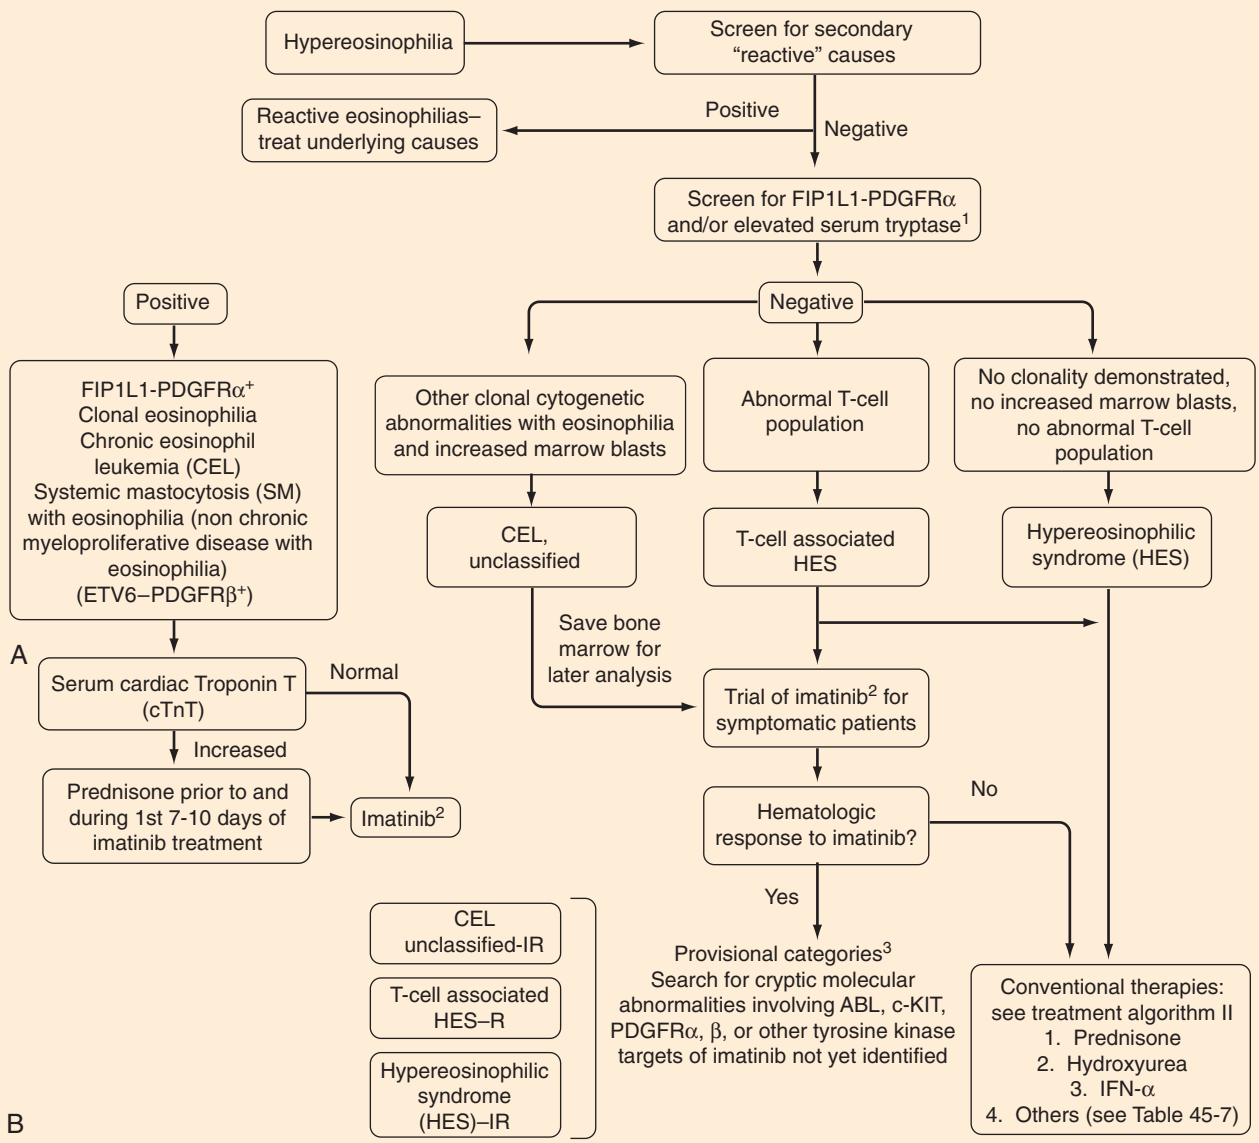
Author (Year)[Reference]	No. Patients Treated With Imatinib	Disease	Response*	Comments
Schaller and Burkland† (2001)[159]	1	HES	CR	Initial report; rapid hematologic remission on imatinib 100 mg/day
Gleich et al† (2002)[163]	5	HES	4 CR	IL-5 levels were normal in responders
Ault et al† (2002)[166]	1	HES	CR	Resolution of 70% eosinophilia in 18 days on imatinib 100 mg/day
Pardanani et al† (2003)[160,166]	7	HES,	3 CR	IL-5 levels were elevated in responders
		Eos-CMD	1 PR	
Cortes et al† (2003)[164]	9	HES	4 CR	3 responses at imatinib 100 mg/day; 1 response at 400 mg/day
Cools et al (2003)[165]	11	HES/CEL	9 CR	*FIP1L1-PDGFRα* fusion present in 5/9 responders
Klion et al (2004)[161]	7	HES-MPD	7 CR	Molecular remission in 5 of 6 patients tested for *FIP1L1-PDGFRα* after 1–12 months of imatinib
Klion et al (2003)[162]	6	HES-MPD	6 CR	Serum tryptase is a surrogate marker for the *FIP1L1-PDGFRα* fusion and imatinib responsiveness; an HES subtype with mast cell dysplasia distinct from SM with eosinophilia
Pardanani et al (2003)[268]	6	SM with eosinophilia	3 CR	Responders had *FIP1L1-PDGFRα* fusion and no *D816V KIT* mutation

CR, complete hematologic remission; Eos-CMD, eosinophilia-associated chronic myeloproliferative disorder; HES-MPD, myeloproliferative variant of HES; PR, partial hematologic remission; SM, systemic mastocytosis.

*Refer to individual studies for their specific response criteria.

†*FIP1L1-PDGFRα* fusion was not assessed in these studies.

Reproduced and updated with permission from Gotlib J, Cools J, Malone JM, et al: The FIP1L1-PDGFRα fusion tyrosine kinase in hypereosinophilic syndrome and chronic eosinophilic leukemia: Implications for diagnosis, classification, and management. Blood 103:2879, 2004.



can be quite difficult.[83] Truly malignant acute eosinophil leukemias have several distinguishing characteristics such as a marked increase in the numbers of immature blood and/or bone marrow eosinophils, greater than 10% blast forms in the bone marrow, tissue infiltration with immature eosinophilic cells, and a clinical course and findings that tend to resemble other acute leukemias, including anemia, thrombocytopenia, and increased susceptibility to infections.[57] However, because the cardiac and neurologic manifestations of HES can also develop in chronic eosinophil leukemia, they cannot be used as distinguishing clinical features.

In contrast, CNS infiltration by eosinophils and the tendency to produce bone myeloblastomas are features more frequently associated with acute eosinophil leukemia.[57] Chromosomal abnormalities may occur with both HES and chronic eosinophil leukemia, but eosinophil leukemia is more frequently associated with chromosomal anomalies characteristic of other acute nonlymphocytic leukemias including 8:21 and 10p+11q− translocations, and trisomy-1. In addition, eosinophil leukemia has been reported as a variant of the M4Eo phenotype of acute myelomonocytic leukemia with eosinophilia, now linked to inversion 16 chromosomal abnormalities.[156–158]

Molecular explanations for the development and pathogenesis of HES and CEL have been elusive, and clinical differentiation between these indolent and often aggressive hypereosinophilias has been difficult at best. However, recent reports indicating that some patients with HES or CEL respond effectively to imatinib mesylate (Gleevec) with complete hematologic and cytogenetic remissions (Table 72–7),[159–166] and at fourfold lower doses in most patients than typically employed to treat chronic myelogenous leukemia (CML) (100 mg/day vs 400 mg/day),[159,163,164,166] suggested that these *BCR-ABL*-negative patients might possess abnormal gene fusions or activating mutations that generate novel tyrosine kinase targets of imatinib. These findings sparked a "reverse" bedside-to-bench translational research effort by several research laboratories to rapidly identify the constitutively active tyrosine kinase targets of imatinib in these HES patients. Possible targets included the known activated kinases such as ABL, platelet-derived growth factor receptor (PDGFR), or c-KIT, all of which have been shown to be inhibited by imatinib mesylate. These efforts rapidly bore fruit with the successful identification of an activated tyrosine kinase gene fusion on chromosome 4q12, which is produced by a novel interstitial chromosomal deletion of the *CHIC2* domain, fusing an uncharacterized human gene known as FIP1-like-1 (*FIP1L1*) to the platelet-derived growth factor receptor-α gene (*PDGFRα*).[163] These findings have significantly changed the current paradigm for the diagnosis and therapeutic options available for patients with HES and CEL (see Table 72–8),[167] with significant implications for the reclassification and management strategies for these hypereosinophilias.[167] Of importance, not all HES and CEL patients respond to imatinib,[163] and the majority of patients who do respond with hematologic remissions have been male and not female.[159–166] (There is apparently only a single report thus far of a female HES patient being imatinib responsive. One of us (JHB) has now treated two female patients who are responsive to Gleevec.) Importantly, approximately 40% of the patients who do respond to imatinib lack the *FIP1L1-PDGFRα* gene fusion,[165,167] suggesting genetic heterogeneity in HES/CEL and the likely presence of other novel fusion genes (eg, with *ABL*, *ARG*, *PDGFRα*, *PDGFRβ*, or *KIT*) or gene mutations thereof, that generate imatinib-sensitive constitutively active tyrosine kinases. As for CML patients with the *BCR-ABL* fusion, HES/CEL patients with the *FIP1L1-PDGFRα* fusion may relapse during imatinib therapy through the acquisition of a resistance mutation (T674I) in the PDGFRα ATP-binding region at the same position as the T315I mutation in *BCR-ABL* known to confer imatinib resistance.[168–170] Of note, a recent study by Cools and colleagues[171] has demonstrated in a murine bone marrow transplant model the efficacy of PKC412, an alternative inhibitor of PDGFRα, as a potentially effective treatment for FIP1L1-PDGFRα-induced disease and imatinib-induced resistance due to the T674I mutation.[171]

Diagnosis and Treatment of Hypereosinophilias

The mechanism of action by which the *FIP1L1-PDGFRα* gene fusion leads to the proliferation and differentiation of the eosinophil lineage over other myeloid lineages in these patients is unclear and under investigation in a number of laboratories. Initial investigations suggest that STAT5 may be one of the downstream targets of FIP1L1-PDFGRα tyrosine kinase activity. Studies have demonstrated that retroviral transduction-mediated overexpression of STAT5a in umbilical cord blood-derived $CD34^+$ human stem/progenitor cells selectively amplifies their commitment, proliferation, and terminal differentiation to the eosinophil lineage in vitro in the presence of IL-5,[172] and that STAT5 activation by tyrosine kinases such as BCR-ABL can contribute to the transformation of leukemic cells.[173] Of interest, it was recently shown in a murine transgenic model that the FIP1L1-PDGFRA fusion gene itself is not sufficient to induce an HES/CEL-like disease independently, but requires a second event, that is, overexpression of IL-5.[174] For a comprehensive discussion of the implications of these breakthrough findings, the new screening and therapeutic options for HES, CEL, and related hypereosinophilias (eg, systemic mastocytosis with eosinophilia), and the reclassification of some forms of classic HES to CEL based on identification of the *FIP1L1-PDGFRα* gene fusion and imatinib responsiveness, the reader is directed to the recent review published by Gotlib and colleagues.[167]

[1] Screen for increased serum tryptase as a surrogate marker if the FIP1L1-PDGFRα test is not available

[2] Assay for increases in cardiac troponin T (cTnT) for the first 7-10 days of imatinib treatment; if elevated, add treatment with prednisone for 7-10 days until serum troponin T levels are normal.

[3] Proposed re-classification of eosinophilic disorders: FIPIL1-PDGFRα-positive chronic eosinophilic leukemia (F-P^+CEL); chronic eosinophilic leukemia, unclassified; hypereosinophilic syndrome (HES); T-cell associated HES
Provisional categories based on imatinib treatment; CEL, unclassified-imatinib responsive (IR); HES–IR T-cell associated HES-IR.

Table 72–8 Therapeutic Options for the Hypereosinophilic Syndrome

Therapy	Indications
None	If no evidence of organ involvement and eosinophil counts <2000/mm^3 (ie, those patients with eosinophilia, but without any other defining features of HES), patients should be monitored closely and periodically without treatment, for at least 6 months and possibly indefinitely. Hold off therapy as long as the eosinophil counts are stable, echocardiograms are normal, and there are no new clinical signs or symptoms of end organ damage. Reinvestigation of the etiology of the eosinophilia is warranted and recommended every 3 months to reconfirm a diagnosis of HES.
First-Line Therapies:	
Prednisone	First-line agent for those with organ involvement; if effective in suppressing peripheral blood eosinophilia, dose (= 7.5 mg/day) may be tapered or changed to every other day, but check eosinophil counts on both the on and off days; response to prednisone is associated with a better patient prognosis. "Pulse" IV with methylprednisolone (1 g/day for 3–5 days) useful for reversing CNS deterioration.
Hydroxyurea	Used in those patients with organ involvement and eosinophilia unresponsive to corticosteroids; anemia, thrombocytopenia, or both, is very common with chronic therapy. Anemia is sometimes responsive to erythropoietin. Not useful as a single agent, but in combination with prednisone or IFN-α, or Gleevec allowing improved response and lower dose of prednisone or IFN-α.
Interferon-α	Biologic response modifier used with success in more than 20 publications worldwide to date. The combination of IFN-α and hydroxyurea works well in many patients. Significant limiting side effect may be depression. May be contraindicated in patients with a $CD3^-/CD4^+$ population[7]
Imatinib mesylate (Gleevec)	Identification of the *FIP1L1-PDGFR*α fusion gene product (interstitial chromosomal deletion of 4q12), increased serum tryptase (surrogate marker for the *FIP1L1-PDGFR*α fusion), evidence of a clonal cytogenetic abnormality (eg, clonal eosinophilia, chronic eosinophil leukemia, increased marrow blasts, or diagnosis of systemic mastocytosis with eosinophilia). However, patients with systemic mastocytosis with the D816V c-kit mutation do not respond to Gleevec, and it may accelerate the disease. Patients with chronic myeloproliferative disease with eosinophilia and the *ETV6-PDGFR*β mutation also respond to Gleevec. Acute cardiac decompensation has been observed. Not useful in "L-HES."
Second-Line Therapies:	
Alkylating agents	Chlorambucil and others; may be administered in 4-day pulse doses repeated as dictated by the magnitude of blood eosinophilia.
Vincristine	May be useful for acute reduction of eosinophil numbers and to treat eosinophil leukemia when eosinophil counts become excessive (= 50,000 to 75,000/mm^3); can be administered episodically to control HES, often with amelioration of thrombocytopenia. Can cause liver failure and is almost never used unless first-line therapies fail to control eosinophilia and other symptoms.
Other biologic response modifiers	Eg, cyclosporine. Experience with these agents is still very limited, but they have been used with some apparent successes in a few case reports. No long-term follow-up data are available.
Cardiac surgery	Indicated for serious mitral regurgitation with bioprosthetic mitral valve replacement; less commonly, thrombectomy or endomyocardectomy.
Other Treatments With Poorly Defined Therapeutic or Management Roles:	
Pheresis	Plasma and leukapheresis have no defined role in long-term management of HES; use is usually restricted to emergency situations for patients developing profoundly high eosinophil counts; cell counts rebound to prepheresis levels within 1 day.
Antiplatelet agents/anticoagulation	Thrombotic/thromboembolic events are a frequent serious HES complication; anticoagulation is administered where thromboemboli or intraventricular thrombi have been identified; effectiveness in HES not established.
Splenectomy	No established role in routine management of HES; may ameliorate platelet sequestration from hypersplenism; relieve pain from splenic distention and infarctions common to those HES patients with splenomegaly.
Stem cell transplantation	Clinical experience still very limited. Minitransplants and stem cell transplants tried with success in a small number of case reports. Risks do not appear to be justified unless patients have an extremely aggressive disease course that is refractory to all other preferred modalities listed here—a last-line therapy.
Monoclonal Antibodies:	
Anti-IL-5 antibody	Currently in clinical trials, but not FDA approved for any indication at present. Clinical data are still very limited, but look very promising for the treatment of a wide range of patients with HES[218,228–231] and possibly other eosinophilias (eg, eosinophilic gastrointestinal syndromes such as eosinophilic esophagitis).[228,234] Thus far shown to be well-tolerated and steroid sparing in a large multicenter trial of Mepolizumab™ treatment of *FIP1L1-PDGFRA*-negative HES patients.[228–234] Not a cure as responses may be temporary.[232]
Anti-CD52	Alemtuzumab—limited experience. Has been useful in cases of "L-HES."[9]

Lymphomas and Hypereosinophilia

A number of lymphomas may be associated with the development of eosinophilia, including Hodgkin lymphoma,[175] T-cell lymphoblastic lymphoma,[176] and adult T-cell leukemia/lymphoma,[177] but the eosinophilia is generally much more modest than that seen in HES. In contrast, there are several reports of patients presenting with classic clinical and hematologic features of HES who have gone on to develop acute lymphoblastic leukemias[178–181] or T-cell lymphomas.[182–185] In a number of T-cell lymphoma cases, the accompanying eosinophilias were shown to be associated with the production of eosinophilopoietic cytokines (GM-CSF, IL-3, or IL-5) by the lymphomas themselves.[186,187]

PATHOGENESIS OF EOSINOPHIL-ASSOCIATED END-ORGAN DAMAGE IN HYPEREOSINOPHILIC SYNDROME

According to the current understanding of eosinophil function and hypereosinophilic conditions, sustained eosinophilia, regardless of origin (whether reactive, clonal, or idiopathic), has the capacity to lead to end-organ damage. The multiple manifestations of such eosinophil-associated end-organ damage are considerable (see Table 72–6), and their identification and management have been discussed in many reports and reviews.[57,82,84,92,124,188] However, not all cases of sustained hypereosinophilia necessarily lead to end-organ damage. For example, patients with syndromes such as eosinophilic pneumonia and episodic angioedema with eosinophilia[13] characteristically fail to develop the cardiac damage characteristic of HES patients. Experimentally, IL-5 transgenic mice, which develop extremely high numbers of peripheral blood eosinophils, do not develop significant end-organ damage, suggesting that other factors in addition to IL-5 are likely necessary for eosinophil recruitment to the tissue, eosinophil activation, and tissue damage.[26,27] Other factors may be necessary to induce eosinophilic end-organ damage, such as secretion of eosinophil-active inflammatory or hematopoietic cytokines (eg, GM-CSF), genetic predisposition, clonal T-cell dysfunction, development of a T_{H2} instead of T_{H1} T-cell profile, or in situ production of cytokines that block eosinophil apoptosis and enhance eosinophil survival and activation. Because of rather limited experience, it is not currently known whether true myeloproliferative eosinophilic disorders of clonal origin have the capacity to lead to end-organ damage. Of note, HES patients in the National Institutes of Health (NIH) series who ultimately developed cardiac disease exhibited features suggestive of a diagnosis of myeloproliferative disease, including splenomegaly, thrombocytopenia, anemia, elevated B_{12} levels, cytogenetic abnormalities, and circulating myeloid precursors and myeloid dysplasia.[82,85] As noted earlier, the eosinophil expresses a number of granule cationic protein mediators capable of inducing thrombotic events,[189] endothelial and endocardial damage,[65] and neurotoxicity (the ribonucleases EDN and ECP).[133,134] Eosinophil granule MBP and ECP are potent cellular toxins capable of damaging normal host cells and tissues in a manner reminiscent of end-organ damage associated with tissue eosinophilia.[1,190] In addition, the eosinophil has the capacity to undergo a potent respiratory burst on activation, generating reactive oxidative species that can directly, or in association with eosinophil peroxidase, induce oxidant-mediated tissue damage.[117,119,191] However, the mechanisms by which eosinophils induce thrombosis and the thromboembolic events associated with hypereosinophilic diseases, such as idiopathic HES, remain unclear, especially because most investigators have failed to identify consistent systemic alterations in coagulation and fibrinolytic pathways in these patients.[85,86] However, studies by Slungaard and colleagues suggest that eosinophil granule cationic proteins have the capacity to alter thrombomodulin activity, suggesting one possible mechanism for thromboembolism in hypereosinophilic heart disease.[118]

THERAPY AND PROGNOSIS FOR HYPEREOSINOPHILIC SYNDROME

The earlier literature on HES is filled with reports of poor to dismal patient prognosis. For example, a 1975 review by Chusid and colleagues of 57 published cases indicated an average survival time of 9 months, with a 3-year survival of only 12%.[11] The high morbidity and mortality reported in these reviews of prior decades likely reflect the fact that most HES patients tended to present late with more advanced disease, in particular, significant cardiovascular problems. Deaths in these patients were generally the result of congestive heart failure and secondary complications of endomyocardial disease, including bacterial endocarditis, progressive valvular incompetence, and the thromboembolic sequelae of the syndrome.[57,124] However, earlier diagnosis of HES, along with improved clinical and echocardiographic methods for monitoring, and use of cardiac medications and cardiothoracic surgical procedures not previously available, has resulted in more successful prevention and management of cardiac disease in these patients, considerably improving clinical outcome and survival. A report in 1989 of 40 HES patients in France reported 80% survival after 5 years and 42% survival at 10 and 15 years.[123] Thus, for many patients, prevention and management of HES end-organ damage, in particular the cardiac sequelae, result in prolonged survival over decades.[82,124] Current previously unavailable supportive therapies for managing the cardiovascular complications of HES, along with therapies aimed at controlling the eosinophilia to prevent end-organ damage in the first place, are the mainstay of HES treatment regimens (Table 72–8).[82] Treatment should focus on controlling end-organ damage, not just on suppressing or eradicating the eosinophilia, especially as the severity of cardiovascular complications of HES do not necessarily correlate with the duration or level of eosinophilia.[104,105] Although more aggressive treatment (eg, cytotoxic chemotherapy or bone marrow transplant) may be indicated and necessary in selected patients, the current goal is chronic maintenance therapy. In a 1992 review of HES, Spry[124] points out that overaggressive cytotoxic therapy for some HES patients may be more deleterious than the HES itself, with the risk of marrow aplasia.[11] Current diagnostic and therapeutic options for the treatment and management of HES are listed in Table 72–4, the box on Diagnosis and Treatment of Hypereosinophilias, and the box on Treatment Strategies for *FIP1L1-PDGFR*α-negative Eosinophilias, and are described in greater detail later. Recent experience with the use of biologic response modifiers, in particular interferon-α, show considerable promise for durable remissions of eosinophilia and clinical signs and symptoms, particularly in patients with resistant disease, but also in HES patients, in general, as a first line-therapeutic option.[84]

INITIAL THERAPEUTIC OPTIONS

Patients meeting the diagnostic criteria for HES (see Table 72–2) or CEL (Tables 72–9 and 72–10) should be managed according to the newest strategies as defined in the two algorithms shown for hypereosinophilias (see box on Diagnosis and Treatment of Hypereosinophilias, and box on Treatment Strategies for *FIP1L1-PDGFR*α-negative Eosinophilias, as adapted and modified from the original algorithm of Schooley and colleagues[192] and recently updated for this chapter based on Gotlib et al[167] with permission). Patients without any overt evidence of organ dysfunction or severe symptoms and with eosinophilia counts less than 1500 to 2000 eosinophils/mm^3 can be monitored closely and periodically without treatment for at least 6 months and possibly indefinitely, so long as their complete blood counts are stable, their echocardiograms normal, and there are no new clinical signs or symptoms of end organ involvement. Periodic reinvestigations of the etiology of the eosinophilia are highly appropriate and recommended every 3 to 6 months to reconfirm the diagnosis of HES. Of note, patients with eosinophilias routinely greater than 2000 eosinophils/mm^3 that meet the previously defined criteria for HES should be treated, regardless of the absence of clinical signs and symptoms of end organ involvement, see box on Diagnosis of Hypereosinophilic Syndrome (HES). Patients with negative clinical evaluations for secondary, reactive causes of their eosinophilia (Table 72–4) should subsequently undergo testing for the *FIP1L1-PDGFR*α fusion gene product, or if this test is unavailable, for elevated serum tryptase as a surrogate marker. Those positive for the fusion or with elevated serum tryptase, or both, can be classified as having one of the *FIP1L1-PDGFR*α-positive clonal eosinophilias (eg, CEL or systemic mastocystosis [SM] with eosinophilia). A negative test for the gene fusion or normal serum tryptase level would classify the patient into one of the three diagnostic categories based on additional laboratory criteria: CEL, unclassified, T cell-associated hypereosinophilic syndrome (HES), or classic HES. A trial of imatinib mesylate is recommended for *FIP1L1-PDGFR*α-positive CEL or SM patients with eosinophilia; there is still some debate whether the latter *FIP1L1-PDGFRA+* patients represent HES with increased bone marrow mast

Table 72–10 Major Factors Supporting a Diagnosis of Clonality in Hypereosinophilia

Cytogenetic abnormalities
FISH for FIP1L1-PDGFRA mutations in eosinophils
G6PD alloenzymes in heterozygote females
Cultured eosinophil colonies with abnormal cytogenetics
Grade III bone marrow fibrosis
Trilineage blood or bone marrow myelodysplasia
Abnormal localization of immature precursors (ALIP)
Activating mutations in the *K ras* oncogene
Abnormal nucleotide content of eosinophils
Clonal T-cell proliferation or T-cell receptor gene rearrangement
Clinical response to a trial of imatinib mesylate (Gleevec)
Elevated levels of serum tryptase (surrogate marker for *FIP1L1-PDGFRα* gene)
Wilms' Tumor gene expression (WTI)[269]
Minor Factors Supporting a Diagnosis of Clonality
Increased serum cobalamin (vitamin B_{12}) and unsaturated B_{12} binding capacity (UBBC)
Hepatomegaly/splenomegaly
Normal levels of interleukins and immunoglobulins
Low neutrophil alkaline phosphatase
Markedly abnormal eosinophil morphology
Anemia or thrombocytopenia
Poor therapeutic response to steroid
Factors of Uncertain Significance
Apoptosis on blood film examination
Thrombotic events
Eosinophilic end organ damage

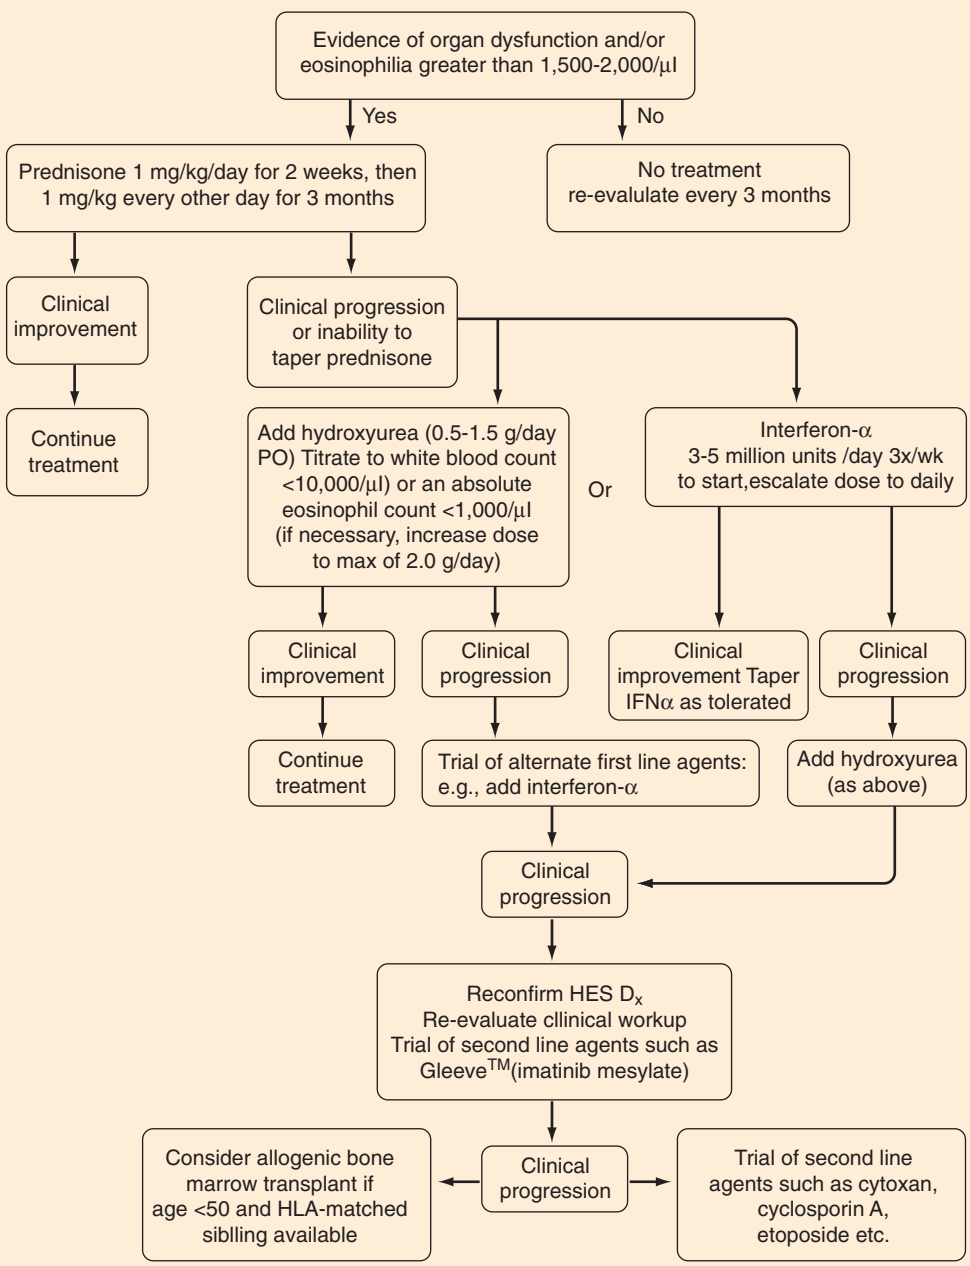
cells or SM with eosinophilia.[193,194] For *FIP1L1-PDGFRα*-negative patients, conventional therapies, or possibly a short trial of imatinib mesylate, is suggested for symptomatic patients. *FIP1L1-PDGFRα*-negative patients who have hematologic remissions with imatinib may be provisionally categorized as imatinib responsive (IR), warranting investigation of potential alternative constitutively active tyrosine kinase targets of the drug. The indication for aggressive initial treatment is evidence of progressive organ involvement or symptoms, or both. In asymptomatic eosinophilic patients with no evidence of end-organ involvement, specific therapy need not be administered immediately if eosinophil counts remain less than 1500 to 2000/μL. However, careful and frequent (3–6 month intervals) clinical and echocardiographic follow-ups should be done to evaluate such patients for the onset of cardiac involvement, which may nevertheless develop insidiously despite blood eosinophil counts less than approximately 2000/μL. It may be valuable in such patients to evaluate the effect of a short course of prednisone (60 mg/day or 1 mg/kg/day) to determine whether their eosinophilia will be responsive to corticosteroid suppression, should organ involvement ultimately develop.

Chemotherapeutic Agents

A trial of imatinib mesylate (Gleevec; initially 100 mg/day) is recommended for *FIP1L1-PDGFRα*-positive CEL or SM patients with eosinophilia (Table 72–7). For *FIP1L1-PDGFRα*-negative patients, conventional therapies, or possibly a short trial of imatinib mesylate (100 mg/day) is suggested for symptomatic patients. *FIP1L1-PDGFRα*-negative patients who have hematologic remissions with imatinib may be provisionally categorized as IR as indicated in the box on Diagnosis and Treatment of Hypereosinophilias, warranting further investigation of potential alternative constitutively active tyrosine kinase targets of the drug.[167] In *FIP1L1-PDGRFα*-negative patients who fail a short trial of imatinib and have evidence of end-organ involvement and steroid-resistant eosinophilia, the decision



Treatment Strategies for *FIP1LI-PDGFRα*-Negative Eosinophilias (Classical Hes, T Cell-Associated Hes, and Unclassified Chronic Eosinophil Leukemia)

Several prognostic features mentioned earlier may predict a good response to corticosteroid therapy, including the presence of angioedema and urticaria, elevated serum IgE levels, and a rapid drop in eosinophil counts in response to the initiation of corticosteroids, since eosinophils have surface receptors for glucocorticoids. Initial therapy in patients presenting with evidence of end organ involvement is with prednisone (1 mg/kg/day or 60 mg/day in adults). If an adequate suppression of blood eosinophil counts is obtained, then doses may be slowly tapered and ultimately switched to alternate day therapy (1 mg/kg/day). However, eosinophil counts should be monitored between doses on the "off" days to confirm that eosinophil counts remain level and adequately controlled. In the NIH series, 38% of patients responded well and 31% partially to prednisone treatment.[100,103,114] Patients less likely to respond favorably to prednisone included those with the poor prognostic signs of splenomegaly, cardiac dysfunction, and neurologic symptoms at the time of presentation. The mechanisms of steroid-refractory eosinophilia in HES have not been defined.

Diagnosis of Hypereosinophilic Syndrome*

Patients presenting with eosinophilia of unknown etiology should undergo a thorough clinical and laboratory evaluation consisting of the following:

- Complete/detailed history and physical examination
- Complete blood count with total eosinophil count and review of peripheral blood smear
- Hepatic and renal function tests, urine analysis
- Serologic assays: erythrocyte sedimentation rate, rheumatoid factor, human immunodeficiency virus (HIV)
- Serum tryptase level
- Quantitation of total IgE level
- Stool for ova, parasites ×3, duodenal aspirate
- Serologic assays for *Strongyloides*, *Trichinella*, *Toxocara*, *E Histolytica*, and *Echinococcus*, *Filariasis*, *Schistosomiasis*
- Bone marrow aspirate and biopsy (with cytogenetics)

Treatment Strategies for FIP1LI-PDGFRα-Negative Eosinophilias (Classical Hes, T Cell-Associated Hes, and Unclassified Chronic Eosinophil Leukemia)—cont'd

- Chest radiograph, computed tomographic scan of chest, abdomen, and pelvis
- Electrocardiogram and echocardiogram
- Patients meeting diagnostic criteria for HES/CEL:

1. persistent eosinophilia of >1500 eosinophils/mm^3 for more than 6 months
2. exclusion of other potential "reactive" etiologies for the eosinophilia including parasitic, allergic, or other causes, and
3. presumptive signs and symptoms of organ system dysfunction or involvement that appears related to the eosinophilia or is of unknown cause in the clinical presentation.

Patients with negative clinical evaluations for secondary, reactive causes of their eosinophilia should subsequently undergo testing for the *FIP1L1-PDGFRα* fusion gene product, or if this test is unavailable, use elevated serum tryptase levels as a surrogate marker. Those positive for the fusion or with elevated serum tryptase, or both, can be classified as having one of the *FIP1L1-PDGFRα*-positive clonal eosinophilias (eg, CEL or SM with eosinophilia). A negative test for the gene fusion or normal serum tryptase level would classify the patient into one of the three diagnostic categories based on additional laboratory criteria: CEL, unclassified, T cell-associated HES, or classic HES. A trial of imatinib mesylate is recommended for *FIP1L1-PDGFRα*-positive CEL or SM patients with eosinophilia (now abbreviated as SM-CEL or HES-MPD).

may be made to use more aggressive cytotoxic chemotherapy. Administration of hydroxyurea (0.5–2 g/day) has demonstrated efficacy in steroid-nonresponsive patients and is given toward the goal of reducing total leukocyte counts to a normal range of greater than 10,000/mm^3. Eosinophil counts begin to diminish after 7 to 14 days of treatment, reflecting the kinetics of eosinophil development and turnover in these patients. Hydroxyurea interferes with DNA synthesis, thereby inhibiting the development of all marrow-derived cells, in addition to eosinophils. The development of anemia and thrombocytopenia as a consequence of hydroxyurea may necessitate red cell transfusions and decreased doses or cessation of therapy. Weekly leukocyte counts may be necessary to monitor idiosyncratic fluctuations in red blood cell or platelet counts, and for consequent adjustment of hydroxyurea dosage.[82] Vinca alkaloids are also effective in HES, and vincristine (1.0–1.5 mg/m^2 at biweekly intervals), which produces a permanent mitotic arrest by disrupting spindle microtubules, has been shown to be beneficial in some patients.[81,195–198] However, the use of vincristine can lead to liver failure and be limited by neurologic complications that may be indistinguishable from the peripheral neuropathies associated with HES in some patients. Because vincristine decreases blood eosinophil counts in 1 to 3 days, it may be particularly efficacious for acute treatment of patients with marked hypereosinophilia (>100,000 eosinophils/mm^3) (see Table 72–8). Other chemotherapeutic agents that have been used with some success in a limited number of patients include etoposide (VP-16) and alkylating agents such as chlorambucil. Etoposide, a podophyllotoxin derivative and topoisomerase II inhibitor that induces DNA damage, has been used successfully in a number of patients to date. Oral followed by parenteral etoposide administered in one patient after cessation of hydroxyurea treatment was effective in controlling symptoms and eosinophil counts for a period of 18 months, but was ultimately withdrawn because of marrow suppression.[193] Two additional patients reported by Bourrat and colleagues[199] responded to etoposide with prolonged and durable remissions, despite discontinuance of the etoposide treatment. In these cases, doses of 300 mg/m^2 were given intravenously over a 2-day course or 200 mg/m^2 on 7 out of 10 days. Use of oral pulses of chlorambucil have been reported by Weller and Bubley[82] at doses ranging from 4 to 10 mg/m^2 daily for 4 consecutive days approximately every second month for 2 years with some efficacy in patients refractory to steroids and intolerant to hydroxyurea.

Biologic Response Modifiers

A number of biologic response modifiers have been used with occasional success in HES patients with a poor response to corticosteroids and hydroxyurea. In fact, the most important recent advance in treating resistant HES has been the use of interferon-α,[84] and eosinophils express a functional receptor for interferon-α.[200–206] Interferon-α has been used successfully to treat a number of leukemias including CML, multiple myeloma, and hairy cell leukemia. Experience by one of us with a series of six HES patients treated with interferon-α at the Mayo Clinic suggests that interferon may be a valuable agent for HES patients who are unresponsive to or intolerant of conventional corticosteroid or hydroxyurea therapies, and for patients with this syndrome who develop incapacitating mucosal ulcers.[143,144] In this series, IFN-α_{2b} was administered subcutaneously at doses ranging from 1.5–8.0 × 10^6 U/day (MU/day) individualized for each patient. These doses were successful in decreasing eosinophil counts to less than 1000/mm^3 in five of six patients, and all patients were able to taper and discontinue prednisone and hydroxyurea.[145,146] Two patients in this series with incapacitating mucosal ulcerations had resolution and no recurrence of their lesions. Additional reports indicate variable success in suppressing eosinophilia and hepatosplenomegaly, clinical and echocardiographic improvements in HES patients treated with interferon-α, and sustained disease remissions.[201–206] In vitro studies have shown that interferon-α inhibits the spontaneous high rate of apoptosis of clonal CD3$^-$/CD4$^+$ Th2 cells from HES patients. In one patient studied, interferon-α use was clinically associated with expansion of the circulating CD3$^-$/CD4$^+$ population, development of peripheral T-cell lymphoma, and recurrence of hypereosinophilia. Hence, in HES patients with an aberrant CD3$^-$/CD4$^+$ population, "L-HES", the use of IFN-α must be carefully considered.[207] In these cases, corticosteroid use has been advocated.[208] Targeting the eosinophil's CD52 antigen with the monoclonal antibody alemtuzumab™ has also proven a successful method to control eosinophilia in patients with abnormal T cells.[209] Thus, there is a growing body of evidence in the literature that IFN-α has a major place in the long-term treatment of HES, particularly in cases that are unresponsive to more conventional therapies, those with intractable mucosal ulcerations, those with cytogenetic abnormalities, and those presenting as myeloproliferative variants of HES lacking the CHIC2 deletion.[210] Cyclosporine, an immunosuppressant that interferes with multiple aspects of immunocompetent T lymphocyte function, has been reported to be effective in a series of four HES patients.[51,211,212] The rationale for use of cyclosporine is the inhibition of production of eosinophilopoietic cytokines (ie, IL-5) from putative T-cell clones thought to drive the eosinophilia in these patients.[51,83,211] Of interest, T-cell clones have been established and characterized from the peripheral blood of many patients with HES,[51] providing the rationale for its use. Cyclosporine has been used in conjunction with low-dose corticosteriods, although the reported duration of therapy has been limited (10 months) and longer-term efficacy or side effects in HES have not been determined. Indeed, Zabel and Schlaak[212] demonstrated corti-

costeroid-sparing effects and durable control of eosinophilia using 4 mg/kg cyclosporine in a series of three HES patients.

Pheresis

As noted in Table 72–8, plasma and leukapheresis have no defined role in the long-term management of HES. The use of leukapheresis has generally been restricted to emergency situations for patients developing profoundly high eosinophil counts. However, cell counts rebound rapidly to pretreatment levels within 1 day of the procedure.[213,214] Even multiple repeated sessions of leukapheresis are usually not sufficient to induce more than a transient decrease in blood eosinophil levels.[213–216] Five repeated plasma and leukapheresis sessions over a period of 2 weeks for a single patient was reported to significantly decrease blood eosinophilia; however, continued sessions in this patient were insufficient by themselves to lower blood eosinophil counts to acceptable levels.[206] The mechanism by which plasmapheresis transiently decreases eosinophil levels is entirely speculative but has been suggested to involve a temporary removal or decrease in the levels of circulating eosinophilopoietic factors.[213,216]

Anticoagulation and Antiplatelet Agents

Because thrombotic and thromboembolic events are frequently serious complications of HES, anticoagulants have often been used, especially in those patients with clear evidence of thromboemboli, neurologic symptoms, and cardiac involvement. Commonly used agents include warfarin, antiplatelet agents, or heparin. However, the efficacy of anticoagulation or antiplatelet agents has not been clearly established in HES disease, and many patients treated with these agents have continued to have thrombotic events, despite their adequate use.[86,124]

Splenectomy

As previously noted, splenomegaly has been reported in approximately 43% of HES patients, and hypersplenism in these individuals may contribute to both thrombocytopenia, anemia, and splenic infarction. Splenic pain induced by capsular distention or infarction is a known complication of HES.[103] In HES, splenectomy has the capacity to ameliorate platelet sequestration from hypersplenism and to relieve the pain associated with splenic distention and infarction.

Stem Cell Transplantation

There is still very limited experience reported with stem cell transplantation for the treatment of HES.[217–221] However, recent reports of stem cell transplantation for refractory HES include two successes with patients apparently in complete remission[219,221] and a third with a course complicated by the development of graft-versus-host-disease (GVHD) requiring cyclosporin-A therapy.[217] In a fourth report, the patient relapsed 40 months after transplantation, but survived for more than 44 months.[220] In a case reported in 1988, an HES patient who received an allogeneic transplant recovered hematologically, but subsequently died within 3 months from a diffuse cytomegalovirus (CMV) infection, thus preventing adequate evaluation of the procedure.[218] Only in HES cases with an extremely aggressive course unresponsive to standard therapies, or in young patients with a refractory course of disease and clinical features suggestive of a myeloproliferative disorder (eg, chromosomal abnormalities) should allogeneic stem cell transplantation be considered a treatment option at this time. Without greater understanding of the underlying mechanisms responsible for the overproduction of eosinophils and the aggressive development of end-organ damage in some of these patients, the risks associated with stem cell transplantation may outweigh its more routine use in treatment of this disorder.

Cardiac Surgery

Treatment of the cardiovascular sequelae of HES continues to be a therapeutic challenge.[57] Surgical intervention in eosinophilic heart disease does not appear to carry any risk of disease recurrence at the operative sites. For patients who develop significant compromise of valvular function, endomyocardial thrombosis, or fibrosis, cardiac surgery has the capacity to provide substantial clinical and quality-of-life improvements.[57] Mitral valve[222] and/or tricuspid valve repair or replacements[223] have been reported in more than 50 eosinophilic patients.[57] Endomyocardectomy and thrombectomy, as performed for advanced stage Löeffler's endomyocardial fibrosis, has also been used effectively in some HES patients[86,224] and ventricular decortication may be performed in combination with valve replacement. For mitral valve replacements, mechanical valves have proven problematic because of recurring thrombotic episodes despite adequate anticoagulation,[224–226] suggesting the use of porcine valves whenever possible.[82,227] HES patients who have received valve replacements have generally experienced long-term improvement in cardiac function,[82] provided the eosinophilia remains controlled.

Ineffective Agents in Hypereosinophilic Syndrome

Agents that have proved either not very useful or totally ineffective in the treatment of HES include antihistamines, anabolic steroids, methotrexate and busulfan (alone or in combination), azathioprine, and cyclophosphamide.

SUMMARY AND CONCLUSIONS

The heterogeneity of HES, ranging from patients with clear features of myeloproliferative disorders, including cytogenetic abnormalities, to patients with more benign clinical courses, such as episodic angioedema with eosinophilia, suggests that multiple disease processes are likely at play. Current research aimed at defining the cause of HES and mechanisms regulating the development of eosinophil-mediated end-organ damage in eosinophil-associated diseases in general, should ultimately lead to more selective and improved therapies. The therapeutic targets for these efforts are likely to include (a) IL-5 and its high affinity receptor; (b) underlying T-cell clones (either immunocompetent or occult T-lymphoid malignancies) that elaborate eosinophilopoietins such as IL-5 or GM-CSF, tissue or organ-specific dysfunctional elaboration of eosinophil-active chemoattractant factors such as eosinophil-selective chemokines (the eotaxins); (c) vascular endothelial adhesion molecules (VCAM/VLA-4); and (d) undefined mechanisms that induce the overproduction of eosinophils and/or serve to recruit and activate eosinophils selectively in certain tissues and organs. The essential absence of end-organ damage in some syndromes of hypereosinophilia contrasts starkly with the morbidity (and mortality) associated with the development of endomyocardial fibrosis in HES and certain other eosinophilias. Because HES patients are clearly a heterogeneous group, clinical management based on current knowledge must be specifically tailored to the individual,[84,167] with the overall goal of controlling the eosinophilia and, in particular, the eosinophil-mediated end-organ damage. In the past 30 years, the clinical and surgical management of patients with idiopathic hypereosinophilias and HES has evolved significantly. Current treatment options permit the control or eradication of eosinophilia and end-organ damage in most HES patients. The recent report of the efficacy of imatinib mesylate in approximately 50% of patients with HES has led to the identification of the *FIP1L1-PDGFRα* gene fusion that encodes a pathogenetically relevant and constitutively active tyrosine kinase. This seminal finding will ultimately lead to a reclassification of hypereosinophilias into several well-defined clinical entities and

should stimulate new research that may ultimately translate into improved clinical characterization and therapeutic options. For patients with imatinib-resistant forms of CEL, or with classic HES that does not respond to conventional therapies such as glucocorticoids, hydroxyurea, and IFN-α, treatment options such as stem cell transplantation may hold promise for durable disease remissions. Importantly, treatment with IFN-α should be considered as an initial first-line option for the management of imatinib nonresponsive HES, either alone or in combination with other therapies.[84] Finally, humanized anti-IL-5 antibody (mepolizumab) is currently in clinical trials, but is not FDA approved. The clinical data with this agent, though still preliminary, looks highly promising for the treatment of a wide range of patients with *FIP1L1-PDGFRA*-negative HES[228–232] and possibly other eosinophilias, for example, eosinophilic gastrointestinal syndromes such as eosinophilic esophagitis.[233,219]

Future research on HES and CEL will likely focus on the molecular basis of imatinib responsiveness in both *FIP1L1-PDGFRα*-positive and -negative patients, addressing specifically how the constitutively activated FIP1L1-PDGFRα or other fusion- or mutant-activated kinases selectively lead to chronic hypereosinophilia and end-organ damage. Studies of the effects of imatinib on the proliferation and terminal differentiation of bone marrow-derived eosinophil progenitors, and the survival and intracellular signaling pathways in eosinophils from imatinib-responsive patients may be particularly revealing in terms of the downstream targets of these novel kinases.

Acknowledgments

The authors greatly acknowledge and appreciate discussions and critical input and advice from Dr. Amy Klion and Dr. Gary Gilliland in the development of the new algorithms for the evaluation and therapeutic options now available for patients with hypereosinophilias, specifically in terms of reviewing the treatment options for patients shown to be *FIP1L1-PDGFRα*-positive versus negative, or to have elevated serum tryptase levels as a surrogate marker for the *FIP1L1-PDGFRα* gene fusion. Dr. Ackerman is supported in part by grants from the National Institute of Allergy and Infectious Diseases, NIH (AI25230 and AI33043).

CHAPTER 73

MAST CELLS AND SYSTEMIC MASTOCYTOSIS

Animesh Pardanani and Ayalew Tefferi

MAST CELLS

Discovery

The discovery of mast cells is credited to Paul Ehrlich,[1] who first described a subgroup of connective tissue cells ("Mastzellen") localized to a great extent around blood vessels; these cells were thought to be morphologically larger than white blood cells and to contain "protoplasmic deposits" (granules) that display a characteristic reactivity toward aniline dyes. In his thesis, Ehrlich stressed that the identification of mast cells was to be based primarily on the specific histochemical reaction that rendered the cell granules metachromatic, and not simply on the microscopic appearance of these cells. Several years later, Ehrlich discovered the presumed nontissue counterpart of mast cells[3,4]; this basophilic granulocyte was identified in the peripheral blood of patients with myeloid leukemia, which suggested that the particular cell (blood mast cell, basophil, or mast leukocyte) had its origin in the bone marrow with subsequent residence in the peripheral blood as do other leukocytes.

Origin

Although the origin of mast cells remained obscure for many years, it is now accepted that these cells originate from $CD34^+$/c-Kit^+/$CD13^+$ pluripotent hematopoietic cells in the bone marrow.[5–8] Mast cells are released into the circulation in the immature state and undergo terminal maturation/differentiation after migration into tissues, where they ultimately reside. In early studies, mouse models were used to investigate the origin and development of mast cells: (a) C57BL/6-bg^j/bg^j, beige Chediak–Higashi syndrome mice. In this model, the giant mast cell granules were used a morphological marker for donor-derived cells.[9] Here, cells from the bone marrow, peripheral blood, liver, thymus, or lymph nodes of beige mice were transplanted into irradiated, congenic C57BL/6 +/+ mice, or alternatively, the beige mouse was parabiosed with a congenic +/+ mouse, (b) dominant white spotting (*W*)- or Steel (*Sl*)-locus mutant mice (vide infra) that are profoundly deficient in mast cells. Kitamura initially demonstrated that the mast cell content in skin and other organs in the adult W/W^v mouse could be restored to normal levels after transplantation of bone marrow cells from congenic +/+ mice.[10]

The relationship between human mast cells and cells belonging to other leukocyte lineages remains unclear. Although mast cells share several features with basophils, namely presence of cytoplasmic basophilic granules, expression of high-affinity IgE receptors (FcεRI), and release of histamine upon stimulation, the two cell types are considered to be distinct. Unlike mast cells, basophils circulate in the blood as mature cells and are thought to be incapable of proliferation; that is, basophils undergo apoptosis after their recruitment and activation in the tissues.[11] Studies of developmental pathways in murine hematopoiesis have not been conclusive as to how mast cell-committed progenitors are generated; that is, whether there is a shared bipotent progenitor for mast cell and basophilic lineages or whether mast cells are derived directly from multipotent progenitor cells.[12–14] Molecular studies in patients with mastocytosis however reveal that the pathogenetically relevant mutation Kit Asp816Val (D816V) is found primarily in mast cells and not basophils, thus suggesting that the two cells do not arise from a common progenitor cell.[15] Furthermore, it has been proposed that mast cells and basophils, both of which are metachromatic staining cells, can be distinguished on the basis of cellular immunophenotype,[16–18] gene expression profile,[19] or growth factor responsiveness.[18] With regards to the latter, interleukin-3 (IL-3) and to some extent IL-5 has been shown to promote the growth and differentiation of basophils but not mast cells in humans.[20–22] In contrast, the primary cytokine for mast cell growth and differentiation is the stem cell factor (SCF)/c-Kit ligand.[23–27] Mast cells resemble monocytes, including their responsiveness to IL-4, the expression of mast cell tryptase in human monocytic cell lines, and the ability of murine mast cells to adopt monocytic features in culture.[28,29]

Growth, Proliferation, Survival

The interaction between SCF and its cognate receptor c-Kit (Kit) plays a key role in regulating mast cell growth and differentiation. Kit is expressed on hematopoietic progenitors and is downregulated upon their differentiation into mature cells of all lineages, except mast cells, which retain high levels of cell surface Kit expression.[30] Insight into the biologic function of Kit and SCF came from observations in mice carrying specific mutations at the dominant white spotting (*W*)[31–38] or Steel (*Sl*) loci, respectively (reviewed in 39, 40). A double gene dose of mutant alleles at either locus produces common pleiotropic effects, including a profound decrease in mast cell number, coat color abnormalities/white-spotting (piebaldism), macrocytic anemia, reduced fertility, and abnormalities in intestinal pacemaker activity. Despite the shared phenotype between *W*- and *Sl*-mutant mice, the mechanism underlying the defect in hematopoiesis is quite different. In W/W^v mice, for instance, transplantation of bone marrow cells from congenic +/+ mice corrected both the anemia and mast cell deficiency, which indicated that the defect was an intrinsic stem cell disorder.[10,41–44] Many independent mutations of the *W* locus have been described; the alleles are semidominant and vary in their phenotypic effect on hematopoiesis, pigmentation, and fertility in the homozygous and heterozygous state.[45] In contrast, the defect is cell-extrinsic in Sl/Sl^d mice; when skin from either W/W^v or Sl/Sl^d mice was grafted onto the back of congenic +/+ mice, mast cells were found to populate the grafted skin from W/W^v mice but not in skin from Sl/Sl^d mice.[9,46] Furthermore, the hematologic defects in Sl/Sl^d mice were not corrected by transplantation of bone marrow cells from a congenic +/+ host[46] indicating that the disorder is microenvironmental in nature.

Activation and Function

Mast cells are ubiquitous and are found in virtually all tissues, but are most numerous at anatomic sites that are in contact with the environment, such as the mucosa of airways and gut, as well as in the skin. Although mast cells have been long identified as key cellular mediators of the allergic inflammatory response,[47–51] they have myriad other physiologic functions, including a key role in innate immunity.[52–55] The study of mast cell function in humans has been difficult for several reasons. First, these cells are relatively inaccessible; in

general, primary culture of mast cells (including those derived from cord blood or peripheral blood-derived progenitor cells) is cumbersome, the yield of cells is quite limited, and it is presently unclear whether fully mature mast cells can be obtained by this approach.[26,56–61] Second, there appears to be significant variation in the functional properties of mast cells depending upon the anatomic location from which they are isolated (eg, skin versus intestinal mucosa).[62–64] Third, mast cells display considerable phenotypic plasticity, with many autocrine, paracrine, or systemic factors influencing various aspects of cell phenotype.[65] Consequently, investigators have often relied on transformed mast cell leukemia cell lines (eg, HMC-1, LAD-1, LAD-2),[66,67] or murine animal models for experimental studies of mast cell function.[52,54] Mouse strains that exhibit a profound mast cell deficiency include (a) *c-kit*/*W* mutant mice (eg, W/W^v mice; vide infra) also display non-mast cell phenotypic abnormalities including sterility, which entails complex breeding strategies, and (b) W^{sh}/W^{sh} mice, which carry an inversion mutation upstream of the *c-kit* coding region, display abnormal pigmentation and reduced mast cell number but have relatively preserved hematopoiesis and fertility.[68–72] The aforementioned mice can be selectively reconstituted with mast cells by systemic (intravenous) or local (eg, intradermal, intraperitoneal) transfer; this adoptive transfer of genetically compatible, in vitro cultured mast cells (eg, from bone marrow cells) provides a useful model (ie, "mast cell knockin mice") for the study of mast cell function in vivo.[73–75] It remains unclear however whether observations from cell line or mouse experiments can be extrapolated to humans, given that neoplastic transformation significantly alters normal cellular function and given the marked interspecies differences in mast cell biology. Mast cells undergo activation, classically following cross-linking of FcεRI-bound IgE by multivalent allergens in sensitized individuals. The tissue mast cell burden is dynamic and has been noted to increase in chronic allergic inflammatory states.[76] Non-IgE triggers for mast cell mediator release include anaphylatoxins of the complement system (C3a and C5a), neuropeptides (eg, vasoactive intestinal peptide, somatostatin, substance P), lipopolysaccharides, chemokines (eg, CCL3, / MIP1α), and Toll-like receptors (reviewed in 52, 53, 55). Other non-IgE triggers for mast cell activation include specific cytokines, such as SCF, and to some extent IL-4 (in cooperation with SCF) as well as IL-3. Upon activation by either IgE-dependent or IgE-independent mechanisms, three classes of mediators are released: (a) preformed mediators that are stored in cytoplasmic granules (eg, amines, proteases, proteoglycans); (b) lipid mediators synthesized de novo (eg, leukotrienes, prostaglandins); and (c) growth factors, cytokines, and chemokines.[11,48,77–86] Mast cells are primed for multiple cycles of degranulation-mediator release, and display distinct patterns of mediator release depending upon the strength and type of stimulus that is provided.[52,87–89] Mast cells display a wide spectrum of "activation levels" in vivo; however, the mechanisms regulating the secretory phenotype of mast cells in a given individual are not completely understood (reviewed in 52). The key mast cell mediators include (a) vasoactive amines, particularly histamine; (b) several distinct tryptases (α, β, and δ) that comprise the principal protein component of mast cells; (c) anionic proteoglycans (eg, heparin, chondroitin sulphate) that confer metachromasia upon staining with toluidine blue; (d) various lipid mediators; these arachidonic acid-derived eicosanoids, which include leukotriene C_4, leukotriene B_4, and prostaglandin D_2, mediate vasodilation, vasopermeability, smooth muscle constriction, mucus secretion, as well as other proinflammatory processes; (e) other proteases (eg, chymase, carboxypeptidase A); and (f) specific cytokines. The secreted cytokines, which recruit and activate specific cells, include IL-3 (basophils), IL-5 (eosinophils), tumor necrosis factor-α/IL-8 (neutrophils), and IL-4/IL-13 (T and B lymphocytes). Mast cells mediate not only early-phase (eg, anaphylaxis, acute asthma) but also late-phase allergic responses, as well as non-type I hypersensitivity reactions through the aforementioned mediators.[90] Furthermore, mast cells mediate upregulation of T_H2-responses and allergen-specific IgE biosynthesis, which contribute to host defenses against parasitic infections.[91,92] Mast cells have also been implicated in other nonallergic diseases, including viral and bacterial infections,[93–95] autoimmune disorders,[96–98] as well as in angiogenesis related to cancer,[99] although its role(s) in these conditions has not yet been precisely delineated.

Role of Kit and Stem Cell Factor in Mast Cell Biology

c-Kit is the cellular homolog of the *v-Kit* oncogene of the Hardy–Zuckerman 4 feline sarcoma virus[100] and encodes for Kit, which belongs to the type III subfamily of receptor tyrosine kinases. Members of this receptor tyrosine kinase subfamily share both sequence similarity and a common overall structure, with an extracellular domain containing 5 immunoglobulin-like motifs that binds SCF, a short transmembrane (TM) domain that anchors Kit to the cell membrane, a cytoplasmic tyrosine kinase (TK) domain that is split by an insert sequence into ATP-binding and phosphotransferase regions, and a juxtamembrane (JM) domain that lies between the TM and TK domains.[101–103] After *c-Kit* was found to be located on human chromosome 4,[101,104] in a region (4q11-q12) homologous to a region of mouse chromosome 5, that includes the *W* gene locus, further studies sought to examine whether the *W* locus was linked to murine *c-Kit*. Using interspecific backcross analysis, it was determined that the two were tightly linked,[105] and *c-Kit* was subsequently found to be disrupted in two spontaneous mutant *W* alleles, W^x, and *W*, [44] confirming that Kit was encoded by the *W* locus.[106] Specific mutations at the *W* locus, such as *W* (78, amino acid TM/JM deletion), W^{37} (JM missense mutation), or W^v, *W*, [41] and W^{42} (TK missense mutations) result in a loss-of-function phenotype and point to the critical role of individual domains/regions in Kit function[38,106–114] (reviewed in 115). The common phenotypic denominator of mutations at the *W* locus is reduced Kit tyrosine kinase activity, whether by expression of decreased number of Kit receptors with normal kinase activity (*W*,[44] W,[57] and W^x alleles), or expression of normal numbers of kinase-defective Kit (*W*,[37] *W*,[42] *W*,[41] W^v, W[55] alleles) (reviewed in 115).

SCF was initially isolated from medium conditioned by Buffalo rat liver cells, and exhibited ex vivo growth factor activity toward primitive hematopoietic progenitors as well as mast cells.[27] The subsequent purification, cloning, and mapping of SCF revealed it to be syntenic with the *Sl* locus on mouse chromosome 10, and SCF sequences were found to be deleted in a number of mutant *Sl* alleles such as Sl^d and Sl^{12H}.[116–118] SCF was shown to be a ligand for Kit by cross-linking of ^{125}I-labeled SCF to Kit-expressing cells[119] and the administration of recombinant SCF in vivo rescued both the macrocytic anemia and the mast cell deficiency exhibited by Sl/Sl^d mice.[118] The Steel–Dickie (Sl^d) mutation is a 4.0-kb deletion within the gene SCF, which renders Sl^d only capable of encoding a soluble truncated growth factor that lacks both transmembrane and cytoplasmic domains.[120,121] SCF is synthesized by a variety of mesenchymal cells, including fibroblasts, that express the cytokine as a transmembrane protein that may be proteolytically cleaved to generate a soluble form; two distinct isoforms with differential susceptibility to proteolysis are synthesized.[122] Soluble SCF exists as a homodimer in plasma and can crosslink two Kit receptors on the cell surface, thereby leading to activation of Kit, as well as downstream signal transduction.[123] SCF promotes mast cell development, survival of mature mast cells, as well as adhesion of mast cells to extracellular matrix proteins. SCF also regulates mediator release from human mast cells, potentially by both IgE-dependent and IgE-independent mechanisms.

Mastocytosis

Mast cell disease/mastocytosis is characterized by the abnormal growth and accumulation of morphologically and immunophenotypically abnormal mast cells in one or more organs in the body. In contrast to normal mast cells, its neoplastic counterparts are more variable in appearance, ranging from round to fusiform variants, with long, polar cytoplasmic processes; they additionally display cytoplasmic hypogranularity with uneven distribution of fine granules, as well as atypical nuclei with monocytoid appearance.[124–126] Immunophe-

notypic evaluation of mast cells reveals virtually invariable expression of aberrant markers in mastocytosis patients.[127–129]

Pathogenesis

Current evidence points to an important role for gain-of-function mutations in *c-Kit*, particularly Kit D816V, in the pathogenesis of mastocytosis. The issue as to whether additional genetic hits are necessary for neoplastic transformation of mast cells, and for full expression of the mastocytosis phenotype, remains to be determined. Other specific mutations, such as *FIP1L1-PDGFRA* and Kit F522C, although rare, exhibit specific genotype–phenotype associations in mastocytosis patients and hence deserve specific mention in this section.

Kit D816V

Furitsu et al showed that Kit expressed on HMC-1 cells, an immature mast cell line established from a patient with mast cell leukemia,[66] was constitutively phosphorylated and activated in the absence of SCF.[130] Sequencing of *c-kit* in these cells revealed two point mutations, one in the juxtamembrane (V560G) and the other in the tyrosine kinase (D816V) domain. Two rodent cell lines, P815 (mouse mastocytoma) and RBL-2H3 (rat mast cell leukemia), were subsequently found to carry mutations corresponding to human D816V (ie, D814Y and D817Y, respectively).[131,132] These mutations, in human, mouse, and rat Kit, were shown to be constitutively activating when expressed in the human embryonic kidney cell line 293T.[130–132] Soon after this report, Nagata et al published the first report of the Kit D816V mutation in human mastocytosis.[133] Since then, other Kit mutations, either involving D816 or an adjacent amino acid residue (eg, D816Y,[134–136] D816F,[134] D816H,[137] I817V or VI815–816,[138] and D820G[139]) or involving other domains (extracellular,[140] transmembrane,[141,142] or juxtamembrane[143,144]) have also been identified in mastocytosis. The juxtamembrane mutations include V560G, K509I, and V559A; some are rare alleles detected in germline DNA in cohorts with familial mastocytosis.[145] Interestingly, several kindreds with combined familial gastrointestinal stromal tumors and mastocytosis, both of which are associated with gain-of-function Kit mutations, have also now been described.[140,143]

Although activating Kit mutations are clearly associated with human mastocytosis, they do not occur universally,[146] and the question as to whether individual mutations are necessary and sufficient to cause mast cell transformation remains currently unsettled. Introduction of human Kit D816V (or its murine homologs) into IL-3-dependent cell lines, either Ba/F3 (pro-B-lymphocyte), IC-2 (mast cell) or FDC-P1 (myeloid), results in their cytokine-independent growth.[147–149] Furthermore, subcutaneous injection of mutant Kit V559G- or Kit D814V-bearing Ba/F3 cells into nude mice produced large mastocytomas and all the mice subsequently died of mast cell leukemia.[148] These experiments do not, however, provide direct confirmation of the neoplastic transformation potential of activating Kit mutations since the IL-3-dependent cell lines are immortalized and have acquired a priori the capacity to self-renew by unknown events. Kitayama and colleagues introduced activated Kit (V559G or D814V) by retroviral infection into murine bone marrow cells and injected these cells into mast cell-deficient irradiated *W/W^v* mice.[150] In vitro colony assays revealed that Kit D814V, and to some extent Kit V559G, stimulated cytokine-independent growth of both mast cell and non-mast cell myeloid colonies. Furthermore, a proportion of the transplanted mice developed acute leukemia, likely of B-lymphoid origin; in addition, a subset of transgenic mice expressing Kit D814V developed acute leukemia/lymphoma of immature B-cell origin at 10 to 80 weeks of age. In another study, human Kit D816V was introduced into murine fetal liver cells, with induction of megakaryocytic differentiation, in the absence of cytokines.[151] In the presence of SCF, Kit D816V-expressing cells showed increased mast cell differentiation, as did Kit-wild type (WT)-expressing cells. The Kit D816V-expressing cells however were not transformed, as assessed by colony assays, regardless of the absence or presence of SCF. Furthermore, introduction of Kit D816V induces myelomastocytic differentiation and cluster formation of Ba/F3 cells but does not enhance their growth.[152] Thus, there is conflicting experimental data from mouse studies as to whether activating Kit mutations are sufficient to cause oncogenic transformation. Similarly, Kit D816V mutation alone may not be sufficient to cause oncogenic transformation in humans. This is consistent with the observation that most mastocytosis patients harboring this mutation have indolent disease. In addition, B cells and monocytes carrying mutated *c-kit* display a nonmalignant behavior, despite being derived from the same precursor that gives rise to lesional mast cells in mastocytosis patients.[153] Thus, it is possible that Kit D816V may affect the differentiation and apoptosis potential of human mast cells rather than providing a potent proliferative signal. In support of this theory, human bone marrow mast cells harboring Kit D816V but not normal mast cells have been shown to survive in a medium devoid of SCF.[154] Moreover, enhanced expression of the antiapoptotic protein Bcl-xL was found in lesional mast cells in patient bone marrow biopsies.[155] It is also possible that Kit D816V affects mast cell function; for instance, Taylor and colleagues showed that hematopoietic progenitors and mast cells carrying Kit D816V migrate to SCF more vigorously.[156] Thus, Kit D816V as a single hit may explain the pathology and clinical course of indolent mastocytosis but not of aggressive mastocytosis or mast cell leukemia.

FIP1L1-PDGFRA

Systemic mastocytosis patients frequently exhibit eosinophilia (SM-eo),[157–160] and in at least some cases the eosinophils can be shown to be derived from the neoplastic clone.[161] A subset of cases with eosinophilia harbor the *FIP1L1-PDGFRA* oncogene, which results from an interstitial deletion in chromosome 4q12—leading to constitutively active platelet-derived growth factor receptor A (PDGFRA) tyrosine kinase activity—that is uniquely sensitive to inhibition by imatinib mesylate.[162] In these patients, *FIP1L1-PDGFRA* involves mast cells and eosinophils in addition to lymphocytes, thus pointing to its origin in a multipotent hematopoietic progenitor cell.[163] The bone marrow mast cell infiltration pattern is unusual as compared to the typical mastocytosis patient harboring Kit D816V, in that the mast cells are diffusely distributed, with fewer pathognomonic mast cell clusters.[164,165] The patients harboring *FIP1L1-PDGFRA* are probably best classified as having chronic eosinophilic leukemia (CEL), although, since in at least some cases, they fulfill criteria for both systemic mastocytosis and CEL, their classification as systemic mastocytosis, subtype SM-CEL, may be appropriate.[166,167] Gain-of-function Kit[168] and PDGFRA[169] mutations have also been identified in gastrointestinal stromal cell tumors, where they have a pathogenetic role. Intriguingly, in both gastrointestinal stromal cell tumors and mastocytosis patients, KIT and PDGFRA mutations appear to be alternative and mutually exclusive genetic events.

Other Mutations/Polymorphisms

Presence of Kit D816V alone does not explain the remarkable clinical heterogeneity of human mastocytosis. Kit mutations are not consistently detected in some patients, such as those with childhood-onset cutaneous mastocytosis. Also, other mutations, polymorphisms, and/or karyotypic abnormalities have been detected in mastocytosis (summarized in 146), which likely influence the disease phenotype whether or not these lesions coexist with Kit D816V. Intriguingly, loss-of-function mutations have also been detected in mastocytosis; the dominant-negative Kit E839K mutation, [170] as well as the IL-4 receptor alpha chain polymorphism, Q576R, that is thought to limit mast cell growth and differentiation,[171] are both associated with relatively limited forms of mastocytosis.

Classification

The classification of mastocytosis has evolved over the years; the first recognition of cutaneous mast cell disease came from Unna's recognition in 1887 that urticaria pigmentosa (UP) lesions were histologically composed of mast cell infiltrates.[172] Although the systemic nature of mastocytosis had been alluded to by Sézary and others in the early 1900s,[173,174] systemic mast cell infiltrates were histologically demonstrated by Ellis only in 1949.[175] Subsequently, a dichotomous view prevailed, wherein benign mastocytosis was separated from malignant mastocytosis, based on the presence or not of UP, organomegaly, particular cytologic and cytochemical features of bone marrow mast cells, as well as the clinical course.[176–179] Following this, based on the recognition that not all patients classified as having benign mastocytosis have a favorable outcome, and that malignant mastocytosis was composed of relatively distinct clinicopathologic entities, updated classifications generally with four or five broad mastocytosis subgroups were proposed.[159,180] More recently, updated diagnostic criteria and an updated consensus classification for mastocytosis was proposed and adopted by the World Health Organization (WHO) in 2001.[181,182] This classification incorporates recent advances in our understanding of mastocytosis, including the role of *c-kit* mutations, aberrant expression of cell surface immunophenotypic markers on neoplastic mast cells, as well as the role of mast cell mediators as surrogate measures of mast cell number and/or function. The current WHO classification classifies mastocytosis into seven variants (Table 73–1):[182] cutaneous mastocytosis (CM), indolent systemic mastocytosis (ISM), systemic mastocytosis with an associated clonal hematological non-mast cell disorder (SM-AHNMD), aggressive systemic mastocytosis (ASM), mast cell leukemia (MCL), mast cell sarcoma, and extracutaneous mastocytoma. In addition, two relatively rare variants of mastocytosis with characteristic clinicopathologic features have also been described: well-differentiated systemic mastocytosis (WDSM) and systemic mastocytosis without skin involvement associated with recurrent anaphylaxis (SM-ana).[138] The WHO classification of mastocytosis mandates a number of staging investigations to define the exact subtype of disease.[182] Identification of B findings (Table 73–2) alone such as more than 30% mast cells in the bone marrow or serum tryptase greater than 200 ng/mL are indicative of a high systemic mast cell burden (ie, smoldering SM), whereas the additional presence of C findings (Table 73–3) such as cytopenias, pathologic fractures, hypersplenism, and so on, indicate impaired organ function directly attributable to mast cell infiltration and are diagnostic for presence of aggressive disease (ie, ASM).

Table 73–1 World Health Organization Variants of Mastocytosis[182]

1. Cutaneous mastocytosis (CM): a. Maculopapular CM b. Diffuse CM c. Mastocytoma of skin
2. Indolent systemic mastocytosis (ISM): a. Smoldering systemic mastocytosis (SSM) b. Isolated bone marrow mastocytosis
3. Systemic mastocytosis with an associated clonal hematological non-mast cell lineage disease (SM-AHNMD): a. SM-MDS b. SM-MPD c. SM-CEL d. SM-CMML e. SM-NHL
4. Aggressive systemic mastocytosis (ASM) With eosinophilia (SM-eo)
5. Mast cell leukemia (MCL) Aleukemic MCL
6. Mast cell sarcoma
7. Extracutaneous mastocytoma

CEL, chronic eosinophilic leukemia; CMML, chronic myelomonocytic leukemia; MDS, myelodysplastic syndrome; MPD, myeloproliferative disorder; NHL, non-Hodgkin lymphoma.

Clinical Features

Mast cell disease has a varied clinical presentation with symptoms that may be broadly grouped as follows:

Skin Rash

There are three major forms of cutaneous mastocytosis recognized by the WHO.[182] The commonest is urticaria pigmentosa (also referred to as maculopapular cutaneous mastocytosis [MPCM]), the others being diffuse cutaneous mastocytosis and solitary mastocytoma of the skin. The skin lesions are typically yellow tan to reddish brown macules, and may less frequently present as nodules or plaques (Fig. 73–1). The lesions generally involve the extremities, trunk, and abdomen, but spare sun-exposed areas, including the palms, soles, and scalp. The lesions commonly exhibit an urticarial response to mechanical stimulation such as stroking or scratching (Darier's sign or dermographic urticaria).[183,184] Biopsies of UP/MPCM lesions demonstrate multi-focal MC aggregates mainly around blood vessels and around skin appendages in the papillary dermis.[184,185] An increase in dermal MC, in the absence of typical UP lesions, is not considered diagnostic of CM, given the relatively nonspecific nature of such a finding.[186–189] Children account for nearly two-thirds of all reported cases of cutaneous mastocytosis, with a majority of cases arising before the age of 2 years.[190–192] In contrast, most adult MCD patients with UP/MPCM have systemic disease (often indolent) at presentation that is most commonly revealed by a bone marrow biopsy done as part of the diagnostic workup.[193]

Table 73–2 B Findings: Indication of High Mast Cell Burden[304]

1. Infiltration grade (mast cells) is greater than 30% in bone marrow in histology and serum total tryptase levels greater than 200 ng/mL
2. Hypercellular marrow with loss of fat cells, discrete signs of dysmyelopoiesis without substantial cytopenias, or WHO criteria for an MDS or MPD
3. Organomegaly: palpable hepatomegaly, splenomegaly, or lymphadenopathy (on CT or ultrasound) greater than 2 cm without impaired organ function

MDS, myelodysplastic syndrome; MPD, myeloproliferative disorder; WHO, World Health Organization.

Table 73–3 C Findings: Indication of Impaired Organ Function Attributable to Mast Cell Infiltration[182]

1. Cytopenia(s): Absolute neutrophil count <1000/μL, or hemoglobin <10 g/dL, or platelets <100,000/μL
2. Hepatomegaly with ascites and impaired liver function
3. Palpable splenomegaly with hypersplenism
4. Malabsorption with hypoalbuminemia and weight loss
5. Skeletal lesions: large-sized osteolysis or severe osteoporosis causing pathologic fractures
6. Life-threatening organopathy in other organ systems that definitively is caused by an infiltration of the tissue by neoplastic mast cells

Figure 73–1 Urticaria pigmentosa lesions in a patient with cutaneous mastocytosis.

Symptoms Related to Mast Cell Degranulation

Most adult patients in this category have a low systemic mast cell burden, commonly exhibit CM lesions, and generally have indolent disease. Presenting symptoms include pruritus, urticaria, angioedema, flushing, bronchoconstriction, neuropsychiatric manifestations, and hypotension.[194] Gastrointestinal features such as nausea, vomiting, abdominal pain, diarrhea, and malabsorption may be prominent in some patients. Histamine receptor stimulation increases gastric acid production, which may cause peptic ulcer disease with potential morbidity from a bleeding peptic ulcer and/or perforation.[195,196] Presyncope, episodic vascular collapse, and sudden death represent the more dramatic clinical presentations of mast cell mediator release.[197]

Musculoskeletal Symptoms

Patients may have indolent or aggressive disease and present with poorly localized bone pain, diffuse osteoporosis or osteopenia, myalgias, arthralgias, pathological fractures, skeletal deformities, and/or compression radiculopathies. In the absence of typical cutaneous lesions (UP/MPCM) or mast cell mediator release symptoms, the diagnosis of systemic mastocytosis may prove challenging and diagnosis is frequently delayed in this setting. Systemic mastocytosis in this setting must be distinguished from other disorders including osteoporosis, metastatic cancer, Paget disease, and multiple myeloma.

Symptoms Related to Organomegaly/Organopathy

Systemic mastocytosis patients in this category are generally older, without CM lesions, frequently exhibit organomegaly and mast cell atypia (ie, high-grade morphology), and commonly experience an aggressive disease course.[125,198,199] Organ infiltration by neoplastic mast cells may lead to hepatomegaly (with or without liver dysfunction and ascites), splenomegaly (with or without hypersplenism), lymphadenopathy, large osteolytic lesions with or without pathologic fractures, and malabsorption with hypoalbuminemia and weight loss. Extensive marrow involvement may result in anemia and eventually to pancytopenia.

Diagnosis

The diagnosis of systemic mastocytosis is based on identification of abnormal mast cells by morphological, immunophenotypic, and/or genetic (molecular) criteria in various organs. The WHO criteria for systemic mastocytosis are shown in Table 73–4.[182]

Bone Marrow Histology

The mast cell burden in normal bone marrow is very low (<0.1%) and increases significantly in systemic mastocytosis patients.[200] Consequently, the diagnosis of systemic mastocytosis is most frequently established by histologic and immunohistochemical examination of bone marrow aspirate and biopsy specimens. The bone marrow is virtually always involved in adults and shows characteristic histologic features; in contrast, histological criteria for non-bone marrow organ involvement have not been clearly defined and, consequently, have not been widely accepted to date. Furthermore, a bone marrow examination allows determination of whether an associated clonal non-mast cell lineage hematological disorder is present. The pathognomonic lesion, which represents the WHO major diagnostic criterion, is presence of multifocal, dense mast cell aggregates, frequently in perivascular and/or paratrabecular locations (Fig. 73–2). These aggregates may be relatively monomorphic, composed mainly of fusiform mast cells, or may be polymorphic, with mast cells admixed with lymphocytes, eosinophils, neutrophils, histiocytes, endothelial cells, and fibroblasts.[180] Eosinophils are most commonly observed at the periphery of mast cell aggregates (often focally), but increased numbers of eosinophils may also be seen in areas not involved by mast cells.[125] Although irregular trabecular thickening is commonly noted, particularly when mast cell aggregates abut the trabeculae, other cases may be characterized by a marked thinning of bone marrow trabeculae and osteopenia. Mast cell infiltrates are commonly associated with a dense network of reticulin fibers; in cases with diffuse marrow infiltration by monomorphous, spindled mast cells that resemble fibroblasts, a diagnosis of primary myelofibrosis may be erroneously made, especially when accompanied with a decrease in normal hematopoietic elements.

Three distinct patterns of bone marrow mast cell infiltration have been described in systemic mastocytosis.[124,125] The commonest, Type I pattern, is frequently associated with urticaria pigmentosa and indolent disease; the mast cells are focally increased (generally 10%–30% of marrow cellularity), with normal distribution of fat and other hematopoietic elements in the uninvolved marrow space. A spectrum of atypical morphological features including cell spindling, cytoplasmic hypogranulation or uneven granule distribution, cytoplasmic processes, and nuclear abnormalities are seen in mast cells from these patients; much less commonly, the mast cells may be relatively normal appearing.[126,159,176,200,201] In contrast, Type II pattern consists of a significant increase in granulopoiesis in areas not involved by mast cells, as may be seen in ASM patients; some of these cases meet WHO criteria for diagnosis of a clonal non-mast cell lineage hematologic disorder associated with mastocytosis (SM-AHNMD) (see Fig. 73–3). The latter (ie, SM-AHNMD) is the second most common mastocytosis category (more frequent than ASM) and may account for up to a third of systemic mastocytosis patients.[176,178,179,202,203] The coexistence of these two entities (ie, mastocytosis and non-mast cell neoplasm) likely reflects their origin in a common multipotent hematopoietic progenitor cell, although in rare cases the two may develop

Table 73–4 World Health Organization Criteria for Diagnosis of Systemic Mastocytosis[182]

MAJOR
Multifocal dense infiltrates of mast cells in bone marrow or other extracutaneous organ sections (>15 mast cells aggregating)
MINOR
a. ≥25% mast cells in tissue sections or bone marrow aspirate smears that are spindle shaped or have atypical morphology
b. C-kit point mutation at codon 816V
c. Expression of CD2 and/or CD25 by mast cells
d. Baseline serum tryptase persistently >20 ng/mL (not valid in presence of another non-mast cell clonal disorder)
Major plus one minor *or* three minor criteria are needed to diagnose systemic mastocytosis

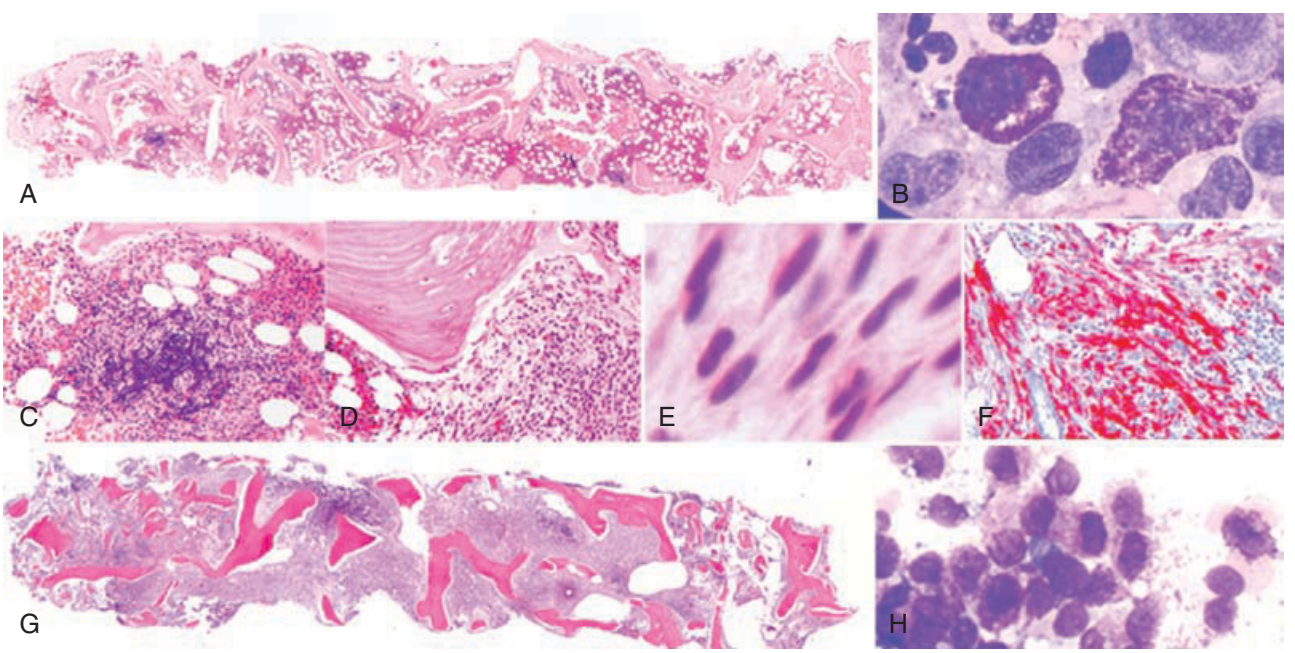

Figure 73–2 Systemic mastocytosis (**A**–**H**). Bone marrow biopsy (**A**) shows multiple small foci of involvement by systemic mast cell disease. The aspirate (**B**) contained only scattered mast cells. The involved areas include nodules of mast cells (**C**, and far left bottom in **A**) with central accumulations of lymphocytes resulting in the so-called bull's eye pattern, and paratrabecular foci (**D**, and far right bottom in **A**), along thickened bone. The latter can easily mimic lymphoma in the bone marrow, which can also exhibit a paratrabecular pattern of infiltration. High power of the mast cell involvement (**E**) illustrates the typical fusiform or spindle appearance of the mast cells. A mast cell tryptase immunohistochemical stain (**F**) is quite useful diagnostically. CD117 and CD25 were also positive. A second case (**G**) illustrates extensive involvement by an aggressive systemic mastocytosis. Note the extensive replacement of the marrow space and the marked osteosclerosis. Numerous mast cells are seen on the aspirate (**H**).

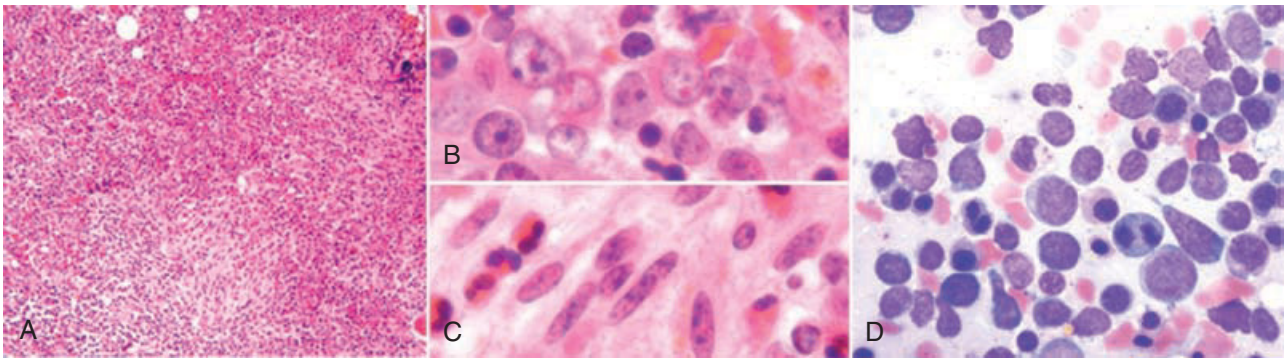

Figure 73–3 Systemic mastocytosis with an associated clonal hematological non-mast cell disorder (**A–D**). Low power of a bone marrow (**A**) from a 57-year-old female with systemic mastocytosis associated with acute myeloid leukemia. A focus of mast cells is present (**A**, bottom center) in the hypercellular marrow. High powers of same area (**B**) demonstrate increased immature cells including blasts, and the mast cell focus (**C**) composed of fusiform mast cells associated with eosinophils. The mast cells were shown to be mast cell tryptase-positive, $CD25^+$ and $CD117^+$. The marrow aspirate (**D**) illustrates increased myeloblasts associated with multilineage dysplasia.

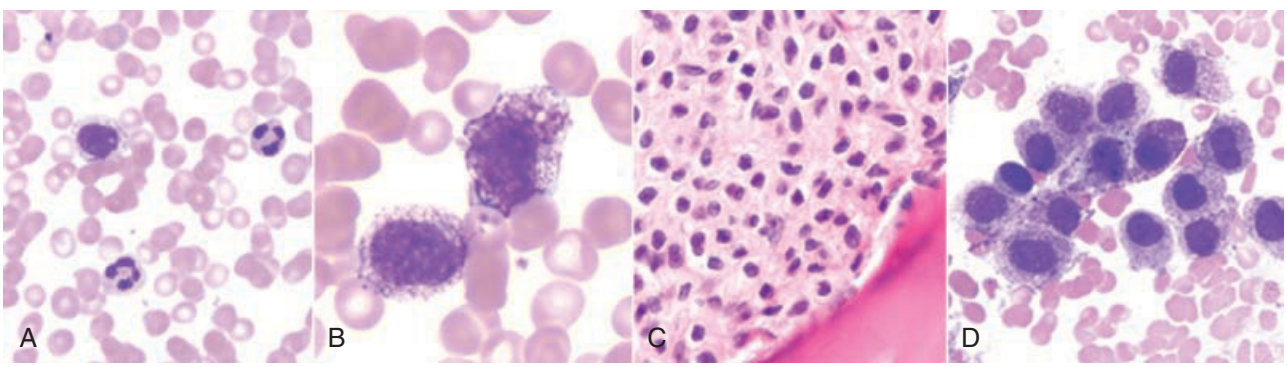

Figure 73–4 Mast cell leukemia (**A–D**). Low power of peripheral blood (**A**) showing 2 granulocytes and a single immature mast cell with sparse metachromatic granules. Two additional circulating mast cells are also illustrated (**B**). The marrow biopsy was packed with mast cells (**C**). Note the cells are held apart from one another due to their abundant cytoplasm. A similar pattern of infiltration is seen in hairy cell leukemia and in acute promyelocytic leukemia. The aspirate (**D**) shows sheets of immature and hypogranular mast cells.

independently.[202,204] The diagnosis of SM-AHNMD is established by WHO criteria, for both the mastocytosis and non-mast cell neoplasm components.[205] In most SM-AHNMD cases, a diagnosis of mastocytosis is made incidentally, usually after an examination of bone marrow for evaluation of the non-mast cell hematologic disorder.[202,203] In such cases, it is difficult to ascertain if mastocytosis existed prior to the onset of the non-mast cell disorder, although some patients provide historical clues (time of onset of UP lesions and/or symptoms of mast cell degranulation) in this regard. In most cases, the non-mast cell neoplasm tends to clinically overshadow the mastocytosis component, thereby reflecting its more aggressive biological nature. The most frequent non-mast cell disorders associated with mastocytosis are the chronic myeloproliferative disorders (except bcr-abl-positive CML), AML, and MDS.[126,179,203] The recognition that chronic myelomonocytic leukemia (CMML), a hybrid myeloproliferative–myelodysplastic disorder, is commonly associated with mastocytosis supports the contention that dysmyelopoiesis is a prominent feature of systemic mastocytosis.[202,204,206,207] In some cases, the bone marrow mast cell involvement may be obscured by the non-mast cell neoplasm if only conventional stains are employed (vide infra).[202] In this regard, mast cell infiltrates are more easily identified within sheets of monotonous blasts in AML than within the polymorphic infiltrates seen in myeloproliferative or myelodysplastic disorders. Patient characteristics that are associated with Type II pattern include older age, absence of UP lesions, organomegaly, anemia, eosinophilia, greater than 10% morphologically atypical mast cells in the bone marrow, elevated serum tryptase level, and a rapid clinical course.[158–160,176,180,200,208] Type III pattern is characterized by diffuse marrow infiltration with atypical mast cells of high-grade morphology, frequently with circulating mast cells; mast cell leukemia (MCL) (see Fig. 74–4) is characterized by increased numbers of mast cells in bone marrow (>20% in aspirate smear) and peripheral blood (>10%), with associated bone marrow failure manifested as peripheral cytopenias. The mast cells are immature, sometimes blastic, and often have sparse metachromatic granules, and hence may be missed on routine staining unless tryptase[200,201] and/or immunophenotyping studies are performed.[209,210] Rare aleukemic variants of mast cell leukemia have also been described.[210] Rarely, patients may present with increased numbers of metachromatically granulated, primitive, blast-like cells. In such cases, differentiating mast cell leukemia from tryptase- and/or kit D816V-positive acute myeloid leukemia (AML),[211,212] acute basophilic leukemia,[213] and myelomastocytic overlap syndrome[214] is a diagnostic challenge, in the absence of well-defined criteria. The aforementioned histologic patterns appear to be relevant for prognosis; in one study, mastocytosis patients with a Type I pattern (ISM) had an actuarial 5-year survival rate of 75%, as compared to 17% and 0% for patients with Type II (ASM or SM-AHNMD) and Type III (MCL) patterns, respectively.[208] Although mast cell cytologic atypia (large, irregularly shaped nuclei, increased mitotic activity, decreased numbers of metachromatic granules, etc) has been historically proposed by some authors as a criterion for aggressive mastocytosis,[199,215–217] such proposals have not been broadly accepted or implemented in routine practice.

In general, mast cells may not be readily recognized by standard dyes such as Giemsa, toluidine blue, or naphthol AS-D chloroacetate esterase (Leder stain), particularly when associated with significant hypogranulation or with abnormal nuclear morphology, and may be confused with a variety of other cells that include fibroblasts,

histiocytes, hairy cells, and monocytes, particularly in polymorphic bone marrow mast cell aggregates.[180,218] Furthermore, the metachromatic staining properties of mast cells may be significantly diminished or lost with conventional tissue processing, particularly decalcification with acidic solutions that is necessary for sectioning of paraffin-embedded bone marrow tissue.[218] Among the immunohistochemical markers, staining for tryptase is considered the most sensitive, being able to detect even small-sized mast cell infiltrates (ie, composed of 10–15 cells) (Fig. 73–2).[219,220] Given that virtually all mast cells, irrespective of their stage of maturation, activation status, or tissue of localization express tryptase, staining for this marker detects even those infiltrates that are primarily composed of immature, poorly granulated mast cells.[209] Tryptase immunostaining is particularly useful for the diffuse pattern of mast cell infiltration, particularly when the cells are loosely distributed, in contrast to discrete mast cell aggregates.[219] It must be emphasized that neither tryptase nor other immunohistochemical markers such as chymase, Kit/CD117, or CD68 can distinguish between normal and neoplastic mast cells.[221] Also, abnormal basophils seen in some cases of acute and chronic basophilic leukemia, as well as in chronic myeloid leukemia, and blasts in some AML cases may be tryptase positive, and may prove difficult to distinguish from mast cells.[202] In contrast, immunohistochemical detection of aberrant CD25 expression on bone marrow mast cells appears to be a reliable diagnostic tool in systemic mastocytosis, given its ability to detect abnormal mast cells in all mastocytosis subtypes, including the rare cases with loosely scattered, interstitial mast cells.[209] A unilateral bone marrow biopsy may not be sufficient to exclude low levels (early stages) of mast cell involvement. In a retrospective analysis of 23 mastocytosis patients who underwent bilateral bone marrow biopsies, 4 cases (17%) only had unilateral involvement.[222] Three of the four patients had low serum tryptase levels (<25 ng/mL), hence the diagnosis of systemic mastocytosis may not have been established without bilateral biopsies.

Mast Cell Immunophenotyping

As mentioned previously, the qualitative and semiquantitative profiling of cell surface antigens by multiparametric flow cytometry can be extremely useful in distinguishing normal bone marrow mast cells from their pathologic counterparts in systemic mastocytosis (reviewed by Escribano et al).[223] Normal mast cells typically express KIT/CD117 and Fc RI, and their typical profile is $CD117^{++}$/Fc RI^{+}/$CD34^{-}$/$CD38^{-}$/$CD33^{+}$/$CD45^{+}$/$CD11c^{+}$/$CD71^{+}$. These cells do not express certain myeloid markers (CD14 and CD15), or lymphoid lineage markers, except CD22.[224] Neoplastic mast cells typically express CD25 and/or CD2, and the abnormal expression of at least one of these two antigens counts as a minor criterion toward the diagnosis of systemic mastocytosis per the WHO system.[182] In general, the detection of CD25 on mast cells, by either flow cytometry or immunohistochemistry, appears to be the more reliable marker (relative to CD2), although some authors have noted significant variation in the percentage of CD2-positive cases by flow cytometry depending upon the specific antibody–fluorochrome conjugate used.[223] Consistent with flow cytometry data,[129] it has been reported that screening for CD2 expression by immunohistochemistry may have relatively low diagnostic value because a significant proportion of cases stain negative, and CD2 expression on bone marrow mast cells is generally weak in the cases that are positive.[209,220,221] Interval monitoring of CD25 expression on bone marrow mast cells may represent one approach for assessing presence of residual disease in patients undergoing mast cell-cytoreductive therapy, generally for the aggressive mastocytosis subtypes.[129,225,226] Other aberrant immunophenotypic features of neoplastic mast cells include abnormally high expression of complement related markers such as CD11c,[227] CD35,[228] CD59,[228] and CD88,[228] as well as increased expression of the CD69 early-activation antigen,[229] and the CD63 lysosomal-associated protein.[230]

Serum Tryptase Measurement

The measurement of tryptase (a mast cell enzyme with trypsin-like enzymatic activity) levels in biological fluids (serum) has proven to be a useful disease-related marker in systemic mastocytosis, and is included as a minor criterion for diagnosing the condition according to WHO guidelines, provided that certain conditions are satisfied.[182,231] There are two major forms of mast cell tryptase–alpha (subtypes alpha 1 and 2) and beta (subtypes beta 1, 2, and 3) (reviewed by Schwartz).[232] Mature beta 2 tryptase is stored in mast cell secretory granules as an enzymatically active tetramer complexed with proteoglycans and is released only during granule exocytosis, thereby largely reflecting mast cell activation. In contrast, the precursor forms of both alpha and beta tryptase are constitutively secreted by mast cells,[233] and the combined total serum levels (including precursor and mature tryptase forms) are thought to correlate with systemic mast cell number, albeit with effects related to tryptase haplotype and gender.[234] The commercially available fluoroimmunoenzymatic assay (Pharmacia, Uppsala, Sweden) measures total tryptase levels; in healthy individuals, levels range from 1 to 15 ng/mL, whereas in most patients with systemic mastocytosis, total serum tryptase levels exceed 20 ng/mL. In cases of suspected mastocytosis, it is important that serum tryptase levels be interpreted in the appropriate context. Elevated levels of serum tryptase have been documented in patients with non-mast cell myeloid malignancies, including acute myeloid leukemia (AML),[211,235] myelodysplastic syndrome (MDS),[236] and chronic myeloid leukemia (CML),[237] which mandates exclusion of such non-mast cell myeloid disorders before reaching a diagnosis of systemic mastocytosis. Furthermore, levels of serum tryptase, particularly mature β-tryptase, can be frequently elevated in association with anaphylaxis or a severe allergic reaction.[231] Total tryptase levels may also be useful for monitoring treatment response in mastocytosis patients; interpretation of levels however has to take into account other clinical/laboratory data, given the potential inherent variability of tryptase levels, as well as other possible confounding effects, such as administration of radiocontrast agents or narcotics, that may lead to mast cell degranulation.

Molecular Studies

In mastocytosis patients molecular studies are important from the diagnostic standpoint and, increasingly, from the therapeutic standpoint as well. Recent studies underscore the high prevalence of the Kit D816V gain-of-function mutation in mastocytosis patients, with high correlation between mutation detection and the proportion of lesional/clonal cells in the sample, as well as the sensitivity of the screening method employed (reviewed by Akin).[145] Accordingly, the likelihood of mutation detection in peripheral blood mononuclear cells in a case of indolent mastocytosis (with low probability of circulating clonal cells), using a low-sensitivity screening test (eg. DNA sequencing), is quite low. Sensitivity of detection may be enhanced by enriching lesional mast cells or other clonal cell populations (eg. neutrophils or eosinophils) by laser capture microdissection, or magnetic bead- or flow cytometry-based cell sorting, respectively.[161,206,238] Furthermore, use of higher-sensitivity methods including allele-specific PCR,[239] or PCR with peptide nucleic acid (PNA) probes to clamp the wild-type allele combined with mutant allele detection with hybridization probes dramatically enhance the probability of mutation detection in bulk cells (sensitivity = 10^{-3}).[136,138] Using the latter method, the D816V mutation was detected in virtually all patients with indolent (ISM) or aggressive (ASM) systemic mastocytosis (93%), but less frequently in patients with well-differentiated systemic mastocytosis (WDSM; vide infra) (29%) in a recent study.[138] Here, Kit mutations other than D816V (eg, I817V, VI815–816) were rarely detected (<3%). Notably, most poor prognosis mastocytosis patients harbored Kit D816V in two or more bone marrow myeloid cell populations (81%), in contrast to indolent mastocytosis cases (27%).

WDSM may represent a distinct, albeit genetically heterogenous, subtype of systemic mastocytosis.[138] A subset of WDSM cases carry the F522C germline mutation located in the Kit transmembrane domain.[142] In contrast to other systemic mastocytosis subtypes, mast cells in WDSM do not (aberrantly) express either CD2 or CD25 antigens and are mature in appearance.

The *FIP1L1-PDGFRA* mutation can be detected by either fluorescence in situ hybridization (FISH) or PCR-based assays.[165,240] Some investigators have suggested that PCR (particularly nested PCR) is a more reliable screening test for *FIP1L1-PDGFRA* (relative to FISH) in primary eosinophilia, given the low sensitivity of FISH in some cases.[240] Limitations of PCR-based assays include the possibility of an unusual *FIP1L1-PDGFRA* transcript, given the heterogeneity of breakpoints with the *FIP1L1* locus and other mechanisms (eg, cryptic splice sites), which may lead to a false-negative test result. Finally, although real-time quantitative PCR assays for monitoring *FIP1L1-PDGFRA* transcript levels have been described, its precise utility in assessing either depth of response with therapy (ie, detection of minimal residual disease) or for molecular relapse remains unclear at this time.

Treatment

Adults with systemic mastocytosis generally seek treatment for one or more of the following disease manifestations: skin rash (eg, UP), symptoms of mast cell degranulation, and/or symptoms related to skeletal involvement or organomegaly/organopathy from mast cell infiltration. Although the treatment of systemic mastocytosis has hitherto been empirically derived, recent advances in our understanding of the molecular pathogenesis of this condition allows for the identification of specific disease subtypes that are uniquely sensitive (or resistant) to specific therapies. Consequently, in this era of increasingly wider access to molecular testing, it is important that mastocytosis patients be molecularly profiled for presence or absence of relevant pathogenetic mutations, to enable optimal therapeutic decisions for a given individual. The relative rarity of mastocytosis, its biologic heterogeneity, and (historically) the lack of simple, widely agreed upon treatment response criteria, have hitherto served as barriers to development of evidence-based therapies for this disorder. Although the therapy of systemic mastocytosis patients has to be individualized, an algorithm illustrating our general treatment approach to these patients is presented in the box below. Investigational therapies for systemic mastocytosis are discussed in the next section. We refer the reader to specialized dermatology texts for the treatment of cutaneous mastocytosis.

Treatment of Mast Cell Degranulation Symptoms

Although mast cell cytoreductive agents (eg, interferon, chemotherapy) can often effectively ameliorate symptoms of mast cell degranulation, these agents may have significant adverse effects; hence, the initial approach to these patients emphasizes measures to prevent mast cell degranulation, as well as use of medications for symptom relief. In all cases, avoidance of triggers for mast cell degranulation (eg, animal venoms, extremes of temperature, mechanical irritation, alcohol, emotional and physical stress) remains the cornerstone of therapy. Some patients cannot tolerate certain drugs or chemicals such as opioid analgesics, alcohol, aspirin/other nonsteroidal anti-inflammatory medications, contrast dyes; the patient history often provides useful clues in this regard. Furthermore, appropriate precautionary measures during anesthesia and surgery are recommended in these patients.[241–244]

Noncytoreductive therapy of mast cell degranulation symptoms includes the use of oral H-1 (eg, hydroxyzine, diphenhydramine, fexofenadine, cetirizine, cyproheptadine, chlorpheniramine) and H-2 (eg, ranitidine, famotidine) antihistaminics for pruritis and peptic ulcer symptoms, respectively, and orally administered cromolyn sodium for nausea, abdominal pain, and diarrhea. Use of the latter is supported by Level I evidence.[187,245] Cromolyn sodium was found in a double-blind crossover study to be therapeutically equivalent to a combination of cimetidine and chlorpheniramine for the treatment of mastocytosis-related symptoms.[246] Corticosteroids are occasionally used for treating recurrent hypotensive episodes, ascites, and diarrhea with malabsorption. Patients with a propensity toward vasodilatory shock ought to wear a medical alert bracelet and carry an Epi-Pen injector for self administration of subcutaneous epinephrine.[247] In the rare case of a patient with severe and/or recurrent life-threatening degranulation-related events that are refractory to the aforementioned agents, cautious consideration may be given to the use of cytostatic or cytoreductive agents; one must keep in mind however the potential adverse effects, including potentially mutagenic effects, of such agents and use them only after a full discussion of potential risks and benefits of such treatment with the patient.

Treatment of Organomegaly/Organopathy Symptoms

Cytoreductive therapy, especially chemotherapy, is generally reserved for patients with progressive symptomatic disease, and organopathy (C findings) that is directly related tissue mast cell infiltration. In certain patients, however, it can be difficult to distinguish whether the organopathy relates to mast cell infiltration or whether it represents an immunological response to the disease or an associated non-mast cell neoplasm (SM-AHNMD). Currently employed first- and second-line therapeutic agents include the following.

Interferon-Alpha (IFN-α)

Interferon-alpha (IFN-α) is often considered the first-line therapy for progressive symptomatic disease, including in the presence of a concurrent non-mast cell myeloproliferative disorder (eg, CMML).[248] IFN-α is generally started at the dose of 1 million units (MU) subcutaneously three times per week, followed by gradual escalation to 3 to 5 MU three to five times per week, if tolerated. IFN-α (with or without concomitant corticosteroids for synergistic effect) has been reported to improve symptoms of mast cell degranulation,[249] decrease bone marrow mast cell infiltration,[250–255] and ameliorate mastocytosis-related ascites/hepatosplenomegaly,[250,251,256] cytopenias,[257] skin findings,[248,252,258] and osteoporosis.[253,254,259,260] Response rates to IFN-α therapy have been difficult to estimate, given the heterogeneous presentation of patients with mastocytosis, use of variable treatment dosages, generally short follow-up, and use of nonuniform treatment response criteria in published studies. The optimal dose and duration of IFN-α therapy for systemic mastocytosis remain uncertain. In a prospective multicenter study, all four patients receiving the highest IFN-α dose (ie, >3 MU/m^2/day) responded to treatment.[249] The time to best response may be up to 12 months or longer[257] and delayed responses to therapy have been described.[261] A significant proportion of patients may experience clinical and/or biochemical relapse within several months of IFN-α treatment being discontinued, outlining the largely cytostatic effect of IFN-α on neoplastic mast cells.[249,251] IFN-α is associated with a variable, but significant, incidence (up to 50%) of dose-limiting toxicity, including flu-like symptoms, bone pain, fever, worsening cytopenias (particularly in patients with baseline organomegaly/cytopenias), depression, and hypothyroidism.[249,251] Anaphylaxis, as a response to IFN-α injections, has been described.[262] Consequently, the dropout rate with IFN-α treatment due to adverse events is not trivial and whether the addition of corticosteroids to IFN-α improves either treatment tolerance or efficacy remains to be proven in a randomized setting.[257]

2-Chlorodeoxyadenosine/Cladribine

Single-agent 2-chlorodeoxyadenosine/Cladribine (2-CdA) has therapeutic activity in systemic mastocytosis in IFN-α refractory/intolerant patients; variable treatment schedules have been employed in this setting.[263–267] In a prospective multicenter pilot study of 10 patients, 2-CdA (0.1–0.13 mg/kg by a 2-hr IV infusion on days 1 through 5

Investigational Therapies

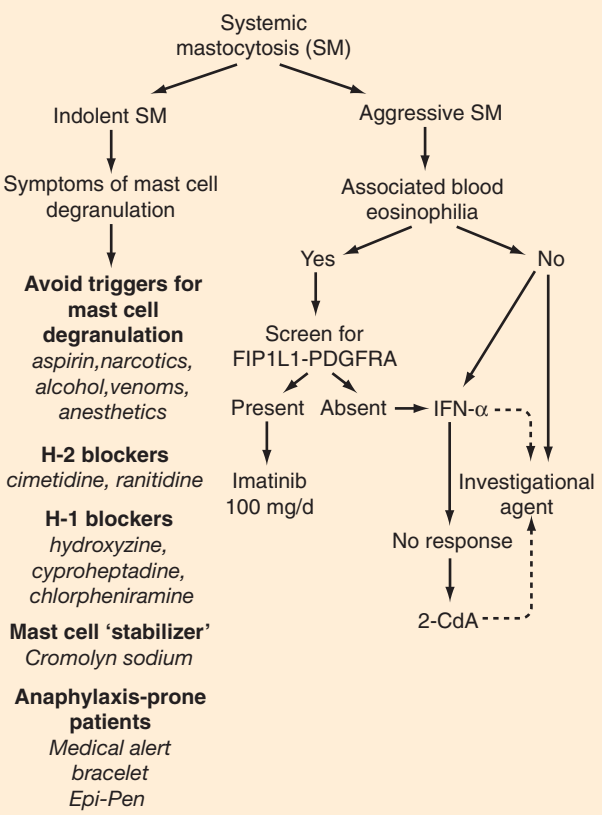
Tyrosine Kinase Inhibitors

PKC412 is an *n*-benzoyl-staurosporine, with inhibitory activity against protein kinase C (PKC), Flt3 (FMS-like tyrosine kinase), Kit, vascular endothelial growth factor receptor-2 (VEGFR-2), PDGFR, and fibroblast growth factor receptor (FGFR) tyrosine kinases.[283,284] PKC412 potently inhibits growth of cell lines harboring Kit D816V,[285,286] and early data suggest activity in patients with advanced systemic mastocytosis[287,288]; preliminary data from the latter Phase II study indicated that six of nine patients responded to PKC412 therapy. PKC412 has limited efficacy as a single agent for treatment of AML[289] but may be active against constitutively activated ZNF198-FGFR1 for the treatment of 8p11 myeloproliferative syndrome (EMS).[290]

Dasatinib (BMS354825) is an orally bioavailable thiazolecarboxamide that is structurally unrelated to imatinib. It is a dual Src/Abl kinase inhibitor that is more potent than imatinib, and demonstrates inhibitory activity against a number of Bcr-Abl mutations linked to imatinib resistance in CML, but not T315I.[291] Dasatinib inhibits cell lines harboring Kit WT or Kit D816V at nanomolar concentrations.[292,293] In contrast to imatinib, dasatinib binds to the Abl and Kit ATP-binding sites irrespective of the activation-loop conformation.[294,295] Preliminary data indicates modest activity in systemic mastocytosis; in one report, although 30% had symptomatic benefit, only 2 of 24 patients achieved significant mast cell cytoreduction (both patients were Kit D816V-negative and achieved complete remission).[296]

Nilotinib (AMN107) is a small-molecule kinase inhibitor with activity against a number of Bcr-Abl mutations linked to imatinib resistance in CML, but not T315I.[297] Nilotinib also has in vitro inhibitory activity against cell lines harboring Kit WT or Kit V560G (juxtamembrane mutant) but has limited activity against Kit D816V (IC_{50} in micromolar range).[285,298] These data suggest that nilotinib may be a less than ideal candidate for treatment of systemic mastocytosis, where a majority of the patients carry the Kit D816V mutation.[285] Data pertaining to clinical activity of AMN107 in mastocytosis patients is not yet available.

MLN518 is a quinazoline-based tyrosine kinase inhibitor, which inhibits cell lines harboring Kit D816V as well as juxtamembrane mutant-Kit, thus making it a promising candidate for mastocytosis treatment.[299]



AP23464/AP23848 are ATP-based inhibitors that have low-nanomolar inhibitory activity against Kit D816V.[300] Interestingly, cell lines harboring Kit WT or juxtamembrane mutant-Kit were less sensitive to inhibition, relative to Kit D816V, suggesting a therapeutic window wherein clones carrying the latter mutation could be selectively suppressed/eliminated in mastocytosis patients without disrupting normal hematopoiesis.

EXEL-0862 is a novel tyrosine kinase inhibitor that has been shown to have greater inhibitory activity against the HMC 1.2 cell line that harbors both Kit D816V and Kit V560G, as compared to HMC 1.1 that harbors the juxtamembrane Kit V560G mutation alone.[301] Thus, EXEL-0862 is a promising candidate for the treatment of mastocytosis and other malignancies harboring active site Kit mutations.

Nontyrosine Kinase Inhibitors

17-AAG (17-(Allylamino)-17-demethoxygeldanamycin) is a geldanamycin derivative that binds to heat shock protein 90 (hsp90), thus enhancing the proteasomal degradation of several hsp90 client kinases, including mutant Kit. In one report, a dose-dependent decrease in phosphorylation of Kit, Akt, and STAT3 was observed in both HMC 1.1 and HMC 1.2 cells.[302] Furthermore, 17-AAG inhibited patient-derived neoplastic mast cells ex vivo, relative to mononuclear cells. 17-AAG is currently in phase II clinical trials for the treatment of mastocytosis.

IMD-0354 is an NF-κB inhibitor, which potently suppresses growth of HMC 1.2 cells that harbor both Kit D816V and Kit V560G mutations, and may have promise for treating mastocytosis patients.[303]

every 4–8 weeks for 6 cycles) was found to be therapeutically active in all mastocytosis subsets.[267] Although all patients had a clinical response, and bone marrow mast cell cytoreduction was also noted in 9 of 10 patients, no complete remissions were observed. Also, in a preliminary report of 33 SM patients treated with 2-CdA (0.15 mg/kg by a 2-hr IV infusion or subcutaneously for 5 days every 4–12 weeks for 1 to 6 cycles), major, partial, or no responses were seen in 24, 2, and 7 patients, respectively.[268] Myelosuppression was the major adverse effect seen in approximately a third of cases in each study. Although single-agent 2-CdA has activity in the treatment of systemic mastocytosis, there is relatively limited experience with its use in this setting; additional data are awaited to clarify the optimal dose/schedule of administration, response rates in specific mastocytosis subtypes, and durability of treatment responses. Given the potential for prolonged bone marrow aplasia and lymphopenia and associated risk of opportunistic infections, its use is probably best restricted to select cases with IFN-α refractory disease, after careful consideration of the risk-to-benefit ratio as well as other available therapies for every patient.

Imatinib Mesylate (Gleevec™)

Imatinib mesylate (Gleevec™) is an orally bioavailable small-molecule inhibitor of Kit, Abl, Arg, and PDGFR tyrosine kinases. The identification of gain-of-function mutations involving *Kit* and *PDGFRA* genes (known imatinib targets) in the pathogenesis of sys-

temic mastocytosis has obvious therapeutic implications in this regard. Consistent with predictions from in vitro data,[154,269] the limited clinical experience to date suggests that the vast majority of mastocytosis patients (who harbor Kit D816V) are likely to be refractory to imatinib therapy.[270,271] In contrast, clinically meaningful responses have been observed for the rare patients with Kit juxtamembrane mutations (eg, F522C, K509I), suggesting that this subgroup of patients has imatinib-responsive disease.[142,144] Furthermore, patients with bone marrow involvement by abnormal mast cells who harbor *FIP1L1-PDGFRA* also uniformly achieve complete clinical, histologic, and molecular/cytogenetic responses with low-dose imatinib therapy, in the absence of mutations that confer imatinib resistance (*PDGFRA*T764I), which may be acquired with clonal evolution (reviewed by Pardanani).[164,165,272–274] Lastly, imatinib is predicted to be effective in systemic mastocytosis with specific mutations such as V560G[275] and del419,[140] although clinical proof of this supposition is lacking to date. The remarkable efficacy of imatinib in treating mastocytosis patients harboring specific mutations provides proof-of-principle for development molecularly targeted therapies for this disease, as well as a treatment-relevant molecular classification. It is currently recommended that patients with primary eosinophilia, particularly in the presence of increased bone marrow mast cells or increased serum tryptase level (ie, SM-CEL), be screened for the presence of *FIP1L1-PDGFRA* by either fluorescence in situ hybridization (FISH) or reverse transcriptase–polymerase chain reaction (RT-PCR). Imatinib mesylate, generally at the 100 mg daily dose level, is considered to be first-line therapy for this group of patients.[276–278] Initiation of imatinib therapy in patients with clonal eosinophilia harboring *FIP1L1-PDGFRA* can rarely lead to cardiogenic shock resulting from rapid onset of eosinophil lysis/degranulation in the endomyocardium.[279,280] Consequently, consideration may be given to starting imatinib concurrently with corticosteroids, particularly in the presence of either an abnormal echocardiogram or an elevated serum troponin level prior to treatment. In contrast to *FIP1L1-PDGFRA*, early data suggest that imatinib is not therapeutically beneficial for patients carrying Kit D816V, who make up the majority of systemic mastocytosis patients.[164,165,271,281] This mutation maps to the Kit enzymatic site and disrupts the imatinib-binding site.[282] For patients harboring D816V or those without detectable imatinib-sensitive mutations, IFN-α may represent an attractive initial treatment option. Although a modest clinical benefit may be observed with imatinib at 400 mg daily in some patients without either Kit D816V or *FIP1L1-PDGFRA*,[281] the use of imatinib in this setting is considered investigational.

FUTURE DIRECTIONS

The approach to a patient with systemic mastocytosis continues to be challenging, with many unanswered questions relating to aspects of (a) diagnosis, (b) pathogenesis, (c) clinical presentation, and (d) treatment of this heterogeneous disorder.

- At the diagnostic interface, a uniform approach to molecular testing is lacking at present; consensus is needed regarding the specific molecular assay(s) as well as biological material(s) that are considered optimal for mutation analysis in mastocytosis patients.
- At present, it is unclear why some mastocytosis patients develop a concurrent non-mast cell hematologic neoplasm (eg, CMML)—do these emerge from the same clone? Are there specific mutations that cooperate with Kit D816V in this regard?
- Questions pertaining to the diverse clinical presentation of mastocytosis patients also remain largely unanswered—for instance, are specific symptoms related to particular mast cell mediators? What determines whether skin rash versus bone disease (or other feature) will be the dominant clinical presentation for a given patient?
- Finally, there is an urgent need for studies of small molecule inhibitors/other novel therapies targeting Kit D816 in mastocytosis patients; given the relative rarity of mastocytosis, this will most effectively be accomplished in the setting of cooperative, multiinstitutional clinical trials.

CHAPTER 74

MYELODYSPLASTIC AND MYELOPROLIFERATIVE SYNDROMES IN CHILDREN

Franklin O. Smith and Mignon L. Loh

INTRODUCTION

The myelodysplastic (MDS) and myeloproliferative syndromes (MPS) are a heterogeneous group of clonal stem cell disorders that result in ineffective hematopoiesis and an increased risk of developing acute myeloid leukemia (AML). In MDS, ineffective hematopoiesis results in progressive cytopenias whereas, in MPS, at least initially, ineffective hematopoiesis leads to excessive proliferation characterized by increased peripheral blood counts. MDS and MPS are rare in children, with the vast majority of cases diagnosed in older adults. Chronic myelogenous leukemia (CML), characterized by the Philadelphia chromosome (*bcr/abl*-positive) is seen in both children and adults, whereas other forms of MPS (polycythemia vera [PV], essential thrombocythemia [ET], primary myelofibrosis [PMF], chronic neutrophilic leukemia [CNL], chronic eosinophilic leukemia [CEL], chronic basophilic leukemia [CBL], chronic myelomonocytic leukemia [CMML], systemic mastocytosis [SM], and stem cell leukemia-lymphoma syndrome [SCLL]) are exceedingly rare in children. Readers interested in CML and disorders that are predominantly found in adults are referred to in chapters 67, 69, and 70. In contrast, two of these MPS disorders are uniquely pediatric: juvenile myelomonocytic leukemia (JMML) and Down syndrome-associated transient myeloproliferative disorder (TMD).

MYELODYSPLASTIC SYNDROMES

The myelodysplastic syndromes are a heterogeneous group of disorders characterized by ineffective hematopoiesis, impaired maturation of hematopoietic cells, progressive cytopenias, and dysplastic changes in the bone marrow.

Epidemiology

MDS is a common malignancy of adults with an incidence of 50 cases per million in people over the age of 60 years.[1] In contrast, MDS accounts for only 3% to 7% of all hematologic malignancies in children, with an unknown true incidence. Several population-based studies have been performed with reported incidences of 4.0 cases per million in Denmark,[2] 3.1 per million in British Columbia,[3] and 1.35 per million in the United Kingdom.[4] The median age of presentation is 6.8 years with an equal sex distribution.[4–6]

Pathobiology

As in adults, MDS in children can be considered as de novo or secondary. In adults, two predominant patterns of primary, de novo MDSs have been observed. In the first of these patterns, the disease is indolent in nature, is characterized by prolonged survival, little accumulated genetic damage, and a low probability of progression to AML. This group of diseases is best exemplified by the 5q− syndrome, an entity not seen in children. Far more common in adults is a disease characterized by the accumulation of genetic damage, progression to marrow failure, and a high probability of developing AML. This form of the disease is characterized as a mutator phenotype.[7] The primary myelodysplastic syndromes seen in children appear to share this mutator phenotype.

As in adults, secondary MDS in children can also arise as sequelae from exposure to chemotherapy and radiation; however MDS in children may also result from constitutional marrow failure syndromes including Fanconi anemia, congenital neutropenia (Kostmann syndrome), Shwachman syndrome, and Diamond–Blackfan anemia.

Ongoing studies are now defining the molecular pathogenesis and interrelationship between MDS, MPS, and AML.[8–10] Accumulating data suggest that aberrant signal transduction resulting from acquired somatic mutations encoding proteins leading to hyperactivation of the Ras pathway may stimulate proliferation without concomitant differentiation.[9] This has been clearly demonstrated in CML (BCR-ABL).[11,12] A number of other putative pathogenetic mutations have been identified in other myeloproliferative disorders, including *JAK*2V617F in PV, ET, and PMF[13]; *KIT*D816V in SM[14]; *FIPL1-PDGFRA* in CEL-SM[15]; *ZNF198-FGFR1* in SCLL[16]; *RAS/NF1/PTPN11* mutations in JMML[17–19]; and *GATA1* mutations in TMD (Fig. 74–1).[20]

AML is the result of cooperating mutations in genes that confer a proliferative and survival advantage without effecting differentiation (eg, activating mutations in receptor tyrosine kinases [FLT3, c-kit]) and genes that impair differentiation and apoptosis (eg, loss of function mutations in transcription factors [CBF, AML/ETO]) (Fig. 74–2). This multistep model for the pathogenesis of AML is supported by murine models,[21,22] the analysis of leukemia in twins,[23–26] and the analysis of patients with familial platelet disorder with a propensity to develop AML (FDP/AML syndrome).[27]

Classification

Until recently, MDS in children has been poorly defined, characterized, classified, and reported. In fact, MDS was not included in the International Classification of Childhood Cancer until 2005.[28] Also contributing to this lack of information was the use of classification and prognostic systems designed for adults that have had limited applicability to children. A number of classification systems for children and adults have now been proposed. The most commonly used system is the French–American–British (FAB) system originally proposed in 1982.[29] This classification system recognized five forms of MDS in adults: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess of blasts (RAEB), refractory anemia with excess of blasts in transformation (RAEB-T) and chronic myelomonocytic leukemia (CMML). Using this system, RAEB, and RAEB-T were commonly reported in children, whereas RA and RARS were thought to be rare in children. However, a recent population-based study in the United Kingdom showed 25% of childhood MDS cases to be RA or RARS[4] suggesting inaccurate diagnosis, or reporting of these subtypes in other pediatric studies. CMML has only rarely been reported in children.

Additional subtypes of MDS are now recognized that do not fit well into the FAB system, including hypoplastic MDS, therapy-related MDS, refractory cytopenias with trilineage dysplasia, MDS associated with myelofibrosis, and MDS associated with inherited disorders (congenital neutropenias, Shwachman syndrome, Fanconi

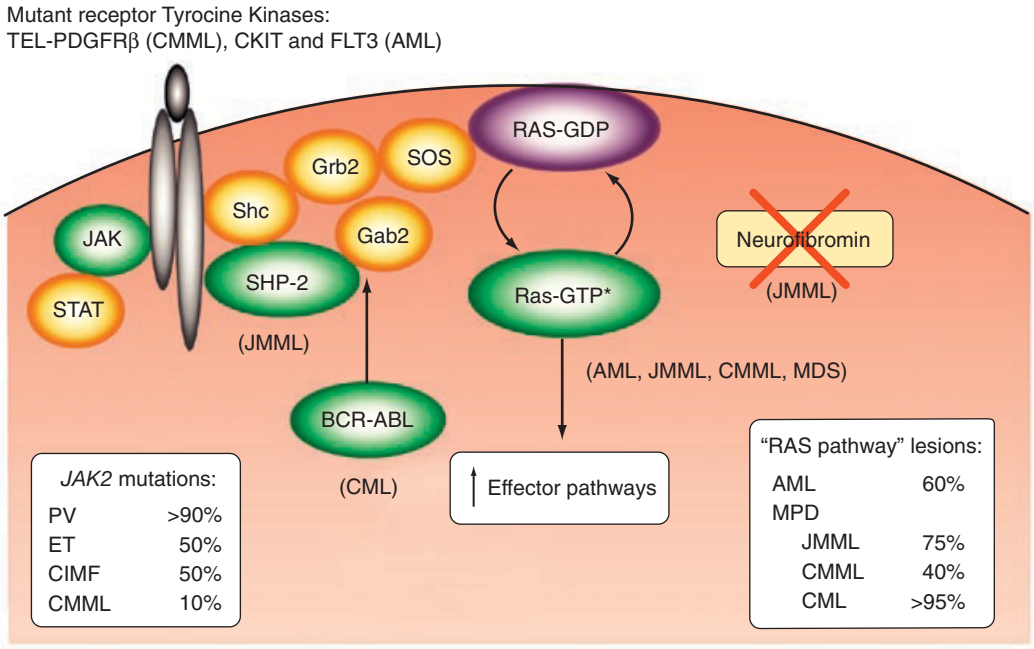

Figure 74–1 Overview of Ras signaling with molecules harboring mutations in patients with myeloid malignancies. AML, acute myeloid leukemia; CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia; GDP, guanosine diphosphate; GTP, guanosine triphosphate; JMML, juvenile myelomonocytic leukemia; MPD, myeloproliferative disorder.

Refractory cytopenias with multilineage dysplasia (RCMD)
RCMD-EB

anemia), Down syndrome, and neurofibromatosis type 1, and mitochondrial cytopathies.[30,31] Therefore, the World Health Organization (WHO) recently proposed changes to the FAB criteria to account for many of these subtypes.[32] Other significant changes included elimination of the RAEB-T subtype with reclassification of MDS with greater than 20% blasts as AML and reassignment of CMML and JMML to a new category of MDS/MPS.

Despite these improvements to the FAB system found in the WHO classification, there are still a number of limitations for children. Therefore, several pediatric-based classification systems for MDS and MPS have been proposed. Among these is a system to parallel the WHO classification (Table 74–1).[33] In this system, there are three major subtypes. The first category includes myeloproliferative disorders of childhood, including JMML, CMML, and Ph– CML. The second category includes patients with Down syndrome with associated TMD or myeloid leukemia. The third category focuses specifically on MDS and consists of refractory cytopenias (RC) (defined as <5% marrow blasts and <2% peripheral blasts), RAEB with 5% to 19% marrow blasts and 2% to 19% peripheral blasts and RAEB-T, defined as 20% to 29% peripheral blood or bone marrow blasts.

A second system based on category, cytology, and cytogenetics (CCC) allows for classification of individual patients into a very large number of categories.[34] The clinical utility of this system is unclear. However, a recent comparison of these two pediatric systems with the adult WHO and FAB systems suggested that both were superior for children than the corresponding adult classification system.[35]

Taken together, it may be useful to think about childhood MDS as primary or secondary, with secondary MDS arising either from a known congenital bone marrow failure syndrome or prior acquired aplastic anemia, or as a complication from prior chemotherapy or

radiation therapy. A diagnosis of primary MDS would then apply to all other cases.

Clinical Manifestations

Signs and symptoms of MDS are nonspecific and are usually attributable to pancytopenia (fever, infections, pallor, fatigue, bruising, and petechiae). Lymphadenopathy, hepatomegaly, and splenomegaly are uncommon presenting signs in children with MDS.

Laboratory Manifestations

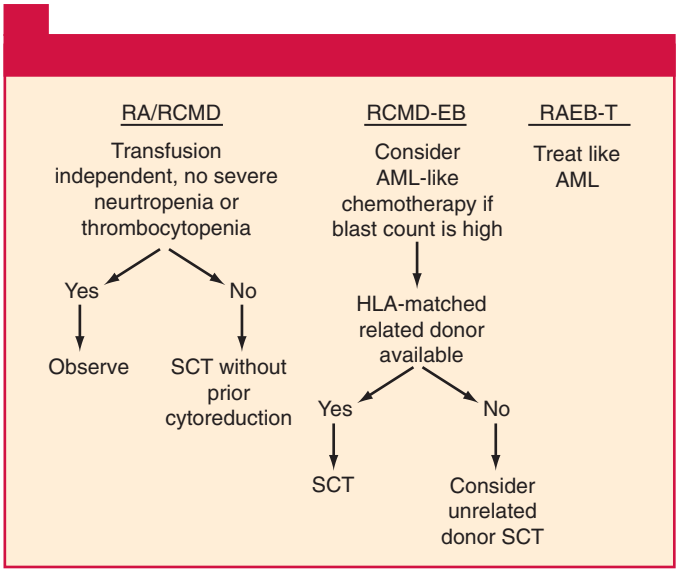
Commonly accepted minimal diagnostic criteria for pediatric MDS would include the absence of common de novo AML karyotypic abnormalities and at least two of the following: (a) sustained, unexplained anemia; neutropenia or thrombocytopenia; dysplastic morphology in the erythroid; granulocytic or megakaryocytic lineages (at least bilineage); (b) an acquired, sustained clonal cytogenetic abnormality and 5% or more blasts in the marrow.[7,33] Almost half of all children with MDS in a series reported by Kardos et al presented with refractory cytopenia, most notably neutropenia and thrombocytopenia.[36]

Morphologically, the bone marrow may be hypocellular, normocellular, or hypercellular. A diagnosis of MDS is made based on the presence of dysplastic changes in at least two cell lineages. The dysplastic changes in the granulocytes (hypogranulation, nuclear hyposegmentation, megaloblastoid maturation, and a left shift with an increased number of myeloblasts), megakaryocytes (micromegakaryocytes, abnormal megakaryocyte nuclei), monocytes (increase in marrow monocytes, abnormal granulation with persistence of azurophilic granules, hemophagocytosis, abnormal nuclei, and giant forms), and/or erythroid lineages (megaloblastoid maturation, nuclear budding and multinucleated forms, and ringed sideroblasts) can be multiple and varied. Similar dysplastic changes can occur in the peripheral blood for each of these lineages. Although dysplastic changes in the marrow are a common feature of MDS, it is important to remember that dysplasia, unto itself, is not diagnostic of MDS because dysplastic features are associated with other conditions and can be found in normal marrow donors.[37]

Although flow cytometric analysis can serve to quantitate the number of blasts based on aberrant cell surface antigen expression and detect populations of PNH-like $CD91^+$ cells,[38] flow cytometric findings analysis is not generally diagnostic of MDS.

Cytogenetic abnormalities are seen in approximately half of children diagnosed with de novo MDS. Karyotypic abnormalities most commonly seen are −7, 7q−, and +8. Abnormalities in chromosomes 6, 9, 11, 12, and 13 are rare in children. Specific abnormalities seen in adults, including −5, 5q−, and −Y are very rarely seen in children. Finally, chromosome abnormalities commonly found in de novo AML including t(8;21), t(15;17) t(9;11), t(16;16), t(11;19), t(11;17), t(8;16), and inv[16] are not commonly seen in MDS.

Differential Diagnosis



Although the history, physical examination, evaluation of the bone marrow and peripheral blood, and cytogenetic analysis will often make the diagnosis of MDS, other diseases should be considered. Congenital disorders such as Down syndrome, Fanconi anemia, Shwachman syndrome, Diamond–Blackfan anemia, congenital dyserythropoietic anemias, and hereditary sideroblastic anemia should be considered. Hypoplastic MDS can be difficult to distinguish from severe aplastic anemia and may require prospective monitoring and serial bone marrow examinations. The differential should also include AML with a low blast count, mitochondrial cytopathies such as Pearson syndrome, and myeloproliferative disorders. Specifically, PNH, while rare in children, should be considered. Deficiencies of vitamin B_{12} and folate can cause megaloblastic changes that resemble the dysplastic changes seen in MDS. Other nutritional deficiencies, including iron, thiamine, riboflavin, and pyridoxine should be considered. Infections due to human immunodeficiency virus, parvovirus, Epstein–Barr virus, cytomegalovirus, and human herpes virus 6 can cause changes that resemble MDS. Finally, the differential should include toxins (insecticides, chemotherapy agents, and arsenic) as well as cytokine exposure and radiation. In cases where the diagnosis is unclear, serial bone marrow examinations may serve as a useful aid.

Therapy

Although MDS is a heterogeneous, clonal disease of hematopoietic stem cells that can manifest different clinical courses, it is not readily curable by conventional chemotherapy and requires allogeneic hematopoietic stem cell transplantation (SCT) for cure in most cases. Some children with RA and refractory cytopenias with multilineage dysplasia (RCMD) who do not have life-threatening neutropenia and who do not require transfusions may only require close observation (see Red Box). Although children with this disease may eventually develop progressive disease requiring SCT, they may have long periods when minimal treatment is required.[36] The use of AML-like chemotherapy for patients with refractory cytopenias with multilineage dysplasia with excess blasts (RCMD-EB) is controversial but may serve to "de-bulk" patients with a high percentage of blasts prior to SCT.[6,39,40] However, this potential benefit may be offset by toxicities associated with AML-like chemotherapy. Finally, patients with RAEB-T, which is now defined as AML, or t-MDS, should be treated like AML.

A multitude of agents have been studied for the treatment of MDS in adults, but only rarely in children. These include low-dose chemotherapy (cytosine arabinoside, melphalan, hydroxyurea, etoposide, topotecan, 6-mercaptopurine, and busulfan), hormones (glucocorticoids and androgens), differentiating agents (13-*cis*-retinoic acid, all-*trans* retinoic acid), hematopoietic growth factors (granulocyte-macrophage colony-forming factor [GM-CSF], granulocyte colony-forming factor [G-CSF] and erythropoietin), demethylating agents (decitabine, 5-azacytidine), proteosome inhibitors, antiangiogenic agents, amifostine, and arsenic.[41–61] Although the potential to better control MDS in adults with azacitidine, decitabine, and arsenic is exciting, there is currently no safety or efficacy data to support the use of these agents in children with MDS.

Most children with MDS will require allogeneic SCT for curative therapy. Although children have been included in published SCT studies for MDS that are largely focused on adult patients, there are

several studies focusing specifically on children.[62–65] Taken together, these studies suggest a probability of disease-free survival in about 50% of patients undergoing HLA-matched related donor SCT.

Prognosis

Although a number of methods have been developed to predict the outcome of adults with MDS, the system now most commonly used in adults is the International Prognostic Scoring System.[66] This system uses percentage marrow blasts, karyotype, and number of cytopenias to assign a score that is then used to predict outcome. Although it is an effective tool for adults, its value for children is very limited.[67]

Secondary Myelodysplastic Syndrome

Secondary MDS can develop in both children and adults after exposure to chemotherapy and radiation. Alkylating agents used to treat Hodgkin disease, non-Hodgkin lymphoma and Ewing sarcoma are particularly concerning in children.[68–80] Interestingly, there is also evidence to suggest that the cardioprotectant, dexrazoxane, a topoisomerase II inhibitor with a mechanism of action that is different from etoposide and doxorubicin, may have increased the incidence of secondary MDS and AML in children treated for Hodgkin disease.[81]

Treatment options for children with secondary MDS are limited. Although AML-like chemotherapy can induce a period of remission and reduction in marrow blasts, it is not curative. Allogeneic SCT has curative potential, but outcomes remain poor, with only 20% to 30% of children surviving.[79,82,83]

MYELOPROLIFERATIVE SYNDROMES

Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia (JMML) is a uniquely pediatric clonal disorder of the hematopoietic stem cell. It is among the most common form of MPS in childhood. There is now international agreement on the diagnostic criteria[84] (Table 74–2) with recent progress toward defining common response criteria.

Table 74–2 Diagnostic criteria for juvenile myelomonocytic leukemia[84]

Required laboratory criteria (all three required)
No Philadelphia chromosome
or no *bcr/abl* rearrangement
Peripheral blood monocyte count >1 × 10^9/L
Bone marrow blasts <20%
Suggestive clinical features
Hepatomegaly
Lymphadenopathy
Pallor
Fever
Skin rash
Additional criteria (minimum of 2 required)
Increased fetal hemoglobin (age corrected)
Myeloid precursors in peripheral blood
White blood cell count >10 × 10^9/L
Clonal abnormalities, including monosomy 7
GM-CSF hypersensitivity of myeloid progenitors in vitro

Epidemiology

The incidence of JMML has been estimated as 0.69 to 0.9 per million,[4,85] although its true incidence is currently not known. There is a male predominance with a median age of diagnosis of 1.8 years.

Pathobiology

Early clonality studies suggested that JMML arose at the level of at least an immature myeloid precursor cell.[84,86–90] More recent data suggest that JMML may arise in a pluripotent stem cell with involvement of the myeloid, erythroid, and megakaryocyte lineages as well as B lymphocytes and T lymphocytes.[84,91–93]

Several potential causative mutations in JMML cells have been identified, including loss of heterozygosity of *NF1*,[94] activating *RAS* mutations,[95–97] and mutations in the *PTPN11* gene (Fig. 74–1).[17,98] The identification of potential molecular mechanisms involved in the pathogenesis of JMML has been facilitated by two human diseases (neurofibromatosis type 1 (*NF1*) and Noonan syndrome [*PTPN11*]). Approximately 10% to 15% of patients with JMML have clinically evident neurofibromatosis type I,[84,94,99–101] and children with NF1 have a 500-fold increase in clonal malignant myeloid diseases, including JMML. The observation that individuals with NF1 are predisposed to JMML, the high incidence of *RAS* mutations in human cancers, and the identification of neurofibromin as a negative regulator that functions as a GTPase-activating protein that inactivates *Ras* from its active GTP-bound state[84,102–104] led to the hypothesis that *NF1* might function as a tumor suppressor gene in myeloid malignancies. Indeed, the demonstration of loss of heterozygosity of the wild-type *NF1* allele in the leukemic cells from children with NF and JMML supported this hypothesis. Subsequent studies clearly demonstrating homozygous inactivation of the NF1 allele (one allele with LOH, the other allele rendered nonfunctional by a constitutionally inherited mutation) in the leukemic cells from these children as well as demonstration of the accumulation of activated Ras proteins in these cells provided formal proof that NF1 functions as a tumor suppressor gene.[18,101,105,106] Finally, accurate murine models of JMML have been engineered by several groups in which either the *NF1* gene has been homozygously deleted or a *Kras(G12D)* allele has been conditionally activated.[96,97,107,108]

Abnormalities in *NF1* are also detectable in an additional small percentage of JMML patients who do not have clinical manifestations of neurofibromatosis.[84,105] Point mutations with a loss of *NF1* tumor suppressor function is demonstrated in approximately 15% of patients with JMML. This finding is mutually exclusive of *RAS* mutations that occur in another 25% of patients, suggesting that both *NF1* and *RAS* mutations are sufficient to initiate JMML.[84,95,105,109,110] The *RAS* family of proteins are of significance in JMML in that they are involved in signaling pathways for GM-CSF.[84,92,111,112] This deregulation in signaling results in GM-CSF hypersensitivity in in vitro dose–response assays.[113] However, JMML cells do not show selective hypersensitivity to G-CSF or IL-3 despite similar signaling components to those of GM-CSF.[113] Therefore, *NF1* may act as a tumor suppressor gene in immature hematopoietic cells by negatively regulating *Ras*.[84,94,101]

In 2001, Tartaglia et al reported that constitutional mutations in PTPN11 were causative of 50% of cases of Noonan Syndrome (NS).[114] NS is a common congenital disorder, with both acquired and sporadic forms. Patients affected by NS have cardiac defects (pulmonic stenosis of hypertrophic cardiomyopathy), variable levels of developmental delay, skeletal defects, and bleeding diatheses. Some children develop a JMML-like MPS in infancy that generally spontaneously recovers, although rare patients progress to frank JMML. Based on the knowledge that *PTPN11* encodes SHP-2, a nonreceptor protein tyrosine phosphatase that relays signals from activated growth factors to Ras, it was logical to hypothesize that somatic mutations in *PTPN11* might exist in the remaining cases of de novo JMML patients who did not have either clinical NF1 or harbor a RAS muta-

tion. Indeed, 35% of patients with JMML were discovered to have mutations in *PTPN11*, in residues that altered the interaction between the N-SH2 and C-SH2 domains, leading to constitutive activity of the phosphatase.[17,98]

Taken together, these data suggest that deregulated Ras/MAPK signaling is a common feature of JMML. The genetic spectrum of *NF1*, *PTPN1,1* and *RAS* (most commonly *N-RAS* and *K-RAS*) mutations in JMML appear to be largely mutually exclusive,[84,105,109] again supporting the hypothesis that these lesions are functionally redundant and that their common biochemical output is hyperactivation of the Ras/MAP kinase pathway.

The molecular abnormalities occurring in the remaining 25% of patients have yet to be determined, but the evidence is overwhelming that the functional consequence of the as yet unidentified lesion will result in hyperactivation of the Ras/MAPK pathway.

Clinical Manifestations

Children with JMML present with signs and symptoms attributable to a heavy cell burden of organ-infiltrating cells that results in hepatosplenomegaly, lymphadenopathy, and skin rash. As a result of its association with neurofibromatosis, patients may also have café-au-lait spots. Death is usually the result of organ dysfunction due to infiltrating cells, infection, or bleeding. Approximately 10% to 20% of children will progress to a blast-like phase consistent with AML.

Laboratory Manifestations

Laboratory abnormalities may include an elevated white blood cell count with an absolute monocytosis, anemia, and thrombocytopenia (see Fig. 74–3). Monocytes, either circulating in the peripheral blood or in the bone marrow frequently appear dysplastic. The peripheral smear often shows leukoerythroblastic changes and there are often circulating nucleated red blood cells. Fifty percent of patients may also present with elevated fetal hemoglobin levels and hypergammaglobulinemia. International criteria mandate that the bone marrow has fewer than 20% blast cells at diagnosis. Other findings typical in the bone marrow include micro-megakaryocytes.

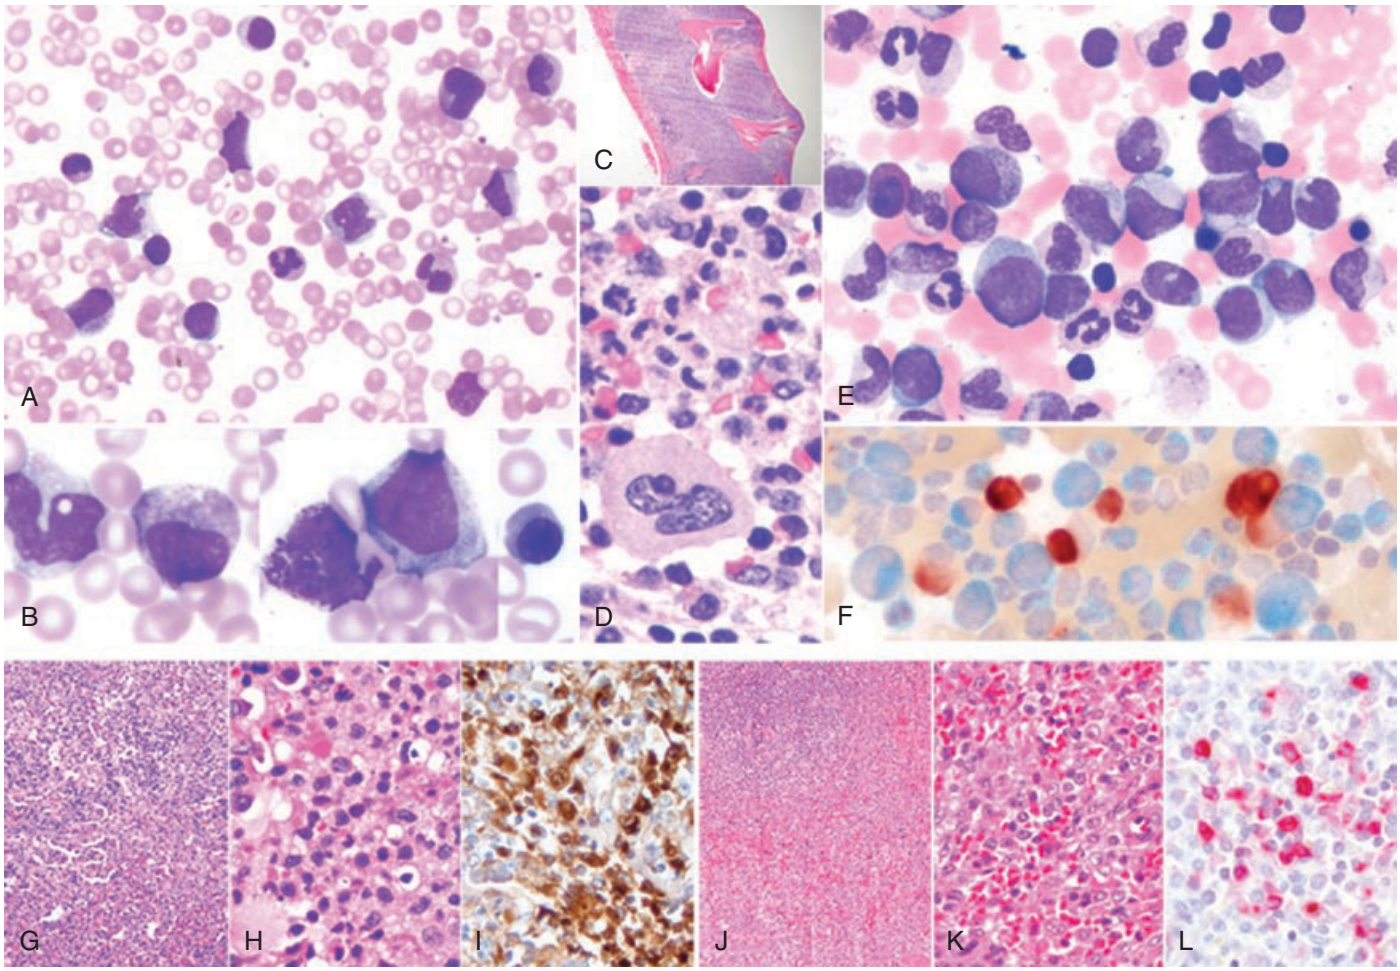


Figure 74–3 Juvenile myelomonocytic leukemia: Blood, bone marrow, lung, and spleen (**A**–**L**). The illustrations are from the case of a 3-year-old boy who was diagnosed with neurofibromatosis at birth. At 1 year of age, he presented with leukocytosis (58 K/μL) and splenomegaly. The peripheral blood (**A**, **B**) showed left-shifted granulocytes and increased monocytes (16%). A bone marrow biopsy (**C**, **D**) was hypercellular as a result of increased granulocytic and monocytic cells that could also be appreciated on the aspirate (**E**). Blasts accounted for only 4% of the marrow elements. A combined esterase reaction (**F**) illustrated the increased monocytes (alpha naphthol butyrate esterase reaction-positive; orange/brown) in the background of granulocytes (chloroacetate esterase reaction-positive; blue). Cytogenetic analysis revealed monosomy 7. At age 2, he presented with respiratory distress and a lung biopsy (**G**, **H**) demonstrated a monocyte infiltrate (lysozyme stain, **I**) consistent with involvement by JMML. This is not uncommon in such patients. At age 3, his blast count began to rise, and he underwent a splenectomy (**J**, **K**; lysozyme stain, **L**) followed by a successful stem cell transplant.

Differential Diagnosis

Making a diagnosis of JMML is not always easy, as its clinical and laboratory presenting features can also be associated with other disorders, including other forms of MPS, infections (Epstein–Barr virus, cytomegalovirus, human herpes 6 virus, histoplasmosis, mycobacterium, and toxoplasmosis), Class I Langerhans cell histiocytosis, hemophagocytic lymphohistiocytosis (HLH), Fanconi anemia, Kostmann syndrome, Shwachman syndrome, and Down syndrome.

Therapy

Children with JMML can have a variable course, with rare patients having a spontaneous remission and long-term survival without treatment whereas others have a rapidly fatal course despite aggressive treatment.[115,116] Age, platelet count, and hemoglobin F level have been used to predict the clinical course of patients not undergoing SCT,[100] but biologic features that can reliably predict an individual patient's clinical courses are not currently known. Currently, the most adverse prognostic factor for outcome is age at diagnosis.[117]

A wide variety of agents have been used to treat children with JMML, including AML-like chemotherapy,[40,100,118–122] low-dose chemotherapy,[123,124] interferon-alpha,[125] and 13-*cis*-retinoic acid.[103] Tipifarnib, a farnesyl transferase inhibitor, was recently tested in a phase II window by the Children's Oncology Group. Although the evaluation of these treatment regimens has been complicated by a lack of consistent response criteria and assays to measure the burden of clonogenic JMML stem cells, the efficacy of chemotherapy appears to be limited. Allogeneic SCT offers the only known potential for cure, with about half of transplanted children surviving disease-free.[117,126] Rapid withdrawal of immunosuppression appears to be important in this disease, as mounting evidence supports a graft-versus-leukemia effect.[127] A number of issues related to SCT for JMML remain uncertain. Among these are the value of pretransplant splenectomy, optimal conditioning regimen and graft-versus-host disease prophylaxis. In the absence of data to suggest superiority of radiation containing preparative regimens, most transplants now occur with chemotherapy-only preparative regimens. The efficacy of reduced intensity preparative regimens is currently under investigation. The most common cause of death following SCT is recurrent disease. The efficacy of second SCT can be life-saving for some children.[128,129] Donor leukocyte infusions (DLIs) are not often successful.[130]

Down Syndrome-Associated Transient Myeloproliferative Disorder

Epidemiology

Down syndrome is one of the most common congenital disorders, affecting approximately 1 in every 800 to 1000 live births. It has been demonstrated in a recent population-based study that children with Down syndrome have a 10- to 20-fold overall increased risk of developing leukemia,[131] a 150-fold increased risk of developing AML, and a 500-fold increased risk of acute megakaryocytic leukemia (AMKL). The median age of diagnosis of AMKL in Down syndrome patients is 2 years.[132] Transient myeloproliferative disorder, also known as transient abnormal myelopoiesis and transient leukemia, is thought to occur in at least 10% of children with Down syndrome, although it has been suggested that when cases of TMD that develop and resolve in utero or result in death prior to delivery are taken into account, the incidence may be as high as 20%.[133] Currently it is estimated that approximately 20% to 30% of children with TMD will subsequently develop AMKL, usually by 3 years of age. The probability of progression to leukemia will be further defined in a recently completed Children's Oncology Group study that prospectively follows a cohort of children with TMD.

Pathobiology

The molecular pathogenesis of TMD and AMKL in children with Down syndrome is now providing valuable insights into myeloid leukemogenesis.[20] Recent studies have shown that virtually all patients with TMD and most patients with AMKL harbor mutations in the hematopoietic transcription factor *GATA1*.[134–138] *GATA1* is a double zinc finger DNA-binding transcription factor expressed primarily in hematopoietic cells. It is required for the development of red blood cells, megakaryocytes, mast cells, and eosinophils. A number of different mutations in *GATA1* have been identified, including insertions, deletions, missense mutations, nonsense mutations, and slice site mutations. All of these mutations lead to a block in the expression of the full-length 50-kd isoform of *GATA1* but allow for the expression of a smaller, 40-kd isoform (*GATA1s*).[139] This smaller isoform lacks the N-terminal transactivation domain but retains both zinc fingers involved in DNA binding as well as interactions with its cofactor, Friend of *GATA1* (FOG1).[134] Recent studies have shown that mutations that alter *GATA1–FOG1* binding in the N-terminal zinc finger or result in the expression of the *GATA1s* isoform uncouple megakaryocyte growth and differentiation.[140–142] Similar studies in cell lines derived from Down syndrome children with AMKL have demonstrated that expression of *GATA1* led to erythroid differentiation whereas expression of *GATA1s* did not alter the characteristics of the cell line.[138] Taken together, current data suggests that the loss of *GATA1* and expression of *GATA1s* directly contribute to leukemogenesis. Although mutations in *GATA1* may be sufficient to cause TMD, these mutations are not sufficient for the development of AMKL, as evidenced by the latency period between resolution of TMD and the development of AMKL as well as the observation that not all children with TMD and *GATA1* mutations will ultimately develop AMKL. Therefore, a multistep pathogenesis model is proposed in Down syndrome patients in which AMKL develops in clones with *GATA1* mutations and additional cooperating mutations. One potential "second hit" mutation may occur in the *JAK3* gene, a member of the Jak family of nonreceptor tyrosine kinases. Several gain-of-function mutations[143,144] and loss-of-function mutations in *JAK3*[145] have been identified in both TMD and AMKL patient samples. Although mutations in *JAK3* might indeed represent a "second hit," the finding of mutations in TMD patients who have not progressed to AMKL may argue against *JAK3* as a second cooperating mutation.

Another particularly important area of investigation is the interaction between *GATA1* and chromosome 21. Identification of critical interactions between *GATA1* and relevant genes on chromosome 21 will serve to further inform us about the pathogenesis of leukemia in children with Down syndrome.

Clinical Manifestations

Down syndrome patients typically will present with TMD within three months after birth, although TMD can be manifest at birth. Some of these children present with hydrops fetalis secondary to anemia and cardiac dysfunction. Although some patients may be asymptomatic, others can have myeloblast infiltration of the heart, liver, and spleen that can result in hepatosplenomegaly; hepatic fibrosis; pleural, pericardial, and peritoneal effusions; and disseminated intravascular coagulopathy. In some cases, organ dysfunction can be severe, with failure of the liver, heart, kidneys, and lungs.

Laboratory Manifestations

The complete blood count in infants with TMD typically demonstrates an elevated white blood cell count with myeloblasts present. The percentage of circulating myeloblasts exceeds the percentage of bone marrow myeloblasts. Rarely a neonate without stigmata of Down syndrome will present with similar features—in these cases workup for either Trisomy 21 mosaicism or a *PTPN11* mutation

should be pursued. Flow cytometric analysis of the myeloblasts from TMD patients and AMKL associated with Down syndrome show many similarities between these disorders as well as patterns of cell surface antigen expression that is distinct from other types of AML in children.[146] Specifically, all TMD and AMKL blasts express CD45, CD38, and CD33 whereas the majority of cases express CD36 and CD34. CD41 and CD61 also are expressed, consistent with megakaryocyte differentiation. CD14 and CD64 are usually negative. Most cases have aberrant expression of CD7, a T-lineage antigen.

Therapy

The treatment of infants with TMD is generally supportive. Patients without significant organ dysfunction can be followed closely without medical intervention. In infants with significant organ impairment, a number of therapeutic approaches aimed at reducing the burden of myeloblasts are routinely employed, including exchange transfusion, leukophoresis, and chemotherapy. According to reports using cytosine arabinoside in Down syndrome children with AMKL,[147,148] cytosine arabinoside is the chemotherapeutic agent now most commonly used in infants with TMD. The efficacy of very low doses of cytosine arabinoside is being tested in prospective clinical trials. Several additional questions related to the treatment of infants with TMD are also the subject of ongoing clinical trials. Among these is the identification of high-, intermediate-, and low-risk populations with treatment stratified on the basis of risk group and a determination of whether treatment with very low dose cytosine arabinoside will prevent progression of TMD to AMKL and hepatic fibrosis.

Prognosis

Recent data from the Children's Oncology Group reporting the results of the POG 9481 prospective clinical trial offer insights into the natural history of TMD and the identification of prognostic factors.[149] This study followed 48 children with TMD. Eighty-nine percent of infants achieved a spontaneous remission, 74% had a normalization of peripheral blood counts and 64% maintained a clinical remission. Seventeen percent of infants had an early death. Factors associated with early death included a high white blood cell count ($P < 0.001$), increased bilirubin and liver function test values ($P < 0.005$), and a failure to normalize blood counts ($P = 0.001$). Nineteen percent of patients had a progression to AMKL at a median of 20 months. The greatest risk factor for progression to leukemia was the presence of karyotypic abnormalities in addition to trisomy 21 in blasts cells.

OTHER DISORDERS

Essential Thrombocythemia

Essential thrombocythemia has an estimated incidence of 1 to 1.25 cases per million in adults but is rarely diagnosed in children, with an estimated incidence of 0.09 cases per million.[150–154] Recent investigations in children and adults suggests that ET is a heterogeneous disease. Recently, mutations in JAK2 have been reported in patients as well as overexpression of polycythemia rubra vera-1 *(PRV-1) RNA*. It has been proposed that ET consists of several subtypes, with some children and adults having monoclonal disease, whereas in others the disease is polyclonal. Further investigation into the mutational status of V617F*JAK2* also demonstrates mutation-positive and mutation-negative patients.[151,155] Studies suggest that a similar proportion of children and adults display PRV-1 RNA overexpression, V617F*JAK*2 mutations, and monoclonal disease.[156]

Patients with ET have thrombocythemia with an increased number of megakaryocytes in the marrow. Platelet clumps on peripheral blood smears are common. Some patients have a concomitant increase in the number of peripheral blood granulocytes. The differential diagnosis includes familial ET (characterized by the dominant-positive activating mutation of *c-mpl*), other forms of MPS, and increased platelets as a reactive process.

Although the clinical course may be uncomplicated, patients can develop thromboembolic complications, including deep-vein thrombosis, transient cerebral ischemia, and peripheral vascular ischemia. The clinical course for children is typically benign, with fewer thrombotic episodes.[156,157] Adult patients have a median survival of at least 10 years, with most deaths due to thrombosis.[158,159] Progression to AML has been reported in adult patients, usually those with a prior exposure to chemotherapy agents.

Asymptomatic children do not require treatment. A number of treatment approaches aimed at controlling thrombocytosis have been attempted for symptomatic patients, including hydroxyurea, interferon-alpha, and anagrelide.[160–162] The successful use of allogeneic bone marrow transplantation has been reported for a small number of adult patients with ET.[163,164] Newer Jak2 inhibitors for those patients harboring *JAK2* mutations are in the early phases of clinical development.

Idiopathic Myelofibrosis

Idiopathic myelofibrosis (IM) is rarely diagnosed in children[165] and should be differentiated from AMKL, metastatic neoplasms, and connective tissue, metabolic, and bone diseases. It is characterized by marrow fibrosis, megakaryocytes with bizarre morphology, splenomegaly, anemia, and extramedullary hematopoiesis. IM is a clonal disorder of unknown pathogenesis but with approximately half of adult patients having mutations in V617F*JAK2*.[166] Recent studies have suggested that angiogenic cytokines produced by megakaryocytes and monocytes and their receptors (platelet-derived growth factor receptors [PDGF-R], vascular endothelial growth factor receptor-2 [VEGF-R2] and fibroblast growth factor [FGF] receptor) may be involved in the pathogenesis of the myelofibrosis.[167]

Numerous treatment approaches have been attempted with variable degrees of success. These include splenectomy, splenic radiation, transfusions, androgens, corticosteroids, hydroxyurea, and interferon-alpha.[168–170] More recently, based on preliminary studies about the potential role of angiogenic cytokines and their receptors, new approaches have been tested, including the tyrosine kinase inhibitor imatinib[171,172] and the antiangiogenic agent thalidomide.[173,174] Finally, allogeneic transplantation has been used successfully, with resolution of marrow fibrosis in donor-engrafted patients.[164,175,176] The survival in children is unknown with a median survival in adults of 4 years.

Polycythemia Vera

Polycythemia vera (PV) has an incidence of 3 cases per 100,000 in adults, but is very rarely seen in children with less than 0.1% of PV patients diagnosed prior to 20 years of age.[177] Polycythemia in children is far more often the result of congenital or acquired causes of an increased red cell mass. These would include primary familial polycythemia (characterized by specific mutations in the thrombopoietic gene (TPO), TPO receptor or erythropoietic receptor gene) and secondary polycythemias due to abnormal hemoglobins, cardiac and pulmonary disease, excessive erythropoietin, and a relative polycythemia that is the result of decreased plasma volume.

Polycythemia vera in children and adults is associated with clonal hematopoiesis,[178] V617F*JAK*2 mutations,[156,179–183] overexpression of PVR-1 RNA,[184,185] and endogenous erythroid colony (EEC) growth.[186,187] However, in contrast to adults, children with PV are less likely to have V617F*JAK2* mutations and EEC growth.[156] Thus, although these biomarkers are useful diagnostic tools in adults, thereby necessitating a revision to the World health Organization's diagnostic criteria,[188] they may not be as helpful in the diagnosis of PV in children. Although the pathogenesis is currently unclear, patients also have abnormalities in tissue factor, endogenous antico-

agulants mechanisms, hyperhomocysteinemia, and acquired von Willebrand syndrome.

Children with PV may present with signs and symptoms associated with an increased red cell mass such as headache, dizziness, fatigue, pruritis, night sweats, and a ruddy complexion. Hepatosplenomegaly may be present. As a result of hyperviscosity of the blood, elevated platelet counts, and coagulation abnormalities, patients can develop thromboses and central nervous system ischemia, although the incidence of thrombotic events may be lower than that reported in adults.[156]

Many different agents have been used to treat PV, including chlorambucil,[189] melphalan,[190] 6-thioguanine,[191] uracil mustard,[192] busulfan,[193] carboquone,[194] anagrelide,[195] imatinib,[196] hydroxyurea,[197] radioactive phosphorous,[198] and interferon.[199] A total of seven randomized clinical trials have been conducted in adults using some of these agents.[200] Despite these efforts, the best approach to patients with PV remains unclear. Therefore, the British Committee for Standards in Hematology recently formulated recommendations for the initial management of PV.[201] Recommendations include phlebotomy to maintain a hematocrit level less than 45, aspirin unless contraindicated, and cytoreduction if there is poor tolerance to phlebotomy, symptomatic or progressive splenomegaly, evidence of disease progression, or thrombocytosis. For patients less than 40 years of age, interferon was the recommendation for first-line cytoreduction with hydroxyurea and anagrelide as second-line. Finally, allogeneic transplantation has been successfully used to treat a limited number of adult patients.[163,164,202,203] Allogeneic transplantation is considered only for patients with significant thrombotic disease or progression to AML.

FUTURE DIRECTIONS

Although a clearer understanding of the biologic mechanisms underlying MDS in children is slow in coming, dramatic progress has been made in our understanding of the biologic mechanisms for TMD, JMML, PV, ET, and IM. There exists a potential for targeted therapeutics for these disorders.

However, progress for both MDS and MPS in children will require international cooperation. The rarity of these disorders and limitations in resources for pediatric cooperative cancer groups make clinical trials within each individual cooperative group increasingly difficult.

CHAPTER 75

PATHOBIOLOGY OF NON-HODGKIN LYMPHOMA

Georg Lenz and Louis M. Staudt

INTRODUCTION

The molecular pathogenesis of non-Hodgkin lymphoma (NHL) has been unraveled over the past two decades, owing to advances in molecular biology and genomics. As with other types of cancer, NHLs arise by a multistep accumulation of genetic aberrations that confer a selective growth advantage on the malignant clone. Recurrent translocations involving the immunoglobulin heavy chain (IgH) locus are often crucial first steps in lymphomagenesis. These translocations juxtapose the potent IgH transcriptional enhancers with various oncogenes that control cell proliferation, survival, and differentiation, leading to their overexpression and/or misexpression. These translocation events alone are insufficient for full malignant transformation, as evidenced by studies of mice engineered to overexpress these oncogenes. Recent efforts have uncovered many additional molecular aberrations that cooperate to produce lymphomas, as detailed below.

Although histologic examination of NHLs has revealed multiple NHL subtypes, the era of genomics has revealed new subtypes that are histologically indistinguishable but yet have distinct molecular etiologies and clinical behaviors. These insights have been achieved using DNA microarrays, which provide a genomewide profile of mRNA expression levels in a cancer sample. The gene expression profile of a tumor sample enables the precise measurement of various biological features of the tumor such as its proliferation rate, the activity of survival pathways, and the nature of nonmalignant tumor-infiltrating cells. By analyzing gene expression profiles and clinical data in concert, molecular models of survival can be constructed that reveal those aspects of tumor biology that are clinically relevant.

This chapter summarizes current concepts about the molecular pathogenesis of the common NHL subtypes. Particular attention is paid to the molecular diagnosis of lymphomas by gene expression profiling, which has led to new pathogenetic pathways and targets for therapeutic attack.

DIFFUSE LARGE B-CELL LYMPHOMA

DLBCL Subgroups Defined by Gene Expression Profiling

Diffuse large B-cell lymphoma (DLBCL) is the most common type of NHL, accounting for 30% to 40% of lymphoma cases in adults.[1] DLBCL has a variable clinical course, with only 40% to 50% of patients cured using anthracycline-based chemotherapy, suggesting that DLBCL is a heterogeneous diagnostic category.[2] This concept was supported by gene expression profiling studies that have distinguished three molecular subgroups of DLBCL, termed germinal center B-cell–like (GCB) DLBCL, activated B-cell–like (ABC) DLBCL, and primary mediastinal B-cell lymphoma (PMBL) (Figs. 75–1 and 75–2).[3–7] These three subgroups differ by the expression of thousands of genes and by this measure are as molecularly distinct as acute myelogenous leukemia and acute lymphoblastic leukemia. The gene expression profiles of these subgroups suggest that they arise from B-cells at different stages of differentiation and use separate oncogenic pathways.[8] Moreover, the DLBCL subgroups differ in clinical presentation and have significantly different survival rates following chemotherapy. Taken together, these observations have led to the view that the DLBCL subgroups represent distinct disease entities that are histologically indistinguishable.

By gene expression profiling, the GCB DLBCL subtype appears to derive from B cells at the germinal center stage of differentiation.[3,4,9] The unique biology of the germinal center reaction requires B cells to proliferate rapidly, mutate their immunoglobulin receptors, undergo positive selection for the ability to bind antigen at high affinity, and be eliminated by apoptosis if they fail to do so. This unique biological repertoire is associated with a broad gene expression signature that distinguishes normal germinal center B cells from other mature B-cell subsets. GCB DLBCLs express most, but not all, of the germinal center B-cell signature genes.[3,4,9] Moreover, GCB DLBCLs frequently have ongoing somatic hypermutation of their immunoglobulin genes within the malignant clone.[10] This specialized mutational mechanism is mediated by AID, an enzyme that is expressed at higher levels in normal germinal center B cells than at other stages of differentiation.[11]

Another gene characteristically expressed in GCB DLBCL is BCL-6, which encodes a key transcription factor that is required for the differentiation of mature B cells into germinal center B cells during an immune response.[12–14] BCL-6 is highly expressed in normal germinal center B cells but is silenced during plasmacytic differentiation.[15] BCL-6 functions as a transcriptional repressor and the target genes that it represses fall into distinct functional categories. Notably, BCL-6 represses *PRDM1*,[16,17] which encodes Blimp-1, a transcriptional repressor that is both necessary and sufficient for plasmacytic differentiation.[18,19] Blimp-1 promotes terminal plasmacytic differentiation by directly or indirectly extinguishing the expression of most mature B-cell differentiation genes as well as *c-myc* and other proliferation-associated genes.[20] BCL-6 also represses a set of genes that are induced when B cells are activated through the B-cell receptor or through CD40, suggesting that BCL-6 may modulate the response of normal germinal center B cells and GCB DLBCLs to antigen and T cells.[16,21,22] A third group of BCL-6 targets are negative regulators of cell cycle progression, including p21 and p27kip1, suggesting that BCL-6 licenses germinal center B cells and GCB DLBCLs for limitless cell cycle progression.[16,23] Finally, BCL-6 blocks the DNA damage response by repressing p53 and perhaps other DNA damage signaling molecules.[24] This function of BCL-6 may allow germinal center B cells and GCB DLBCLs to tolerate the double-stranded breaks that are induced by the enzyme AID, the effector of immunoglobulin somatic hypermutation and class switch recombination.[11] It is likely that BCL-6 expression imparts on GCB DLBCLs several biological attributes of normal germinal center B cells, including unfettered replicative potential and insensitivity to DNA damage.

ABC DLBCL may derive from B cells that are trapped between the germinal center B-cell and plasma-cell stages of differentiation.[4,5] This notion is based on the observation that ABC DLBCLs have downregulated most germinal center B-cell signature genes, including *BCL-6*, and express many genes that are characteristic of plasma cells. In particular, ABC DLBCLs express a key regulator of the secretory phenotype of plasma cells, *XBP-1*, as well as many of its downstream target genes.[5,25] Notably, inactivating mutations, deletions, and rearrangements of *PRDM1* and consequent loss of Blimp-1 expression are present in roughly one quarter of ABC DLBCLs but not in GCB DLBCLs.[26,27]

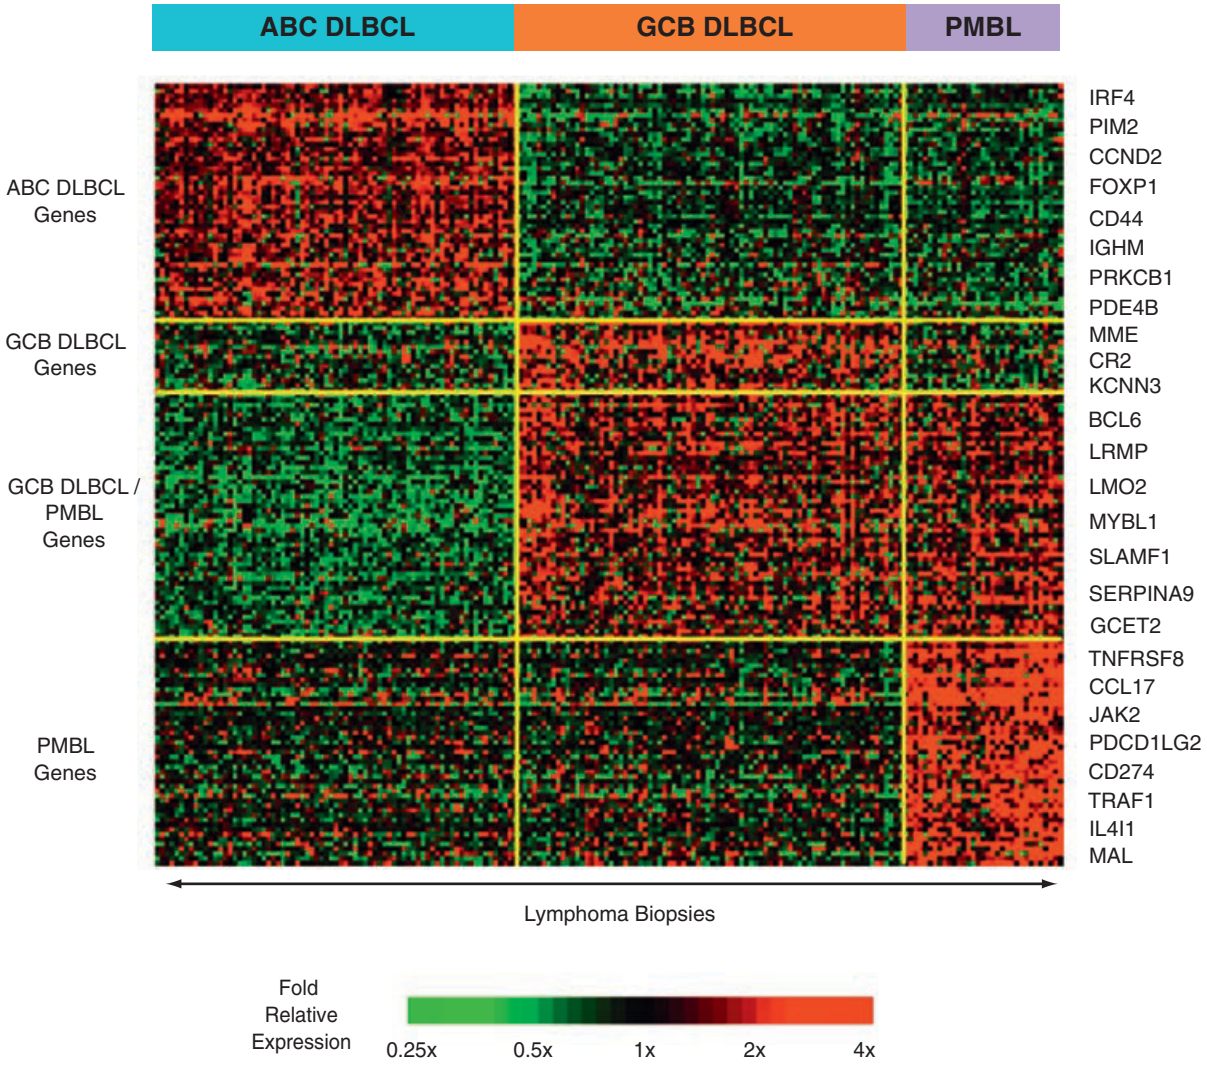

Figure 75–1 Genes characteristically expressed by subgroups of DLBCL: Activated B-cell–like (ABC) DLBCL, germinal center B-cell–like (GCB) DLBCL, and primary mediastinal B-cell lymphoma (PMBL). Each column represents gene expression data from a single DLBCL biopsy sample and each row represents expression of a single gene. Relative gene expression is indicated according to the color scale shown.

Moreover, BCL-6 translocations and genomic alterations in *PRDM1* have not been detected in the same ABC DLBCL cases.[27] Furthermore, BCL-6 translocations are more than twice as common in ABC DLBCL than in GCB DLBCL.[28] These observations support the hypothesis that ABC DLBCLs arise as a result of a block in B-cell differentiation, mediated either by Blimp-1 genomic aberrations or by translocation of BCL-6 and consequent repression of Blimp-1 expression. As further evidence of a post–germinal center origin, ABC DLBCLs carry a high load of mutations in their immunoglobulin genes but rarely have ongoing immunoglobulin gene mutation.[10]

Another characteristic feature of the ABC DLBCLs is the constitutive activation of the nuclear factor-κB (NF-κB) pathway, which suppresses apoptosis.[29] NF-κB signaling is mediated by a family of heterodimeric transcription factors that contribute to a wide range of cellular activation responses (reviewed in 30–32). Several of these factors are kept inactive in the cytoplasm by binding to inhibitory proteins of the IκB family. Stimulation though various receptors activates IκB kinase beta (IKKβ), which phosphorylates the IκBs, leading to translocation of NF-κB factors to the nucleus, where they transactivate their target genes. ABC DLBCLs, but not GCB DLBCLs, are characterized by high expression of NF-κB target genes.[29] ABC DLBCL cell lines have constitutive activation of the NF-κB pathway owing to constitutive activity of IKKβ. Inhibition of NF-κB using a dominant active form of IκBα or a dominant negative form of IKKβ is toxic to ABC DLBCL but not GCB DLBCL cell lines.[29] Moreover, small-molecule inhibitors of IKKβ are selectively toxic to ABC DLBCL cell lines, confirming that ABC DLBCLs are "addicted" to the antiapoptotic effects of NF-κB.[33]

Many upstream signaling pathways can activate NF-κB, generally in a transient fashion.[30–32] Insight into the upstream pathways causing constitutive NF-κB activity in ABC DLBCLs was provided by a genetic screen in DLBCL cell lines using a library of small hairpin RNAs (shRNAs), that mediate RNA interference.[34] shRNAs targeting *CARD11*, *MALT1*, and *BCL10* were all found to be toxic to ABC DLBCL but not GCB DLBCL cell lines. In normal B and T cells, CARD11, MALT1, and BCL10 form an oligomeric signaling complex (the CBM complex) following antigenic stimulation that leads to IKKβ activation.[35] CBM complex formation in normal lymphocytes is transient whereas in ABC DLBCLs it is constitutively engaged to activate IKKβ. The molecular aberrations leading to constitutive formation of the CBM complex in ABC DLBCLs are currently unknown.

PMBL, the third subgroup of DLBCL, was initially defined by clinical criteria.[36] In contrast to other forms of DLBCL that mainly affect patients older than 60 years of age,[37] PMBL typically occurs in young patients, often female, with a median age of only 30 to 35 years. In the majority of patients, the mediastinum is the only site of lymphoma manifestation.[38,39] On pathologic examination, a thymic remnant often can be found associated with the tumor mass, suggesting that PMBL arises from a rare B-cell subpopulation residing in

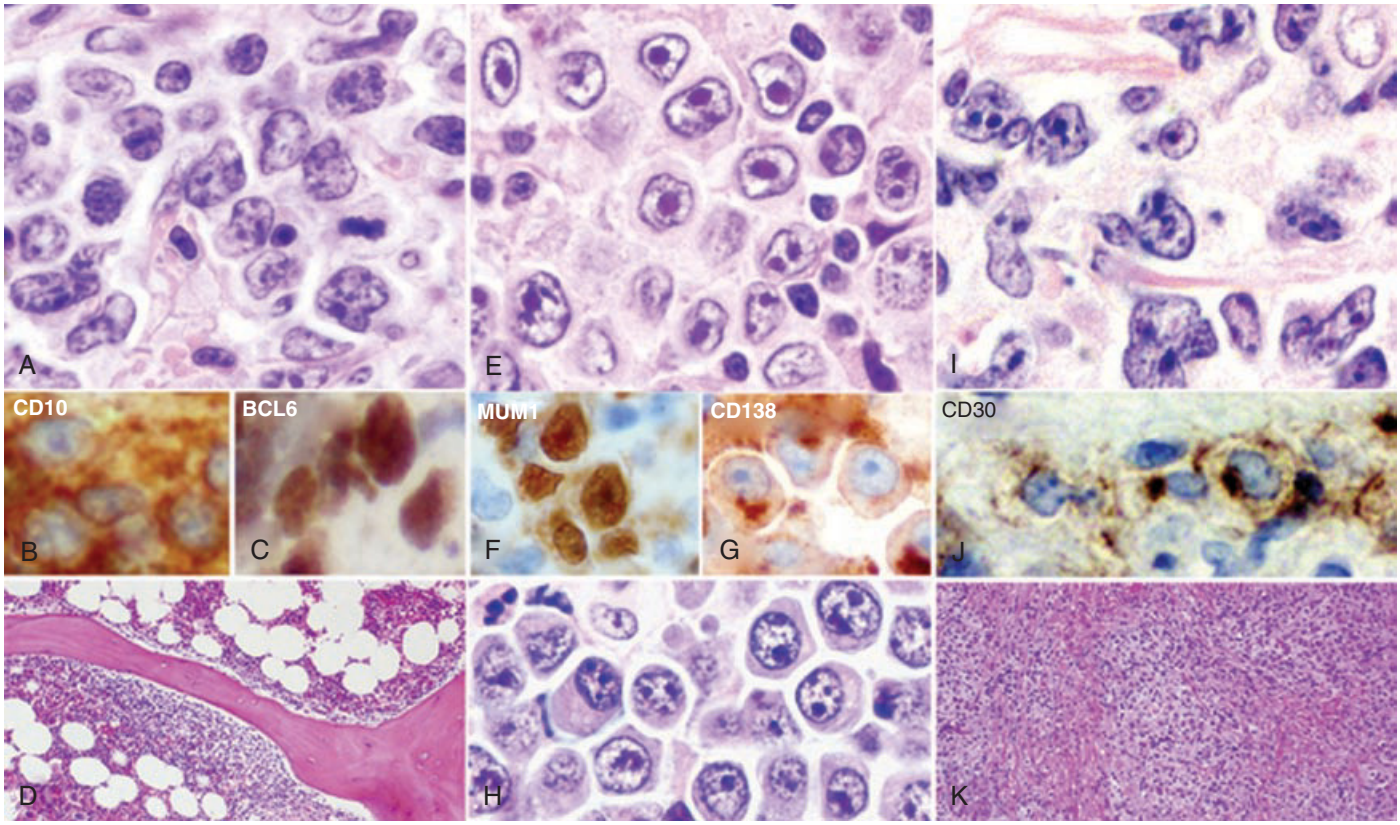

Figure 75–2 Three types of large B-cell lymphoma: germinal center B-cell–like, activated B-cell–type, and primary mediastinal B-cell–type (**A–L**). Germinal center B-cell–like, or germinal center-derived large B cell lymphomas usually have a centroblastic morphology (**A**), are CD20$^+$, and express the germinal center markers CD10 (**B**) and BCL6 (**C**). In this case, the patient's staging bone marrow (**D**) showed paratrabecular involvement by small cleaved cells (centrocytes), indicating that the large B-cell lymphoma likely arose from a lower-grade follicular lymphoma. Activated B-cell like large B-cell lymphoma can sometime have an immunoblastic morphology (**E**), and can typically express MUM1 (**F**) and CD138 (**G**). These post–germinal center cell-type of lymphomas can also have a plasmablastic morphology (**H**), as sometimes seen in HIV-related cases. Primary mediastinal large B-cell lymphomas are frequently composed of multilobated centroblasts (**I**). They are typically CD45$^+$, CD20$^+$, and usually CD30$^+$ (**J**), but CD15-negative. Surface immunoglobulin may be negative on such cases. PMBL is commonly associated with fibrosis, which is present in broad bands (**K**) or surrounding individual cells (as in **I**).

the thymus.[40] By gene expression, PMBL can be reliably diagnosed by virtue of a characteristic gene expression signature that distinguishes it from GCB DLBCL and ABC DLBCL.[6,7] PMBLs express some genes in common with GCB DLBCLs, including *BCL-6*, but do not express the ABC DLBCL signature genes and, particularly, do not express genes associated with plasmacytic differentiation.[6] Importantly, PMBL cannot be diagnosed reliably on clinical grounds alone; roughly one-quarter of the cases diagnosed as PMBL by clinical criteria were not PMBL by gene expression, and were instead other types of DLBCL that happened to have prominent mediastinal involvement.[6]

Gene expression profiling revealed an unexpected molecular relationship between PMBL and nodular sclerosis Hodgkin lymphoma.[6,7] More than one-third of genes that distinguish PMBL from the other DLBCL subgroups were also highly expressed in Hodgkin lymphoma cell lines, and many were expressed in the malignant Reed-Sternberg cells of Hodgkin lymphoma.[6] Among those genes are known markers for PMBL (IL4I1, Mal) and Hodgkin lymphoma (CD30).[40,41] In addition, both PMBL and Hodgkin lymphoma express targets of the NF-κB pathway.[6,7,42,43] A PMBL cell line[33,44] and several Hodgkin lymphoma cell lines[42,43] depend on constitutive activity of the NF-κB pathway for survival. The molecular mechanisms of constitutive NF-κB activity in PMBL are unknown, but the CARD11/MALT1/BCL10 pathway is not involved.[44]

The molecular relationship between PMBL and Hodgkin lymphoma extends the previous observation that these two lymphoma entities share several clinical and pathologic features.[45] Both entities often affect young patients, especially women, who present with a mediastinal tumor that has prominent sclerosis. In addition, rare patients with Hodgkin lymphoma who have a complete response to therapy may nonetheless relapse with PMBL. Histologically, a set of "grey zone" lymphomas have been recognized that have features of both PMBL and Hodgkin lymphoma. These considerations suggest that both PMBL and Hodgkin lymphoma originate from the same rare B-cell population in the thymus, which shares some molecular features with these malignancies such as expression of Mal.[40] Despite their similarities, PMBL and Hodgkin lymphoma are readily distinguished histologically and by gene expression, and thus must differ in detail in their oncogenic mechanisms.[6]

Genetic Aberrations in DLBCL Subgroups

The three gene expression subgroups of DLBCL exhibit striking differences in the frequency of genomic abnormalities, supporting the hypothesis that they represent distinct diseases that use different oncogenic mechanisms (Table 75–1). Two common recurrent genetic aberrations in DLBCL are the t(14; 18) translocation involving the *BCL-2* gene and amplification of the *c-rel* locus on chromosome 2p. The t(14;18) translocation is present in almost half of GCB DLBCLs but never in ABC DLBCLs.[4] Likewise, c-rel amplification occurs in one sixth of GCB DLBCLs but is absent in ABC DLBCLs.[4]

In contrast, roughly one-quarter of ABC DLBCLs have trisomy 3 or gain and amplification of chromosome arm 3q, abnormalities

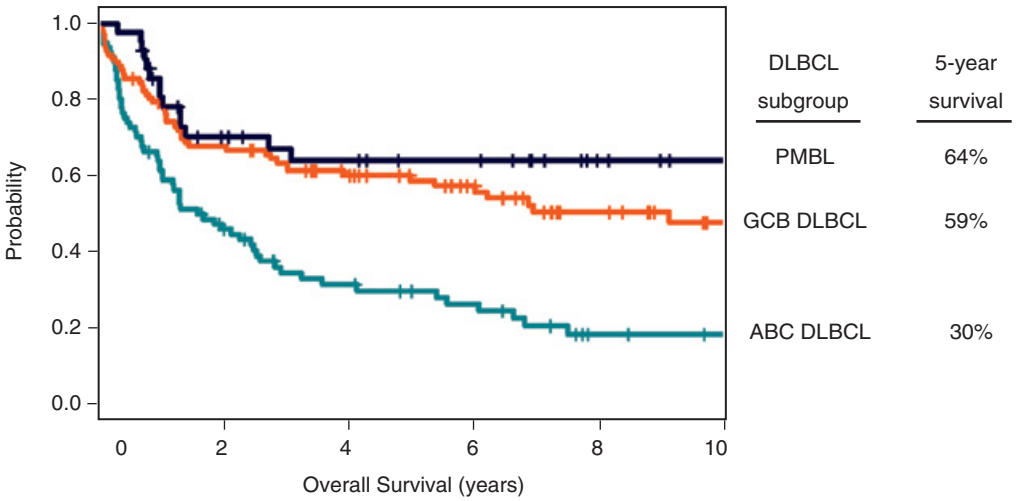

Figure 75–3 Kaplan–Meier plot of overall survival for different DLBCL subgroups treated with anthracycline-containing chemotherapeutic regimens.

Table 75–1 Frequency of Recurrent Genetic Aberrations in DLBCL Subtypes

	GCB DLBCL	ABC DLBCL	PMBL
BCL2 translocation, t(14;18)	45%	0	18%
BCL2 amplification, 18q21	10%	34%	16%
REL amplification, 2p13	16%	0	25%
Gain or amplification of 3q	0	26%	5%
Gain or amplification of 9p24	0	6%	43%
PRDM1 mutation/deletion (Blimp-1)	0	24%	n.d.
BCL6 translocation	11%	29%	23%

Compiled from References 4, 6, 26–28, 46, 77. n.d.: not determined.

that never occur in GCB DLBCLs.[46] Trisomy 3 is also a recurrent feature of MALT lymphomas, raising the possibility that ABC DLBCL might derive from this lymphoma type.[47] However, ABC DLBCLs do not harbor the t(11;18) translocation,[34] a recurrent and characteristic feature of MALT lymphoma, suggesting that trisomy 3 may have a separate selective advantage in both MALT lymphoma and ABC DLBCL. Interestingly, the presence of these chromosome 3 abnormalities in ABC DLBCL is associated with low expression of the "lymph node" signature, which reflects a nonmalignant host response to DLBCL[46] (see below). ABC DLBCLs also have frequent amplifications of a region on chromosome 18q21 containing the *BCL2* and *MALT1* genes, events that are uncommon in other DLBCL subgroups.

PMBLs frequently have gains or high-level amplifications of chromosome band 9p24,[48] events that occur rarely in ABC DLBCL and never in GCB DLBCL.[6,46] This abnormality is also recurrent in Hodgkin lymphoma,[49] in keeping with the clinical and molecular similarities between PMBL and Hodgkin lymphoma. These amplicons include the *JAK2* gene,[6,50] which encodes a key tyrosine kinase that regulates cytokine signaling through STAT family transcriptional factors. A role for cytokine signaling in both PMBL and Hodgkin lymphoma is further supported by recurrent inactivation of *SOCS1*, a negative regulator of cytokine signaling.[51–54] In addition, the PMBL amplicon encodes PD-L1 and PD-L2, which are ligands for the PD receptor on T cells that are highly expressed in PMBL.[6] Engagement of the PD receptor by its ligands generally inhibits signaling through the T-cell receptor, raising the possibility that the chromosomal amplification of these genes modulates the interaction between the PMBL cells and surrounding T cells in the thymus.[6]

The expression of AID is likely to cause two types of genetic instability in DLBCL. AID can mutate cellular genes other than immunoglobulin genes, albeit at a lower frequency. For example, the BCL-6 gene is mutated in normal germinal center B cells and in NHLs at a rate that is roughly 100-fold lower than immunoglobulin genes.[55,56] Some BCL-6 mutations in DLBCL occur in a negative autoregulatory site in the first noncoding exon, thereby increasing BCL-6 expression by relieving BCL-6 of self-repression.[57,58] DLBCLs accumulate AID-dependent somatic mutations in many other cellular genes, including several oncogenes such as *MYC* and *PIM1*.[59] These mutations are generally within 1 to 2 kilobases of the start of transcription, so for some genes, the mutations can alter protein function.

A second form of AID-dependent genetic alteration is aberrant immunoglobulin class switch recombination.[60] In addition to its role in somatic hypermutation, AID catalyzes the deletional joining of immunoglobulin switch regions, thereby effecting a change in immunoglobulin heavy chain isotype.[11] In aberrant class switch recombination, AID-induced breaks in the immunoglobulin switch regions are substrates for joining reactions with other double-stranded breaks in the genome, leading to so-called switch chromosomal translocations. This process is distinctly more common in ABC DLBCL than in other forms of DLBCL or in MALT lymphoma.[60] In addition to switch translocations, ABC DLBCLs have frequent internal deletions, mutations, and duplications with the switch N and switch γ regions, and these are ongoing processes within the malignant clone.[60] Moreover, ABC DLBCLs have a significantly lower frequency of legitimate class switch recombination. Of note, AID is one of the few germinal center B-cell–restricted genes that is expressed at higher levels in ABC DLBCL than in GCB DLBCL.[5,60,61] Because ABC DLBCLs are impaired in normal immunoglobulin class switching, their high AID activity may increase double-stranded breaks in the IgH locus and eventually culminate in translocations.

Clinical Differences in DLBCL Subgroups

Overall survival rates following anthracycline-based chemotherapy differ among the three molecular subgroups of DLBCL. In an initial cohort of patients studied by gene expression profiling, GCB DLBCL and PMBL had relatively favorable 5-year overall survival rates of 64% and 59%, respectively, whereas ABC DLBCL had only a 30% 5-year survival rate (Fig. 75–3).[4,6] The superior survival of patients with GCB DLBCL was subsequently confirmed in two other large cohorts studied by gene expression.[62–64] An immunohistochemical method has been developed that roughly mirrors the GCB DLBCL/ABC DLBCL distinction.[65] This approach divides DLBCLs into a GC phenotype (roughly equivalent to GCB DLBCL) and a non-GC

Table 75–2 International Prognostic Index Table

	Score = 0	Score = 1
Age	<60	>60
ECOG performance status	≤1	>1
Ann Arbor stage	≤2	>2
LDH	<Upper limit of normal	>Upper limit of normal
Extranodal sites	≤1	>1

phenotype (including ABC DLBCLs and other unclassified DLBCLs). In multiple DLBCL cohorts treated with CHOP chemotherapy, this method confirmed that GC cases had a better overall survival rate than non-GC cases.[65–72]

The prognostic value of the DLBCL subgroup distinction is statistically independent of the features included in the International Prognostic Index (IPI),[73] (Table 75–2) demonstrating that this distinction is not merely a surrogate of known clinical prognostic attributes.[3,4] Nonetheless, there are significant differences in the frequency of individual components of the IPI (Table 75–2) in the different DLBCL subtypes. A significantly higher proportion of ABC DLBCL patients are older than 60 years of age and more patients in this cohort have a poor performance status (ECOG > 2). In contrast, PMBL patients are younger, with a median age of 33, and have more frequent extranodal involvement.[4,6] The pattern of extranodal involvement also differs: PMBL frequently involves various thoracic structures, often by direct extension, whereas ABC DLBCL and GCB DLBCL most commonly involve the gastrointestinal tract, bone marrow, liver, and muscle.[6]

Recently, standard therapy for DLBCL has changed to include the anti-CD20 monoclonal antibody rituximab; in patients older than 60 years of age, overall survival in DLBCL is improved by approximately 10% to 15% with the CHOP-Rituximab (CHOP-R) regimen compared to CHOP alone.[74] Immunohistochemical studies using antibodies to BCL-2 and BCL-6 have suggested that biological subgroups of DLBCL may respond preferentially to the addition of rituximab. The expression of BCL-2 protein is an adverse prognostic factor with CHOP chemotherapy but not with CHOP-R.[75] DLBCLs express BCL-2 protein by two distinct mechanisms. Among GCB DLBCLs, those with the t(14;18) translocation express BCL-2 whereas the others do not.[4,76] In ABC DLBCL, many tumors express BCL-2, not by translocation but by transcriptional activation and, in some cases, amplification of the BCL-2 locus on chromosome 18.[46,65] However, a minority of ABC DLBCLs do not express BCL-2 protein, and these have a more favorable prognosis with CHOP chemotherapy.[77] For BCL-6, tumors that lack expression are associated with poor survival with CHOP chemotherapy, but not with CHOP-R.[78] Whole-genome gene expression profiling of tumors in the context of CHOP-R treatment will be needed to fully understand which DLBCL patients are benefiting most from rituximab and which patients are yet to be cured by the current standard of care.

PREDICTION OF SURVIVAL FOLLOWING CHEMOTHERAPY BY GENE EXPRESSION

Other gene expression profiling studies have taken a "supervised" approach to correlate gene expression patterns with the clinical outcome.[4,80] In this approach, statistical methods are used to identify genes whose expression patterns across a series of cancer specimens are associated with favorable or inferior survival. Often, these survival-associated genes can be classified into gene expression signatures, which are sets of coordinately expressed genes that reflect a particular biological phenotype such as cell lineage, stage of differentiation, or activity of an intracellular signaling cascade.[81] In one study of DLBCL, the majority of survival-associated genes could be assigned to one of four gene expression signatures, termed "germinal center B cell," "MHC Class II," "lymph node," and "proliferation."[4] The germinal center B cell, MHC Class II, and lymph node signatures were associated with favorable outcome whereas the proliferation signature was associated with poor survival.

The germinal center B-cell signature consists of genes characteristically expressed in normal germinal center B cells; this signature is another way of identifying the prognostic difference between GCB DLBCL and ABC DLBCL. In a supervised survival analysis of an independent DLBCL cohort,[80] two genes that were strongly associated with inferior prognosis encode protein kinase C β1 and phosphodiesterase 4b, both of which are more highly expressed in ABC DLBCL than in GCB DLBCL.[5,82]

Three other signatures are cross-cutting in that they are variably expressed within GCB DLBCL, ABC DLBCL, and PMBL. The MHC class II signature includes genes encoding the various MHC class II proteins and invariant chain, all of which are involved in antigen processing during an immune response.[4] Immunohistochemical stains showed that the variation of expression of this signature was due to differences in MHC class II protein expression in the malignant tumor cells, not in the nonmalignant bystander cells.[83,84] In addition, tumors with low expression of the MHC class II signature were found to have fewer infiltrating $CD8^+$ cytotoxic T cells.[83] Plausibly, therefore, the inferior prognosis of tumors with decreased expression of the MHC class II signature may reflect an inadequate host immune response.

The third gene expression signature associated with favorable outcome was dubbed the lymph node signature because it reflects the infiltration of nonmalignant cells into the tumor in lymph node biopsies.[4] This signature includes various genes encoding extracellular matrix components as well as genes expressed in macrophages. Histologically, this signature reflects a sclerotic reaction that is a feature of certain DLBCLs. High expression of the lymph node signature is more common in GCB DLBCL and PMBL than in ABC DLBCL but is a variable feature within each subgroup. The reason why this signature confers a favorable prognosis is unclear, but one hypothesis suggests that this signature indicates a dependence of the malignant cell upon the lymph node's microenvironment. This dependence may limit the ability of the malignant cell to establish itself in extranodal environments. Interestingly, certain chromosomal abnormalities in DLBCLs were associated with either low expression or high expression of the lymph node signature, suggesting the nature of the malignant cell may dictate its mode of interaction with its microenvironment. Specifically, gain or amplification of chromosome arm 3q, which occurs exclusively in ABC DLBCLs, was associated with low expression of the lymph node signature whereas gain of chromosome band Xp21 was associated with high expression of the lymph node signature.[46]

The majority of genes associated with poor overall survival in DLBCL belong to the proliferation gene expression signature,[4] called so because these genes are more highly expressed in dividing cells than in quiescent cells.[81] Although the proliferation signature was a variable feature of each DLBCL subgroup, it was most highly expressed in ABC DLBCLs, on average.[4] The particular proliferation genes that predict survival in DLBCL are a specific subset of the proliferation genetic program, specifically the transcriptional network regulated by c-myc.[4,8] Interestingly, c-myc and its target genes are more highly expressed on average in ABC DLBCL than in the other DLBCL subtypes.[85] One of the primary cellular phenotypes controlled by c-myc is cell growth, which specifically refers to an increase in cell size.[86] In this regard, it is notable that ABC DLBCLs frequently have an "immunoblastic" morphology,[4] a cellular phenotype that could be a consequence of c-myc activity.

A multivariate model of survival in DLBCL was constructed from these four gene expression signatures.[4] For every biopsy, a "survival predictor score" was calculated as a weighted average of the four signatures in the biopsy. After ranking according to these scores, DLBCL patients were divided into four equal quartile groups that had 5-year

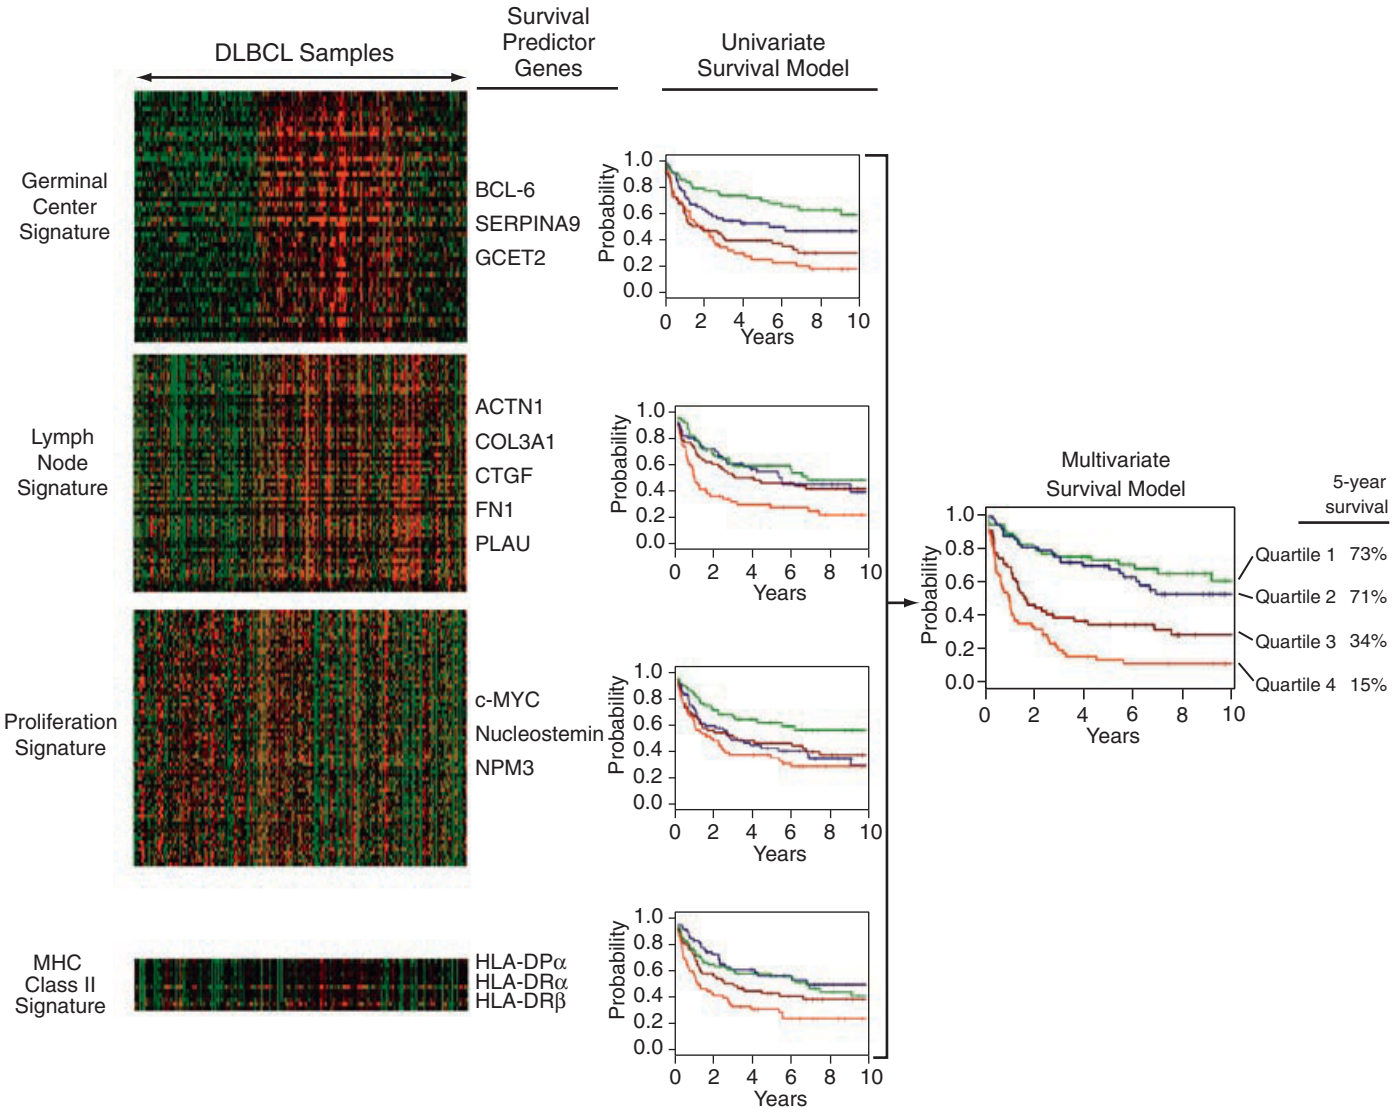

Figure 75–4 Gene-expression–based model of survival following chemotherapy for DLBCL. The left panel shows the expression of the four gene expression signatures used to create the survival model in DLBCL. Expression of the germinal center, lymph node, and MHC class II signatures is associated with favorable prognosis, whereas expression of the proliferation signature is associated with inferior survival. Representative genes from each signature used to create the survival model are shown. For each signature, patients were divided into four equal quartiles based on the expression of the signature in their biopsy samples. The four Kaplan–Meier plots in the middle depict the survival of patients in each signature quartile. These four signatures were combined into a multivariate model of survival and patients were divided into four quartile groups based on this model. The Kaplan–Meier plot at the right depicts the survival of each quartile group of the multivariate model.

survival rates of 73%, 71%, 34%, and 15% (Fig. 75–4).[4] This gene-expression–based predictor was statistically independent of the clinical variables in the IPI (Table 75–2), suggesting that it reflects meaningful aspects of DLBCL biology that alter the response to therapy.

CONCLUSIONS

DLBCL is a heterogeneous diagnostic category consisting of at least three different molecular subtypes. Like subtypes of acute leukemia, these DLBCL subtypes differ with respect to the expression of thousands of genes, in part because they derive from different stages of B-cell differentiation. Perhaps as a consequence of this varied origin, they use different oncogenic pathways and harbor specific chromosomal abnormalities. These attributes, along with their clinical differences, support the view that the DLBCL subtypes are distinct disease entities. These three DLBCL subgroups account for roughly 82% of the cases, demonstrating that additional, less common subtypes of DLBCL remain to be discovered. Layered on top of this subtype distinction is the variable expression of other signatures that reflect biological attributes of the tumors that have prognostic import.

Burkitt Lymphoma

Burkitt lymphoma (BL) (see Fig. 75–5) is a highly aggressive NHL that is often characterized by extranodal involvement or leukemic presentation.[87] BL often arises in adolescents or young adults[88] and is curable in a high fraction of cases by intensive multiagent chemotherapy.[89–91] Three different forms of BL can be distinguished: sporadic BL, endemic BL (occurring mainly in equatorial Africa), and immunodeficiency-associated BL.

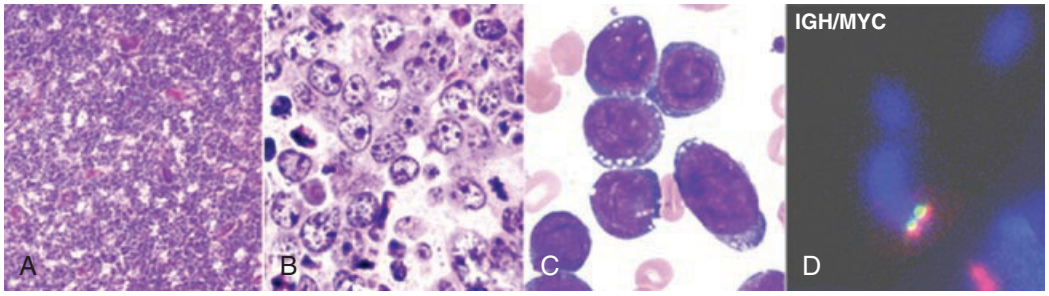

Figure 75–5 Burkitt Lymphoma (**A–D**). A case of Burkitt lymphoma illustrated at low power (**A**), showing the "starry sky" appearance. This is due to the dense proliferating cells producing the dark sky, and the scattered lighter-staining tingible body macrophages (stars) phagocytizing dying cells. Higher magnification (**B**) illustrating the syncytia of intermediate-sized cells with coarse chromatin and multiple nucleoli. Note the tingible body macrophage with abundant light cytoplasm and ingested debris (center bottom). Burkitt cells as seen on a Wright-stained bone marrow aspirate (**C**) in a patient with Burkitt leukemia. Notice deep blue cytoplasm with numerous vacuoles. Fluorescence in situ hybridization (FISH) with probes to MYC and IgH (**D**) illustrate the IgH/MYC fusion (courtesy of Dr. Yanming Zhang, University of Chicago).

Chromosomal Translocations Involving *c-myc*

BL is characterized by chromosomal translocations that dysregulate the expression of the protooncogene *MYC*, encoding the transcription factor c-myc, located on chromosome band 8q24.[92–94] Approximately 80% of cases harbor a t(8; 14) (q24; q32) that juxtaposes *MYC* with IgH enhancer elements, whereas in the remaining cases, *MYC* is translocated to the Igμ or Igκ locus.[95,96] The position of the chromosomal breakpoints in *MYC* and in the Ig genes are widely dispersed.[97] In endemic BL, cases with a t(8; 14) often show breakpoints on chromosome 8 more than 100 kb 5′ of *MYC* whereas the breakpoints on chromosome 14 can be mapped in the Ig joining regions (J_H). The involvement of the J_H regions indicates a role for the Rag1 and Rag2 recombinases that are active during early B-cell development.[98] By contrast, in sporadic BL and immunodeficiency-associated BL, the chromosome 8 breakpoints occur between *MYC* exons 1 and 2 or within a few kilobase 5′ of *MYC*, and the chromosome 14 breakpoints often involve the Ig switch regions.[95,99] It highly likely, therefore, that the AID recombinase that is central to Ig class switching plays an important role in these *MYC* translocations, as illustrated by the ability of AID to direct IgH-*MYC* translocations in mouse B cells.[100] These observations suggest that sporadic BL arises from earlier stages of B-cell differentiation than endemic or immunodeficiency-associated BL.

c-myc is a multipotent transcription factor that may regulate as many as 15% of all genes.[86] Consequently, c-myc plays an important role in many fundamental cellular responses, including cell proliferation, cell growth, protein synthesis, metabolism, differentiation, and apoptosis. The transcription of *MYC* itself is tightly regulated in normal cells, by virtue of a complicated promoter that has built-in autoregulation.[101] Translocations in BL that juxtapose *MYC* with the powerful immunoglobulin enhancers presumably upset this regulatory balance, thereby altering the expression of c-myc target genes in ways that are not fully understood.

Gene Expression Profiling

The importance of constitutive c-myc expression to the biology of BL was confirmed by gene expression profiling experiments comparing sporadic BL with DLBCL.[9] A gene expression signature of *MYC* target genes is more highly expressed in BL than in DLBCL (Fig. 75–6). These signature genes are expressed highly in a subset of DLBCLs bearing the t(8;14) translocation, but BLs have yet higher expression of this signature.[9]

The distinction between BL and DLBCL does not just rely upon *MYC* and its target genes. BL is also characterized by high expression of a subset of the genes that are characteristic of normal germinal center B cells, consistent with an origin of BL from this stage of B-cell differentiation (Fig. 75–6).[9] This "BL-high" subset of the germinal center B-cell signature (eg, *CD10* and *GCET2*) is expressed at much lower levels in GCB DLBCL, even though this lymphoma subtype also originates from germinal center B cells. Conversely, a "BL-low" subset of germinal center B-cell genes (eg, *LMO2*, *CD80*, *CD86*) is more highly expressed in GCB DLBCL than BL. Yet other germinal center B-cell signature genes are expressed equivalently in BL and DLBCL (eg, *BCL6*, *PAG*). One explanation for these observations could be that BL and GCB DLBCL derive from different germinal center B-cell subpopulations. Alternatively, differences in the oncogenic mechanisms of BL and GCB DLBCL may affect the germinal center B-cell gene expression program.

A gene expression signature that is expressed at exceedingly low levels in BL compared to DLBCL is the NF-κB signature.[9] Normal germinal center B cells have very low expression of NF-κB target genes, which may facilitate the apoptosis that is a prerequisite for the antigen-based selection for high-affinity B-cell receptors that occurs in the germinal center.[81,102] BLs inherit this low NF-κB phenotype from their normal counterparts, which may account for the high rate of spontaneous apoptosis in BLs and their characteristic "starry sky" histology.

Finally, in comparison to DLBCL, BL is characterized by low expression of all MHC class I genes.[9] BLs are characterized by a notable lack of immune cell infiltration, which may be due to their inability to effectively present antigens via the MHC class I pathway.

The gene expression differences between BL and DLBCL were used to fashion a molecular diagnosis of BL.[9] In BL cases in which there was no diagnostic disagreement among pathologists, the molecular predictor of BL had 100% accuracy. However, for a number of cases, an original diagnosis of BL was revised to be DLBCL based on the best available pathologic techniques. For some of these cases, the gene-expression–based diagnosis nevertheless declared the sample BL. Treatment of these patients with CHOP chemotherapy was unsuccessful, bolstering the view that they were indeed BL. Overall, one-sixth of the cases that were BL according to gene expression were misdiagnosed as DLBCL by the expert panel of pathologists using the current gold standard diagnostic techniques. Similar results were obtained by another large gene expression profiling study of BL and DLBCL.[63] An incorrect diagnosis of DLBCL in these cases would lead to the use of CHOP chemotherapy, which is incapable of curing BL. Therefore, a gene expression-based diagnosis of BL has the potential to significantly improve the choice of treatment for patients with these aggressive lymphomas.

Additional Genetic Aberrations

Epstein–Barr virus (EBV) infection is detectable in virtually all cases of endemic BL and in 20% to 40% of sporadic and immunodefi-

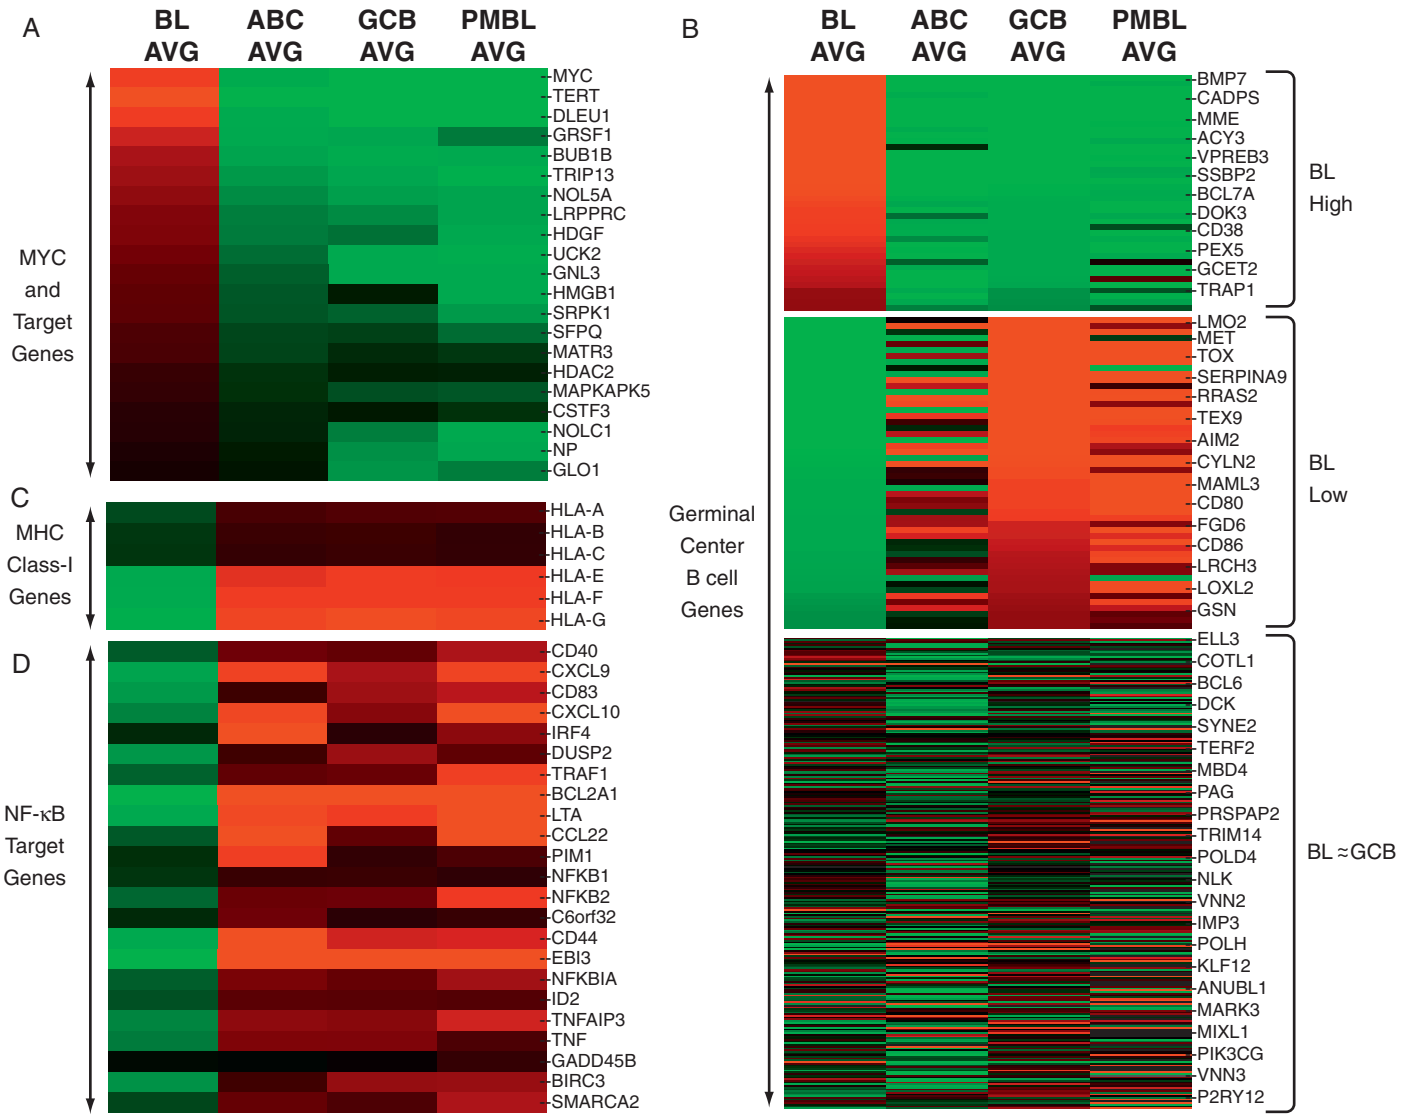

Figure 75–6 Relative expression of genes that distinguish Burkitt lymphoma (BL) from subgroups of DLBCL (ABC DLBCL, GCB DLBCL, and PMBL) is categorized into gene-expression signatures: c-myc and its target genes (**A**); genes that are expressed in normal germinal-center B cells (**B**) and are expressed more highly (BL-high), less highly (BL-low), or equivalently (BL≈GCB) in BL than in GCB DLBCL; MHC class I genes (**C**); and genes targeted by the NF-κB signaling pathway (**D**). Germinal-center B-cell signature genes are those that were overexpressed in normal germinal-center B cells, compared to blood B cells. The "BL-high" genes were expressed at levels twice as high in BL as in GCB DLBCL ($P < 0.001$). The "BL-low" genes were expressed at levels twice as high in GCB DLBCL as in BL ($P < 0.001$). The expression levels of the "BL≈GCB" genes did not differ significantly between the two lymphoma subtypes.

ciency BL.[103–106] This epidemiologic data is compelling evidence for a role of EBV in BL pathogenesis, but no satisfactory molecular mechanism has been elucidated.[107] An additional recurrent genetic event in BL is mutation or deletion of the *p53* tumor suppressor gene, present in approximately 30% of cases.[108]

Like normal germinal center B cells, most cases of BL do not express BCL-2. However, a minority of cases have a t(14;18) translocation or express BCL-2 by an unknown transcriptional mechanism, and these cases have a poor clinical outcome.[109] Interestingly, these BL cases were enriched in the set of cases that were misdiagnosed by pathologists as DLBCL, suggesting that the BCL-2 translocation may define a biologically and clinically distinct subtype of BL.[9]

Follicular Lymphoma

Follicular lymphoma (FL) is the most frequent low-grade NHL and accounts for approximately 20% of all NHL cases (see Fig. 75–7).[1] FL has a variable clinical course with a median overall survival of 8 to 10 years, with 10% to 15% of patients surviving more than 15 years. Conversely, 10% to 15% of patients have a rapidly progressive disease, often associated with transformation to DLBCL and poor prognosis.[110,111]

Chromosomal Translocation Involving *BCL2*

In approximately 90% of FL cases, a t(14; 18)(q32; q21) translocation juxtaposes the *BCL2* gene and the IgH locus,[112,113] thereby deregulating the key antiapoptotic protein BCL-2.[114,115] Less commonly, *BCL2* is deregulated by translocation to the Igκ and Igλloci. Normal germinal center B cells have essentially no BCL-2 expression[116,117] and have a high rate of apoptosis that they require for efficient selection of B cells with high affinity for antigen. The forced expression of BCL-2 due to the t(14;18) allows a B cell to escape this physiological cell death, a first step toward malignancy. A minority of FL cases do not express BCL-2 protein and lack *BCL2* transloca-

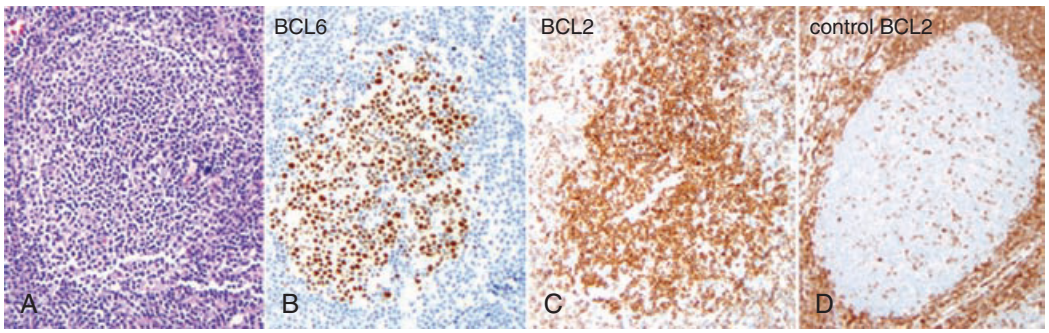

Figure 75–7 Follicular lymphoma (**A–D**). Details from a case of follicular lymphoma, grade 1 of 3 associated with t(14;18)(q32;q21). Malignant follicle (**A**), with immunohistochemical stains for the germinal center marker, BCL6 (**B**), and for BCL2 (**C**). Note the overexpression of BCL2 when compared to a reactive follicle (**D**).

tions[118]; alternative antiapoptotic mechanisms in these cases remain to be elucidated. Interestingly, a subset of FLs lacking BCL-2 expression harbor a BCL-6 translocation, which is otherwise rare in FL.[119]

The t(14; 18), the initiating event in FL, is apparently mediated by the RAG recombinase proteins, which cleave at J segments in the IgH locus and at an unusual non-B-form DNA structure in BCL2.[120] Expression of the RAG proteins is confined to early stages of B-cell differentiation, suggesting that the t(14; 18) occurs in the bone marrow. Interestingly, healthy individuals harbor the t(14;18) in their normal blood B cells.[121–123] These B cells have a surface phenotype and molecular features of memory B cells, suggesting that they have traversed the germinal center and could conceivably be precursors to FL.[124] Indeed, a type of in situ FL has been described in which a t(14;18)-positive B-cell follicle is identified in an otherwise normal lymph node biopsy—some of these cases progress to FL but others remain benign for many years.[125]

The t(14;18)-positive B cells of normal individuals have Ig switch recombination events on the t(14;18) allele, consistent with the activity of the AID recombinase and a germinal center derivation.[124] Nonetheless, the surface expression of IgM and IgD is invariably maintained on these cells, as is also the case in FL. These results suggest that stimulation of the B cells through their IgM/IgD antigen receptors plays a role in the derivation of both the benign t(14;18) B cells and FLs. Analysis of Ig V region sequences in FL is consistent with an antigen-driven selection of high-affinity variable region mutations.[126] Additionally, in most FL cases, somatic mutation creates new sites for N-linked glycosylation in the immunoglobulin variable regions.[127] This process is also observed in DLBCL, but only in those cases with a GCB phenotype harboring the t(14;18).[128] The meaning of these findings is a matter of conjecture but it is possible that sugar addition to the surface immunoglobulin receptor might allow the malignant B cell to participate in pathogenic interactions with lectin-like molecules in the germinal center microenvironment.

Gene Expression Profiling

Like GCB DLBCL, FL is characterized by expression of the germinal center B-cell signature, indicating its close relationship to this stage of B-cell differentiation.[3] Accordingly, FLs have ongoing mutation of their immunoglobulin genes, a hallmark of the germinal center stage of differentiation.[129] Nonetheless, FL and GCB DLBCL are relatively easy to distinguish by gene expression profiling.[3]

The length of survival following diagnosis of follicular lymphoma is highly variable, with some patients living for more than 20 years and others succumbing to the disease in a few years. Gene expression profiles of tumor biopsies at the time of diagnosis can be used to predict the length of survival. In a gene expression profiling study of 191 patients with FL, genes that were associated with longer and shorter overall survival were identified and organized into gene expression signatures by hierarchical clustering.[130] This analysis revealed two signatures associated with overall survival, both of which consist of genes known to be expressed in normal immune cells. One signature, termed "immune-response 1" was associated with favorable overall survival whereas the other signature, termed "immune-response 2," was associated with inferior survival. These two signatures were combined into a statistical model that produced a "survival predictor score" for each patient. After ranking according to these scores, the patients were divided into four equal quartiles that had remarkable differences in median overall survival (Fig. 75–8). Three-quarters of the patients had a very indolent disease, with a median survival of 11.7 years, but one-quarter had an aggressive disease and a median survival of only 3.9 years.

Biologically, the immune-response 1 signature reflects a mixture of immune cells that is enriched for T cells, because many genes in this signature are T-cell–restricted in expression (eg, *CD7*, *CD8B1*, *ITK*). However, this signature is not merely a reflection of the total number of infiltrating T cells in a sample because the expression of pan T-cell gene expression signature was not associated with survival. This implies the presence of specialized T-cell subsets in these tumors and/or the admixture of other immune cells. By contrast, the genes in "immune-response 2" signature reflect an immune infiltrate that is relatively devoid of T cells and enriched for macrophages and/or dendritic cells, as judged by expression of *TLR5*, *FCGR1A*, or *LGMN* and other genes characteristic of these cell types.

Recent studies evaluating immune subsets in FL by immunochemical means support the prognostic value of the immune-response 1 and immune-response 2 signatures. In two studies, a higher tumor CD8 T-cell number was associated with favorable survival,[131,132] consistent with the fact that the CD8 T-cell–restricted gene *CD8B1* is a component of the immune-response 1 signature.[130] Other studies have found associations between higher tumor CD4 cells with favorable survival.[133] Conversely, adverse overall survival has been associated with a high content of CD68-positive or STAT1-positive macrophages.[134,135]

Two general hypotheses that are not mutually exclusive could account the prognostic import of the immune response signatures.[8,130] In an immune-response hypothesis, the reason why the immune-response 1 signature is favorable is that it reflects an active antitumor immune response, dominated by T cells. In a "microenvironment addiction" hypothesis, the immune-response 1 signature represents a quasi-normal germinal center reaction in which the FL cells depend on trophic signals from the immune cells in the microenvironment. Tumors with the immune-response 2 signature may have developed ways to survive independently from the germinal center microenvironment, allowing them to spread more widely and rapidly. It is also certainly possible that genetic differences in the malignant cells, not readily detectable by gene expression, might evoke different immune response signatures.

Clearly, current data provide only a glimmer of the complexity of immune reactions in FL, but the nature of the immune cells could logically have an impact on response to immune modulatory thera-

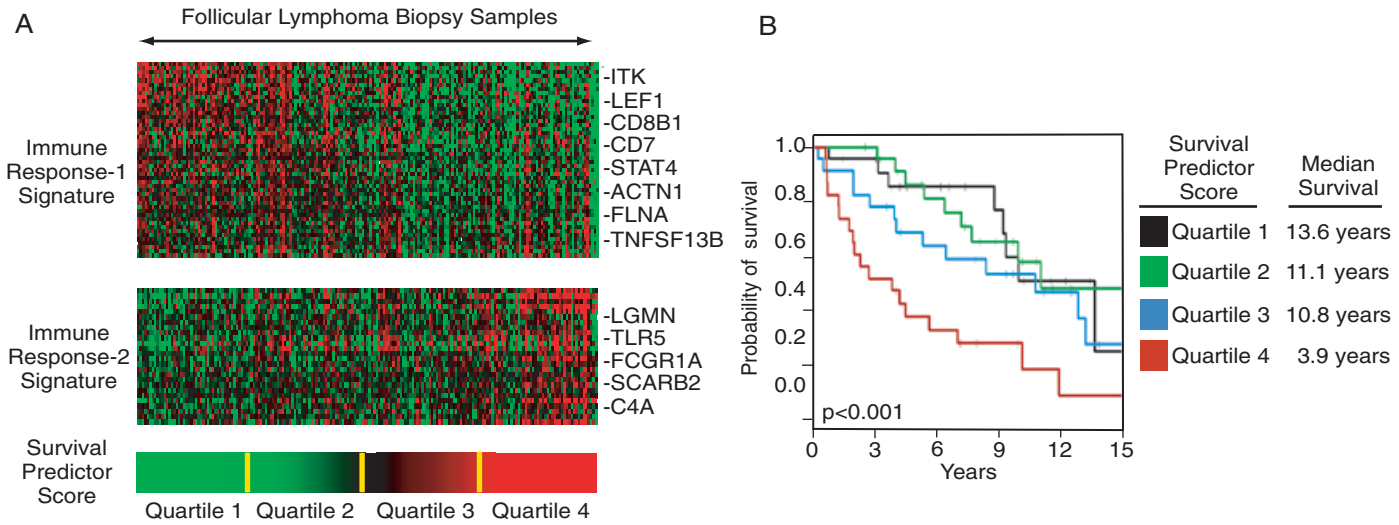

Figure 75–8 **A**, Two sets of coordinately expressed genes, termed the immune response-1 and immune response-2 signatures, are associated with survival in follicular lymphoma. The expression pattern of each gene in these two signatures is shown for follicular lymphoma biopsy samples. Expression of the immune response-1 signature is associated with favorable survival following diagnosis and expression of the immune response-2 signature is associated with adverse survival. These signatures are combined into a multivariate model of survival that generates a survival predictor score for each patient. Patients are ranked according to this survival predictor and divided into four equal quartiles as shown. **B**, Kaplan–Meier plot of overall survival of patients in the four quartiles of the survival predictor.

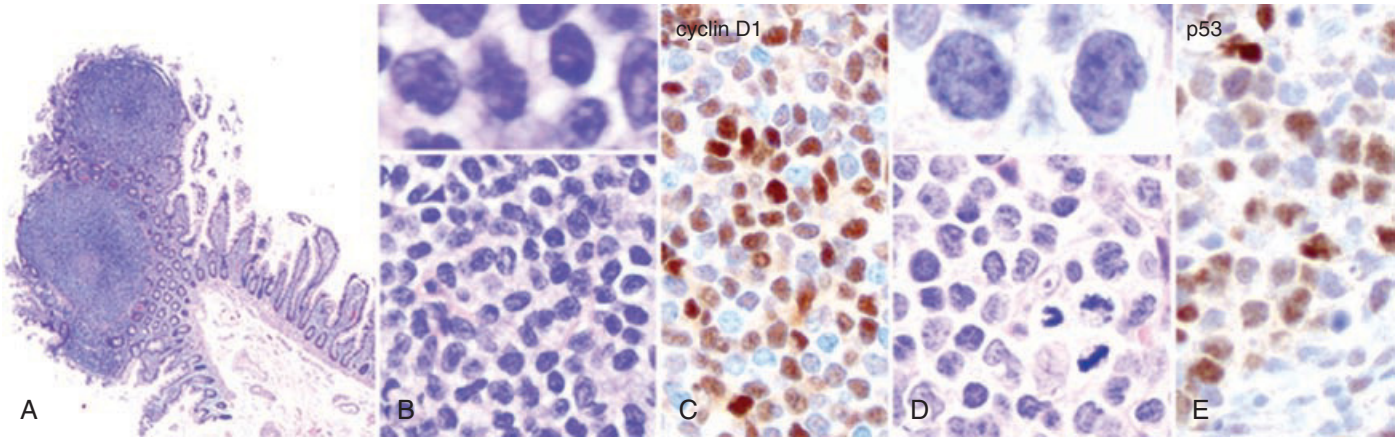

Figure 75–9 Mantle cell lymphoma (**A–E**). A case of mantle cell lymphoma presenting as lymphomatoid polyposis (**A**). The lymphoma cells are small to intermediate in size and have irregular nuclear contours and condensed nuclear chromatin (**B** and detail). The cells were CD19+, monoclonal B cells with lambda light chain restriction, coexpression of CD5, FMC-7, and lack of CD23. The cells showed cyclin D1 expression by immunohistochemical staining (**C**). The t(11;14)(q13;q32) was detected by conventional cytogenetic analysis. In comparison, the blastoid variant of mantle cell lymphoma (**D**) has larger cells with a high mitotic rate and fine chromatin. These cases frequently overexpress p53 (**E**) and are associated with a complex karyotype, including t(11;14).

pies such as idiotype vaccines or rituximab. Response to rituximab could be influenced by the nature and abundance of Fc-receptor bearing immune cells in the tumors because genetic polymorphisms that alter Fc-receptor binding of Rituximab are associated with response to this treatment.[136]

Additional Genetic Aberrations

The t(14;18) is not sufficient to induce lymphoma development in mouse models, suggesting that additional oncogenic hits are required to generate frank FL.[137] Thus far, however, these additional oncogenic mechanisms remain poorly understood. Other genes commonly involved in lymphomagenesis, such as *p53* or *c-myc*, are not frequently altered in FL. By classical cytogenetics, deletions on chromosomes 1 and 6 as well as gains on chromosomes 7, 12, and X are detectable in 20% to 30% of FL samples.[138–140]

During histologic transformation of FL into DLBCL, various genetic aberrations have been defined, including *p53* mutations and inactivation of *p16*.[141,142] By gene expression profiling, transformation appears to occur by two distinct mechanisms, one in which the DLBCL is distinctly more proliferative than the antecedent FL and another in which there is no change in proliferation.[143,144] Of note, *p53* mutation and *p16* inactivation are confined to cases in which transformation is accompanied by increased proliferation.[143]

Mantle Cell Lymphoma (MCL)

With a median age of 65 years at diagnosis, mantle cell lymphoma (MCL) is a disorder of the elderly, with males accounting for roughly 90% of cases.[36,145] Although MCL accounts for only 5% to 10% of all lymphoma diagnoses, it contributes disproportionately to lymphoma deaths because of its often aggressive clinical course and lack of curative therapy; median survival with MCL is only 3 years.[146] Histologically, two forms of MCL can be distinguished, one with "classic" morphology and the other with a "blastoid" morphology that is associated with a worse prognosis (see Fig. 75–9).[145,147,148] As detailed below, these histologic variants correspond to different rates of tumor cell proliferation. MCL is derived in the vast majority of cases from a naive pre–germinal center B cell because its rearranged immunoglobulin genes are unmutated. However, some cases with mutated immunoglobulin loci have recently been described that seem to have a more indolent clinical course.[149]

Deregulation of Cyclin D1 by Chromosomal Translocation

The genetic hallmark of MCL is the chromosomal translocation t(11;14) (q13; q32) that juxtaposes the *CCND1* gene to the IgH locus, leading to overexpression of the cell cycle regulator cyclin D1. The three D-type cyclins (D1, D2, and D3) play an important role in cellular proliferation by propelling cells from G_1 to S phase of the cell cycle. Each forms heterodimers with the cyclin-dependent kinases CDK4 and CDK6, thus forming active kinase complexes.[150] These complexes inactivate the tumor suppressor retinoblastoma protein (RB) by phosphorylation, thereby inhibiting its activity as a molecular brake on G1- to S-phase progression.[145,151] Of equal importance, cyclin D-CDK4/6 complexes bind stoichiometrically to p27kip1, an inhibitor of cyclin E-CDK2 complexes. This sequestration of p27kip1 allows the cyclin E-CDK2 complexes to drive entry into S phase. Cyclin D1 is not expressed at appreciable levels in normal B cells and thus the t(11;14) significantly alters cell cycle regulation in MCLs.

Gene Expression Profiling

An extensive gene expression signature distinguishes MCL from other forms of NHL, which undoubtedly imparts a unique biology on this malignancy (Fig. 75–10).[152] Interestingly, rare NHL cases have this characteristic signature but lack both the t(11;14) translocation expression and cyclin D1 expression.[153] Instead, these cases express either cyclin D2 or D3 and, in some cases, bear a translocation involving the cyclin D2 gene.[154] These findings emphasize the primacy of D-type cyclins in the pathogenesis of MCL. Another important gene expressed at high levels in most MCLs is *BCL2*. Although MCLs lack *BCL2* translocations, they express *BCL2* mRNA and protein at levels that equal or surpass those in t(14;18) GCB DLBCL. Such high expression of this antiapoptotic gene may confer sensitivity to BCL-2-targeted therapies.[155,156]

Gene expression profiling can also be used to predict the length of survival following diagnosis of MCL.[152] A proliferation signature that reflects tumor cell proliferation rate is a strong predictor of overall survival, with high expression of the signature associated with shorter survival. This signature includes genes involved in cell cycle control, DNA synthesis, DNA repair, and other cellular processes that need to be upregulated to enable cellular proliferation to proceed. The average expression of the proliferation signature can be used to calculate a survival predictor score for each patient with MCL. In a study of 91 MCL patients, patients were ranked according to these scores and divided into four equal quartile groups, with median

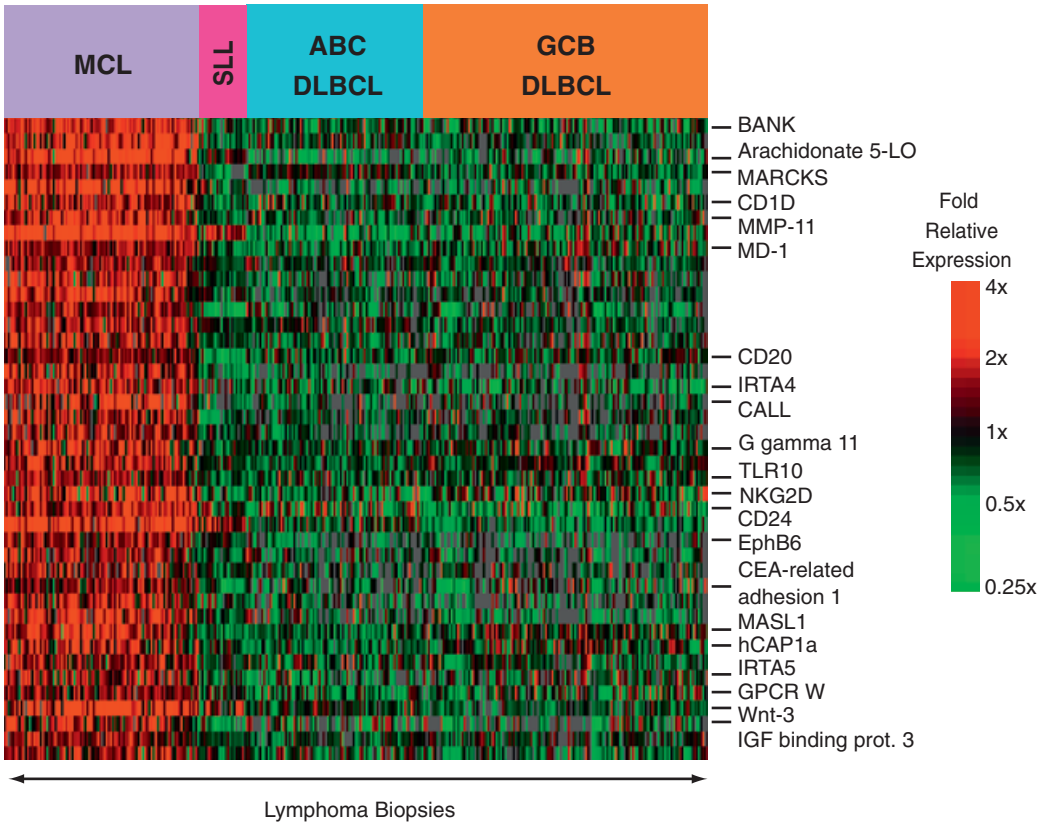

Figure 75–10 Hierarchical clustering of expression measurements from 42 Mantle cell lymphoma (MCL) signature genes that are more highly expressed in MCL samples compared to SLL, ABC DLBCL, and GCB DLBCL samples. Each column represents a single lymphoma specimen, and each row represents expression of a single gene. Red squares indicate increased expression and green squares indicate decreased expression relative to the median expression level according to the color scale shown.

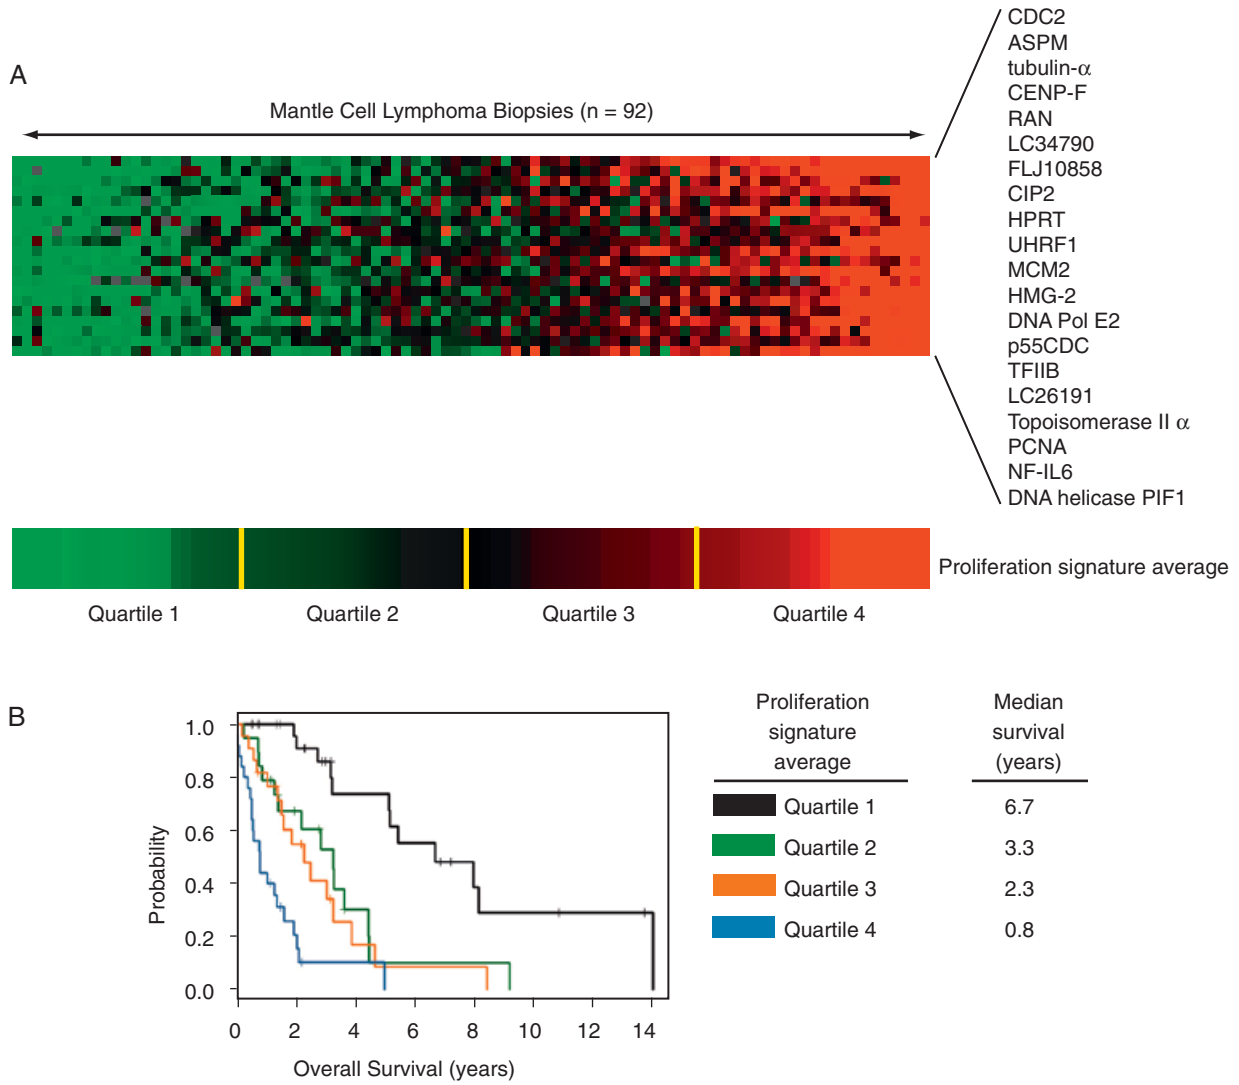

Figure 75–11 **A**, Differential expression of proliferation signature genes in samples from MCL. The expression patterns of 20 genes from the proliferation signature are shown across 92 MCL biopsy samples. The expression of each of these genes was found to be associated with short survival. The expression levels of these 20 genes were averaged to create the proliferation signature average, which was divided into four quartile groups as shown.
B, Kaplan–Meier plot of overall survival of patients with MCL, divided into four quartile groups according to the expression of the proliferation signature in their tumors.

survival rates of 0.8, 2.3, 3.3, and 6.7 years, respectively (Fig. 75–11). Other ways to determine the proliferation rate, such as counting the number of mitoses or the extent of immunohistochemical staining for Ki-67, also demonstrate an association between high proliferation and short survival.[147,157–159] However, the proliferation gene expression signature provides a quantitative measurement of the proliferation rate that outperforms most previous prognostic tests in MCL.

It is important to distinguish the MCL proliferation signature from the proliferation signature that has prognostic value in DLBCL (see above). The DLBCL proliferation signature is primarily composed of c-myc and its target genes, and most likely reflects an increase in cell metabolism and size. Conversely, the MCL proliferation signature is focused on cell cycle progression.

Additional Genetic Abnormalities

Many recurrent genetic alterations in MCL target the G1–S phase of the cell cycle, and their combined action is reflected in the proliferation signature.[152] One of the most illustrative examples involves Cyclin D1 itself. Though most MCLs bear a t(11;14) translocation that deregulates *Cyclin D1*, levels of *Cyclin D1* mRNA differ significantly among MCL tumors. Elevated *Cyclin D1* mRNA levels are associated with both higher expression of the proliferation signature and shorter overall survival.[152] MCL tumors may express a full-length 4.5-kb mRNA isoform, termed Cyclin D1a, but also may express shorter isoforms in some cases.[160,161] Whereas the longer isoform includes an extended 3′ untranslated region (UTR) that harbors an mRNA-destabilizing element, the shorter isoforms lack the mRNA-destabilizing element and essentially only include the coding region.[161–164] Consequently, the short *Cyclin D1* mRNA isoforms are more stable and accumulate to higher levels. In MCL cases with a high proliferation rate, the short Cyclin D1 isoforms are frequently expressed.[152,164] Many of these cases have discrete genomic deletions of the t(11;14) translocated allele that remove the portion of the 3′ UTR containing the mRNA-destabilizing element.[160,161,164] Other tumors have somatically acquired point mutations that create new polyadenylation and cleavage site in the 3′ UTR of *Cyclin D1* just downstream of the coding region.[164] These events are functionally equivalent to genomic deletions in the 3′ UTR because they give rise to short mRNAs lacking the mRNA destabilizing element. Given the

central role of Cyclin D1 in the G1–S phase transition of the cell cycle, it is likely that the higher expression of Cyclin D1 caused by these somatic genetic aberrations contributes directly to higher tumor proliferation.

A second common genetic alteration in MCL affecting the G1–S transition is homozygous deletion of the *INK4A-ARF* locus on chromosome band 9p21.[165,166] This locus encodes two important tumor suppressors, p16(INK4a) and p14(ARF), that share amino-terminal sequences but are unrelated in structure in their carboxy-terminal regions. p16(INK4a) prevents CDK4/6 from interacting with the D-type cyclins, resulting in a block in the cell cycle at the G1–S phase boundary.[150,167] Loss of p16(INK4a) is associated with higher expression of the proliferation signature and shorter survival.[152] MCL tumors that are highly proliferative can also have amplification and/or overexpression of *BMI1*, which encodes a chromatin repressor that can silence the *INK4A-ARF* locus.[152,168] Moreover, *CDK4* can be amplified and overexpressed in some proliferative MCLs.[169] Finally, the *RB* gene, which encodes a critical regulator of the G1–S phase transition, is mutated and inactivated in rare MCL cases with a high proliferation rate.[170]

These findings suggest that MCL tumor proliferation rate is a biological integrator of multiple oncogenic events that separately affect the G1–S phase transition.[152] Indeed, a quantitative model of the MCL proliferation rate (as measured by the proliferation signature) can be constructed using *Cyclin D1* mRNA levels and p16(INK4a) loss as variables.[152] This model suggests that these oncogenic abnormalities quantitatively alter the levels of Cyclin D1-CDK4/6, thereby causing p27kip1 to be neutralized to a varying degree in different MCL tumors. This in turn frees Cyclin E/CDK2 from p27kip1-mediated inhibition, favoring entry into S phase. In this view, the probability of progression from G1 to S phase is regulated in cycling cells as a continuous variable, not in a binary on–off fashion. In keeping with this model, essentially all of the p27kip1 in MCL tumors is physically associated with Cyclin D1 complexes.[171]

MCLs invariably delete or inactivate both p16(INK4a) and p14(ARF), unlike some other cancers that only mutate p16(INK4a), highlighting the potential role of p14(ARF) in MCL pathogenesis. p14(ARF) blocks MDM2-mediated ubiquitination of p53, leading to p53 stabilization. In addition, p14(ARF) blocks proliferation in ways that are not yet understood.[172,173] Thus, p14(ARF) could play an important role in the MCL pathogenesis in addition to p16(INK4a).

p53 mutations are associated with poor prognosis in MCL and are also associated with higher tumor proliferation.[174–177] The rationale for the specific genetic selection of p53 mutations in the more proliferative MCLs is not clear but may relate to the role that p53 plays in cellular senescence.[178,179] Senescence is a process triggered by a variety of oncogenes that limits proliferation. Of note, p16(INK4a) is also an important mediator of senescence.

Another frequently observed genetic abnormality in MCL is mutation or loss of the *ATM* gene, which is detected in 40% to 75% of MCL cases.[152,177,180,181] ATM plays a central role in the cellular response to DNA damage and ATM inactivation is associated with a high frequency of chromosomal aberrations, suggesting that these mutations, at least in part, might be responsible for chromosomal instability of MCL. *ATM* mutations are not associated with the proliferation status of MCL tumors, and are not associated with differences in the overall survival. Given their high frequency in MCL, *ATM* mutations are most likely early genetic events in MCL pathogenesis. The role of *ATM* inactivation in MCL is likely to be unrelated to p53 because *ATM* mutations are not associated with higher MCL proliferation rate, unlike p53 inactivation.

The therapy of MCL remains problematic, but recently a rapamycin analogue has shown clinical activity as a single agent, suggesting a role for the mTOR pathway in this lymphoma type.[182] The protein kinase mTOR lies downstream of signaling by PI-3 kinase and AKT kinase, and controls cellular utilization of nutrients.[183] Phosphorylation and activation of AKT is present in the majority of proliferative MCLs.[184] Furthermore, *PTEN*, a lipid phosphatase that controls PI-3 kinase activation, is recurrently mutated, deleted, or silenced in MCL.[184] Therefore, the activity of rapamycin analogues in MCL may be based on the underlying genetic abnormalities in the PTEN-PI3 kinase-AKT-mTOR pathway.

PERSPECTIVES

This chapter is not meant to exhaustively describe known biological mechanisms in lymphomas but rather emphasize biological themes pertinent to multiple lymphoma subtypes:

1. Quantitative molecular analysis of tumor specimens provides a molecular diagnosis that can define biologically distinct subgroups and reveal the differential engagement of oncogenic pathways. Certain diagnostic distinctions, such as between BL and DLBCL, cannot be made reliably by conventional pathologic methods but are readily distinguished by gene expression profiling. In DLBCL, gene expression profiling has revealed at least three diseases that arise from different stages of normal B-cell development and require distinct genetic aberrations to become malignant. Other diagnostic categories, like MCL, appear to represent single diseases. Nonetheless, gene expression profiling has uncovered signatures of biological pathways that account for differences in survival among patients with the same diagnosis. The logical conclusion from these observations is that quantitative technologies such as gene expression profiling have the potential to greatly enhance the diagnosis and treatment of lymphoma patients. Incorporation of these technologies into clinical trials should help elucidate the molecular differences between responders and nonresponders.
2. Lymphomas interact critically with their microenvironment. In both DLBCL and FL, gene expression signatures of nonmalignant cells in tumor biopsies are strong predictors of survival. These clinical correlations suggest that lymphomas vary in the manner and extent to which they interact with immune cells and stromal cells in their microenvironment. Furthermore, many lymphoma types may depend upon stimulation by either self or foreign antigens. In certain notable cases, such as in marginal zone lymphomas, eradication of the foreign antigen can cure the malignancy.[185–187] In the future, it will be important to model these cell–cell interactions in vitro and in mouse models because this may yield new perspectives on how to interfere with lymphoma biology therapeutically.
3. Pathway-targeted agents hold great promise for the treatment of lymphoma. Inhibitors of the NF-κB pathway may prove active in ABC DLBCL, PMBL, HL (Hodgkin lymphoma), MALT lymphoma, and T cell lymphomas.[30] Inhibitors of B-cell receptor signaling may be toxic for lymphoma types that are stimulated by antigens in their microenvironment, potentially including FL. Such inhibitors may target a wider range of lymphomas given the dependence of normal B cells on tonic B-cell receptor signaling.[188] BCL-2 inhibitors are exciting new agents for those lymphomas with high expression of BCL-2, including t(14;18)-positive GCB DLBCL, ABC DLBCL, MCL, and small lymphocytic lymphoma.

Given the rapid progress that has been made toward a molecular understanding of lymphoma pathogenesis, it seems likely that rational and patient-specific treatments of lymphoma will become a clinical reality.

CHAPTER 76

PATHOBIOLOGY OF HODGKIN LYMPHOMA

Stefano A. Pileri, Brunangelo Falini, Claudio Agostinelli, and Harald Stein

INTRODUCTION

Hodgkin disease is a lymphoid tumor that represents approximately 1% of all de novo neoplasms occurring every year worldwide. Its diagnosis is based on the identification of characteristic multinucleated giant cells within an inflammatory milieu. These cells—termed Reed-Sternberg (RS) or diagnostic cells—correspond to the body of the tumor: they measure 20 to 60 μm in diameter and display a large rim of cytoplasm and at least two nuclei with acidophilic or amphophilic nucleoli, covering more than 50% of the nuclear area (Fig. 76–1). The population of cells within the tumor also includes a variable number of mononuclear elements—Hodgkin (H) cells—showing similar cytological features to RS cells and neoplastic cell variants, each in relation to a specific subtype of Hodgkin disease. Molecular studies have recently shown that in most if not all cases, RS cells, Hodgkin cells, and cell variants actually belong to the same clonal population, which is derived from peripheral B and T lymphocytes in approximately 98% and 2% of cases respectively.[1–10] Accordingly, Hodgkin disease has been included among malignant lymphomas and the term *Hodgkin lymphoma* (HL) has come into use.[6,11,12]

Although regarded as diagnostic, Hodgkin and RS (H&RS) cells are not exclusive of HL, because similar elements may be observed in reactive lesions (such as infectious mononucleosis), B- and T-cell lymphomas, carcinomas, melanomas, or sarcomas.[13] Thus, the presence of an appropriate cellular background—along with the results of immunophenotyping—is basic for the diagnosis. The reactive milieu—which can even represent 99% of the whole examined population—consists of small lymphocytes, histiocytes, epithelioid histiocytes, neutrophils, eosinophils, plasma cells, fibroblasts, and vessels in different proportions depending on the histological subtype of HL. It is sustained by autocrine and/or paracrine production of cytokines including IL-1, -2, -5, -6, -7, -8, -9, -10, -13, TNF-α, GM-CSF, M-CSF, TGF-β, bFGF, VEGF, MCP-1, MIP-1α, MIP-1β, IP10, MIG, TARC, CD70, CD80, and CD86.[14–23] In addition, various numbers of H&RS cells may express cytokine receptors, such as CD30, CD40, IL-2R (CD25/CD122), IL-3R (CD123), IL-6R (CD126), IL-7R (CD127), IL-13R (CD213), TNF-R (CD120), TGF-βR (CD105/endoglin), M-CSF-R (CD115), SCF-R (CD117/c-kit receptor), and FasL (CD178)[14,15,19,20,24–26]; chemokine receptors and their ligands (eg, CXCR6, CCR10, CXCL 16, and CCL28)[27]; and receptor tyrosine kineses (see PDGFRα, DDR2, EPHB1, RON, TRKA, and TRKB).[28] The release of these molecules is also responsible for the characteristics of the nonneoplastic component[29,30] and most of the symptoms recorded in HL patients as well as for the growth and immunosurveillance escape of neoplastic cells. It has also been proposed that hepatocyte growth factor (HGF) and its receptor (c-MET) might constitute an additional signaling pathway between RSC and the reactive cellular background, affecting adhesion, proliferation, and survival of H&RS cells.[31]

HISTOPATHOLOGIC CLASSIFICATION

In 1832, Sir Thomas Hodgkin provided the first description of the process in a paper entitled "On Some Morbid Appearances of the Absorbent Glands and Spleen."[32] In 1898 and 1902, Carl Sternberg and Dorothy Reed independently described the typical "diagnostic" cells.[33,34] In 1944, Jackson and Parker proposed the first comprehensive classification of the tumor (Table 76–1).[35] This classification, however, was subsequently found to be clinically irrelevant, because most patients belonged to the granulomatous subtype and the response to therapy greatly differed from case to case.

In 1956, Smetana and Cohen identified a histopathologic variant of granulomatous Hodgkin disease, provided with a better prognosis and characterized by sclerotic changes[36]: this variant was termed "nodular sclerosis Hodgkin disease" in the classification proposed by Lukes, Butler, and Hicks in 1964 (Table 76–1).[37] The latter classification, simplified at the Rye Conference in 1965, (Table 76–1) was routinely used for some decades, because of the high inter- and intrapersonal reproducibility and satisfying clinicopathologic correlations.[38]

In 1994, in the light of morphologic, phenotypic, genotypic, and clinical findings, HL was listed in the Revised European-American Lymphoma (REAL) classification[39] and subdivided into two main types: lymphocyte-predominant (LP-HL) and classical HL. The latter further included the following subtypes: (a) nodular sclerosis classical HL, (b) mixed cellularity classical HL, (c) lymphocyte depletion classical HL, and (d) lymphocyte-rich classical HL (Table 76–1). In 2001, this approach was adopted by the World Health Organization (WHO) (Table 76–1), which promoted lymphocyte-rich classical HL from provisional entity to accepted entity.[40] On this occasion, the concept of lymphocyte-rich classical HL has been expanded by including a nodular form of the process, as proposed by the European Lymphoma Task Force.[41]

It is worthy of note that HL subtyping should be performed only in lymph node biopsies at the onset of the disease: in fact, chemo- and/or radiotherapy actually modify the histopathologic picture by inducing a lymphocyte-depleted pattern.

LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA

LP-HL represents 4% to 5% of all HL cases[42] and significantly differs from the classical type in terms of morphology, phenotype, genotype, and clinical behavior (Table 76–2). The only feature shared by LP-HL and classical HL is the low amount of neoplastic cells. For a long time, following the Rye Conference, the tumor was also called "nodular paragranuloma," a designation adopted by the Kiel Group[43] based on the term *paragranuloma* introduced much earlier by Jackson and Parker.[35] This designation intended to underline the differences existing between this type of HL and the remaining ones.

Clinicopathologic Findings

LP-HL displays features that are not generally encountered in classical HL and make its behavior closer to that of "indolent" B-cell lymphomas.[44] First of all, it has a unimodal age distribution, with a single peak in the fourth decade, which contrasts with the two peaks usually observed in classical HL.[44] The disease most often affects a single node rather than groups of nodes. Bone-marrow involvement is only occasionally found during staging procedures in patients whose disease appears to be limited to a single node[44]: this pattern of spread differs from the orderly progression classically seen in classical

Lymphocyte-Predominant Hodgkin Lymphoma

Growth pattern:
Nodular (80% of cases)
Diffuse (20% of cases)
Characteristics of neoplastic cells:
Lymphohistiocytic/popcorn cells scattered, but easily found
Hodgkin and Reed–Sternberg cells rare
- B-cell phenotype (CD20$^+$, CD79a$^+$, J-chain$^{+/-}$)
- CD45$^+$
- EMA$^{+/-}$
- CD30$^-$
- CD15$^-$
- LSP1$^-$
- TARC$^-$

IgD$^+$/CD38$^+$/IgM$^-$/CD27$^-$ in 27% of cases (corresponding to a subgroup of young male patients presenting with laterocervical lymphadenopathy)
Signaling molecule expression: Fyn$^+$, Syk$^+$, BLNK$^+$, PLC-gamma2$^+$
Transcription factor expression: BASP$^+$, Bcl-6$^+$, Oct-2$^+$, PU.1$^+$, BOB.1$^+$
Follicular dendritic cell meshwork in the nodular form
IgV_H gene status: clonal rearrangements with somatic mutations (ongoing in approximately 50% of cases)
Aberrant somatic hypermutations of PIM1, PAX5, RhoH/TTF, or c-MYC gene in 80% of cases (two or more genes mutated in 50% of cases)
Recurrent genomic imbalances
No correlation with Epstein–Barr virus infection
Normal counterpart: germinal center cell
Reactive milieu:
Small B-lymphocytes in the nodular form
CD57$^+$ T-cell rosettes around neoplastic cells in the nodular form
T lymphocytes predominant in the diffuse form
Possible association with diffuse large B-cell lymphoma
Differential diagnosis with T cell-rich B-cell lymphoma and lymphocyte-rich classical Hodgkin lymphoma.

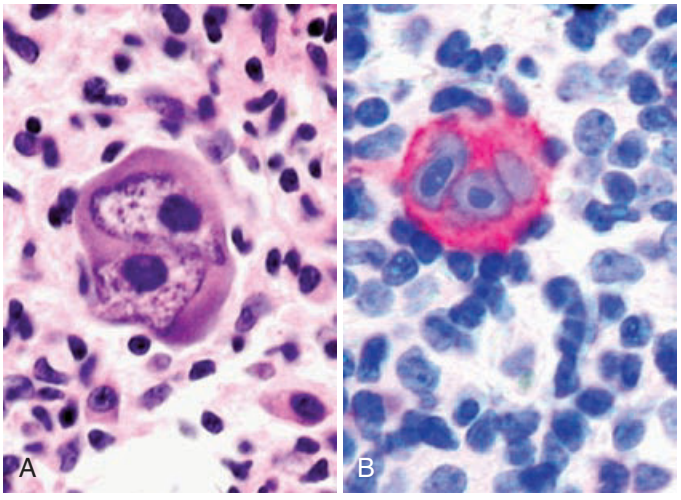

Figure 76–1 A characteristic diagnostic Reed–Sternberg cell (**A**) measuring up to 60 µm shows prominent inclusion-like nucleoli (hematoxylin and eosin, ×800). Another Reed–Sternberg cell (**B**) strongly expressing CD30 is contained within an inflammatory milieu (APAAP technique, Gill hematoxylin counterstain, ×500).

Table 76–1 Approaches Used to Classify Hodgkin Lymphoma

Jackson and Parker Classification (1944)
1. Paragranuloma
2. Granuloma
3. Sarcoma
Lukes and Butler Classification (1964)
1. Lymphocytic and/or histiocytic, nodular
2. Lymphocytic and/or histiocytic, diffuse
3. Nodular sclerosis
4. Mixed cellularity
5. Diffuse fibrosis
6. Reticular
Rye Conference Classification (1965)
1. Lymphocyte predominance
2. Nodular sclerosis
3. Mixed cellularity
4. Lymphocytic depletion
REAL/WHO Classification (1994/2001)
1. Lymphocyte predominance, nodular or diffuse
2. Classical Hodgkin lymphoma:
- Lymphocyte-rich classical HL*
- Nodular sclerosis (grades 1 and 2)
- Mixed cellularity
- Lymphocyte depletion

*This form—regarded as a provisional entity in the REAL Classification—includes a nodular (common) and a diffuse (rare) form in the WHO scheme.

HL.[45] Involvement of the thymus is uncommon, unlike the other types of HL.[44] The tumor has a very indolent course with prolonged disease-free intervals, despite a high rate of late relapses, which usually respond well to therapy.[44,46] The benign nature of these relapses and the incidence of delayed treatment-related toxicity have raised questions about the need for an aggressive upfront approach and prompt to the search for novel targeted therapies.[47] At times, LP-HL can be associated with diffuse large B-cell lymphoma: most authors think that the latter behaves more favorably than de novo forms, although conflicting data have been reported.[44,48,49] All these findings per se justify a distinction between LD-HL and classical HL, a concept that is further supported by morphologic and phenotypic data (see also the following morphologic findings and phenotypic findings sections).

Morphologic Findings

In most instances, the growth is—at least in part—nodular (Fig. 76–2).[39,40,44] The detection of a diffuse variant of the process is rare and usually corresponds to the histological progression of a nodular form.[39,40,45,50] Interestingly, Fan et al have proposed a subclassification of LP-HL, based on the prevalent growth pattern: classic nodular, serpiginous or interconnected nodular, nodular with prominent extranodular neoplastic cells, nodular with T cell-rich background, diffuse with T cell-rich background, and diffuse with B cell-rich background.[51] The neoplastic population consists of large elements, called L&H (lymphohistiocytic) or "popcorn" cells.[39,40,44] Although commonly used in the literature, the term L&H is actually incorrect in the light of the definitely proven lymphoid origin of the tumoral elements.[2–7] L&H/popcorn cells show nuclei resembling those of centroblasts, with polylobated profile, finely dispersed chromatin and small nucleoli, that are more often adjacent to the nuclear membrane (Fig. 76–3).[39,40,44] Their cytoplasmic rim is narrow and moderately basophilic at Giemsa staining. Occasionally, neoplastic elements display the features of H&RS cells and/or of lacunar cells of nodular sclerosis classical HL and are associated with minimal sclerosis[39,40,44]:

Table 76–2 Differential Diagnoses Between T Cell-Rich Large B-Cell Lymphoma, Lymphocyte Predominant Hodgkin Lymphoma, and Classical Hodgkin Lymphoma

Diagnostic criteria	TCRBCL	LP-HL Nodular/ diffuse	CHL
Neoplastic component

B symptoms	+/–	–	–/+
Bone-marrow involvement	+/–	–	–
Orderly progression in the spread	–	–	+
Aggressiveness	High	Low	Variable

CGH, comparative genomic hybridization; CHL, classical Hodgkin lymphoma; EBV, Epstein–Barr virus; EMA, epithelial membrane antigen; FDC, follicular dendritic cells; LP-HL, lymphocyte predominant Hodgkin lymphoma; TCRBCL, T cell-rich large B-cell lymphoma.

Note: +, 70% to 100% of cases positive; +/–, 40% to 70% of cases positive; –/+, 10% to 40% of cases positive. Rare, 1% to 10% of cases positive; –, all cases usually negative; NE, not evaluated. n, nodular form of LP-HL.

*Weakly positive in some instances.

**Negative in rare instances.

***Usually overexpressed.

#In 1% to 2% of the cases TCR gene rearrangement.

under these circumstances, immunophenotyping plays a fundamental role for the differential diagnosis between LP-HL and lymphocyte-rich classical HL (see Table 76–2). The reactive milieu consists of small lymphocytes with some plasma cells and epithelioid elements, which at times become so numerous as to mimic a histiocyte-rich large B-cell lymphoma (see also the following differential diagnosis section).[52]

As mentioned before, sometimes diffuse large B-cell lymphoma can be concurrently or subsequently detected in patients with nodular LP-HL: when occurring in the same lymph node, the large B-cell component often surrounds LP-HL nodules.[44,53–56]

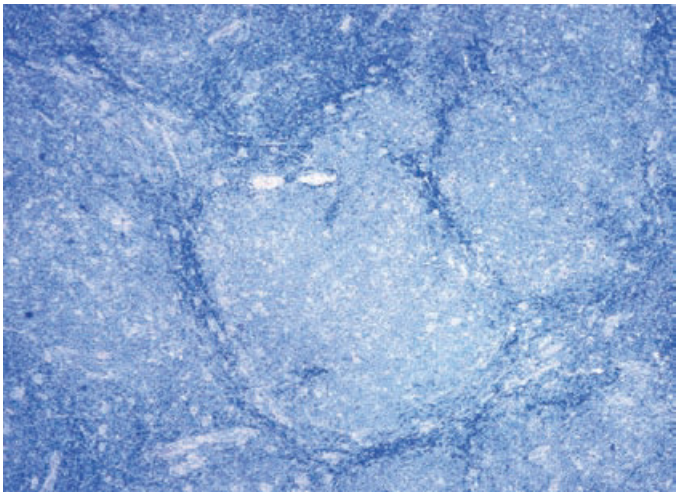

Figure 76–2 Nodular lymphocyte predominant–Hodgkin lymphoma: at panoramic view, the tumor appears as nodular densely packed cellular areas mostly consisting of small lymphocytes (Giemsa, ×40).

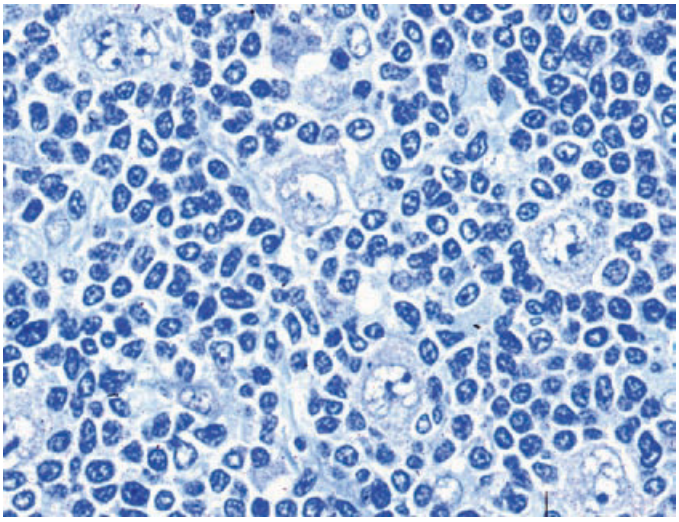

Figure 76–3 Nodular lymphocyte predominant–Hodgkin lymphoma: at closer examination, lymphohistiocytic/popcorn cells are situated among small lymphocytes (Giemsa, ×400).

PROGRESSIVELY TRANSFORMED GERMINAL CENTERS

Progressively transformed germinal centers, first described by Lennert in 1978,[57] represent a peculiar form of follicular hyperplasia, which can be confused with LP-HL.

Progressively transformed germinal centers occur in children and young adults, who have a slightly higher risk of developing LP-HL than the average population. In particular, progressively transformed germinal centers can precede, concur with, or follow LP-HL.[43,44]

On morphologic grounds, progressively transformed germinal centers are 2 to 3 times larger than reactive follicles and predominantly consist of small lymphocytes—mainly mantle cells—intermingled with some centroblasts and follicular dendritic cells (Fig. 76–4). Progressively transformed germinal centers can be differentiated from LP-HL because of the lack of L&H/popcorn elements and their cytologic composition. The latter correspond to a mixture of B (CD20+) and T (CD3+) lymphocytes, histiocytes, and follicular dendritic cells, which overall produce a "moth-eaten" appearance.[57,58]

Molecular studies highlight that progressively transformed germinal centers carry somatic hypermutation, clonal expansion, and antigen selection as classical germinal centers; however, no clonal

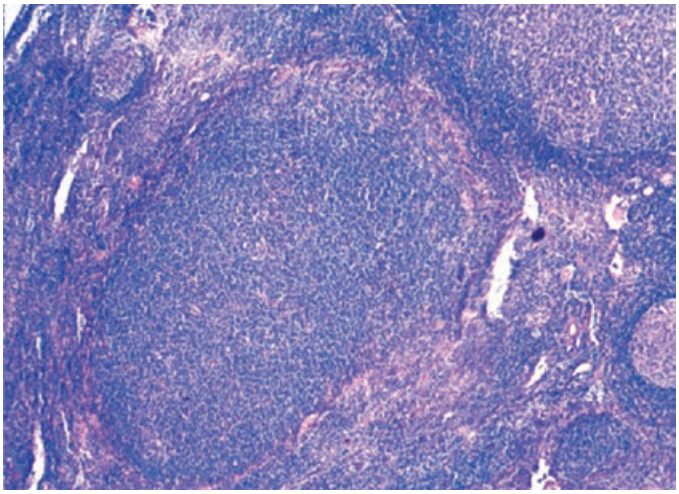

Figure 76–4 Progressively transformed germinal center: at low power, it resembles the nodules of lymphocyte predominant–Hodgkin lymphoma (Giemsa, 40×).

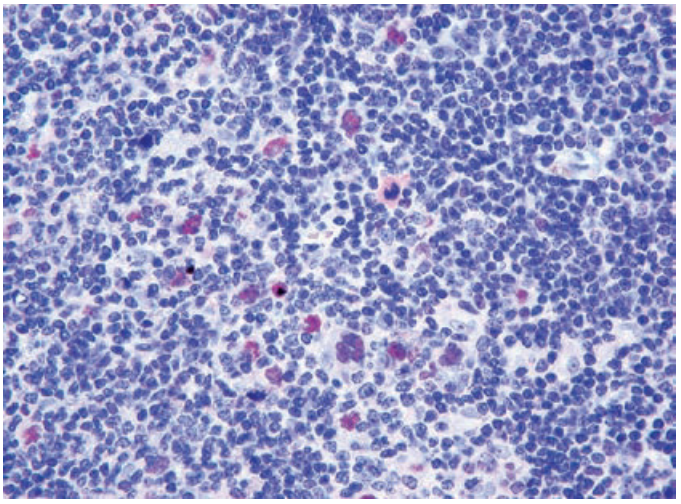

Figure 76–6 Nodular lymphocyte predominant–Hodgkin lymphoma: lymphohistiocytic/popcorn cells carry the Bcl-6 protein (APAAP technique, Gill hematoxylin counterstain, ×200).

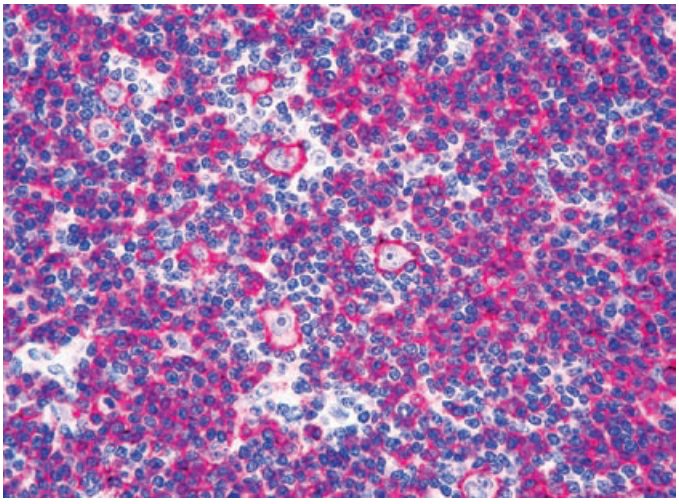

Figure 76–5 Nodular lymphocyte predominant–Hodgkin lymphoma: lymphohistiocytic/popcorn cells and most small lymphocytes within a nodule express CD20 (APAAP technique, Gill hematoxylin counterstain, ×200).

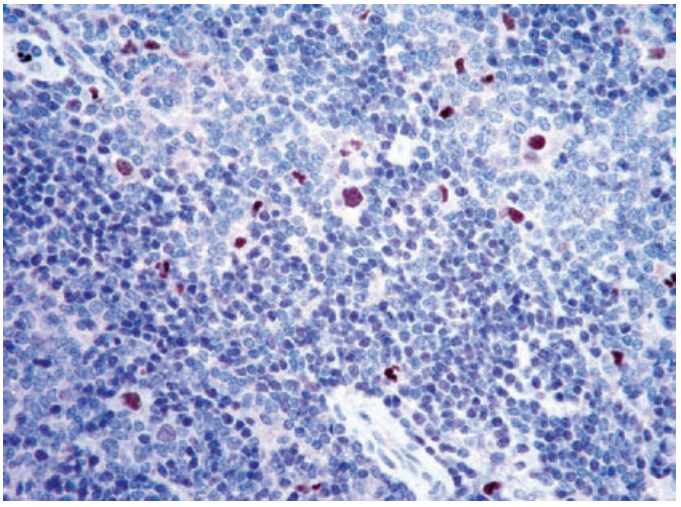

Figure 76–7 Nodular lymphocyte predominant–Hodgkin lymphoma: positivity of neoplastic elements at the determination of the PU.1 transcription factor (Envision+ Method, Gill hematoxylin counterstain, ×200).

expansion across the borders of individual PTGC is found in contrast to the monoclonal pattern of nodular LP-HL.[59]

Phenotypic Findings

Neoplastic cells—that are primarily cycling as determined by the Ki-67 staining—display a distinct profile, which differs from that of classical HL.[6,39–41,44,60–66] In particular, LP-HL cells are CD45$^+$, CD20$^+$, CD79a$^+$, Bcl-6 protein$^+$, PU.1$^{+/-}$, Oct-2$^+$, BOB.1$^+$, J-chain$^{+/-}$, epithelial membrane antigen (EMA)$^{+/-\text{or}-/+}$, CD3$^-$, CD10$^-$, LSP1$^-$, and CD15$^-$ (Figs. 76–5, 76–6, 76–7, and 76–8). Interestingly, CD20 may be lost following rituximab therapy.[67] Expression of Bcl-2 and CD30 is unusual and—when detected—definitely weak.[60,68] Notably, a certain number of extrafollicular reactive blasts (smaller than L&H/popcorn cells) are marked by the anti-CD30 antibodies: in the past, they have been misinterpreted as malignant elements.[41] Recently, Prakash et al have reported that in 27% of LP-HL cases, neoplastic cells express IgD and CD38 in the absence of IgM and CD27.[69] These cases seem to correspond to a distinctive subset of patients with a younger median age (21 vs 44 years), striking male predominance

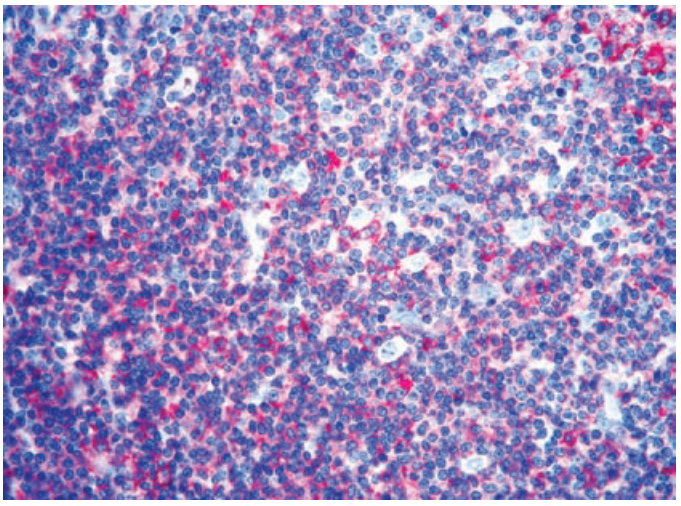

Figure 76–8 Nodular lymphocyte predominant–Hodgkin lymphoma: neoplastic cells are LSP1 negative conversely to the surrounding small lymphocytes (APAAP technique; Gill hematoxylin counterstain, ×200).

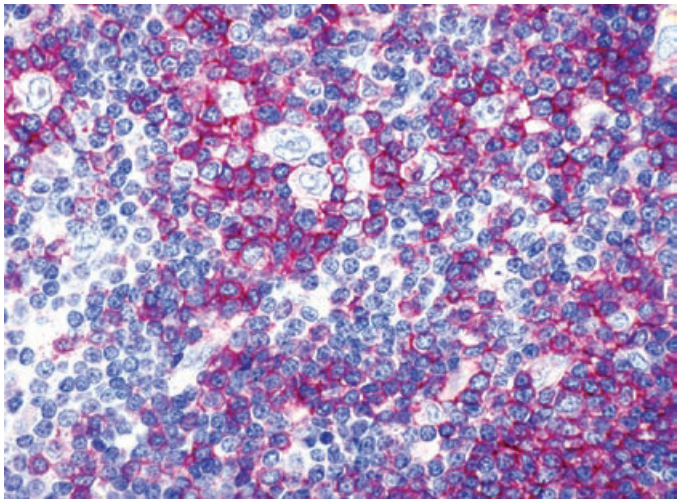

Figure 76–9 Nodular lymphocyte predominant–Hodgkin lymphoma: lymphohistiocytic/popcorn cells are surrounded by rosettes of CD57+ T lymphocytes (APAAP technique, Gill hematoxylin counterstain, ×300).

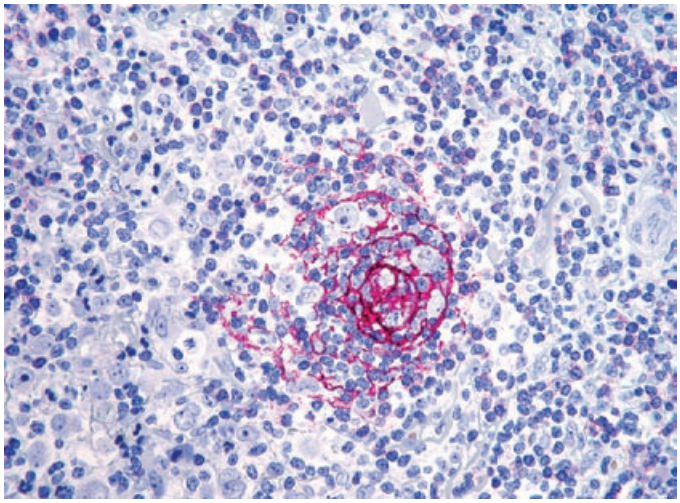

Figure 76–10 Nodular LP–Hodgkin lymphoma: delicate meshwork of CD21+ follicular dendritic cells (APAAP technique, Gill hematoxylin counterstain, ×300).

(32 : 1 vs 1.5 : 1), and more frequent cervical lymph node involvement (56% vs 18.2%).[69]

Phenotypic analysis shows a series of findings that have pathobiological implications. These data support the derivation of L&H/popcorn cells from germinal-center B elements because of

1. their positivity for Bcl-6 protein, CD40, and CD86[60,70–75];
2. their close contact with rosettes of CD4+/CD57+ T-lymphocytes (ie, the same T-cell component found in normal germinal centers and PTGC) (Fig. 76–9)[75]; and
3. their relationship with a meshwork of FDCs (CD21+/CD35+), at least in the nodular form of the disease (Fig. 76–10).[76]

Second, it underlines that LP-HL is not affected by an almost complete silencing of the B-cell program, in contrast to classical HL. This is supported not only by the above-mentioned positivities for CD20, CD79a, J-chain, and transcription factors, but also by the regular detection of intracellular signaling molecules (ie, Fyn, Syk, BLNK, and PLC-gamma2) that are usually abrogated in classical HL.[77]

In the nodular form, the small lymphocyte component mainly consists of B-cell elements.[39,40,44] The progression to a diffuse form, however, is characterized by an increase in the number of T lymphocytes that can finally predominate over B cells. Some recent reports have highlighted that T lymphocytes can coexpress CD4 and CD8.[78] This finding is in keeping with the concept that a proportion of tumor-associated reactive T cells bear an activation profile.[79]

Genotypic Findings

Further evidence of the derivation of the tumor from germinal-center B cells has been provided by recent molecular studies, based on single-cell polymerase chain reaction (PCR).[1–7] These studies have shown that popcorn cells in any given case represent a monoclonal population derived from germinal-center B cells, because of the consistent occurrence of monoclonal Ig gene rearrangements and the high load of somatic hypermutations within variable-region genes. Ongoing mutations are detected in about half LP-HL cases: this finding—not observed in classical HL—identifies mutating germinal-center cells as the precursors of the neoplastic elements.[2,5] The pattern of mutation within these gene segments suggests that tumoral cells, their precursors, or both have been selected for expression of functional antigen receptors.[2,5]

A clonal relationship between the neoplastic cells of nodular LP-HL and concurrent diffuse large B-cell lymphoma was proven by Ohno and coworkers through selective microdissection of immunostained tissue sections and sequence analysis of the immunoglobulin heavy chain gene (IgH) complementary determining region (CDR) III in two cases.[56] This leads to the possible genetic similarities between LP-HL and DLBCL recently suggested by two studies.[80,81] Of these, the former shows that—besides Ig genes—the somatic hypermutation process aberrantly involves four targets (PIM1, PAX5, RhoH/TTF, c-MYC) previously identified in DLBCL.[80] The latter demonstrates recurrent rearrangement of the BCL-6 gene in 48% of LP-HL cases that involve Ig and non-Ig loci similar to those found in DLBCL.[81]

Comparative genomic hybridization studies reveal recurrent genomic imbalances in LP-HL. In particular, gain of 1, 2q, 3, 4q, 5q, 6, 8q, 11q, 12 q, and X and loss of chromosome 17 have been recorded in 36.8% to 68.4% of 19 cases analyzed by Franke and coworkers.[82]

Finally, in situ hybridization studies with EBER1/2 probes, as well as conventional Southern blot, PCR, and immunohistochemistry for the latent membrane protein-1 (LMP-1) show that the L&H/popcorn cells of LP-HD have so far never been found to be infected by Epstein–Barr virus (EBV), conversely to the neoplastic component of classical HL.[83,84] Isolated small lymphocytes belonging to the reactive background carry EBV infection in 25% of cases.[41]

Differential Diagnosis

The distinction between LP-HL, classical HL, and T-cell/histiocyte-rich large B-cell lymphoma is sometimes blurred.[41,52,76,85–88] This is not surprising if one considers that (a) LP-HL and lymphocyte-rich classical HL were in the past lumped under the generic label "lymphocyte-predominant Hodgkin disease"[41] and (b) LP-HL and T cell-rich B-cell lymphoma might share a common histogenesis.[86,87] The difficulties encountered in this field are clearly underlined by the recent proposal of three subtypes of T cell-rich B-cell lymphoma (L&H-like, centroblastic/immunoblastic-like, and RS-like) based on the morphologic and phenotypic characteristics of the neoplastic cells in individual cases.[87] Table 76–2 summarizes the main criteria to be applied to this critical differential diagnosis,[41,66,69,85,88–94] which is of paramount importance because of the dramatic differences in terms of clinical aggressiveness and therapeutic approach among the above-mentioned tumors.[95,96]

CLASSICAL HODGKIN LYMPHOMA

Classical Hodgkin lymphoma represents approximately 95% of all HL cases and shows a typical bimodal age distribution with a peak at approximately 20 years of age and a second peak in late life.[39] It

is characterized by a series of clinical, morphologic, phenotypic and genotypic features, which are integrated by specific findings in the four subtypes of the process (nodular sclerosis, mixed cellularity, lymphocyte depletion, and lymphocyte-rich). Classical HL recognizes peripheral B-cell derivation in approximately 98% of cases, the remaining ones originating from peripheral T lymphocytes.[7,8]

Clinicopathologic Findings

Patients with classical HL most often present with lateral-cervical lymph node enlargement whereas peripheral extranodal involvement is definitely rare. Approximately 50% of patients are staged I or II. A mediastinal mass is observed in most nodular sclerosis classical HL cases, at times showing the characteristics of "bulky" disease. Systemic symptoms—fever, night sweats, and body weight loss—are detected in approximately 25% of patients. Conversely to what was reported in the past, the histological subtype is not regarded as a major prognostic indicator.

Morphologic Findings

In classical HL, typical RS cells (Fig. 76–1) can be easily found: their number (from few to many) differs from case to case. They may be associated with peculiar cell variants and an inflammatory background related to the histological subtype. The lymph node structure is largely effaced, although remnants of normal follicles can be detected in some cases. The type of structural alteration is indeed characteristic in nodular sclerosis classical HL.

Phenotypic Findings

In 1982, Schwab et al described a new monoclonal antibody, termed Ki-1, which seemed to specifically identify H&RS cells and a small subset of normal lymphocytes with a perifollicular location. However, with wide use, this antibody was shown not to be specific for H&RS cells, as originally thought, but to react with a variety of lymphoid tumors, including a previously unrecognized category, anaplastic large-cell lymphoma.[97–99] Following the evaluation of Ki-1, other reagents with similar characteristics have been developed[13,100] that were assessed at the III Workshop on Leukocyte Differentiation Antigens (Oxford, 1986) to form the 30th cluster of monoclonal antibodies (CD30). The target recognized by these antibodies is a glycoprotein of 120 kd, expressed by lymphoid elements following activation and formed by three distinct domains (intracytoplasmic, transmembranic, and external).[13] It is encoded by a gene located at 1p36, whose activity is modulated by the number of ATCC-repeats in the 5′ region of the promoter, and represents a member of the receptor superfamily of tumor necrosis factor (TNF).[101,102] Recently, CD30 overexpression has been reported to induce constitutive

Classical Hodgkin Lymphoma

Histotypes:
Nodular sclerosis classical Hodgkin lymphoma (grades I and II, cellular phase, syncytial)
Mixed-cellularity classical Hodgkin lymphoma (interfollicular, epithelioid cell-rich)
Lymphocyte-depleted classical Hodgkin lymphoma (fibrotic, sarcomatous)
Lymphocyte-rich classical Hodgkin lymphoma (nodular, diffuse)
Characteristics of neoplastic cells:
Typical Hodgkin and Reed–Sternberg cells easily found (predominant in the lymphocyte-depleted sarcomatous histotype)
"Lacunar" cell variants in the nodular sclerosis histotype
Mummified (apoptotic) cells possibly found
Null phenotype in most instances ($CD20^-$; $CD79a^-$; J-chain$^-$; T-cell markers$^-$)
B-cell phenotype ($CD20^+$ and more rarely CD79a) in 20% to 25% of cases
T-cell phenotype in 1% to 2% of cases
Cytoplasmic and surface immunoglobulins$^-$
$CD45^-$
EMA^-
$CD30^+$
$CD15^{+/-}$
$LSP1^+$
$TARC^+$
$AFT3^+$
$HGAL^{+/-}$
ALK protein$^-$
Signaling molecules expression: $Fyn^{+/-}$, Lyn^-, Syk^-, $BLNK^-$, PLC-gamma2$^-$
Transcription factor expression: $BASP^+$, $IRF4^+$, T-bet$^+$, Bcl-6$^-$, Oct-2$^-$, PU.1$^-$, BOB.1$^{-/+}$
Follicular dendritic cell meshwork partly preserved in the "follicular form" of the nodular sclerosis histotype (cellular phase)
IgV_H gene status: clonal rearrangements with somatic mutations (not ongoing), crippling in 25% of cases
Aberrant somatic hypermutations of PIM1, PAX5, RhoH/TTF or c-MYC gene in 55% of cases (2 or more genes mutated in 30% of cases)
TCR clonal rearrangements in approximately 1% of cases
Constitutive NF-κB activation
Defective cytokinesis
Recurrent chromosomal aberrations involving 2p, 4p, 8q, 9p, 12p, 14q, and 16q
Correlation with Epstein–Barr virus (EBV) infection in 20% to 40% and 50% to 75% of nodular sclerosis and mixed-cellularity cases, respectively; latency II EBV infection pattern ($LMP\text{-}1^+$, $EBER1/2^+$, $EBNA2^-$)
Normal counterpart: post–germinal-center cell?
Reactive milieu:
Small B and T lymphocytes in the lymphocyte-rich histotype
Organized fibrotic bands originating from the lymph node capsule (regularly thickened) and circumscribing nodules with variable reactive cell component in the nodular sclerosing histotype
A mixture of small lymphocytes (predominantly T), plasma cells, neutrophils, eosinophils, and histiocytes in the mixed cellularity histotype
Abundant and randomly distributed collagen fibers in the fibrotic variant of the lymphocyte-depleted histotype
A few lymphocytes in the sarcomatous variant of the lymphocyte-depleted histotype
Possible association with non-Hodgkin lymphoma (B-CCL, follicular lymphoma, extranodal marginal zone lymphoma, diffuse large B-cell lymphoma, Burkitt lymphoma, peripheral T-cell lymphoma, anaplastic large-cell lymphoma)
Differential diagnosis with anaplastic large-cell lymphoma, peripheral T-cell lymphoma, diffuse large B-cell lymphoma (including T cell-rich B-cell lymphoma and primary mediastinal large B-cell lymphoma), fibrosarcoma, malignant fibrous histiocytoma, and undifferentiated nasopharyngeal carcinoma
Possible pathologic unfavorable prognostic indicators: lymphocyte depletion; nodular sclerosis grade II; expression/overexpression of one or more of the following molecules: Bcl-2, Bax, $Bcl\text{-}X_L$, p53, p21, MMP-2, PCNA, and Ki-67; low and high infiltration of $FOXP3^+$ and $TIA\text{-}1^+$ cells, respectively; genes related to microenvironment, cell growth/apoptosis, and regulation of mitosis (surrogated by the following molecules: ALDH1A1, STAT1, SH2D1A, TOP2A, RRM2, PCNA, MAD2L1, and CDC2)

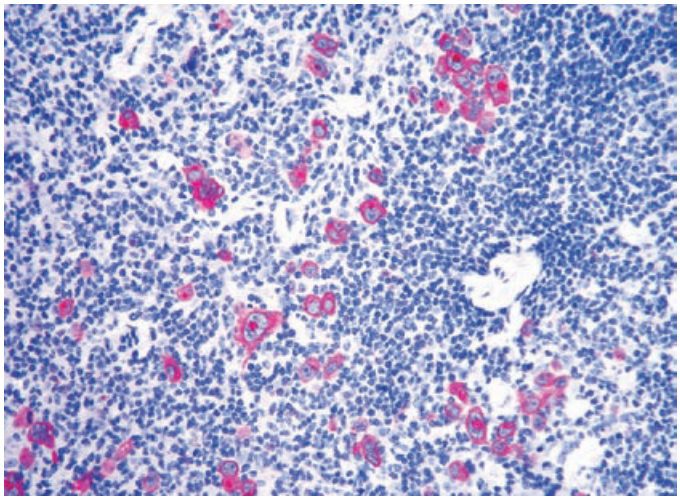

Figure 76–11 Classical Hodgkin lymphoma: Hodgkin and Reed–Sternberg cells express CD30 both at the cytoplasmic membrane level and in the Golgi area (dot-like positivity) (APAAP technique, Gill hematoxylin counterstain, ×250).

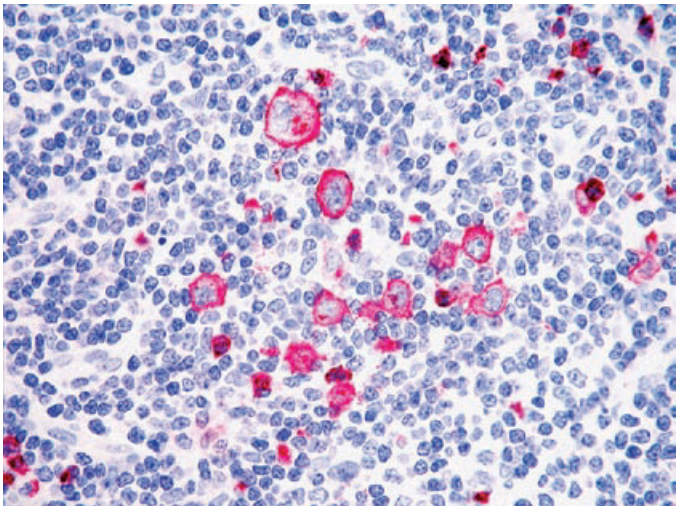

Figure 76–12 Classical Hodgkin lymphoma: neoplastic cells display CD15 membrane-bound and dot-like positivities (APAAP technique, Gill hematoxylin counterstain, ×300).

nuclear factor kappaB (NF-κB) activation (see below).[102] As expected, the CD30 ligand (CD30L) belongs to a group of molecules with homology to TNF: within the classical HL context, it seems to be mostly expressed by tissue mast cells.[103] The external domain of CD30 is cleaved by a metalloproteinase.[13] The levels of soluble CD30 have been reported to correlate with the size and extent of the tumor at presentation, thus representing a new possible prognostic indicator, independent of age, race, symptoms, and bulky disease.[104] The CD30 molecule has also been proposed as a possible therapeutic target for specific antibodies conjugated with plant toxins or iodine-131 for classical HL for therapeutic purposes: such antibodies have produced promising results in cases refractory to conventional therapies, although severe hematotoxicity has been recorded.[105–112]

Following immunohistochemical analysis both of paraffin and frozen sections, CD30 antibody staining results in different patterns: membrane-bound, dot-like in the Golgi area (corresponding to the accumulation of the 90-kd proteic precursor), and diffuse Fig. 76–11). The first two patterns are exclusive of lymphoid elements with the exception of embryonic carcinoma,[13,113,114] whereas the third one can occur in a variety of malignant tumors other than lymphomas, including pancreatic cancer, nasopharyngeal undifferentiated carcinoma, mesothelioma, and malignant melanoma.[100,114] Therefore, the immunophenotypic diagnosis of HL should always be based on the application of a panel of antibodies, including anticytokeratins, melanoma-associated antigens, CEA, and PLAP.[13] Expression of the CD30 molecule by H&RS cells is observed in more than 98% of classical HLs, although the intensity of the immunostaining can vary from case to case and even within the same case. The antigen is sensitive to fixation (especially prolonged fixation in formalin or fixation in B5): thus very efficient antigen retrieval techniques are required to achieve reliable results.[115]

CD15 is another valuable marker for H&RS cells (Fig. 76–12), which is detected in approximately 80% of cases of classical HL.[98,116] CD15 is characteristic, but not specific for H&RS cells, because it can de detected—rarely—in B- and T-cell lymphomas as well as in nonlymphoid tumors.[98,116–119] Among the antibodies available, the MMA seems to be superior for the diagnosis of classical Hodgkin lymphoma.[120]

H&RS cells usually do not express CD45 and epithelial membrane antigen (EMA), whereas B- and T-cell markers are observed in a proportion of cases.[121–130] In particular, CD20 (Fig. 76–13) is observed in 20% to 30% of examples of classical HL—usually EBV—and CD79a even more rarely.[123,126–128] Positivity for one or more T-cell markers is detected in a minority of H&RS cells (Fig. 76–14).[129,130] Under these circumstances, single-cell PCR studies

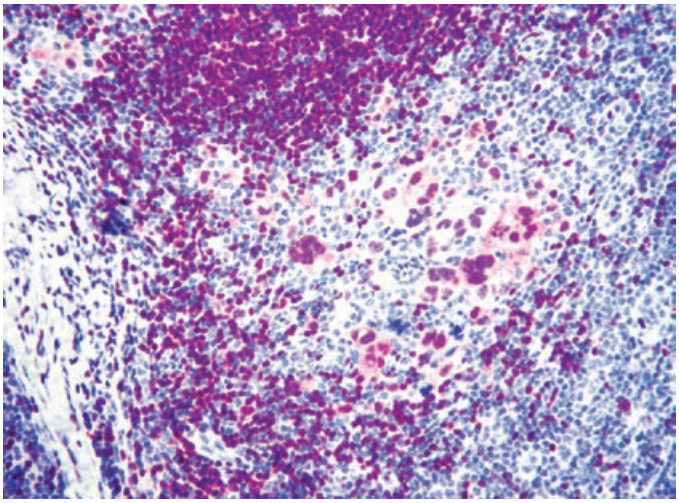

Figure 76–15 Classical Hodgkin lymphoma: neoplastic cells reveal a strong–moderate positivity for B-cell specific activator protein (BSAP); small B lymphocytes stain more intensively (APAAP technique, Gill hematoxylin counterstain, ×250).

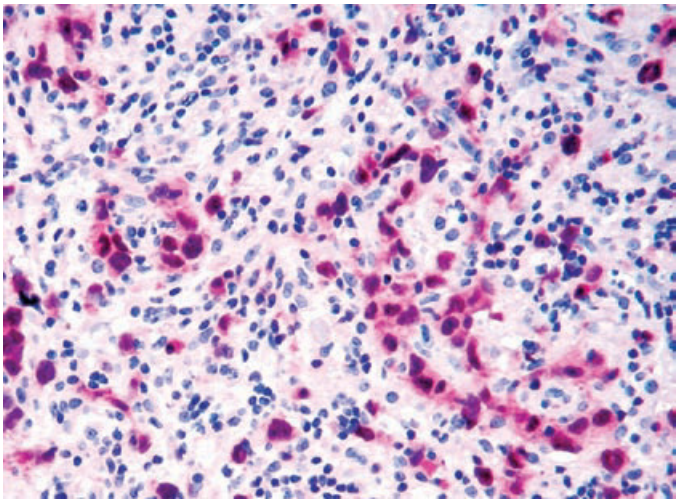

Figure 76–16 Classical Hodgkin lymphoma: Hodgkin and Reed–Sternberg cells express IRF4 (APAAP technique, Gill hematoxylin counterstain, ×250).

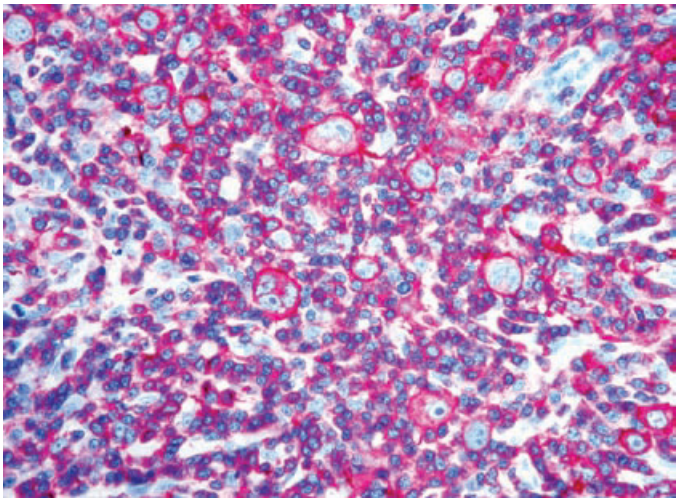

Figure 76–17 Classical Hodgkin lymphoma: neoplastic cells and reactive small lymphocytes strongly express LSP1 (APAAP technique, Gill hematoxylin counterstain, ×300).

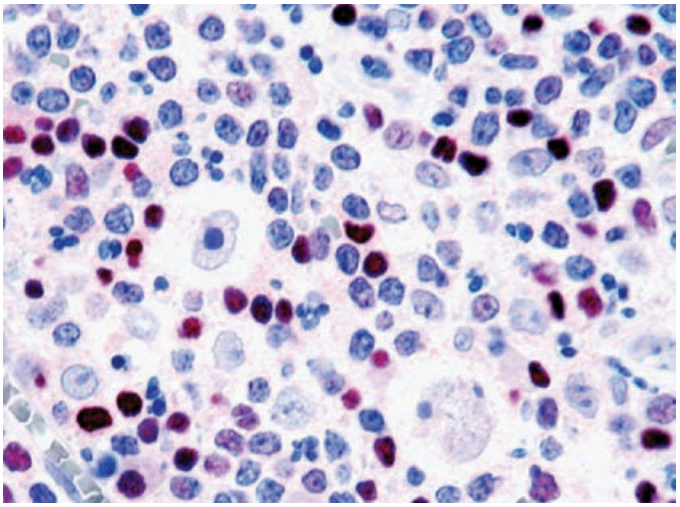

Figure 76–18 Classical Hodgkin lymphoma: Hodgkin and Reed–Sternberg cells lack the Oct-2 transcription factor; the surrounding positive small B lymphocytes represent the internal control (APAAP technique, Gill hematoxylin counterstain, ×500).

have so far shown T-cell receptor (TCR) gene rearrangement in only a few instances, clonal Ig gene rearrangements in fact occurring in most cases of classical HL cases with T-cell marker expression.[8,131,132] In contrast to LP-HL, the elements of classical HL are generally negative for the Bcl-6 molecule.[70,133] In addition, they are usually positive for LSP1, HGAL, PAX5/BSAP, and MUM1/IRF4 and more often negative for BOB.1, Oct-2, and PU1 (see also the following genotypic findings section) (Figs. 76–15, 76–16, 76–17 and 76–18).[7,8,61–65,70,133–136] With the exception of one case report,[132] BSAP has been found to effectively discriminate between classical HL and anaplastic large-cell lymphoma in large series of cases (for further details on this topic, see Table 76–3 and the Nodular Sclerosis Classical HL section).[137,138] In particular, this molecule is expressed throughout all the steps of B-cell differentiation, with the exclusion of plasma cells.[70] Its detection strongly favors classical HL over anaplastic large-cell lymphoma, in the light of the fact that the former recognizes B-cell origin in 98% of cases,[1–8,39,40] whereas the latter indicates—by definition—a T- or null-cell derivation.[39,40] The anaplastic (large cell) lymphoma kinase (ALK) represents another important tool for the differential diagnosis between classical HL and anaplastic large-cell lymphoma. It is expressed in 60% to 80% of cases of anaplastic large-cell lymphomas,[139–145] whereas it has not been

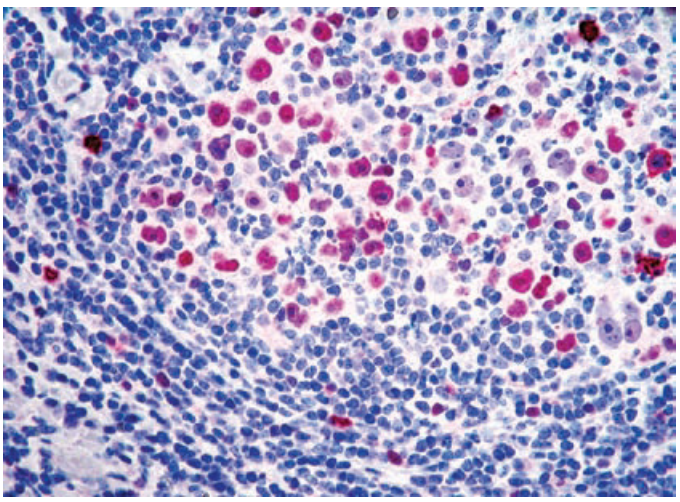

Figure 76–19 Classical Hodgkin lymphoma: neoplastic cells show p53 overexpression (APAAP technique, Gill hematoxylin counterstain, ×300).

Table 76–3 Differential Diagnosis Between Anaplastic Large-Cell Lymphoma Hodgkin-Like and Classical Hodgkin Lymphoma

	ALCL-HL	HL
Morphologic characteristics		
Neoplastic component	Usually cohesive	Usually dispersed
Reactive component	Often minor	Usually prevalent
Reed-Sternberg cells	May be present	Always present
Intrasinusoidal diffusion	Typical	Exceptional

ALCL-HL, Anaplastic large-cell lymphoma–Hodgkin lymphoma; ALK, anaplastic lymphoma kinase; EBV, Epstein–Barr virus; EMA, epithelial membrane antigen; BSAP, B-cell–specific activator protein; TARC, thymus and activation-regulated chemokine; TRAF1, tumour necrosis factor receptor–associated factor 1.

Note: +: 70% to 100% of cases positive. +/–: 40% to 70% of cases positive. /+: 10% to 40% of cases positive. Rare: 1% to 10% of cases positive. –: all cases usually negative.

*The intensity of immunostaining may vary within the same case.

**Results can vary depending on the fixative used.

***Membrane-bound and/or dot-like positivity.

#Some cases showing morphology and phenotypic profile consistent with ALCL-HL (including BSAP negativity) can lack t(2;5)/ALK protein expression: these cases need further studies to assess their definitive inclusion among anaplastic large cell lymphomas.

observed in classical HL,[146–150] with the exception of two controversial studies.[151,152] In anaplastic large-cell lymphoma, ALK overexpression is due to the synthesis of a chimeric protein caused by the occurrence of t(2;5)(2p23;5q35) or more rarely of a variant translocation, which leads to the formation of a hybrid construct between the ALK gene domain encoding for the transmembranic portion of the kinase and the promoter of another gene.[144,145,147,153,154] The latter is represented by nucleophosmin (NPM) in the classical t(2;5).[144,145,147,153] Finally, T-bet, TRAF1, and TARC are additional markers useful for the distinction between classical HL (mostly positive) and anaplastic large-cell lymphoma or diffuse large B-cell lymphoma (usually negative),[91,155,156] whereas clusterin and fascin are unreliable tools.[157,158]

It has been suggested that phenotypic findings might be of prognostic significance. In particular, the value of the following parameters was assessed in a retrospective analysis based on 1751 HL cases: CD30 expression, CD15 positivity, CD20 staining, age, sex, histotype, stage, B symptoms, Hb level, and ESR.[159] CD15-negative cases were characterized by a higher incidence of relapse ($P = 0.0022$) and a shorter survival rate ($P = 0.0035$), independently of the remaining prognostic indicators.[159] Two recent studies, one of which was based on the tissue microarray technology, have further documented that CD20 expression is prognostically relevant in cases treated between 1974 and 1980 but not in patients who received current therapeutic approaches.[127,128] Chemoresistance and tendency to relapses seem to be also influenced by the expression of molecules that determine cell proliferation, such as Bcl-2, Bax, Bcl-X_L, p53, p21, MMP-2, PCNA, and MIB-1 (Fig. 76–19).[160–164] On the whole, tumors with H&RS cells showing expression or overexpression of one or more of these molecules tend to have a poor response to treatment and/or short survival. Very recently, gene expression profiling studies (see also the following genotypic findings section) have identified eight candidate molecules (ALDH1A1, STAT1, SH2D1A, TOP2A, RRM2, PCNA, MAD2L1, and CDC) as surrogates of therapeutically relevant abnormalities related to microenvironment, cell growth/apoptosis, and regulation of mitosis.[165] In line with this, low and high infiltration of $FOXP3^+$ and $TIA\text{-}1^+$ reactive T cells respectively have been found to correlate with an unfavorable clinical course.[166]

Genotypic Findings

The origin of RS cells of Hodgkin disease has long been a mystery.[167] As previously discussed in the LP-HL section, micromanipulation of single RS cells isolated from tissue sections and PCR analysis of the cells for rearranged Ig genes have shown that the vast majority of both LP-HL and classical HL cases are of B-cell origin.[1–7] Conversely to that seen in LP-HL, ongoing mutations are not detected in classical HL,[7] including the lymphocyte-rich type.[168] This suggests that classical HL originates from a late germinal-center or post–germinal-center B cell possibly corresponding to "asteroid" cells of thymic medulla or interfollicular dendritic B cells of the lymph node.[169]

To explain the lack of Ig synthesis, emphasis was initially given to the occurrence of mutations resulting in stop codons within originally functional rearrangements of the variable region of the immunoglobulin heavy chain (IgV_H) gene.[5] Such mutations are expected to occur in IgV_H genes of germinal-center B cells, but under physiologic conditions "crippled" germinal-center cells (incapable of functional antibody expression) rapidly undergo apoptosis. RS cells might carry additional crippling mutations contributing to Ig gene silencing, which are not easily detectable, such as replacement mutations interfering with antigen binding or heavy- and light-chain pairing.[5] Marafioti et al, however, showed that crippling mutations were absent from 75% of classical HL cases, thus indicating that they cannot be responsible for the general absence of the Ig transcripts.[7] The latter event was then related to the downregulation of the transcription factors BOB.1, Oct-2 and PU.1.[62–65] Nevertheless, this finding, although characteristic of HL, was not observed in normal B-cell subsets and B-cell non-Hodgkin lymphomas[170] and cannot per se be responsible for the abrogated Ig synthesis. In fact, not sustained by genomic imbalances or gene rearrangements,[171] it likely represents only an epiphenomenon within the context of a much more complex process that leads to silencing of the B-cell program.[172,173] As mentioned in the previous section, clonal TCR gene rearrangements have been documented in rare cases.[8,131,132]

The BCL-6 gene has been found to carry somatic mutations only in the classical HL cases of B-cell derivation: these are represented by irrelevant somatic base substitutions without consequences for Bcl-6 protein expression and classical HL pathogenesis.[174] In contrast to LP-HL, no BCL-6 gene rearrangements have so far been detected in classical HL, thus further supporting the concept that the neoplastic cells of classical HL and LP-HL correspond to different steps of B-cell maturation.[175] Recently, Liso et al have shown that the at least PIM1, PAX5, RhoH/TTF, or c-MYC genes might be involved by an aberrant somatic hypermutation process in 55% of classical HL cases, two or more being mutated in 30% of patients.[80] Such rates are indeed lower than those recorded in LPHL (80% and 50%, respectively).[80]

During the last few years, "gene expression profiling" studies have been carried out mostly using classical HL-derived cell lines.[165,176–182] These studies—whose results might be in the future modified by the analysis of micro-dissected primary H&RS cells—[183] have shown that HL cell lines carry the gene profile of a germinal-center B lymphocyte that resists apoptosis through CD40 signaling and NF-κB activation (see also the following Cell kinetics section).[176] In particular, 45 genes have been recognized whose expression seem to be regulated by NF-κB: seventeen of them are novel NF-κB target genes.[179] The NF-κB-dependent gene profile is composed of chemokines, cytokines,

receptors, apoptotic regulators, intracellular signaling molecules, and transcription factors, the majority of which maintain a marker-like expression in H&RS cells. For instance, the downregulation of the intracellular signaling genes Lyn, Syk, BLNK, and PLC-gamma2 has been validated by the lack of the corresponding products at the immunohistochemical level.[77] Using chromatin immunoprecipitation, it has been found that NF-κB is recruited directly to the promoters of several target genes, including the signal transducer and activator of transcription (STAT)5a, interleukin-13, and CC chemokine receptor 7. Intriguingly, NF-κB upregulates STAT5a expression and signaling pathways in H&RS cells, and promotes its persistent activation, as also supported by the detection of the corresponding product in most tumor cells of classical HL. The gene profile thus underscores a central role of NF-κB in the pathogenesis of HL and potentially of other tumors with constitutive NF-κB activation.[179] Other studies have suggested the possible (positive or negative) prognostic impact of the deregulation of genes related to the tumor microenvironment, cell growth/apoptosis, and regulation of mitosis.[165,177] Further studies have focused on the different patterns of gene dysregulation occurring in anaplastic large-cell lymphoma and classical HL.[178,181] A recently published report has provided evidence that the HL cell lines L428, HDLM2, KMH2, and L1236 cluster as a distinct entity, irrespective of their B- or T-cell derivation, and their gene expression resembles that of EBV-transformed B cells and cell lines derived from diffuse large B-cell lymphoma with features of in vitro-activated B cells.[182] Twenty-seven genes, most of which were previously unknown to be expressed in H&RS cells, were reported to be aberrantly expressed, including the transcription factors GATA-3, ABF1, EAR3, and Nrf3. In addition, the gene encoding for the nonreceptor tyrosine kinase FER has been found to be upregulated: this might contribute the constitutive activation of STAT-3.[182] The results of this study might shed new light on the pathogenesis of classical HL and allow the identification of new targets for both diagnostic and therapeutic purposes.[182] Finally, Schweing and coworkers have reported that H&RS cells of classical HL show loss of the B-cell lineage-specific gene expression program, a finding that might explain the lack of characteristic surface markers and Ig as well as of the transcription factors required for their expression, such as Oct-2, BOB.1, and PU.1.[182] Some explanations of this phenomenon have been provided, ranging from downregulation of a few master transcription factors due to hypermethylation[172] to overexpression of the helix-loop-helix proteins ABF-1 and Id2 that antagonize the function of the B cell determining transcription factor E2A.[173]

Several cytogenetic abnormalities have been detected in classical HL, although they may vary from case to case with frequent intraclonal variability, thus suggesting chromosomal instability.[184] Some tumors show 14q alterations, as seen in B-cell lymphomas, but without occurrence of t(14;18), others 2p, 4p, 9p, 8q, 12p, and 16q abnormalities.[184–187] In particular, aberrations of chromosomes 2p and 9p might involve the REL and JAK2 oncogene loci.[187] FISH studies have recently shown recurrent chromosomal breakpoints affecting Ig loci in H&RS cells,[188] whereas CESH has suggested that classical HL can be distinguished from all NHLs, including ALCL-like HL by unsupervised hierarchical cluster analysis.[189]

Cell Kinetics

It is well known that the antibodies raised against the nuclear associated antigens Ki-67 and PCNA (Fig. 76–20) react with the vast majority of H&RS cells, thus indicating that they have entered the cell cycle.[190,191] However, in spite of the Ki-67 and PCNA marking, tumoral cells do not rapidly overwhelm the reactive component.[190,191] A possible explanation for this phenomenon was provided by Leoncini and coworkers, who postulated that H&RS cells have a defective cytokinesis that prevents both their progression in the cell cycle and their entrance into an apoptotic pathway.[192,193] This assumption has recently found support in a series of studies, part of which was based on the application of tissue microarray technology.[164,194,195] They have shown that H&RS cells carry multiple alterations in different pathways and checkpoints, including G1/S and G2/M transition and apoptosis. Relevant findings are the overexpression of cyclins A, B1, D3 and E, CDK2, CDK6, STAT1, STAT3, Hdm2, p16, p23, Rb, Bcl-2, Bcl-X_L, surviving, and NF-κB proteins (Figs. 76–21 and 76–22).[164,194–196] Garcia et al have reported that the overexpression of some of these markers affects survival.[164] In the past, special emphasis was given to the frequent p53 positivity of H&RS cells,[160] which, however, does not correspond to mutations of exons 4 to 8 of the gene.[197] P53 accumulation in the nuclei of neoplastic elements might else be the result of elevated MDM2 protein levels and/or p14(ARF)/Hdm2 nucleolar complexes resulting in stabilization of p53 protein.[198,199] Additional mechanisms influencing proliferation and apoptosis in classical HL cells can be the expression of Notch1, Jagged1, c-FLIP, caspase 3, CCR7, and TRAF proteins.[200–204] The over-expression of CCR7 and TRAF proteins is related to constitutive NF-κB activity, which is characteristic of H&RS cells and causes protection from apoptosis.[205] Studies have recently suggested that the persistent activation of NF-κB in H&RS cells is probably due to defects of members of the I-κB family that are the natural inhibitors of NF-κB[206–208] or by the aberrant activation of I-κB kinase.[209] Additional factors contributing to this activation can be constitutive acti-

vated AP-1 and CD30 and LMP-1 overexpression.[210–212] As mentioned above, NF-κB activity maintains high expression of a gene network, which plays a basic role in H&RS cell survival.[179,213]

EPSTEIN–BARR VIRUS INFECTION

Epstein–Barr virus (EBV) studies reveal viral integration in the genome in classical HL cells in a variable percentage of patients (20%–80%). In particular, in Western countries 20% to 40% of cases of nodular sclerosis and lymphocyte-depleted cases and 50% to 75% of the mixed-cellularity cases are associated with expression of LMP-1 and/or EBER-1/2 (Fig. 76–23) but not EBNA2, thus showing a pattern characteristic of latency type II EBV infection.[214,215] Interestingly enough, these percentages can remarkably vary according to the geographic area examined, as shown by Leoncini and coworkers, who found significant differences in the EBV incidence between classical HL patients from Kenya and Italy (92% vs 48%).[216] In addition, Takeuchi et al have observed that the EBV-positivity rate has significantly decreased among Japanese patients with nodular sclerosis classical HL during the period 1955 to 1999.[217] The type of EBV strain also varies between different geographic areas: in developed countries strain 1 prevails, in developing countries strain 2.[218] HL

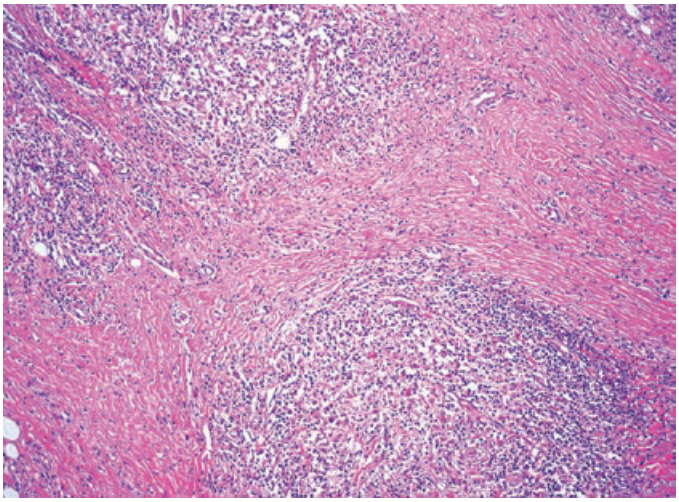

Figure 76–24 Nodular sclerosing classical Hodgkin lymphoma: the lymph node structure is largely effaced because of a nodular growth; the nodule is surrounded by thick collagen bands originating from the capsule (hematoxylin and eosin, ×40).

that is positive for EBV at diagnosis is usually also positive at relapse with persistence of the same EBV strain.[219] The exact role of EBV in the pathogenesis of HIV classical HL (transforming agent as suggested by LMP-1 expression or cofactor for the maintenance of malignant growth?) is still open to question.[84] Niedobitek and coworkers have recently shown that EBV-infected H&RS cells strongly express EBI3: this molecule, which corresponds to an EBV-induced cytokine homologous to the IL-12 p40 subunit, might heterodimerize with IL-12 p35, thus inhibiting the development of a Th1 immune response directed against both the tumor and virus.[220] No convincing data have so far been provided concerning the prognostic impact of EBV-infection in classical HL cases.[221,222] Finally, Huang et al have found amplifiable hCMV DNA in 11/33 EBV-negative classical HL cases recorded in a cohort of Chinese patients; based on this observation, these authors speculate that hCMV infection might play a role in the pathogenesis of HL, particularly in EBV-negative cases.[223]

NODULAR SCLEROSIS

Morphologic Findings

Nodular sclerosis represents the most frequent subtype of classical HL in Italy and the United States, where it corresponds to 75% to 80% of all HL cases; the incidence of the process, however, significantly varies among different geographic areas.[224,225] As stated by Lukes et al in 1966, the tumor is characterized by sclerosis, lacunar cells, and a nodular pattern.[37]

Sclerosis

Fibrotic phenomena do always occur in nodular sclerosis classical HL: they more often correspond to the formation of broad collagen bands, which originate from a regularly thickened lymph node capsule (Fig. 76–24) and subdivide the lymphoid parenchyma into large nodules, at times visible at gross examination. Fibrotic tissue displays a typical birefractive green color with the use of polarized light microscopy, a finding not observed in lymphocyte-depleted classical HL.

Lacunar Cells

Lacunar cells represent the cell variant characteristic of nodular sclerosis classical HL. Lukes et al originally described lacunar cells as large elements with polylobated nuclei, small- to medium-sized

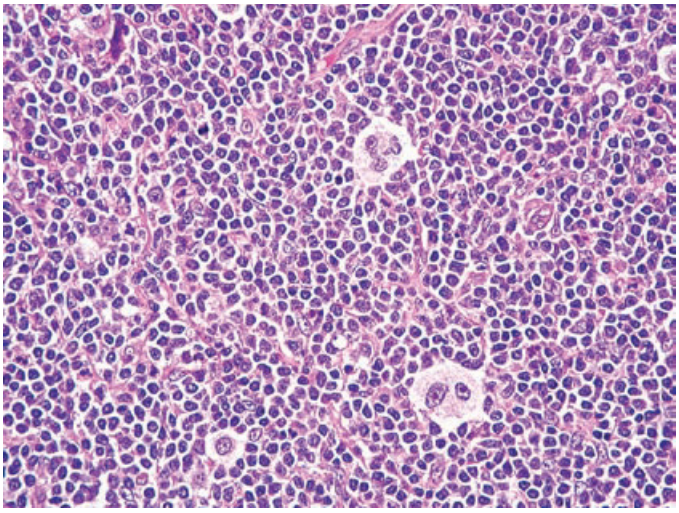

Figure 76–25 Nodular sclerosing classical Hodgkin lymphoma: scattered lacunar cells are detected within a nodule (hematoxylin and eosin, ×300).

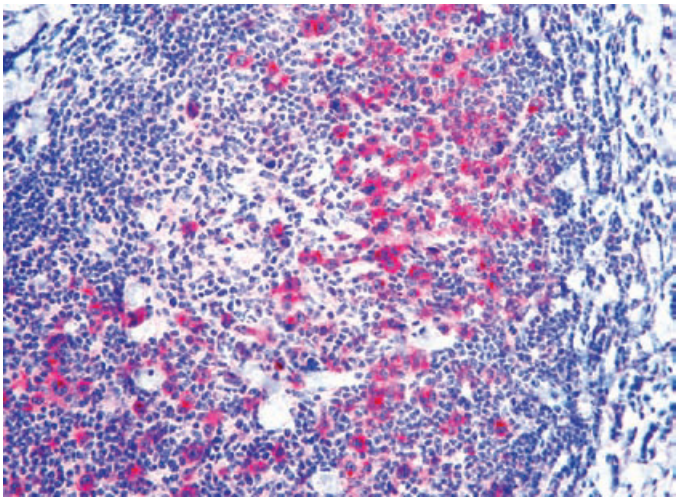

Figure 76–26 Nodular sclerosing classical Hodgkin lymphoma, cellular phase: $CD30^+$ lymphomatous elements display a nodular aggregation without the overt deposition of collagen bands (APAAP technique, Gill hematoxylin counterstain, ×200).

nucleoli and a wide rim of clear or slightly acidophilic cytoplasm, very sensitive to formalin fixation (Fig. 76–25).[37] The latter in fact causes perinuclear condensation of the cytoplasm, which remains connected to the cell membrane via some narrow filaments, limiting empty "lacunar" cytoplasmic spaces. Lacunar cells display a much higher degree of pleomorphism than originally thought. They may be uninucleated, multinucleated, and/or show huge nucleoli, which traits are indeed similar to those of typical RS cells. This morphologic variability seems to depend on the characteristics of the inflammatory component present.[226] Although lacunar cells are easily found, H&RS cells are rare; it should be emphasized that some neoplastic elements appear "mummified" because of apoptotic changes.

Nodular Pattern

The nodules—which should be detected in at least part of the lymph node involved—can contain foci of necrosis and actually show a great variability in terms of inflammatory cell component (from lymphocyte predominance to lymphocyte depletion).

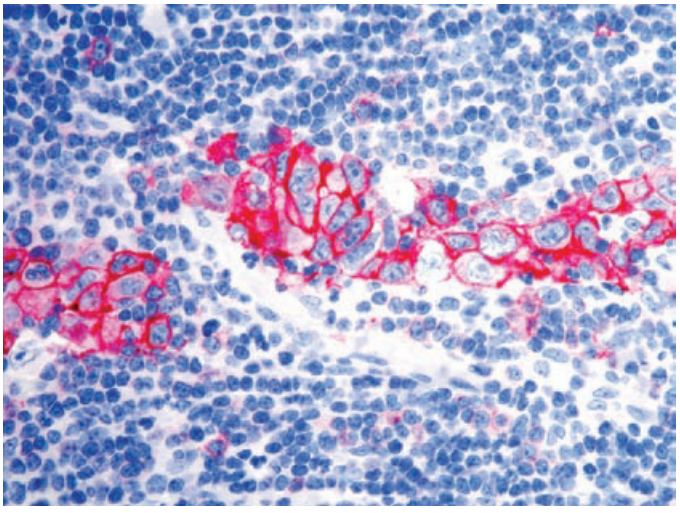

Figure 76–27 Nodular sclerosing classical Hodgkin lymphoma, syncytial variant: $CD30^+$ neoplastic cells show a cohesive growth (APAAP technique, Gill hematoxylin counterstain, ×400).

Nodular Sclerosis Classical Hodgkin Lymphoma: Cellular Phase

In nodular sclerosis classical HL, the amount of collagen fibres varies remarkably. In the so-called cellular phase, there is a clear-cut tendency to nodule formation without overt collagen band deposition (Fig. 76–26). However, there are typical lacunar cells, often located at the periphery of the nodules or around residual follicles. The latter situation has been termed "follicular Hodgkin lymphoma" by Kansal and coworkers, who underlined that the antigenic profile of the neoplastic cells ($CD30^+$, $CD15^+$, $CD20^{-/+}$, $CD79a^{rare}$) allows its easy distinction from nodular LP-HL.[227] The reactive component mainly consists of small lymphocytes with the phenotype of mantle B cells ($CD20^+$, $CD79a^+$, $CD5^+$, IgM^+, IgD^+, $CD3^-$).[228] The secretion of cytokines by neoplastic cells is currently thought to be the cause of progressive attraction of T lymphocytes, histiocytes, plasma cells, and eosinophils, which give rise to nodules replacing the preexisting follicles and producing the typical pattern of nodular sclerosis classical HL. Within the nodules, there are numerous follicular dendritic cells that seem to represent a favorable prognostic indicator.[229]

Nodular Sclerosis Classical Hodgkin Lymphoma: Syncytial

The term *syncytial* nodular sclerosis Hodgkin disease was coined by Butler in 1983 and then reproposed by Strickler in 1986.[230] This variant is thought to represent 16% of all the nodular sclerosis classical HL cases[231] and to be associated with a more aggressive clinical course,[230] because of the occurrence of mediastinal bulky disease and stage III/IV in 88% of the patients. This variant is characterized by large sheets of neoplastic cells (partly with a lacunar appearance), which may undergo central necrosis (Fig. 76–27).[230] In the past, similar cases have been diagnosed as non-Hodgkin lymphoma, metastatic melanoma, carcinoma or sarcoma, thymic carcinoma, or germ cell tumor. The differential diagnosis requires the application of an adequate panel of antibodies, which allow the identification of the characteristic phenotype: $CD3^-$, $CD15^+$,

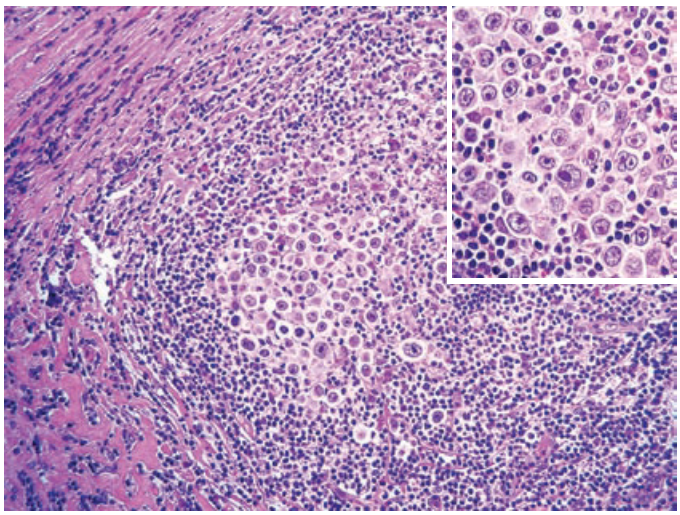

Figure 76–28 Nodular sclerosing classical Hodgkin lymphoma, grade II: mostly mononuclear neoplastic cells cover more than 25% of the examined area (hematoxylin and eosin, ×200); inset: cytologic details at higher magnification (hematoxylin and eosin, ×300).

$CD20^{-/+}$, $CD30^{+}$, $CD45^{-}$, $CD79a^{-}$, cytokeratins^{-}, PLAP^{-}, protein S-100^{-}, HMB.45 melanoma-associated antigen^{-}, EMA^{-}, and ALK protein^{-}.

Histologic Grading of Nodular Sclerosis Classical Hodgkin Lymphoma

The British National Lymphoma Investigation (BNLI) Group has repeatedly proposed to subclassify nodular sclerosis classical HL into two grades: grade II tumors seem to represent 15% to 25% of all nodular sclerosis cases and which have a more aggressive clinical course,[232,233] a finding not confirmed by all studies.[234,235] In the recently developed WHO scheme, the BNLI grading system has been maintained in order to test its real prognostic value in a larger series.[40] It is based on the degree of cellularity of the nodules, the amount of sclerosis and the number and atypia of neoplastic cells. The term *grade II* is applied to cases showing one of the three following patterns:

1. more than 25% of the nodules have a cellular composition consistent with the pleomorphic or reticular subtype of lymphocyte-depleted HL (Fig. 76–28);
2. more than 80% of the nodules display a fibrotic or fibrohistiocytic composition; and
3. more than 25% of the nodules contain numerous large bizarre or anaplastic cells, in the absence of any depletion of the reactive small lymphoid component.

Very recently, the German Hodgkin Lymphoma Study Group has proposed a new grading system based on three criteria: eosinophilia, lymphocyte depletion, and atypia of H&RS cells.[236] In particular, these findings seem to represent useful prognostic indicators in intermediate and advanced stages.[236]

Differential Diagnosis

Anaplastic Large-Cell Lymphoma

The boundaries between classical HL and anaplastic large-cell lymphoma are not always easily defined: in the past this had led to the creation of the category of anaplastic large-cell lymphoma–Hodgkin like, which in approximately 85% of cases presents with a mediastinal mass and stage II disease.[237,238] On practical grounds, this distinction is relevant, because anaplastic large-cell lymphoma can be cured in 80% of cases by the administration of third-generation chemotherapy regimens, whereas HL usually requires different therapeutical approaches.[237] The problems in differential diagnosis are essentially due to the fact that anaplastic large-cell lymphoma–Hodgkin like shares with nodular sclerosis classical HL architectural and cytologic features, including fibrotic reaction and nodule formation. In the authors' experience, the diagnosis of anaplastic large-cell lymphoma–Hodgkin like should be considered only in those cases that display nodules almost exclusively consisting of basophilic blasts with a minimal reactive cell component and phenomena of intrasinusoidal spread.[238] When these morphologic criteria are applied, most of the cases in the past diagnosed as anaplastic large-cell lymphoma–Hodgkin like would be now reclassified as nodular sclerosis classical HL (grade II or syncytial) and might tentatively be termed "anaplastic large cell lymphoma–like Hodgkin disease."[142] By applying more restrictive diagnostic criteria, rare examples of anaplastic large-cell lymphoma–Hodgkin like do still exist.[239] Immunohistochemical and molecular biological analyses are helpful in distinguishing between HL and anaplastic large-cell lymphoma, as shown in Table 76–3. In problematic cases the expression of CD15, possibly in conjunction with positivity for B-cell markers (with special reference to BSAP),[239] and the lack of TCR gene rearrangements and ALK protein favor HL, whereas negativity for CD15, the expression of T-cell markers and/or ALK protein, and the presence of clonal TCR gene rearrangements or an NPM/ALK hybrid gene support the diagnosis of anaplastic large-cell lymphoma; cases that cannot be resolved by the use of the combination of morphology, phenotype, and molecular data should be regarded as "unclassifiable" and submitted to a second biopsy or a treatment equally effective for anaplastic large-cell lymphoma and classical HL.[6]

Primary Mediastinal (Thymic) Large B-Cell Lymphoma

Primary mediastinal large B-cell lymphoma (PMBL) is a distinct clinicopathologic entity, which represents approximately 2.4% of all malignant lymphomas[240] and more often affects young females.[6,39,241,242] The presence of a certain amount of T lymphocytes, eosinophils, and RS-like elements, along with sclerosis, possible nodularity, and frequent CD30 expression by neoplastic cells[243] may suggest classical HL. In most instances, the two processes can be distinguished by the fact that PMBL expresses B-cell markers (CD19; CD20; CD22; CD79a), Bcl-6, Oct-2, BOB.1, PU.1, and the MAL protein (in 70%–75% of cases) and is CD15 negative.[243,244] Nonetheless, similarities between PMBL and classical HL have been observed. For instance, PMBL lacks both Ig mRNA and protein expression, in spite of functional Ig gene rearrangements and intact transcriptional machinery.[243] This concept has been further strengthened by two independent gene expression profiling studies that have shown that the molecular signature of PMBL differs from that of other diffuse large B-cell lymphomas and shares several features of classical HL,[245,246] including the constitutive NF-κB activity that promotes cell survival and favor antiapoptotic TNF-α signaling.[247] Thus, a grey zone between PMBL and classical HL has been proposed that can explain transitional features between NSHL and PMBL.[248,249] Whether the two tumors represent the extremes of the same disease or the ends of a spectrum of biologically related diseases remains uncertain. A recent study has, for instance, shown that the signaling molecules Syk, BLNK, and PCL-gamma2 characteristically silenced in classical HL are regularly expressed in PMBL: a finding that is characteristic to diffuse large B-cell lymphoma rather than to HL.[250]

Undifferentiated Nasopharyngeal Carcinoma

Undifferentiated nasopharyngeal carcinoma occurs in young patients and is associated with involvement of laterocervical nodes, which is

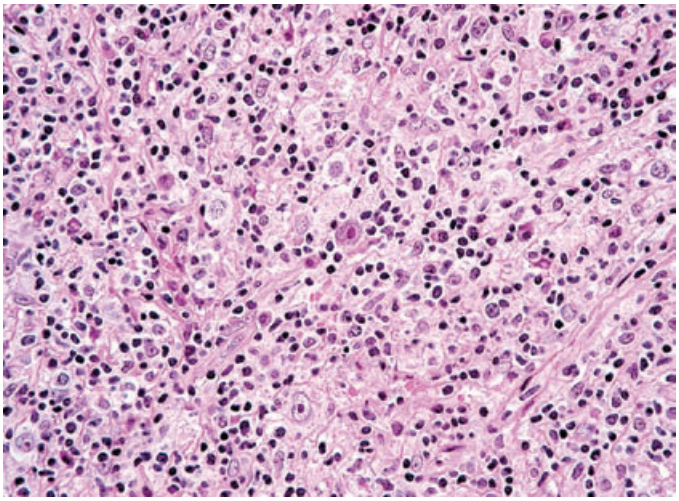

Figure 76–29 Mixed-cellularity classical Hodgkin lymphoma: Hodgkin and Reed–Sternberg cells are seen within a cellular milieu consisting of small lymphocytes, some plasma cells, histiocytes, and granulocytes (hematoxylin and eosin, ×250).

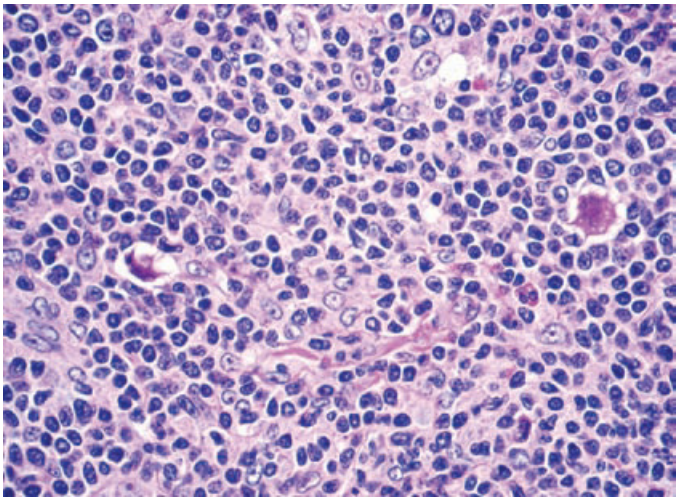

Figure 76–30 Mixed-cellularity classical Hodgkin lymphoma: two mummified (apoptotic) neoplastic cells (hematoxylin and eosin, ×350).

the usual site of diagnostic biopsy. On morphologic grounds, neoplastic cells can resemble H&RS cells and produce a nodular growth with sclerosis, plasmacytosis, and eosinophilia. Because the primary tumor may remain occult, morphologic features can contribute to a misdiagnosis of nodular sclerosis classical HL.[251,253] Immunohistochemistry, however, allows the easy distinction between undifferentiated nasopharyngeal carcinoma and classical HL by showing positivity of the neoplastic cells for cytokeratins, EMA, and LMP-1. The latter is due to regular EBV integration, as shown by in situ hybridization with EBER1/2 probes and PCR techniques.

MIXED-CELLULARITY HODGKIN LYMPHOMA

Mixed-cellularity HL was originally described by Lukes et al as intermediate between LP and lymphocyte-depleted Hodgkin disease.[37] Later on, Lukes included in this category all the cases that according to his criteria remained unclassified, transforming it into a "basket."[253]

Approximately 15% to 25% of HL cases belong to the mixed-cellularity classical HL group.[39,40] The histological picture is characterized by a diffuse growth with frequent paracortical location.[39,40] Involvement of the capsule and necrosis are rare. The term *mixed-cellularity classical HL* reflects the cellular composition of the reactive milieu that consists of plasma cells, epithelioid histiocytes, eosinophils, and T lymphocytes ($CD3^+$, $CD57^-$) forming rosettes around neoplastic elements.[39,40] The latter correspond to H&RS cells that are rather numerous and easy to find, without lacunar or popcorn variants (Fig. 76–29).[39,40] Some neoplastic elements, as in the nodular sclerosis subtype, appear "mummified" because of apoptotic changes (Fig. 76–30).

Morphologic Variants of Mixed Cellularity

Interfollicular Variant

The interfollicular variant is rarely observed and likely represents partial lymph node involvement by classical HL. It is characterized by the occurrence of rather numerous H&RS cells around reactive follicles, which display germinal centers either in the second phase of development[254] or in regressive transformation. The latter usually resemble the germinal centers seen in hyaline-vascular Castleman disease and are probably related to the release of cytokines, such as IL-6, by H&RS cells.[255] This unusual variant of mixed-cellularity classical HL should be taken into consideration to avoid possible confusion with follicular hyperplasia or Castleman disease.

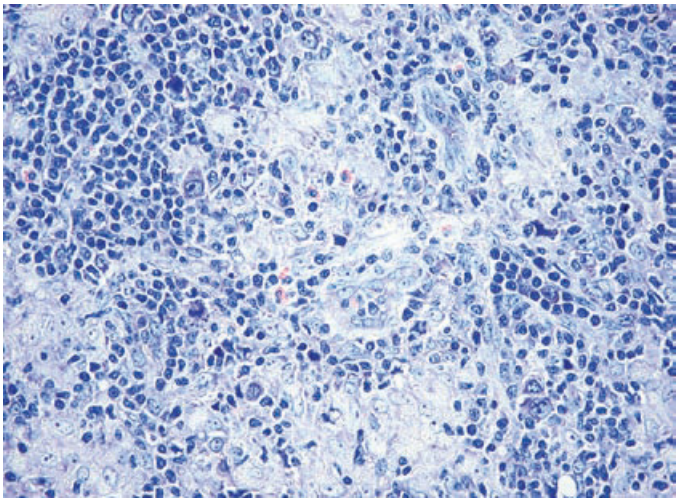

Figure 76–31 Mixed-cellularity classical Hodgkin lymphoma with a high content of reactive epithelioid cells (Giemsa, ×250).

Epithelioid Cell-Rich Variant

It is relatively frequent and shows prominent epithelioid cell reaction with granulomata formation and occasional Langerhans cells (Fig. 76–31). Within this context, typical H&RS cells are always detected, at times following a laborious search. The epithelioid cell-rich variant of mixed-cellularity classical HL should be differentiated from the so-called Lennert lymphoma because of the different therapeutic approaches applied to the two tumors.

Differential Diagnosis

Lennert Lymphoma

Lennert lymphoma is a peripheral T-cell lymphoma characterized by a high content of epithelioid elements and some blasts resembling RS cells.[39] By no means, part of the cases in the past diagnosed as atypical Hodgkin disease do actually correspond to peripheral T-cell

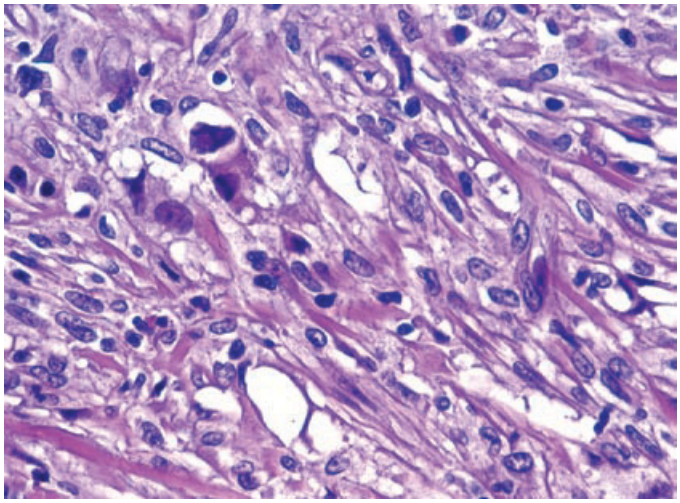

Figure 76–32 Lymphocyte-depleted classical Hodgkin lymphoma, fibrotic variant: rare neoplastic cells are present within a fibrotic matrix; some histiocytes and scanty lymphocytes are seen (hematoxylin and eosin, ×450).

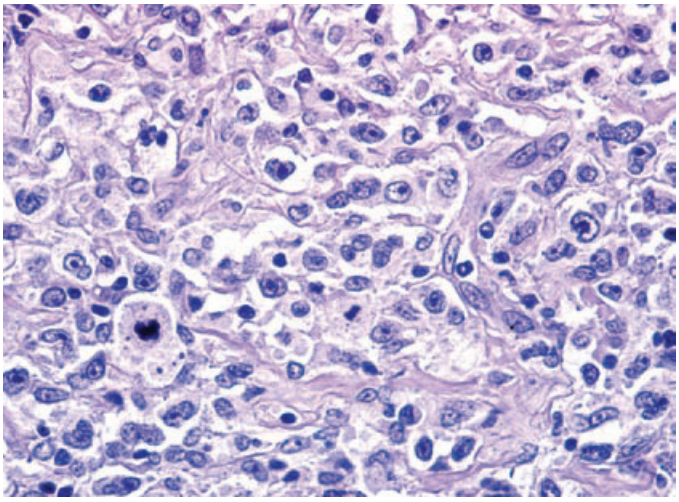

Figure 76–33 Lymphocyte-depleted classical Hodgkin lymphoma, sarcomatous variant: Hodgkin and Reed–Sternberg cells predominate; small lymphocytes are indeed rare (hematoxylin and eosin, ×400).

lymphomas with a high content of epithelioid elements.[226] The following features are of paramount importance for the recognition of Lennert lymphoma: (a) the marked irregularity of the nuclear profiles of the lymphoid component, as opposed to the regular nuclear outline of reactive lymphocytes in HL[256]; (b) the phenotypic profile of the atypical population, which in turn is $CD3^+$, $CD45^+$, $CD30^{occasionally+}$, and $CD15^-$, although some cases can partially lack T-cell markers[117,257]; and (c) higher mitotic index.[258]

T Cell/Histiocyte-Rich Large B-Cell Lymphoma

T cell-rich large B-cell lymphoma, first described in 1984,[259] is an aggressive tumor, usually presenting as stage III–IV disease with splenomegaly, bone-marrow involvement, and mesenteric lymphadenopathy, that is, findings that are rarely observed at the onset of HL.[260–263] The main differences between classical HL and T cell/histiocyte-rich large B-cell lymphoma are summarized in Table 76–2.[52,76,85–87,89,91,92,261–263].

LYMPHOCYTE-DEPLETED HODGKIN LYMPHOMA

Lymphocyte-depleted HL is indeed rare, accounting for approximately 1% of HL cases, and is associated with the worst clinical behavior and prognosis. In most instances, patients present with III–IV disease and display B symptoms and bone marrow involvement.[264] Histopathologically, it is characterized by the paucity of the lymphoid component, absolute or relative abundance of RS cells, and variable fibrotic reaction. According to Lukes et al, two subtypes of lymphocyte-depleted classical HL can be distinguished: fibrotic and reticular/sarcomatous.[37]

Fibrotic Variant

The fibrotic variant is characterized by complete effacement of the nodal structure with possible capsule preservation and has (Fig. 76–32) the following distinctive features:

a) low cellular density with fairly small, although variable amounts of lymphocytes;
b) prominent diffuse reticulin fibre formation, which is not organized in birefringent collagen bands,[253] but includes single neoplastic elements and is associated with deposition of amorphous material (procollagen) around sinusoids;
c) the high variability in the number of H&RS cells, whose detection requires at times a long and laborious search.

At low power, the histopathological picture can resemble the depletion phase of HIV-lymphadenopathy: therefore, careful node examination is required to make a firm diagnosis.[265]

Reticular or Sarcomatous Variant

The reticular or sarcomatous variant is characterized by the huge amount of H&RS cells, some of which appear "mummified" (Fig. 76–33). There is diffuse effacement of the normal lymph node structure; small lymphocytes, plasma cells, histiocytes, and granulocytes are scanty; foci of necrosis are usually found, their extent varying from case to case.

Differential Diagnosis

Thanks to the extensive application of immunohistochemistry and molecular biology techniques, it is now evident that most of the cases diagnosed in the seventies and early eighties as sarcomatous lymphocyte-depleted classical HL are in fact examples of anaplastic large-cell lymphoma,[266] peripheral T-cell lymphoma,[267] primary mediastinal large B-cell lymphoma,[268] or syncytial variant of nodular sclerosis classical HL. In the authors' experience, the differential diagnosis should also include some nonlymphoid tumors, such as inflammatory fibrosarcoma,[269] Langerhans cell sarcoma, inflammatory and giant cell malignant fibrous histiocytoma,[270] lymphocyte-rich well-differentiated liposarcoma,[271] and undifferentiated nasopharyngeal carcinoma. Under these circumstances, immunophenotyping is essential for a correct diagnosis.

LYMPHOCYTE-RICH CLASSICAL HODGKIN LYMPHOMA

Several reports suggest the existence of HL cases with a lymphocyte-predominant background, but differing from the prototypic description of LP-HL due to the presence of some eosinophils, sclerosis, typical H&RS cells, or aberrant phenotypic features (eg, the expression of CD30 and CD15).[43,74,224,272,273] In 1994, the REAL Classifica-

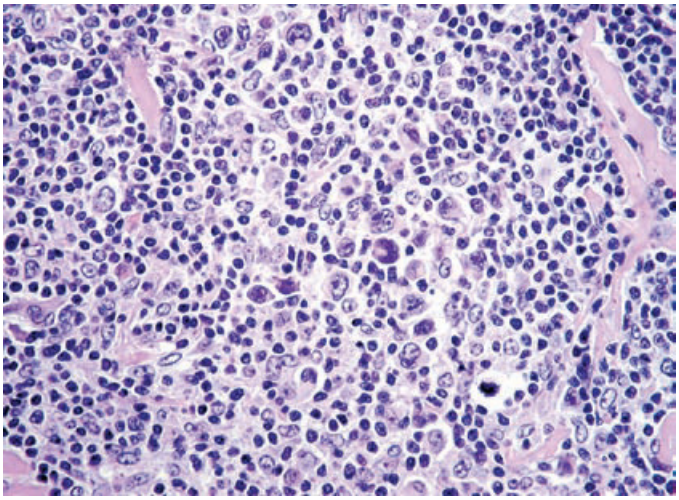

Figure 76–34 Lymphocyte-rich classical Hodgkin lymphoma: mononuclear and diagnostic neoplastic elements are situated within a cellular milieu mostly consisting of small lymphocytes (hematoxylin and eosin, ×300).

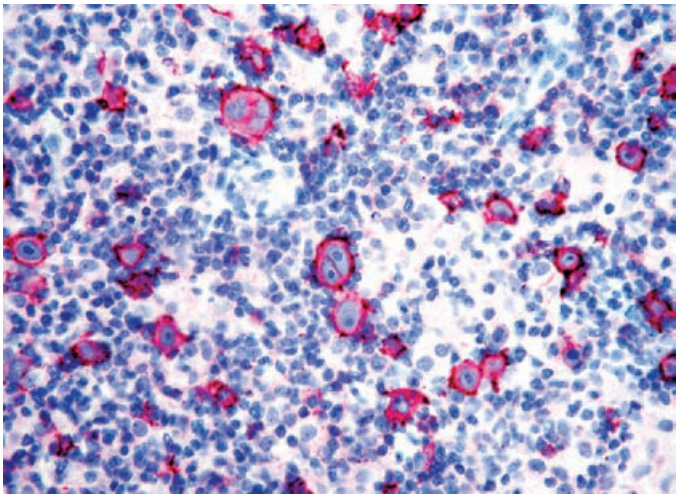

Figure 76–35 Lymphocyte-rich classical Hodgkin lymphoma: neoplastic cells express CD30 (APAAP technique; Gill hematoxylin counterstain; ×350).

tion included a provisional entity called "lymphocyte-rich classical Hodgkin disease," which was thought to have a diffuse growth pattern in most instances.[39] Following two workshops held by the European Association for Hematopathology in 1994 and the European Lymphoma Task Force in 1995, the concept of lymphocyte-rich classical HL was definitely accepted and further expanded by the recognition of two subtypes of the tumor, nodular and diffuse, which should be differentiated from LP-HL and T cell-rich B-cell lymphoma (Table 76–2).[41,88,260,274]

Morphologically,[40] most lymphocyte-rich classical HL cases have a vague nodularity, admixed histiocytes and absent neutrophils and eosinophils, thus closely resembling nodular LP-HL, particularly at low power. Furthermore, a proportion of the neoplastic cells can exhibit features of L&H/popcorn elements. In contrast to LP-HL, however, many lymphomatous cells have the cytomorphologic features of classical H&RS cells, and the nodular structures frequently contain small germinal centers (Fig. 76–34). Focal sclerosis can sometimes be seen.

On phenotypic grounds,[40] the neoplastic cells usually express CD30 and CD15 (Fig. 76–35). Expression of CD20 and CD79a are found in 32.5% and 8.7% of cases, respectively, figures that are much lower than those observed in LP-HL. Approximately 50% of the examples of lymphocyte-rich classical HL harbor EBV-positive H&RS cells. The reactive component consists of abundant mantle B cells with surface IgD and IgM expression and variable amounts of $CD3^+$ T lymphocytes, which produce rosettes around neoplastic elements but seldom express CD57. CD21 immunostaining reveals a loose, ill-defined meshwork of follicular dendritic cells, which becomes much denser and sharper as compared to the small residual germinal centers, when present.

The clinical characteristics of this variant of classical HL, which accounts for approximately 6% of all HL cases,[50,159] has been the object of several studies, including those promoted by the International Project on LP-Hodgkin Disease and the German Hodgkin Lymphoma Study Group.[50,159] These studies have shown that the patients with lymphocyte-rich classical HL differ from those with nodular sclerosis or mixed-cellularity classical HL, because they are usually older than 50 and have a higher incidence of stages I–II and subdiaphragmatic location. On the other hand, they rarely have bulky disease, B symptoms, and mediastinal or extranodal involvement. The clinical profile of lymphocyte-rich classical HL is thus closer to that of LP-HL, although it is associated with a lower frequency of stage II and more common splenic infiltration. By comparison with other types of classical HL, lymphocyte-rich classical HL is associated with more frequent late relapses, which have a low aggressive behavior pattern.

Owing to its peculiar clinicopathologic features, lymphocyte-rich classical HL has been accepted as a distinct entity in the WHO Classification.[40]

UNCLASSIFIABLE HODGKIN LYMPHOMA

In cases with partial lymph node involvement, with small amounts of tissue available for examination or with extranodal location, the classification of HL can be difficult or even impossible. In the past, these problem cases were usually included in the MC subtype. Because it is important to follow the criteria for distinguishing the subtypes of HL as fashion for the purposes of prospective clinicopathologic studies, both the REAL Classification and WHO schema list cases with ambiguous features or insufficient biopsy material as HL unclassified.

EXTRANODAL INVOLVEMENT BY HODGKIN LYMPHOMA

Although the onset is typically nodal, HL can secondarily affect extranodal organs. The criteria for the diagnosis of HL at extranodal sites vary significantly depending on the clinical history and kind of tissue involved. In fact, in needle biopsies taken from the bone marrow (Fig. 76–36) and liver during staging procedures, the diagnosis of HL can confidently be made according to "minimal criteria," that is, by the detection of HC in the appropriate cellular milieu.[256] By contrast, the diagnosis of HL at other extranodal sites requires the recognition of typical "diagnostic" cells and appropriate phenotypic markers, especially in patients without a previous history of HL.

THERAPY-RELATED HISTOLOGIC CHANGES

Relapses of HL at previously treated sites may have morphologic features that completely differ from those recorded at the time of presentation. Under these circumstances, the histologic picture is characterized by numerous atypical H cells, rare RS cells, and severe lymphocyte depletion, which can make the distinction from diffuse large B-cell lymphoma difficult.[226,275]

In patients with bulky disease, a residual mass is often detected following chemo- and radiotherapy, placing into question the efficacy of the administered therapy. In the authors' experience, histological examination of the residual mass frequently shows a fibrotic reaction with sclero-jaline changes and epithelioid cell palisades around necrotic foci, but no active tumor.

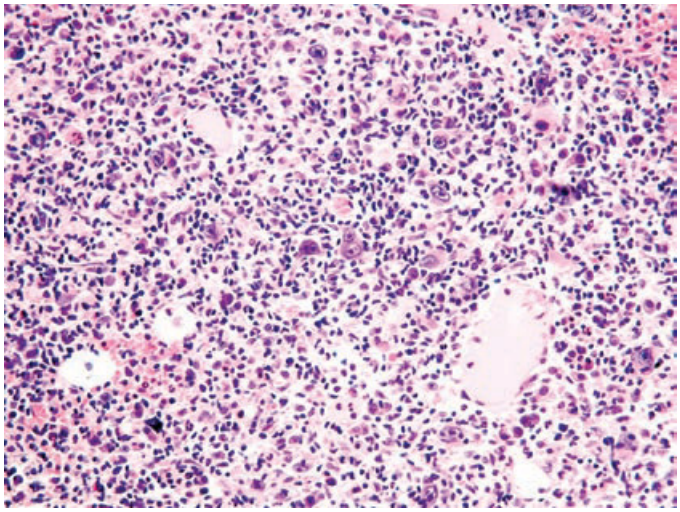

Figure 76–36 Bone-marrow involvement in classical Hodgkin lymphoma: Hodgkin and Reed–Sternberg cells are seen in an inflammatory cellular background that produces a certain fibrotic reaction (hematoxylin and eosin, ×250).

Chemo- and radiotherapy can produce toxic damages in organs not primarily involved by the process, such as postradiation interstitial pneumonitis, thyroid fibrosis, cardiomyopathies, or bone-marrow aplasia. In addition, patients treated for HL have an increased risk of developing acute leukemias, malignant lymphomas, and more rarely nonlymphoid tumors. This concept especially applies to individuals who have received MOPP chemotherapy.[226] On the whole, autopsies performed in subjects with a previous history of HL often show that the cause of death was a therapy-related complication without detectable residual disease.[226]

RELATIONSHIPS BETWEEN HODGKIN LYMPHOMA AND IMMUNODEFICIENCY DISORDERS

Patients with HIV are more at risk than the normal population to develop HL, especially the lymphocyte-depleted or mixed-cellularity types.[276] The tumor frequently presents with extensive subdiaphragmatic and extranodal involvement, a mediastinal mass rarely being detected.[277] Involvement of the liver, bone marrow, skin, or lung may occur in the absence of splenic and regional or mediastinal node involvement. On the whole, HL in HIV patients behaves differently than individuals without HIV, having more extensive dissemination,[226] a more aggressive clinical course and a worse prognosis.[278] On molecular grounds, neoplastic elements in HIV^+ HL are more often $CD20^+$ and $Bcl\text{-}6^-/CD138^+$. The latter finding differs from that usually observed in HIV^- LP-HL (regularly $Bcl\text{-}6^+/CD138^-$) and classical HL (which displays a mixture of $Bcl\text{-}6^-/CD138^+$ and $Bcl\text{-}6^+/CD138^-$ RSC).[279] In addition, most if not all HIV^+ HL cases are positive for EBV, as shown by LMP-1 expression and in situ hybridization studies. This observation suggests an active role for EBV in the process of lymphomagenesis in HIV^+ HL[267] also in the light of the well-known LMP-1-transforming ability.[280] In particular, in 89% of HIV^+ cases (vs 32% of the seronegative ones) the LMP-1 gene has a 30-bp deletion, which allows LMP-1 prolonged half-life and accumulation in the infected cells.[280,281]

Classical HL can occur also in immunosuppressed patients following bone-marrow or solid organ transplantation. In this setting, a HL-like posttransplant lymphoproliferative disorder (PTLD) had also been reported. It remains controversial whether it is truly a form of HL or should be more appropriately classified as a form of B-cell PTLD.[282]

ASSOCIATION OF HODGKIN LYMPHOMA WITH NON-HODGKIN LYMPHOMA

The occurrence of HL and a synchronous or metachronous form of non-Hodgkin lymphoma (NHL) in the same patient is rare. The most frequent combination of the two is a diffuse large B-cell lymphoma that develops following LP-HL.[4,44,48,53–56] However, also classical HL has been reported in conjunction with different types of NHL, including follicular lymphoma, marginal zone lymphoma, diffuse large B-cell lymphoma, B-cell chronic lymphocytic leukemia, anaplastic large-cell lymphoma, Burkitt lymphoma, MALT lymphoma, and peripheral T-cell lymphoma.[283–296]

There are three possible explanations for the occurrence of this association: (a) both neoplasms arise coincidentally from two unrelated lymphoid elements; (b) the HL progresses from a previous NHL lymphoma; and (c) both lymphomas are derived from a common precursor cell. In the past, no reliable answer could be given to these challenging questions. In the last few years, the introduction of single-cell PCR has allowed the molecular analysis of some cases showing simultaneous or subsequent occurrence of HL and NHL. Past reports suggested a direct progression from NHL to HL (either classical or lymphocyte predominant).[53–56,290] Recent studies, however, have revealed that in most instances NHL cells and H&RS cells display the same monoclonal Ig gene rearrangements, as well as the presence of somatic mutations, thus supporting the concept that the two tumors stem from a common precursor cell (ie, a mature germinal-center B cell).[4,292–295]

CHAPTER 77

HODGKIN LYMPHOMA: CLINICAL MANIFESTATIONS, STAGING, AND THERAPY

Volker Diehl, Beate Klimm, and Daniel Re

BACKGROUND

In his historic paper entitled "On Some Morbid Appearances of the Exorbant Glands and Spleen," Thomas Hodgkin,[1] in 1832, presented the clinical history and postmortem findings of the massive enlargement of lymph nodes and spleens of seven patients.[2] Hodgkin assumed that these pathologic findings more resembled an autonomous lymphatic process that started in the lymph nodes located along the major vessels in the neck, chest, or abdomen than an inflammatory condition or an infectious disease such as syphilis or tuberculosis.

As late as 1865, Sir Samuel Wilks for the first time linked Thomas Hodgkin's name to the disease that he described as "Cases of the Enlargement of the Lymphatic Glands and Spleen (or Hodgkin's Disease)."[3] He was also the first to describe Hodgkin Lymphoma (HL)-associated B symptoms such as anemia, weight loss, and fever. In 1878, Greenfield was the first to publish drawings of the pathognomonic giant cells, which later were named after Carl Sternberg (1898) and Dorothy Reed (1902), who contributed the first definitive microscopic descriptions of HL.[4,5]

Because HL was frequently clinically associated with tuberculosis, for a long time it was considered to be a peculiar form of a granulomatous disease such as tuberculosis. Despite the very strong evidence for the malignant nature of HL over the past century, it has been only recently shown that Hodgkin and Reed-Sternberg (HRS) cells are definitely clonally expanding, preapoptotic, germinal center-derived B lymphocytes that resemble true malignant cells.[6]

The management of HL has undergone a paradigm shift as a result of the availability of effective drug regimens capable of inducing high remission rates, the use of combined chemoradiotherapy with involved field irradiation in patients with early-stage disease, the introduction of effective salvage chemotherapy for relapsed HL with peripheral blood stem cell transplantation (PBSCT), and a more sensitive realization of the magnitude of late-treatment mortality. Future developments will be based on a better understanding of biological prognostic factors and the implementation of PET imaging to allow a more individualized treatment approach.

ETIOLOGY, EPIDEMIOLOGY, AND GENETICS

Incidence and Age of Onset

HL is an uncommon disorder with an annual incidence of 2 or 3 cases per 100,000 persons in Europe and the United States.[7] In industrialized countries, the onset of HL has a bimodal distribution, with a first peak occurring in the third decade and a second peak occurring after the age of 50 years. Because of more refined molecular, cytologic, and immunohistologic techniques offering sensitive discrimination between HL subtypes and non-Hodgkin lymphomas (NHLs), the second peak seems to have disappeared, mainly because the lymphocyte-depleted subtype of HL was recognized more frequently as large B-cell lymphomas.[8] Slightly more men than women (1.4 : 1) develop this malignancy. Among the group of young adults, the most common subtype is nodular sclerosing HL (NSHL), which occurs at a higher frequency (2 : 1) than the mixed-cellularity subtype of HL (MCHL). The frequency of MCHL increases with age, whereas incidence of the NSHL subtypes reaches a plateau in the group of young adults older than 30 years. According to the World Health Organization (WHO) classification, the subtypes of lymphocyte rich-classic HL (LRCHL), nodular lymphocyte-predominant HL (LPHL), and lymphocyte-depleted HL (LDHL) are less commonly diagnosed, with a frequency of 3% to 5% (LPHL and LRCHL) and less than 1% (LDHL) in Western countries.[9,10] There is a great difference in incidence of this disease between developing and industrialized countries. In developing countries, the disorder occurs predominantly during childhood, and its incidence decreases with age, whereas in industrialized countries, young children are much less commonly diagnosed with HL compared with adolescents or young adults. In industrialized countries, there are associations for early birth order, low number of siblings and playmates, high level of maternal education, single-family dwellings during childhood, and occurrence of HL in younger patients.[11,12]

Similar characteristics had also been observed in the epidemiology of poliovirus infection. These similarities suggested that HL might represent the rare consequence of an infection with a common agent that led to HL after a prolonged delay.[13] Several factors point in the direction of an infectious or at least inflammatory pathogenesis of HL: clinical symptoms of fever, night sweats, and weight loss, and the laboratory findings of elevated erythrocyte sedimentation rate (ESR) or increased serum concentrations of inflammatory cytokines such as interleukin-1 (IL-1), IL-2, IL-5, IL-6, IL-10, tumor necrosis factor (TNF), and growth factors such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF).[14]

Role of Epstein-Barr Virus in the Pathogenesis of Hodgkin Lymphoma

Several studies have suggested that the Epstein-Barr virus (EBV) might be a transforming agent in HL. Mueller and colleagues[15] analyzed EBV titers in predisease sera and found enhanced EBV activation before the onset of HL. Patients with a history of EBV-related infectious mononucleosis have a twofold to threefold increased risk for development of HL. Another study confirmed that patients with a serologically diagnosed infectious mononucleosis had a fourfold increased relative risk of EBV-positive but not EBV-negative Hodgkin lymphoma.[16] The estimated median incubation time from mononucleosis to EBV-positive Hodgkin lymphoma was 4.1 years making a causal association between infectious mononucleosis-related EBV infection and the EBV-positive subgroup of Hodgkin lymphomas likely in young adults.

To substantiate the role of EBV in HL, a number of researchers investigated EBV in HRS cells using novel molecular techniques and found that EBV DNA is present in the tumor cells of HL patients more frequently in developing than in industrialized countries. In Western countries, about 50% of all cases of classic HL are EBV positive (ie, carry the virus within the tumor cells), with 15% to 30% of NSHL cases being positive and up to 70% of mixed-cellularity subtypes (MCHL) harboring EBV DNA.[17] For comparison, 90% or more of HRS cells are positive for EBV in developing countries.[18] EBV positivity in underprivileged patients and children from indus-

trialized countries shares the frequency of that observed in developing countries.[19] It was also shown that impaired immune status may contribute to the development of EBV-positive cHL in older patients.[20]

HRS cells in EBV-positive patients show an expression pattern of EBV-encoded genes resembling that found in endemic nasopharyngeal carcinoma or in a subset of T-cell lymphomas, called *type 2 latency*. This pattern includes expression of the EBV latent genes *LMP1, LMP2A*, and *EBNA1*. Recently it was shown by three independent studies that EBV can rescue BCR deficient germinal center B-cells from apoptosis adding evidence that EBV plays a role in malignant transformation in HL.[21–23]

Because EBV is present in only half the tumor cells of patients with HL in the Western world, investigators were prompted to search for other viruses involved in the pathogenesis of HL. Although measles virus has been discussed to be associated with HL,[24] the role of other viruses than EBV for the pathogenesis of HL remains uncertain. More specifically, despite initial reports that SV40 virus is present in a variety of lymphomas including HL,[25] polyomaviruses were not detected in HL samples in follow-up studies.[26]

Taken together, these data suggest that EBV is involved in the transformation process in EBV-positive HL cases. In EBV-negative cases, a "hit and run" mechanism was hypothesized, but evidence of EBV as a transforming agent in negative cases is scant.[27]

Inheritance Pattern

In general, a family history of hematopoietic malignancy is associated with an approximately twofold increased risk of HL.[28] More specifically, the risks of family members of patients affected by HL for developing the same disease are three to nine times those of the expected values. These observations led to the hypothesis that at least a portion of cases occurs as an inherited disorder.[29] Mack and colleagues found that of 179 monozygotic twin pairs with HL; both twins in 10 pairs developed HL, strongly supporting the idea of a genetic component in a subset of HL.[30] Recent linkage studies associated family or personal history of autoimmune or chronic inflammatory disease to the development of HL suggesting that characteristics of the immune system might be important for the development of HL.[31,32] Another analysis of the Swedish Cancer Registry found HL fourth in a list of cancers with high familial clustering (52 first-degree relatives, 8766 HL cases), just behind cancers affecting the eye or testis.[33] However, familial HL is estimated to constitute only a minority of cases. No consistent mechanism of inheritance has been identified, and evidence for a genetic translocation unique to all cases of familial HL is lacking.

Hodgkin and Reed-Sternberg Cells and Their Origins

The affected tissue in HL is characterized by a heterogeneous infiltrate with typical mononucleated and multinucleated giant cells in an inflammatory background composed of stroma, lymphocytes, histiocytes, eosinophils, and monocytes (see Chapter 76). In classic HL, the giant cells are called *Hodgkin* and *Reed-Sternberg* (HRS) cells, and in LPHL, they are called *lymphocytic* and *histiocytic* (L&H) cells. Typically, HRS cells represent only 0.1% to 1% of the affected tissue.

Because immunophenotyping did not lead to the identification of the origin of the HRS cells, molecular approaches were used to resolve this issue. Küppers[34] was the first to show that HRS cells harbor somatically mutated clonal rearranged immunoglobulin (Ig) heavy chain genes by using single-cell polymerase chain reaction (PCR) methods on primary HRS cells.

From these results, it was concluded that HRS cells were derived from germinal center B cells. Amplification of identically rearranged and mutated Ig genes from different HRS cells showed they were clonal in origin—a key criterion of malignancy. HRS cells expand clonally within one affected lymph node, clonally disseminate in advanced-stage disease, and recur even after clinical complete remission. Some studies indicate that in a small subset of HL, the HRS cells are probably of T-cell origin.[35,36] HRS cells are derived from germinal center or post-germinal center B cells in most cases. In contrast, lymphocytic and histiocytic cells in LPHL harbor ongoing mutations in their rearranged Ig genes and therefore seem to be malignant B cells at a different stage of maturation.[37]

Malignant Transformation of Hodgkin and Reed-Sternberg Cells

Despite significant progress in understanding the cellular origin of HRS cells, little is known about the mechanisms responsible for the initial transformation event. EBV has been identified as a virus with potential involvement in the transformation of a subpopulation of HL cases. Constitutive activation of nuclear factor-kappa B (NF-κB) seems to be a central mechanism that results in the exit of cells from the hostile environment of the germinal center and contributes to their proliferation and resistance to apoptosis.

Infected HRS cells express the EBV-encoded latent genes *LMP1, LMP2*, and *EBNA1*. Products of the latent genes have transforming capacity. *LMP1*, for instance, can transform primary B cells by mimicking the function of constitutively active CD40, a transmembrane receptor molecule of the TNF receptor family. Physiologically, CD40 ligation results in activation of a signaling cascade terminating in activation of the transcription factor NF-kB. NF-kB itself initiates transcription of proinflammatory and antiapoptotic genes. Constitutively, activation of NF-kB has been demonstrated to be a characteristic feature of HRS cells.[38] Abrogation of constitutive NF-kB activation results in massive, spontaneous apoptosis of HRS cells by downregulation of an antiapoptotic signaling network, thereby providing evidence for its central role in the transformation and acquisition of the apoptosis-resistant phenotype.[39]

SUMMARY OF MECHANISMS UNDERLYING MALIGNANT TRANSFORMATION

Although much has been learned about the derivation of the HRS cells, little is known about the basic mechanisms underlying malignant transformation of HL. The HRS cells in HL are derived from preapoptotic germinal center B cells in most cases, but in some cases, they are of T-cell origin. The expression of EBV latent genes in EBV-positive cases (50%) may play a role in cellular transformation by upregulating the transcription factor NF-kB. The events underlying the transformation process in the EBV-negative cases, however, are still not understood. Several studies have focused on the apoptosis-resistant phenotype of HRS cells, and some data suggest that constitutively expressed Flice-inhibitory protein (FLIP), a protein that inhibits FAS-mediated apoptosis, contributes to apoptosis resistance in HL.[40] Genetic instability is a typical feature of HRS cells, and studies point to distinct genetic imbalances rather than subtle genetic alterations such as point mutations or microsatellite instability.[41] Besides NF-kB, other transcription factors are deregulated in HRS cells contributing to the lost B cell identity of malignant cells in HL.[42,43] The discovery that the HRS cells themselves contribute to the ineffective immune response by expressing immunosuppressive cytokines or by expressing chemokines that predominantly attract Th2 lymphocytes that are incapable of cell killing has widened our understanding of the environmental crosstalk of these peculiar cells.[44]

DIAGNOSIS AND STAGING

From the beginning, it was postulated that HL spread from one lymph node area by contiguity to adjacent lymph node chains. Only

in the middle of the 20th century was this knowledge used by investigators such as Peters, Kaplan, Tubiana, and Musshoff for the development of strategies for the treatment of this disorder.[45–47]

The applicability of new radiologic techniques and the information derived from routine exploratory staging laparotomies have provided important insights into the presentation and evolution of HL.[47,48] Although there is strong evidence that HL starts in a single group of lymph nodes and then spreads by the lymphatic route, there is mounting evidence that the gradually more aggressive tumor cells tend to disseminate through the bloodstream rather early and disseminate to organs such as bone marrow, liver, and lung. For the initial diagnosis of HL, an excisional biopsy of a suspicious lymph node should be performed. Assessment of the bone marrow is important for staging and for an evaluation of the normal bone marrow cells before therapy. Bone marrow involvement occurs rarely both in early stage disease (<1%) and in advanced stage disease (<5%).

The extent of HL can be classified using the four-stage Ann Arbor classification. The absence (A) or presence (B) of systemic symptoms (eg, fever, night sweats, and weight loss) further characterizes the severity of disease. The Cotswolds classification is a modification of the Ann Arbor classification using information from staging and treatment gathered over the past 20 years. This classification was proposed in 1989 during a meeting held in the Cotswolds, England.[49] Information about prognostic factors such as size of the mediastinal mass, presence of bulky nodal disease, and the extent of subdiaphragmatic disease is included in this classification (Table 77–1).

The staging procedures recommended for determining the extent of disease have become less invasive in recent years. Staging laparotomy and splenectomy are used only in patients with limited, often infradiaphragmatic or occult disease, for which ultrasound- or computed tomography (CT)-guided fine-needle biopsy is impossible or not informative. CT of the neck, chest, abdomen, and pelvis is routinely performed in the diagnostic evaluation of a patient with HL.

Table 77–1. Cotswolds Staging Classification

Classification	Description
Stage I	Involvement of a single lymph node region or lymphoid structure (eg, spleen, thymus, Waldeyer ring) or involvement of a single extralymphatic site (IE)
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (hilar nodes, when involved on both sides, constitute stage II disease); localized contiguous involvement of only one extranodal organ or site and lymph node regions on the same side of the diaphragm (IIE). The number of anatomic regions involved should be indicated by a subscript (eg, II3)
III1	With or without involvement of splenic, hilar, celiac, or portal nodes
III2	With involvement of paraaortic, iliac, and mesenteric nodes
Stage IV	Diffuse or disseminated involvement of one or more extranodal organs or tissues, with or without associated lymph node involvement
	Designations applicable to any disease stage
A	No symptoms
B	Fever (temperature, >38°C [100.4°F]), drenching night sweats, unexplained loss of >10% of body weight within the preceding 6 months
X	Bulky disease (a widening of the mediastinum by more than one-third of the presence of a nodal mass with a maximal dimension greater than 10 cm)
E	Involvement of a single extranodal site that is contiguous or proximal to the known nodal site

Two-thirds of patients with newly diagnosed HL have radiographic evidence of intrathoracic involvement. A *large mediastinal mass* has been arbitrarily defined as a mass in which the ratio is greater than one third for the largest transverse diameter of the mediastinal mass over the transverse diameter of the thorax at the diaphragm on a standing posteroanterior chest radiograph.[49] Alternatively, others have defined extensive mediastinal disease as greater than 35% of the thoracic diameter at T5–6, or wider than 5 to 10 cm. Patients with large mediastinal masses are at increased risk for relapsing in nodal and extranodal sites above the diaphragm after radiation therapy alone.[50,51]

Gallium 67 scintigraphy was used in evaluating the mediastinum or in the evaluation of residual masses in HL patients after treatment but has been replaced by ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET). According to the international harmonization project,[51a] FDG-PET can be used to improve staging techniques at initial diagnosis by detecting lesions not detected by CT; to assess tumor response while on treatment; and to evaluate residual tumor masses at the end of treatment, allowing discrimination between active lymphoma and fibronecrotic tissue.

When using PET in addition to conventional imaging techniques for the initial workup of patients, approximately 10% of HL patients are up-staged and another 10% down-staged[52] but it remains unclear, whether patients would benefit from a subsequent change of the treatment plan. Therefore the value of PET for initial staging of HL patients is limited. When assessing early tumor response rates in HL patients already after one to three cycles of chemotherapy. Hutching and Gallamini[52,53] found a significant correlation between the PET results and the clinical outcome of the patient in terms of progression free survival (PFS) and overall survival (OS).[52] Results are comparable with other published data[54] but patient numbers are small. Whether such an early PET response will be useful to tailor therapies more individually in the future needs to be clarified by prospective trials such as the HD18 trial of the GHSG and future trials of the EORTC.

If PET is used at the end of treatment, it shows an excellent negative predictive value between 91% and 95% in several monocentric studies.[55,56] In contrast, the positive predictive value of PET is around 50%. Based on this data the ongoing HD15 trial evaluates the prognostic value of PET in patients with residual lesions ≥ 2.5 cm at the end of chemotherapy. Only patients with a positive PET scan receive additional radiotherapy in this ongoing trial. Appropriate staging procedures for the initial workup of HL are summarized in the box on Recommended Staging Procedures for HL.

CLINICAL FEATURES

History

Patients with NSHL or MCHL have a central pattern of lymph node involvement (eg, cervical, mediastinal, paraaortic). In 70% to 80% of patients with the subtypes of classic HL, primary lymphadenopathy occurs in the left cervical or supraclavicular region or in the mediastinum. NSHL patients more often have a supradiaphragmatic onset of disease. MCHL patients present with smaller disseminated nodes and predominantly subdiaphragmatic nodes or organ involvement. In contrast, certain nodal chains (eg, mesenteric, hypogastric, presacral, popliteal) are seldom involved. Patients with LPHL always present initially with involved peripheral nodes in the cervical, submandibular, axillary, or inguinal region (in approximately 75% of cases of stage IA disease). B symptoms and involvement of the spleen or other organs rarely occur. The incidence of subclinical node involvement in patients with negative radiographic staging ranges from 6% to 35%. The spleen is involved more frequently in patients with adenopathy below the diaphragm, systemic symptoms, and MCHL histology. Involvement of the liver in untreated patients is rare and almost always occurs with concomitant splenic involvement. Infiltration of the bone marrow at diagnosis is rare, usually focal, and

Recommended Staging Procedures for Hodgkin Lymphoma

The following staging procedures are recommended for the initial workup of Hodgkin lymphoma:

1. Adequate surgical biopsy reviewed by an experienced hematopathologist
2. Core-needle biopsy of bone marrow from the posterior iliac crest; needle or surgical biopsy of any suspicious extranodal (eg, hepatic, osseous, pulmonary, cutaneous) lesions; and cytologic examination of any effusion
3. Detailed history, with attention to the presence or absence of systemic symptoms, and a careful physical examination, emphasizing node chains, size of the liver and spleen, and inspection of Waldeyer ring
4. Routine laboratory tests: complete blood cell count, erythrocyte sedimentation rate, and liver function tests
5. Chest radiographs (posteroanterior and lateral) with measurement of the mass-to-thoracic ratio
6. Neck, chest and abdominal CT
7. 18-FDG PET scan

almost always associated with extensive disease, systemic symptoms, and unfavorable histology.

Bulky lymph node involvement or a contiguous collection of smaller lymph nodes (>10 cm in diameter) may result in regional complications such as vascular, tracheal, bronchial, or gastrointestinal compression or obstruction. Invasion of adjacent anatomic regions such as the lung, pericardium, pleura, chest wall, or bone can occur in patients with HL histology, more with the NSHL subtype. Effusions of the pericardium, pleural cavity, or peritoneal cavity often are associated with extranodal involvement and invasive growth into neighboring structures. Despite a large mediastinal mass, superior vena cava syndrome is seldom observed; if it occurs, it is often associated with venous thrombosis.

The recommended staging procedures have become less invasive in recent years. Staging laparotomy (with splenectomy, needle and wedge biopsy of the liver, and biopsies of para-aortic, mesenteric, portal, and splenic hilar lymph nodes) is necessary only rarely in cases of early-stage HL for which use of limited radiation therapy alone depends on pathologic staging.

Compared with the NHLs, bulky infradiaphragmatic lesions with obstructive symptoms are rare in HL. The spleen is involved in about 30% to 35% of patients at diagnosis, less frequently with NSHL histology, and only rarely in patients with LPHL. Spleen involvement is often subclinical and hard to diagnose with modern imaging techniques. Tumor involvement is not necessarily associated with splenic enlargement; a small spleen can have diffuse HL involvement. Details of organ extranodal involvement (so called E-lesions) are given in Table 77–2.

Hematopoietic spread to organs is mainly seen in the lung, liver, bone marrow, and bone, and it must be distinguished from disease invasion into adjacent organs by extranodal tumor that penetrates the capsule of a lymph node. Skin involvement is seen very rarely and can appear as small, opaque, or red papules or as ulcerating lesions. Involvement of the central nervous system can occur by extension from nodes within the paraaortic region through the intervertebral foramina, manifesting as neurologic symptoms and pain.[57] Similarly, primary involvement of the intestinal wall never occurs, but secondary invasion of the gut from adjacent mesenteric lymph nodes can be seen. Bone marrow infiltration is usually focal and, in most cases, is associated with extensive disease, including systemic symptoms and hematopoietic insufficiency.

A considerable number of undiagnosed patients with HL present with systemic symptoms before the discovery of enlarged lymph nodes. Typical symptoms include fever, drenching night sweats, and weight loss (ie, B symptoms). The characteristic HL-associated fever (ie, Pel-Ebstein type) occurs intermittently and recurs at variable intervals over several days or weeks. Fever and drenching night sweats are identified in 25% of all patients at the time of initial presentation, increasing to 50% of patients with more advanced disease. Other nonspecific symptoms include pruritus, fatigue, and the development of pain shortly after drinking alcohol. This pain is usually transient at the site of nodal involvement and may be severe. Pruritus, although not a defined B symptom, may be an important systemic symptom of disease, although it affects less than 20% of patients. It often occurs months or even a year before the diagnosis of HL.[58] The underlying pathophysiologic mechanisms leading to pruritus are unknown, but possible causes include an intrinsic production of cytokines such as growth factors by the HRS cells and an autoimmune reaction in which a number of cytokines are activated by tumor lysis.

Table 77–2. Sites of Disease Involvement in Untreated Patients with Hodgkin Lymphoma

Anatomic Site	Involvement (%)
Waldeyer ring	1–2
Cervical nodes	60–70
Axillary nodes	30–35
Mediastinum	50–60
Hilar nodes	15–35
Paraaortic nodes	30–40
Iliac nodes	15–20
Mesenteric nodes	1–4
Inguinal nodes	8–15
Spleen	30–35
Liver	2–6
Bone marrow	1–4
Total extranodal	10–15

Adapted from Gupta RK, Gospodarowicz MK, Lister TA: Clinical evaluation and staging of Hodgkin's disease. In Mauch PM, Armitage JO, Diehl V, et al (eds): Hodgkin's Disease. Philadelphia, Lippincott Williams & Wilkins, 1999.

Is Laparotomy Necessary for Staging?

Staging laparotomy is rarely used in patients with limited, infradiaphragmatic or occult disease when ultrasound- or CT-guided fine-needle biopsy is not feasible or the results would not be representative. With the greater use of reproducible and clinically relevant prognostic factors and imaging techniques to stage patients, most centers and treatment groups determine treatment strategy based on the risk of primary progressive or relapsing disease, applying reduced doses of radiotherapy or chemotherapy in a combined-therapeutic approach.

CHOICE OF TREATMENT

Prognostic Factors and Treatment Groups

Prognostic factors define the likely outcome of the disease of an individual patient at diagnosis allowing selection of appropriate treatment strategies. Despite an enormous effort to define clinically relevant and generally acceptable prognostic factors, there are still two major methods for dividing HL patients according to a risk- or prognosis-adapted therapeutic approach: stage and systemic symptoms. A third factor meets general trans-Atlantic acceptance: massive local tumor burden (ie, bulky disease >10 cm in diameter). Prognostic factors are rarely the subject of specific clinical studies but are recognized and evaluated using data from large cohorts of uniformly

Table 77–3 Definition of Treatment Groups According to the EORTC/GELA and GHSG

Treatment Group	EORTC/GELA	GHSG	NCIC/ECOG
Early-stage favorable	CS I-II without risk factors (supradiaphragmatic)	CS I-II without risk factors	Standard risk group: favorable CS I-II (without risk factors)
Early-stage unfavorable (intermediate)	CS I-II with ≥1 risk factors (supradiaphragmatic)	CS I, CSIIA ≥ 1 risk factors; CS IIB with C/D but without A/B	Standard risk group: unfavorable CS I-II (at least one risk factor)
Advanced stage	CS III-IV	CS IIB with A/B; CS III-IV	High risk group: CS I or II with bulky disease; intraabdominal disease; CS III,IV
Risk factors (RF)	A large mediastinal mass B age ≥50 years C elevated ESR* D ≥4 involved regions	A large mediastinal mass B extranodal disease C elevated ESR* D ≥3 involved areas	A ≥ 40 years B not NLPHL or NS histology C ESR ≥ 50 mm/h D ≥ 4 involved nodal regions

*erythrocyte sedimentation rate (≥50 mm/h without or ≥30 mm/h with B-symptoms).
ECOG, Eastern Cooperative Oncology Group; EORTC, European Organization for Research and treatment of Cancer; GELA, Groupe d'Etude des Lymphomes de l'Adulte; GHSG, German Hodgkin Study Group; NCIC, National Cancer Institute of Canada.

treated, well-documented, and reliably followed patients, usually from large clinical trials.[59,60]

In the United States, most centers still treat HL patients according to the traditional separation of *early stages* (I-II, A and B), representing about 45% of newly diagnosed patients, and *advanced stages* (III-IV, A and B or any stage with bulky disease >10 cm in diameter), representing about 55% of newly diagnosed patients. Patients with early-stage disease are treated with radiotherapy alone or, in most centers or trials, with combined-modality strategies. Patients with advanced-stage disease (IIIB or IV) are assigned to intensive chemotherapy protocols, sometimes followed by adjuvant radiotherapy.

The European Organization for Research and Treatment of Cancer (EORTC) identified in the H1 and H2 trials additional prognostic factors that are now used to assign clinical stage I or II patients to a more unfavorable-prognosis group. The EORTC has, since 1982, defined clinical stage I or II (supradiaphragmatic only) patients as having an *early unfavorable prognosis* HL if any of the following factors is present: age older than 50 years, asymptomatic with an ESR higher than 50, B symptoms with an ESR higher than 30, and a large mediastinal mass. In previous trials, stage II disease with MCHL or LDHL histology and number of involved regions had also been counted as adverse factors.[61]

The German Hodgkin Study Group (GHSG) has, since 1988, assigned clinical stage I or II patients to an *intermediate group* (Table 77–3) if they had any of the following adverse factors: large mediastinal mass (>1/3 of maximum thoracic diameter), three or more involved lymphatic regions (which is not equivalent to lymphatic areas), elevated ESR, and localized extranodal infiltration.[62] Because of the rarity of splenectomy, massive splenic involvement was seldom reported and was abandoned for the current generation of trials. It can be difficult to distinguish consistently between E-lesions and stage IV disease, and various assessments of the prognostic value of this feature have been obtained by different investigators. In 1980, Stanford University began to provide combined-modality treatment for clinical stage I or II patients with large mediastinal masses or multiple E-lesions.

Until recently, the following general treatment strategies have been employed in the United States and in Europe:

1. Early stages, favorable: irradiation alone (extended field)
2. Early stages, unfavorable (intermediate): moderate amount of chemotherapy (typically four cycles) plus irradiation
3. Advanced stages: extensive chemotherapy (typically eight cycles) with or without consolidation (usually local) irradiation

Most centers and groups both in the United States and in Europe tended to favor combined-modality treatment, even for early stage favorable-prognosis patients. Such treatment includes chemotherapy and reduced irradiation therapy. More recently, chemotherapy alone is tested in early stage disease while chemotherapy alone can already be considered standard treatment for patients with advanced stage HL and a complete response after chemotherapy. These typical strategies and the investigation of alternatives are reported in the following sections.

An attempt has also been made to identify very good risk and very poor risk subgroups. The EORTC has investigated the use of localized radiotherapy in a "very favorable subgroup" of early-stage patients. Inclusion criteria were stage IA disease for female patients younger than 40 years and NSHL or LPHL histology without an elevated ESR or large mediastinal mass. However, the failure rate was 29% at six-year follow-up,[63] and this policy was abandoned. Similarly, advanced-stage patients at particularly high risk for failure for intensified therapy were treated with early high-dose chemotherapy (HDCT) with autologous stem cell transplantation (ASCT).[64] As neither the definition of the prognostic groups nor the choice of treatment is uniform, no conclusive data about this early intensification is available.

Despite the different mode of action of chemotherapy compared with radiotherapy, similar prognostic factors have emerged from analyses of cohorts treated with irradiation and with combined-modality therapy. The usefulness of the factors previously listed for radiation-treated patients has been reliably confirmed in cohorts who also received chemotherapy[65,66] in early or in advanced stages of disease. This similarity of prognostic effects is supported by the observation from a meta-analysis of irradiation versus combined-modality treatment in patients with early-stage disease that the difference in failure-free survival between these two treatment strategies was essentially constant across different prognostic groups.[67]

The EORTC includes in its advanced-stage cohorts stage III and IV patients only, without regard to other factors, as did the US National Cancer Institute and several US cooperative groups. Certain other trial groups also include stage I-II patients in the advanced-stage group, if they have B symptoms or bulky disease.[68] The GHSG includes both stage III-IV patients and patients with stage IIB disease and a large mediastinal mass or E-lesions in the advanced-stage cohort. The gradual shift towards more intensive therapy is thus based on the incorporation of prognostic factors into treatment algorithms.

Prognostic Factors for Advanced-Stage Hodgkin Lymphoma

International consensus about uniform treatment strategies and longer and better controlled follow-up periods with a greater fre-

Table 77–4. Final Cox Regression Model of the International Prognostic Score

Prognostic Factor	Log Hazard Ratio	Relative Risk	*P* Value
Serum albumin <4 g/dL	0.40 + 0.10	1.49	<0.001
Hemoglobin <10.5 g/dL	0.30 + 0.11	1.35	0.006
Male gender	0.30 + 0.09	1.35	0.001
Stage IV disease	0.23 + 0.09	1.26	0.011
Age ≥45 years	0.33 + 0.10	1.39	0.001
White blood cell (WBC) count ≥15,000/mm^3	0.34 + 0.11	1.41	0.001
Lymphocyte count <600/mm^3 or <8% of WBC count	0.31 + 0.10	1.38	0.002

quency of treatment failure events have permitted more conclusive and generally applicable prognostic factor analyses for the advanced-stage disease compared with early-stage disease. The International Prognostic Factor Project produced an International Prognostic Score (IPS),[66] which is not necessarily completely comprehensive, but is widely accepted (Table 77–4).

All of the factors in Table 77–4 were shown to be highly significant in a multivariate analysis of data from 5141 patients treated in 25 centers, and their prognostic power was confirmed in an independent sample. Serum albumin and hemoglobin levels, male gender, and age of 45 years or older are also prognostic factors for early-stage patients. All seven factors were associated with similar relative risks of between 1.26 and 1.49. It was recommended that these factors be combined into a single score by counting the number of adverse factors and giving an integer prognostic score between 0 and 7. However, even patients with five or more factors (7% of cases) had a 5-year failure-free rate of more than 40%. The best failure-free rate was close to 80% for patients with at most one adverse factor (29% of cases), suggesting that a group of advanced-stage patients with a relatively favorable prognosis could be recognized (1618 patients included in the final analysis for freedom from treatment failure according to whether the prognostic score was 0 to 2 or 3 or higher).

A number of other factors have been shown to correlate with prognosis in advanced stages, but their independent importance has not been proved because of conflicting results or lack of validation in a large independent data set. These include pathologic grade in nodular sclerosis HL, the amount of tissue eosinophilia, inguinal involvement, serum lactic dehydrogenase concentration, and β 2-microglobulin level.

Prognostic factors may subsequently be used to for treatment intensification or for treatment reduction. Concerning intensification, various investigators have treated a poor-prognosis subset of advanced-stage patients who had attained a remission by conventional chemotherapy, with HDCT accompanied by hematologic stem cell support.[64] Proctor and coworkers[69] constructed a continuous numeric index for this purpose as a weighted sum of the variables, including age, stage, lymphocyte count, hemoglobin level, and the presence of bulky disease, and included patients with an index greater than 0.5 in the poor-prognosis subset. Federico and colleagues[70] included patients with two or more factors (high lactate dehydrogenase levels, very large mediastinal mass, two or more extranodal sites, inguinal involvement, low hematocrit, and bone marrow involvement) in a high-dose chemotherapy/autologous stem cell transplantation arm after four cycles of ABVD and compared it to eight cycles of ABVD. At 5 years, FFTF rates were in favor of conventional therapy (82% vs. 88%), and OS was 88% in both arms. Relapse rates were slightly higher in the transplantation arm although this was not statistically significant. This observation indicates that the early high-dose intensification is unlikely to result in clinically relevant long-term survival benefit compared with conventional treatment.

In conclusion, the three-level scheme of division into early favorable, early unfavorable (intermediate), and advanced-stage cases remains a suitable instrument to tailor risk-adapted therapy according to our current knowledge. Because clinical and biologic factors do not discriminate the 10% to 15% of advanced-stage patients who will progress or experience an early relapse (<12 months), biologic molecular parameters are urgently needed to save most patients from overtreatment or allow even more intensive treatment for the 10% to 15% of patients resistant to the best modern treatment modalities. There is hope that current approaches using on-treatment imaging techniques such as PET, gene expression profiles of primary tumor material,[71] individual drug metabolism[72] or cytokine profiles of serum samples will detect patterns that can identify poor prognosis patients.

EARLY-STAGE HODGKIN LYMPHOMA

Early-Stage Favorable Disease

The treatment of early-stage HL is changing. In the 1990s, extended field irradiation was considered standard treatment. However, because of recognition of the high relapse rate and the fatal long-term effects, the use of extended field radiotherapy is being abandoned by most study groups. Instead, for favorable-prognosis early-stage disease, limited amounts of chemotherapy for the control of occult lesions is routinely combined with involved field irradiation and there is even evidence, that chemotherapy alone might be sufficient to control disease.

Extended field radiotherapy alone produces complete remissions in 90% to 98% of patients with early-stage favorable HL.[73,74] Unfortunately, 30% to 40% of those patients will relapse, but salvage chemotherapy or combined-modality treatment yields remissions in most of these cases. Taken together, approximately 75% to 85% of patients with early-stage, favorable-prognosis disease who receive extended field radiotherapy as first-line treatment are alive after 10 years.[75,76]

Increasing concern about the long-term consequences of treatment prompted many investigators to reexamine the aggressive approaches developed for early-stage favorable disease in the 1970s and 1980s. Several follow-up studies reported an increased risk of secondary cancer for long-surviving patients. Cumulative risks varied between 17.6% at 15 years,[77] and 26.3% at 30 years for children treated under the age of 16 years.[78] Follow-up evaluation of more than 12,000 patients by the International Database on HL similarly revealed a cumulative incidence rate of 11.2% at 15 years.[79] In the latter study, less than 10% of patients with secondary neoplasias had received chemotherapy alone, whereas most patients were treated with radiotherapy alone or radiotherapy in combination with chemotherapy. Among the high incidence of cancer, breast cancer in young women treated with mantle field irradiation between the age of 15 and 25 years is of a special concern, as the relative risk of breast cancer was elevated by 56-fold in women treated under the age of 19.[80] It was also discussed in that context, that chemotherapy-dependent hormonal factors also play an important role in the pathogenesis of breast cancer.[81]

Considering the impact of chemotherapy in addition to radiotherapy, there is conflicting data. One study pointed out that the occurrence of second malignancies is increased in patients treated with both chemotherapy and radiotherapy when compared to patients treated with irradiation alone.[82] In contrast to that trial, a recent meta-analysis[83] compared data from randomized trials testing radiation therapy versus combined modality treatment (3343 patients), chemotherapy versus combined modality treatment (2861 patients), radiation therapy versus chemotherapy or involved-field versus extended-field radiation therapy (3221 patients) for untreated HL came to different results. It was concluded that administration of chemotherapy in addition to radiation therapy as initial therapy for HL decreases overall risk for second malignancies by reducing relapse and need for salvage therapy. Administration of radiation therapy

additional to chemotherapy marginally increased overall risk for second tumors in advanced stages. Breast cancer risk was substantially higher after EF-RT. It has to be pointed out that caution is needed in applying findings of these two trials to current therapies as treatment strategies, drugs and radiation techniques changed considerably over the years.

Besides the occurrence of second cancers, treatment results are challenged by the development of long-term toxicities such as pulmonary dysfunction[84] or heart failure.[85] In a retrospective study analyzing 415 patients that received radiation including the heart or carotid or subclavian arteries, the rates of clinically significant valvular dysfunction (6.2% at 22 years), and coronary artery disease (10.4% at 9 years) were higher than expected.[86]

Many of the ongoing and recently completed studies were developed in an attempt to reduce the long-term complications of treatment without increasing mortality from HL. These include studies that evaluate reduction of radiation dose or field size or even the omission of radiotherapy and evaluate combined-modality treatment in an attempt to identify the optimal chemotherapy regimen, the optimal number of cycles of chemotherapy, and to determine the optimal radiation volume and dose when combined with chemotherapy.

Radiation Dose

Based on a Kaplan meta-analysis showing a continuous reduction in recurrence rates up to doses of 40 Gy, extended field radiotherapy was usually administered to a total dose of 40 Gy as a sole treatment modality.[87] However, subsequent dose-response analyses indicated a plateau in cure rates starting around 30 Gy.[88]

The GHSG thus planned a multicenter, randomized, controlled trial (HD4) to test whether subclinical disease can be adequately controlled by a total radiation dose of 30 Gy (extended field). In this multicenter trial, 376 pathologically staged patients with stage I or II disease without adverse risk factors (eg, large mediastinal mass, E-lesions, massive splenic disease, elevated ESR, ≥3 tumor-involved areas) were recruited.[89] Patients were randomly assigned to receive 40 Gy of extended field radiotherapy (arm A) or 30 Gy of extended field radiotherapy followed by an additional 10 Gy to involved lymph node regions (arm B). Complete remission was attained in 98% of patients in each arm. With a median follow-up of 86 months, the 7-year relapse-free survival rates (78% for arm A and 84% for arm B) and overall survival rates (91% for arm A and 96% for arm B) did not differ significantly. In conclusion, subclinical involvement of HL is sufficiently treated with 30 Gy of radiotherapy alone. However, the relapse-free survival rate in this favorable subgroup of patients treated with radiotherapy alone is unsatisfactory.

Combined-Modality Treatment with Extended Field Irradiation versus Extended Field Radiotherapy Alone

To reduce the high relapse rates observed with radiotherapy alone, combined-modality therapies were introduced and compared with radiotherapy alone in patients with early-stage, favorable-prognosis HL. The HD7 trial (1994–1998) of the GHSG randomized 650 favorable-prognosis clinical stage IA-IIB patients to subtotal nodal and splenic irradiation alone or to two courses of ABVD and extended field radiation therapy.[90] The final analysis after a median follow-up of 87 months showed an advantage in freedom from treatment failure in the patients receiving ABVD (88%) compared with those treated with irradiation alone (67%, $P < 0.0001$). Probably due to effective salvage therapy, overall survival (94% and 92%) did not differ between the two treatment arms.[91]

Results of an American Intergroup phase III trial (#9133) have been published comparing three cycles of doxorubicin and vinblastine (AV) plus subtotal lymphoid irradiation with subtotal lymphoid irradiation alone in clinical stage IA-IIA patients with supradiaphragmatic disease that did not undergo staging laparotomy.[92] The trial had to be closed at the second interim analysis because of a marked superior failure-free survival rate for patients on the combined-modality arm (94% versus 81%, respectively, at a median follow-up of 3.3 years). Nevertheless, the two previously described studies used EF radiotherapy and did not address the issue of whether radiation therapy could be reduced safely when coadministering chemotherapy.

Combined-Modality Treatment with Involved Field Radiotherapy versus Extended Field Radiotherapy Alone

Randomized trials of combined-modality therapy have been based on the premise that this approach results in a very high freedom from recurrence rate and that this high degree of efficacy can even be maintained when using less toxic chemotherapy and radiation therapy regimens. In the EORTC H7F trial (333 favorable patients), six cycles of the EBVP regimen (ie, epirubicin, bleomycin, vinblastine, and prednisone, with one dose per cycle) plus involved field irradiation were compared with mantle and para-aortic-splenic nodal irradiation (STNI) for favorable-prognosis clinical stage IA-IIA patients. At 10 years, the event-free survival rate was significantly better for patients on the combined chemotherapy and radiation therapy arm compared with those receiving radiation therapy alone (88% versus 78%, $P = 0.01$), with similar survival rates (92%) (Table 77–5).[93] As the H7U trial showed that EBVP is less efficient than a hybrid of MOPP (mechlorethamine, vincristine [Oncovin], procarbazine, and prednisone) and ABVD,[93] the latter regimen was used in subsequent studies.

The EORTC H8F trial (1993–1998) testing three cycles of MOPP/ABV and involved field irradiation against mantle and para-aortic-splenic irradiation for favorable-prognosis clinical stage IA-IIA patients was activated in 1993 (n = 543 patients). This trial asked the question whether three cycles of standard chemotherapy are sufficient to control subclinical HL. Because relapse-free survival differed significantly between the two groups (98% versus 74%; $P < 0.001$), it was concluded that combined-modality treatment was the new gold standard of therapy (see Table 77–5).[94] Taken together, these EORTC trials were the first to demonstrate, that STNI could be safely replaced by a combined modality regimen, as smaller radiotherapy (IF) in combination with chemotherapy was shown to be superior to STNI.

Compared with the 12-week Stanford V regimen given to patients with poor-prognosis HL, patients with favorable-prognosis clinical stage IA-IIA disease received a modified eight-week Stanford V regimen that included involved field irradiation to sites of initial disease involvement. This regimen provides information about the ability of brief but intense chemotherapy to control HL beyond the initially involved sites in favorable-prognosis clinical stage I-II patients.[95]

With the objective of reducing acute toxicity and chronic morbidity, Horning and colleagues developed a presumably less toxic chemotherapy regimen of vinblastine, methotrexate, and bleomycin (VBM), which was tested in a randomized trial of pathologic stage IA-IIB and pathologic stage IIIA patients.[96] The trial compared subtotal nodal/total nodal irradiation with involved field irradiation (44 Gy) followed by VBM. The freedom from disease progression at 9 years favored involved field irradiation and VBM (98%) over subtotal nodal/total nodal irradiation alone (78%) ($P = 0.01$). No differences were seen in overall survival ($P = 0.09$) (see Table 77–5).[97] The British National Lymphoma Investigation (BNLI) has confirmed the efficacy of VBM with involved field irradiation, but in their experience, this approach produced unacceptable pulmonary and hematologic toxicity.[98]

Table 77–5. Favorable Prognosis Stage I-II Hodgkin Lymphoma: Studies Analyzing the Radiation Fields and Doses and the Optimal Chemotherapy

Trial	Treatment Regimens	No. of Patients	Outcomes	
			FFTF	*SV (7 yr)*
GHSG HD7[91]	A. EF RT 30 Gy (IF 40 Gy)	311	67%	92%

ABVD regimen, doxorubicin, vinblastine, bleomycin, and dacarbazine; CS, clinical stage; EF, extended field; EORTC, European Organization for Research and Treatment of Cancer; EBVP regimen, epirubicin, bleomycin, vinblastine, and prednisone; GELA, Groupe d'Etude des Lymphomes de l'Adulte; FFTF, freedom from treatment failure; FU, follow-up; GHSG, German Hodgkin's Lymphoma Study Group; HL, Hodgkin's disease; IF, involved field; LP, lymphocyte-predominance histology; MOPP regimen, mechlorethamine, vincristine (Oncovin), procarbazine, and prednisone; NS, not significant; OS, overall survival; RFS, relapse-free survival; RT, radiation therapy; Stanford V regimen, mechlorethamine, doxorubicin, vinblastine, prednisone, vincristine, bleomycin, and VP-16; STLI (S), subtotal lymph node irradiation (splenic irradiation); SV, survival; SWOG, Southwestern Oncology Group.

Involved Field Radiation Dose in Combined-Modality Treatment

Two trials enrolling patients with early stage favorable HL are evaluating radiation dose to involved sites after chemotherapy (see Table 77–5). In the multicenter international HD10 trial of the GHSG, 1370 patients were randomized to two or four cycles of ABVD followed by 20 or 30 Gy of involved field radiation therapy. This trial will help to determine the optimal number of cycles of ABVD needed to control occult HL in the abdomen and to prevent recurrence of HL in apparently uninvolved sites. The fourth interim analysis in August 2006 showed no significant differences in overall survival and FFTF between two and four cycles of ABVD (96% and 97% for OS; 91% and 92% for FFTF, respectively) after a median observation time of 53 months.[99] This trial also showed that 20 Gy of involved field radiotherapy is sufficient to control early stage disease.

The HD13 study of the GHSG is designed to determine whether the rather toxic components of the ABVD regimen of bleomycin (lung) and dacarbazine (gastrointestinal) can safely be eliminated in combined-modality treatment schedules. The data safety monitoring committee closed the AV and the ABV arm in 2005 and 2006 due to a fourfold increase in HL related events compared with ABVD alone. ABVD and AVD recruitment will continue probably until 2008.

Another two trials tested chemotherapy-only approaches for early stage patients. The EORTC/GELA H9F trial (n = 783) is evaluating doses of 36 Gy, 20 Gy, or no radiation to involved sites in patients who have achieved complete remission after six cycles of EBVP II (n = 591). The final analysis with arm comparison showed higher relapse rates than expected in the chemotherapy-only arm, which had to be closed early. The event-free survival at 4 years was 88%, 85% and 69% for 36 Gy, 20 Gy and no radiation therapy, respectively ($P < 0.001$) showing that IF could not be skipped when combined with a mild chemotherapy regimen.[63] Although data are not yet mature, it was postulated that 20 Gy are equally efficient than 36 Gy in these patients.

More recently, Meyer et al published a trial conducted by the National Cancer Institute of Canada Clinical Trials Group and the Eastern Cooperative Group.[100] Patients with stage I-IIA were allocated to a favorable and an unfavorable cohort (inclusion criteria: age

>40 years, erythrocyte sedimentation rate >50 mm/h, mixed cellularity or lymphocyte-depleted histology, and >4 sites of involvement) before random assignment to ABVD as single modality or a radiotherapy containing combined modality treatment. Patients in the chemotherapy-only group received up to six cycles of ABVD. Patients in the radiotherapy group were treated with STNI only or two cycles of ABVD and STNI, if allocated to the favorable or the unfavorable cohort, respectively. There was a statistically significant difference in terms of freedom from progression (FFP) in favor of the radiation-containing regimen (93% vs. 87%) but rates for event-free and overall survival did not reach statistical significance at a median follow-up time of 4.2 years. It might be speculated that the reduced FFP rate for the chemotherapy only arm will be outweighed by a reduced rate of long-term toxicities and secondary malignancies, which needs to be confirmed in a longer follow-up.

Recommendations and Future Directions for Favorable-Stage I-II Hodgkin Lymphoma

Current clinical trials are evaluating the use of alternative chemotherapy combinations, shortened courses of chemotherapy, chemotherapy with smaller radiation fields or lower radiation doses, and chemotherapy without radiation therapy. Fortunately, death from HL of patients with favorable-prognosis, early-stage disease is unusual and overall survival is not a useful parameter to evaluate midterm results in early-stage HL. Current trials should be judged by freedom from first recurrence rates and acute morbidity. On the basis of the available data, it can be concluded that patients with early-stage favorable HL benefit from a short course of ABVD chemotherapy in combination with involved field radiotherapy. Although there is some evidence that radiotherapy might not be necessary for those patients that achieve a complete remission (CR) after two courses of ABVD chemotherapy, it is still advisable to treat all patients with early-stage favorable HL with a combined modality regimen as follow-up of these patients is still too short. Ongoing studies using PET after two courses of ABVD and giving IF-RT only to PET positive patients will demonstrate whether consolidative RT is necessary after achieving a CR after two ABVD.

Early-stage Unfavorable Hodgkin Lymphoma

It is generally accepted that early-stage, unfavorable-prognosis HL patients (see Table 77–3) qualify for combined chemotherapy and radiotherapy. However, the prognostic impact of a single risk factor, the optimal chemotherapy regimen, the number of chemotherapy cycles, the field sizes, and the dosage of radiation within these fields are subjects of debate.

Trials to Identify the Best Chemotherapy Regimen

The first combined-modality trial to test MOPP versus ABVD in patients with unfavorable-prognosis, early-stage disease was the Milan study conducted between 1974 and 1982. Using split-course treatment (ie, 3 cycles of chemotherapy followed by subtotal nodal irradiation), this study did not show a significant difference in freedom from progression between the two treatment groups.[101] However, in the EORTC H6U trial (1982–1988) comparing split-course MOPP and ABVD, the 10-year survival rate was equivalent in both arms, but the freedom from treatment failure rate was significantly higher with ABVD than with MOPP.[102] In the EORTC H7U trial (n = 389), the event-free survival rate was 68% for the EBVP regimen plus involved field irradiation, compared with 88% (P = 0.001) for MOPP/ABV plus involved field irradiation leading to 10-year OS rates of 79% and 87%, respectively (P = 0.0175) (Table 77–6).[93]

The Grupo Argentino de Tratamiento de la Leucemia Aguda (GATLA) trial and the EORTC H7U trial studied modified nonalkylating agent regimens versus standard alkylating agent regimens in patients with unfavorable-prognosis, early-stage disease. All patients received combined radiation therapy and chemotherapy. In the GATLA trial, the event-free survival rate was 66% with the AOPE regimen (ie, doxorubicin, vincristine, prednisone, and etoposide) and 85% (P = 0.009) with the CVPP regimen (ie, cyclophosphamide, vinblastine, procarbazine, and prednisone).[103] In the EORTC H7U and the GATLA trials, the arms using modified chemotherapy were associated with significantly higher recurrence rates. Compared with the effect on favorable-prognosis stage I-II HL, less toxic and less intense chemotherapy regimens in combined-modality therapy regimens do not appear to be equally effective in patients with unfavorable-prognosis disease (see Table 77–6).

Chemotherapy modalities using reduced numbers of cycles of chemotherapy or modified chemotherapy regimens have been also tested in nonrandomized trials.[104,105] Another nonrandomized trial tested the efficacy of the 12-week Stanford V regimen (ie, nitrogen mustard, doxorubicin, vincristine, vinblastine, etoposide, bleomycin, and prednisone plus 36 Gy of involved field irradiation). In that study, 142 patients with stage III-IV disease or locally extensive mediastinal stage I-II HL were enrolled to receive this brief and dose-intense combined-modality regimen.[106] At 5.4 years, the rate of freedom from progression was 89%, and the overall survival rate was 96%. The estimated rates of 5-year freedom from progression for stage I-II and stage III-IV patients were 96.7% ± 6.5% and 84.7% ± 7.4%, respectively. Freedom from progression and overall survival also depended significantly on the IPS (0 to 2 compared with >3). Progressive disease was not observed during treatment. The investigators stressed the fact that there were no treatment-related deaths, no secondary leukemia, and no myelodysplasia and that 42 pregnancies occurred after competition of treatment. The E2496 Intergroup trial which was closed in 2006 is evaluating the benefits and late complications of the Stanford V protocol comparing it with ABVD chemotherapy.

Based mainly on trial results from advanced HL, ABVD has also become the standard regimen for clinical stage I-II patients. ABVD is thus compared in the already mentioned E2496 trial and in three other trials with more intense regimens. The EORTC H9U and the GHSG HD11 trials compared four cycles of ABVD with four cycles of BEACOPP-baseline (ie, bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), procarbazine, and prednisone), and involved field radiotherapy is limited to a dose of 20 or 30 Gy, respectively. The fifth interim analysis of the HD11 trial was presented at the end of 2005.[107] After a median observation time of 3 years, FFTF was 87% and OS was 96%. For both FFTF and OS, there was no significant difference neither between ABVD (FFTF 87% and OS 97%) and BEACOPP (FFTF 88% and OS 96%) nor between 30 Gy (FFTF 90% and OS 97%) and 20 Gy IF-RT (FFTF 87% and OS 97%). The relatively low FFTF rate led the GHSG to investigate the efficacy of two cycles of BEACOPP escalated followed by two cycles of ABVD within the ongoing HD14 trial.

Radiation Field and Dose

In preceding studies, the GHSG randomized responding patients with early-stage, unfavorable-prognosis disease to 40 Gy of extended field irradiation or 20 Gy of extended field irradiation plus 20 Gy of involved field radiotherapy (HD1 trial), with no outcome difference. In the follow-up trial (HD5), patients received 30 Gy of extended field irradiation plus 10 Gy to sites of bulky disease.[108] These trials demonstrated that radiation dose in the extended field can safely be reduced to at least 30 Gy (with 10 Gy delivered to bulky tumors) when given after two cycles of alternating ABVD and COPP (ie, cyclophosphamide, vincristine [Oncovin], procarbazine, and prednisone). Similarly, other groups have aimed at improving combined-modality treatment for HL patients with early-stage, unfavorable-prognosis disease. The cooperative study reported by Zittoun and coworkers[109] compared six cycles of MOPP sandwiched

around 40 Gy of radiotherapy applied by an involved field or extended field technique (see Table 77–6). In a total of 173 patients evaluated, there was no difference in terms of disease-free survival (87% versus 93%) and overall survival (92% versus 91%).

An Italian study headed by the Milan group[110] (see Table 77–6) entered patients in a randomized study comparing STNI with involved field irradiation after four cycles of ABVD. With a median follow-up of 12 years, treatment outcomes were very similar in both arms (freedom from progression rates of 94% and 93%; survival rates of 96% and 94%, respectively). In their H8U trial, the EORTC compared six cycles of MOPP/ABV plus 36 Gy of involved field irradiation, four cycles MOPP/ABV plus 36 Gy of involved field irradiation, and four cycles of MOPP/ABV plus STLI. There were no differences among the three arms in terms of response rates, failure-free survival, and overall survival, although the median follow-up was still rather short (4 years).[94]

The question of whether radiation fields can be reduced to the involved sites after adequate chemotherapy was answered by the HD8 trial of the GHSG (see Table 77–6).[111] This trial compared 30 Gy of extended field irradiation plus 10 Gy to sites of bulky disease (>5 cm in diameter) with 30 Gy of involved field radiotherapy plus 10 Gy to bulky disease sites after two alternating cycles of COPP/ABVD. Between 1993 and 1998, 1204 patients were randomized. The median observation time was 54 months. The overall survival rate for all eligible patients was 91%, and the freedom from treatment failure rate was 83%. Comparisons of both arms showed similar rates for freedom from treatment failure (86% and 84%) and overall survival at 5 years (91% and 92%). There were also no significant differences between the two arms in terms of complete remission, progressive disease, relapse, death, and secondary neoplasias. In contrast, acute side effects, including leukopenia, thrombocytopenia, nausea, and gastrointestinal and pharyngeal toxicity, occurred more frequently in the extended field arm. This study defines a new standard of treatment for patients with early-stage, unfavorable-prognosis HL consisting of four cycles of effective chemotherapy followed by involved field radiotherapy. The shortcoming of this study is that about 5% of patients with intermediate-stage disease will suffer from progressive disease while on ABVD-like chemotherapy and another 15% will relapse within the next 5 years.

Two large randomized trials are evaluating whether four cycles of combination therapy are equally effective as six cycles in combination with radiotherapy. The EORTC H8U study randomized patients to involved field or STLI irradiation and four or six cycles of MOPP/ABV; at a follow-up neither relapse-free survival nor overall survival differed significantly among the three groups (see Table 77–6).[94] The EORTC H9U trial randomized patients to four or six cycles of ABVD or four cycles of BEACOPP followed by irradiation. According to a recent interim analysis, similar FFTF rates are observed in patients treated with 4 or 6 cycles of ABVD, while BEACOPP basis did not add any benefit but appeared to be more toxic.[112]

Besides the HL6 trial of the National Cancer Institute of Canada reported above,[100] there is only one more prospective trial comparing chemotherapy alone to a combined-modality therapy in unfavorable-prognosis stage I-II HL. The GATLA trial randomized 104 patients with unfavorable disease to six cycles of CVPP alone or six cycles of CVPP sandwiched around involved field irradiation (30 Gy). The 7-year survival rates were 66% and 84%, and the freedom from relapse rates were 34% and 77% ($P < 0.001$), both favoring combined-modality treatment.[113] This trial, however, may not be relevant in view of the fact that there is international agreement that C-MOPP (ie, cyclophosphamide, vincristine [Oncovin], procarbazine, and prednisone; also called COPP regimen) or derivatives are no longer the treatment of choice for any stage of HL.

Summary and Treatment Recommendations

The outcome of treatment for patients with unfavorable-prognosis stage I-II HL has improved dramatically in the past three decades. This mainly results from the use of combined-modality therapy, because radiation therapy alone or chemotherapy alone historically was associated with recurrence rates of approximately 50%. Four cycles of ABVD chemotherapy followed by 30 Gy of involved field radiotherapy is a new standard for patients with unfavorable-prognosis early-stage HL. Nevertheless, this standard is challenged by more intense regimens such as Stanford V and BEACOPP escalated as 5% of the patients progress and another 15% experience a relapse within 5 years when treated with conventional ABVD and radiotherapy. Most clinical trials are exploring new combinations of more effective chemotherapy and reduced radiation doses to determine optimal treatment, with the aim of decreasing late morbidity and mortality while maintaining a high probability of freedom from first recurrence. Whether four to six cycles of chemotherapy without irradiation can produce long-lasting remissions has to be awaited.

ADVANCED-STAGE HODGKIN LYMPHOMA

Treatment Strategies

MOPP: Pioneer Combination Therapy

Up to the middle of the 20th century, patients with advanced stages of HL were incurable. With the advent of more effective drugs used early in childhood leukemia, de Vita and colleagues at the NCI were

the pioneers who paved the road for the incredible success of modern chemotherapy in oncology by achieving a 50% cure rate for advanced-stage HL patients with the drug combination MOPP.

The MOPP regimen was administered with each of the four drugs given at full dose over 2 weeks, with a complete remission rate of 81%. These excellent results were confirmed at other centers with complete remission rates of 73% to 81%, long-term freedom from progression rates of 36% to 52%, and long-term overall survival rates of 50% to 64%.[114–116]

Despite the promising initial results with MOPP therapy, many investigators used alternative regimens to improve the efficacy or reduce toxicities. The omission of single drugs, such as the alkylating agents nitrogen mustard or procarbazine, from the MOPP regimen was shown by the Cancer and Acute Leukemia Group B (CALGB) to be associated with inferior complete remission rates.[117] The *four-drug principle* therefore was considered as the standard at that time, with which any other drug combination had to be compared.

A five-drug regimen developed by the ECOG containing carmustine, cyclophosphamide, vinblastine, procarbazine, and prednisone (BCVPP) was compared with MOPP[118] and showed a significantly higher freedom from progression rate (50% versus 33%) and overall survival rate (83% vs 75%) at 5 years. However, a rather heterogeneous selection of patients made the interpretation of these results rather difficult.

In the United Kingdom, the ChlVPP regimen (ie, chlorambucil, vinblastine, procarbazine, and prednisolone) demonstrated similar efficacy with less acute toxicity compared with MOPP, although no randomized comparison was performed. The BNLI performed a randomized trial to compare LOPP (ie, lomustine, vincristine [Oncovin], procarbazine, and prednisone) with MOPP. No significant differences were observed in complete remission or overall survival rates.[119]

In summary, the described efforts to improve the efficacy and reduce the toxicity of the original MOPP regimen did not result in higher cure rates but possibly resulted in acute gastrointestinal and neurologic toxicities.

ABVD: Second Combination Regimen

Despite great accomplishments with MOPP and MOPP-like regimens, there were major drawbacks. Between 15% and 30% of the patients did not obtain a complete remission, and only about 50% of patients could be cured. The use of MOPP was associated with significant acute toxicity and with an increased risk of sterility and acute leukemia because of the use of alkylating agents.

In 1975, Bonadonna and colleagues[120] introduced the ABVD regimen (ie, doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine) in an attempt to develop a treatment for patients who had failed MOPP therapy. Vinblastine had demonstrated high activity as a single agent and lacked cross-resistance with vincristine. Doxorubicin and bleomycin were very active drugs and produced objective responses in about 50% of patients. Dacarbazine was added because it was active as a single agent and showed synergism with doxorubicin.

The Milan group started to compare MOPP and ABVD, using three cycles of each drug combination, followed by extended field irradiation and three additional cycles of the same chemotherapy regimen. The comparison demonstrated a significant superiority for ABVD, with freedom from progression rates of 63% for MOPP compared with 81% for ABVD.[121] Because both regimens were highly active and had no overlapping toxicities, it was therefore appropriate to test MOPP and ABVD in various combinations to further increase cure rates.

The Milan group randomized patients with stage IV disease to MOPP or MOPP/ABVD for up to 12 cycles.[114] The results were significantly superior for the alternating program, with a statistically significant difference in freedom from progression at 8 years (36% for MOPP versus 65% for MOPP/ABVD, $P < 0.005$). Subsequently, three large cooperative trial groups (ECOG, CALGB, and EORTC) confirmed these results and demonstrated superior results with the combination of MOPP/ABVD over MOPP or a MOPP-like regimen. ECOG compared the MOPP derivative BCVPP with MOPP followed by ABVD. Rates for complete remission and overall survival were superior with the MOPP/ABVD combination.

Results of prospective multicenter trials using the traditional standard regimens of MOPP, ABVD, or alternating, sequential, or hybrid combinations of these two very effective, non–cross-resistant drug regimens (mostly supplemented with radiotherapy) have shown complete remission rates of up to 80% to 90%. However, the failure-free survival and overall survival rates at 5 years were only 65% to 70% and 75% to 85%, respectively. The pivotal CALGB trial of treatment for advanced HL, which compared MOPP, ABVD and alternating MOPP/ABVD without additive radiotherapy, revealed equal therapeutic results for ABVD and MOPP/ABVD as far as progression-free survival and overall survival rates were concerned.[122] Both regimens were superior to MOPP. ABVD had less germ cell and hematopoietic stem cell toxicities.[123] Long-term (>15 years) follow-up of this study demonstrated a 45% to 50% progression-free survival rate and a 65% overall survival rate for ABVD and MOPP/ABVD.[124]

Hybrid Regimens

Goldie and Coldman[125] related drug sensitivity of tumors to their spontaneous mutation rate. The model formed the basis of hybrid schemes that were tested by several groups for the treatment of advanced-stage HL. Investigators in Vancouver and Milan independently designed two hybrids of MOPP and ABVD to test the Goldie-Coldman hypothesis prospectively.

The National Cancer Institute of Canada compared the MOPP-ABV hybrid with alternating MOPP/ABVD in patients with stage IIIB-IV HL. At 5 years, there was no significant difference in the overall survival rates between the two arms, but the hybrid regimen was associated with greater hematologic and nonhematologic toxicities.[126]

The Milan group compared their MOPP/ABV hybrid with alternating MOPP/ABVD. Freedom from progression and overall survival rates at 10 years revealed no significant difference between the hybrid and alternating chemotherapy arms.[68]

In the HD5 and the HD6 trial, the GHSG compared a new hybrid scheme of COPP/ABV/IMEP (which included iphosphamide, methotrexate, and etoposide) with their standard COPP/ABVD. Complete remission rates, freedom from treatment failure, and overall survival rates showed no statistically significant difference between the two treatment arms.[127]

The Goldie-Coldman hypothesis could not be confirmed in advanced-stage HL, although this might be attributed to the fact that the optimal hybrid regimen has not been identified. Subsequently, large multicenter trials were started in the United States and Europe to compare the MOPP/ABV hybrid with alternating MOPP/ABVD and sequential MOPP/ABVD. These multicenter trials demonstrated that the MOPP/ABV hybrid was equally effective as alternating MOPP/ABVD but more effective than sequential MOPP/ABVD.[128,129]

As a conclusion to the sequence of these comparative trials, Duggan and associates[130] addressed the important question of whether the inclusion of MOPP in the conventional setting and scheduling adds therapeutic benefit to ABVD or merely enhances toxicity. The investigators presented a carefully designed, randomized US intergroup trial in which they compared ABVD with the MOPP/ABV hybrid in 856 adult patients with stage IIIA, IIIB, or IV HL or following relapse after radiotherapy. Therapy was given for 8 to 10 monthly cycles; radiotherapy and the use of prophylactic hematopoietic growth factors were not permitted. There was no statistical difference observed between the ABVD and the MOPP/ABV arms as far as failure-free survival and overall survival were concerned. After a median observation time of 5 years, the failure-free survival rate after ABVD was 63%, and after MOPP/ABV, it was 66%. The rate of overall survival was 82% after ABVD and 81% after MOPP/ABVD. However, significantly greater toxicity was seen during

therapy and after completion of treatment in the MOPP/ABV group, especially concerning objectively measurable parameters, such as hematologic and pulmonary toxicities, and subjective features such as the well-being of patients because of anorexia, fatigue, and hypotension. The total number of treatment-related deaths was 25 for MOPP/ABV and 15 for ABVD, which was not significantly different. Fifty-six of 96 total deaths in the ABVD arm and 49 of 94 deaths in the MOPP/ABV arm were caused by progressive HL, accounting for more than 50% of the total deaths in each arm. After a median follow-up of 6 years, 46 second malignancies have been reported, 18 for ABVD and 28 for MOPP/ABV, with 11 cases of acute myeloid leukemia or myelodysplastic syndrome (AML/MDS) in the MOPP/ABV arm and 2 cases in the ABVD arm. Both patients with leukemia in the ABVD arm received alkylating agents as rescue treatment.

ABVD alone is equally effective as the MOPP/ABV hybrid but less toxic, and all combinations are more effective than MOPP alone. ABVD alone has the advantage of less acute toxicity, especially an absence of sterility, and few or no patients developed secondary AML/MDS. One concern is the cardiotoxicity due to doxorubicin and pulmonary side effects due to bleomycin with the application of six to eight courses of ABVD and even more with consolidation radiotherapy. However, it is internationally accepted that ABVD should be the standard regimen against which all experimental drug combinations should be tested.

Treatment Duration

Many groups have compared different lengths of treatment and numbers of cycles.[122] As a result of these experiences, 8 to 12 cycles of chemotherapy have been given in the phase III trials. From these studies, although the optimal duration or total dose of drugs is not known precisely, it becomes evident that at least six, but maximally eight, cycles of an anthracycline-containing drug combination appear to be sufficient.

Newer Chemotherapy Regimens

The proved comparable efficacy of ABVD and combinations containing alkylating agents in recent trials indicate that cure of advanced-stage HL patients is possible without alkylating agents. However, the pulmonary toxicity of bleomycin, which is especially pronounced in children and in combination with mediastinal irradiation, remains a major issue with the continued use of ABVD. A number of drugs showing significant responses in relapsed HL have become candidates for use in first-line therapy. The topoisomerase inhibitor etoposide has been of special interest to several groups because a 20% to 60% response rate in refractory HL has been reported with single-agent use.[131] Based on these considerations, several etoposide-containing drug regimens have been developed.

Stanford V is a seven-drug regimen, including doxorubicin, vinblastine, mustard, bleomycin, vincristine, etoposide, and prednisone (Table 77–7).[132] The program was applied weekly over a total of 12 weeks. Sophisticated consolidation radiotherapy to sites of initial bulky disease was employed. In a phase II trial, 126 patients had been recruited. The estimated 5-year freedom from progression rate was 89%, and the overall survival rate was 96% at a median observation time of 4.5 years. In this single-center study, results were as expected,[106] however, they were not reproducible and were clearly inferior in a randomized comparison with ABVD and MOPPEBVCAD,[133] which in parts may be explained by the use of smaller consolidating radiotherapy fields in the randomized setting. Reduced long-term toxicities with preserved fertility were major goals and could be achieved in men and women. An intergroup trial of Stanford V versus ABVD has been initiated in select patients with low-risk advanced HL.

The Manchester group developed an abbreviated, 11-week chemotherapy program of VAPEC-B (ie, vincristine, doxorubicin, prednisone, etoposide, cyclophosphamide, and bleomycin) (see Table 77–7). In a randomized trial, VAPEC-B was compared with the hybrid ChlVPP/EVA, with radiotherapy applied to previous sites of bulky disease or residual disease in both arms.[134] This study was stopped after 26 months because of a threefold increase in the rate of progression after VAPEC-B. The final analysis of this important trial[135] (Table 77–8) described 282 untreated patients with stage I-II disease (plus mediastinal bulky lymphadenopathy or B symptoms, or both) and clinical stage III-IV disease at three UK centers and one Italian center who received 6 monthly cycles of ChlVPP/EVA hybrid or 11 weekly cycles of VAPEC-B. Radiotherapy was given to sites of bulky disease (>10 cm in diameter) or residual disease. After a median follow-up time of 4.9 years, freedom from progression, event-free survival, and overall survival rates were significantly better with ChlVPP/EVA than with VAPEC-B (freedom from progression: 82% versus 62%; event-free survival: 78% versus 58%; overall survival: 89% versus 79%). The superiority of ChlVPP/EVA was seen especially in the high-risk group (IPS > 2 risk factors, bulky disease); for the group with fewer risk factors, results were comparable.

Table 77–7 shows the doses and scheduling of combination-chemotherapy regimens used most frequently within and outside clinical trials for advanced-stage HL. Caution should be exercised when comparing results of different trials, because the amount of consolidation radiation therapy varies widely and can influence the outcome significantly. Large prospective, randomized trials provide the only reliable comparison between regimens. The results of such trials are summarized in Table 77–8.

Dose Density and Dose Intensity

Experiences with treating several tumors in animal models have demonstrated a clear relationship between chemotherapy dose and tumor response. Retrospective analyses of drug delivery with MOPP chemotherapy showed that patients with HL who received less than the intended doses had inferior outcomes.[136] Such dose-response relationships also were observed independently with mustard, procarbazine, and vincristine.

Until recently, no prospective, randomized trials that analyzed the role of dose intensity in the treatment of advanced-stage HL had been conducted. There are two principal ways to test the effect of dose intensity on treatment outcome. Doses of cytotoxic drugs can be intensified by increasing individual drug dose or by shortening the interval between treatments, or both. Gerhartz and associates[137] compared COPP/ABVD with a dose and time-escalated COPP/ABVD regimen administered with GM-CSF support. The delivered dose intensity in the dose-intensified arm was 1.22, compared with 0.92 in the standard arm (1.0 = standard intended dose). The analysis revealed a higher complete remission rate in the intensified arm, but definitive results have not been reported.

In 1992, the GHSG initiated a series of clinical trials to address the role of dose intensity in advanced HL in a comprehensive way. Starting with a mathematical model of tumor growth and chemotherapy effects, the data from 705 patients with advanced-stage disease who were treated in previous GHSG studies were reassessed in this model.[138] The investigators predicted that moderate dose escalation would increase tumor control by 10% to 15% at 5 years. The BEACOPP regimen (ie, bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) was devised and used as a standard combination-chemotherapy regimen (see Table 77–7).[139] After establishing excellent tolerability and efficacy in a pilot trial, a second regimen of escalated BEACOPP was developed in which the doxorubicin dose was increased to a fixed level and doses of cyclophosphamide and etoposide were increased in a stepwise fashion with G-CSF support.[140] Maximum tolerated doses were determined in a multicenter pilot study to be 190% of the standard dose for cyclophosphamide and 200% for etoposide.

The GHSG then designed a three-arm study, the HD9 trial, comparing COPP/ABVD, standard BEACOPP, and BEACOPP-escalated in patients with advanced HL (see Table 77–8).[141] Radiotherapy was administered to bulky disease at diagnosis or for residual disease after eight cycles of chemotherapy. About two thirds of

patients received consolidation radiotherapy. In September 1996, at the time of a planned interim analysis, the COPP/ABVD arm of this trial was closed to accrual because of superior outcomes in the combined BEACOPP arms. In the final analysis in June 2001, 1201 patients were evaluated. Superiority over the COPP/ABVD arm for freedom from treatment failure was observed, with 87% for BEACOPP-escalated, 76% for BEACOPP-baseline, and 69% for COPP/ABVD after a median of 5 years, a highly significant result. A major difference was observed in the rate of primary progressive disease during initial therapy, which was significantly lower with BEACOPP-escalated (2%) than with BEACOPP-baseline (8%) or COPP/ABVD (10%) ($P < 0.001$).

The overall survival rates were 83% for COPP/ABVD, 88% for BEACOPP-baseline, and 91% for BEACOPP-escalated. The survival differences were highly significant ($P < 0.002$), and the survival difference between the COPP/ABVD and BEACOPP-escalated regimens reached an impressive degree of significance ($P < 0.002$).

As expected, BEACOPP-escalated was associated with a greater degree of hematologic toxicity, including the need for a greater number of red blood cell and platelet transfusions. Second malignancies, including AML possibly related to etoposide, were reported: with BEACOPP-escalated, 9 cases of AML/MDS; with BEACOPP-baseline, 4 cases of AML/MDS; and with COPP/ABVD, 1 case of AML/MDS. However, the total rate of secondary neoplasias was highest in the COPP/ABVD arm, with 4.2% compared with 3.4% in the BEACOPP-escalated arm. The death rate at 5 years, including all acute and late causes of deaths, was 18.8% (49 of 260 patients) for the COPP/ABVD arm, 13% (61 of 469 patients) for BECOPP-baseline, and 8.6% (40 of 460 patients) for BEACOPP-escalated.

Dosage, dose intensity, and total dose are decisive factors when comparing similar drug regimens. It is difficult to predict the relative efficacy of regimens that use different drugs. As mentioned above, Hasenclever[138] proposed a theoretical framework as a first step to accomplish that task. Different drug doses in a regimen are assumed to be roughly additive in an efficacy scale when appropriately weighted. If the drug weights are known, a total chemotherapy dose can be derived. This total dose must be further corrected for different treatment durations, assuming a typical regrowth kinetic for each lymphoma entity. The resulting quantity, the effective dose, is a reasonable first-order predictor of relative treatment efficacy. Hasenclever derived drug weight estimates from a model based meta-analysis of all randomized chemotherapy comparing trials of treatment for HL and provided an estimate of the slope of the effective dose-cure rate relationship.

Applying the effective dose model and using the weights estimated from trials up to 1998, MOPP/ABVD, MOPP/ABV, and BEACOPP-baseline were predicted not to be notably different from ABVD in cure rates (all within ±5%) because their effective doses are similar. However, Stanford V was predicted to be of reduced efficacy when given with less additional radiotherapy. This prediction was confirmed by an Italian study.[133]

High-Dose Chemotherapy in Combination with Stem Cell Support as Induction Therapy

The effective dose model predicted that early HDCT with ASCT would not be a promising option to improve the outcome as first-line therapy for advanced-stage HL. The reason is that the total dose in

such high-dose therapy is roughly equivalent to two or three conventional cycles of standard chemotherapy, and the effective doses are not sufficiently different. This was confirmed by three trials comparing HDCT and ASCT with conventional chemotherapy (see Table 77–8).[70,142,143]

These three groups tried to improve the outcome of patients at very high risk for treatment failure by using a high-dose regimen such as BEAM (ie, CCNU, etoposide, cytosine arabinoside, and melphalan) or high doses of etoposide and melphalan as first-line therapy after three or four cycles of conventional chemotherapy. Proctor[143] used a numeric prognostic index in a defined population of advanced-stage HL patients to identify a group with a poor prognosis. Of 930 registered patients, he identified 179 (19%) in the poor-prognosis category. There was no difference between the two treatment arms, with one group treated with three cycles of PVACEBOP (ie, prednisolone, vinblastine, doxorubicin, chlorambucil, etoposide, bleomycin, vincristine, and procarbazine) plus high-dose etoposide and melphalan and another group treated with five courses of PVACEBOP. Ninety-three percent of the patients after three courses reached a complete remission; after a median observation time of six years, the high-dose arm had a time to treatment failure rate of 79%, and the conventional arm had a time to treatment failure rate of 85%.

A second French and Italian study[142] defined high-risk HL patients as having a mediastinal mass ratio greater than 45%, more than five involved nodal areas (INAs), or clinical stage IV with more than two contiguous visceral sites, alone or in combination. Sixty patients received four courses of ABVD plus BEAM plus stem cell support (Table 77–8). In the other arm, 53 patients received three monthly courses of intensive chemotherapy with VABEM (ie, vindesine by continuous infusion on days 1 through 5, doxorubicin [Adriamycin], BCNU, etoposide, and prednisolone). Patients in partial or complete remission in both arms received involved field irradiation (20 Gy) plus 20 Gy to INAs. Complete remission rates were 90% for the high-dose arm and 84.9% for the intensive-chemotherapy arm. Rates for freedom from progression at 4 years were 75.3% for the high-dose arm and 81.4% for the comparison arm.

In the third study, Federico and colleagues[70] randomized 160 patients with poor-prognosis, advanced-stage HL who had experienced a good partial response after four courses of ABVD to four additional cycles of ABVD (arm A) or to HDCT plus ASCT (arm B) (see Table 77–8). No additional irradiation was administered. The complete remission rate in arm A was 91%, in arm B 89%. After a median follow-up of 50 months, the event-free survival rate was 85% for arm A and 83% for arm B. Overall survival rates for the two arms were not different. In conclusion, these studies did not show any benefit for late intensification during first-line therapy when ABVD or an equally effective regimen was used.

The 14-Day Variant of the BEACOPP-21 Regimen: the BEACOPP-14

Increased dose intensity can be achieved by two means: increasing the dosage in the same timeframe or shortening the intervals between the treatment courses and shortening the time scale in which drugs are applied. The experiences with the highly effective but toxic BEACOPP-escalated regimen (given in 21-day intervals) led the GHSG to consider a BEACOPP variant, in which the drug dosage and time architecture were altered according to the effective dose model of Hasenclever, with the hope of accomplishing the same efficacy but with a reduced toxicity, especially the rate of AML/MDS development.[144]

The result was the construction of a time-intensified BEACOPP-baseline regimen, which was given in 14-day intervals and administered with G-CSF support for advanced-stage HL (BEACOPP-14) (see Table 77–7). In a multicenter pilot study with 32 centers, the GHSG tested the feasibility, toxicity, and efficacy of the regimen in 99 patients in stage IIB with large mediastinal masses or extranodal disease (23%) or stage III-IV disease (77%) from July 1997 until March 2000. The final analysis with 94 evaluable patients was performed in August 2002 (see Table 77–8).

Ninety-one percent of the 94 patients received eight cycles of therapy; 77% were given within 16 days, and 94% were given within 22 days. Seventy percent of the patients received consolidation radiotherapy. Seven patients with initial bulky disease were not irradiated. Eighty-eight (94%) achieved a complete remission, and only four patients had progressive disease. With a median follow-up of 34 months, five patients relapsed, only one developed a high-grade NHL, and three patients died, one of toxicity and two of progressive disease. The estimated rate for freedom from treatment failure was 90%, and the overall survival rate was 97% at a median of 34 months of observation time.

Acute hematotoxicity was moderate, ranging between that of the escalated and the baseline BEACOPP-21 regimen, with 75% of patients experiencing WHO grade 3 or 4 leukopenia. Twenty-three percent of patients experienced thrombocytopenia, and 65% had anemia, in a few cases necessitating the use of erythropoietin or blood transfusions. Treatment results with the BEACOPP-14 baseline regimen are promising and may help to treat advanced-stage HL patients more effectively and safely.

Role of Radiotherapy in Advanced-stage Hodgkin Lymphoma

Several reports have indicated that patients treated with chemotherapy alone failed to respond or progressed, primarily in previously involved nodal sites. However, the benefits of consolidation radiotherapy must be balanced with the risk for serious side effects, particularly a second malignancy in the irradiated field.

Several phase III trials investigated the role of consolidation radiotherapy after primary chemotherapy with divergent results. After MOP-BAP (ie, mechlorethamine, vincristine [Oncovin], procarbazine, bleomycin, doxorubicin [Adriamycin], and prednisone) chemotherapy, 80% of relapses were detected in initially involved sites; 61% of patients who achieved complete remission were randomized to low-dose involved field radiotherapy or no further treatment in this SWOG study. In this trial, no significant differences in remission duration or overall survival were detected.[145]

The GHSG analyzed the role of low-dose (20 Gy) involved field radiotherapy versus two cycles of additional consolidation chemotherapy in 288 patients in complete remission after initial chemotherapy with COPP/ABVD. There were no significant differences in freedom from progression or overall survival rates between the two treatment arms.[146]

To overcome the insufficient power of randomized studies with too few patients to detect a relevant difference, Loeffler and colleagues[147] performed a meta-analysis of 14 studies involving more than 1700 patients. Two study designs were compared; in the *additional design*, irradiation was added to the same chemotherapy regimen, and in the *parallel design*, more cycles of chemotherapy were substituted for irradiation. In the additional design, radiotherapy reduced the hazard rate by about 40%. The benefit of irradiation was most pronounced among patients with mediastinal involvement and provided no reduction in relapse among patients with stage IV disease. There was no survival benefit detected for radiotherapy in any subgroup analyzed. In the parallel design, there was no significant difference in disease-free survival. However, overall survival was significantly higher among patients treated with chemotherapy alone. In the combined-modality group, there were more deaths from causes other than HL, including leukemia.

An important issue is determining the added efficacy of radiotherapy as adjuvant treatment to modern anthracycline-containing chemotherapy and the added late toxicity of this combined-modality treatment. Prospective, randomized trials, such as the comparison of MOPP-ABV hybrid plus consolidation radiotherapy by the EORTC, are needed to address these questions (Table 77–8).[148] In this trial, patients in complete remission after MOPP/ABV received two further

chemotherapy cycles followed by randomization to involved field radiotherapy or observation. This important study recruited patients for more than 10 years and completed the accrual with 700 patients in 2001. A first detailed analysis showed that involved field irradiation did not improve relapse-free survival or overall survival in patients who already achieved a complete remission with MOPP/ABV. Remarkably, those who reached a partial remission and were treated with additional involved field irradiation had comparable overall outcomes compared with those who reached a complete remission. The added late toxicity associated with irradiation was not evaluated in this report because of the short observation time.[149]

A similar approach with a potentially more active chemotherapy regimen, BEACOPP, was performed by the GHSG (HD12 study) (Table 77–8). In this trial, patients were randomized to eight cycles of BEACOPP-escalated or four cycles of BEACOPP-escalated plus four cycles of BEACOPP-baseline. Subsequently, patients were randomized to receive radiotherapy to initial sites of bulky and residual disease or to no further treatment. The fourth interim analysis of HD12 in 2004 with a median follow-up of 30 months showed a FFTF rate of 88% and an OS rate of 94% for the total cohort with a similar toxicity profile as described in the HD9 trial but a reduced number of AML/MDS cases (0.8%). Although there was no difference between the treatment arms with or without radiotherapy, 18% of patients with large residual tumors received consolidating radiotherapy in the non-RT arms.[150]

In the still recruiting HD15 trial, the GHSG is comparing treatment of advanced-stage HL with eight cycles of BEACOPP-escalated with six courses of BEACOPP-escalated plus eight courses of BEACOPP-14 (see Table 77–8). In this trial, radiation therapy is administered only to PET-positive residual tumors.

OUTCOMES

The progress of clinical research in the treatment of HL in the past 40 years is reflected in tumor-free survival rates at 10 years of between 80% and 90% for nearly all stages (see Fig. 77–1). These gains have led to the question of how much overtreatment and how much long-term negative side effects should be allowed to justify such high success rates at the beginning of the course of treatment. We offer some possible solutions to this dilemma:

1. Give six to eight cycles of ABVD to low-risk patients (IPS = 0 to 2) and rescue the 10% to 15% of patients with relapsing or progressive disease with more aggressive salvage strategies, such as HDCT with stem cell rescue. The downside of this approach is high degrees of toxicity for relapsing patients, including secondary leukemias. BEACOPP-escalated is significantly superior to COPP/ABVD in terms of primary progression (2% versus 12%) and freedom from treatment failure (91% versus 72%). The GHSG uses BEACOPP-escalated in all patients independently of risk factors.
2. Give a more intensive initial regimen for patients at higher risk for failure (IPS > 3), such as BEACOPP-escalated with a 10% to 20% higher freedom from progression and an overall survival benefit of about 8% over ABVD or C-MOPP/ABVD at 5 years, accepting the higher initial burden of acute toxicity and higher rate of AML/MDS due to the more aggressive induction treatment.

These strategies are created at the time when an international prospective trial is being conducted under the leadership of the EORTC and with participation of most large cooperative study groups in Europe, Canada, and Australia (EORTC trial #20012).

Table 77–9 demonstrates the risk of early progression, treatment failure rate, and overall survival rates at 5 years when patients are stratified based on IPS scores of 0 to 2 and 3 to 7, as well as treatment with COPP/ABVD (as effective as ABVD), BEACOPP-baseline, and BEACOPP-escalated (see Table 77–8).

Table 77–9. Early Progression Rates and 5-Year Kaplan-Meier Freedom from Treatment Failure Rates According to Treatment Arm and Prognostic Subgroup

International Prognostic Score*	COPP/ABVD	BEACOPP Baseline	BEACOPP Escalated
Early Progression (%)			
0–2	12% (7%–18%)	8% (5%–13%)	2% (0.5%–4%)
3–7	12% (6%–22%)	8% (4%–13%)	2% (0.5%–7%)
5-Year FFTF (%)			
0–2	72% (64%–80%)	77% (71%–83%)	91% (88%–5%)
3–7	66% (55%–77%)	71% (64%–79%)	82% (75%–89%)
5-Year OS (%)			
0–2	86% (83%–89%)	93% (91%–95%)	94% (92%–96%)
3–7	79% (74%–84%)	82% (79%–85%)	86% (83%–89%)

*The International Prognostic Factor Project produced an international prognostic score (IPS): 0–2, 49% of all patients; 3–7, 30% of all patients, the rest were not evaluable for IPS.
ABVD regimen, doxorubicin, vinblastine, bleomycin, and dacarbazine; BEACOPP (baseline) regimen, bleomycin, etoposide, Adriamycin (doxorubicin), cyclophosphamide, Oncovin (vincristine), procarbazine, and prednisone; BEACOPP (escalated) regimen, bleomycin, etoposide, Adriamycin (doxorubicin), cyclophosphamide, Oncovin (vincristine), procarbazine, prednisone, and granulocyte colony-stimulating factor; COPP regimen, cyclophosphamide, vincristine, procarbazine, and prednisone; FFTF, freedom from treatment failure; OS, overall survival.

The question concerning consolidation irradiation to sites of bulky or residual disease after intensive chemotherapy will be answered by the final analysis of the results of the described trials (see Table 77–8) (see also box on Primary Treatment of Hodgkin Lymphoma Outside of Clinical Trials.)

PRIMARY PROGRESSIVE AND RELAPSED HODGKIN LYMPHOMA

Depending on stage and risk factor profile, up to 95% of patients with HL after initial presentation achieve complete remission after standard treatment. Depending on their initial treatment, patients who relapse have different treatment options, including radiotherapy for localized disease in previously nonirradiated areas, conventional salvage chemotherapy, or HDCT followed by ASCT. Conventional chemotherapy is the treatment of choice for patients relapsing after initial radiotherapy for early-stage HL. The survival of these patients is at least equal compared with patients with advanced-stage disease initially treated with chemotherapy.[151] In contrast, patients with relapsed HL after primary chemotherapy generally have a poorer prognosis. The therapeutic options include salvage radiotherapy, salvage chemotherapy, and HDCT with ASCT.

Newer approaches such as sequential HDCT, tandem HDCT, allogeneic SCT, or nonmyeloablative conditioning with allogeneic blood stem cell transplantation (ie, mini-transplantation) have been investigated in cases of relapsed HL.[152–154] Because more aggressive approaches are associated with increased toxicity, an accurate pretreatment prognostic assessment of patients is required to help select the most appropriate therapeutic regimen.

Prognostic Factors for Patients Relapsing After Primary Radiotherapy

Primary radiation therapy is now less often used in the treatment of localized HL. It has been replaced by combined-modality therapy, in which various numbers of cycles of combined chemotherapy are given before low-dose radiotherapy, which is limited to the involved field rather than the extensive radiation therapy used in the past. Combined-modality therapy has reduced the relapse rate to less than 20% for patients presenting with clinical stage I-IIA disease. In the future, chemotherapy alone may replace combined-modality treatment. This is the subject of a number of prospective, controlled trials.

The relapse rate after primary radiation therapy is 30% to 35% and most relapses occur within 3 years of the completion of radiotherapy, although late relapses after 4 years have occurred in 5% to 7% of patients. This small fraction of late disease recurrence is noteworthy because this is generally a more favorable prognostic group when treated with systemic therapy. Their overall survival rate is not different from that of patients who never relapse.[76,155,156]

Most patients who relapse after radiotherapy are treated with systemic combination chemotherapy, often with the inclusion of involved-field radiotherapy if a nodal site was previously unirradiated. The long-term survival of patients varies significantly according to the pattern of relapse. Three major prognostic factors for response to second-line therapy include age (>40 or 50 years), stage at relapse, and the type of therapy used for the treatment of relapse (ie, chemotherapy alone or chemotherapy and radiation). In some series, mixed cellularity or lymphoid-depleted histology were also adverse prognostic factors.

The salvage rate of relapsing patients is likely to get better than the current 60% range with the potential for earlier diagnosis with more sensitive diagnostic techniques such as PET. For those who fail conventional-dose salvage chemotherapy, high-dose therapy can still result in long-term disease-free survival for an additional 30% to 50% of patients.

Recommendations for the Primary Treatment of Hodgkin Lymphoma Outside of Clinical Trials

Group	*Stage*	*Recommendation*
Early stages (favorable)	CS I-II A/B, no RFs*	2 cycles ABVD; 6 cycles EBVP; *or* VBM ± IF RT, (20–30Gy)
	Early stages (unfavorable, intermediate) CS I-II A/B + RFs	4–6 cycles ABVD; BEACOPP-baseline, Stanford V; *or* MOPP/ABV ± IF RT, 20–30Gy
Advanced stages	CS IIB + RFs, CS III A/B, CS IV A/B	6–8 cycles ABVD; MOPP/ABV; ChlVPP/EVA; BEACOPP-escalated *or* BEACOPP-14 ± RT, 20–30 Gy for residual tumor (PET positive) and/or bulk disease

*See Table 77–3 for risk factors (RFs)
ABVD regimen, doxorubicin, vinblastine, bleomycin, and dacarbazine; BEACOPP-baseline regimen, bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), procarbazine, and prednisone; BEACOPP-escalated regimen, bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), procarbazine, prednisone, and G-CSF; BEACOPP-14 regimen, bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), procarbazine, prednisone, and G-CSF; ChlVPP/EVA regimen, chlorambucil, vinblastine, procarbazine, prednisolone, etoposide, vincristine, Adriamycin (doxorubicin); CS, clinical stage; EBVP regimen, epirubicin, bleomycin, vinblastine, and prednisone; IF, involved field; MOPP regimen, mechlorethamine, vincristine (Oncovin), procarbazine, and prednisone; PET, positron emission tomography; RT, radiation therapy; Stanford V regimen, nitrogen mustard, doxorubicin, vinblastine, bleomycin, vincristine, etoposide, and prednisone; VBM regimen, vinblastine, methotrexate, and bleomycin

Prognostic Factors for Patients Relapsing After Primary Chemotherapy

It was first noticed in 1979 that the length of remission to first-line chemotherapy had a marked effect on the ability of patients to respond to subsequent salvage treatment.[157] In 1992, the NCI updated their experience with the long-term follow-up of patients who relapsed after combination-chemotherapy regimens.[158] Derived primarily from investigations involving failures after MOPP and MOPP variants, the conclusions are relevant to other chemotherapy programs. On this basis, chemotherapy failures can be divided into three subgroups:

1. Primary progressive HL (approximately 10% of all cases); (ie, patients who never achieved a complete remission)
2. Early relapses within 12 months of complete remission (approximately 15% of all cases)
3. Late relapses after complete remission lasting longer than 12 months (approximately 15% of all cases)

Using conventional chemotherapy for patients with primary progressive disease, virtually no patient survives more than 8 years. In contrast, the projected 20-year survival rate for patients with early relapse or late relapse was 11% and 22%, respectively.

Prognostic Factors for Patients with Primary Progressive Hodgkin Lymphoma

Patients with primary progressive disease, defined as progression during induction treatment or within 90 days after the end of

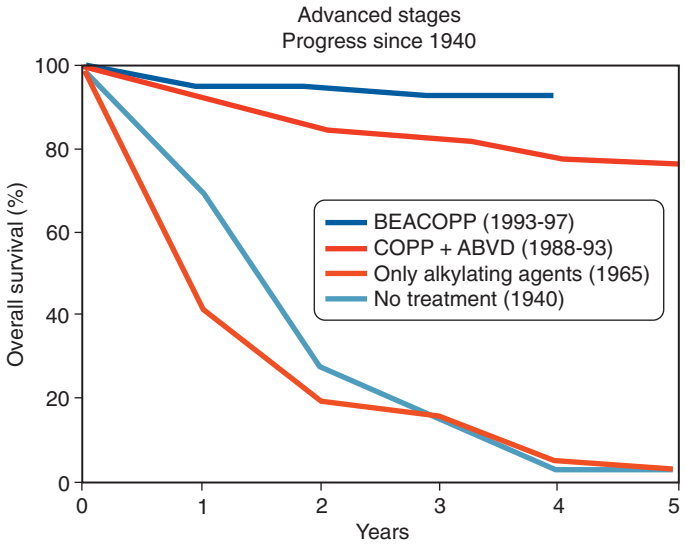

Figure 77–2. Progress made in the treatment of advanced stage Hodgkin lymphoma during the last 40 years. *(modified from: DeVita VT Jr.: The consequences of the chemotherapy of Hodgkin's disease: The 10th David A. Karnofsky Memorial Lecture. Cancer 47:1, 1981; including data from GHSG trials.)*

treatment, have a particularly poor prognosis. Treatment of patients with primary progressive HL has consisted of salvage chemotherapy, radiotherapy, and HDCT with ASCT. Conventional salvage regimens have led to disappointing results for most patients. Response to salvage treatment is low, and the duration of response is often short. The 8-year overall survival rate is between 0% and 8%. The rate of freedom from treatment failure in second remission is 0% at 4 to 8 years in the small series reported.[158,159] Extensive disease often limits the use of radiotherapy.

The GHSG retrospectively analyzed 206 patients with prior disease to determine the outcome after salvage therapy and identified prognostic factors (Fig. 77–2).[160] Rates for the 5-year freedom from second failure and overall survival for all patients were 17% and 26%, respectively. As reported from a number of transplantation centers, the 5-year freedom from second failure and overall survival rates for patients treated with HDCT were 42% and 48%, respectively, but only 33% of all patients were able to receive HDCT.

A high proportion of those rapidly succumb to progressive disease. Life-threatening severe toxicity on institution of salvage treatment occurred in 11% of patients. Insufficient stem cell harvests, poor performance status, and older age also contributed to an ineligibility to participate in HDCT. In a multivariate analysis, Karnofsky performance score at the time to progression ($P < 0.0001$), age ($P = 0.019$), and attainment of a temporary remission to first-line chemotherapy ($P = 0.0003$) were significant prognostic factors for survival. Patients with none of these risk factors had a 5-year overall survival rate of 55%, compared with an overall survival rate of 0% for patients with all three of these unfavorable prognostic factors.

HDCT is an effective treatment for a proportion of patients with primary progressive HL. Because of the poor outcomes of HL patients with progressive disease, future trials must aim at identifying patients at very high risk for induction failure and modifying primary treatment in this group to avoid progressive disease.

Prognostic Factors for Early and Late Relapsed Hodgkin Lymphoma

The overall prognosis is worse for patients relapsing after first-line chemotherapy when treated with conventional chemotherapy. HDCT followed by ASCT is the treatment of choice for patients with relapsed HL after first-line combination chemotherapy. Two randomized studies performed by the BNLI and the GHSG/European Bone Marrow Transplant Registry (EBMT) (HLR1) have shown improved outcome for patients with relapsed HL treated with HDCT.[161,162] Although the results reported with HDCT in patients with late relapse have been superior to those reported in most series of conventional chemotherapy, the use of HDCT in late relapses has remained an area of controversy. Patients with a late relapse have satisfactory second complete remission rates when treated with conventional chemotherapy, with an overall survival rate between 40% and 55%.

However, the HDR1 trial of the GHSG showed improved freedom from treatment failure after HDCT compared with conventional chemotherapy in patients with late relapse. HDCT should be considered as standard treatment for all patients with previous chemotherapy, including those with late relapse. Although these results indicate the superiority of HDCT compared with conventional chemotherapy in patients with relapsed HL, a proportion of patients with early relapse will develop recurrent disease after HDCT. However, a considerable number of good-risk patients may be overtreated with the use of HDCT. An effective assessment of prognostic factors available at the time of relapse is required to guide the physician in selecting the most appropriate therapeutic regimen and to evaluate new experimental approaches in very poor-risk relapses.

Many prognostic factors have been described for patients relapsing after first-line chemotherapy. These include age, gender, histology, relapse sites, stage at relapse, B symptoms, performance status, and extranodal relapse. The impact of these variables is difficult to assess because of a variety of confounding factors, including small numbers of patients, and inclusion of primary progressive HL. Multivariate analyses were not performed systematically.

Lohri and colleagues[163] observed favorable outcomes for patients with favorable risk factors such as an initial stage of less than stage IV at diagnosis, an absence of B symptoms at relapse, and an initial remission duration of more than 12 months. The 5-year failure-free survival rate was 82% for patients lacking all three parameters (n = 22) and 17% for those with one or more risk factors (n = 49). Fermé and coworkers[164] analyzed 100 patients with relapsed or refractory HL who were treated with salvage therapy before high-dose therapy. By univariate analysis, patients with long initial remissions (>12 months), untreated relapses, and a good performance status enjoyed improved overall survival. Reece and associates[165] reported an analysis of 58 patients treated with HDCT and ASCT at the same institution. Four prognostic subgroups were identified according to the presence of the following parameters at relapse: B symptoms, extranodal disease, initial remission duration of less than 12 months, and no risk factors. Patients with no risk factors had a 3-year progression-free survival of 100%, compared with 81% in patients with one factor, 40% in those with two factors, and 0% in patients with all three adverse risk factors.

Brice and colleagues[166] performed one of the largest studies evaluating prognostic factors in relapsed HL. One hundred eighty-seven patients who relapsed after a first complete remission were included. At first relapse, 44% of patients received conventional treatment (chemotherapy or radiotherapy, or both), and 56% received HDCT followed by ASCT. Two prognostic factors were identified by multivariate analysis as correlating with freedom from second failure and overall survival. These factors were the initial duration of first remission (ie, <12 months or >12 months; $P < 0.0001$) and stage at relapse (I-II versus III-IV; $P = 0.0013$). Freedom from second failure rates were 62% and 32%, respectively, and overall survival rates were 44% and 87% according to the presence of 0 or 2 parameters, respectively.

The GHSG performed a retrospective analysis that included a much larger number of relapsed patients (n = 422) than previously reported. The analysis of various prognostic parameters suggests that the prognosis of a patient with relapsed HL can be estimated according to several factors. The most relevant factors were combined into a prognostic score. This score was calculated on the basis of duration

Table 77–10. Prognostic Scores for Patients with Relapsed Hodgkin Lymphoma

Prognostic Factor	4-Year Overall Survival Rates
Duration of first remission	
Early relapse	47%
Late relapse	73%
Stage at relapse	
Stage III/IV	46%
Stage I/II	77%
Hemoglobin level (anemia) at relapse	
F < 10.5; M < 12.0 [g/dL]	40%
F ≥ 10.5; M ≥ 12.0 [g/dL]	72%

From Josting A, Franklin J, May M, et al: New prognostic score based on treatment outcome of patients with relapsed Hodgkin's lymphoma registered in the database of the German Hodgkin's Lymphoma Study Group. J Clin Oncol 20:221, 2002.

of first remission, stage at relapse, and presence of anemia at relapse. Early recurrence within 3 to 12 months after the completion of primary treatment, relapse with stage III or IV disease, and hemoglobin levels at relapse (<10.5 g/dL for female patients, <12 g/dL for male patients) were counted in a score with possible values of 0, 1, 2, and 3 in order of worsening prognosis (Table 77–10).[167] This prognostic score allows the examiner to distinguish patients with different rates of freedom from second failure and overall survival. The actuarial 4-year rates for freedom from second failure and overall survival for patients relapsing after chemotherapy with three unfavorable factors were 17% and 27%, respectively. In contrast, patients with none of the unfavorable factors had rates of freedom from second failure and overall survival at 4 years of 48% and 83%, respectively. The prognostic score could also predict the major candidate groups for dose intensification: patients relapsing after radiotherapy and patients relapsing after chemotherapy who were treated with conventional therapies or with HDCT followed by ASCT.

Treatment of Primary Progressive and Relapsed Hodgkin Lymphoma

Patients who relapse after achieving an initial complete remission can achieve a second complete remission with salvage treatment, including radiotherapy for localized relapse in previously nonirradiated areas, conventional salvage chemotherapy, or HDCT with ASCT. Salvage radiotherapy alone offers an effective treatment option for a selected subset of patients with relapsed HL. This applies to patients with localized relapses in previously non irradiated areas. In a retrospective analysis from the GHSG database including 624 relapsed or refractory HL patients, 100 patients were eligible to receive salvage radiotherapy alone: the 5-year freedom from second failure (FF2F) and OS rates were 28% and 51%, respectively. Prognostic factors for OS were B-symptoms, stage at relapse, performance status and duration of first remission in limited stage relapses.[168] The survival of patients treated with conventional chemotherapy after relapse of irradiated early-stage disease is at least equal to that of patients with advanced-stage disease initially treated with chemotherapy. Rates of overall survival and disease-free survival range from 57% to 71%.[169,170] Patients who relapse after radiation therapy alone for localized HL have satisfactory results with combination chemotherapy and are not considered candidates for HDCT and ASCT.

The optimal treatment for recurrence after primary chemotherapy is less clear. Different modalities such as salvage radiotherapy, conventional chemotherapy, second-line chemotherapy and HDCT with ASCT or allo-SCT are being employed. HDCT followed by ASCT has been shown to produce long-term disease-free survival rates of 30% to 65% in select patients with refractory or relapsed HL.[154,171–174] The reduction of early transplantation-related mortality from the rates of 10% to 25% reported in earlier studies to less than 5% in later studies has led to the widespread acceptance of HDCT and ASCT.

Although results of HDCT have generally been better than those observed after conventional-dose salvage therapy, the validity of these results has been questioned because of the lack of randomized trials. The most compelling evidence for the superiority of HDCT and ASCT in treating relapsed HL comes from two reports from the BNLI and the GHSG together with the EBMT.

In the BNLI trial, patients with relapsed or refractory HL were treated with a combination of carmustine (BCNU), etoposide, cytarabine, and melphalan at a conventional-dose level (mini-BEAM) or a high-dose level BEAM with ASCT.[161] The actuarial 3-year rate for event-free survival was significantly better for patients who received HDCT (53% versus 10%).

The largest randomized, multicenter trial was performed by the GHSG/EBMT to determine the benefit of HDCT in relapsed HL. Patients who relapsed after combination chemotherapy were randomly assigned to four cycles of DexaBEAM (ie, dexamethasone, BCNU, etoposide, cytosine arabinoside, and melphalan) or two cycles of DexaBEAM followed by HDCT (BEAM) and ABMT/PBSCT. The final analysis of 144 evaluable patients revealed that for 117 patients with partial or complete remissions after two cycles of chemotherapy, the freedom from treatment failure rate for the HDCT group was 55%, compared with 34% for the patients receiving an additional two cycles of standard chemotherapy. Overall survival was not significantly different.[175]

Sequential High-Dose Chemotherapy

Sequential HDCT has increasingly been employed in the treatment of solid tumors and hematologic and lymphoproliferative disorders. Initial results from phases I and II studies indicate that this kind of therapy offers safe and effective treatment.[176–179] In accordance with the Norton-Simon hypothesis,[180] after initial cytoreduction, non–cross-resistant agents are administered at short intervals. In general, the transplantation of PBSCs and the use of growth factors allow the application of the most effective drugs at the highest possible doses at intervals of 1 to 3 weeks. Sequential HDCT enables the highest possible dosing over a minimum period (ie, dose intensification).

In 1997, a multicenter phase II trial with a high-dose sequential chemotherapy program and a final myeloablative course was started to evaluate the feasibility and efficacy of this novel regimen in patients with relapsed HL.[181] Patients between the ages of 18 and 60 years with histologically proved relapsed or primary progressive HL in second relapse with no prior HDCT and an ECOG performance status 0 to 1 were eligible for this study.

The treatment program consisted of two cycles of dexamethasone, cytosine arabinoside, and cisplatin (DHAP regimen) in the first phase to reduce tumor burden before HDCT. Patients with partial or complete remissions after two cycles of DHAP received sequential HDCT consisting of cyclophosphamide (4 g/m^2 given IV), methotrexate (8 g/m^2 given IV), vincristine (1.4 mg/m^2 given IV), and etoposide (2 g/m^2 given IV). The final myeloablative course was BEAM followed by PBSCT with at least 2×10^6 CD34$^+$ cells/kg.

At the last interim analysis, 102 patients were available for the final evaluation. At the end of treatment, 10 patients had experienced multiple relapses, 17 patients had progressive disease, 30 patients experienced early relapses, and 45 patients experienced late relapses. After a median of 30 months of follow-up (range, 3 to 61 months), results were as follows. The response rate after DHAP was 87% (23% complete remissions, 64% partial remissions), and the response rate at final evaluation was 77% (68% complete remissions, 9% partial remissions). Toxicity was tolerable, with no treatment-related deaths. Rates of freedom from treatment failure and overall survival rates for patients with early relapse were, respectively, 64% and 87% for early relapse, 68% and 81% for late relapse, 30% and 58% for patients

with progressive disease, and 55% and 88% for patients with multiple relapses. This three-phase treatment regimen appears to be well tolerated and feasible in patients with relapsed and primary progressive HL. The preliminary data suggest high efficacy of treatment for relapsed HL patients, warranting further randomized studies.

In January 2001, the GHSG, EORTC, and EBMT started a prospective, randomized study to compare the effectiveness of a standard HDCT (BEAM) with a sequential HDCT after initial cytoreduction with two cycles DHAP. Patients with histologically confirmed early or late relapsed HL and patients in second relapse with no prior HDCT fulfilling the entry criteria receive two cycles of DHAP followed by G-CSF. Patients achieving no change, partial remission, or complete remission after DHAP are centrally randomized to receive BEAM followed by PBSCT (ie, arm A of the study) or high-dose cyclophosphamide plus G-CSF followed by high-dose methotrexate plus vincristine, followed by high-dose etoposide plus G-CSF and a final myeloablative course with BEAM (ie, arm B of the study).[182] The results of this study are eagerly awaited.

Allogeneic Transplantation after Reduced Conditioning in Hodgkin Lymphoma

Allogeneic bone marrow transplantation (allo-BMT) has clear advantages compared with ASCT. Donor marrow cells uninvolved by malignancy are used avoiding the risk of infusing occult lymphoma cells, which may contribute to relapse in patients who undergo autologous transplantation. Donor lymphoid cells can potentially mediate a graft-versus-lymphoma effect.

Generally, the constraints of donor availability and age have limited broader application of allo-BMT in HL. Moreover, allo-BMT is associated with a high treatment-related mortality rate of up to 75% for patients with induction failure, which casts doubt on the feasibility of this approach in HL patients.[183–186] In most cases, allogeneic transplantation from HLA-identical siblings is not recommended for patients with HL. The reduced relapse-rate associated with a potential graft-versus-tumor effect is offset by lethal graft-versus-host toxicity. Nevertheless, patients with induction failure and relapsed patients with additional risk factors also have a poor prognosis after HDCT and ASCT. The role of allo-BMT should be further evaluated in these patients, taking advantage of newer developments such as non-myeloablative conditioning regimens and allo-PBSCT.

To circumvent the problems inherent to the toxicity and treatment-related mortality associated with allografting, the possibility to achieve engraftment of allogeneic stem cells after immunosuppressive therapy combined with myelosuppressive but nonmyeloablative therapy has been assessed. Several groups have updated their experiences with non-myeloablative conditioning regimens.[152,187,188]

As discussed in a recently published article, TRM might be significantly reduced by employing reduced-intensity conditioning (RIC).[189] Furthermore, another recent study using RIC in 49 HL patients indicates the potential for durable responses in patients who have previously had substantial treatment for Hodgkin lymphoma. The low non–relapse-related mortality suggests that allo transplants should be considered earlier in the course of the disease.[190]

Allogeneic SCT following RIC might thus become an appropriate strategy in selected subgroups of young poor-risk patients, eg for those failing autologous transplantation, or patients with early relapse and further risk factors who are chemotherapy sensitive.[191] However to date, the number of patients treated is small, requiring further clinical studies and information in order to define clear indications.

The EBMT together with the Grupo Espanol de Linfomas-Transplante Autologo de Medula Osea (GEL/TAMO) and the GHSG activated a multicenter phase II study to evaluate the treatment-related mortality of patients with primary progressive or relapsed HL (ie, early relapse, multiple relapses, and relapse after ASCT). Patients with an HLA-compatible sibling donor or an HLA-matched unrelated donor are initially treated with one or two cycles of DHAP or other salvage protocols to reduce tumor burden before allo-PBSCT. PBSCs are collected after G-CSF priming of the donor and reinfused after conditioning with fludarabine and melphalan.

SPECIAL CONSIDERATIONS

Lymphocyte-Predominant Hodgkin Lymphoma

The clinical relevance of the Revised European-American Lymphoma (REAL) and WHO classifications, particularly the distinction between LPHL and LRCHL, has been clarified by the international retrospective study of the European Task Force on Lymphoma (ETFL).[192]

Clinical Features

LPHL patients show a similar age distribution to patients with MCHL but are somewhat older on average than patients with NSHL. Approximately 75% of patients are male, which is similar to the profile for MCHL and different from NSHL (only 50%). Fifty-three percent of LPHL patients had stage I disease, and only 6% had stage IV disease. Thus, the proportion of patients with early-stage disease is consistently high compared with classic HL. B symptoms were present in only 10% of cases, far less than in classic HL. LPHL seems to predominantly manifest in lymph nodes in the peripheral upper neck and inguinal node sites and to occur relatively seldom in central sites such as lymph nodes in the mediastinum and upper abdomen.[193]

Treatment

There are reports that certain LPHL patients do well without any therapy beyond excision. LPHL cases appear to relapse just as frequently as other subtypes, but the relapse is less aggressive, resulting in frequent multiple relapses and reasonable survival rates.[192] More recently, the GHSG published data on 131 patients with LPHL stage IA demonstrating no statistical significance in terms of remission induction between IF-RT, EF-RT and combined modality treatment. Patients with early unfavorable or advanced-stage LPHL (20% to 25%) should be treated similarly to patients with classical HL because of worse FFTF and OS rates compared to those with stage IA.[194]

In the case of relapse, the monoclonal CD20 antibody rituximab might be an optional treatment. Two phase 2 trials showed promising results with overall response rates of 86%[195] and 100%.[196] In a follow-up of the GHSG trial, the median time to progression was 33 months while the median OS was not reached yet. Due to these promising results in relapsed patients, the GHSG will start a trial for patients with stage IA LPHL using rituximab as a first-line monotherapy.

Transformation to Non-Hodgkin Lymphoma

In an analysis from the International Database on Hodgkin's Disease,[77] LPDH was associated with a significantly higher risk for developing secondary NHL, by a factor of 1.8, compared with NSHL and MCHL. Several smaller LPHL studies report secondary NHL, occurring at a rate of 2% to 3% on average. Miettinen[197] reported four secondary NHLs among 31 cases of untreated LPHL, suggesting that some, if not all such NHLs develop independently of treatment.

Hodgkin Lymphoma in the Elderly Patient

Clinical experience and data from large prospective trials demonstrate that patients older than 60 years experience more relapses and suffer more treatment-related toxicity than younger patients. From popula-

tion-based clinical trials, it is known that about 10% to 15% of all patients with HL are older than 60 years.[198,199]

The patient's physical and mental condition, disease history, and the presence of concurrent disorders influence the treatment strategy. Age in general is not a contraindication to aggressive treatment but significantly fewer elderly patients received the intended full chemotherapy dose (75% versus 91%). The survival analysis of one large retrospective trial of the GHSG showed a significantly poorer treatment outcome for elderly patients in terms of 5-year OS (65% v 90%) and FFTF (60% v 80%).[199] Nevertheless, biologically young patients in good physical and mental condition should be treated in a stage-adapted manner, analogous to conventional treatment protocols for patients younger than 60 years. In this subgroup, complete remission, relapse-free survival, and overall survival rates appear to be as good as in younger cohorts.[200] Combined-modality treatment with a conservative combination-chemotherapy regimen and limited radiation fields is considered the standard therapy for favorable- and unfavorable-prognosis, early-stage HL. In advanced stage disease, six to eight cycles of ABVD combination represents a safe regimen for older patients, while more aggressive regimens causing severe hematologic toxicity should be avoided. For instance, the escalated BEACOPP-21 regimen, which has proved especially effective in advanced-stage HL patients under the age of 60 years, appeared to be too toxic for patients older than 60 years.[201] Close monitoring of toxicity (eg, electrocardiogram, echocardiography, pulmonary function tests) and response to treatment are important to modify treatment at any time.

Treatment for patients with impairment of lung, liver, heart, or kidney should be individually adapted. Depending on preexisting impairment of organ function, single drugs with organ-specific toxicities (eg, bleomycin, doxorubicin) may be omitted from the chemotherapy regimen, replaced, or modified in dose. Involved field radiotherapy, or the use of less aggressive drugs such as gemcitabine and Navelbine with or without dexamethasone are possible treatment alternatives. Of note, a concomitant application of bleomycin and gemcitabine should be avoided due a high incidence of pulmonary toxicity in one trial.[202] The GHSG is currently conducting a trial for elderly patients over the age of 60 years introducing gemcitabine as first-line therapy for patients with intermediate- or advanced-stage HL. Patients are treated with six to eight cycles of PVAG (prednisone, vinblastine, doxorubicin, and gemcitabine). They are additionally irradiated (36 Gy) in case of residual lymph nodes at the end of chemotherapy.

Hodgkin Lymphoma During Pregnancy

HL is the fourth most common cancer occurring during pregnancy.[203] One case of HL has been reported per 1000 to 6000 deliveries. Several studies have shown that pregnancy is not associated with a worse clinical course and that the 20-year survival rate of pregnant women with HL is not different from that of nonpregnant women.[204]

The clinical presentation of HL is not influenced by pregnancy. However, there are significant limitations on the ability of the clinician to stage and treat the pregnant patient. CT should be avoided because it exposes the fetus to ionizing radiation. Ultrasound is helpful for assessing the fetal status and detecting tumor lesions in the abdomen of the mother. Magnetic resonance imaging can complete the radiologic staging because it appears not to be associated with risk to the fetus. Decisions about the need for a chest radiograph should be made on the basis of clinical examination.

If HL is diagnosed in the first trimester, most experts agree that a therapeutic abortion should be encouraged. If the mother wishes to continue her pregnancy, treatment should be deferred until the second trimester, if possible, because therapeutic options are limited during the first trimester. If therapy is urgently indicated and the mother does not want an abortion, supradiaphragmatic irradiation with a dose of less than 10 Gy or vinblastine chemotherapy for more advanced disease may be considered.

In the second or third trimester, patients with stage I-II disease may be closely observed, and treatment can be postponed until an early delivery is achieved, usually between gestational weeks 32 and 34. If there is any sign of accelerated disease progression, especially supradiaphragmatic lymphadenopathy, radiotherapy alone is recommended. Most studies recommend doses of 10 to 36 Gy delivered as mantle field or involved field irradiation with abdominal shielding. At this time of fetal development, the risk of adverse sequelae for the child from supradiaphragmatic irradiation is low. In patients with infradiaphragmatic lymphadenopathy or advanced disease, combination chemotherapy is the treatment of choice. Because most chemotherapeutic agents freely cross the placenta and enter the fetal circulation, the patient and the fetus should be closely monitored. Chemotherapy administered in the second and third trimesters may increase the risk of intrauterine growth retardation, microcephaly, and mental retardation.[205] Application of cytotoxic drugs shortly before birth may be particularly hazardous because the placenta is also the primary means of drug elimination, and metabolism and excretion are delayed in the neonate. The current concept is that antimetabolites, especially methotrexate, carry a high risk of teratogenesis, whereas doxorubicin, bleomycin, etoposide, and the vinca alkaloids appear acceptable. The ABVD regimen may be used when chemotherapy is indicated beyond the first trimester. Because chemotherapeutic agents accumulate in the milk, mothers are best advised not to breastfeed during treatment.

Hodgkin Lymphoma in HIV-Positive Patients

Epidemiology and Clinical Presentation

HL is the most common non–AIDS-defining tumor diagnosed in HIV-infected patients. Some reports claim that HIV-associated HL only occurs in patients with high CD4 lymphocyte counts.[206] This goes along well with the observation that at the onset, most HL patients have a perturbed but not depressed immune response and with the fact that HL seldom or never occurs as a consequence of intrinsic or iatrogenic immunosuppression. The impact of HAART on the epidemiology of HL remains unclear.[207]

There are hints that EBV may play a definitive role in the pathogenesis of HIV-associated HL. EBV is found in HRS cells in 80% to 100% of tumors from HIV-infected patients.[208] Tumor cells of most cases of HIV-associated HL express EBV-encoded latent membrane protein 1 (LMP1).[209]

The clinical characteristics differ strikingly from those of HIV-negative HL patients. HL in HIV-infected patients is characterized by the predominance of unfavorable histologic subtypes, mainly mixed cellularity.[210] NSHL occurred less frequently (0% to 40%). The lymphocyte-predominant subtype is rare; in contrast, more than 20% of all cases were classified as lymphocyte depletion.[211]

At the time of diagnosis, 70% to 90% of all patients with HIV-associated HL present with advanced disease. Extranodal involvement is common (60%). The most common sites of involvement include bone marrow, liver, and spleen. In HIV-infected patients, noncontiguous spread of lymphoma can be observed, such as liver involvement without splenic disease or lung involvement without mediastinal adenopathy. Bone marrow involvement occurs in 40% to 50% of patients and may be the first indicator of the presence of HL in almost 20% of cases.[212] HL tends to develop as an early manifestation of HIV infection, at a time when the CD4 cell count is still in a higher range and most patients initially present with persistent generalized lymphadenopathy. Physicians should consider HIV-associated HL in the differential diagnosis of lymphadenopathy in HIV-infected patients.

Treatment

Because of the underlying immune deficiency caused by HIV, treatment of HIV-associated HL is a major problem and may worsen the

status of the patient and increase the risk of opportunistic infections by inducing further immunosuppression. Most patients have been treated with combination-chemotherapy regimens such as MOPP and ABVD as they suffer from advanced stage HL. According to one trial, survival of patients with HIV-associated HL is short, with response rates far less than that of HIV-negative patients with HL.[213] There are reports on the use of reduced-intensity regimens such as epirubicin, bleomycin, and vinblastine (EBV) in combination with antiretroviral therapy (in the pre-HAART era), resulting in better responses and fewer opportunistic infections. Overall survival, however, was not significantly improved.[214] Response rates and overall survival could be improved by full-dose regimens such as EBVP[215] or ABVD[216] in combination with antiretroviral therapy with prophylaxis of the most common opportunistic infections, such as *Pneumocystis carinii*, and the use of G-CSF. Treatment with BEACOPP baseline showed promising results regarding complete remission, toxicity, and median survival while it is discouraged from treating HIV positive patients with the dose intense BEACOPP escalated regimen.[217] Hoffmann and colleagues who analyzed 57 patients with HIV-HL found that the only factors independently associated with overall survival were response to highly active antiretroviral therapy (HAART), complete remission after chemotherapy, and age below 45 years. This resulted in a median survival time of 18.6 months for patients without HAART response, whereas the median survival time for patients with HAART response was not reached (89% OS at 24 months).[218]

In summary, treatment of HIV-associated HL is a great challenge for the specialist in infectious diseases and the hematologist, who should closely cooperate in this demanding task. The combination of not too aggressive but still effective chemotherapy and more effective HAART, prophylaxis of opportunistic infections, and the use of hematopoietic growth factors will probably improve survival of more patients with HIV-associated HL.

SEQUELAE OF TREATMENT

Long-Term Complications of Treatment

Because most HL patients can be cured with modern treatment modalities and can have a life expectancy equivalent to age-matched healthy individuals, it is of utmost importance in the formulation of the treatment strategy to take into account the acute treatment-related toxicities and the long-term side effects of chemotherapy and radiotherapy. In a study analyzing 1261 young HL patients treated before 1987, the relative risk of death from all causes other than HL was 6.8 times that of the general population, and still amounted to 5.1 after more than 30 years.[219] This rate of complications counterbalanced the initial success rates for high numbers of tumor-free survivors and resulted in a late decline of the survival curves due to deaths that were consequences of treatment and not caused by the primary disease.

Modern combined-modality treatment strategies with reduced radiation fields and doses and declining intensities of induction chemotherapy regimens probably will diminish the high rate of late complications. Long-term complications of upper diaphragmatic irradiation include lung, heart, and thyroid dysfunction and secondary cancers of the breast and lung (Table 77–11).

Table 77–11. Long-Term Toxicities after Curative Treatment for Hodgkin Lymphoma

Minor Toxicities
Endocrine dysfunctions (eg, hypothyroidism, hypomenorrhea, amenorrhea, decreased libido)
Long-term immunosuppression
Viral infections (eg, herpes simplex, varicella-zoster, papillomaviruses)
Serious Toxicities
Lung fibrosis from radiation therapy plus bleomycin
Myocardial damage from anthracyclines and radiation therapy
Sterility in men and women
Growth abnormalities in children and adolescents
Opportunistic infections
Psychological problems
Psychosocial disturbances
Fatigue
Potentially Fatal Toxicities
Acute myeloid leukemia, myelodysplastic syndrome
Non-Hodgkin lymphomas
Solid tumors (eg, lung, breast, and colon cancers, sarcomas)
Overwhelming bacterial sepsis after splenectomy or splenic irradiation

Pulmonary Complications

Radiation pneumonitis typically occurs 1 to 6 months after completion of mantle radiation therapy. The overall incidence of symptomatic pneumonitis is less than 5% after mantle field irradiation; patients with large mediastinal adenopathy or combined chemotherapy and radiation therapy have a twofold to threefold greater risk (10% to 15%) of developing this complication.[220] A mild nonproductive cough, low-grade fever, and dyspnea on exertion characterize symptomatic radiation pneumonitis. Radiographically, pneumonitis is characterized by the formation of infiltrates confined to the original radiation fields. Infection rather than pneumonitis is more likely if the infiltrates extend into areas of the lung initially protected from radiation. Severe pneumonitis may require treatment with steroids.

Cardiac Complications

Chemotherapy and radiotherapy have overlapping toxic effects on the heart. Modern treatment strategies avoid large radiation fields and doses and excessive doses of cytotoxic drugs such as bleomycin (eg, alveolitis, pneumonitis, lung fibrosis) and anthracyclines such as doxorubicin (eg, myocarditis, myocardial necrosis and fibrosis, arrhythmias, myocardial infarction, pericarditis, coronary syndrome). These sequelae have become less common but still affect 2% to 5% of patients.[220,221] It was found in a retrospective study analyzing 415 patients who received radiation including the heart or carotid or subclavian arteries, that the rates of clinically significant valvular dysfunction (6.2% at 22 years), especially aortic stenosis, and coronary artery disease (10.4% at 9 years) are higher than expected.[86]

The risk of chronic cardiomyopathy appears to increase as the cumulative dose of doxorubicin exceeds 400 to 450 mg/m^2. It is still unknown whether there is an increased risk of cardiomyopathy at lower cumulative does in patients treated with mediastinal irradiation before or after chemotherapy. Careful cardiac evaluation of patients treated with combined radiation therapy and chemotherapy is recommended because mediastinal irradiation may predispose to accelerated coronary arteriosclerosis, especially when increased doses of anthracyclines are administered.

Secondary Neoplasia

The steady but continuing late decline of the historic survival curves in the second half of the 20th century was mainly attributed to the increasing number of secondary tumors.[219] The increasing radiotherapy associated incidence of secondary malignancies is potentiated by the administration of potentially carcinogenic drugs such as nitrogen mustard, procarbazine, and cyclophosphamide.

The highest incidence of acute leukemia usually spikes within the first 10 years after initial treatment and is reported to range from 2% to 6%.[222–224] The incidence and outcome of secondary acute myeloid

leukemia (AML) and myelodysplastic syndrome (MDS) was also assessed retrospectively in 5,411 patients with HL treated within GHSG studies (1981 and 1998). After a median observation time of 55 months, incidence of secondary AML/MDS was 1%. Most patients were treated with (COPP)/ABVD or similar combinations (n = 30) or with BEACOPP (n = 11). After 24 months of observation, no difference in freedom from treatment failure and overall survival (2% and 8%, respectively) was observed in patients who developed AML or MDS.[224]

The classic form of a treatment-related leukemia is characterized by a relatively long latency period of 3 to 5 years, a preceding myelodysplastic phase, trilineage bone marrow dysplasia, and abnormalities of chromosome 5 and/or 7. Topoisomerase II inhibitors, primarily the epipodophyllotoxins but also anthracyclines when given in combination with alkylating agents, have been implicated in the development of a clinically and cytogenetically distinct form of secondary AML in adult and pediatric patients.[225]

The histologic pattern of NHLs occurring after HL include intermediate-grade or high-grade histology and are similar to lymphomas seen in patients with immunodeficiency diseases or under chronic immunosuppression after organ transplantation or because of autoimmune disorders. These lymphomas have a cumulative risk of 1.2% to 2.1% at 15 years.[226,227]

The incidence of solid tumors in treated HL patients increases with time and does not reach a plateau, even in the second decade after treatment. The causative role of radiotherapy and chemotherapy is debated, but most epidemiologists tend to place greatest blame on the intensive irradiation with large fields and doses higher than 40 Gy. The major risks appear to be lung cancer (mostly in smokers) and breast cancer among women who were irradiated at a young age during the developmental phase of the breast.[228] A recent study of the GHSG with a median follow-up of 72 months, showed that the cumulative risk of a second malignancy is 2% (relative risk for lung cancer, colorectal cancer and breast cancer is 3.8, 3.2, and 1.9, respectively). This figure is expected to increase over time due to the rather short median observation time and slow progression of solid malignancies.[229] Other cancers include sarcomas, melanomas, connective tissue and bone tumors, and salivary, stomach, and skin cancers.[227,230]

A case-control study[231] from a collaborative group of population-based registries and cancer centers that maintains data on 25,665 cases of HL showed that HL patients treated with chemotherapy alone had about twice the risk of developing lung cancer as those treated by radiotherapy alone or with both modalities. Most of these reports may no longer be relevant because of changes in combination-chemotherapy regimens and reduced-intensity irradiation programs.

Gonadal Dysfunction

Loss of libido, sexual discomfort, impotence, and sterility are major problems for young, sexually active HL patients. Because the mean age of the more than 10,000 patients accrued over the past 25 years in the GHSG is 28 years, treatment-related disturbances of sexual function affect approximately 80% of all treated patients and influence the quality of their lives tremendously.

In men, C-MOPP or C-MOPP-like chemotherapy induces azoospermia in 50% to 100% of male patients. This finding is associated with germinal hyperplasia and increased follicle-stimulating hormone levels, with normal levels of luteinizing hormone and testosterone. Only 10% to 20% of male patients will eventually show recovery of spermatogenesis after a long interval. After MOPP alternating with ABVD, the incidence of permanent azoospermia is about 50%. Results of a current analysis show azoospermia in 64%, dyspermia in 30% and normospermia in 6% of men after HL treatment. Azoospermia is more frequent after BEACOPP compared with COPP/ABVD (85% v 63%, $P = 0.029$). A correlation between abnormal FSH level after treatment and azoospermia has been documented. Of note, when ABVD is administered, azoospermia is observed only in a few patients.[232,233] As already reported before,[234] most HL patients (70%–80%) have inadequate semen quality already prior to treatment.[235] Sperm banking before HL treatment has become standard.

In an analysis which included 405 women, menstruation before the beginning of therapy was mostly (90%) regular. After a median follow-up of 3.2 years, 51% of the women receiving 8 cycles of dose-escalated BEACOPP had continuous amenorrhoea. Amenorrhea was significantly more frequent after dose-escalated BEACOPP compared to ABVD, COPP/ABVD or standard BEACOPP ($P = 0.0066$). Amenorrhea after therapy was most pronounced in women with advanced-stage HL ($P < 0.0001$), in those older than 30 years at treatment ($P = 0.0065$), and in women who did not take oral contraceptives during chemotherapy ($P = 0.0002$).[236]

The preservation of fertility in women is complicated. Methods consist of embryo cryopreservation and cryopreservation of oocytes, requiring 10 to 14 days of ovarian stimulation. Live births after cryopreservation of ovarian tissue and orthotopic transplantation have been reported.[237,238] The protection of fertility with the application of GnRH analogues or oral contraceptives during chemotherapy in women has been reported in single case studies and is currently been tested in a randomized clinical trial of the GHSG. There is still no standard cotreatment for the reduction of ovarian failure in young women during treatment for malignant diseases.

Other Complications

Abnormalities of endocrine function often are not detected or are neglected, but they can be very disturbing to patients. Hypothyroidism is a common event, occurring in about 30% of patients after mantle field irradiation, and typically is detected by an elevated level of thyroid-stimulating hormone. Hormone replacement therapy is required. Herpes zoster infection is another complication, occurring in one third of patients of patients treated with radiation therapy or chemotherapy alone, but the incidence appears higher after combined-modality treatment. Early treatment with antiviral agents may limit the intensity and duration of the infection. Acute, transient radiation myelopathy or Lhermitte sign (ie, paresthesias down the dorsal portion of the extremities after neck flexion) occurs in about 10% to 15% of patients after intensive irradiation, but it is seen rarely with reduced radiation doses and fields. This particular complication typically occurs 6 weeks to 3 months after radiotherapy, and its course is self-limited, persisting for weeks to months. Xerostomia is a temporary complication of mantle irradiation; saliva production returns to normal usually within 6 months of treatment. However, xerostomia may be prolonged in older patients, especially after irradiation of the Waldeyer ring. Fluoride supplementation and careful dental care can minimize the risks of developing radiation-related dental caries. Postsplenectomy sepsis can occur, particularly in children,[239] but the risk can be minimized by immunization with pneumococcal vaccine. Vaccines also have been developed against *Haemophilus* and *Neisseria*, the other microorganisms associated with a small but definite risk of developing overwhelming postsplenectomy sepsis.

Quality of Life

Because 80% to 90% of patients with HL can be cured of their disease, it is of great importance for health providers to know that patients are alive and what that their lives are like. Clinicians should aim at assessing the quantity and quality of life of patients.

A review of the pediatric oncology literature by Bradlyn and colleagues[240] demonstrated that only 3% of all randomized clinical trials reported quality of life data. Primarily retrospective analyses of the quality of life of long-term survivors of HL have been performed.[241,242] These analyses showed that a substantial subgroup of patients still suffers serious side effects of the disease and its treatment many years after therapy. To obtain more complete data, quality of life investiga-

tions should be a mandatory component of the clinical trial design and part of the inclusion criteria.[243] Several studies including a quality of life approach have highlighted the difficulties that survivors may experience even long after completion of treatment, including symptoms such as general fatigue, poor health, and social problems.

FUTURE DIRECTIONS IN HODGKIN LYMPHOMA

Generally accessible and innovative experimental therapeutic strategies for HL patients in relapse or with proved or suspected residual disease are being evaluated. Such approaches include immunotherapy with antibody-based regimens for specific targeting of malignant cells and with cellular vaccines. The combination of experimental strategies with chemotherapy seems to offer promise.

Native Monoclonal Antibodies

The CD20 antigen is expressed on all malignant cells in nodular LPHL, and thus may prove to be a good target for treatment with the anti-CD20 antibody rituximab. Two phase 2 trials showed promising results with overall response rates of 86% and 100%.[195,196] In a follow-up study of the GHSG trial, the median time to progression was 33 months while the median OS was not reached yet.[244] Due to these promising results in relapsed patients, the GHSG will start a trial for patients with stage IA LPHL using rituximab as a first-line monotherapy. It has been concluded that rituximab provides safe and effective treatment in a subgroup of patients with $CD20^+$ HL.

Very recently, it was proposed to use anti-CD20 antibodies independently of CD20 expression on the malignant cells with the ultimate aim to target nonmalignant bystander cells and the micorenvironment.[245] In one phase II trial including advanced stage patients (n = 72), the addition of rituximab to ABVD chemotherapy showed overall survival of 100% at a 32 months follow-up. Clinical studies testing this hypothesis have to be performed to add evidence to this experimental approach.

Anti-CD30 antibodies are directed against the mostly H-RS-specific CD30 antigen. Currently, there are two anti-CD30 antibodies under clinical investigation: the humanized chimeric antibody SGN-30 and the fully human antibody MDX-060. Although SGN-30 showed promising activity against CD30-positive H-RS-cells in preclinical tests,[246] Bartlett et al[247] demonstrated only a modest antitumor activity in a first phase 1 clinical trial in 2 of 13 patients without serious side effects. The following phase I/II trial included 24 patients with CD30-positive lymphomas (21 with HL) who received six doses of SGN-30. Five patients with HL showed disease stabilization, and 1 patient suffering from anaplastic large-cell lymphoma (ALCL) achieved a CR.[248] It was speculated that the antibody could be used as a chemosensitizer in future trials.[249] The fully human antibody MDX-060 mediates antibody-dependent cellular cytotoxicity in vitro and xenograft models.[250] No dose-limiting toxicity was found in a phase I/II dose escalation study including patients with relapsed and refractory HL, ALCL, or other CD30-positive lymphomas. In a currently ongoing phase 2 trial, 48 patients have been treated with MDX-060 (40 patients with HL, 6 patients with ALCL, and 2 patients with other lymphomas). CR was observed in two patients (1 ALCL and 1 HL), while 3 patients showed partial response (1 ALCL and 2 HL).[251] Overall, clinical results with anti-CD30 antibodies for relapsed HL patients show some mild antitumor activity but must be considered disappointing to date.

Pfreundschuh and coworkers[252] constructed a CD16/CD30 bi-specific antibody using hybridoma technology, with one arm directed against the CD30 antigen on the HRS cells and with the other arm directed against the IgG-Fc-receptor-III on NK cells. Heavily pretreated patients with refractory HL showed some modest clinical response after intravenous infusions of the CD16/CD30 (A9/HRS-3) antibody.[217,253] Other CD30/CD64 bi-specific molecules have been developed as well.[254] Ten patients were enrolled and were evaluable for toxicity and response. Responses to the H22xKi-4 antibody included one complete remission and three partial remissions. It was concluded that the H22xKi-4 antibody could be given safely and that it showed measurable activity in heavily pretreated patients with refractory HL.

Radioimmunoconjugates

Radioimmunoconjugates are constructed by linking a monoclonal antibody to radioisotopes without significantly altering the immunologic specificity of the protein. The most important advantage of these constructs compared with all other antibody-based therapeutic strategies is that beta particles emitted by radionuclides can kill adjacent tumor cells through a crossfire effect, regardless of whether cells express the target antigen or not.

A phase I trial is investigating the safety of the ^{99}Tc-labeled anti-CD30 antibody Ber-H2 for immunoscintigraphy and possible therapy in patients with refractory HL and large-cell anaplastic lymphoma. Results obtained demonstrate the antibody conjugate is well tolerated and exhibits satisfactory efficacy for imaging purposes. One trial using an iodine-131 conjugated murine anti-CD30 antibody showed 6 responses in 22 patients.[255] Nevertheless, this treatment was associated with severe long-lasting hematotoxicity in seven patients which will make further clinical application difficult.

Vriesendorp and colleagues[256] performed a phase I/II study with ^{90}Y-labeled polyclonal anti-ferritin antibodies for refractory HL followed by autologous bone marrow transplantation. Seven of 17 patients achieved complete remissions lasting 2 to 26 months or longer, and four patients achieved partial remissions of 2 to 6 months. Twelve patients received a reduced dose (20 mCi) because of bone marrow involvement or unsuccessful marrow harvest. Complete remissions were observed in two patients, and partial remissions were achieved in five of them. Response rates were better in patients with small tumor burden. Based on these encouraging results, radioimmunotherapy appears to be a new promising option for relapsed or refractory HL patients, alone or in combination with chemotherapy or immunotherapy, or both, but toxicity is a limiting factor for an application in mostly heavily pretreated patients.

Cellular Therapy

Modulation of EBV-directed T-cell activity may be an immunotherapeutic option for the treatment of HL because approximately 40% of HL cases are positive for EBV. Heslop and colleagues[257] developed EBV-specific cytotoxic T lymphocytes (CTLs) for treatment of EBV-associated lymphoma after bone marrow transplantation. This approach was adopted for EBV-positive cases of HL where autologous EBV CTL lines containing clones reactive with LMP2 were generated in vitro and reinfused into patients.[258] Nine patients with active, relapsed HL and four patients in complete remission after first or subsequent therapy were treated with these autologous EBV-specific CTLs. A 100-fold reduction of EBV-DNA was observed in all patients; in two patients, B symptoms disappeared.[259] Five patients were in a continuous complete remission at 40 months follow-up. Of note is that this approach is limited to EBV-positive HL cases and requires establishment and preclinical testing of autologous cells for each individual to be treated. Considering immunologic approaches, it is noteworthy to mention that vaccination strategies with keyhole limpet hemocyanin (KLH) administered together with autologous anti-idiotype vaccines-similar to current phase 3 trials in follicular lymphoma-are not applicable to HL due to the lack of Ig gene expression in HRS cells.

Small Molecules

The antiapoptotic phenotype is one of the hallmarks of the malignant H-RS cells in HL.[260] It might therefore be promising to target mole-

cules that mediate apoptosis resistance. Among those, cFLIP and XIAP were shown to inhibit the CD95-/TRAIL-mediated and mitochondria- associated apoptosis in H-RS cells, respectively. Compounds that target these molecules are available, but so far only preclinical data are available. Besides the antiapoptotic phenotype, another attractive target to attack in H-RS cells is the NF-KB signaling pathway as NFKB upregulation is one of the characteristic features of H-RS cells. Inhibition of the IKK-IKBa-NFKB cascade, using IKK inhibitors, proteasome inhibitors or direct NFKB inhibitors, might be attempted clinically. Among those, bortezomib (PS-341), a reversible inhibitor of the 26S proteasome, has been shown to be only modestly effective in about 10% of relapsed and refractory HL patients. In any instance, it will be necessary to perform prospective clinical trials with novel compounds to assess their value for the treatment of HL.

NEWER DRUGS ACTIVE IN HODGKIN LYMPHOMA

Vinorelbine is a vinca alkaloid and is a semi-synthetic analog of vinblastine. The main side effect of vinorelbine is myelosuppression. WHO grade 3 or 4 neutropenia occurs in up to 70% of patients, but it has a very short duration and low incidence of infectious complications.[261] Vinorelbine used as single-agent therapy in HL was administered in a weekly schedule at a dose of 30 mg/m^2. Devizzi and associates[262] reported 22 patients with HL refractory or resistant to at least two chemotherapy regimens; 50% (n = 11) showed an objective response (3 complete remissions, 8 partial remissions), with a median duration of 6 months, to therapy with this agent.

Gemcitabine is a derivative of deoxycytidine and thus a pyrimidine antimetabolite with unique metabolic and mechanistic properties among the nucleoside analogs. Although structurally similar to cytarabine, gemcitabine differs pharmacokinetically and pharmacologically. It acts as a competitive substrate for incorporation into the DNA, where it leads to chain termination. Based on the impressive results in solid tumors such as non–small cell lung cancer and pancreatic cancer, gemcitabine was given in a multicenter clinical phase II study to patients with multiple-relapsed or refractory HL who had received at least two prior chemotherapeutic regimens.[263] Gemcitabine was administered in a weekly schedule of 1250 mg/m^2 on days 1, 8, and 15 of a 28-day cycle. An interim analysis of this trial showed an overall response of 39%; of 23 patients, 2 had complete remissions, and 7 had partial remissions. Another 10 patients had stable disease. Myelosuppression was the main toxic side effect. In ongoing trials, classical chemotherapeutic drugs as well as novel compounds including antibodies are tested in various combinations with gemcitabine.

CHAPTER 78

THE PATHOLOGIC BASIS FOR THE CLASSIFICATION OF NON-HODGKIN LYMPHOMAS

Elaine S. Jaffe and Stefania Pittaluga

INTRODUCTION AND HISTORICAL BACKGROUND

The classification of the malignant lymphomas has undergone significant reappraisal over the past 50 years. These changes have resulted from insights gained through the application of immunologic and molecular techniques, as well a better understanding of the clinical aspects of lymphoma through advances in diagnosis, staging and treatment.

Early classifications were based on architectural and cytologic characteristics of the neoplastic elements; however, with increasing knowledge of the complexity of the immune system a more functional approach was sought.[1,2] This attempt was only partially successful, because of the limited array of tools available to the pathologist in the 1970s and 1980s. The integration of immunologic functions with morphologic descriptions of that era was best exemplified by the Kiel classification. The identification of morphologically distinct cell types within normal lymphoid tissue provided a conceptual framework into which malignant lymphomas could be placed and matched with their normal counterparts. However, the proposed differentiation scheme was not always supported by experimental evidence, and despite extensive study, the definition of lymphoid compartments in humans and movement of cells between these compartments still contain many uncertainties. Lymphomas, like most other tumors, are typically classified according to their presumed normal counterpart, to the extent possible. However, there are difficulties in defining the full extent of the neoplastic clone in individual cases of lymphoma, and some well-defined lymphoma types lack obvious normal counterparts. Consequently, although differentiation schemes provide useful conceptual frameworks for understanding lymphomas (Fig. 78–1), and suggest important new lines of research, our current understanding of both the immune system and the lymphomas appears to be inadequate to support a biologically "correct" lymphoma classification. Thus, a classification strictly based on a theoretical relationship of tumors to normal stages of differentiation is both unrealistic and unnecessary for the practical categorization of human lymphomas. Such an approach also overlooks the relationship of molecular pathogenesis to the definition of disease entities.

The International Lymphoma Study Group in 1994 concluded that the most practical approach to lymphoma categorization was to define the diseases that one can recognize with currently available morphologic, immunologic, and genetic techniques.[3] Thus, a lymphoma classification was proposed based on these principles and comprised a list of well-defined disease entities. The REAL classification departed from previous traditional schemes and represented a new paradigm for the classification of lymphomas. Each variant could be distinguished by a combination of morphologic, immunophenotypic, and genotypic analyses, and each was associated with a characteristic clinical behavior, pattern of spread, and response to therapy. In addition it stressed the distinction between histologic grade and clinical aggressiveness and emphasized that histologic grade should be applied within individual diseases and not across the entire spectrum of lymphoid neoplasms. It further noted that the site of involvement (eg, nodal vs extranodal) often was an indicator of important biological distinctions. It stressed that many disease entities are associated with distinctive clinical presentations and natural histories, even though treatment options may still be limited.
