Experience with use of fibrin sealants in patients with hemophilia both as a hemostatic agent and as a promoter of wound healing is growing. Fibrin sealant has reduced blood loss and requirements for factor replacement therapy in major and minor surgical procedures, including circumcisions and dental procedures.[179] Fibrin sealants also have been used successfully to limit hemorrhage from the cavities remaining after percutaneous evacuation of hemophilic pseudotumors (see box on Pseudotumors in Hemophilia).[180–182]

Pseudotumors in Hemophilia

Hemophilic pseudotumors are large encapsulated hematomas that represent progressive cystic swelling from persistent bleeding and incomplete resorption. This serious complication is evident in approximately 1% to 2% of severely affected patients, usually adults. The pseudotumor is composed of clot and necrotic tissue.

Three types of pseudotumors predominate in hemophilia. The most common type arises from repeated hemorrhage and inadequate clot resorption and usually is confined within fascial and muscle planes. Radiologically they appear as simple cysts; infrequently, they expand to involve adjacent structures or erode through the skin layers. The second type involves large muscle groups, such as the gluteus maximus and iliopsoas. These lesions are especially problematic because they may gradually enlarge, develop a fibrous capsule, and eventually destroy adjacent underlying structures by pressure necrosis. Skeletal fractures and bony deformities produced by cortical erosion may result. The third and rarest type of pseudotumor arises from within bone itself, often secondary to subperiosteal bleeding. This lesion typically is observed in the long bones of the lower extremities and pelvis but has been reported to occur within the calcaneus, cranium, and mandible (Fig. 125–5). As the periosteum expands, it is stripped and raised, leading to displacement and erosion of adjacent muscle and bone. Most such pseudotumors arise in adults and occur in proximal skeletal structures; distal lesions occur more frequently in children before skeletal maturity and are associated with a better prognosis.

Pseudotumors are best diagnosed by computed tomographic scanning, magnetic resonance imaging, ultrasonography, and vascular injection studies. Although the presence of one or more progressively enlarging pelvic or skeletal masses in a hemophiliac is consistent with the diagnosis of a pseudotumor, the lesions may resemble osteomyelitis, metastatic neoplasms, Ewing sarcoma, primary osteosarcomas, tuberculosis abscesses, aneurysmal bone cysts, giant cell tumors, or plasmacytomas. Chondrosarcomas and liposarcomas have occurred in such patients. Preoperative biopsy is contraindicated because catastrophic complications, including life-threatening bleeding and infection, are common. Distal pseudotumors respond well to conservative treatment consisting of aggressive clotting factor replacement and cast immobilization. Because conservative treatment has not been nearly as successful for lesions of the proximal musculoskeleton and because complete regression is rare,[180] this approach is reserved primarily for inhibitor patients with high-titer inhibitors. High- and low-intensity radiotherapy regimens have been successful in eradicating pseudotumors in the long bones and may offer an alternative conservative approach.[181] Surgical extirpation is the most effective therapy for pseudotumors and is the treatment of choice when it can be performed in major hemophilia centers. Nevertheless, the operative mortality rate approaches 20%.[182] Depending on the size and location of the pseudotumor, percutaneous evacuation of the cavity and subsequent introduction of fibrin sealant or cancellous bone may be considered.

Orthopedic and Musculoskeletal Bleeding

Occasionally, repetitive bleeding occurs in a single joint despite intensive prophylactic factor replacement therapy and physiotherapy. The synovitis and pain in this "target joint" warrant definitive treatment to prevent progressive degeneration. Prophylaxis (see box on Prophylaxis: The Joint Outcome Study), that is, the infusion of factor concentrate two or three times weekly, may prevent bleeds by maintaining a level of at least 0.01 U/mL, sufficient to prevent spontaneous bleeding. New data support the concept that prophylaxis prevents recurrent bleeds and ongoing joint damage, which may prevent long-term adverse joint outcomes, if initiated early enough.[183] However, if prophylaxis is started after joint damage has occurred (i.e., "secondary prophylaxis"), cartilage destruction may continue, as evidenced radiographically.[184] Because prophylaxis may be difficult to maintain in young children due to complicated venous access and the need for a dedicated individual to perform the infusion, some families have opted for surgery despite the risks and lack of evidence-based data supporting this approach. Among the surgical procedures for chronic hemophilic arthropathy, arthroscopic synovectomy is considered for some children in whom joint damage is increasing and prophylaxis is unsuccessful or impractical, or for adults who prefer not to undergo a major surgical procedure. By contrast, open synovectomy usually is performed in adults with long-standing joint pain and disability.

Standard scoring systems for hemophilic arthropathy, including the Arnold-Hilgartner scale,[97] which measures single joint pathology, and the Pettersson score,[185] which measures multiple joint pathology radiologically, now are used together with MRI,[186] which provides for earlier detection of synovial hypertrophy than possible by physical examination or radiography. MRI is increasingly used in clinical hemophilia management and in prospective outcome studies. Open surgical or arthroscopic synovectomy may reduce the frequency of hemarthroses and reduce pain by removing inflamed tissue and most of the blood vessels in the joint. Synovectomy should not be performed with the sole intent of improving joint mobility, because loss of motion in the affected joint often occurs after surgery. Arthroscopic surgery is increasingly being used to control recurrent bleeds and slow progression of joint disease.[187] In this procedure, thickened synovium is removed, reducing the number and frequency of joint hemorrhages but not the relentless radiographic deterioration.[188] In those with advanced arthropathy, improvement may be transient. The optimal time to perform this procedure is unknown.

An alternative approach, nonoperative synovectomy ("synoviorthesis" or "radionuclide synovectomy"), involves injection of a radioisotope (usually phosphorus-32) into the joint space. The procedure may be appropriate for selected patients to ablate inflamed synovial tissue or for inhibitor patients in whom control of bleeding often is problematic. Although radionuclide synovectomy results in better preservation of range of motion than is obtained with operative synovectomy,[189] it may not eliminate hemarthroses as effectively as opera-

Prophylaxis: The Joint Outcome Study

Prophylaxis, the three to four times weekly infusion of factor to prevent hemorrhages, is considered optimal therapy and is recommended for children as soon as recurrent bleeds in joints occur. A number of studies have demonstrated that, if begun early, when patients are 1 to 4 years old, prophylaxis decreases spontaneous bleeds, arthropathy, joint scores, radiologic abnormalities, and surgical intervention.[207,208] The success of prophylaxis is based on administering factor VIII or factor IX concentrates 25 to 40 U/kg three times weekly for hemophilia A and twice weekly for hemophilia B to achieve factor levels of 1% to 2%, essentially converting a patient with severe disease into one with mild or moderate disease, essentially eliminating *spontaneous* bleeds. Outcomes are correlated with both the intensity of treatment and the level of compliance[209,210] and translate into decreased absence from school or work, fewer bleeds and days spent in the hospital, increased personal and professional productivity, improved overall performance status, and a healthier self-image.[209] Although "prophylactic" treatment was long thought to be more effective than "episodic" or "on-demand" treatment in terms of long-term joint outcomes,[209] no comparison of these modalities were available and this conjecture remained unproven until the "Joint Outcome Study."

A multicenter, prospective randomized trial, the Joint Outcome Study for the first time confirmed that prophylaxis reduces or prevents acute joint bleeds as well as clinical joint damage and is superior to episodic on-demand treatment.[211] Studying a group of 65 children with hemophilia A, the investigators randomized half (n = 32) to receive factor VIII prophylaxis every other day at a dose of 25 U/kg and half (n = 33) to receive intensive episodic treatment in three or more infusions totaling greater than 80 U/kg factor VIII concentrate at the time of each joint bleed. Subjects between the ages of 12 and 30 months were enrolled and were followed to age 6 years. At baseline, each child was required to have two or fewer hemorrhages into any one joint with normal roentgenogram and magnetic resonance MR) imaging studies. Compared with patients receiving episodic treatment, those receiving prophylaxis had 10-fold fewer bleeds per year (0.47 vs 4.9 per year, $P < 0.01$. Moreover, those receiving prophylaxis also had lower joint scores (4.7 vs 8.6, $P < 0.01$). Not unexpectedly, prophylaxis requires a significantly greater total amount of factor and is more costly than episodic treatment: patients receiving prophylaxis used 3.5-fold more factor per year than did those receiving episodic treatment ($P < 0.001$). Thus, this clinical trial for the first time demonstrated the efficacy of prophylaxis, including both acute and intermediate-term benefits. Longer followup is needed to establish long-term clinical and structural joint improvement as defined clinically, radiographically, and by magnetic resonance imaging.

A study of 60 hemophilic children has shown that prophylaxis does prevent long-term radiographic evidence of arthopathy.[212] Furthermore, a case-control study of 100 children with hemophilia A (60 with inhibitors and 40 noninhibitor controls) provides preliminary yet compelling evidence that early initiation of prophylaxis also protects against inhibitor development.[213] No study has provided evidence that prophylaxis, when started early in childhood, increases the incidence of inhibitor antibody formation.

Factor concentrate expense is substantially greater with prophylaxis. Cost may be substantially reduced if the factor is administered by continuous infusion and dosing is based on measured pharmacokinetics.[214,215] In addition to cost, children receiving prophylaxis may develop infectious and thrombotic complications of CVADs,[216,217] which are commonly placed to facilitate access (see Complications of Factor Replacement Therapy). These potential risks may dissuade some families from initiating prophylaxis.[218]

"Primary prophylaxis" (i.e., prophylaxis initiated prior to joint damage and/or recurrent hemarthroses in a target joint) is the preferred "preventive" approach. "Secondary prophylaxis" (i.e., prophylaxis initiated after onset of significant joint damage) may be beneficial in patients reluctant to begin primary prophylaxis. However, it should be recognized that although stabilization of articular function and joint scores may occur over time, reversal of joint damage or radiographic deterioration of previously damaged joints may not be possible.[184]

tive synovectomy. Of considerable concern is the finding that radionuclide synovectomy has been complicated by the occurrence of acute lymphoblastic leukemia in two hemophilic children within 1 year of the procedure.[190,191] Because leukemia rarely, if ever, occurs in hemophilia,[192] longer surveillance will be required before the long-term safety of this procedure is established.

Orthotics may play an important role in management of joint disease, and orthotic intervention can serve as an interim measure before definitive reconstructive surgery. The goal of orthotic intervention is to transform a subluxed, flexed joint into a functional stiff limb rather than a functional articulation. Ankle guards and arch supports are useful in patients with ankle arthropathy and can assist in maintaining and improving gait and weight bearing. Shoe lifts can equalize the lengths of the lower extremities. Otherwise, orthotics are applied most commonly to the knees and occasionally to the elbows. Dynamic braces equipped with adjustable hinges to correct extension deformities of joints with successive, painless manipulations have supplanted traditional plaster casting of the joint with serial extension wedging, which requires anesthesia, is painful, and does not permit active muscle contraction.[193] These methods do not address subluxation deformities; however, promising results have been reported with the Ilizarov apparatus, which applies significant skeletally mediated forces simultaneously in both the subluxation and the extension planes.[193,194]

Pain and deformity that limit mobility, quality of life, and performance status are indications for joint reconstruction. Arthroplasty with prosthetic joint replacement has been performed to restore function in knees, hips, elbows, and shoulders.[195] Improvements in durability and design of joint prostheses allow their use in younger patients, in whom knee prostheses may remain intact for more than 15 years. Prosthetic loosening is observed in hip replacements within 6 to 10 years after surgery and is due to increased stresses on the joint, probably from weight bearing and abnormal torque produced by the ipsilateral or contralateral knee.[196] Staged surgical procedures or multiple joint procedures in a single operative session performed in patients with hemophilia should be considered because the costs of rehabilitation and clotting factor replacement are considerably lower using this approach.[197] An evaluation of orthopedic surgery in HIV-infected hemophiliacs with an absolute CD4 count of 200/μL or less suggests that arthroplasty increases the risk of infection 10-fold, particularly staphylococcal prosthetic joint infection, chronic osteomyelitis, and sepsis.[198] Although not a universal experience,[199] this finding suggests that surgical intervention should be based on the overall balance of risks and potential benefits.

Arthrodesis (surgical fixation) is reserved for painful joints with greatly compromised mobility. Fixation is most commonly performed on the ankle by interposition of autologous iliac crest bone, which fuses the juxtaposed bone surfaces. Fixation of bones into a single, well-aligned unit can be facilitated with intramedullary nails or external fixators; however, pin site infections may occur in up to 10% of patients. Arthroscopic ankle arthrodesis has been developed using demineralized bone matrix–bone marrow slurry as a graft substitute. Although this approach has not yet been widely applied for hemophilic arthropathy, it has the potential to obviate open surgery and reduce the need for factor replacement.[200] Ankle fusion allows patients good mobility in normal shoes because the joints of the feet and toes are less commonly affected by bleeds, and the pain and frequency of hemarthroses are markedly diminished. Supramalleolar varus osteotomy may be a useful alternative in hemophilic arthropathy with secondary valgus deformity.[201]

Intramuscular Hematoma

Approximately 30% of bleeding episodes in persons with hemophilia occur in muscles. Although most intramuscular hematomas are trivial and resolve spontaneously, some produce significant morbidity and, depending on their location and size, can lead to death. Intramuscular bleeds occur less commonly than hemarthroses and usually are not life threatening. The most serious hematomas occur in the iliopsoas muscle or retroperitoneal space, where bleeding can be profuse. These lesions can mimic hip hemarthroses and appendicitis. Large hematomas can produce fever, neutrophilia, ecchymoses, hyperbilirubinemia, and elevated lactate dehydrogenase levels. They may be painful and may impair the sensory and motor function of adjacent nerves, which they entrap and compress. Occasionally, flexion contractures involving muscles innervated by these nerves develop (e.g., in the hip). Muscle bleeds are precipitated by incidental trauma in severe hemophilia and by more significant degrees of trauma in moderate or mild disease (e.g., contact sport injuries). Iatrogenic hematomas may form in association with intramuscular injections of medications (e.g., vaccines) and can be prevented by administering replacement clotting factor beforehand. All significant muscle bleeds should be treated aggressively to raise the factor level above 50% of normal.

Mucous Membrane Bleeding

Although fatal gastrointestinal tract bleeding was a greater problem before the introduction of factor concentrates, significant hemorrhage occurs in 13% of adult patients with hemophilia.[202] Gastric mucosal bleeding has become more common in recent years with the increased use of NSAIDs for treatment of painful hemophilic hemarthropathy. NSAIDs have supplanted aspirin as the major cause of this complication. In patients with hemophilia, aspirin in any form should be avoided altogether and NSAIDs prescribed judiciously for limited time periods under strict medical supervision.

Hemorrhagic complications of portal hypertension in long-term survivors of viral hepatitis have occurred more commonly as hemophilia patients have lived longer. Massive, life-threatening melena and hematemesis can result from esophageal varices in patients with hemophilia complicated by portal hypertension. Sclerotherapy at the site of bleeding varices has been successful for treatment of gastrointestinal bleeding, as has the transjugular intravenous portal vein–systemic shunt procedure for decompression of varices, and probably is safer than aggressive open surgical procedures. In selected patients, orthotopic liver transplantation offers another option for treatment of symptomatic portal hypertension complicating terminal liver failure. This approach has the additional advantage of providing a cure of the underlying hemophilia by restoring normal coagulant factor synthesis.[155–157] Gastrointestinal blood loss in a patient with hemophilia demands an exhaustive evaluation for anatomic lesions, as in any other patient.

Bleeding from the mucous membranes of the nose and mouth is common in hemophilia. Posttraumatic tongue bleeding must be treated aggressively to prevent progressive airway obstruction, which can develop rapidly. In infants, the frenulum is a frequent site of bleeding, and as the hemophilic child grows older, the loss of deciduous teeth and the eruption of secondary dentition can be complicated by prolonged bleeding. Fortunately, these episodes usually respond well to antifibrinolytic agents (e.g., ε-aminocaproic acid, tranexamic acid) or fibrin sealants without factor replacement. Factor replacement may be required for more difficult cases. For major dental surgery, particularly those necessitating nerve blocks, factor replacement to achieve 15% to 25% of normal activity should prevent bleeding into the tissue planes of the neck, which can lead to respiratory embarrassment. In mild hemophilia, intranasal or subcutaneous/intravenous DDAVP is an excellent choice, with or without antifibrinolytics or fibrin sealants. Spontaneous epistaxis is relatively uncommon without an anatomic lesion or trauma. Nevertheless, it may necessitate factor replacement, packing, cauterization, or fibrinolytic therapy. Urologic bleeding is common in patients with hemophilia[203–206] and usually is spontaneous, episodic, and painless. In addition to factor replacement, fluid intake should be increased. If bleeding is protracted and severe, a short course of steroids may be helpful. If the hematuria is caused by nephrolithiasis, extracorporeal shock lithotripsy can be performed safely under coverage of factor replacement.

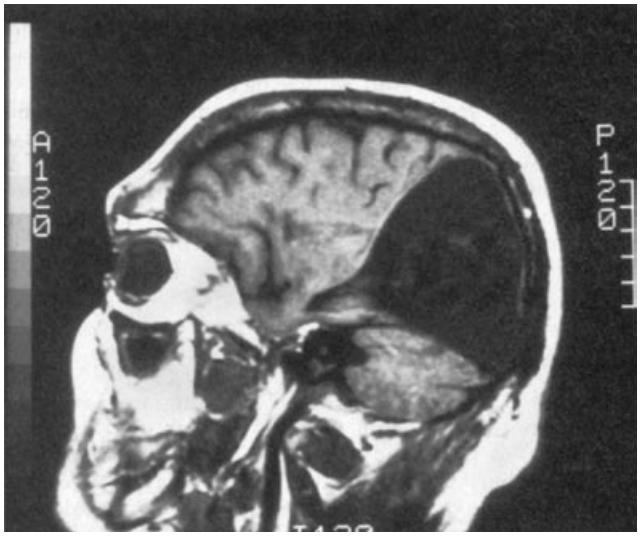

Figure 125–5 Massive pseudotumor resulting from repeated intracranial hemorrhage in a patient with hemophilia.

Complications of Factor Replacement Therapy

With the virtual elimination of pathogen risk through the introduction of recombinant factors and the chemical and physical inactivation of plasma-derived and recombinant clotting factor products, the major complications of hemophilia are spontaneous life-threatening and disabling central nervous system (CNS) bleeds, inhibitor formation, and central venous access device (CVAD) infection. Currently, individuals exposed to HIV and HCV through infusion of blood products represent approximately bout 40% and 80% of adults with hemophilia, whereas those younger than 20 years remain free of HIV or HCV.[145] With the introduction of HAART, HIV infection is a chronic treatable disease, with a life expectancy in patients with hemophilia similar to that before the HIV epidemic (Fig. 125–5).[35,36,43,219] Among patients with hepatitis C, fibrosis and cirrhosis may occur in 20% or more of patients and up to twofold or more higher among those who are HIV positive. Several large prospective studies, including the HHH (Impact of HIV on Hepatitis C Infection in Hemophilia A), will determine the incidence of fibrosis and end-stage liver disease, comparing HIV-negative with HIV-positive subjects. Hepatitis C remains the major cause of morbidity and the leading cause of death among individuals with hemophilia.[135] Nearly all patients with HIV infection are coinfected with HCV, and HIV upregulates cytokines that increase liver fibrosis and progression to end-stage liver disease. Among coinfected patients with end-stage liver disease, liver transplantation, which effects phenotypic cure of hemophilia, now is considered safe and effective.[150]

CNS bleeding, including intracranial hemorrhage[220] (see Fig. 125–3) and soft-tissue hemorrhage in or around vital areas such as the airway or internal organs, is particularly life threatening in patients with hemophilia. The estimated lifetime risk of intracranial hemorrhage, based on clinical presentation, has been reported to be 2% to 8%. After HCV and HIV infections, intracranial hemorrhage constitutes the third leading cause of death among individuals with hemophilia.[145,221] Clinically, early signs of CNS bleeding may include headache, nausea and vomiting, and increased sleepiness, which, if missed, may delay treatment and worsen outcome. Psychomotor retardation, cerebral palsy, and/or seizures may occur in a substantial proportion of patients; the most common inciting event is trauma, including birth trauma.[222] In a longitudinal study of children with hemophilia, in whom the prevalence of intracranial hemorrhage was assessed by both clinical surveys and radiologic imaging (head MRI), the combined rate of symptomatic and silent intracranial hemorrhage was 12%.[223] However, this figure may underestimate the true frequency, as a significant fraction of cases of intracranial hemorrhage diagnosed by MRI are clinically silent[223] (see box on Intracranial Hemorrhage in Hemophilia).

Intracranial Hemorrhage in Hemophilia

Intracranial hemorrhage is the third leading cause of death in patients with hemophilia, after hepatitis C and HIV infection.[145,221] This complication develops in 10% of patients with severe hemophilia, with a mortality rate greater than 30%. Survivors have a significant incidence of psychoneurologic sequelae, including mental retardation, seizure disorders, and motor dysfunction. Because even minimal trauma to the head may precipitate severe hemorrhage and serious intracranial pathology, aggressive treatment with clotting factor concentrates should be initiated immediately to achieve 100% levels of factor VIII or IX, *even if there is only a clinical suspicion of bleeding.* Replacement therapy should precede any diagnostic procedures because less than 5% of acute head injuries in hemophiliacs are accompanied by early abnormalities on computed tomographic scan.[220] When intracranial injury is demonstrated on computed tomographic scans, neurologic deficits, vomiting, or altered mental status is apparent on physical examination. Neurosurgical intervention may be necessary but carries high risks despite maintenance of adequate hemostasis with clotting factor concentrates.

Intracranial hemorrhage in the neonate is invariably preceded by mild to moderate head injury. The risk of serious bleeding associated with vaginal delivery is small, but vacuum extraction has been associated with subgaleal bleeds (Fig. 125–3) and should be avoided when delivering offspring of known hemophilia carriers. In hemophilic adults, CNS bleeding may arise in individuals with hepatitis C and end-stage liver disease associated with portal hypertension and thrombocytopenia or in those with HIV-associated immune thrombocytopenia. However, the latter is responsive to HAART. The risk of CNS bleeding in patients with hemophilia increases when the platelet count falls below 50,000/μL, likely in association with factor VIII or IX deficiency. For this reason, regular (every other day) treatment with factor is recommended to prevent CNS bleeding.[240]

Factor VIII inhibitors alloantibodies directed at infused factor VIII or, less commonly, factor IX are the major noninfectious complication of factor replacement. These IgG antibodies typically occur after a median of nine factor exposures and at a median age of 2 years.[224] They are more common in patients with severe disease and in Caucasians, although the prevalence is twofold higher among African Americans with hemophilia.[224] Inhibitor formation has been linked to genetic factors, including large deletion phenotypes, African American race, and familial occurrence. However, the nonconcordance of inhibitor formation in brother studies suggests that nongenetic factors play an important role. Several small studies have reported that the earlier[225] and the more intense[213,226,227] the exposure to factor VIII, the greater the likelihood of inhibitor development in patients with hemophilia A. These findings will require prospective studies for confirmation. Because inhibitor patients are difficult to treat, they have greater associated morbidity and a somewhat shorter life expectancy than do noninhibitor patients.[228]

CVADs are widely used in children with hemophilia for factor infusion to prevent joint bleeding (prophylaxis) and for induction of immune tolerance. Yet, despite the potential benefits of these devices, their use is complicated by CVAD infection, which accounts for significant cost, morbidity, hospitalization, sepsis, and sepsis-related deaths. From 30% to 40% of patients receiving prophylaxis may develop CVAD infection,[216] with an incidence of 0.66 per 1000 CVAD days.[229] The rate of CVAD infection appears to be related to the frequency of access, with twice as many infections occurring in patients undergoing daily tolerance induction versus prophylaxis three to four times per week.[216,229,230] Increasing evidence suggests that

small clots propagated in CVADs by frequent factor infusion serve as a nidus for surface bacteria and propagate CVAD infection.[231] An alternative to standard ports for venous access in children with hemophilia is use of arteriovenous fistulae. In a 3-year study of 27 hemophilia patients, half of whom had inhibitors, proximal forearm fistulae were well tolerated, although thrombosis occurred in one and inadequate AVF maturation occurred in five with inhibtors.[232] Whether arteriovenous fistula placement will prove to be a practical alternative approach to venous access is not known.

Hemophilia as a chronic disease has been recognized to affect the physical and cognitive growth of affected children independent of HIV serologic status. Data from the United States indicate that a significant proportion (approximately 25%) of hemophilic children 6 to 18 years old exhibit below-normal performance in motor skills, lower-than-expected academic performance (measured by IQ scores), and more behavioral and emotional problems than expected, as reported by parents.[233] The presence of HIV and the absolute $CD4^+$ counts were not related to neuropsychological performance at baseline. Causality has not been established, but the potential contributions of minimal head trauma with clinically silent bleeding and the effects of hemophilia on the emotional well-being of the family cannot be overlooked.

The major cause of death in individuals with hemophilia is liver disease, followed by HIV disease and CNS bleeding.[145,219] Only rarely do individuals with hemophilia or hemophilic carriers develop or succumb to myocardial infarction or stroke.[219,234] Of note, only approximately 20% of the expected number of deaths from cardiovascular disease occur, suggesting a protective effect of hemophilia A.[41,228]

Prognosis

Before the widespread use of replacement therapy, the prognosis for patients with severe hemophilia was poor and their quality of life greatly diminished. The outlook improved dramatically in the modern era of hemophilia treatment, beginning in the 1960s with the development of cryoprecipitate,[235] factor VIII concentrates[236] (for hemophilia A), and prothrombin complex concentrates[237] (for hemophilia B). It then became possible to achieve high levels of factor VIII or factor IX without volume overload, which limits plasma therapy. This advance permitted effective therapy for life-threatening soft tissue bleeding, which requires high doses of factor VIII or factor IX for prolonged periods. Furthermore, the convenience of factor concentrates made home therapy of hemarthroses practicable. Use of lyophilized factor concentrates administered at home saved many patients from the delays, expense, and inconvenience of hospital- or clinic-based treatment with cryoprecipitate or plasma. The availability of factor concentrates facilitated prophylactic therapy, which has been shown to virtually eliminate bleeding episodes and actually prevent joint deterioration, especially when started early in life (i.e., at age 1–2 years)[207] (see box on Prophylaxis: The Joint Outcome Study[184,208–212,218]).

Many large studies documented the dramatic gains in life expectancy of patients with hemophilia during the era of replacement therapy. The life expectancy of patients with severe hemophilia, which had remained relatively constant from the nineteenth century to the 1960s, has risen from 11 years (or less) for severely affected patients up to 50 or 60 years by the early 1980s in reported series.[16,18,22–26,35,238,239] Significant progress has been evident even in patients with mild or moderate disease, for whom life expectancy is closer to that for the normal population in the pretreatment era (Fig. 125–6).

With the efficacy of prophylaxis in reducing the frequency of joint hemorrhage demonstrated in a randomized clinical trial[183] (see box on Prophylaxis: The Joint Outcome Study), primary prophylaxis is expected to become a more acceptable approach to treatment. Accordingly, chronic orthopedic disability resulting from progressive hemophilic arthropathy and the associated social and economic consequences should become less common. Results of a study of U.S. boys 6 to 12 years old with factor VIII levels less than 2% of normal indicate that those on prophylactic treatment regimens had higher total academic achievement and mathematical scores than those receiving "on demand" treatment.[241] The superior academic performance was associated with less absenteeism, which was correlated with less frequent bleeding episodes per year (6 vs 25) and better scores on the Physical Summary aspect of the Child Health Questionnaire (48.4 vs 41.3). These findings make a case for prophylactic treatment as a method by which children with hemophilia can reach their full academic and physical potential.

Significant impairment of physical stature and sexual maturation has been observed in HIV-infected boys with hemophilia compared with uninfected boys or population norms.[242] The discrepancy between total serum testosterone levels (compared with age-adjusted levels in HIV-uninfected boys) and observed physical changes arises as a result of HIV infection and the impact on the immune and endocrine systems; thus, the effects are potentially reversible with HAART.

The combined morbidity and mortality associated with hemophilia and its treatment constitute a powerful argument for prophylactic treatment, development of safer concentrates, elimination of inhibitor antibodies when they occur, and gene therapy, which currently is the only prospect (other than liver transplantation) for the cure of hemophilia.

Gene Therapy

Gene therapy or, more correctly, gene transfer can be defined as the clinical delivery of gene constructs whose expression compensates for a missing protein.

Hemophilia has attracted a great deal of attention from investigators interested in gene therapy for several reasons: (a) the complementary DNAs (cDNAs) have been cloned,[243,244] (b) fully functional factor VIII and factor IX may be produced in various cell types if the correct posttranslational modifications are made and the protein is delivered to the circulation, and (c) the amount of factor VIII or factor IX required to improve the bleeding phenotype can be as little as 1% of normal plasma levels. There may be some margin for error with regard to overexpression due to regulation of factor VIII/factor IX enzyme activity by anticoagulant proteins C and S and antithrombin III. Although elevated factor VIII or factor IX levels may be risk factors for thrombotic diseases,[245,246] it seems unlikely that prolonged superphysiologic levels of factor VIII or factor IX would ensue from current gene transfer technology. Factor VIII and factor IX knockout mice[247–250] and spontaneous hemophilia A and B dog colonies[67,68,251–253] have facilitated preclinical gene therapy development. It also has proved possible to detect epitope-tagged human factor VIII[254] or normal human factor IX[255–258] in normal rhesus monkeys after gene transfer with various vectors, which permits testing of gene transfer vectors in nonhuman primates.

Skin fibroblasts or keratinocytes, readily obtained and easily transduced by gene transfer vectors, may be reintroduced to the patient for delivery of the secreted protein to the bloodstream. Therapeutic levels of factor IX or factor VIII have been achieved in rodents using this approach.[259–264] A recurring problem is the lack of sustained expression of factor VIII or factor IX, which may be due to cell-mediated immunity or promoter shutdown in implanted cells.[265] Factor VIII-transfected skin fibroblasts reimplanted in the omentum of hemophilia A subjects in a phase I trial achieved levels that were only marginally therapeutic and were not sustained.[266]

Gene transfer to muscle cells can be performed ex vivo or in vivo, although the latter approach is more practical because of the lack of suitable human muscle cell lines that can be used in immune-competent humans.

The most successful application of in vivo gene therapy has been gene transfer with adeno-associated virus (AAV) vectors. AAV vectors can transfer only DNA with a total length of less than 4.5 kilobases, which is sufficient for factor IX gene transfer but not for factor VIII gene transfer. In vivo preclinical studies with AAV vectors in hemo-

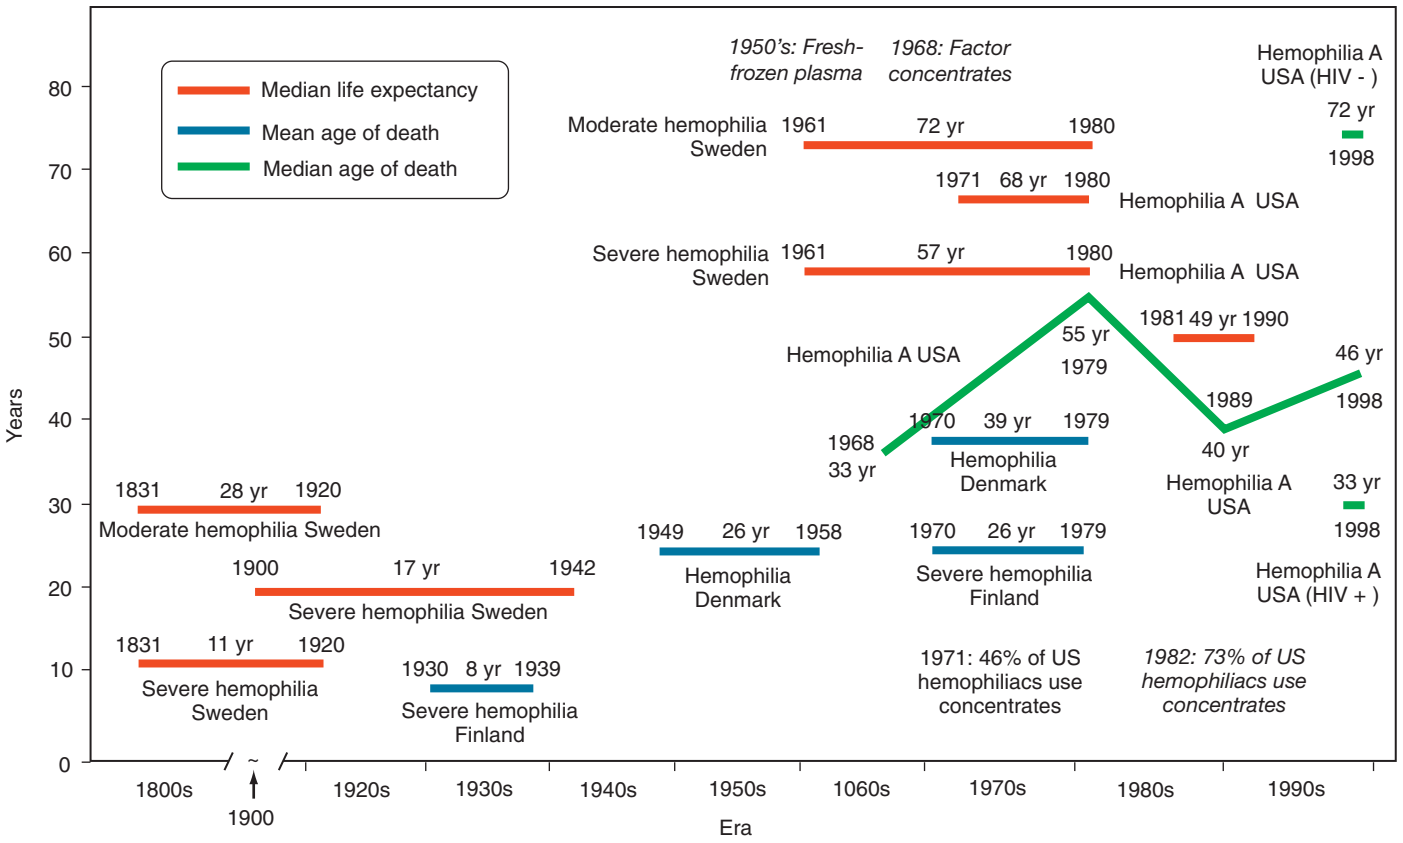

Figure 125–6 Effect of therapy with plasma and plasma-derived factor concentrates on the prognosis of hemophilia. The natural history of hemophilia in the era before the advent of effective therapy is documented in the Scandinavian data from the nineteenth and early twentieth centuries. Progress is seen beginning in the 1950s and 1960s with the introduction of plasma, cryoprecipitate, and factor concentrates. The effect of human immunodeficiency virus (HIV) infection on life expectancy in the 1980s is especially pronounced in the United States, where nearly all patients with severe hemophilia received concentrates made from pooled contaminated plasma. The subsequent elimination of HIV and hepatitis virus from factor concentrates has permitted their use, with minimal risk for viral infection. The median age at death for patients with hemophilia in the United States has risen, from a local nadir of 40 years in 1989 to 46 years as of 1998. The dramatic effect of HIV infection is apparent when the data for HIV-seropositive and HIV-seronegative patients in the United States are compared.

philia B knockout mice and hemophilia B dogs have shown that clinically relevant levels of factor IX in the plasma can be achieved for sustained periods using this approach.[267–274] A key problem directly related to the use of muscle as a target for gene transfer has been poor delivery of recombinant factor IX from muscle into plasma because of binding of factor IX by type IV collagen.[275] Clinical trials of AAV factor IX gene transfer in vivo targeting muscle have demonstrated therapeutically significant plasma factor IX levels (approximately 1% of normal) at doses of 2×10^{11} vector genomes per kilogram of body weight.[276] Although the trial was an open label study and a placebo effect cannot be excluded, patients did report a lower frequency of joint bleeds.[266] Fortunately, there were no inhibitors or other safety issues in these subjects.[277] However, long-term followup of these patients and two subsequent groups receiving threefold and ninefold higher vector doses, although not associated with toxicity or inhibitor formation, showed no improvement from the initial results.[278] Levels greater than 1% are unlikely to be achieved with higher doses because the volume and number of intramuscular injections become impractical.

Hepatocytes, which synthesize plasma proteins including factors VIII and IX as well as albumin, may be transduced by various vectors. As with muscle cells, hepatocytes are not easily propagated ex vivo, but in vivo gene transfer has been accomplished in animals using adenovirus, AAV, and retrovirus vectors. Adenovirus vectors are capable of high-efficiency factor VIII or IX gene transfer to hepatocytes in vivo in mice,[279–291] monkeys,[254,256,257] and hemophilic dogs,[292–296] although this is limited by the lack of integration of the vector DNA into the target cell DNA and gradual loss of gene expression. Adenovirus vector proteins may be toxic by inducing the cytokine cascade,[297] which may be immediately toxic to the recipient, by removing transduced cells by cell-mediated immunity, and by inducing the formation of antibodies to the expressed gene.[256,293,294,298] Based on the observation that removal of adenovirus genes may permit longer periods of gene expression and reduced immune response,[298] gutted adenoviral vectors (most of the adenovirus genes deleted) have been tested for hemophilia gene therapy[284,287,299–301] but are limited by problems in large-scale production. Clinical use of adenovirus vectors also is limited by the common presence of neutralizing antibodies in the population and the likelihood of subsequent anamnestic response with repeated administration of the vector.[302]

AAV-mediated factor VIII gene transfer to liver has been performed in animals[303–305] but because of size constraints of vector DNA packaging, AAV gene transfer to liver has focused primarily on factor IX. In vivo gene transfer of factor IX by intravenous, portal vein, or hepatic artery injection of AAV vectors has resulted in expression of factor IX in mice,[306–314] dogs,[307,315,316] and nonhuman primates.[258] However, although transient therapeutic levels of factor IX (>10% of normal) were achieved in hemophilia B patients for up to several weeks,[317] levels were not sustained, coincident with immune-mediated elimination of vector-transduced hepatocytes as evidenced by asymptomatic liver transaminase elevation and T-cell reactivity to AAV capsid proteins.[278,317] Vector shedding in the semen was detected in several subjects but was asymptomatic and transient[318] and was not predicted in animals.[319] Thus, even if reasonably safe, repeated

administration of AAV-factor IX vector is hampered by the humoral immunity to vector capsid proteins.

Although long-term expression of clotting factor and phenotypic correction of hemophilia A and B have been accomplished in animal models of hemophilia by retroviral vector given systemically,[320] in bone marrow stromal cells, epidermis, or rapidly dividing hepatoycytes,[321] and by AAV vector in skeletal muscle[278] and in mature hepatocytes,[317] long-lasting expression has not been accomplished in humans.[278,317,320] Some of the new gene transfer approaches being developed in murine hemophilia models include assessment of transient cytotoxic suppression of the acute humoral response to AAV-mediated gene transfer, induction of immune tolerance to factor IX by hepatic gene transfer,[322] factor VIII-targeted expression in megakaryocytes,[323] and endothelial targeted factor VIII expression by a sleeping beauty transposon.[324] Gene therapy in hemophilia will become practicable when the emerging issues of vector safety, vector immune response, and inhibitor antibody formation are eliminated and optimal levels of transgene expression are determined. Differing approaches to gene transfer likely will be needed in hemophilia (e.g., hepatocyte-directed gene transfer might be avoided in patients with underlying liver disease).

Interest continues in the development of factor VIII and factor IX products with lower immunogenicity, longer duration, and greater efficacy. A number of potential new products are in the pipeline, including substituted or mutated factor VIII A2, C2 immunogenic epitopes to reduce inhibitor formation[325] and pegylated factor VIII molecules of longer duration.[326] There Progress is being made with regulation of protein expression (when gene transfer becomes a reality), including use of silencing mRNA that allows for transcription correction or enhanced functional factor IX production.[327]

CHAPTER 126

INHIBITORS IN HEMOPHILIA A AND B

Ara Metjian and Barbara A. Konkle

Patients with factor VIII deficiency (hemophilia A) or factor IX deficiency (hemophilia B) are at risk for developing neutralizing antibodies after receiving factor replacement therapy. Patients with severe factor VIII deficiency (<1%) are particularly at risk. With the availability of plasma-derived and recombinant replacement products safe from transmission of known infectious agents, the development of inhibitors has become the major complication of hemophilia treatment.

Inhibitor formation in hemophilia was first reported in 1941.[1] A 44-year-old man with classic hemophilia had been treated numerous times with blood products, and his coagulation time subsequently became refractory to transfusions. The authors realized that transfusion may have caused this heretofore unknown complication and suggested that coagulation times should be checked after administration of blood products to monitor for the phenomenon. This report soon was followed by numerous cases[2–5] reporting the development of a substance that counteracted infused blood product components. The nature of the inhibitor was shown to be an IgG antibody of the IgG4 subclass.[6]

HEMOPHILIA A

Epidemiology

The formation of inhibitors is more common in hemophilia A than in hemophilia B.[7] In hemophilia A, the severe phenotype most often is due to a null mutation, which is less common in hemophilia B. Null mutations result in a complete absence of the protein product and are more likely to predispose to inhibitor formation. Second, factor IX shares significant homology with the other vitamin K-dependent clotting factors, possibly protecting against inhibitor development.[8] Finally, it is hypothesized that because factor IX is a smaller and more abundant protein than factor VIII, enough protein may cross the placenta to induce tolerance in the developing fetus.[8]

Patients with severe hemophilia are at highest risk for inhibitor formation. Among those with hemophilia A, approximately 30% of patients with severe disease will develop an inhibitor versus 3% of those with moderate hemophilia and 0.3% with mild hemophilia.[9] Inhibitor formation occurs early after initiation of replacement therapy. Data from prospective clinical trials of recombinant factor VIII reveal that inhibitor development typically arises within a median of 8 to 10 exposure days, but a wide range is not uncommon.[10] The risk of inhibitor development decreases with more days of treatment and is extremely uncommon after 150 exposure days. For patients with mild or moderate disease, inhibitors are reported to develop after periods of intense replacement, during times of surgery or other "inflammatory states."[9]

Both genetic and environmental factors place individuals at risk for inhibitor development (Table 126–1). Family history of inhibitor formation, race, and underlying mutation resulting in the hemophilia are important genetic risk factors. Among many studies, the Malmö International Brother Study, which examined the genetics of monozygotic and dizygotic twins and of brother pairs, found an inhibitor rate that was higher than could be explained by chance alone. Having a first-degree relative with an inhibitor raised the risk of inhibitor development threefold, resulting in an approximately 50% chance of inhibitor development compared to a baseline 15% risk.[11,12]

Patient race as a risk factor was first noted in studies examining the prevalence of inhibitors.[13] In the prospective recombinant factor VIII trials, African Americans were observed to have twice the rate of inhibitor formation compared to Caucasians. In a retrospective survey, Latinos were observed to have a trend toward a higher prevalence rate. Although no definitive genetic cause has been identified, this observation implicates a broad genetic mechanism in inhibitor formation.[14,15]

The type of mutation is an important factor in inhibitor formation.[8] Three general categories of mutations in factor VIII place a patient at "high risk" for inhibitor formation: (a) inversions of intron 22, (b) large deletions affecting more than one domain, and (c) nonsense mutations involving the light chain.[7] These mutations either eliminate circulating factor VIII or alter exposed areas on factor VIII to make exogenously administered factor VIII appear "foreign."[16] The "low-risk" mutations consist of small deletions/insertions, missense mutations, and splice site mutations. It has been postulated that these mutations, although significant enough to diminish the coagulant activity of factor VIII, even to undetectable levels by our current clinical assays, allow generation of enough endogenous factor VIII such that tolerance can be achieved.[7]

Despite the strong genetic influences that underlie inhibitor formation, there exist clinical observations of an environmental pressure for the creation or inhibition of inhibitors. First, the Malmö International Brother Study cohort contains discordant monozygotic twins (i.e., identical twin brothers with the same mutations) of which only one brother developed an inhibitor.[17] Second, among the high-risk mutations, only 30% to 35% of patients with hemophilia and the intron 22 inversion form inhibitors. Even with multidomain deletions, the highest estimated risk approaches 75%,[18] implying other patients with the same mutation are somehow protected against inhibitor formation.

Age at first treatment has been evaluated as a risk factor for inhibitor development, and a relationship with earlier exposure to factor VIII-containing products and the development of inhibitors has been observed.[19–22] This is in contrast to a case-control study that observed an initial trend toward an increase in inhibitor formation in children who were treated at a younger age. However, when the severity of the genetic mutation was factored into the analysis, it ceased to be statistically significant. In fact, there appeared to be a protective effect against the formation of inhibitors when children were started on prophylaxis early in life.[23]

The method of factor VIII infusion in provoking an alloimmune response is another matter of speculation. Administration of factor VIII via continuous infusion has the advantage of requiring less factor replacement and avoiding the peaks and troughs seen with bolus intravenous administration.[24] However, intense replacement of factor VIII, especially in the form of a continuous infusion, has been observed to provoke the generation of inhibitors in patients who are otherwise considered to be at low risk.[25,26] This usually is seen in patients with mild hemophilia A who are undergoing surgery. These patients have less historical exposure to factor concentrate, which could place them at higher risk for inhibitor development when exposed to concentrate.[27]

Table 126–1 Risk Factors for Inhibitor Formation

Established Risk Factors	Possible[a]
Type (hemophilia A > hemophilia B)	Age at first exposure
Severity (severe > mild/moderate)	Type of factor concentrate (plasma-derived vs recombinant factor VIII)
Underlying mutation (e.g., intron 22)	Method of infusion (continuous vs bolus)
Race (African/Latino > Caucasian)	Prophylaxis vs on-demand
Family history	

aConflicting results reported in the literature.

The most controversial "environmental" factor is the type of factor VIII concentrate used, low-/intermediate-purity plasma-derived factor VIII versus high-purity plasma-derived factor VIII or recombinant factor VIII, in inhibitor formation. For more than 15 years, the debate on whether recombinant factor VIII leads to a higher inhibitor incidence remained largely unresolved.[28,29] This originated with the prospective trials of first-generation recombinant factor VIII in previously untreated patients. Part of the trial design consisted of frequent monitoring for inhibitor formation at least every 3 months.[30,31] In the Kogenate trial, the total incidence of any inhibitor formation in patients with severe hemophilia A was 29.2% within a median of 9 exposure days.[32] A similar inhibitor incidence rate of 31.5% was found in a prospective trial of Recombinate.[33] Thus, compared to historical values and older retrospective studies that used low-/intermediate-purity plasma-derived factor VIII with reported rates of approximately 10%,[34] recombinant factor VIII appeared to be more immunogenic.

A number of factors likely account for this observation. The recombinant factor VIII trials of previously untreated patients were the first large prospective clinical trials of hemophilia treatment, so their comparison to anecdotal or retrospective case reports and case series is largely untenable.[30–33] The trials of previously untreated patient were also the first to monitor routinely for the development of inhibitors prospectively. Prior to this study, historical references tested for inhibitors only when clinically indicated, and even then testing was performed twice yearly at most. Prospective monitoring of patients receiving high-purity plasma-derived factor VIII revealed a similar inhibitor rate.[35] Continued analysis of the recombinant factor VIII trials results showed that almost half (11/23) of the inhibitors in the Kogenate trial were transient in nature, decreasing the prevalence of inhibitors upon extended observation.[32] A similar pattern was observed in the Recombinate trial, in which alloantibodies disappeared in 14 of 22 study subjects who had developed an inhibitor, even with continued treatment, reducing the prevalence rate to 11.1%.[33] The older studies likely missed these ephemeral inhibitors.

Potential causes of increased immunogenicity of factor VIII products include neoantigen formation during manufacturing and, among other variables, the absence of von Willebrand factor (VWF), which is present in low-/intermediate-purity plasma-derived factor replacements.[21,36] New factor VIII concentrates can be immunogenic, as in the case of a double virus inactivated factor VIII product that was used in Belgium[37] and two new plasma-derived factor VIII products that were used in the Netherlands and Belgium.[38,39] However, when currently available factor VIII products were given to previously treated patients, the rate of inhibitor formation has been low, confirming low immunogenicity in this setting.[40]

The role of VWF in the factor concentrate is under study. Compared to historical controls using VWF-containing concentrates, lower response rates of immune tolerance have been reported with use of recombinant factor VIII than with use of VWF-containing plasma-derived factor VIII.[41] Goudemand et al.[21] reported a 2.5- to 3-fold increased risk for inhibitor generation when recombinant factor VIII was used. A possible mechanism is that VWF protects factor VIII from endocytosis by dendritic cells and subsequent presentation to factor VIII-specific T cells.[42]

Pathobiology

Circulating antigens initially are taken up by antigen-presenting cells.[43] These proteins undergo proteolysis, and the digested peptides are placed upon major histocompatibility (MHC) II molecules for presentation to $CD4^+$ T cells. Interactions between antigen-presenting cells and $CD4^+$ T cells include binding between MHC II and the T-cell receptor and costimulatory molecules. The costimulation allows for activation and differentiation into T_H1 or T_H2 cells. T_H2 cells secrete interleukin (IL)-4, IL-5, and IL-10, which promote the synthesis of noncomplement binding immunoglobulins, namely IgG4.[43]

Once the appropriate B cells have been stimulated, the expressed immunoglobulin is secreted, and further changes in the B-cell genome and evolution enhance its binding and eventually its inhibitory characteristics. The ultimate production of a polyclonal antibody response leads to disruption of factor VIII function on numerous levels.[44] These phenomena have provided an in vivo revelation of the structure, function, and biochemical impact of factor VIII inhibitors.

The role of MHC II alleles in factor VIII inhibitor formation has been investigated. There are some weak associations, with some MHC class I/II alleles being "risk" alleles.[45,46] T-cell involvement in inhibitor formation is evidenced by the presence of isotype switching and somatic hypermutation of the B cells, both of which are T cell dependent.[47] There exists within the factor VIII molecule several epitopes against which $CD4^+$ T cells react strongly.[48–50]

Factor VIII exists as a heterodimer, with a heavy chain containing the A1, A2, and B domains connected with a light chain containing the A3, C1, and C2 domains (Fig. 126–1). Short intervening acidic regions (*a1*, *a2*, and *a3*) aid in binding to factor X and serve as important sites for proteolysis by thrombin and factor Xa.[51] By serving as a cofactor for factor IX in the "Xase" complex, it aids in the conversion of factor X to its active form, factor Xa, which along with factor V on a phospholipid bilayer cleaves prothrombin to form thrombin, which in turn amplifies the coagulation cascade (see Chapter 123).[52]

Normally when factor VIII is secreted, it is noncovalently bound to vWF via the light chain, particularly through interactions with *a3* and the C2 domain.[53] Upon thrombin activation, factor VIIIa dissociates from VWF and via the C2 domain, which is no longer bound by VWF, binds to phosphatidylserine on the platelet membrane.[54] Inhibitors interrupt this process through a number of different mechanisms (see Fig. 126–1): by preventing factor VIII interaction with VWF, thereby significantly decreasing its half-life; by slowing the release of factor VIIIa from VWF after thrombin activation, increasing the time for inactivation prior to association with the Xase complex; and by preventing C2 domains from binding with phospholipids.[55–59]

Other mechanisms of inhibition rely upon antibodies that recognize the Arg484-Ile508 epitope in the A2 domain, which is responsible for binding with the protease domain of factor IXa.[60] Interference at this site interrupts the cofactor activity with factor IXa, inhibiting Xase function.[61] When bound by inhibitors, the A3 domain, which contains a binding site for factor IX, prevents factor VIII from binding to factor IX, inhibiting the Xase complex.[62–64]

Although inhibitors that react with the acidic regions and the A1 and C1 domains are reported,[65–67] they usually constitute the minority of the polyclonal immune response in hemophilia A. Patients treated with plasma-derived factor VIII tend to have antibodies directed against the light chain and the C2 domain, whereas patients treated with recombinant factor VIII have antibodies targeting the A2 domain.[68] One other mechanism of inhibition is an alloantibody that catalyzes proteolysis of factor VIII.[69–71]

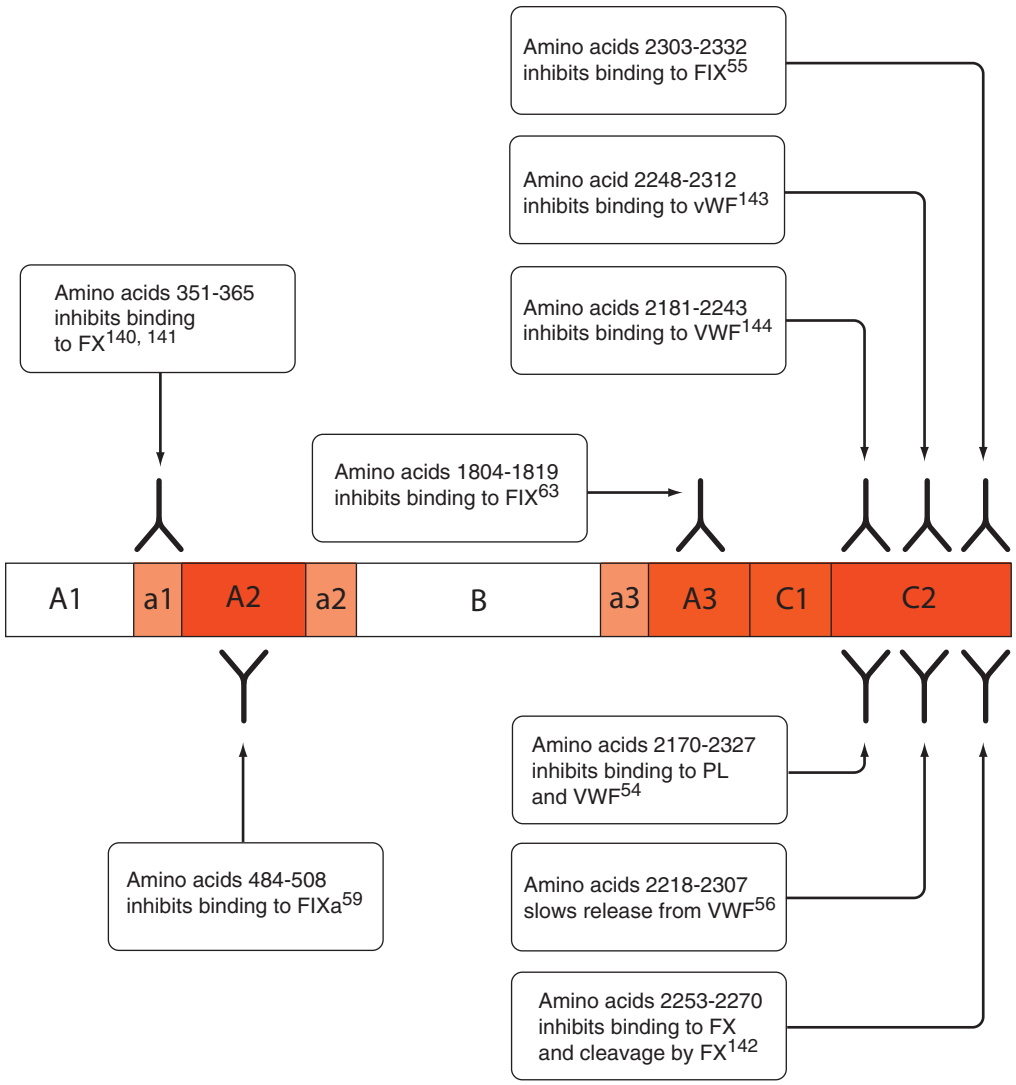

Figure 126–1 Factor VIII domains and binding site by amino acid location and effect on factor VIII. Intensity of color reflects the frequency of inhibitors to the epitope.[140–144] FIX, factor IX; FIXa, activated factor IX; FX, factor X; PL, phospholipid; VWF, von Willebrand factor.

Clinical Manifestations

In patients with severe hemophilia, acquiring an inhibitor does not initially increase the frequency of bleeding. However, as treatment options are less effective in preventing and treating bleeding, these patients are more likely to develop damaged joints that bleed more frequently.[72] Inadequate treatment of joint bleeds may result in progressive severe arthropathy with resultant disability. General health status and quality of life of these patients are reduced compared to those without inhibitors.[73] They have more hospital visits and absences from school or work, and they are more likely to need assistive devices such as a wheelchair or crutches.[74] In the past, development of an inhibitor increased the mortality risk, but with current therapy the mortality rate is nearly identical to the rate in patients without an inhibitor.[75]

In patients with mild to moderate hemophilia, development of an inhibitor usually occurs after a period of intense factor replacement.[9,26] The clinical indication that a patient with mild to moderate hemophilia has developed an inhibitor is the patient's failure to respond to factor replacement or his or her lack of appropriate recovery after factor VIII infusion. Even worse, a patient with mild disease may convert to a severe phenotype and present with spontaneous bleeding, reminiscent of severe hemophilia, when the inhibitor cross-reacts with endogenous factor VIII, reducing the patient's factor VIII activity to less than 1%.[76]

Any person with hemophilia, regardless of severity, who is undergoing treatment and fails to respond should be promptly evaluated for the development of an inhibitor. Any change in clinical responsiveness should be investigated for the development of an inhibitor.[77–79] Testing a patient for the presence of an inhibitor prior to any major surgical procedure is recommended.

Laboratory Diagnosis

In 1975 the Bethesda assay was devised as a simple and reproducible method for determining antibody titer. It is based on the ability of patient plasma to inactivate factor VIII in normal plasma. The result is expressed in Bethesda units (BU).[80] Patient plasma is serially diluted in normal plasma, incubated for 2 hours at 37°C, and residual factor VIII activity measured using a one-stage assay. One BU correlates to a patient factor VIII activity of 50%. A standard curve is generated, and the patient's plasma is diluted until factor VIII activity is between 25% and 75%, the linear portion of the standard curve. The inhibitor units are read from the graph and multiplied by the dilution factor to determine the number of BU in the undiluted plasma (Fig. 126–2).

In order to improve the specificity and reliability of the Bethesda assay, two groups developed the Nijmegen modification to the Bethesda assay.[81] The Bethesda assay can produce false-positives results, usually evidenced as low-titer inhibitors due to decreased factor VIII activity as pH increased and protein concentration decreased. The Nijmegen modification made two important changes to the Bethesda assay. (a) The normal plasma and control mixture

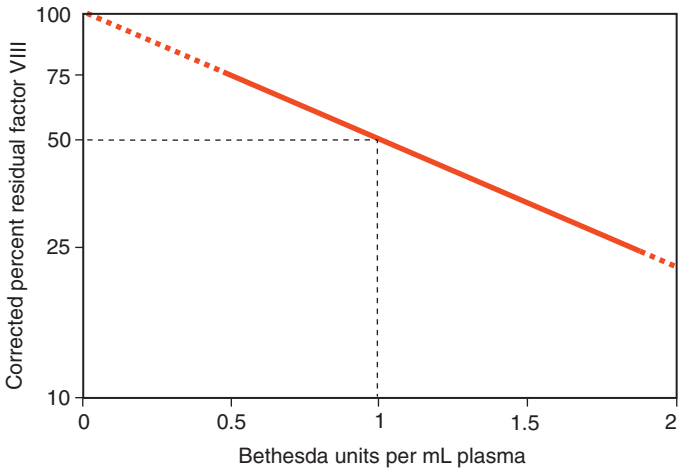

Figure 126–2 Bethesda assay for factor VIII inhibitor quantitation. Relationship between corrected residual factor VIII activity and Bethesda titer is shown. If the result is less than 25%, serial dilutions of the patient's plasma are tested until the result is between 25% and 75%. The result is multiplied by the dilution to assign the Bethesda titer. One Bethesda unit is defined by a corrected residual factor VIII of 50% in the assay (dotted line). (From Konkle BA: Clinical approach to the bleeding patient. In Colman RW, Marder VJ, Clowes AW, George JN, Goldhaver SZ [eds.]: Hemostasis and Thrombosis. Philadelphia, Lippincott, Williams & Wilkins, 2006, p 1147.)

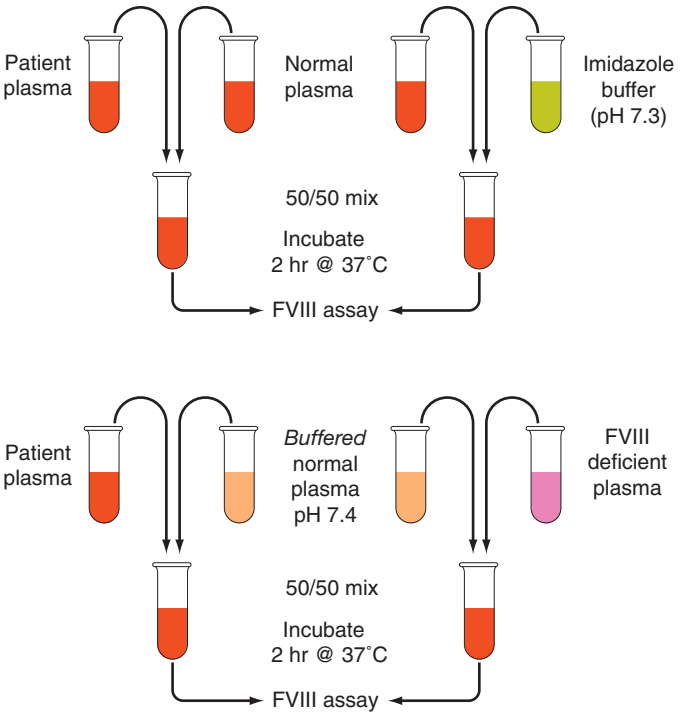

Figure 126–3 Methodologic differences between the classic Bethesda assay[80] and the modified Nijmegen assay.[81] (From Giles AR, Verbruggen B, Rivard GE, Teitel J, Walker I: A detailed comparison of the performance of the standard versus the Nijmegen modification of the Bethesda assay in detecting factor VIII:C inhibitors in the haemophilia A population of Canada. Association of Hemophilia Centre Directors of Canada. Factor VIII/IX Subcommittee of Scientific and Standardization Committee of International Society on Thrombosis and Haemostasis. Thromb Haemost 9:872, 1998.)

were buffered with imidazole to a pH of 7.4, which prevented factor VIII:C inactivation at higher pH. (b) The imidazole buffer used in the control mixture was replaced with plasma that was depleted of factor VIII in order to have similar protein concentrations (Fig. 126–3). This is the recommended method for diagnosis of inhibitors.[82]

Based upon the results of the inhibitor assay, a value less than 5 BU is considered a low-titer inhibitor. If the inhibitor titer fails to rise despite repeated challenges with factor, the patient is termed a low responder. In contrast, a patient in whom the inhibitor titer is greater than 5 BU is considered a high responder.[83]

Pharmacokinetics studies should be performed in patients who show clinical behavior of inhibitor formation but have a negative inhibitor assay.[77,79] Although a distinct minority of the inhibitor repertoire, not all antibodies that are raised against factor VIII interfere with its coagulant function. These inhibitors shorten the half-life of infused factor VIII and are suspected only when factor VIII recovery or half-life is shortened.[44]

Monitoring for inhibitor development in previously untreated patients is of paramount importance, especially when starting treatment or prophylaxis because inhibitor development occurs early in the course of treatment.[30–32] Guidelines recommend screening previously untreated patients every fifth exposure day up to the 20th exposure day, and then every 3 months up until the 150th exposure day.[77,79] Repeat testing should be performed before any invasive procedure or elective operation.[77,79] If porcine factor VIII is available, antiporcine antibody titers can be tested to determine the feasibility of this treatment option.[84]

Treatment

The standard of care dictates that patients with hemophilia receive comprehensive and routine therapy at a hemophilia treatment center having specialized care and experience in the treatment of individuals with severe bleeding disorders. In cases requiring emergency treatment or surgery, patients should be transferred to the hemophilia treatment center after their condition has been stabilized (see box on Treatment of Bleeding in a Patient with Factor VIII Deficiency and an Inhibitor).

Minor Bleeding Episodes

In low responding patients with a known inhibitor titer, larger doses of factor VIII can be given to overcome the inhibitor and provide therapeutic levels of factor VIII. Optimally, the titer is *less than* 5 BU. Equation 126–1 approximates the dose necessary to overcome a low titer:

$$\text{Loading Dose} = 2\ (\text{Body Weight})[(80)(100 - \text{Hematocrit})/100]\ (\text{B.U.})$$

However, after this loading dose, factor levels must be determined to ensure that therapeutic levels are sustained.[85] Treatment should be maintained ideally with continuous infusion. If bolus dosing is used, the treatment interval will need to be shortened. With both approaches, factor levels must be followed closely.

In high responding patients who have inhibitor titers that have decreased to *less than* 10 BU, factor VIII replacement therapy should be avoided. This attempt to avoid an anamnestic response is made for two reasons. If immune tolerance therapy is possible, keeping the titer low will increase the chances for success. More importantly, a low titer will allow for use of factor VIII therapy in bleeds that are life or limb threatening. Controversy exists whether anamnesis occurs with activated prothrombin complex concentrates, which contain a small amount of factor VIII.[10,77–79]

For patients with mild to moderate hemophilia and an inhibitor, treatment with desmopressin (desamino-8-arginine vasopressin [DDAVP]) is an alternative. These patients should undergo DDAVP testing in advance to gauge their response. DDAVP can be used prior to minor procedures and in cases of mild bleeding.[86]

Treatment of Bleeding in a Patient with Factor VIII Deficiency and an Inhibitor

Low Titer, Low Responder

Mild Bleeding

- Local and conservative measures, such as rest, ice, compression, and elevation
- If the patient is known to respond to DDAVP (i.e., mild hemophilia A), 0.3 μg/kg IV or 300 μg intranasal (150 μg for patients <50 kg), for minor bleeding or treatment before minor surgery
- Antifibrinolytic therapy (ε-aminocaproic acid or tranexamic acid) for mucosal bleeding
- Factor VIII dosing to raise the level to 50%
- Recombinant factor VIIa, 90–120 μg/kg, followed by 90 μg/kg every 2–3 hours
- Activated prothrombin complex concentrates, 50–100 U/kg, with maximum daily dose of 200 U/kg
- Concurrent treatment with antifibrinolytics is discouraged

Life- or Limb-Threatening Bleeding

- Factor VIII dosing to maintain factor VIII activity levels at 100%
- Recombinant factor VIIa, 90–120 μg/kg, followed by 90 μg/kg every 2–3 hours
- Activated prothrombin complex concentrates, 50–100 U/kg, with maximum daily dose of 200 U/kg
- Concurrent treatment with antifibrinolytics is discouraged

Low Titer, High Responder

Mild Bleeding

- Local and conservative measures, such as rest, ice, compression, and elevation
- If the patient is known to respond to DDAVP (i.e., mild hemophilia A), 0.3 μg/kg IV or 300 μg untranasal (150 μg for patients <50 kg), for minor bleeding or treatment before minor surgery
- Antifibrinolytic therapy (ε-aminocaproic acid or tranexamic acid) for mucosal bleeding
- Recombinant factor VIIa, 90–120 μg/kg, followed by 90 μg/kg every 2–3 hours
- Activated prothrombin complex concentrates, 50–100 U/kg, with maximum daily dose of 200 U/kg
- May induce anamnesis

Life- or Limb-Threatening Bleeding

- Factor VIII in high doses to maintain levels of 100 U/mL
- Frequent monitoring for an anamnestic response, usually within 5–7 days
- After the anamnestic response develops:
  - Recombinant factor VIIa, 90–120 μg/kg, followed by 90 μg/kg every 2 hours
  - Activated prothrombin complex concentrates, 50–100 U/kg, with maximum daily dose of 200 U/kg

High Titer, High Responder

Mild Bleeding

- Local and conservative measures, such as rest, ice, compression, and elevation
- If the patient is known to respond to DDAVP (i.e., mild hemophilia A), 0.3 μg/kg IV or 300 μg/kg intranasal (150 μg/kg for patients <50 kg), for minor bleeding or treatment before minor surgery
- Antifibrinolytic therapy (κ-aminocaproic acid or tranexamic acid) for mucosal bleeding
- Recombinant factor VIIa, 90–120 μg/kg, followed by 90 μg/kg every 2–3 hours
- Activated prothrombin complex concentrates, 50–100 U/kg, with maximum daily dose of 200 U/kg
- Concurrent treatment with antifibrinolytics is discouraged

Life- or Limb-Threatening Bleeding

- If available, immunoadsorption can be attempted to rapidly lower the inhibitor titer so as to allow use of factor VIII
- Recombinant factor VIIa, 90–120 μg/kg, followed by 90 μg/kg every 2 hours
- Activated prothrombin complex concentrates, 50–100 U/kg, with maximum daily dose of 200 U/kg

Severe Bleeding Episodes

For patients who have an inhibitor titer less than 5 BU, use of factor VIII therapy should be considered if factor VIII levels can be monitored closely. This likely provides the most effective therapy if adequate factor VIII levels can be maintained. Patients should be monitored closely for anamnesis, which should be expected in patients with a history of a high-titer inhibitor, because switching to a bypassing agent will be needed.

In the case of a severe bleed or a life-threatening emergency, an immediate assay of the patient's inhibitor titer should be determined but should not delay initial treatment. For patients with a known and persistently high-titer antibody, prompt treatment should consist of therapy with a bypass agent, either an activated prothrombin complex concentrates or factor VIIa.[78,79]

Surgery

Surgery in patients with hemophilia, especially those who have an inhibitor, requires the involvement of an entire facility experienced in the preoperative and postoperative care of such patients.[87] However, treatment recommendations for surgical procedures are similar to those for hemorrhage. In a patient who is a low responder, adequate hemostasis can be achieved with higher doses of factor VIII. For the high responding patient, use of activated prothrombin complex concentrates or recombinant factor VIIa has been shown to be effective in the postoperative setting.[88–90]

Prothrombin Complex Concentrates

Prothrombin complex concentrates originally were used for treatment of hemophilia B. Their use evolved to encompass hemophilia A with inhibitors because of their thrombogenic properties. Prepared from large volumes of plasma, prothrombin complex concentrates contain the vitamin K-dependent clotting factors prothrombin, factor VII, factor IX, and factor X.[91] Heparin or antithrombin is added to some preparations to limit coagulation during the manufacturing process and administration. All prothrombin complex concentrate products undergo a viral inactivation process. In comparison to placebo, a prothrombin complex concentrate was effective in controlling approximately 50% of bleeding episodes in patients with inhibitors compared to 25% for product containing albumin alone.[92]

Activated Prothrombin Complex Concentrates

Activated prothrombin complex concentrates are prothrombin complex concentrates that undergo partial "activation" during the manufacturing process. Although results comparing prothrombin complex concentrates to activated prothrombin complex concentrates have not been definitive,[93,94] activated prothrombin complex concentrates may be more effective treatment and are more commonly used to treat bleeding in patients with FVIII inhibitors.[72,85,91,95]

Clinical studies have shown that activated prothrombin complex concentrates are effective in treating bleeding in 81% to 93% of joint bleeds.[96,97] Use of activated prothrombin complex concentrates has allowed for surgery in inhibitor patients and has been reported to be effective.[97] A review of surgical cases of patients with an inhibitor and an activated prothrombin complex concentrate showed adequate hemostatic control without any adverse outcomes.[88]

During an acute bleed, activated prothrombin complex concentrates are administered at 50–100 U/kg, every 6 to 12 hours based upon the clinical severity, with the maximum daily dose capped at 200 U/kg.[78] This broader time frame allows for use at home for treatment of acute bleeds, as well as prophylaxis. A study compared an activated prothrombin complex concentrate (factor eight inhibitor bypassing activity [FEIBA, Baxter], 85 IU/kg) with one to two doses of recombinant factor VIIa (NovoSeven [Novo Nordisk Health Care AG] ≈105 μg/kg) for response at 6 hours to treatment of joint bleeding. Although both products showed 80% to 90% efficacy at some time point, equivalency was not shown due to differences in rating by a substantial proportion of patients.[98]

Use of activated prothrombin complex concentrates is hampered by the lack of a laboratory test to measure efficacy, the possibility of anamnesis with the amounts of factor VIII present in the product, and the risk of thrombotic events. The risk of thrombosis is increased with dosing that varies from the recommended dosage and in patients with increased risk for thrombotic events (elderly, coronary artery disease).[77,78]

Recombinant Factor VIIa

Factor VIIa was purified from plasma and first used to treat a patient with an inhibitor in 1983.[99] Later it was produced by recombinant technology and found to be effective for treatment of bleeding and in allowing surgery. A randomized dose finding trial found recombinant factor VIIa to be effective in 71% of joint and muscle bleeds within two to three doses, given every 2 to 3 hours.[100] Likewise, a prospective randomized dose finding study in surgery found that although 35 μg/kg of recombinant factor VIIa was effective for minor procedures, 90 μg/kg was statistically superior in achieving adequate hemostasis during major surgical procedures, with an efficacy rate of 83% to 100%.[101] However, use of recombinant factor VIIa is limited by the lack of effective laboratory monitoring, very short half-life (≈2 hours) requiring frequent administration, potential for thrombotic events, and expense.[85]

For serious hemorrhages or for surgery, an initial dose of 90 μg/kg is recommended. Some experts advise an initial dose of 120 μg/kg, followed by the 90 μg/kg dose.[102] With serious bleeds or after surgery, current recommendations are to continue with dosing every 2 hours for 1 to 2 days and then to start tapering to every 3 hours for another 2 days, followed by every 4 to 6 hours for days 5 to 14, depending on the type of surgery.[103] Although continuous infusion is an option to decrease cost and avoid prolonged troughs, it still is being investigated as a viable alternative to 2-hour dosing.

Combining Bypass Agents

For bleeding that is unresponsive to treatment with an activated prothrombin complex concentrate or recombinant factor VIIa alone, use of both products in an alternating regimen has been reported.[104,105] This combination is not recommended by the product manufacturers. Laboratory tests document increased coagulation activation. Given the risk of thrombosis, this regimen should be considered only under extreme, emergent conditions.

Fibrinolytic Inhibitors

ε-Aminocaproic or tranexamic acid has a long safety record and is commonly used as a treatment alone or in combination with factor replacement for mucosal bleeding or dental procedures. Fibrinolytic inhibitors are routinely used with factor for orthopedic surgery.[106]

For children, ε-aminocaproic acid is administered at 50 to 100 mg/kg/dose every 6 hours. If used prior to a procedure, the first dose should be given 4 hours before the start of the procedure. In adults, a loading dose of 4 to 5 g is given initially, followed by 1 g/hour for 8 hours or until bleeding is controlled. Fibrinolytic inhibitors should not be used when activated prothrombin complex concentrates are used, and care must be used in the case of urogenital bleeding. These agents are considered safe for use with recombinant factor VIIa.[77]

Immune Tolerance Therapy

The ultimate therapy for a patient with hemophilia and an inhibitor is induction of immune tolerance. The goal of this procedure is eradication of the inhibitor. Successful immune induction therapy enables use of factor VIII replacement therapy for both acute bleeding and prophylaxis to prevent joint arthropathy.

The first episode of immune tolerance arose from an emergency situation in 1974 when a child with a high-titer inhibitor (>500 BU) required immediate treatment.[107] The clinical decision was made to treat the child with high doses of factor VIII and a prothrombin complex concentrate, which controlled the child's hemorrhage. A serendipitous finding was that the child's inhibitor titer fell to almost 40 BU. This marked the first episode where high-dose factor VIII led to a decrease in inhibitor titer and ushered in the "Bonn protocol," which uses high doses of factor VIII (100 IU/kg) given twice daily.[108,109] Activated prothrombin complex concentrates are administered based on the bleeding tendency of the patient. This regimen is followed until the inhibitor has disappeared, sometimes as long as 3 years.[107,110]

The Malmö protocol also developed out of the need for emergent elimination of an inhibitor in a patient with hemophilia B who required urgent orthopedic surgery.[111] Unique among other immune tolerance regimens, the Malmö protocol uses a number of immunomodulatory therapies to lower the inhibitor level. Among them is serial use of a *Staphylococcal aureus* protein A column to adsorb out the inhibitory immunoglobulin(s) until the inhibitor titer is less than 10 BU. This regimen is coupled with administration of intravenous immunoglobulin,[112] which is thought to exert antiidiotypic effects. Cyclophosphamide is given to prevent or attenuate the formation of new antibodies. Like the Bonn protocol, high doses of factor VIII are given so that the inhibitors are neutralized and therapeutic levels are maintained.[113,114]

In contrast to the other immune tolerance protocols that use higher doses of factor VIII as part of the regimen, a low-dose regime has been used with success. In 1981, the van Creveld clinic, which cares for a majority of the patients with hemophilia with inhibitors in the Netherlands, adopted a protocol of immune tolerance using low-dose factor VIII infusions, starting at 25 IU/kg every other day, a 16- to 24-fold less dose than the other high-dose immune tolerance protocols used. These studies found that low-dose factor VIII was very effective in inducing immune tolerance, without the need for immunoadsorption, immunosuppression, or lengthy treatment courses.[115–117]

Several retrospective immune tolerance registries have been established.[118–126] Although several key facets remain in disagreement with each other, most registries have found that the most consistent

predictors of success were (a) beginning immune tolerance therapy when the inhibitor titer is as low as possible (ideally <10 BU), and (b) lower historical peak antibody titers.[122]

Uncertainty remains regarding the optimal total dose of factor VIII, the age at which to start immune tolerance therapy, the interval time between development of the inhibitor and start of immune tolerance therapy, the use of immunosuppressives, and especially the type of factor replacement used in immune tolerance therapy. Use of low-/intermediate-purity factor concentrate containing vWF may be more efficacious than use of recombinant factor VIII.[36,127,128] These questions currently are being addressed in a multinational immune tolerance trial comparing two different dosing regimens that allows investigators choice of treatment with a recombinant or a vWF-containing factor VIII product.[129]

HEMOPHILIA B

The development of inhibitors in hemophilia B follows the same general principles as in hemophilia A. Inhibitory antibodies arise after treatment with infused factor IX-containing products, and this phenomenon was observed very soon after hemophilia B was differentiated from hemophilia A.[130] However, several distinct differences in the epidemiology and treatment of hemophilia B deserve special mention. These differences include the lower incidence and prevalence of inhibitors in hemophilia B, the risk of anaphylaxis to infused factor IX-containing concentrates, the lower success rate of immune tolerance therapy, and the risk of nephrosis associated with immune tolerance therapy.[131]

Epidemiology

Overall, the incidence of inhibitors in severe hemophilia B is much less than that of severe hemophilia A (≈3% vs ≈30%).[132] A very-low-risk mutation for inhibitor development is one with a single amino acid substitution and is considered to have a risk of almost 0%, whereas an unknown genotype generally is assigned a risk of approximately 3%.[133] The risk of inhibitor development approaches 20% with more significant mutations such as frameshift mutations, premature stop codons, and splice site mutations.[133] Patients with hemophilia B who are at highest risk for development of inhibitors have a severe phenotype as a result of large gene deletions or another significant aberration of the gene product, such as nonsense mutations. Although these significant mutations affect only a fraction of the hemophilia B population, they account for approximately 50% of the inhibitor population.[133]

Diagnosis

Similar to hemophilia A, an inhibitor should be suspected in hemophilia B when a patient ceases to respond to conventional treatment. Given the possibility of anaphylaxis that may occur during the initial treatment episodes, patients with high-risk mutations must be regularly screened for the generation of inhibitors. The laboratory diagnosis for inhibitors in hemophilia B involves a modification of the Bethesda assay, in which factor IX-deficient plasma is used instead of factor VIII-deficient plasma.[77]

Treatment

Treatment of hemophilia B in patients with inhibitors mirrors that of hemophilia A, ranging from use of conservative local measures to infusion of bypassing agents. Both activated prothrombin complex concentrates and factor VIIa are useful for treatment of bleeding and for control of hemorrhage after surgery.[77] However, because activated prothrombin complex concentrates contain significant amounts of factor IX, recombinant factor VIIa is more commonly used.

A major complication is the development of anaphylaxis upon the initial receipt of factor IX concentrates. Although only an estimated 35 cases have been reported, given the paucity of hemophilia B patients with inhibitors, these cases nevertheless represent a significant complication.[131,134–136] Because these severe reactions occur only after initiation of treatment, they have been observed exclusively in children (median age 12 months), occurring at a median of 11 exposure days. The development of anaphylaxis also has been noted to occur at the same time as the appearance of an inhibitor. The major risk factor for developing an anaphylactic reaction is the presence of a null mutation, leading to an absence of circulating factor IX.[137]

Although experience with anaphylaxis occurring in response to factor replacement is limited by the relative scarcity of its occurrence, some general practice recommendations have been posed. For newly diagnosed hemophilia B patients, especially those with high-risk mutations, the initial treatments should be conducted in a medical facility with resuscitation equipment available.[131] Immune tolerance is generally ineffective in these patients, although tolerance to factor IX has been reported with progressively increasing doses of factor IX administered with hydrocortisone.[136]

Unlike hemophilia A, immune tolerance therapy in hemophilia B has a much lower rate of success.[131] This is further complicated by the risk of developing nephrotic syndrome during immune tolerance therapy, especially in patients who had an allergic reaction to factor IX replacement. The limited data available suggest that this syndrome is not due to immune complex deposition and is not responsive to corticosteroids.[138,139] The development of nephrosis should be monitored by frequent urinalysis during immune tolerance therapy. Should nephrosis occur, factor IX doses should be reduced or discontinued.[139]

CHAPTER 127

RARE COAGULATION FACTOR DEFICIENCIES

David Gailani and Anne T. Neff

Inherited deficiencies of blood clotting proteins distinct from those involved in hemophilia A and B are rare, and the clinical presentations, diagnostic options and treatments differ from those for deficiencies of factor VIII (see Chapters 123 and 125) and factor IX (see Chapters 124 and 125). The rare disorders include deficiencies of fibrinogen; the plasma protease zymogens prothrombin, factors VII, X, XI, and XII, and prekallikrein; the cofactors factor V and high-molecular-weight kininogen; and the transaminase factor XIII. Reactions involving these proteins are shown in Fig. 127–1. Conversion of soluble fibrinogen to fibrin at a wound site is triggered by binding of factor VIIa to tissue factor (Fig. 127–1, *A*).[1–3] The factor VIIa/tissue factor complex converts factor X to Xa, which then converts prothrombin to thrombin in the presence of factor Va. Mice lacking prothrombin, factor VII, factor X, or factor V die in utero or soon after birth,[4] consistent with the rarity of these deficiencies in humans. Thrombin has many functions, including conversion of fibrinogen to fibrin through limited proteolysis (Fig. 127–2). Factor IX is also activated by factor VIIa/tissue factor and, with factor VIIIa, sustains thrombin generation by activating factor X.[1–3] Factor IX activation by factor XIa is required in some situations.[5] In the model shown in Fig. 127–1, *B,* which serves as the basis for the prothrombin time and partial thromboplastin time (PTT) assays, factor XI activation requires factor XII, prekallikrein, and high-molecular-weight kininogen, the contact factors.[6] However, deficiency of a contact factor does not result in abnormal bleeding, and other mechanisms likely exist for factor XI activation. For example, thrombin can activate factor XI (Fig. 127–1, *A*).[7] Finally, factor XIII is activated by thrombin and cross-links fibrin monomers to complete the process of fibrin formation.[8] The number from the Online Mendelian Inheritance in Man (OMIM) database for each congenital deficiency is given in the section title, and each section references Web sites that compile and regularly update lists of mutations that cause factor deficiencies.

Most coagulation protein disorders are recessive traits, with severe deficiency occurring in one in 500,000 to 2,000,000 individuals. This implies a carrier frequency of approximately 1 : 1000,[9] which is 10-fold higher than the frequency of mutant alleles causing factor VIII deficiency (≈1 : 10,000). Therefore, these disorders are rare because they are recessive traits and not because of low allele frequencies. As with any recessive trait, incidences are higher in areas where consanguineous marriages are common. Overall, the rare factor deficiencies represent approximately 3% to 5% of all coagulation factor deficiencies.[10] An international database for these disorders (www.rbdd.org) has been established for the purpose of collecting clinical, genetic, and therapeutic information to facilitate development of evidenced-based diagnostic and treatment recommendations.[10]

FIBRINOGEN DEFICIENCY (OMIM 202400)

The fibrous nature of a blood clot has been recognized for centuries.[11] The plasma precursor of the fibrin component of the clot, fibrinogen, was first purified in the late nineteenth century.[11] Fibrinogen and fibrin are designated factors I and Ia, respectively, by the committee that established the nomenclature system currently used for coagulation proteins.[12] In 1947, fibrinogen was identified as a major component of cryoprecipitate, the preparation commonly used in the United States to treat fibrinogen deficiency.[13] Congenital absence of fibrinogen (*afibrinogenemia*) was first described in 1920[9] and has an estimated incidence of 1 : 1–2,000,000.[14] Partial deficiency of fibrinogen is called *hypofibrinogenemia.* Afibrinogenemia and hypofibrinogenemia traditionally have been considered separate disorders, however, it now is clear that they represent the homozygous and heterozygous states, respectively, for mutations affecting plasma fibrinogen concentration.

Fibrinogen is a 340,000 molecular weight plasma glycoprotein composed of two heterotrimers, each containing an Aα, Bβ, and γ chain (see Fig. 127–2).[15] The protein is synthesized in hepatocytes,[16] and the three chains are encoded by separate genes within a 50-kb region on chromosome 4.[17] Fibrinogen in platelet α granules is taken up from the plasma by a glycoprotein IIb/IIIa–dependent mechanism.[18] Thrombin converts fibrinogen to fibrin monomer through proteolysis, removing fibrinopeptides A and B from the N-termini of the Aα and Bβ chains, respectively (Fig. 127–2).[15,19] Fibrinogen also binds to glycoprotein IIb/IIIa, facilitating platelet aggregation.[20]

Afibrinogenemia is an autosomal recessive disorder caused by homozygosity or compound heterozygosity for mutations in the fibrinogen genes, with the Aα gene most often affected.[21] Afibrinogenemic patients have undetectable or nearly undetectable levels of fibrinogen (<10 mg/dL; normal 150–400 mg/dL) by activity-based clotting assays and by measurement of immunoreactive fibrinogen. Hypofibrinogenemia is associated with partial deficiency of fibrinogen due to heterozygosity for a mutation. Since the first report of a causative mutation in 1999,[22] more than 70 abnormalities have been described in the fibrinogen genes of afibrinogenemic/hypofibrinogenemic patients (www.geht.org/databaseang/fibrinogen).[21,23] Most are deletions, frameshifts, splice site mutations, or nonsense mutations. A relatively small number of missense mutations that are clustered in the C-termini of the Bβ and γ chains in the D domain (see Fig. 127–2) interfere with protein secretion. Missense mutations such as Glyγ284Arg (Fibrinogen Brescia)[24] and Argγ375Trp (Fibrinogen Aguadilla)[25] cause hypofibrinogenemia with accumulation of fibrinogen in hepatocytes, leading to hepatic dysfunction and cirrhosis (endoplasmic reticulum storage disease).

Acquired hypofibrinogenemia is common in disseminated intravascular coagulation and primary fibrinolysis. Fibrinogen levels typically are normal or increased in liver disease but may be low (<100 mg/dL) in cirrhosis with hepatic failure or with fulminant hepatic necrosis.[26] A severely depressed fibrinogen level due to hepatic insufficiency indicates a poor prognosis.[27] Patients receiving L-asparaginase for hematologic malignancies may develop severe hypofibrinogenemia (<20 mg/dL),[28] with normal or only slightly reduced levels of other coagulation factors.

Hemorrhagic symptoms in fibrinogen deficiency are most significant when the plasma level is less than 50 mg/dl.[29,30] Most afibrinogenemic patients have bleeding from the umbilical cord and from mucosal surfaces.[29,31,32] Bleeding from the skin, gastrointestinal tract, and genitourinary tract are common, as is menorrhagia.[33–35] Hemarthroses (54%) and muscle hematomas (72%) were frequent in one series.[29] However, hemarthrosis-related arthropathy appears to be less pronounced than in hemophilia. Intracranial bleeding is a frequent

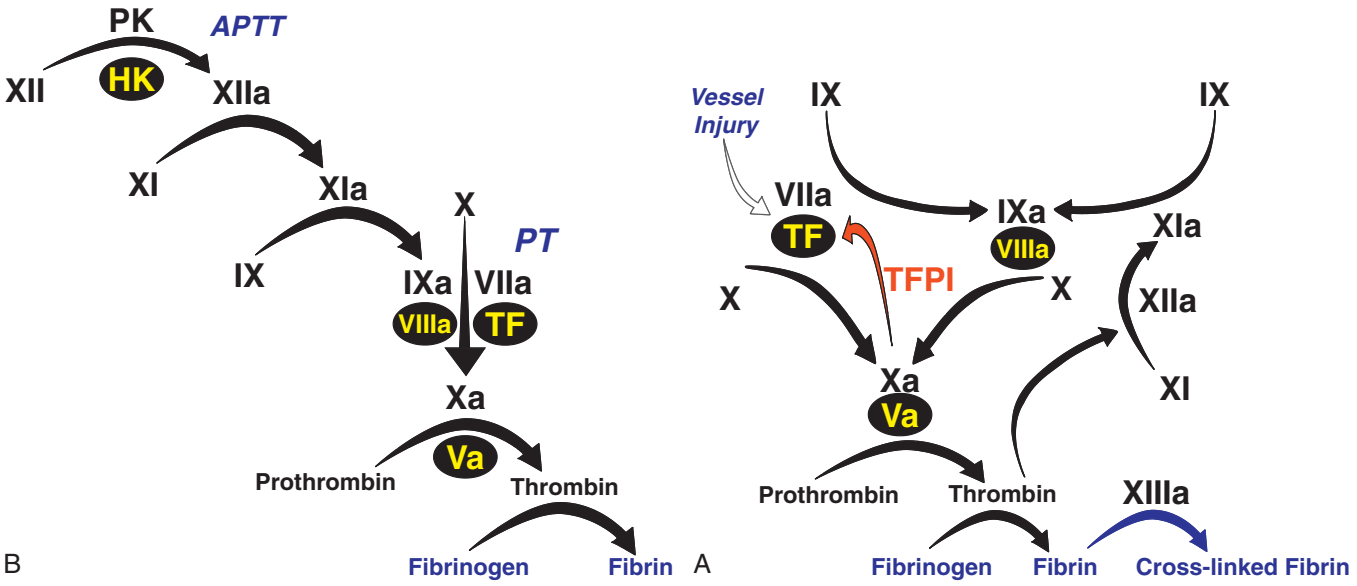

Figure 127–1 Models of plasma coagulation. Unactivated factors are indicated by a Roman numeral, and activated factors by Roman numerals followed by a lower case "a." Enzymes are indicated by black lettering and cofactors by yellow lettering in black ovals. Black arrows indicate reactions involving factor activation, blue arrow indicates fibrin cross-linking by factor XIIIa, and red arrow indicates the factor Xa–dependent inhibition of the factor VIIa/tissue factor (TF) complex by tissue factor pathway inhibitor (TFPI). **A,** Model of TF-initiated hemostasis. See introduction for a description of the events leading to formation of a fibrin clot. **B,** Cascade/waterfall model of hemostasis. This model serves as the basis for the prothrombin time and activated partial thromboplastin time (PTT) assays. In the prothrombin time assay, a reagent containing TF is added to plasma, and the factor VIIa/TF complex induces clot formation through activation of factor X. In the PTT assay, a reagent containing a negatively charged substance initiates clot formation through activation of factor XII (contact activation; see Fig. 127–3 for details). HK, high-molecular-weight-kininogen; PK, plasma prekallikrein.

cause of death in these patients.[32–35] Spontaneous rupture of the spleen has been reported.[36] Hypofibrinogenemic patients usually are asymptomatic but may have excessive bleeding with trauma or surgery, particularly if the fibrinogen level is less than 50 mg/dL. Some mutations causing hypofibrinogenemia result in liver insufficiency due to accumulation of fibrinogen in the endoplasmic reticulum of hepatocytes,[24,25] similar to the syndrome associated with α_1-antityrpsin deficiency.[37]

The incidence of spontaneous abortions is high in afibrinogenemic and hypofibrinogenemic woman.[29,38–40] Fibrinogen-deficient mice also have difficulty sustaining pregnancies,[41] confirming the importance of the maternal protein to fetal viability. Prepartum and postpartum bleeding are relatively common,[39,40] and intraabdominal bleeding from ruptured corpus luteal cysts have been reported. Arterial and venous thrombotic events have been described in afibrinogenemic patients.[42] Although some cases are associated with other risk factors for thromboembolism or with administration of replacement therapy, in most instances no risk factor was identifiable. Fibrinogen and fibrin have been shown to downregulate thrombin activity, providing a possible explanation for these events.[43,44] Alternatively, some thrombotic episodes could occur in patients with dysfibrinogenemia or hypodysfibrinogenemia who have been mistakenly diagnosed as afibrinogenemic.

Plasma assays measuring time to fibrin clot formation, such as the prothrombin time, PTT, and thrombin time, will be infinitely prolonged in afibrinogenemia. The template bleeding time and platelet aggregation studies often are abnormal.[34,45] Fibrinogen is absent, but other coagulation factor levels are normal. The von Clauss method is the most commonly used technique for measuring fibrinogen in clinical laboratories.[46] It is based on determining the time to clot formation after addition of thrombin to plasma. This assay is not reliable at very low fibrinogen levels (<10 mg/dL) and may give falsely low readings with fibrin variants that polymerize slowly (dysfibrinogenemia) or if substances that interfere with fibrin polymerization (paraproteins, high levels of fibrin degradation products) are present. Therefore, it is important to demonstrate the absence of immunoreactive fibrinogen to confirm the diagnosis of afibrinogenemia.[47] In hypofibrinogenemia, functional and antigenic fibrinogen levels are proportionately decreased. A disproportionately lower functional level suggests the diagnosis of dysfibrinogenemia. The prothrombin time and PTT are relatively insensitive to fibrinogen and may not be prolonged in mild to moderate hypofibrinogenemia. The thrombin time is more sensitive in these situations. Afibrinogenemic patients have low erythrocyte sedimentation rates and develop little induration in skin tests for delayed hypersensitivity because of the absence of fibrin deposition.[48]

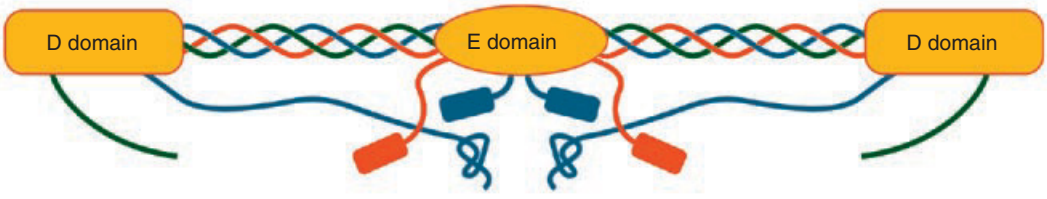

Figure 127–2 Model of human fibrinogen. Each half of the molecule contains an Aα (blue), Bβ (red), and γ (green) chain. The amino-termini of the six chains that compose the whole molecule are linked by disulfide bonds in the central E domain. The carboxy-terminal regions of the polypeptides form two nodular D domains at the extremes of the molecule. Fibrinopeptides A (blue boxes) and B (red boxes) reside in the E domain and are removed by the proteolytic activity of thrombin during conversion of fibrinogen to fibrin. (Adapted from Mosesson MW: Fibrinogen and fibrin structure and functions. J Thromb Haematol 3:1894, 2005, with permission.)

Afibrinogenemic and hypofibrinogenemic patients can be treated with cryoprecipitate, fresh frozen plasma, or fibrinogen concentrate, depending on availability. In the United States, cryoprecipitate is used most frequently. A 30- to 50-mL unit contains approximately 300 mg of fibrinogen. Fibrinogen has an extravascular distribution of approximately 30%, and an afibrinogenemic adult with an estimated 3-L plasma volume will require 12 units of cryoprecipitate to achieve a plasma level of 100 mg/dL. Recommendations regarding target levels for treating bleeding range from 30–50 mg/dL[30] to 100 mg/dL.[40] The following are guidelines for treating afibrinogenemia from the United Kingdom Haemophilia Centre Doctors Organization.[40] For significant bleeding, the plasma fibrinogen level should be increased to 100 mg/dL until hemostasis is achieved and then maintained above 50 mg/dL until wound healing is complete. A similar strategy is recommended for managing surgery patients. The half-life of transfused fibrinogen is 3 to 5 days,[49] and every-other-day treatment usually is adequate to maintain levels in the absence of consumption. Infusions may need to be more frequent in certain clinical settings, and close monitoring of fibrinogen levels is recommended to facilitate dosing. Data are insufficient to base recommendations for primary prophylaxis to prevent bleeding. However, secondary prophylaxis is reasonable to prevent recurrent intracranial hemorrhage, with trough levels kept above 50 mg/dL.

Administration of regular infusions of fibrinogen is recommended to maintain pregnancies in afibrinogenemic woman and to reduce the incidence of postpartum hemorrhage.[50,51] Therapy should be initiated as early as possible because fetal loss in the first trimester is frequent. Fetal loss has occurred in some patients with fibrinogen levels above 50 mg/dL; therefore, it is recommended that levels be kept above 100 mg/dL through the duration of the pregnancy.

Antifibrinolytic therapy with ε-aminocaproic acid may be an effective replacement for blood products for some mucosal bleeding and for dental extractions (see box on Antifibrinolytic Therapy for Congenital Factor Deficiencies). However, this therapy is associated with an increased risk for thrombotic events and must be used cautiously in patients with a history of thrombosis, pregnancy, surgery, or immobilization. Fibrin glues also may be useful for tooth extraction, and estrogen/progesterone therapy may be helpful for controlling menorrhagia.[52]

Antifibrinolytic Therapy in Congenital Factor Deficiencies

The antifibrinolytic agents ε-aminocaproic acid and tranexamic acid are effective adjuncts to factor replacement in many situations when treating bleeding disorders and may be useful alternatives to replacement therapy for mild bleeding or minor procedures. These drugs inhibit clot dissolution by blocking plasminogen activation and plasmin activity. They are particularly valuable when bleeding involves tissues with high fibrinolytic activity, such as the oral cavity, and have been useful for treating menorrhagia, limiting blood loss at surgery, controlling epistaxis, and reducing some forms of gastrointestinal bleeding. A typical loading dose of ε-aminocaproic acid is 50 to 100 mg/kg, followed by 2 to 4 g every 6 hours. If bleeding subsequently occurs, the dose can be increased to a maximum of 24 g in 24 hours. ε-Aminocaproic acid is available in oral and intravenous formulations, and identical dosing can be used for either preparation due to excellent bioavailability. For dental extraction in patients with factor VIII or IX deficiency, many hemophilia centers use a single 50% to 100% loading dose of clotting factor concentrate, followed by 7 days of ε-aminocaproic acid as the sole prophylaxis. It is reasonable to extrapolate this approach to patients with some of the rare bleeding disorders. Patients with factor XI deficiency do well with antifibrinolytic agents alone for tooth extractions. Dental procedures such as scaling or root canal can be performed safely using ε-aminocaproic acid mouthwash prepared from the intravenous formulation three to four times daily with or without systemic antifibrinolytic therapy.

Prolonged therapy with antifibrinolytic agents must be used with caution in patients who are not mobile, who have a history of thromboembolic events, or who have significant urogenital bleeding because of an increased risk for thrombus formation. These drugs interfere with urokinase-mediated fibrinolytic activity in the genitourinary tract and can cause renal outflow obstruction by thrombotic occlusion of the ureter. Concomitant use of antifibrinolytic agents with activated prothrombin complex concentrates or, possibly, recombinant factor VIIa may result in a particularly high risk for thrombus formation. Patients may develop nausea or vertigo with high doses of ε-aminocaproic doses and, rarely, rhabdomyolysis.

DYSFIBRINOGENEMIA (OMIM 134820 Aα CHAIN, 134830 Bβ CHAIN, AND 134850 γ CHAIN)

In *dysfibrinogenemia*, structural variants of fibrinogen circulate in the plasma. These abnormal proteins are designated by the city of origin of the patient in whom they are identified, with additional Roman numerals if more than one variant is found in a city. Cases in which the dysfunctional protein is present at low levels in plasma are referred to as *hypodysfibrinogenemia.* The first family with dysfibrinogenemia (fibrinogen Paris I, 15-amino-acid insertion after Gln350 in the γ chain)[53] was described in 1964.[54] The actual incidence for congenital dysfibrinogenemia is not known because the majority of patients appear to be asymptomatic, and most probably do not come to medical attention. Although a rare cause of excessive bleeding, it has been estimated that 0.8% of patients with a history of venous thromboembolism have dysfibrinogenemia.[55]

Congenital dysfibrinogenemia and hypodysfibrinogenemia are predominantly autosomal dominant disorders caused by a missense mutation in one of the fibrinogen genes, although some insertions and deletions have been identified.[9] More than 100 mutations associated with dysfibrinogenemia (www.geht.org/databaseang/fibrinogen/) have been identified in approximately 300 families. The types of functional defects most often reported are largely determined by the clinical assays available for assessing fibrin formation and likely do not represent the full spectrum of mutations that can cause fibrinogen dysfunction. Variants that are easily detected by conventional clinical assays primarily have defects in fibrinopeptide release (e.g., Fibrinogens Bicêtre [AαArg16His] and Metz [AαArg16Cys]; see Fig. 127–2)[56] or polymerize slowly (e.g., Fibrinogen Caracas II [AαSer434Asn]).[57] Fibrinogens Bicêtre and Metz cumulatively have been reported more than 70 times, likely reflecting the ease with which these variants are detected by functional fibrinogen assays found in most clinical laboratories and their relatively high frequency.

Thrombotic events have been reported in numerous patients with dysfibrinogenemia.[55,58] A subcommittee of the International Society on Thrombosis and Haemostasis concluded that a significant relationship exists between certain fibrinogen variants and venous thrombosis.[55] Thrombosis-associated mutations tend to cluster at the C-terminus of the Aα chain and near the thrombin cleavage site on the Bβ chain[58]; however the mechanisms by which these variants cause thromboembolism are not well understood. Abnormalities in fibrin polymerization,[59] cross-linking,[59,60] clot structure,[61,62] and susceptibility to fibrinolysis[60,62,63] have been described. The "Dusart syndrome"[62] associated with fibrinogen Paris V (AαArg554Cys)[64] has been identified in several apparently unrelated families (Fibrinogens Chapel Hill III and Nashville).[64,65] In one family, this mutation was associated with multiple cases of venous thromboembolism and sudden death in teenagers and young adults.[65]

A group of mutations in the C-terminus of the fibrinogen Aα chain is associated with autosomal dominant hereditary amyloidosis in which the amyloid deposits contain fragments of the variant fibrinogens.[16,66–68] The kidneys are primarily affected, but wider visceral and nerve involvement may occur with time.[66–68] Renal grafts subse-

quently become involved with amyloid,[16,66] and liver transplantation may be a better option for treating this condition.[16,69,70] The allele frequency for one responsible mutation, the AαGlu526Val variant, is relatively common and may account for 5% of patients with apparent sporadic amyloid.[68]

Acquired dysfibrinogenemia is most frequently diagnosed in liver disease, with up to 80% to 90% of patients with cirrhosis or liver failure showing some degree of fibrinogen dysfunction.[71,72] Increased sialic acid content leading to an enhanced negative charge likely is responsible for the impairment in fibrin polymeirzation.[73] Homocysteine-induced modifications of fibrinogen have been proposed to contribute to the hypercoagulable state associated with elevated plasma levels of homocysteine.[74] The monoclonal antibody in patients with multiple myeloma can interfere nonspecifically with fibrin polymerization in tests such as the thrombin time[75] but usually do not cause abnormal hemostasis. Acquired dysfibrinogenemia also has been associated with malignancies,[76,77] bone marrow transplantation,[78] and rarely with medications such as mithramycin.[79]

The majority of patients with dysfibrinogenemia (55%–60%) are not symptomatic, and the condition is identified by an abnormal result on a coagulation screening assay.[55] Approximately 25% of patients have abnormal bleeding, and 20% have thrombotic episodes.[55] Correlation between functional abnormalities and clinical symptoms is difficult in many cases. The relatively common AαArg16His and AαArg16Cys variants have been observed in asymptomatic individuals as well as in patients with bleeding or thrombotic events.[9] Epistaxis, easy bruising, and menorrhagia are relatively common.[75,80] Many bleeding episodes are mild, but significant events, including soft-tissue hematomas, hemarthroses, postoperative hemorrhage, and bleeding during pregnancy and postpartum, have been observed.[75,80] Abnormalities with wound healing and spontaneous abortions have been reported.[80] Thrombosis primarily involves the venous circulation (deep vein thrombosis, pulmonary embolism, thrombophlebitis), although some arterial events or combinations of venous and arterial thrombosis have been reported.[55] Approximately one fourth of patients with thrombotic symptoms also experience excessive bleeding.

Most cases of dysfibrinogenemia present as abnormalities on routine coagulation screening tests such as the prothrombin time and PTT. The thrombin time is considered the primary screening test for dysfibrinogenemia, although its sensitivity is not established.[80] The test involves measuring the time to clot formation in citrated plasma after addition of a standard amount of thrombin. The specificity of the thrombin time is relatively poor because a low level of fibrinogen, the presence of heparin, elevated fibrin degradation products, and high levels of some paraproteins may affect the result. The reptilase time has been used as an alternative screen for dysfibrinogenemia and is useful in combination with the thrombin time.[75] The assay involves inducing clot formation with an enzyme from the venom of *Bothrops jararaca* or *Bothrops atrox* that cleaves fibrinopeptide A from fibrinogen and is not sensitive to heparin. Plasma concentration of clottable fibrinogen as determined by the von Clauss method may be low in some types of dysfibrinogenemia. Levels of immunoreactive fibrinogen usually are normal but are decreased in some cases (e.g., hypodysfibrinogenemia). With some variants, fibrin degradation products may be elevated using certain assays because the variant fibrinogen is not incorporated into a clot. This may lead to the false impression that disseminated intravascular coagulation is present.

Given that most dysfibrinogenemic patients are asymptomatic and that symptoms correlate poorly with abnormalities in coagulation assays, generalized recommendations for treating dysfibrinogenemia are not possible. Therapy must be individualized, and most patients will not require treatment. The patient's personal and family histories are useful for guiding therapy. Active bleeding can be treated with replacement therapy as described for afibrinogenemia, and replacement may be indicated in some patients prior to invasive procedures with a high risk of bleeding.

In general, patients with thrombosis and dysfibrinogenemia should be treated similarly to other patients with hypercoagulable conditions. No data are available on which to formulate recommendations regarding duration of therapy. The past history, family history, coexisting conditions, and the nature (idiopathic, pregnancy, postsurgery) and seriousness of the thrombotic event all must be taken into consideration. As with any thrombotic event, the risk of bleeding associated with prolonged therapy must be considered. Recurrent spontaneous abortions have been associated with dysfibrinogenemia in several families, and some pregnancies have been carried to term under replacement therapy with cryoprecipitate.[29]

PROTHROMBIN DEFICIENCY (OMIM 176930)

More than a century ago, Morawitz proposed that an insoluble fibrin clot is formed from fibrinogen through the activity of *fibrin ferment* or thrombin.[11,81] Thrombin was generated from a precursor, prothrombin, by thrombokinase (probably factor Xa). Prothrombin and thrombin are designated factors II and IIa.[12] Total prothrombin deficiency probably is not compatible with life, as absence of the protein has not been observed in humans and prothrombin null mice die in utero or shortly after birth.[4] Congenital partial prothrombin deficiency (*hypoprothrombinemia*) and abnormal circulating prothrombin (*dysprothrombinemia*) affect an estimated 1:2,000,000 persons (Table 127–1).[14] Prothrombin deficiency is relatively common in Puerto Rico, accounting for 6% of non–von Willebrand disease congenital bleeding disorders seen at the University of Puerto Rico Hemophilia Center. The estimated carrier frequency is 1:700 in the Puerto Rican population.[82]

Prothrombin is a 72,000 molecular weight protein that is converted to thrombin by factor Xa in complex with factor Va on phospholipid surfaces (see Fig. 127–1, *A*).[1,2] Thrombin is a pivotal protease in hemostasis, with multiple procoagulant activities including cleavage of fibrinopeptides A and B from fibrinogen to form fibrin (see Fig. 127–2), activation of factors V, VIII, XI, and XIII, and cleavage of protease activated receptors.[83] Thrombin also downregulates fibrinolysis by activating the metalloproteinase thrombin activatable fibrinolysis inhibitor,[84] forms a complex with thrombomodulin to downregulate coagulation through the activation of protein C,[85] and has cytokine and growth factor-like properties.

Prothrombin deficiency is an autosomal recessive disorder manifested as hypoprothrombinemia (reduced activity and antigen; cross-reactive material negative deficiency [CRM–]), dysprothrombinemia (reduced activity with normal to moderately reduced antigen; cross-reactive material positive deficiency [CRM+]), or a combination of both. Plasma prothrombin activity typically is approximately 1% to 10% of normal in hypoprothrombinemia and 1% to 20% in dysprothrombinemia. Heterozygotes for either condition have approximately 50% normal activity and are not symptomatic. More than 50 prothrombin gene mutations have been described (www.med.unc.edu/isth/; www.hgmd.org).[86] In dysprothrombinemia, missense mutations cause defects in prothrombin conversion to thrombin (e.g., prothrombin Puerto Rico I [Arg457Gln][82] and Madrid [Arg271Cys][87]) or result in functionally defective thrombin (e.g., prothrombin Tokushima [Arg418Trp][88]).

Prothrombin deficiency can be inherited in combination with deficiencies of other vitamin K–dependent proteins (see Combined Deficiency of Vitamin K–Dependent Proteins below). Acquired prothrombin deficiency occurs with warfarin therapy, poisoning with rodenticides such as brodifacoum, with vitamin K deficiency or liver disease, and in disseminated intravascular coagulation. Cephalosporins, particularly those with *N*-methyl-thiotetrazole side chains, can decrease prothrombin levels.[89] Antiprothrombin antibodies are common antiphospholipid antibodies in patients with lupus anticoagulants or the antiphospholipid antibody syndrome.[90] More rarely, patients with lupus anticoagulants or systemic lupus erythematosus have antibodies that enhance prothrombin clearance, causing true deficiency.[91,92] Formation of neutralizing antibodies after replacement therapy in congenital prothrombin deficiency has not been reported.

Prothrombin gene mutations are associated with variable levels of activity (1%–50% of normal) that may correlate poorly with clinical

Table 127–1 Properties of Plasma Coagulation Factors and Characteristics of Deficiency States

Protein	Incidence of Severe Congenital Deficiency	Inheritance Pattern	Sources for Proteins in Blood	Other Names for Deficiency States	Bleeding Diathesis	Null Mouse phenotype
Fibrinogen	≈1 : 1–2 × 10^6	Autosomal recessive or dominant	Liver		Mild to severe	Severe bleeding, reduced fertility
Prothrombin	≈1 : 2 × 10^6	Autosomal recessive	Liver		Mild to severe	Lethal in utero or perinatal
Factor V	≈1 : 1 × 10^6	Autosomal recessive	Liver, megakaryocytes?	Parahemophilia	Mild to moderately severe	Lethal in utero or perinatal
Factor VII	≈1 : 5 × 10^5	Autosomal recessive	Liver	Serum prothrombin conversion accelerator deficiency	Mild to severe	Lethal in utero or perinatal
Factor X	≈1 : 1 × 10^6	Autosomal recessive	Liver	Stuart-Prower factor deficiency	Mild to severe	Lethal in utero or perinatal
Factor XI	≈1 : 1 × 10^6	Autosomal recessive or dominant	Liver	Hemophilia C, plasma thromboplastin antecedent deficiency	Asymptomatic to moderate	No bleeding diathesis, protected from thrombosis
Factor XII	Unknown	Autosomal recessive	Liver	Hageman trait	None	No bleeding diathesis, protected from thrombosis
Prekallikrein	Unknown	Autosomal recessive	Liver	Fletcher trait	None	Not available
High-molecular-weight kininogen	Unknown	Autosomal recessive	Liver	Flaujeac trait, Williams trait, Fitzgerald trait	None	No bleeding diathesis
Factor XIII	1 : 1–5 × 10^6	Autosomal recessive	A chain: liver, platelets, monocytes B chain: liver	Fibrin stabilizing factor deficiency	Moderate to severe	Bleeding diathesis, reduced fertility

symptoms. Life-threatening bleeding occurred in a patient with 8% normal activity, whereas patients with 2% activity were asymptomatic.[93,94] The bleeding diathesis can present at circumcision in neonates; it also can present as easy bruising, epistaxis, or menorrhagia, or with trauma or surgery. Muscle hematomas and hemarthroses were the most frequent manifestations in a series of patients.[35] Central nervous system hemorrhage was reported in 8% of prothrombin-deficient patients in one registry and in 20% of patients with less than 1% normal activity.[33]

In the prothrombin time and PTT assays, prothrombin is converted to thrombin by factor Xa in complex with factor Va on phospholipids vesicles (see Fig. 127–1, *B*), and severe prothrombin deficiency prolongs both test results. Some prothrombin time and PTT reagents are relatively insensitive to reductions in prothrombin level, and mild deficiencies may be missed. The diagnosis is confirmed and the degree of deficiency established by a modified prothrombin time assay using prothrombin-deficient plasma. Prothrombin deficiency must be distinguished from deficiencies of fibrinogen, factor V, or factor X, which are also associated with a prolonged prothrombin time and PTT.

Prothrombin complex concentrates approved for use in factor IX deficiency contain variable amounts of prothrombin and factors VII and X (Table 127–2) and are the preferred product for treating prothrombin deficiency, although they are not approved for this use by the Food and Drug Administration. Prothrombin complex concentrates are derived from human plasma and undergo viral inactivation to enhance safety. The prothrombin activity in these concentrates is comparable to or higher than the factor IX activity. Hemostatic levels of prothrombin are estimated to be approximately 30% of normal, and 20 to 30 factor IX units/kg of prothrombin complex concentrate produces plasma prothrombin levels of 20% to 30%.[95] The half-life of prothrombin is approximately 3 days, and dosing every 2 to 3 days maintains adequate levels until healing is complete.[14] Use of prothrombin complex concentrates has been associated with thrombotic events, and it is recommended that levels of factors VII, IX, and X be kept below 150% to minimize this risk.[14] Dental procedures or minor hemorrhage may respond to antifibrinolytic therapy with ε-aminocaproic acid.[35] Prothrombin deficiency also can be treated with fresh frozen plasma for bleeding episodes or surgical intervention (15–20 mL/kg loading dose followed by 3 mL/kg/day). Due to the long half-life, additional doses may not be required in all situations. Cryoprecipitate is not a source of prothrombin, and plasma prothrombin levels do not increase after infusion or inhalation of desmopressin (L-desamino-8-D-arginine vasopressin [DDAVP]). These agents should not be used to treat prothrombin deficiency.

FACTOR V DEFICIENCY (OMIM 227400)

In 1943, Quick reported that aged plasma clotted more slowly than fresh plasma in a prothrombin time assay and proposed that a *labile factor* distinct from prothrombin was required for normal coagulation.[96] At the same time, Owren noted that a patient with a lifelong bleeding problem appeared to lack a factor normally found in plasma that does not adsorb onto aluminum hydroxide, in contrast to prothrombin.[97] It subsequently was determined that Owren's patient was deficient in the labile factor described by Quick, which now is called *factor V.* Congenital deficiency of factor V has been estimated to occur in 1 : 1,000,000 persons (see Table 127–1).[98,99]

Factor V is the 330,000 molecular weight precursor of factor Va, which facilitates prothrombin activation by factor Xa on phospho-

Table 127–2 Treatment Considerations for Rare Coagulation Factor Deficiencies

Protein	Plasma Half-Life (hours)	Blood Sources	Concentrate Available	Level for Major Surgery	Dosing Frequency (hours)	Minimum for Hemostasis	Other Considerations
Fibrinogen	72–120	Cryoprecipitate plasma	Available, but not in the United States	100 mg/dL	q24–48h	30–50 mg/dL	Level of 100 mg/dL is recommended in pregnancy
Prothrombin	60–100	Plasma	Prothrombin complex concentrate	30%	q2–3days	≈5%	
Factor V	12–14	Plasma, platelets	No	25%	q12–24h	≈10%	Platelets may be used if factor V inhibitor is present
Factor VII	3–4	Plasma	Recombinant factor VIIa, prothrombin complex concentrate	15%–25%	q2–3h for factor VIIa q4–6h for fresh frozen plaza	5%–10%	Frequent infusion of plasma due to short half-life can cause volume overload
Factor X	20–40	Plasma	Prothrombin complex concentrate	25%–40%	q24h	≈10%	Deficiency in amyloidosis will respond poorly to replacement therapy
Factor XI	45	Plasma	Hemoleven®, LFB, Les Ulis, France, received orphan-designation from FDA, November 2007	30%–45%	q1–2days	15%	Limit plasma exposure to prevent inhibitor development
Factor XII	60	Plasma	No	Not required	None	0	No bleeding diathesis
Prekallikrein	Unknown	Plasma	No	Not required	None	0	No bleeding diathesis
High-molecular-weight kininogen	170	Plasma	No	Not required	None	0	No bleeding diathesis
Factor XIII	240–336 (10–14 days)	Plasma, cryoprecipitate	Available in the United States as part of a protocol	20%–50%	q5–6weeks for prophylaxis qweek for pregnancy, surgery	1%–2%	Plasma levels may need to be maintained above 10% to sustain pregnancy

lipid surfaces (see Fig. 127–1, *A*).[1,2] Most factor V (80%) is in plasma; the remainder is stored in a partially proteolyzed form in platelet α granules.[99,100] In humans, platelet factor V is primarily of plasma origin.[101] Severe factor V deficiency is an autosomal recessive trait. Approximately 40 factor V gene mutations associated with factor V deficiency have been described (www.med.unc.edu/isth/; www.hgmd.org).[99] Two thirds result in premature termination of protein synthesis, and most are unique to specific families,[99,102] although Tyr1702Cys has been identified several times in the Italian population.[103] No large gene deletions have been found, and most patients have some detectable factor V antigen in plasma. Studies of factor V missense mutations indicate that most abnormal polypeptides are degraded within the cell, resulting in low factor V antigen in plasma (CRM− deficiency). The only well characterized CRM+ factor V mutation is factor V New Brunswick [Ala221Val],[104] which interferes with stability of factor Va.

Patients with low plasma factor V also have low platelet factor V. A few patients with disproportionately low platelet factor V compared to plasma activity have been identified. Factor V Quebec is an autosomal dominant bleeding disorder with low platelet factor V levels and normal plasma factor V.[105] Proteolytic degradation of multiple α granules proteins in this syndrome is possibly due to deficiency or abnormality of the protein multimerin.[106] Factor V New York is associated with defective platelet factor V not related to generalized proteolysis of platelet proteins.[107] The underlying mutations in factor V Quebec and factor V New York are not known. Combined deficiency of factor V and factor VIII may be caused by mutations in proteins required for secretion of both proteins (see Combined Factor V and Factor VIII Deficiency below).

Acquired factor V deficiency occurs in liver disease and disseminated intravascular coagulation. Factor V inhibitors may occur with antibodies to thrombin in patients exposed to topical bovine thrombin or human thrombin in fibrin sealants or glues.[108] Most patients with these inhibitors are asymptomatic, but some have significant bleeding. Factor V inhibitors have been observed in deficient patients treated with plasma, in otherwise normal individuals, in patients with malignancies and autoimmune disease, after treatment with aminoglycosides, and in association with systemic amyloidosis.[108,109]

Bleeding in patients with severe factor V deficiency (1%–10% of normal levels) varies considerably.[99] Although significant bleeding occurs, the frequency tends to be less than in severe factor VIII or factor IX deficiency. Common presenting findings include bruising, epistaxis, prolonged bleeding from lacerations, and soft-tissue hemorrhage.[98] Hemarthroses are less common than in hemophilia, and debilitating arthropathy is not common.[98] Bleeding into the central nervous system has been reported.[99] Heavy menses and postpartum hemorrhage are common in severe factor V deficiency.[110] Trauma, surgery, and dental extraction are associated with a high risk of bleed-

ing in untreated patients. Bleeding with surgery involving the urogenital tract, nose, or mouth may be particularly problematic because of high fibrinolytic activity in these tissues. Mild (heterozygous) factor V deficiency (25%–60% of normal factor level) usually is not associated with excessive bleeding,[14] although approximately 10% of patients are symptomatic.

An association between factor V deficiency and thromboembolism has been observed.[42,111] In some cases, factor V deficiency may simply have not been sufficient to prevent thrombosis. With the exception of deficiencies of prothrombin and factor X, thrombosis has been reported with all coagulation factor deficiencies.[42] However, the situation with factor V is more complex. Factor V deficiency can occur in patients with the procoagulant polymorphism factor V Arg506Gln (factor V Leiden).[99,111,112] If Arg506Gln and a mutation causing deficiency occur on opposite alleles (*in trans*), most factor V in blood is factor V Leiden, resulting in a significantly increased risk of thrombosis (pseudohomozygous activated protein C resistance).[111,112] Alternatively, Arg506Gln may occur on the same allele as a null mutation (*in cis*), and the prothrombotic effect of Arg506Gln is masked.[113] These patients may have a bleeding tendency.

Factor V is required for normal prothrombin activation by factor Xa (see Fig. 127–1, *B*), and factor V deficiency causes prolongation of both the prothrombin time and the PTT. The diagnosis and severity are established by a modified prothrombin time using factor V–deficient plasma. In some cases of severe factor V deficiency, the template bleeding time also is prolonged, perhaps related to low levels of factor V in platelet α granules.[114] Patients with factor V deficiency should also be tested for factor VIII deficiency so that combined deficiency is not missed.

Managing factor V deficiency is challenging because factor V concentrate is not commercially available (see Table 127–2). Mucosal bleeding from the nose and mouth may respond to ε-aminocaproic acid, and superficial lacerations often respond to local pressure. Administration of fresh frozen plasma is the preferred treatment for serious bleeding or in preparation for surgery. The minimal factor V level for hemostasis is approximately 10% to 20%,[33] although some patients in this range have bleeding symptoms. A plasma level of at least 25% is recommended for major surgery.[115,116] Estimates of the factor V plasma half-life vary widely, but 12 to 14 hours should be assumed for replacement purposes. Infusion of a loading dose of fresh frozen plasma (20 mL/kg over 3–4 hours) prior to surgery and then 5 to 10 mL/kg every 12 hours usually is adequate. Infusions should be continued for 7 to 10 days to maintain adequate hemostasis. Factor V–deficient women can have significant bleeding with childbirth and should be treated in a similar manner.[117,118] Care must be taken to avoid fluid overload from large volumes of fresh frozen plasma, especially in older patients. Plasma exchange has been successful in a few factor V–deficient patients requiring surgery.[119] Although the defect caused by factor V deficiency hypothetically would render therapy with recombinant factor VIIa relatively ineffective, a single case of successful use of this agent in a patient with severe factor V deficiency requiring surgery has been reported.[120]

Platelets are a source of factor V and may be particularly useful in patients with factor V inhibitors, as platelet factor V either may be protected from inhibition or differ in structure from plasma factor V sufficiently to not cross-react with the antibody.[121] However, platelet transfusions are not routinely recommended for treating factor V–deficient patients because of concern for developing antiplatelet alloantibodies. Cryoprecipitate is not a source of factor V, and plasma levels do not respond to administration of DDAVP.[122]

FACTOR VII DEFICIENCY (OMIM 227500)

Factor VII deficiency was first reported in 1951 by Alexander et al.[123] and was called *serum prothrombin conversion accelerator deficiency*. Factor VII deficiency is the most common of the nonhemophilic coagulation deficiencies (see Table 127–1), with an estimated prevalence of 1 : 500,000 for the severe form (activity <2% of normal).[95]

Factor VII is the 50,000 molecular weight precursor of the protease factor VIIa.[1,2] Factor VII/VIIa binds to tissue factor to initiate coagulation through activation of factors X and IX (see Fig. 127–1, *A*).[1–3] Mice lacking factor VII develop normally in utero but succumb to bleeding at birth.[4] An infant born with complete absence of factor VII died at 12 days with intracerebral hemorrhage[124]; however, another child survived with replacement therapy.[125] Thus, low levels of factor VII activity appear necessary to sustain life. Factor VII deficiency is considered an autosomal recessive trait, although observations of symptomatic heterozygotes call this into question.[33,126]

More than 100 factor VII gene mutations have been found in factor VII–deficient patients, with CRM+ missense mutations predominating (http://www.med.unc.edu/isth/; http://193.60.222.13/). Ala244Val accounts for 84% of abnormal factor VII alleles in 88 unrelated Iranian-Jewish and Moroccan-Jewish patients.[127] Arg304Gln may have originated more than once.[128] Mutations such as Ala294Val[129] appear to result from a founder effect. Some factor VII variants demonstrate variable activity in the prothrombin time assay, depending on the species of origin (e.g., rabbit or human) of the tissue factor used. The name "factor VII Padua" has been applied to these variants, and several cases are associated with a missense mutation (Arg304Gln) in the tissue factor binding site.[130,131] Factor VII deficiency has been reported in conjunction with abnormalities of bilirubin metabolism, mental retardation, microcephaly, epicanthus, cleft palate, and persistent patent ductus arteriosus.[132] It also has been seen in cases of trisomy 8,[133] and a chromosome 13 q34 deletion causes loss of the factor VII and factor X genes. The latter condition may be associated with carotid body tumors and other malformations.[132] Inherited factor VII deficiency may occur in combination with deficiencies of other vitamin K–dependent proteins (see Combined Deficiency of Vitamin K–Dependent Proteins below).

Reduced levels of factor VII occur with warfarin therapy, liver disease, biliary tract disease, vitamin K deficiency, and cephalosporin therapy.[134] In these situations, other vitamin K–dependent factors usually are decreased, although the effect on factor VII often is the greatest. Inhibitors of factor VII have been reported in deficient patients after replacement therapy.[135]

The clinical spectrum of bleeding in factor VII deficiency is broad. Significant bleeding is greatest with severe deficiency, and patients with levels less than 1% may have a syndrome similar to hemophilia, with spontaneous joint and soft-tissue bleeding leading to hemarthrosis-related arthropathy.[136,137] Central nervous system hemorrhage is common (4%–17%).[33,138,139] Patients with factor VII activity 5% of normal or greater tend to have milder symptoms, such as epistaxis, menorrhagia, and bruising. Although little bleeding occurs in patients with levels of 10% to 15%, some describe significant bleeding that occurs either spontaneously or in response to challenges.[140] In one report, 36% of heterozygotes (factor VII activity 21%–69%) reported bleeding problems, mostly involving skin and mucous membranes.[33] Excessive bleeding often complicates dental extraction and surgery on the oropharynx or urogenital tract in untreated patients. Abdominal surgery and hysterectomy are associated with fewer problems, likely related to varying levels of fibrinolytic activity in different tissues. Postpartum bleeding is not common in factor VII–deficient women.[136,141]

Thrombosis associated with factor VII deficiency has been reported.[142] The database of the International Factor VII Deficiency Study Group contained nine thromboembolic events among 514 entries in 2002.[143] Failure to bind tissue factor pathway inhibitor (see Fig. 127–1, *A*), the natural inhibitor of factor VIIa/tissue factor, has been proposed as an etiology, although a mutation operating by this mechanism has not been identified. Some patients may have factor VII Padua, and apparent low activity may be an artifact of the thromboplastin reagent used.

In the prothrombin time assay, factor VII/VIIa binds to tissue factor in the thromboplastin reagent. The factor VIIa/tissue factor complex then activates factor X (see Fig. 127–1, *B*). In severe factor VII deficiency the prothrombin time is prolonged, but the PTT is normal. The diagnosis is confirmed and the factor level determined by a modified prothrombin time assay using factor VII–deficient

plasma. With some very sensitive thromboplastin reagents, the prothrombin time may be prolonged, with factor VII levels at the lower end of the normal range. When assessing patients for factor VII deficiency, the source of the tissue factor must be considered, as factor VII Padua-type variants interact poorly with reagents containing rabbit tissue factor.[131]

A major consideration when treating factor VII–deficient patients is the short 3- to 4-hour plasma half-life of the protein. Factor replacement can be accomplished with a variety of products (see Table 127–2). Recombinant factor VIIa is approved for use in congenital factor VII deficiency. The recommended dose is 15 to 30 μg/kg body weight every 2 to 6 hours, with the frequency adjusted to the clinical situation. Hemarthroses often respond to single infusions, whereas prophylaxis for invasive procedures may require treating every 2 to 3 hours. Bleeding can be treated with infusions every 4 to 6 hours until hemostasis is achieved.[144] Fresh frozen plasma is widely used for factor VII deficiency, but limited information on efficacy is available. The plasma factor VII level required for surgery is not formally established, but levels of 15% to 25% usually are adequate, and most bleeding episodes respond to infusions every 6 to 12 hours despite the short plasma half-life of factor VII. Use of frequent doses of fresh frozen plasma may result in volume overload. Prothrombin complex concentrates contain variable amounts of factor VII and have been used to treat factor VII deficiency. However, these products are not favored because they contain other vitamin K–dependent factors that are thrombogenic at high concentrations.[14,145] Cryoprecipitate is not a source of factor VII, and plasma levels do not respond to administration of DDAVP.

Not all bleeding in factor VII–deficient patients requires replacement. Minor injuries may be controlled with local measures, and fibrinolytic inhibitors such as ε-aminocaproic acid may be effective as single agents for minor bleeding, dental procedures, or other procedures involving mucous membranes. Fibrin glues may be effective in some situations.[95]

FACTOR X DEFICIENCY (OMIM 227600)

Factor X deficiency was described in two patients in the 1950s.[146,147] The missing plasma factor was called *Stuart-Prower factor* after the two index cases and subsequently was designated *factor X*. Patient Stuart originally was thought to have factor VII deficiency, but mixing of his plasma with factor VII–deficient plasma corrected the abnormalities in clotting assays.[146] Patient Prower had a bleeding tendency and multiple coagulation assay abnormalities, including a prolonged thromboplastin generation test and prothrombin time.[147] Prevalence rates for symptomatic factor X deficiency are thought to be approximately 1 : 1,000,000 (see Table 127–1).[148,149]

Factor X is a 58,000 molecular weight protein that is the precursor of factor Xa.[1,2] Factor X may be activated by the factor VIIa/tissue factor complex or by the factor IXa/factor VIIIa complex (see Fig. 127–1, *A*).[1–3] Factor Xa converts prothrombin to thrombin in the presence of factor Va, phospholipid, and calcium ions; it also catalyzes conversion of factor V to factor Va.

Congenital factor X deficiency is an autosomal recessive trait, with severely affected persons having activity levels less than 1%. Rarely, heterozygotes bleed abnormally.[33] Factor X–deficient mice die in utero or shortly after birth from hemorrhage,[4] and most patients with severe factor X deficiency probably have traces of plasma factor X. Most (75%) of the approximately 60 known mutations identified in the factor X gene are missense mutations, and many are CRM+ variants (www.med.unc.edu/isth/; www.hgmd.org). Mutations affecting the catalytic activity of factor Xa or its interactions with prothrombin or factor V (e.g., Gly381Asp)[150] cause abnormalities in both the prothrombin time and PTT. Mutations that preferentially interfere with activation of factor X by factor VIIa/tissue factor, such as Gla14Lys (Factor X Vorarlberg),[151] preferentially prolong the prothrombin time, whereas Thr318Met (factor X Roma)[152] interferes with interactions with factor IXa, preferentially prolonging the PTT. Factor X deficiency can be inherited with deficiencies of other vitamin K–dependent proteins (see Combined Deficiency of Vitamin K–Dependent Proteins below).

Acquired factor X deficiency occurs with warfarin therapy, vitamin K deficiency, liver disease and disseminated intravascular coagulation, all of which cause concomitant decreases of other coagulation factor levels. Factor X deficiency has been reported with malignancy,[153] infections,[154] and medication.[155] There are rare reports of acquired factor X inhibitors,[156] some after exposure to topical thrombin.[157] Amyloidosis has been implicated in acquired factor X deficiency,[158,159] occurring in 8.7% of patients with AL amyloidosis in one study[160] but rarely in secondary (AA) amyloidosis.[161] Factor X binds to amyloid fibrils, greatly reducing the plasma half-life of the protein.[159] Distinguishing this type of factor X deficiency from the inherited disorder is based on the clinical setting and poor clinical response to infusion of factor X–containing products in the amyloidosis patients.

Bleeding in factor X deficiency is severe and occurs earlier in life in patients with the lowest plasma levels.[149] Factor X–deficient patients bleed more severely than do patients with other rare congenital coagulopathies.[162] The most frequent symptom is epistaxis (72%), but soft-tissue hematomas and menorrhagia are common.[149] Hemarthrosis, hematuria, postoperative bleeding, central nervous system hemorrhage, and gastrointestinal bleeding occur in severe deficiency, and umbilical stump bleeding in newborns is common (28%). Mildly affected persons (factor X activity >15%) may have increased bruising or bleeding with trauma. Most heterozygotes are asymptomatic. However, one third may have excessive bleeding from mucous membranes or after invasive procedures.[33]

As the first protein in the common pathway (see Fig. 127–1, *B*), factor X deficiency typically prolongs the prothrombin time and PTT and must be distinguished from deficiencies of fibrinogen, prothrombin, and factor V, which are associated with similar test results. Definitive diagnosis and determination of severity are established by a modified prothrombin time or PTT assay using factor X–deficient plasma. Some factor X variants preferentially prolong either the prothrombin time or the PTT. Distinguishing congenital factor X deficiency from acquired deficiency associated with amyloidosis cannot be determined in the coagulation laboratory because assays that are dependent on factor X will correct after mixing with normal plasma in both conditions. The findings of a serum M protein, signs of amyloidosis, and histologic confirmation of amyloid in tissues point toward AL amyloidosis. A poor response to factor X infusion in the absence of an inhibitor distinguishes the two conditions.

Factor X–deficient patients are treated with fresh frozen plasma[163] or prothrombin complex concentrate[164,165] for most bleeding episodes (see Table 127–2). A level of 10% to 15% usually is sufficient for hemarthroses and soft-tissue bleeding. The half-life of factor X is approximately 20 to 40 hours,[166] and levels of 10% to 20% are easily obtained with fresh frozen plasma. Recommended fresh frozen plasma doses are 20 mL/kg initially and 3 to 6 mL/kg every 24 hours to keep trough activity levels at 10% to 20%.[95] Higher factor X levels may be required for severe bleeding or surgery, and accumulation of factor X in plasma can be achieved by increasing the transfusion frequency to every 12 hours. Prothrombin complex concentrates contain approximately 1 unit of factor X per unit of factor IX, and doses of 20 to 30 units/kg daily or every other day have been suggested for major surgery.[14,35] Risk of thromboembolism and disseminated intravascular coagulation is a concern when using prothrombin complex concentrates, and it is recommended that plasma factor X levels not exceed 50% of normal, unless absolutely required.[14,164,165] Minor bleeding episodes can be treated with local measures and/or ε-aminocaproic acid. Cryoprecipitate lacks factor X, and DDAVP infusion has no effect and should not be used.

Patients with acquired factor X deficiency and amyloidosis usually are unresponsive to administration of products containing factor X. Treatment has been based on chemotherapy,[166] splenectomy,[167] plasma exchange,[168] prothrombin complex concentrates,[169] and activated factor VIIa.[170]

FACTOR XI DEFICIENCY (OMIM 264900)

In 1953, Rosenthal et al.[171] described three members of a family with abnormal hemostasis, prolonged time to clot formation in a glass tube, and normal prothrombin times. In mixing studies, patient plasma shortened the clotting times of factor VIII–deficient or factor IX–deficient plasma. Unlike the X-linked hemophilias, the new disorder, sometimes referred to as *hemophilia C,* was transmitted as an autosomal trait.[172] The missing factor was called *plasma thromboplastin antecedent* and subsequently factor XI. Early estimates placed the incidence of factor XI deficiency at 1 : 1,000,000.[173] However, other studies suggest an incidence as high as 1%,if symptomatic cases with mild deficiency are included (see Table 127–1).[174,175] Severe factor XI deficiency is common in persons of Ashkenazi Jewish decent, with an incidence of 1 : 450.[176]

Factor XI, the precursor of the 160,000 molecular weight protease factor XIa, is a dimer of two identical polypeptides.[1,2] This structure is unique among coagulation proteases and has implications for inheritance patterns in factor XI deficiency. In the PTT assay, factor XI is activated by factor XIIa (see Fig. 127–1, *B*). However, in vivo factor XI is likely to be activated by factor XII–independent processes as well, because factor XII deficiency does not cause abnormal bleeding.[6] Factor XI may be activated by thrombin, factor XIIa, or factor XIa,[7] and factor XIa activates factor IX (see Fig. 127–1, *A*).[1–3]

The carrier (heterozygous) frequency for factor XI deficiency in Ashkenazi Jews is 5% to 11%, and severe deficiency (<15% of normal) occurs in 0.1% to 0.3%.[5] Early observations of factor XI–deficient parents passing severe deficiency to their children suggested an autosomal dominant or incompletely recessive mode of inheritance.[172,177] It is likely that the unaffected parent in many cases was an asymptomatic carrier, and it is the current opinion that factor XI deficiency in the Jewish population is an autosomal recessive disorder.[176,178] Asakai et al.[179] identified three factor XI gene mutations, two of which account for more than 90% of abnormal factor XI alleles in Jews.[178,180] Glu117Stop codes for a truncated protein, and homozygotes lack plasma factor XI antigen and activity.[179] Phe283Leu causes a partial defect in dimer formation with retention of monomerie protein within the cell of origin.[181] Phe283Leu homozygotes have plasma factor XI activity and antigen levels of 10%,[5] and the plasma protein is dimeric.[181] Compound heterozygotes for Glu117Stop and Phe283Leu have activity of approximately 3%, and heterozygotes have activities of approximately 50% to 60%.[5]

More than 100 mutations in the human factor XI gene have been identified (www.med.unc.edu/isth/; www.hgmd.org; www.FactorXI.org). Cys38Arg has an allele frequency of approximately 0.5% in French Basques,[175] and Cys128Stop[174] accounts for approximately 10% of mutant factor XI alleles in Great Britain.[173] In most cases, plasma factor XI activity and antigen are comparably reduced (CRM– deficiency).[182–184] A classification scheme with three categories has been proposed for CRM– deficiency.[185] The first category contains mutations that prevent factor synthesis (e.g., Glu117Stop), whereas the second contains mutations that interfere with dimer formation (e.g., Phe283Leu). Inheritance in both categories likely follows an autosomal recessive pattern, as mutant polypeptide would not interfere with the product of the normal allele in a heterozygote. The third category includes mutations that block secretion but do not prevent dimerization (e.g., Gly400Val).[185,186] In heterozygotes, mutant polypeptides form dimers with wild-type factor XI, trapping the normal protein in the cell (dominant negative effect). This mechanism may account for families in which severe to moderate factor XI deficiency appears to be a dominant trait. CRM+ factor XI mutations are rare and usually involve catalytic defects (e.g., Gly555Glu).[187] Factor XI Ser248Asn has activity similar to normal factor XI in the PTT assay but binds poorly to platelets,[188] possibly explaining the bleeding disorder associated with the mutation.

Factor XI levels decrease in liver disease and disseminated intravascular coagulation but are not affected by vitamin K deficiency or warfarin therapy. Mild factor XI deficiency is common in patients with Noonan syndrome[189] and the carbohydrate-deficient glycoprotein syndrome, a group of genetic disorders involving multiple organ systems caused by defects in glycosylation of secretory glycoproteins.[190] Antibody inhibitors to factor XI are a relatively common consequence of replacement therapy in factor XI–deficient patients, with up to one third of homozygotes for the Glu117Stop mutation developing inhibitors, often after a single exposure to plasma.[178,191]

Significant bleeding in severe factor XI deficiency is triggered by trauma or surgery.[177,178,192] Spontaneous soft-tissue bleeding or bruising is uncommon.[177,182,184] Bleeding may start at the time of injury or be delayed several hours, and oozing from wounds such as tooth extraction sites may persist for hours to days. Bleeding correlates relatively poorly with plasma factor XI levels.[182,184] Patients with severe deficiency may not bleed excessively, even during surgery without treatment,[5] whereas patients with milder deficiency (15%–50% of normal) may have abnormal hemostasis.[182,184,192] A patient may exhibit different bleeding tendencies over time.[177,184] A study of severe factor XI deficiency clarified this situation by showing that both factor XI level and site of injury influence bleeding.[5] Injury to tissue with high fibrinolytic activity, such as the oral cavity or urinary tract, is associated with excessive bleeding in two thirds of cases, regardless of genotype. Bleeding with surgery or injury at other locations is less frequent but is more common in patients with the lowest factor XI levels.[5,193,194] Thus, homozygotes for Phe283Leu experienced less bleeding than did homozygotes for Glu117Stop or compound heterozygotes.

The association between abnormal hemostasis and mild factor XI deficiency is controversial. Some studies demonstrated minimal bleeding with procedures including tooth extraction, tonsillectomy, nasal surgery, and urologic surgery,[5,195] others found poor correlation between factor XI levels and bleeding,[193,196] and some suggest it is difficult to distinguish severe from mild deficiency based on bleeding tendency.[184,195] Using a logistic regression model, Brenner et al.[193] assessed bleeding in 45 families with factor XI deficiency and determined the odds ratios for bleeding were 13.0 and 2.6 for homozygotes and heterozygotes, respectively. Thus, mild factor XI deficiency may be a mild risk factor for bleeding, but with a significantly smaller risk than for severe deficiency.

In the PTT assay, factor XI is bound to the contact surface through high-molecular-weight kininogen and is activated by factor XIIa (see Figs. 127–1, *B*, and 127–3). Factor XIa then activates factor IX. Therefore, factor XI deficiency prolongs the PTT. Diagnosis and severity are established by a modified PTT using factor XI–deficient plasma. The PTT may be normal in heterozygotes.

Planning perioperative therapy is a challenge in factor XI–deficient patients (see box on Treating Factor XI–Deficient Patients). Factor XI concentrates are available in some countries. Replacement therapy with fresh frozen plasma is used most often in the United States (see Table 127–2). Cryoprecipitate does not contain factor XI, and factor XI levels do not respond to DDAVP. The half-life of factor XI from fresh frozen plasma is approximately 45 hours. When deciding which patients require replacement therapy, it is important to consider the type of hemostatic challenge anticipated. In patients with severe deficiency, most major surgery or procedures involving tissues with high fibrinolytic activity (oropharynx or urinary tract) should be covered with fresh frozen plasma to keep plasma levels at approximately 45% for 10 to 14 days.[197] In the past, it has been recommended that surgery at other sites be treated with replacement to achieve a target of approximately 30% for 5 to 7 days. However, a current retrospective analysis has confirmed that for certain procedures such as circumcision, orthopedic surgery, and appendectomy, the risk of bleeding is low, and replacement therapy can be withheld, unless bleeding occurs.[194] Similar "on-demand" recommendations have been made for treating women during and after labor, which usually is not associated with excessive bleeding.[184,196] Dental procedures, such as tooth extraction, and minor surgical procedures should be covered with antifibrinolytic therapy and in most cases do not require replacement therapy.[198] Patients with factor XI levels greater than 40% do not require replacement therapy for surgery.[195]

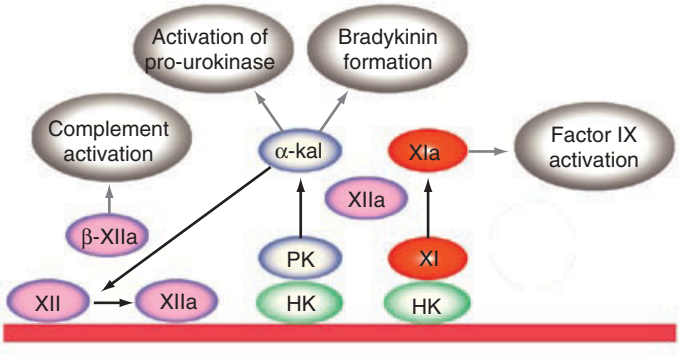

Figure 127–3 Contact activation reactions. Contact activation is initiated by activation of factor XII (XII) to α-factor XIIa (XIIa) when plasma is exposed to a negatively charged surface. Factor XIIa converts prekallikrein (PK) to the active protease α-kallikrein, and α-kallikrein reciprocally activates additional factor XII, amplifying the contact process. Factor XIIa initiates coagulation in the activated partial thromboplastin time assay through conversion of factor XI (XI) to factor XIa (XIa). Note that both PK and factor XI require high-molecular-weight kininogen (HK) to bind properly to the negatively charged surface. The products of the contact activation process can contribute to activation of several host defense mechanisms, at least in vitro. Factor XIa promotes thrombin generation and fibrin clot formation through activation of factor IX. A fragment of α-factor XIIa (β-XIIa—Hageman factor fragment) can initiate the complement cascade through activation of C1. α-Kallikrein cleaves HK to liberate the nanopeptide bradykinin, which has important effects on inflammation and on regulation of local blood flow. α-Kallikrein also can convert prourokinase to the plasminogen activator urokinase, initiating fibrinolysis. Large black arrows indicate the main reactions of contact activation that require the negatively charged surface. Gray arrows indicate subsequent effects on host defense mechanisms that are not surface dependent.

Factor XI concentrates have shown efficacy in factor XI–deficient patients[199,200] but have not been available in the United States. In November 2007, the plasma factor XI concentrate Hemoleven® (LSB, Les Ulis, France) was granted orphan-designation by the Food and Drug Administration. The use of these concentrates has been associated with evidence of intravascular coagulation and thromboembolic events,[201,202] particularly in elderly patients with cardiovascular disease receiving doses greater than 30 U/kg. Current concentrates contain antithrombin and heparin to reduce the procoagulant nature of the product. Factor XI–deficient patients with inhibitors usually do not have an increased bleeding tendency. Activated prothrombin complex concentrates and recombinant factor VIIa both have been used successfully for major surgery in patients with inhibitors.[203,204]

DEFICIENCIES OF THE CONTACT FACTORS: FACTOR XII, PREKALLIKREIN, AND HIGH-MOLECULAR-WEIGHT KININOGEN

Factor XII, prekallikrein, and high-molecular-weight kininogen along with factor XI are involved in the "contact phase" that initiates coagulation in the PTT (see Figs. 127–1, *B,* and 127–3). Patients with deficiency of these proteins have prolonged PTTs but do not have abnormal bleeding, even with major surgery.[6] Therefore, either these proteins do not participate in hemostasis, or redundant mechanisms compensate for their absence. No specific therapy is required to prepare deficient patients for invasive procedures. It is clinically important to distinguish factor XII, prekallikrein, and high-molecular-weight kininogen deficiency from deficiencies of factors VIII, IX, or XI, which also prolong the PTT but cause abnormal hemostasis.

Treating Factor XI–Deficient Patients

When preparing patients with severe factor XI deficiency (plasma level <15%) for an invasive procedure, it is important to remember that (a) a negative bleeding history does not indicate low risk with subsequent procedures, (b) certain procedures are associated with low bleeding risk, and (c) patients with very low factor XI levels (<1%) may develop neutralizing inhibitors when exposed to factor XI. These observations have led to refinements in treatment recommendations that limit exposure to factor XI. Antiplatelet drugs should be stopped 1 week before surgery. Dental extraction can be managed with antifibrinolytic drugs alone (tranexamic acid 1 g qid or ε-aminocaproic acid 4–6 g qid), starting 12 hours before the procedure and continuing for 7 days. Surgery on the oropharynx, nasopharynx, or urinary tract should be treated with fresh frozen plasma for 10 to 14 days, as more than half of patients will bleed if not treated. A similar strategy is appropriate for neurosurgery, head and neck surgery, and cardiothoracic procedures. Antifibrinolytic therapy is a useful adjunct to replacement for surgery on the oropharynx or nasopharynx. Fresh frozen plasma infusion is not necessary prior to circumcision, orthopedic surgery, or appendectomy, as the incidence of excessive bleeding is less than 5%. If bleeding subsequently occurs, fresh frozen plasma should be administered. For vaginal delivery, replacement may be withheld unless bleeding occurs. A similar approach may be acceptable for cesarean section, although data are limited. It is not clear if epidural anesthesia is safe in the absence of factor coverage, and replacement therapy should be used. Patients with factor XI levels greater than 40% do not require replacement, and a history of excessive bleeding in these individuals suggests the presence of other hemostatic abnormalities. Replacement therapy to reach appropriate target levels may be required for factor XI levels of 15% to 40%, depending on the procedure. Aspirin or clopidogrel can be used in factor XI–deficient patients with myocardial infarction or other manifestations of atherosclerosis. Atrial fibrillation or venous thromboembolism should be treated with warfarin, with the goal of not allowing the international normalized ratio to exceed 2.5.

Factor XII Deficiency (OMIM 234000)

In 1955, Ratnoff and Colopy[205] described three asymptomatic individuals with a novel abnormality of surface-induced coagulation. The missing plasma component was called *Hageman factor* after the index case[206] and later was designated *factor XII.* The incidence of severe factor XII deficiency is not known. Many deficient persons go undiagnosed due to the absence of a phenotype. Moderate to severe factor XII deficiency was reported in 1.5% to 3.0% of healthy blood donors. This unexpectedly high prevalence may be related to antibodies to factor XII or antiphospholipid antibodies that interfere with factor XII activity assays.[207,208]

Factor XIIa is an 80,000 molecular weight protease that activates factor XI and prekallikrein during the contact phase of the PTT.[1,2] A 46C/T polymorphism in the 5′-untranslated region of the factor XII gene strongly influences plasma levels, with the 46T allele associated with lower plasma factor XII compared to 46C.[209] The frequency of 46T is high (73%) in East Asians (compared to 20% in Caucasians), who have lower factor XII levels than other ethnic groups. Factor XII activity and antigen usually are reduced in parallel in deficient individuals, and circulating dysfunctional variants are rare.[210] A small number of factor XII gene mutations have been identified (www.hgmd.org), most residing in the protease domain.[211] Factor XII deficiency is not associated with spontaneous or excessive posttraumatic bleeding, and most cases are identified by the incidental finding of a prolonged PTT. There is controversy regarding an association between factor XII deficiency and thrombosis[212] or recurrent

abortion.[213] Although studies indicate no increased risk for thrombosis,[214,215] results from the SMILE (Study of myocardial infarction—Leiden) project demonstrated an inverse relationship between factor XII levels and risk of myocardial infarction.[212] In contrast, factor XII–deficient mice are relatively protected from developing pathologic thrombi.[216] An association between factor XII deficiency and thrombosis in humans remains uncertain.

Factor XII undergoes autoactivation when exposed to the contact surface in the PTT. Factor XIIa activates factor XI and prekallikrein, with α-kallikrein reciprocally activating additional factor XII (see Fig. 127–3). In severe factor XII deficiency, the PTT is very prolonged. Definitive diagnosis is established by a modified PTT using factor XII–deficient plasma. Antiphospholipid antibodies may disproportionately affect measurement of factor XII by PTT-based assays.[217] In addition, factor XII antibodies have been detected in up to half of plasmas with antiphospholipid antibodies[207,208] and may account for many or most cases of presumed mild factor XII deficiency.

Prekallikrein Deficiency (OMIM 229000)

In 1965, Hathaway et al.[218] reported on members of a family with long plasma clotting times that corrected on prolonged incubation with glass. The family had no history of bleeding. The missing plasma component, initially called *Fletcher factor* after the index cases, subsequently was shown to be prekallikrien.[219] Severe prekallikrein deficiency apparently is a rare disorder. However, many mild cases may be missed because 2% to 5% of normal plasma prekallikrein activity is sufficient to bring some PTT assays into the normal range.

Prekallikrein is the 95,000 molecular weight precursor of the kininogenase α-kallikrein. Prekallikrein deficiency is an autosomal trait, presenting in the homozygous or compound heterozygous forms with plasma levels less than 1%. CRM+ prekallikrein variants account for about half of cases and are common in Caucasian and Japanese patients; most black patients are CRM–.[6] Few prekallikrein gene mutations have been identified (www.hgmd.org). Partial prekallikrein deficiency (10%–50%) may be seen in patients with severe high-molecular-weight kininogen deficiency,[220] likely due to increased catabolism or clearance, because prekallikrein circulates as a complex with high-molecular-weight kininogen. Severe prekallikrein deficiency presents as an incidental prolongation of the PTT in a person without a history of excessive bleeding. Although thrombotic events have been described with prekallikrein deficiency, whether the deficiency contributes to thrombosis is unclear.

In the PTT assay, prekallikrein is converted to α-kallikrein by factor XIIa, which reciprocally activates factor XII (see Figs. 127–1B and 127–3). Severe prekallikrein deficiency causes a prolonged PTT, and the diagnosis is confirmed by a modified PTT using prekallikrein-deficient plasma. The prolonged PTT in prekallikrein deficiency may be shortened by prolonged incubation with the contact reagent, which allows factor XII sufficient time to activate by prekallikrein-independent mechanisms. This distinguishes prekallikrein deficiency from other deficiencies associated with a prolonged PTT, which do not correct with prolonged incubation. Some PTT reagents use the contact activator ellagic acid, which is relatively insensitive to prekallikrein deficiency and may fail to detect some patients with prekallikrein deficiency.

High-Molecular-Weight Kininogen Deficiency (OMIM 228960)

In 1974, Schiffman and Lee[221] reported that a plasma factor distinct from prekallikrein was required for factor XI activation by factor XIIa. In 1975, three asymptomatic patients from three separate families with in vitro abnormalities of coagulation, fibrinolysis, and kinin generation were described who appeared to lack the unknown factor. The condition, originally named for the affected families (Fitzgerald trait, Williams trait, and Flaujeac trait),[6,220] subsequently was determined to be due to high-molecular-weight kininogen deficiency. The disorder appears to be very rare.

High–molecular-weight kininogen is a 110,000 molecular weight glycoprotein that contains the vasoactive peptide bradykinin.[222,223] Prekallikrein and factor XI circulate in plasma as complexes with high-molecular-weight kininogen. Low-molecular-weight kininogen and high–molecular-weight kininogen are alternatively spliced products of a single gene; however, low–molecular-weight kininogen does not play a role in coagulation in vitro. High-molecular-weight kininogen deficiency is an autosomal recessive trait. Depending on the genetic abnormality (www.hgmd.org), patients may have isolated high-molecular-weight kininogen deficiency or combined high-molecular-weight kininogen and low-molecular-weight kininogen deficiency.[6] Patients with high-molecular-weight kininogen deficiency usually are identified by the incidental finding of a prolonged PTT and do not have excessive bleeding.

In the PTT assay, high-molecular-weight kininogen facilitates binding of prekallikrein and factor XI to the contact surface, enhancing their activation by factor XIIa (see Fig. 127–1B and 127–3). Severe high-molecular-weight kininogen deficiency is characterized by a very prolonged PTT, and definitive diagnosis is established by modified PTT using high-molecular-weight kininogen–deficient plasma. Partial prekallikrein deficiency is common in severe high-molecular-weight kininogen deficiency, likely due to increased catabolism of prekallikrein when it is not in complex with high-molecular-weight kininogen.[220]

FACTOR XIII DEFICIENCY (OMIM 134570 [A SUBUNIT] AND 134580 [B SUBUNIT])

In 1944, Robbins[224] demonstrated that fibrin formed from purified components was soluble in weak acid, whereas fibrin formed in the presence of serum or plasma was not. He proposed that a *fibrin stabilizing factor* was present in plasma, and that its deficiency would cause excessive bleeding. This idea was confirmed in 1960, when Duckert et al.[225] described the first patient with deficiency of fibrin stabilizing factor, which subsequently was designated *factor XIII*. The incidence of symptomatic factor XIII deficiency is estimated to be 1:1–5,000,000 (see Table 127–1).[226]

Plasma factor XIII is a 330,000 molecular weight tetramer composed of two catalytic "A" subunits and two carrier "B" subunits.[8,227] About half of factor XIII in blood is in platelets, with a small amount in monocytes. Platelet and monocyte factor XIII consist only of A subunits. Factor XIII is converted to the transglutaminase factor XIIIa by thrombin and catalyzes formation of γ-glutamyl-ε-lysyl bonds between fibrin monomers (see Fig. 127–1, *A*), resulting in a fibrin meshwork that is insoluble in mild acids and urea. Factor XIIIa also cross-links fibrin to plasma, extracellular matrix, and cytoskeleton proteins, facilitating clot adherence to an injury site. Congenital factor XIII deficiency is an autosomal recessive trait. In type I deficiency, A and B subunits are reduced, whereas in type II deficiency A subunits are reduced and in type III deficiency B subunits are reduced.[228] Deficiency usually is caused by mutations in the A subunit.[35] B subunit mutations are rare (www.med.unc.edu/isth/; www.hgmd.org). The incidence of factor XIII mutations probably is higher than the incidence of the bleeding diathesis, as hemorrhage and screening test abnormalities occur almost exclusively with severely decreased plasma activity (<1%–2%). For some mutations, a founder effect is likely. For example, Leu660Pro in the A subunit is relatively prevalent in Palestinian Arabs.[229] The molecular heterogeneity of factor XIII deficiency may explain variability in bleeding, with mutations in specific areas of the molecule affecting certain functions.

Plasma factor XIII levels are low in disseminated intravascular coagulation. Significant deficiency is rare in liver disease and may indicate a poor prognosis. Acquired deficiency has been seen in inflammatory disorders, including Henoch-Schönlein purpura,[230]

and inflammatory bowel disease.[231] Factor XIII neutralizing antibodies rarely occur in deficient patients as a consequence of factor replacement but have been observed in collagen vascular disorders such as systemic lupus erythematosus[232] and with therapy with isoniazid, penicillin, procainamide, and phenytoin.[233]

Newborns with factor XIII deficiency frequently bleed from the umbilical stump.[234–236] Ecchymoses, soft-tissue hematomas, and prolonged bleeding with trauma are common, and recurrent soft-tissue bleeding may lead to formation of hemorrhagic cysts (pseudotumors).[234,235] Hemarthroses is less frequent than in factor VIII or IX deficiency. Bleeding often is delayed 12 to 36 hours postinjury[225] but may be immediate. Bleeding at the time of invasive procedures may be minimal, but delayed hemorrhage often occurs. Intracranial hemorrhage is more frequent in factor XIII deficiency than in other inherited coagulation disorder; its incidence of 25%[235–237] justifies prophylactic factor XIII replacement. Delayed wound healing has been observed in deficient patients, possibly related to a defect in angiogenesis.[238] Recurrent spontaneous abortions occur with most pregnancies in untreated factor XIII–deficient women,[239] possibly due to abnormal formation of the cytotrophoblastic shell and poor attachment of the placenta to the uterus.[240]

The prothrombin time and PTT measure time to fibrin clot formation; they do not assess clot stability. Therefore, results of these assays are normal in factor XIII–deficient patients. Clots in factor XIII–deficient plasma are soluble in 5 M urea or 1% monochloroacetic acid, whereas normal clots are stable for at least 24 hours.[241] Solubility in 5 M urea (urea clot stability assay) is the most frequently used clinical assay for screening for factor XIII deficiency or inhibitors. Clots from plasma lacking α_2 antiplasmin also may show increased solubility in this assay[242] and can be identified with specific assays. Specific assays measuring factor XIIIa activity are available but have yet to achieve widespread clinical use.[241]

The plasma half-life of factor XIII is 10 to 14 days,[243] and hemostasis can be achieved in most situations by maintaining levels above approximately 5%, thus facilitating prophylactic replacement therapy to prevent intracranial bleeding. Factor XIII concentrate (Fibrogammin) is available in the United States only as part of a company-sponsored study (see Table 127–2),[244,245] A regimen of 10 to 20 U/kg every 5 to 6 weeks is sufficient for normal hemostasis. Single doses of 10 to 20 U/kg have been used successfully for treatment of poor wound healing. If concentrate is not available, fresh frozen plasma (1–2 units every 4–6 weeks) or cryoprecipitate (1 unit/10–20 kg body weight every 3–4 weeks) can be used. Limited information is available to guide the use of replacement therapy during surgery or major bleeding. Factor XIII concentrate (50–75 U/kg) has been recommended for these situations.[245] Adequate hemostasis has been achieved during intracranial surgery by administering concentrate to achieve a level of 50% during surgery and then maintaining the level above 20% for the first few postoperative weeks before returning to prophylactic dosing.[246] Factor XIII levels higher than those achieved with prophylactic dosing are also required to prevent fetal loss during pregnancy.[38,247] In pregnancy, factor XIII replacement should be started early, preferably before gestational week 5, as decidual bleeding from implantation will occur without replacement. The optimal plasma factor XIII concentration in pregnancy is not clear, but at least 10% of normal is recommended.[247] This can be achieved by infusing 250 units of concentrate every 7 days through week 22 of gestation and 500 units per week for the remainder of pregnancy, with a bolus of 1000 units during labor.[247]

CONGENITAL DEFICIENCIES INVOLVING MULTIPLE COAGULATION FACTORS

Cases of congenital deficiencies of more than one coagulation factor have been described. Some likely represent chance coinheritance of distinct factor deficiency states, but several represent familial syndromes (Table 127–3). Such syndromes likely are caused by abnormalities in intracellular processing of factors (e.g., type 1 deficiency) or alterations in the structure/activity of multiple factors (e.g., type 3 deficiency). Remember that common nonspecific inhibitors such as lupus anticoagulants interfere with coagulation assays and can lead to erroneous interpretations when they suggest multiple factor deficiencies (see box on Laboratory Testing in Rare Coagulation Factor Deficiencies). Similarly, potent inhibitors directed at a single coagulation factor (e.g., factor VIII) occasionally may interfere with assays for other factors. Two familial multiple factor deficiency states, combined factor V and VIII deficiency (type 1) and deficiency of vitamin K–dependent factors (type 3), are well characterized.

Combined Factor V and Factor VIII Deficiency (OMIM 227300)

Combined factor V and factor VIII deficiency was first recognized in 1954.[248] The familial form is an autosomal recessive trait caused by mutations (www.med.unc.edu/isth/) in either the LMAN1 (mannose binding lectin, formerly ERGIC-53) or MCFD2 (multiple combined factor deficiency protein) gene.[249,250] These proteins form a complex required for transport of factors V and VIII from the endoplasmic reticulum to the Golgi apparatus.[251] Although very rare, the allele frequency is high (≈1%) in Tunisian Jews originating from a community on the island of Djerba.[252]

Deficiency of either LMAN1 or MCFD2 causes a partial defect in factor V and VIII secretion, lowering plasma levels to approximately 5% to 30%. The mutation in Tunisian Jews is a T to C transition at a donor splice site in intron 9 of the LMAN1 gene.[252] A history of consanguinity, cosegregation of the factor deficiencies, and similar reductions in factor V and VIII favor the familial disorder. Homozygotes or compound heterozygotes bleed primarily after trauma, and epistaxis, gingival bleeding, easy bruising, and menorrhagia are common.[253,254] Nontrauma-related hemarthrosis may occur in 20% of patients, but bleeding from the gastrointestinal

Table 127–3 Combined Familial Deficiency States

Type	Deficient Factors	OMIM Designation	Reference	Underlying Cause
1	V, VIII	227300	249, 250	Mutations in LMAN1 or MCFD2
2	VIII, IX	134510	266	Unknown
3	II, VII, IX, X, protein C, protein S	277450 (γ-glutamyl carboxylase) 608547 (vitamin K oxidoreductase)	259, 260, 262	Mutations in γ-glutamyl carboxylase or vitamin K oxidoreductase
4	VII, VIII	134430	266	Unknown
5	VIII, IX, XI	134520	267	Unknown
6	IX, XI	134540	267	Unknown

Laboratory Testing in Rare Coagulation Factor Deficiencies

When considering one of these diagnoses, remember that (a) acquired conditions causing multiple factor deficiencies are far more common than is congenital deficiency of a single factor, and (b) common nonspecific coagulation inhibitors such as lupus anticoagulants and heparin can interfere with coagulation assays. Unexplained prolongation of the prothrombin time or partial thromboplastin time (PTT) should be evaluated in a qualified laboratory. A mixing study with normal plasma is recommended as an initial step to determine if the abnormality is related to a factor deficiency or an inhibitor. The mixing study should be done with and without incubation (1–2 hours), as some inhibitors show a time-dependent pattern of inhibition. Slight prolongation of the prothrombin time or PTT can be difficult to evaluate with a mixing study, and we frequently test for lupus anticoagulants in these cases prior to specific assays for coagulation factors. Ideally, samples should be collected by venipuncture and not from central lines or ports, because contamination of samples with heparin may distort results. Many laboratories use the thrombin time assay to screen samples for possible heparin contamination. Tests for hepatic function (albumin) or injury (transaminases) facilitate interpretation. If a vitamin K–dependent protein (prothrombin or factor VII, IX, or X) is low, a level for factor V and at least one other vitamin K–dependent factor should be determined. If levels of multiple vitamin K–dependent factors are low and factor V is normal, a process affecting vitamin K is likely. If factor V also is low, liver disease or disseminated intravascular coagulation should be considered. Distinguishing disseminated intravascular coagulation from liver disease can be difficult, because standard tests may be abnormal in both conditions. Measuring factor V and factor VIII levels can be useful in this situation, because both factors usually are low in disseminated intravascular coagulation, whereas the factor VIII level often is normal or elevated in liver disease.

Patients with factor XI, XII, prekallikrein, or high-molecular-weight kininogen deficiency may require anticoagulation for thromboembolism or other indications. However, the PTT cannot be used for monitoring therapy with unfractionated heparin or thrombin inhibitors such as lepirudin and argatroban. Measuring heparin with a factor Xa-based chromogenic assay or by protamine titration can be done but requires a sophisticated laboratory. Alternatively, low-molecular-weight heparin, which usually does not require monitoring, may be used. Specific tests for direct thrombin inhibitors have been developed, some based on modifications of the thrombin time assay.

tract or intracranial hemorrhage is less common. Postpartum hemorrhage occurs in most affected women, and invasive procedures including dental extraction usually are accompanied by excessive bleeding without replacement therapy. In one study, approximately 13% of heterozygotes reported excessive bleeding; however, there was no correlation between symptoms and factor levels.[253] The disorder is associated with a prolonged prothrombin time and PTT (see Fig. 127–1, *B*). Isolated factor V deficiency also gives this pattern, so it is recommended that factor VIII levels be measured in patients with factor V deficiency so that combined deficiency is not overlooked.

Patients with mucosal bleeding and menorrhagia may respond to antifibrinolytic therapy. For more significant bleeding, surgical procedures, or tooth extraction, a combination of fresh frozen plasma and factor VIII concentrate should be used. DDAVP can raise factor VIII[253] but not factor V levels.[255] Trough levels of approximately 50% for both proteins have been recommended for surgery. Plasma exchange to raise factor V levels has been suggested to avoid volume overload from large volumes of fresh frozen plasma.[255]

Combined Deficiency of Vitamin K–Dependent Proteins (OMIM 277450 and 608547)

In 1979, Chung et al.[256] described a newborn girl with a prolonged prothrombin time and PTT, low levels of prothrombin and factors VII, IX, and X and no evidence of liver disease or malabsorption. She had a partial response to large doses of vitamin K. In subsequent cases, low protein C and protein S levels also were noted[257,258] in association with mutations in the γ-glutamyl carboxylase gene.[259,260] The condition is a rare autosomal recessive trait.[261]

Prothrombin, factors VII, IX, and X, proteins C and S, and some bone proteins require γ-carboxylation of glutamic acid residues in the N-terminal Gla domain (see Chapter 130).[1,2] γ-Carboxylation is mediated by γ-glutamyl carboxylase, which uses reduced vitamin K as a cofactor. γ-Carboxylation results in formation of vitamin K 2,3-epoxide, which must be reduced by vitamin K oxidoreductase to replenish the pool of vitamin K. Mutations in the γ-glutamyl carboxylase gene (e.g., Arg394Leu; www.hgmd.org) or vitamin K oxidoreductase gene (e.g., Arg98Trp) can impair this process and result in low levels of all vitamin K–dependent proteins.[260,262] The factors are reduced to 10% to 50% of normal, resulting in a variable bleeding tendency that may be severe. Some patients have skeletal abnormalities, possibly related to reduced function of vitamin K–dependent bone proteins.[263] Low levels of vitamin K–dependent proteins are also seen in patients receiving warfarin, in poisoning with rodenticides such as brodifacoum, and in vitamin K deficiency. The levels of these proteins are low in liver failure, in conjunction with other proteins synthesized in the liver.

The low levels of prothrombin and factors VII, IX, and X cause prolongation of the prothrombin time and PTT. Protein C and S levels also are reduced. The abnormalities correct upon mixing with normal plasma. Failure to correct suggests that a nonspecific inhibitor such as a lupus anticoagulant is interfering with the assay. Patients with deficiencies of vitamin K–dependent proteins should be evaluated for liver disease and for exposure to warfarin or rodenticides containing vitamin K antagonists such as brodifacoum. Due to their long half-lives, these agents can be identified by toxicology screens long after ingestion. Some patients have adequate clinical response to vitamin K but require unusually high doses. Nonresponders or responders with significant bleeding episodes can be treated with fresh frozen plasma or prothrombin complex concentrate.[261,264,265]

CHAPTER 128

STRUCTURE, BIOLOGY, AND GENETICS OF VON WILLEBRAND FACTOR

David Ginsburg and Denisa D. Wagner

The adhesive glycoprotein von Willebrand factor (VWF) was named after Dr. Erich von Willebrand, who described in 1926 a new bleeding disorder[1] distinct from hemophilia. von Willebrand disease (VWD) was later recognized to be caused by qualitative or quantitative defects in VWF.[2] VWF circulates in plasma at concentrations of 5 to 10 μg/mL. Some of the molecules are complexed with factor VIII, protecting factor VIII against degradation. VWF is synthesized by only two cell types: endothelial cells and megakaryocytes.[3,4] Besides plasma, VWF is found in platelets, endothelial cells, and the basement membrane of blood vessels.[5] All these pools of VWF contribute to the protein's main function: to promote attachment of platelets to areas of vessel injury. To optimize the availability of VWF at the site of injury, a highly active form of the protein is stored in secretory granules of platelets and endothelial cells. When these cells sense tissue injury (eg, by contact with thrombin), they instantly mobilize the stored protein. The released VWF binds to glycoprotein Ib (GPIb) on the platelet surface and to components of the basement membrane, forming a bridge that can withstand the high sheer stress of blood flow. VWF is necessary for this initial attachment step of platelets to the injured area.[6] Together with other adhesive proteins, such as fibrinogen, fibronectin, and thrombospondin, VWF interacts with glycoprotein IIb (GPIIb)/IIIa on activated platelets and contributes to platelet spreading and aggregation. VWF is a large protein composed of many subunits held together covalently by disulfide bonds. In this way, the protein acquires multiple binding sites for platelets and the basement membrane, which may strengthen its interactions during hemostasis. The ultra-large forms of VWF assembled within the endothelial cell are processed to smaller forms in circulating plasma through the action of a recently identified plasma protease, ADAMTS13.[7–9] Deficiency of this protease is now known to be the cause of thrombotic thrombocytopenic purpura (TTP) (see Chapter 139). This is presumably because of the abnormally enhanced adhesive function of unprocessed ultra-large VWF multimers. In contrast, qualitative or quantitative deficiency of VWF adhesive function results in the common bleeding disorder, VWD (see Chapter 129).

THE VON WILLEBRAND FACTOR GENE

The full-length VWF complementary DNA (cDNA) sequence predicts a protein of 309,000 molecular weight (2813 amino acids).[10–13] In addition, the location of *N*- and *O*-linked glycosylation sites within the mature VWF subunit have been determined by direct protein analysis.[14] Comparison of the cDNA and primary amino acid sequences identified a large propeptide (741 amino acids) preceding the mature VWF subunit sequence. This propeptide is identical to a previously observed immunologic activity in plasma called VWF antigen II. This propeptide plays an important role in VWF multimer assembly and processing but has no known function after secretion. The *VWF* gene is located on the short arm of human chromosome 12[10,12] and a partial, nonfunctional duplication (pseudogene) is on human chromosome 22.[15] The structures of the unusually large *VWF* gene and pseudogene are shown schematically in Fig. 128–1.[16,17] The gene is composed of 52 exons spanning a total of 178 kb of the human genome. It is similar in size to the factor VIII gene (see Chapter 123) and more than 100 times larger than the gene for β-globin (see Chapter 33). The *VWF* gene accounts for approximately 0.1% of human chromosome 12. The *VWF* pseudogene duplicates the middle portion of the gene from exons 23 to 34, including the intervening sequences. The pseudogene is approximately 97% homologous to the authentic gene and is only present in humans.[17]

Analysis of the VWF amino acid sequence identifies a pattern of homologous repeated segments, designated by the letters A through D in Fig. 128–1. This pattern suggests that the *VWF* gene arose by a complex series of partial gene duplications. The expression of the *VWF* gene is tightly regulated and restricted exclusively to endothelial cells and megakaryocytes.[18] For this reason, VWF is frequently used as a primary histochemical marker to identify cells of endothelial cell origin. A 734-base pair DNA fragment extending from approximately 500 base pairs upstream of the transcription start site into the first intron confers endothelial cell-specific *VWF* gene expression in vitro[19] and directs gene expression to a subpopulation of endothelial cells in transgenic mice.[20] However, as in the case of β-globin, another highly tissue-specific regulated gene (see Chapter 27), critical transcription regulatory sequences located a great distance from the 5′ end of the *VWF* gene may be required for the high-level expression observed in a wide range of endothelial cells in vivo.

Comparison of the *VWF* DNA sequence to that of other known genes identifies potential relationship to a number of other adhesive proteins. A superfamily of proteins sharing sequence similarity with VWF A domains contains a number of proteins associated with the extracellular matrix, hemostasis, or cell adhesion. The crystal structure of the VWF A1 and A3 domains have been solved[21,22] and are remarkably similar to the structure for the homologous I domain of the integrin α2/β1.[23] The structure of the VWF A1 domain in complex with GPIbα demonstrates that the latter platelet receptor wraps around one side of the A1 domain, providing two areas of contact bridged by charged interactions. These findings may explain the effect of mutations in type 2B VWD and provide a model for activation of the VWF molecule.[24]

Exons of *VWF* range in size from 40 base pairs to 1.4 kb for exon 28, one of the larger known single exons. This latter exon encompasses most of the A1 and A2 homologous repeats, a region containing several important VWF functional domains, as well as most human mutations associated with type 2A and 2B VWD.

DOMAIN STRUCTURE

VWF exists as a series of multimers varying in molecular weight between 0.5 (dimer) and 20 million (multimer). Electron microscopic observations of VWF molecules reveals that they are filamentous and contain subunits arranged in a head-to-head and tail-to-tail configuration.[25,26] The building block of multimers is a dimer, held together by disulfide bonds located near the carboxyl-terminal end of each subunit. The dimers are joined to each other by disulfide bonds located near the *N*-terminal end of the mature subunit.[27,28] The mature subunit has a mass of approximately 270 kd and contains 18.7% carbohydrate.[14] *N*- and *O*-linked carbohydrates are found clustered at both ends of the subunit. All 169 cysteine residues (8.2% of the amino acid content) are involved in interchain or intrachain disulfide bonds.[29] Two Arg-Gly-Asp (RGD) sequences are found in pro-VWF. The one in the mature VWF subunit is part of the binding site for the platelet integrin receptor, GPIIb/IIIa (see Fig. 128–1).

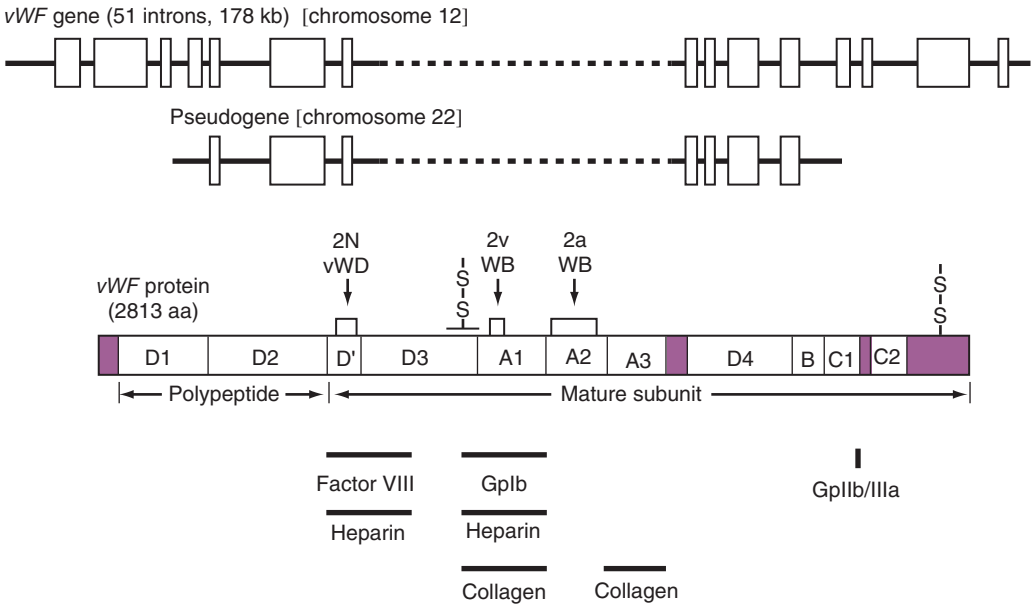

Figure 128–1 The structure of the *VWF* gene and protein. The structures of the *VWF* gene and pseudogene are indicated schematically at the top of the figure. The corresponding protein is also depicted, including the homologous repeat domain structure. The localization within VWF of point mutations associated with VWD variants are also indicated. AA, amino acids; VWD, von Willebrand disease; VWF, von Willebrand factor. *(Adapted from Ginsburg D, Bowie EJW: Molecular genetics of von Willebrand disease. Blood 79:2507, 1992.)*

The significance of the other RGD sequence located on the propeptide is unknown.

Several functional domains in VWF have been identified on the VWF subunit (see Fig. 128–1).[30] Two collagen-binding sites have been mapped to the mature VWF subunit and potentially a third to the propeptide. However, studies of recombinant VWF suggest that the major physiologically active binding site for fibrillar collagen lies within the A3 domain.[31,32] VWF also has at least two binding sites for heparin and may interact with heparin-like molecules in the basement membrane. The factor VIII–binding domain is located in the *N*-terminal portion of the VWF subunit[33] and interacts with the *N*-terminal portion of the factor VIII light chain.[34,35] VWF also has affinity for two platelet receptors. VWF binding to GPIb plays a pivotal role in the early events of hemostasis, leading to the attachment of platelets to the area of injury.[6] Several potential, short-binding sequences for GPIb on VWF have been identified, all localized to a large disulfide loop contained within the VWF A1 repeat (see Fig. 128–1).[36,37] The binding region of VWF to GPIIb/IIIa on activated platelets is located in the carboxyl-terminal portion of the mature subunit. This recognition site can be specifically inhibited by the Arg-Gly-Asp sequence contained within peptides and is, therefore, likely to include the Arg-Gly-Asp-Ser sequence. VWF (with other adhesive proteins, such as fibrinogen and fibronectin) may compete for binding to this glycoprotein. In vivo studies in knock-out mice demonstrate that all three of these adhesive ligands (VWF, fibrinogen, and fibronectin) contribute to platelet adhesion in thrombus formation following vascular injury.[38] Finally, the VWF A2 domain contains the cleavage site for the plasma protease ADAMTS13, which reduces VWF multimer size and biologic activity.

BIOSYNTHESIS

The processing steps leading to the formation of mature VWF multimers have been studied chiefly in endothelial cells,[39] but evaluation of megakaryocyte biosynthesis indicates an identical pattern of synthesis (Fig. 128–2).[4] VWF is first synthesized as a pro-VWF monomer.[40–42] Co-translationally, high-mannose carbohydrate is added to the polypeptide chain. There are 13 potential *N*-linked glycosylation sites on mature VWF and 4 on the propeptide. Although residing within the endoplasmic reticulum, the carboxyl-termini of the pro-VWF subunits are linked together by an unknown number of disulfide bonds.[43] Only dimeric molecules are transported to the Golgi apparatus, where their processing continues.

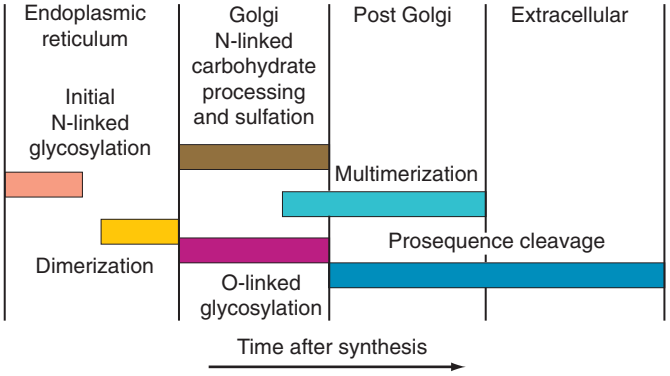

Figure 128–2 Map of processing steps in the biosynthesis of VWF. Interchain disulfide bonds are formed in two steps (dimerization and multimerization, pink). The propeptide is cleaved late in VWF processing (prosequence cleavage, red). VWF, von Willebrand factor. *(Adapted from Handin RI, Wagner DD: Molecular and cellular biology of von Willebrand factor. Prog Hematol 9:233, 1989.)*

In the Golgi apparatus, common modifications, including the addition of *O*-linked carbohydrate, high-mannose carbohydrate processing, and sulfation, take place (see Fig. 128–2). In addition, a unique processing event includes the multimerization of dimers by disulfide bond formation. VWF is the only protein known that has disulfide bonds formed late in protein synthesis, as disulfide bonds are usually formed in the endoplasmic reticulum. The latter process is catalyzed by the enzyme disulfide isomerase. The contents of the last compartment of the Golgi apparatus (*trans*-Golgi), and the post-Golgi secretory vesicles are slightly acidic. It is likely that multimerization occurs in these acidic compartments because this process can be completely inhibited by culturing cells in the presence of a weak

base[44] that increases the pH of acidic cellular compartments. The VWF propeptide plays an active role in the interdimer disulfide bond formation. When prepro-*VWF* cDNA is expressed in a monkey kidney cell line or other cells that normally do not synthesize VWF, these cells are capable of supporting VWF multimerization. By contrast, if pre-*VWF* cDNA (with the cDNA coding for the propeptide deleted) is expressed in these cells, only dimeric molecules are synthesized and secreted.[45,46] In in vitro multimerization experiments, pro-VWF dimers spontaneously form larger multimers, whereas VWF mature dimers remain dimeric. The in vitro multimerization is promoted by a slightly acidic environment (optimal pH is ~5.8) and will not occur at a neutral or basic pH.[47] Under these acidic pH conditions, the propeptide may catalyze disulfide bond formation among the mature VWF subunits. The propeptide contains sequences similar to those found at the active site of protein disulfide isomerase. These are cysteines separated by two amino acids that readily interchange with disulfide bonds in the substrate. When an additional amino acid was inserted between the cysteines of the propeptide by site-specific mutagenesis, the VWF expressed did not form multimers.[48] During the biosynthesis of VWF multimers, the propeptide self-associates, but it is not known whether this association is linked to noncovalent multimer assembly that likely precedes the interchain disulfide bond formation.[49]

The propeptide cleavage is one of the final processing steps in the biosynthesis of VWF. Similar to other prosequences, the VWF propeptide is cleaved adjacent to two basic amino acids, Lys-Arg at residues −2 and −1. An Arg at −4 position from the cleavage site is also part of the cleavage recognition sequence, providing evidence that an enzyme with furin-like specificity is responsible for the intracellular prosequence cleavage.[50] Multimerization and propeptide cleavage are separate events. Site-specific mutagenesis of the cleavage site inhibits propeptide cleavage, but the expressed protein has a normal multimeric composition.[51] Propeptide cleavage and multimerization occur after sulfation in the *trans*-Golgi network but prior to formation of the Weibel-Palade body.[52]

Although VWF processing is chiefly intracellular, some modifications to the protein occurs after secretion. Cleavage of the propeptide, which begins in the *trans*-Golgi compartment, may continue extracellularly.[53] The largest VWF multimers found in plasma are smaller than those found in endothelial cells.[54] A plasma protease,[55,56] ADAMTS13,[7–9] specifically cleaves VWF in the circulation between Tyr 842 and Met 843 in the VWF A2 domain,[57] resulting in reduction of unusually large multimers to smaller species. Mutant VWF in group II type 2A VWD exhibits increased susceptibility to cleavage by this protease,[58] the apparent mechanism for loss of large VWF multimers in this disorder. In addition, genetic or acquired deficiency of this protease activity is responsible for most cases of TTP (see Chapter 139). Mice engineered to be genetically deficient in ADAMTS13 exhibit enhanced platelet adhesion and thrombus formation on injured blood vessels, suggesting that ADAMTS13 functions as a natural antithrombotic by regulating VWF multimer structure.[59,60]

VON WILLEBRAND FACTOR STORAGE AND SECRETION

VWF is the only known adhesive protein that is stored and undergoes regulated secretion from cells other than platelets.[39] Both the platelet pool and the endothelial pool of VWF are important physiologically, as demonstrated by crossed bone marrow transplantation experiments between normal and VWD pigs.[61,62] In platelets, VWF is present in the α-granules with many other stored proteins. Only a few secreted proteins, including angiopoietin-2, tissue plasminogen activator (tPA) and interleukin (IL)-8 have been shown to be co-stored in the Weibel-Palade bodies of endothelial cells, along with VWF and the VWF propeptide.[63,64] In both organelles, the stored VWF molecules appear to form tubular structures, 150 Å in diameter.[65,66] These tubules are absent in the α-granules of pigs with VWD.[67] A transmembrane glycoprotein of the α-granule, P-selectin, is a component of the Weibel-Palade body membrane. Like VWF, the biosynthesis of this protein is restricted to endothelial cells and to megakaryocytes. When expressed on the plasma membrane, P-selectin promotes the adhesion of monocytes, neutrophils, and some other subsets of leukocytes.[68,69] Weibel-Palade bodies originate from the Golgi apparatus. They are up to 4 μm long and 0.1 μm thick (Fig. 128–3) and are found in endothelial cells of virtually all blood vessels types. There is, however, variation in the number of Weibel-Palade bodies per cell in endothelium of different origin.[70]

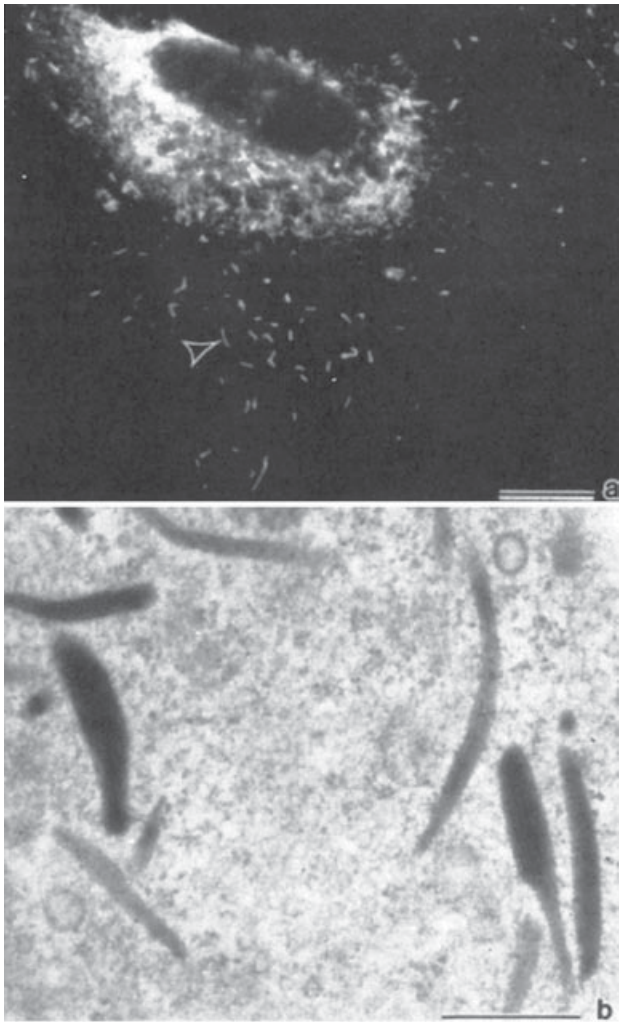

Figure 128–3 Weibel-Palade bodies of endothelial cells. **A**, Immunofluorescence staining of a human umbilical vein endothelial cell with anti-VWF antiserum. VWF is present in the perinuclear region, where it is synthesized and in the Weibel-Palade bodies (*arrowhead*) throughout the cytoplasm. Bar = 10 μm. (**B**) Electron micrograph of Weibel-Palade bodies of the same origin. Bar = 0.5 μm. VWF, von Willebrand factor.

Fully processed VWF is secreted from cultured endothelial cells by one of two pathways. The constitutive pathway is directly coupled to VWF synthesis and occurs without stimulation. The regulated pathway, involving VWF stored in Weibel-Palade bodies, is initiated by the action of secretagogues. Another important difference between the two pathways is the biologic activity of the VWF secreted. Although mostly small multimers are secreted constitutively, only the largest, biologically most potent multimers are stored in Weibel-Palade bodies (Fig. 128–4).[71,72] It is not known whether the large multimers are selected for storage or whether the conditions found in the Weibel-Palade body promote multimer assembly. The VWF stored in platelet α-granules is also enriched in large multimers.[73] All the N-terminal D domains (D1–D3) appear to be necessary for VWF storage. Deletions of these individual domains lead to constitutive

secretion of the expressed protein.[74,75] Although the propolypeptide remains in the Weibel-Palade bodies noncovalently associated with the mature subunit,[52] cleavage of the prosequence has to occur for efficient formation of the storage granules.[76] Although the VWF propeptide is required for VWF multimerization, as well as VWF storage in the Weibel-Palade body, these functions can be dissociated, and VWF multimerization is not required for storage.[77] The biologic function of the two secretory pathways may be different. The largest multimers released from Weibel-Palade bodies at the time of vascular injury may act to attach platelets to the injured endothelium and the vessel wall. Some of the released large VWF molecules remain associated with the endothelial membrane,[72] where their highly adhesive interaction with circulating platelets is regulated by ADAMTS13 proteolysis.[59,60,78] Circulating VWF may also self-associate on the endothelial surface to facilitate platelet adhesion.[79] Binding of VWF to the GPIb receptor of platelets and the integrin-type receptors, such as the GPIIb/IIIa complex on platelets and the vitronectin receptor on endothelial cells, is enhanced by the presence of large numbers of binding sites on VWF multimers. The exceptional adhesive activity of ultralarge VWF multimers may be regulated by its sequestration in storage organelles, with rapid local release at the site of vascular injury.

Secretagogues for VWF that may be of physiologic importance include thrombin,[80] fibrin,[81] histamine,[82] the terminal complement proteins C5b-9,[83] and several bioactive lipids such as sphingosine-1 phosphate.[84] The release of Weibel-Palade bodies appears to be coupled to Ca^{2+} influx. Thrombin activity as a secretagogue is related to its proteolytic activity and the cleavage of a specific receptor.[80,85] Interaction with a cellular receptor is a likely mechanism for fibrin release of VWF. A specific N-terminal fragment of the fibrin β-chain appears to interact with the endothelium.[86] Histamine-induced release can be blocked by histamine H_1-receptor antagonists.[82] Desamino-8-arginine vasopressin (DDAVP) administration results in VWF release from endothelial cells and a two- to threefold increase in plasma levels of VWF and factor VIII, the basis for use of this agent as a key treatment modality for VWD and mild hemophilia (see Chapters 125 and 129). DDAVP appears to induce VWF secretion by binding to the vasopressin V2 receptor, which is expressed on microvascular endothelial cells.[87] The regulation of Weibel-Palade body exocytosis is important for many biologic processes, and the cellular machinery involved is only beginning to be understood.[88]

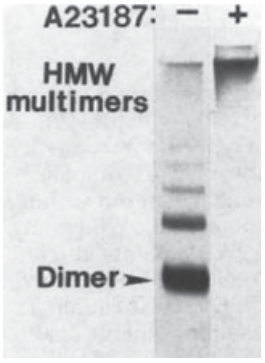

Figure 128–4 Multimeric composition of VWF secreted by endothelial cells in culture. Human umbilical vein endothelial cells were metabolically labeled with 35S-methionine and the constitutively secreted protein (–), which, released during a 10-minute treatment with the secretagogue A23187(+), were purified and analyzed nonreduced on an agarose gel. The autoradiograph of the gel is shown. The protein secreted constitutively is composed predominantly of small multimers, whereas the VWF secreted from Weibel-Palade bodies is only of high molecular weight (HMW multimers). VON WILLEBRAND DISEASE

Molecular Genetics

With the availability of *VWF* cDNA and genomic sequences, a molecular genetic approach to the characterization of VWD became possible. Southern blot analysis identified large gene deletions as the molecular basis for VWD in a small subset of patients with severe, or type 3, disease.[2,15] With the advent of the polymerase chain reaction (PCR), extensive direct DNA sequence analysis has been conducted on material from patients with a variety of VWD variants, using platelets as a source for *VWF* messenger RNA (mRNA) or by direct analysis of genomic DNA. A large number of human mutations have been cataloged (Fig. 128–5).[2,89] A database of known *VWF* mutations and polymorphisms is maintained by the VWF Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis.[90] Molecular genetic analysis has shed important light on the molecular pathogenesis of VWD and promises to improve diagnosis. For some VWD variants, mutations have been

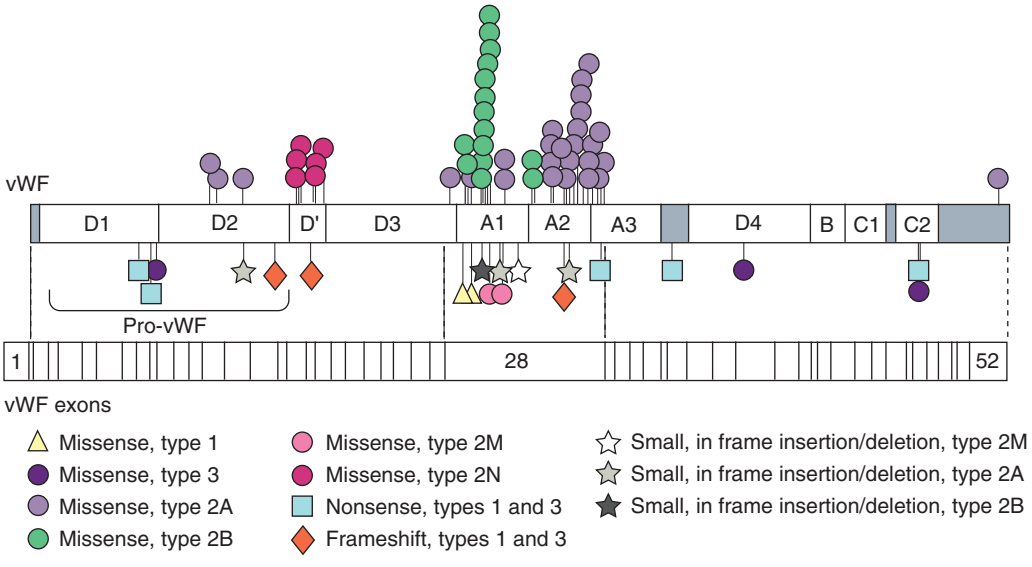

Figure 128–5 VWD mutations. The location of all point mutations and small, in-frame insertions and deletions reported to the VWD database[90] as of 1997 are shown schematically here within the VWF domain structure. The relative positions of each of the 52 VWF exons are shown below. VWD, von Willebrand disease; VWF, von Willebrand factor. *(From Nichols WC, Ginsburg D: von Willebrand disease. Medicine 76:1, 1997.)*

identified in most patients studied, and precise diagnosis and classification by DNA screening may soon become practical.

VWD can be divided into two general categories: those variants caused by a pure quantitative deficiency and those caused by a qualitative structural or functional abnormality within the VWF protein. Total disruption of gene function by deletion of a segment of the gene or a nonsense mutation (abrupt termination of the protein by insertion of a stop codon into the coding sequence) results in quantitative VWF abnormalities. Conversely, most qualitative variants are a result of mutations resulting in single amino acid substitutions that interfere with protein structure or function. The current classification scheme for VWD is based on an improved understanding of molecular pathogenesis.[91,92]

Types 1 and 3 von Willebrand Disease

Quantitative VWF abnormalities can be either mild or pronounced. Patients with type 3 (severe VWD) suffer from a profound bleeding disorder (see Chapter 129) with very little or no detectable plasma or platelet VWF. Type 3 VWD is a relatively rare disease, with an incidence of approximately 1:1 million.[93] By contrast, type 1 is the most common form of VWD, accounting for 70% to 80% of cases; it is associated with a mild to moderate quantitative decrease in VWF (levels in the range of 20% to 50% of normal). Type 3 VWD appears to result from the inheritance of a dysfunctional *VWF* gene from both parents. Gene deletions varying from 2.3 kb to more than 180 kb have been identified in several patients and may be associated with an increased risk for developing VWF inhibitor antibodies.[2] Several other defects resulting in complete loss of VWF function have been identified in patients with type 3 VWD, including nondeletion defects resulting in loss of mRNA expression,[94] as well as specific nonsense mutations or frameshift mutations resulting in disruption of the VWF protein coding sequence (see Fig. 128–5).[2]

Until recently, only a limited number of point mutations responsible for type 1 and 3 VWD had been identified, compared with the large number of mutations reported for the less common qualitative VWD variants described in the following section (see Fig. 128–5). This is caused, at least in part, by the complexity of screening all 52 exons of the *VWF* gene in a patient with type 1 or 3 VWD. In contrast, for many of the qualitative variants, the observed clustering of mutations focuses the search to a limited region of *VWF*. Several mutations resulting in truncation or disruption of the VWF protein coding sequence have been identified in patients with type 3 VWD. A particularly common frameshift mutation in exon 18, because of the deletion of a single cytosine, accounts for approximately 50% of type 3 VWD alleles in Sweden and has also been shown to be the molecular defect in the original patient reported by von Willebrand.[95] The resulting frameshift produces a stable mRNA encoding a truncated protein that is rapidly degraded in the cell.[96] This mutation is also common in the German population[97] but not in the United States.[96]

In the most straightforward model, type 1 VWD would simply represent the heterozygous form of type 3 VWD. However, there is some controversy on this point.[98] Type 3 VWD has classically been defined as "recessive" in inheritance and parents, who are obligate carriers for the defect and are often completely asymptomatic with normal laboratory numbers. However, in other cases, parents are affected with classic type 1 VWD. In addition, the reported prevalence of type 1 VWD (~1% of the population[99,100]) would predict a much higher frequency of type 3 VWD (1:40,000) than is observed (1:1 million). This discrepancy may be explained in part by over diagnosis of type 1 VWD in patients with only mildly decreased plasma VWF levels near the lower limit observed in the general population.[92,101]

The spectrum of mutations known to be responsible for type 1 VWD has recently been markedly expanded through two large studies, one in Europe[102] and the other in Canada.[103] These reports include more than 200 index cases, with VWF gene mutations identified in 60% to 70% of the patients analyzed. In the European study,[102] approximately one-third of the cases could be reclassified as a type 2 variant, with mutations detected in 95% of this subgroup. For the remaining "true" type 1 VWD families, mutations were only identified in 55%. In both reports, patients with lower VWF levels were more likely to carry VWF gene mutations. Previous studies have suggested that a subset of type 1 VWD mutations may produce a mutant VWF subunit that interferes in a dominant-negative way with the normal allele, accounting for the autosomal dominant inheritance and resulting in particularly reduced VWF levels. Mutations at cysteine residues in the D3 domain of VWF have been identified in several patients with moderately severe VWD. Expression of recombinant VWF carrying one of these mutations (Cys1149Arg) resulted in a mutant protein that was retained within the endoplasmic reticulum, potentially acted in a dominant negative manner when co-transfected with wild-type VWF.[104]

The observations that ~80% of reported mutations in type 3 VWD are predicted to lead to null alleles, whereas only 11% of type 1 VWD mutations are predicted to be null[102] suggests that the penetrance of clinical bleeding in patients heterozygous for a null mutation may in general be much lower than the corresponding penetrance in patients heterozygous for a VWF amino acid substitution. This hypothesis could explain the apparent recessive inheritance of type 3 VWD, as well as the high frequency of missense mutations identified in symptomatic type 1 VWD patients. The underlying mechanisms for VWD in the 30% to 50% of mild type 1 patients in whom no VWF gene mutation is detected remain unknown. Some of these patients may have regulatory mutations in distant parts of the VWF gene not covered by current sequence analysis. The possibility of locus heterogeneity (ie, defects in other genes giving rise to a disorder clinically indistinguishable from VWD) has also been proposed. Consistent with this idea, studies of an animal model of type 1 VWD in the mouse identified a mutation in a glycosyltransferase gene (*B4galnt2*) that results in reductions of plasma VWF levels of up to 20-fold.[105] Although comparable effects for non-*VWF* genes in human VWD have not yet been demonstrated, other genetic factors are known to significantly modify human VWF levels, including ABO blood group (see Chapter 129). The effects of such modifying genes are likely to determine the penetrance of symptomatic type 1 VWD, particularly in patients with "milder" type 1 VWD mutations. In addition, the combined effects of several modifier genes could conceivably account for type 1 VWD in a subset of patients with two normal *VWF* gene alleles. Consistent with this idea, inheritance of type 1 VWD in some families does not clearly track with the VWF gene.[2,102,103] Recently, a subset of type 1 VWD has been identified, which results from accelerated clearance of VWF from plasma.[106] Although the four reported families all carry VWF gene missense mutations, the accelerated clearance in other patients could result from mutations in components of the protein clearance machinery or in genes responsible for VWF posttranslational modification.

Type 2A von Willebrand Disease

Type 2A VWD is the most common qualitative abnormality of VWF and is associated with selective loss of large and intermediate-sized VWF multimers (see Chapter 129). Direct sequence analysis from platelet mRNA and genomic DNA has identified a panel of mutations within *VWF* exon 28, accounting for most of patients with type 2A VWD.[2,89] Nearly all of these mutations are clustered within the VWF A2 repeat (see Figs. 128–1 and 128–5). One particular mutation (Arg1597Trp) accounts for approximately one-third of type 2A VWD cases around the world. In vitro analysis of recombinant VWF containing type 2A VWD mutations suggests that two distinct mechanisms contribute to the pathogenesis of this disorder (Fig. 128–6).[107] In the first group, the single amino acid substitution results in a defect in VWF intracellular processing, with retention of the abnormal VWF in the endoplasmic reticulum. In the second group, VWF synthesis and processing in vitro is normal, and the loss of multimers is caused by increased sensitivity to proteolysis in plasma by ADAMTS13 at a site within the type 2A VWD mutation cluster in

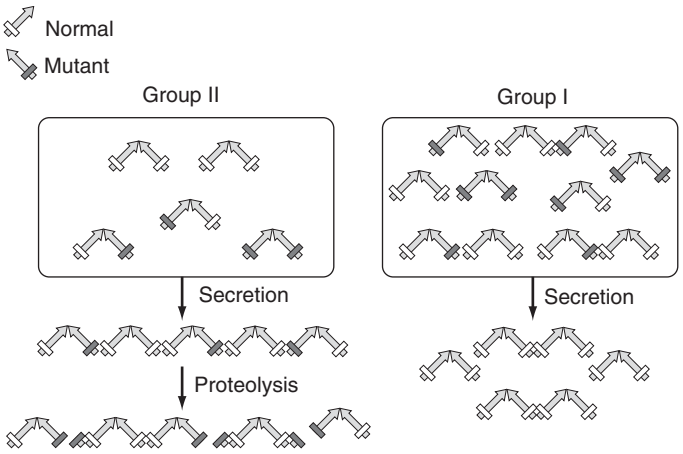

Figure 128–6 Two mechanisms for the molecular pathogenesis of type 2A VWD. Each VWF monomer is indicated as a gray arrow with the normal sequence indicated by white boxes and mutant sequence by black boxes. Within the cell, mixed dimers are formed, as well as homodimers of mutant and wild-type monomers. In group II, full-size multimers are assembled and proteolyzed after secretion. In group I, mutant subunits are held up in the endoplasmic reticulum; only homomultimers of normal subunits are secreted, predominantly of small size, VWD, von Willebrand disease; VWF, von Willebrand factor.

the VWF A2 domain (Tyr 1605-Met 1606).[7–9,57] Recombinant VWF carrying type 2A mutations shows increased sensitivity,[58] and recombinant VWF deleted for the A2 domain is resistant to cleavage by this protease.[108]

Type 2B von Willebrand Disease

Type 2B VWD is also characterized by the loss of large VWF multimers but through a unique mechanism, distinct from those described earlier for type 2A VWD. A panel of mutations has been identified in type 2B VWD patients, all located within a short stretch of the VWF A1 domain (see Fig. 128–5). Four of these mutations, clustered within a 35-amino acid segment of the 2813-amino acid *VWF* coding sequence, account for more than 90% of type 2B VWD patients studied.[2,89] Therefore, screening for this panel of mutations could provide precise and rapid DNA diagnosis for this disorder.

These observations also identify a critical region of VWF involved in binding to the platelet GPIb receptor. Each of these single amino acid substitutions is thought to result in a unique *gain of function*, leading to spontaneous binding of VWF to platelets. Under normal conditions, plasma VWF is inert in its interaction toward platelets until it encounters an exposed subendothelial surface. Binding of VWF to collagen or other ligands within the vessel wall at sites of vascular injury presumably results in a secondary conformational change, which then facilitates binding to the GPIb platelet receptor. In type 2B VWD, the mutant VWF is capable of spontaneously binding to GPIb in the absence of subendothelial contact. Analysis of recombinant VWF demonstrates very similar increases in VWF binding to platelets for each of six distinct type 2B VWD mutations, supporting the hypothesis that the VWF GPIb binding domain can adopt either a discrete "on" or "off" conformation.[109] The large multimers appear to have the highest affinity for GPIb (presumably because of multivalency) and are rapidly cleared from plasma, along with the bound platelets, resulting in the characteristic loss of large multimers, as well as thrombocytopenia.

Type 2N von Willebrand Disease

Type 2N is a unique variant of VWD that has important implications for the differential diagnosis of hemophilia and provides an instructive example of genetic locus heterogeneity. Rare cases of "autosomal" hemophilia have been reported in the past, in which deficiencies in factor VIII activity were inherited in an apparently autosomal manner. Biochemical analysis in several families identified a defect residing within the patient's plasma VWF, interfering with its ability to bind and stabilize factor VIII.[110,111] This variant is called type 2N,[91] although it is sometimes referred to as VWD Normandy, after the province of origin of one of the first patients.[112]

DNA sequence analysis in type 2N VWD has identified several mutations, mostly clustered in a region at the N-terminus of VWF previously shown to be important for factor VIII binding (see Figs. 128–1 and 128–5).[2,30,89] One of these mutations, Arg854Gln, appears to be particularly common.[113] Although usually silent in the heterozygote, homozygosity or compound heterozygosity for a type 2N *VWF* allele can result in clinically significant factor VIII deficiency. Therefore, type 2N VWD should be considered in the differential diagnosis of hemophilia A, particularly in a female patient or in the context of other features suggesting an autosomal pattern of inheritance.[112] Most type 2N VWD mutations result in only mild to moderate reductions in plasma factor VIII. However, at least one mutation (Glu787Lys) is associated with factor VIII levels as low as 1%, when co-inherited with a type 3 VWD allele.[114] This latter observation suggests that a diagnosis of type 2N VWD should also be considered in patients with more profound reductions in factor VIII level.

Prenatal Diagnosis

With the advent of molecular tools for the analysis of VWD, prenatal diagnosis has become possible and has been applied in a few cases. Given the generally mild clinical manifestations of most VWD variants, prenatal diagnosis is generally not indicated. However, in the case of type 3 or severe VWD, the indications for prenatal diagnosis are similar to those of severe hemophilia. For those VWD variants for which the mutation is known, direct analysis of chorionic villus samples or amniotic fluid can be performed rapidly by polymerase chain reaction and can be expected to provide a highly accurate, specific, and rapid diagnosis. For VWD families in which the specific mutation is unknown, genetic linkage analysis can be performed using a large panel of highly informative DNA sequence polymorphisms (http://www.shef.ac.uk/vwf/index.html). One particularly useful polymorphism is a highly variable TCTA repeat in intron 40, which has been reported to have more than 100 distinct alleles. Although all cases of type 3 VWD analyzed to date appear to be linked to defects within the *VWF* gene, the possibility of locus heterogeneity (ie, involvement of other genes outside of *VWF*) should be considered when performing this kind of analysis.

CHAPTER 129

VON WILLEBRAND DISEASE: CLINICAL ASPECTS AND THERAPY

Gilbert C. White, II and J. Evan Sadler

von Willebrand disease (VWD) is an inherited hemorrhagic disorder caused by a deficiency or dysfunction of von Willebrand factor (VWF), a large adhesive glycoprotein found in plasma, platelets, and endothelial cells. As a result, the interaction of platelets with the vessel wall is defective, and primary hemostasis is impaired.

VWD was first reported in 1926 by Erik von Willebrand,[1] who described a 5-year-old Finnish girl from the Åland Islands with a bleeding disorder that could be distinguished from classic hemophilia by an autosomal pattern of inheritance, mucocutaneous hemorrhage rather than joint and soft tissue hemorrhage, a prolonged bleeding time, and normal clot retraction. Of 66 family members, 23 had a similar hemorrhagic diathesis. Two years later, George Minot[2] reported a similar bleeding disorder in five patients and described the intermittent nature of the bleeding. von Willebrand originally attributed the bleeding defect in his patients to either a platelet defect or abnormal capillaries.[1] In 1953, three independent groups reported deficiency of factor VIII in VWD,[3–5] and in 1957, Nilsson and coworkers[6] showed that the infusion of fraction I-0 from normal human plasma led to a greater-than-expected increase in factor VIII levels in patients with VWD, suggesting that the defect might be found in the plasma. More importantly, the infusion of fraction I-0 from hemophilic plasma also led to a greater-than-expected increase in factor VIII, indicating that the plasma component was something other than factor VIII.[7]

The abnormal interaction between platelets and the vessel wall in VWD was first demonstrated in 1960 by Borchgrevink[8] and was confirmed by numerous workers.[9,10] The next major discovery was the observation by Zimmerman and colleagues[11] that an antigen associated with factor VIII was decreased in patients with VWD. This antigen is now known as VWF and is a protein distinct from factor VIII. The in vitro measurement of VWF activity was facilitated by the observation by Howard and Firkin[12] that ristocetin, an antibiotic isolated from the actinomycete species *Nocardia lutea*, induced agglutination of platelets in the presence of VWF. The primary structure of VWF was determined in 1985, when the complementary DNA (cDNA) for VWF was independently cloned and sequenced by four groups.[13–16] Recent analysis has identified the *VWF* gene mutation in the families from the Åland islands first studied by von Willebrand.[17]

PREVALENCE

The apparent prevalence of VWD depends on how patients are ascertained and on the criteria for diagnosis. Patients with severe mucocutaneous bleeding and very low or dysfunctional VWF are easily diagnosed but also are relatively uncommon. The more typical patient with bleeding and only modest quantitative VWF deficiency is a diagnostic challenge. Based on the number of persons from specific geographic regions who are evaluated for bleeding in hematology clinics, VWD affects 35 to 100 per million (0.0035%–0.01%), which is comparable to the prevalence of hemophilia A.[18] Population screening discovers more potential patients but with a risk of increased diagnostic uncertainty. For example, screening of schoolchildren for bleeding symptoms and VWF defects has suggested that the prevalence of VWD is 0.82% to 1.6%.[19] However, few patients so identified have medically significant bleeding, and their families rarely exhibit cosegregation of low VWF levels with either bleeding or *VWF* genotype.[20] The prevalence of heterozygosity for null *VWF* alleles also can be estimated from the prevalence of severe (recessive) VWD type 3, which affects between 0.55 to 6 per million people. Taking these values as estimates for q^2, heterozygosity for nonfunctional *VWF* alleles ($2pq$) would affect 1480 to 3580 persons per million.[18] A comparison of this number with estimates of prevalence based on bleeding symptoms suggests that less than 10% of these heterozygotes will have medically significant bleeding.

GENETICS

The *VWF* gene is on human chromosome 12,[13,14] and VWD usually exhibits an autosomal pattern of codominant inheritance: One mutant *VWF* allele may cause disease (although penetrance and expressivity can be variable), and two mutant alleles usually cause more severe disease. Some less common variants exhibit recessive inheritance, so that only homozygotes or compound heterozygotes have symptoms. Recent studies suggest that autosomal recessive VWD may be more common than previously recognized. Several families with type 2A (some formerly designated type IIC)[21,22] and type 1 VWD[23] appear to fit this pattern. In addition, the VWF protein is multimeric, which provides opportunities for mutant VWF subunits to disrupt the assembly, secretion, or function of associated normal subunits. In such cases, a single mutant *VWF* allele may cause exceptionally severe, dominant disease. von Willebrand disease illustrates some limitations of the terms *dominant* and *recessive* for the description of genetic disease. Nevertheless, these terms usually are satisfactory in practice.

Modifiers unlinked to the *VWF* locus also influence plasma VWF levels and may cooperate with *VWF* mutations to affect the severity of bleeding symptoms. For example, blood type O is overrepresented among patients diagnosed with VWD type 1, probably because the mean VWF level for persons with blood type O is at least 25% lower than for those with other ABO blood types (Table 129–1).[24] The basis for this relationship is not fully understood. However, some *N*-linked oligosaccharides on VWF bear ABO blood group determinants, and the absence of A or B antigens appears to slightly decrease the circulatory half-life of VWF.[25,26]

ABO blood type accounts for approximately 30% of the observed heritable variation in plasma VWF level,[27] suggesting that additional modifying loci remain to be identified. Studies in mice suggest that several other changes in protein glycosylation could affect VWF levels by a mechanism analogous to that proposed for ABO blood type. In the RIIIS/J mouse, ectopic expression of the *N*-acetylglucosaminyltransferase (*Galgt2*) gene in endothelial cells causes abnormal glycosylation of VWF and leads to its rapid clearance from plasma.[28] These mice have VWF levels substantially lower than strains with normal *Galgt2* expression. Similarly, mice deficient in ST3Gal-IV sialyltransferase have a bleeding disorder associated with reduced levels of VWF, probably because of the increased hepatic clearance of VWF bearing oligosaccharides that lack certain sialic acid residues.[29]

Table 129–1 Influence of ABO Blood Group on VWF : Ag in Blood Donors

ABO Type	n	VWF : Ag Geometric Mean	VWF : Ag Geometric Mean ±2 SD
O	456	74.8	35.6–157.0
A	340	105.9	48.0–233.9
B	196	116.9	56.8–241.0
AB	109	123.3	63.8–238.2

Entries for VWF : Ag are in IU/dL. For unselected blood donors, the range of values for VWF : Ag ± 2 SD was 45–203 IU/dL (Montgomery RR, personal communication). All groups are significantly different in pair-wise comparisons except for B vs. AB. VWF : Ag, von Willebrand factor antigen immunoassay; SD, serologically detectable. Adapted from reference 24.

Table 129–2 Common Laboratory Tests in von Willebrand Disease

Property Assessed	Test Name or Method (Abbreviation)
Screening Tests	
VWF-platelet GPIb binding	Ristocetin cofactor activity (VWF : RCo)
VWF-collagen binding	VWF binding to immobilized collagen (VWF : CB)
VWF protein concentration	Immunoassay (VWF : Ag)
Factor VIII stabilization in vivo	Factor VIII coagulation assay (FVIII : C)
Specialized Tests	
VWF-platelet GPIb binding	Ristocetin-induced platelet aggregation (RIPA)
VWF multimer distribution and structure	Multimer gel electrophoresis
VWF-factor VIII binding	Factor VIII binding to immobilized VWF (VWF : FVIIIB)

GPIb, glycoprotein Ib; VWF, von Willebrand factor; Nomenclature for VWF and its activities is according to reference 228.

LABORATORY TESTING

A typical screening laboratory evaluation for VWD includes assays of plasma VWF mediated platelet function, VWF antigen level, and factor VIII level. In most laboratories, measurement of VWF-mediated platelet function consists of platelet binding activity, but it is increasingly apparent that collagen-binding activity should also be measured. Depending on the clinical situation, additional specialized tests may be indicated to assess the structure and distribution of VWF multimers or factor VIII binding activity (Table 129–2). Assays of platelet VWF antigen, activity, or multimer structure may be useful in selected patients.[30]

A similar unit definition is used for all quantitative assays of plasma VWF: The concentration in suitably pooled normal plasma is defined as 1 IU/mL, and 95% of values obtained in healthy populations lie between approximately 50 and 200 IU/dL. In general, laboratories should calibrate all of their assays with respect to the current World Health Organization (WHO) VWF reference plasma standard.

von Willebrand Factor Platelet-Binding Activity

When added to a suspension of platelets in plasma that contains VWF, ristocetin promotes the binding of VWF to platelet membrane glycoprotein Ib (GPIb), which causes platelet agglutination at a rate that depends on the concentration of VWF and ristocetin.[12] Ristocetin dimerizes in solution with a dissociation constant of approximately 1 mg/mL. Ristocetin dimers bind VWF at multiple proline-rich sites and also bind to platelets, which alters the affinity of VWF binding to platelet GPIb by a mechanism that has not been fully elucidated.[31]

Two main assay designs are used. Ristocetin cofactor activity (VWF : RCo) is measured by adding a fixed concentration of ristocetin to a suspension of formalin or paraformaldehyde-fixed platelets in a sample of patient plasma, and agglutination is assessed macroscopically or in an aggregometer.[32–34] The initial rate of agglutination varies directly with the concentration of VWF, which is determined by comparison to results obtained with dilutions of a calibrated plasma standard. Automated methods to measure VWF : RCo have been developed that appear to have similar characteristics to conventional aggregometric methods.[35] Regardless of methodology, VWF : RCo assays are somewhat imprecise and insensitive. In laboratory surveys, the coefficient of variation typically is 30% or greater and is even higher when the plasma level of VWF : RCo is less than 15 IU/dL.[36,37] Assay variations employing purified platelet GPIb in an enzyme-linked immunosorbent assay (ELISA) method have been described that are more sensitive and reproducible but are not widely available at this time.[38]

Ristocetin-induced platelet aggregation (RIPA) is the second major ristocetin-dependent assay of VWF activity. RIPA is measured by adding increasing concentrations of ristocetin to platelet-rich plasma and assessing the rate and extent of platelet aggregation by aggregometry. In samples from healthy persons, RIPA is absent or very weak at 0.3 to 0.5 mg/mL ristocetin and brisk at greater than 1.2 mg/mL ristocetin. Because RIPA uses the patient's own platelets, it gives abnormal results if the platelet count is low or if platelet GPIb is defective. For example, Bernard–Soulier syndrome[39] is caused by congenital deficiency of platelet GPIb (see Chapter 141), and in this condition RIPA is absent, but VWF : RCo (performed with exogenous platelets) is normal. RIPA also is relatively insensitive at low concentrations of VWF. The major use of RIPA is to distinguish between qualitative defects of VWF that are associated with decreased affinity for GPIb (type 2A, some type 2M) or increased affinity for GPIb at low concentrations of ristocetin (type 2B).[40] Because RIPA can only be performed with fresh platelet-rich plasma, the test requires scheduling with a specialized laboratory capable of performing platelet aggregometry.

The venom of *Bothrops jararaca* and closely related snakes contains a protein named botrocetin[41] that binds tightly to the A1 domain of VWF and promotes binding to platelet GPIb, possibly by forming a ternary complex.[42] When added to a suspension of platelets, botrocetin causes platelet aggregation or agglutination in a VWF-dependent manner similar to that observed with ristocetin, although botrocetin and ristocetin interact with different sequences of the VWF molecule.[43] These properties have been exploited to devise an assay of *botrocetin-cofactor activity* that has been used mainly in a research setting.

von Willebrand Factor Collagen-Binding Activity

Another function of VWF is binding to collagen because VWF mediates the interaction of platelets with collagen. This function depends on multimer size and on the properties of the major collagen-binding site in VWF domain A3. Collagen-binding activity (VWF : CB) may be measured by an ELISA-style method in which a preparation of fibrillar collagen is immobilized in microtiter wells. Patient plasma is added, and bound VWF is detected immunologically.[44] The behavior of the assay depends critically on the kind of collagen used.[45] In general, decreased VWF : CB correlates with decreased VWF concentration, decreased high molecular weight multimers, or (rarely) specific defects in collagen binding.

von Willebrand Factor Antigen

Immunoassays for VWF antigen (VWF:Ag) are performed by ELISA or newer automated methods, or, sometimes, by quantitative immunoelectrophoresis (Laurell assay).[46,47] The results with Laurell assays may be dominated by the smallest VWF multimers, which migrate faster on electrophoresis. Consequently, the Laurell method may overestimate the concentration of VWF:Ag in VWD type 2A.

Factor VIII Activity

Factor VIII circulates in a complex with VWF, and factor VIII levels usually are roughly proportional to VWF levels. Factor VIII coagulant activity is usually measured by a one-stage clotting assay using human factor VIII-deficient plasma as substrate.[48] Factor VIII levels also are reduced in patients with hemophilia A, factor VIII inhibitors, and sometimes in disseminated intravascular coagulation (see Chapters 125, 126, 132).

von Willebrand Factor Multimers

In normal human plasma, VWF is present as a series of multimers composed of dimers of 300-kd VWF subunits. Multimers range in size from dimers of 600 kd to species of more than 20,000 kd in increments of 600 kd (Fig. 129–1), and the largest multimers are most effective at mediating platelet adhesion.[49] The VWF multimers are analyzed by sodium dodecyl sulfate (SDS)-agarose gel electrophoresis and immunodetection of VWF.[50,51] The ability of the method to discriminate among certain VWD subtypes depends strongly on the technique used.

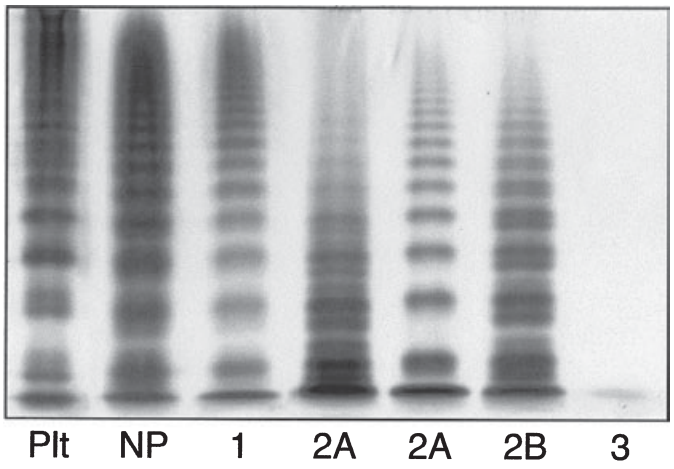

Figure 129–1 von Willebrand factor (VWF) multimer patterns. Samples were electrophoresed on a 1.2% agarose gel and VWF was visualized by binding ^{125}I-labeled anti-VWF antibody followed by autoradiography. Platelet lysate (Plt) contains larger multimers than are present in normal plasma (NP). Platelet multimers contain only intact VWF subunits and have no smaller satellite bands under the major bands, whereas plasma multimers show some evidence of degradation. Plasma samples were analyzed for patients with von Willebrand disease (VWD) types 1, 2A, 2B, and 3 as indicated. The type 2A sample in lane 4 is from a patient with enhanced sensitivity to proteolysis typical of mutations in VWF domain A2. The type 2A sample in lane 5 is from a patient with impaired multimer assembly typical of mutations in the VWF propeptide. *(Image provided courtesy of Marlies Ledford.)*

Factor VIII Binding

Abnormal binding of factor VIII to VWF may be caused by mutations in the factor VIII binding site on VWF, and such defects occur in VWD type 2N.[52,53] Distinguishing VWD type 2N from mild hemophilia A may require a direct assessment of factor VIII-VWF binding (VWF:FVIIIB), which usually is performed in an ELISA-style assay. For example, plasma samples are added to microtiter wells coated with antibody to VWF. Endogenous factor VIII (if any) is removed from the bound VWF by washing with high ionic strength buffer. After incubation with a fixed concentration of pure factor VIII, the amount of bound factor VIII is determined enzymatically, and the amount of immobilized VWF in the same sample is determined immunochemically. Defects in factor VIII-VWF binding are identified by a decreased slope of the regression line of factor VIII versus VWF, compared with the result obtained using a VWF standard.[54,55] An autosomal pattern of inheritance is a strong clue of VWD type 2N as opposed to hemophilia.

Other Tests

VWF-mediated platelet function may be assessed by measurement of the bleeding time, an in-vivo general test of platelet-vessel wall interactions (see Chapter 122).[56] The bleeding time usually is performed using a modification of the technique described by Ivy and coworkers.[57] Standardized incisions are made on the volar aspect of the forearm, keeping venous pressure at 40 mm Hg with a blood pressure cuff. Blood from the incisions is blotted to filter paper every 30 seconds, and the bleeding time is the time required for bleeding to stop.

Although the bleeding time has been a traditional measurement of VWF-mediated platelet function, a prolonged bleeding time is not specific for defects in VWF. The bleeding time procedure is difficult to standardize and results are critically dependent on the experience of the person performing the test. Differences in mean bleeding time can be demonstrated between sufficiently large groups of healthy controls and patients with VWD. However, the broad range of normal values and extreme lack of reproducibility makes the bleeding time very difficult to interpret for most patients.[58]

A platelet function analysis (PFA-100) has been developed as an automated in-vitro test of platelet function. The PFA-100 test involves passing citrated whole blood through a perforated membrane that is coated with collagen plus adenosine diphosphate (ADP) or collagen plus epinephrine. The aperture becomes occluded by a platelet plug, and the time required (the closure time) is prolonged by defects in platelet function or VWF. The closure time is sensitive to many other variables, including hematocrit and leukocyte count; and the distribution of closure times in healthy controls is broad. Nevertheless, the PFA-100 closure time appears to be more sensitive and reproducible than the bleeding time, and has replaced the bleeding time as a test for platelet-dependent hemostasis at some centers (see Chapter 122). Like the bleeding time, PFA-100 closure times do not correlate with surgical blood loss,[59] and the role of PFA-100 testing for the diagnosis of VWD or the assessment of bleeding risk remains uncertain.[60,61]

CLASSIFICATION AND MOLECULAR DEFECTS

Many mutations have similar effects on VWF structure and function, which permits a simpler classification of VWD-based mainly on pathophysiologic mechanism. Three major VWD types are designated: Type 1 refers to partial quantitative deficiency of VWF; type 2 includes qualitative defects of VWF; and type 3 refers to virtually complete absence of VWF (Table 129–3).[62] von Willebrand disease type 2 is further divided into four subtypes that have distinct mechanisms and clinical features. There is a good correlation between VWD type 2 subtypes and the location of causative *VWF* gene mutations. A database of *VWF* gene mutations and polymorphisms[63,64] is

Table 129–3 Classification of von Willebrand Disease

Type	Description
1	Partial quantitative deficiency of VWF
2	Qualitative deficiency of VWF
2A	Decreased platelet-dependent VWF function with selective deficiency of high-molecular-weight multimers
2B	Increased affinity for platelet GPIb
2M	Decreased platelet-dependent VWF function with high-molecular-weight multimers present
2N	Markedly decreased binding of factor VIII to VWF
3	Complete deficiency of VWF

GPIb, glycoprotein Ib; VWF, von Willebrand factor.

von Willebrand Disease Type 1

von Willebrand disease type 1 is characterized by partial quantitative deficiency of VWF, and bleeding risk is attributed to decreased amount of VWF with normal function. The values for VWF:Ag typically fall between less than 10 IU/dL and 50 IU/dL (or 2 standard deviations [SD] below the normal mean). Values for VWF functional assays and factor VIII are decreased concordantly. In practice, a common rule of thumb is to require the value of VWF:RCo, for example, to be greater than 70% of the value for VWF:Ag, although this criterion may not be reliable, especially when the VWF:Ag level is low (eg, VWF:Ag < 40 IU/dL).[65] The distribution of plasma VWF multimer is normal. Specifically, the proportion of high molecular weight multimers is not decreased; whether to include patients with exceptionally large VWF multimers (eg, VWD Vicenza[66,67]) is controversial. von Willebrand disease type 1 is the most commonly diagnosed variant of VWD, accounting for 60% to 80% of cases.

von Willebrand disease type 1 usually is transmitted dominantly with variable penetrance. In general, the lower the VWF level, the more likely that both the VWF level and the associated bleeding phenotype will be penetrant. Apparently recessive inheritance of partial quantitative VWF deficiency does occur with a relatively low frequency, usually through the acquisition of a null allele from one parent and a hypofunctional allele from the other parent.[23,68] The occurrence of more severe bleeding symptoms in such compound heterozygous patients may explain the phenotypic variability observed in certain families.

A few patients with VWD type 1 are heterozygous for null alleles that produce undetectable or greatly reduced amounts of messenger RNA (mRNA) for VWF.[69–71] However, most patients with particularly severe forms of VWD type 1 appear to have missense mutations that interfere with the VWF secretion or promote the rapid clearance of VWF from the circulation. Such patients usually have VWF levels <20 IU/dL.[23,72,73] Examples have been reported in Canada[74] and Italy[75] of highly penetrant VWD type 1 mutations that occur in an extended *VWF* haplotype, consistent with descent from one founder in each population.

Although the diagnosis of VWD type 1 depends on testing of plasma VWF, examination of platelet VWF reveals additional heterogeneity (Table 129–4). Some patients have concordant decreases of both plasma and platelet VWF. This group was described previously as type I-1[76] or type I-platelet low[30] and proposed to be caused by defective VWF synthesis. Other patients have low plasma VWF and normal platelet VWF. This phenotype, termed type I-2[76] or type I-platelet normal,[30] was proposed to be caused by impaired release from cellular stores, although increased clearance from plasma would

*Whether von Willebrand disease (VWD) Vicenza is best considered VWD type 1 or type 2M is controversial. The most recent classification places it under VWD type 1.[62]

be an alternative mechanism. An additional variant in which plasma VWF is normal and platelet VWF multimers are reduced was termed type I-3.[76] Interestingly, VWF-mediated platelet function in patients with VWD type I-platelet normal was normal or nearly normal, suggesting that platelet VWF content may correlate inversely with bleeding tendency.[30,77] Patients with normal platelet VWF also appeared to have a better response to 1-desamino-8-D-arginine vasopressin (DDAVP; desmopressin).[30]

Despite the straightforward definition of VWD type 1, some patients present a difficult diagnostic challenge. Those with exceptionally low values of VWF are relatively easy to diagnose. Very low VWF levels (eg, 10 to 30 IU/dL) and significant bleeding symptoms usually cosegregate within a family as dominant traits, and linkage analysis or DNA sequencing often supports the existence of an intragenic VWF mutation.[78,79] These mutations can have dominant negative effects. For example, different single amino acid substitutions in the VWF D3 domain may cause VWD type 1 by reducing the secretion[80] or intravascular survival[67] of VWF multimers.

In contrast to patients with very low VWF levels, subjects with VWF levels just below the normal range often do not fit comfortably into a diagnosis of VWD type 1. The population distribution of VWF levels is very broad, and mild mucocutaneous bleeding symptoms are common (see Chapter 121). As a consequence, chance association of low VWF and bleeding also is common.[81] In such cases, it is common to find that bleeding symptoms and low VWF levels do not cosegregate, or that low VWF levels are not associated with specific VWF alleles within a family.[20,78,79,82,83] Furthermore, the bleeding risk conferred by a VWF level just below the normal range is not known precisely but probably is modest. For example, the relative risk for menorrhagia, given a low VWF level, appears to be approximately 3.9.[81] The limited ability of low VWF to predict bleeding also is illustrated by a longitudinal study of children diag-

nosed with VWD through population screening. Among 1218 school children in Italy, 9 new cases of VWD were identified based on a low VWF and bleeding symptoms plus a family history of bleeding and at least 1 relative with low VWF.[19] However, in these families there was no concordance between low VWF levels and bleeding symptoms, and none of the new cases had medically significant bleeding during 13 years of follow-up.[20] The modest bleeding risk and lack of heritability suggest that a low VWF level could be treated as a modest risk factor for bleeding, without necessitating the diagnosis of a genetic disorder.

von Willebrand Disease Type 2

von Willebrand disease type 2 is characterized by qualitative abnormalities of VWF. Patients may have normal levels of VWF:Ag, but the protein is dysfunctional. These variants account for 7% to 30% of cases. Four subtypes are currently recognized. The distribution among the subtypes varies among centers. For example, in France patients with VWD type 2 were partitioned as follows: type 2A equaled 30%, type 2B equaled 28%, type 2M (or unclassified) equaled 8%, and type 2N equaled 34%.[84] In contrast, the distribution in Bonn, Germany, was type 2A equaled 74%, type 2B equaled 10%, type 2M equaled 13%, and type 2N equaled 3.5%.[51]

Von Willebrand disease type 2A refers to qualitative variants of VWD in which platelet-VWF interactions are markedly decreased because hemostatically effective large VWF multimers are absent. The VWF:Ag may be normal or decreased. The VWF:RCo is decreased disproportionately. A VWF:RCo/VWF:Ag ratio of less than 0.7 may be used as criterion of abnormal function,[85] although VWF:RCo may be extremely low in VWD type 2A. On multimer gels, the high-molecular-weight and intermediate multimers are absent or markedly decreased. Satellite multimer bands may or may not be normal. Patients previously classified as II-1, II-2, and II-3,[76] I-platelet discordant,[30] IIA,[50] IB,[86] IIC,[87] IID,[88] IIE,[89] IIF,[90] IIG,[91] IIH,[92] and II-I[93] are included under VWD type 2A (see Table 129–4).

At least two distinct mechanisms cause VWD type 2A: (1) abnormal assembly and secretion of large VWF multimers; and (2) increased susceptibility of VWF to proteolysis in the circulation. The two mechanisms may be distinguished by examining platelet VWF, which lacks large multimers if assembly is abnormal but has a normal multimer pattern if the VWF has increased susceptibility to proteolysis. The mutations that cause VWD type 2A by interfering with multimer assembly can act at any of several steps in the biosynthetic process, and the location of these mutations often can be inferred from the appearance of the VWF multimers. For example, mutations in the propeptide D1 and D2 domains (Fig. 129–2) interfere with multimerization in the Golgi apparatus and cause a recessive variant originally named *type IIC* that exhibits an exceptionally clean multimer pattern characterized by the absence of prominent satellite bands (see Fig. 129–1).[87,94,95] Mutations in the D3 domain that interfere with multimerization have also been identified in patients with the dominant variant originally named *type IIE* (see Fig. 129–2), with an indistinct or "smeary" multimer pattern.[89,96] Mutations in the cystine knot (CK) domain prevent dimerization in the endoplasmic reticulum and cause a dominantly inherited variant originally named *type IID* (see Fig. 129–2), which exhibits a characteristic single satellite band between the major bands consistent with some multimers having an odd number rather than the normal even number of subunits.[88,97]

Some mutations within the A2 domain render VWF more susceptible to proteolytic digestion by the metalloprotease ADAMTS13, probably by destabilizing the domain structure and facilitating exposure of the bond to be cleaved. Other mutations within domain A2 or adjacent domains have more extreme effects on structure and cause VWD type 2A at least partly by impairing multimer assembly.[98–100] Mutations in domain A2 frequently appear to be responsible for most cases of the variant originally named *type IIA* (see Fig. 129–2).

Although VWD type 2A mutations throughout the VWF subunit interfere with distinct steps of multimer assembly that correlate with distinct satellite band patterns on multimer gels, or spare the process of multimer assembly and instead promote intravascular degradation of VWF, ultimately they all appear to promote bleeding through a shared mechanism, by reducing the concentration of large VWF multimers and thereby impairing platelet binding to VWF at sites of vascular injury.

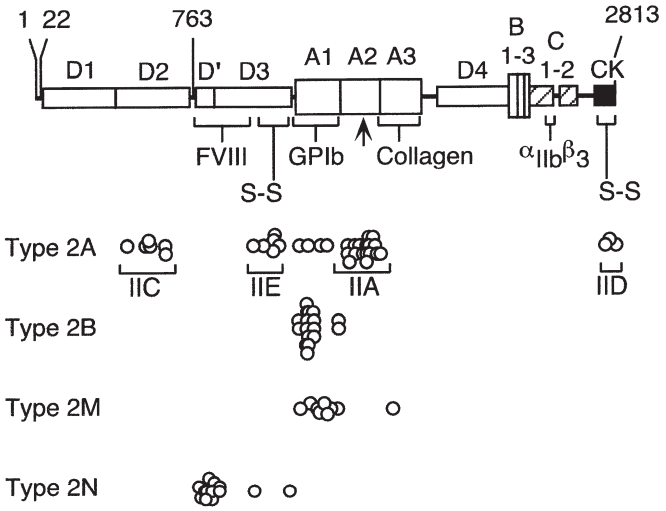

Figure 129–2 von Willebrand factor mutations in von Willebrand disease (VWD) type 2. Amino acid residues of prepro-VWF are indicated by codon number. The signal peptide comprises residues 1–22, the propeptide contains residues 23–763, and the mature subunit contains residues 764–2813. Conserved structural domains (A, B, C, D, and CK) are labeled. Multimers are linked together by disulfide bonds (S-S) located in the D3 and CK domains. Binding sites are indicated for factor VIII (FVIII), platelet GPIb (GPIb), collagen, and platelet integrin αIIbβ3. The metalloprotease ADAMTS13 cleaves the Tyr[1605]-Met[1606] bond in domain A2 (*arrow*). *Circles* indicate the position of mutations that cause the VWD types indicated at the left. For VWD type 2A, the *lettered brackets* show the location of mutations that correspond to variants with characteristic multimer patterns as discussed in the text, including type 2A, caused by increased sensitivity to proteolysis (IIA) or by defective multimer assembly because of mutations in the propeptide (IIC), the D3 domain (IIE), or the cystine knot (CK) domain (IID).

VWD type 2B is caused by a qualitative abnormality of VWF in which there is increased platelet-VWF interaction because of an increased affinity of VWF for its platelet receptor, GPIb. Patients previously diagnosed with VWD types IIB,[40] I-New York,[101] and Malmö[102] are included in this category (see Table 129–4). The hallmark of type 2B VWD is brisk RIPA at low concentrations of ristocetin (0.3–0.5 mg/mL) that do not induce platelet aggregation in normal platelet-rich plasma. In the most common form of type 2B VWD, high-molecular-weight multimers are absent from plasma (see Fig. 129–1) but are present in platelets. A full range of normal multimer sizes is synthesized, but the largest multimers bind spontaneously to platelets and are cleared rapidly[103] because of the increased affinity of VWF for platelet GPIb.[40] Patients with type 2B VWD often have mild thrombocytopenia.

The mutations that cause VWD type 2B are within or adjacent to the Cys1272-Cys1458 disulfide loop in the A1 domain of VWF (see Fig. 129–2).[63,96,104] The A1 domain binds directly to a site near the N-terminus of platelet GPIb, and type 2B mutations appear to stabilize the bound conformation.[105]

VWD type 2M (*M* for *multimer*) refers to qualitative variants in which decreased platelet-dependent VWF function is not caused by the absence of high-molecular-weight multimers, but instead is caused by mutations that interfere with VWF binding to platelets or subendothelium.[62] Previous VWD types B,[106] IC,[107] and ID[108] are grouped in this category (see Table 129–4). Assays of VWF activity are decreased disproportionately relative to levels of VWF:Ag and factor VIII. The VWF multimer distribution is typically normal, and

there may be even larger-than-normal multimers. The satellite bands may be abnormal. In many cases, mutations have been identified with VWF domain A1 that interfere with binding to platelet GPIb (see Fig. 129–2).[63,96,104] Defects in VWF binding to subendothelium also may impair platelet adhesion and cause VWD type 2M.[62] For example, in a mother and daughter with VWD type 2M, a missense mutation in VWF domain A3 has been described that reduces VWF binding to collagen (see Fig. 129–2).[109]

VWD type 2N was named for Normandy, the province in France where one of the first reported patients was born. VWD type 2N is caused by homozygous or compound heterozygous *VWF* mutations that impair binding to factor VIII. Because the VWF-factor VIII interaction is necessary for normal factor VIII survival in the circulation, VWD type 2N masquerades as an autosomal recessive form of hemophilia A.[52,53] Patients typically have normal levels of VWF:Ag and VWF:RCo, but reduced factor VIII and VWF:FVIIIB is absent or markedly decreased.[54,55] With few exceptions, mutations that cause VWD type 2N occur in the D′ or D3 domain of VWF (see Fig. 129–2).[55,63]

von Willebrand Disease Type 3

VWD type 3 is characterized by complete or nearly complete deficiency of VWF and accounts for less than 5% of patients with VWD. This recessive, severe form of VWD is the result of homozygosity or compound heterozygosity for *VWF* alleles that produce little or no protein. The prevalence of VWD type 3 is approximately 0.5 per million for many European countries,[110] approximately 1.4 per million for North America,[111] approximately 3 per million for Sweden,[110] and up to 6 per million for populations in which consanguinity is prevalent, such as Iran.[18,112] In most cases, VWF:RCo and VWF:Ag are undetectable and factor VIII levels are less than 10 IU/dL. Multimeric analysis of plasma from patients with VWD type 3 disease shows essentially no multimers because of the marked reduction in VWF. The gene defects associated with VWD type 3 usually are nonsense mutations or frameshifts because of small insertions or deletions; large deletions, splice-site mutations and missense mutations are less common. The mutations are distributed throughout the *VWF* gene and most are unique to the family in which they were first identified.[63,113,114]

APPROACH TO DIAGNOSIS

If the diagnosis of VWD is suspected, VWF:Ag, VWF:RCo, factor VIII and platelet count may be used as screening tests, in addition to other testing that may be considered, such as a prothrombin time and activated partial thromboplastin time (see Chapter 122). In some patients with VWD, the level of factor VIII may be decreased sufficiently to prolong the activated partial thromboplastin time. Thrombocytopenia may cause bleeding similar to that observed in VWD, although the platelet count also may be low in VWD type 2B. The bleeding time and PFA-100 closure time have been recommended as screening tests in the diagnosis of VWD, but as discussed in a preceding section (Laboratory Testing, Other Tests), they are not specific and have very limited predictive power to exclude or support the diagnosis.[58,60,61,115]

Normal values in screening assays, including a normal VWF:RCo/VWF:Ag ratio (eg, >0.7), exclude medically significant VWD with a few caveats discussed under Issues in Diagnosis and Classification. A decreased but detectable level of VWF, with proportionate decrease in factor VIII and no evidence of qualitative VWF defect, suggests a diagnosis of VWD type 1. Disproportionate decreases in VWF:RCo or VWF:CB, with ratios of VWF:RCo/VWF:Ag or VWF:CB/VWF:Ag (eg, less than 0.7,[65,85,109]) suggest a diagnosis of VWD type 2A, 2B, or 2M, and merit further specialized testing for discrimination.

The absence of high-molecular-weight VWF multimers excludes VWD type 2M[62] and narrows the possibilities to type 2A and type 2B. Sometimes the multimer pattern is so characteristic of a specific VWD type 2A mechanism[51,96,104] that VWD type 2B also can be excluded, but in most cases, RIPA is necessary. Markedly impaired RIPA is typical of VWD type 2A, and increased RIPA at low ristocetin concentrations is required to diagnose VWD type 2B.[50]

If high-molecular-weight multimers are present but the VWF:RCo or VWF:CB is disproportionately decreased, then the most likely diagnosis is VWD type 2M.[65,104] However, some VWD type 2B mutations do not markedly alter the VWF multimer distribution,[101,102] and RIPA may be necessary to distinguish VWD type 2M from these uncommon forms of VWD type 2B.

In the evaluation of patients for possible VWD type 2M, VWF:RCo and VWF:CB could be considered complementary because each assesses a different binding function. In practice, however, most centers have chosen one or the other as a measure of VWF functional activity, which means that certain VWD type 2M defects may be overlooked. The VWF:CB does not detect mutations that specifically impair binding to platelet GPIb. Conversely, VWF:RCo would be normal in patients with isolated collagen-binding defects, although only one such family has been reported so far.[109] The prevalence of collagen-binding defects in VWD type 2M may be low but will not be known until more experience is obtained with the VWF:CB assay.

A normal level of VWF, a decreased level of factor VIII, and evidence against X-linked inheritance suggest a diagnosis of VWD type 2N, although assays of factor VIII-VWF binding (VWF:FVIIIB) may be necessary to exclude hemophilia A.[55] In VWD type 2N, the ratio FVIII:C/VWF:Ag generally is less than 0.5. Patients with *VWF* gene mutations that severely impair factor VIII binding had FVIII:C levels of 8.4 ± 5.2 IU/dL, and those with less severe binding defects had FVIII:C levels of 21.8 ± 9.8.[54] VWF:FVIIIB results for patients with VWD type 2N are typically less than 0.1 and the results for heterozygous carriers cluster around 0.5, where the result for normal standard VWF is defined to be 1.0.[54]

The absence of detectable VWF is characteristic of VWD type 3. In most cases, the factor VIII level also is below 10 IU/dL.[112,116,117] A small subset of patients with VWD type 3 has higher factor VIII levels of 12 to 32 IU/dL. In contrast to other patients with VWD type 3, some of those with relatively high baseline values for factor VIII may have a clinically useful increase in factor VIII level after treatment with desmopressin.[118]

ISSUES IN DIAGNOSIS AND CLASSIFICATION

von Willebrand Disease Type 1 or Low von Willebrand Factor

The diagnosis of VWD type 1 is easy if the level of VWF is very low, but it becomes problematic as the level of VWF approaches the lower end of the normal population distribution. For example, VWF levels less than 30 IU/dL have been associated with recurrent and medically significant bleeding, a clearly dominant pattern of inheritance, and mutations in the *VWF* gene.[30,75,78,79,80] For patients with such dominant, symptomatic, and relatively severe VWF deficiency, the diagnosis of VWD type 1 is likely to be useful for counseling them about their bleeding risk and facilitating appropriate treatment.

In contrast, VWF levels near the lower end of the normal distribution usually are not associated with significant bleeding, tend not to be heritable, often do not cosegregate with any bleeding symptoms that may occur, and do not show consistent linkage to the *VWF* locus.[20,78,79,82,83] Many factors contribute to this uncertainty. Increases in VWF are associated with pregnancy, hyperthyroidism, renal failure, and the stress of exercise, fainting, inflammation, trauma, or surgery.[119–124] Levels of VWF also vary during the menstrual cycle in women,[125] although there are significant discrepancies among studies concerning the timing of minimum and maximal levels. Consequently, test results for persons having moderately low VWF levels

may be intermittently normal or abnormal.[82,126] In addition, a modestly low VWF level confers only a modestly increased risk of minor bleeding that rarely requires medical treatment or a change in lifestyle. For example, the relative risk of menorrhagia was estimated to be approximately 3.9 for women with VWF levels of approximately 30 to 50 IU/dL.[81] Rather than labeling them with the diagnosis of VWD type 1, patients with VWF levels in this range could be informed that they have "low VWF," which is a modest risk factor for minor bleeding. Conversely, serious bleeding symptoms associated with only moderately low levels of VWF should prompt investigation for a disorder other than VWD.

von Willebrand Disease Type 1 or Type 2

Similar concerns apply to distinguishing between VWD type 1 and VWD type 2, or among the VWD type 2 variants. Very abnormal VWF phenotypes are easy to recognize, but subtle defects can be difficult to characterize. As a general rule, however, the closer the laboratory phenotype approximates that of VWD type 1, the more likely the clinical course will be as well. For example, patients with the VWD type 2N mutation R816W have low levels of factor VIII (<10 IU/dL) and a poor response to desmopressin, whereas patients with the VWD type 2N mutation R854Q tend to have higher levels of factor VIII (20–40 IU/dL) and a clinically useful response to desmopressin.[127] Differentiating VWD type 1 from VWD type 2M can be particularly difficult because the distinction depends on the VWF:RCo/VWF:Ag ratio, and VWF:RCo assays are notoriously imprecise. VWF:RCo/VWF:Ag ratios of <0.6 or <0.7 have been proposed for the diagnosis of VWD type 2M, but a recent clinical study observed that satisfactory discrimination from VWD type 1 required a VWF:RCo/VWF:Ag ratio <0.4.[65] Therefore, diagnoses based on the VWF:RCo/VWF:Ag ratio may require repeated testing or confirmation by other methods.

Influence of ABO Blood Type

Because VWF plasma level varies with ABO blood type, some laboratories employ different normal ranges for different ABO blood types,[24] but the value of this refinement for VWD diagnosis is uncertain. Also, the risk of bleeding associated with a particular VWF level does not appear to depend on ABO blood type.[128] Consequently, the use of ABO-adjusted reference ranges for VWF parameters may not significantly increase the precision of VWD diagnosis.

Mixed von Willebrand Disease Phenotypes

Mutations may disrupt the function of *VWF* alleles in many distinct ways, and, therefore, compound heterozygosity can sometimes produce VWD phenotypes that combine features of several VWD subtypes. For example, inheritance of a factor VIII binding defect from one parent and a hypofunctional allele from another can produce a mixed phenotype of VWD type 2N and VWD type 1. Such interactions may contribute to the variability in laboratory findings and symptoms observed in certain families.[23] In favorable cases, such combined defects may be deciphered by genetic and phenotype studies of the patient's relatives.

DIFFERENTIAL DIAGNOSIS

Bleeding symptoms in VWD include those characteristic of platelet dysfunction and sometimes of factor VIII deficiency. Consequently, the differential diagnosis includes other defects of platelets and blood clotting, both congenital and acquired. Such disorders usually can be identified readily, but some can pose special problems.

Hemophilia A

Factor VIII deficiency occurs in both VWD and hemophilia A (see Chapter 125), and a patient with hemophilia who ingests aspirin, or who has another cause for platelet dysfunction, can have a combination of bleeding symptoms that resembles VWD type 3. Hemophilia A and VWD can be distinguished by appropriate laboratory testing (see Chapters 122 and 125). VWF:Ag and VWF:RCo are normal in hemophilia and absent in VWD type 3. However, factor VIII is selectively low in both hemophilia A and VWD type 2N. Without a clear pattern of X-linked recessive inheritance to support hemophilia A, or autosomal recessive inheritance to support VWD type 2N, distinguishing between these diagnoses may require testing of factor VIII binding to patient VWF (VWF:FVIIIB). The VWF:FVIIIB is normal in hemophilia A and markedly decreased in VWD type 2N. In a screening study of 177 patients previously diagnosed with hemophilia A, 5 were found instead to have VWD type 2N.[129]

Thrombocytopenia

Thrombocytopenia associated with VWD type 2B may be discovered incidentally during a medical evaluation for other reasons and may be exacerbated by pregnancy,[130–133] surgery,[134] or other physiologic stress. Platelet counts less than 20,000 cells/μL may occur under these conditions. This finding sometimes has led to the erroneous diagnosis of autoimmune thrombocytopenia, resulting in unnecessary treatment with corticosteroids, intravenous immunoglobulins, and splenectomy.[130–136] VWD type 2B also may present as neonatal thrombocytopenia.[137,138]

Platelet-Type Pseudo-von Willebrand Disease

Platelet-type pseudo-VWD was first described by Miller and Castella[139] and Weiss and coworkers[140] as a hemorrhagic disorder caused by gain-of-function defects in the platelet receptor for VWF (see Chapter 141). Phenotypically, patients with platelet-type pseudo-VWD are similar to patients with VWD type 2B. Multimeric analysis shows the absence of high-molecular-weight multimers and factor VIII, VWF:RCo, and VWF:Ag are variably reduced. RIPA is enhanced in response to low concentrations of ristocetin (0.3–0.5 mg/mL), and mild thrombocytopenia is commonly present. However, in contrast to VWD type 2B, in which the abnormality is in the VWF, the defect in platelet-type pseudo-VWD is in platelet GPIb. The mutant GPIb binds VWF with increased affinity, and the deficiency of high-molecular-weight VWF multimers is thought to occur as a consequence of increased binding to platelets. Platelet-type pseudo-VWD can be distinguished from VWD type 2B by suitable mixing experiments. In platelet-type pseudo-VWD, the addition of normal human VWF to a patient's platelet-rich plasma induces platelet aggregation, whereas in VWD type 2B it does not.[141] The converse test also can be useful: In VWD type 2B the VWF in patient plasma binds to formalin-fixed platelets at low concentrations of ristocetin, whereas in platelet-type pseudo-VWD it does not.[142]

Platelet-type pseudo-VWD is caused by missense mutations in the VWF binding site located in the N-terminal end of the platelet GPIb α-chain; the substitutions Gly233Val and Val239Met have been reported in different families.[143–145] When VWF binds GPIbα, conformational changes occur in both proteins, and the crystallographic structures of the bound and free proteins suggest that the mutations that cause platelet-type pseudo-VWD increase the affinity of binding by stabilizing the bound conformation of GPIbα.[105]

Acquired von Willebrand Syndrome

Deficiency of VWF may occur as an acquired condition, in which case it is referred to as *acquired von Willebrand syndrome* (AvWS).

The laboratory findings in AvWS are similar to those in VWD, with decreased values for VWF:Ag, VWF:RCo, and factor VIII. The VWF multimer pattern often shows a decrease in large multimers compatible with a diagnosis of VWD type 2A, but the multimer distribution also may be normal.[146,147]

AvWS usually appears to be caused by one of three mechanisms involving VWF: autoimmune clearance, fluid shear stress-induced proteolysis, or increased binding to platelets or other cells. Immune mechanisms are thought to explain AvWS that occurs in association with lymphoproliferative disorders, monoclonal gammopathy of unknown significance, systemic lupus erythematosus, autoimmune hypothyroidism, other autoimmune diseases, and some cancers. Antibodies to VWF have been found only in less than 20% of such patients, suggesting that current methods for antibody detection are too insensitive, or that AvWS associated with these conditions may not always have an immunologic basis.

Some cardiovascular conditions expose the blood to increased fluid shear stress and thereby appear to increase the proteolytic cleavage of VWF, probably by the metalloprotease ADAMTS13, which causes the loss of large VWF multimers and may cause AvWS. For example, AvWS has been reported in patients with aortic stenosis, mitral valve prolapse, pulmonary hypertension, ventricular septal defect, and patent ductus arteriosus. The AvWS resolves or improves on surgical correction of the vascular defect or pharmacologic treatment of pulmonary hypertension.[146–151]

AvWS may result from increased binding of VWF platelets in patients with thrombocytosis caused by myeloproliferative disorders, such as essential thrombocythemia, polycythemia vera, and chronic myelogenous leukemia or by reactive thrombocytosis after splenectomy. There is an inverse relationship between platelet count and the proportion of high-molecular-weight VWF multimers, and measures to reduce the platelet count can restore a normal multimer distribution and normal hemostatic function.[152–154] Binding of VWF to the surface of malignant lymphocytes or other tumor cells also has been reported to cause AvWS. In some cases, increased VWF binding may be a consequence of the abnormal expression of GPIb or other VWF binding proteins on the cell surface.[146,147]

A few other conditions may cause AvWS. Mildly decreased VWF levels may occur in hypothyroidism by nonimmune mechanisms and are corrected with appropriate thyroid hormone therapy.[155] Case reports have described AvWS in patients receiving valproic acid, ciprofloxacin, griseofulvin, or hydroxyethyl starch.[146,147]

Recognizing AvWS is important because treatment of associated predisposing conditions may improve the hemostatic defect. If correction of the underlying disorder is not possible, then several strategies may be tried to control bleeding. Despite the fact that most AvWS is caused by rapid clearance of VWF, treatment with desmopressin reportedly is effective in approximately one-third of patients. As is true of VWD, a test dose of desmopressin appears to predict future responses in AvWS. Factor VIII-VWF concentrates were effective in a similar fraction of cases.[146] The likelihood of response to desmopressin or factor VIII-VWF concentrates appears to be greatest for AvWS associated with autoimmune clearance. Approximately one-third of patients with immune-mediated AvWS also respond well to high-dose intravenous immunoglobulin, although a good response seems to be less likely for patients with IgM monoclonal gammopathy.[156] If these interventions are ineffective, then plasmapheresis or extracorporeal immunoadsorption may be considered.[146]

In contrast to the relatively good outcome in immune-mediated disease, AvWS associated with either high fluid shear stress or increased binding to platelets does not usually respond well to desmopressin, factor VIII-VWF concentrates, or intravenous immunoglobulin.[146] However, AvWS in the setting of cancer, particularly Wilms tumor,[147] may be quite responsive to desmopressin and also have good responses to factor VIII-VWF concentrates.[146]

CLINICAL MANIFESTATIONS

Bleeding Symptoms

Depending on the subtype, bleeding in VWD may have features of bleeding because of platelet dysfunction or factor VIII deficiency, and VWD type 3 combines these hemostatic defects. Bruising, recurrent severe nosebleeds, oral cavity bleeding, and menorrhagia are characteristic of platelet adhesion defects, whereas joint and deep tissue bleeding are more likely to be caused by factor VIII deficiency (see Chapter 121). A recent study summarized bleeding episodes in 385 patients with VWD type 3, 182 of whom were women.[112] The reported symptoms included gastrointestinal bleeding in 20%, hemarthrosis in 37%, postoperative bleeding in 41%, muscle hematoma in 52%, menorrhagia in 69%, oral cavity bleeding in 70%, and severe nosebleeds in 77%. Compared with these figures for VWD type 3, patients with hemophilia A had approximately twice the frequency of bleeding into joints and muscles and a similar frequency of postoperative bleeding but rarely had bleeding from mucosal surfaces. Pregnancies in VWD type 3 were not associated with excessive bleeding and did not require prophylactic replacement therapy prior to delivery. However, postpartum bleeding that delayed discharge from the hospital or required blood transfusion occurred in 15% of pregnancies. Menorrhagia requiring medical treatment, causing iron deficiency, or requiring transfusion of blood or plasma occurred in at least two-thirds of women with VWD type 3.[112,157] In addition to menorrhagia, women may experience midcycle pain with ovulation and significant bleeding into the corpus luteum, which rarely may cause life-threatening hemoperitoneum.[158,159]

Patients with other types of VWD may experience some or all of the symptoms associated with VWD type 3, depending on the severity of VWF dysfunction and on whether the defect affects mainly platelet adhesion, factor VIII level, or both. Women with VWD are more frequently symptomatic than are men, mainly because of the hemostatic challenges of the menstrual cycle and childbirth. Including all VWD types, women account for approximately two-thirds of patients.[82,158]

Standardized bleeding questionnaires have been developed and tested retrospectively on patients with VWD type 1 (see Chapter 121).[160,161] The most common symptoms were bleeding after tooth extraction, nosebleeds, menorrhagia, bleeding into the skin, postoperative bleeding, and bleeding from minor wounds. At least one bleeding symptom was reported by 98% of index cases, 89% of affected relatives, 32% of unaffected relatives, and 12% of healthy controls. Such questionnaires may be useful in deciding whether a patient's bleeding symptoms merit laboratory testing for VWD.

Other Disorders Associated With von Willebrand Disease

Many conditions that affect hemostasis, directly or indirectly, can interact with VWD and exacerbate bleeding symptoms, which contributes to the phenotypic heterogeneity of VWD. For example, recurrent bleeding from gastrointestinal angiodysplasia is relatively common in AvWS and in VWD types 2 and 3.[162–164] Similarly, VWD may be associated with bleeding at various sites in hereditary hemorrhagic telangiectasia[165] and Ehlers-Danlos syndrome.[166,167]

THERAPY

The aim of therapy in VWD is to correct abnormalities of VWF-dependent platelet function and blood coagulation, as necessary, usually by raising plasma levels of VWF and factor VIII. In contrast to hemophilia, which frequently is associated with severe spontaneous bleeding, few patients with VWD require chronic prophylactic treatment to prevent bleeding. The major indications for treatment in

VWD are to stop bleeding episodes and to prevent surgical or postpartum bleeding. As a general rule, mucosal bleeding responds to correction of the platelet adhesion defect by raising the level of hemostatically effective, large VWF multimers,[168–170] whereas surgical and soft tissue bleeding respond to correction of the blood clotting defect by raising the level of factor VIII.[171,172] Recommendations for specific clinical situations are summarized in Table 129–5.

Patients with VWD can have venous thrombosis, particularly when receiving treatment with factor VIII-VWF concentrates,[173,174] and should receive prophylactic antithrombotic therapy when indicated by other aspects of the clinical situation.

DESMOPRESSIN

The synthetic vasopressin analog, 1-desamino-8-D-arginine vasopressin (desmopressin) lacks the pressor activity of vasopressin (antidiuretic hormone [ADH]) and was developed initially for the treatment of diabetes insipidus. When given at much higher doses to normal volunteers or to persons with mild hemophilia A or VWD, desmopressin was found to induce a rapid increase in plasma levels of VWF and factor VIII, with peak levels achieved approximately 30 minutes after intravenous administration.[119,175] Desmopressin promotes the secretion of VWF from storage sites in endothelium. One study has demonstrated the loss of VWF staining of capillary endothelial cells after desmopressin administration.[176] The rapid changes in factor VIII and VWF levels coincide, suggesting that factor VIII is released from cells in which both proteins are stored together, although the identity of these cells is unknown at present.

Bleeding and Surgery in von Willebrand Disease

Desmopressin (DDAVP; Aventis, Ferring) is available in an injectable or a nasal spray formulation. The injectable preparation (4 μg/mL) usually is administered intravenously and maximal responses are obtained with a dose of 0.3 μg/kg. The total dose is diluted in normal saline (eg, 50 mL) and infused over 30 minutes. Healthy controls and patients with type 1 VWD or mild hemophilia A usually obtain a reproducible twofold to fivefold increase in VWF and factor VIII within 30 minutes after the end of the infusion.[175] Subcutaneous administration produces similar peak levels of factor VIII and VWF but with a delay of 1.5 to 2 hours.[175,177] For subcutaneous administration, 0.3 μg/kg of injectable desmopressin is administered at less than 1.5 mL/site, and a single treatment may require three or four subcutaneous injections.

Because of its decreased bioavailability, approximately 10-fold more intranasal desmopressin must be given to achieve a useful hemostatic response. Two intranasal preparations are available. One is a dilute solution (100 μg/mL) used for patients with diabetes insipidus that cannot be used to treat VWD. The other is a concentrated preparation (Stimate, 1.5 mg/mL) specifically formulated for self-treatment of bleeding in hemophilia A and VWD. The spray pump delivers 0.1 mL (150 μg), and the usual dose is two sprays (one per nostril) for a total of 300 μg. Patients weighing less than 50 kg may use a single spray. Maximal levels of factor VIII and VWF are reached in approximately 1.5 hours, and usually are less than those achieved with optimal intravenous dosing and similar to those reached after an intravenous dose of 0.2 μg/kg.[175,177,178]

For all routes of administration, the half-life of the stimulated increase in factor VIII and VWF is approximately 5 to 8 hours in most patients.[175,177] Therefore, a dose interval of 24 hours is usually sufficient. Patients with VWD type 1 caused by rapid clearance of VWF, or VWD type 2A caused by intravascular proteolysis of VWF may have very brief responses to desmopressin. A dose interval of 12 hours may be required in such patients, or desmopressin may simply be ineffective. The individual response to desmopressin is reproducible, and an elective test dose (see box on Performing a Desmopressin Test Dose) is advisable to characterize the response to desmopressin before depending on it for hemostasis.

Tachyphylaxis to desmopressin is common but does not always impair its hemostatic effect. The levels of factor VIII and VWF after the second dose are approximately 30% less than after the first dose, and responses to subsequent doses tend to be similar.[179] Because some patients (≈20%) fail to sustain effective responses after the initial dose,[179] desmopressin alone should not be relied on for hemostasis over several days unless the patient's pattern of response is known to be satisfactory. In practice, one can follow factor levels and switch to coverage with factor VIII-VWF concentrates if necessary.

Common immediate side effects of intravenous desmopressin include transient headache, facial flushing, and mild hypotension with compensatory tachycardia. These symptoms generally abate with a reduction in the dose or the rate of infusion. Among patients using intranasal desmopressin, headache, and flushing occurred with approximately 3% of doses; nausea, vomiting, dizziness, abdominal cramping, and peripheral edema were reported infrequently (in total, 0.14% of doses).[180]

Desmopressin has potent antidiuretic activity and can cause hyponatremia and seizures if free water intake is not restricted appropriately. This complication appears to be a particular concern for infants and young children but may occur at any age. The risk of hyponatremia is increased for patients who receive repeated intravenous doses of desmopressin and intravenous hydration[181] but has occurred after a single intranasal dose of desmopressin followed by excessive oral fluid intake.[182] Patients using intranasal desmopressin should be instructed about the importance of restricting water intake and the significance of symptoms that may be associated with hyponatremia. For patients receiving intravenous desmopressin, monitoring of water intake, body weight, and serum electrolytes should be considered for children or for persons of any age given intravenous fluids or repeated doses of desmopressin.

Performing a Desmopressin Test Dose

Desmopressin 0.3 μg/kg in 50 to 100 mL of normal saline is infused intravenously over 30 minutes with monitoring of vital signs and for side effects of flushing or headache. Levels of factor VIII, VWF:RCo (or VWF:CB), and optionally VWF:Ag are checked 1 hour and 4 hours, respectively, after the start of the infusion. Bleeding time need not be measured because it does not correlate with clinical efficacy. The values for factor VIII and VWF at 1 hour indicate the maximum response. The values at 4 hours permit calculation of the half-life of the endogenous factors and, therefore, predict the duration of an effective response. In most patients the half-life of the increased factor VIII and VWF is 5 to 8 hours.[175,177] The subset of patients with VWD type 1 who have normal platelet VWF content often exhibit an exaggerated peak increase (up to 20-fold) of both VWF and factor VIII but with a very short half-life of approximately 1 hour, adequate for oral surgery but possibly not for major surgery.[183] Patients with VWD type 2N exhibit dissociation between a normal VWF response and a brief and often insufficient factor VIII response.[22,127] Patients with VWD type 2A may have a satisfactory factor VIII response but a small or very brief VWF:RCo response.[103,184] Comparison of peak VWF:RCo and VWF:Ag values can help to discriminate between qualitative and quantitative VWF defects when the distinction is unclear from assays before treatment.

Peak factor VIII and VWF:RCo values of 40 to 60 IU/dL may be sufficient for minor surgery including dental extractions. Peak values of greater than 100 IU/dL are satisfactory for major surgery if the trough level can be maintained above approximately 50 IU/dL with a dose interval of 12 or 24 hours, depending on the duration of response based on the test dose.

Performing a Desmopressin Test Dose

Desmopressin 0.3 μg/kg in 50 to 100 mL of normal saline is infused intravenously over more than 30 minutes with monitoring of vital signs and for side effects of flushing or headache. Levels of factor VIII, VWF:RCo (or VWF:CB), and optionally VWF:Ag are checked 1 hour and 4 hours, respectively, after the start of the infusion. Bleeding time need not be measured because it does not correlate with clinical efficacy. The values for factor VIII and VWF at 1 hour indicate the maximum response. The values at 4 hours permit calculation of the half-life of the endogenous factors and, therefore, predict the duration of an effective response. In most patients the half-life of the increased factor VIII and VWF is 5 to 8 hours.[175,177] The subset of patients with VWD type 1 who have normal platelet VWF content often exhibit an exaggerated peak increase (up to 20-fold) of both VWF and factor VIII but with a very short half-life of approximately 1 hour, adequate for oral surgery but possibly not for major surgery.[183] Patients with VWD type 2N exhibit dissociation between a normal VWF response and a brief and often insufficient factor VIII response.[22,127] Patients with VWD type 2A may have a satisfactory factor VIII response but a small or very brief VWF:RCo response.[103,184] Comparison of peak VWF:RCo and VWF:Ag values can help to discriminate between qualitative and quantitative VWF defects when the distinction is unclear from assays before treatment.

Peak factor VIII and VWF:RCo values of 40 to 60 IU/dL may be sufficient for minor surgery including dental extractions. Peak values of greater than 100 IU/dL are satisfactory for major surgery if the trough level can be maintained above approximately 50 IU/dL with a dose interval of 12 or 24 hours, depending on the duration of response based on the test dose.

Myocardial infarction, stroke, and venous thromboembolism have been reported rarely in association with desmopressin use in adults. In clinical trials evaluating desmopressin to reduce blood loss during surgery, the incidence of thrombosis was similar in the treated and untreated groups.[185] Therefore, the risk of thrombosis appears to be small, but desmopressin should not be used in patients with significant coronary or cerebrovascular atherosclerosis.

Desmopressin is effective for most patients with VWD type 1, who make reduced amounts of a functionally normal VWF molecule.[175] The subset of VWD type 1 characterized by normal levels of platelet VWF (VWD type 1 platelet normal) appears to be caused by accelerated clearance of VWF from the blood, and these patients often have exaggerated responses to desmopressin that are of relatively short duration but are hemostatically effective.[183]

Desmopressin usually is not effective in patients with VWD type 2 or type 3. In VWD type 2A, the VWF secreted in response to desmopressin usually has markedly abnormal function and good hemostatic responses are uncommon.[103] Desmopressin causes acute, reversible thrombocytopenia in VWD type 2B[186] (and in platelet-type pseudo-VWD[187]), and usually does not correct the hemostatic defect.[103,186,188] Therefore, many consider desmopressin to be contraindicated in VWD type 2B, although good responses have been reported for a few patients.[138,189–192] Published experience in VWD type 2M is limited, but the properties of the mutant VWF suggest that desmopressin should be ineffective. Aside from patients with the mutation R854Q, which causes a relatively mild factor VIII binding defect, desmopressin usually does not effectively increase the level of factor VIII in VWD type 2N.[22,127] With a few exceptions,[118] desmopressin does not change VWF or factor VIII levels in VWD type 3.[103] The relatively rare patients with VWD type 2 or type 3 who respond satisfactorily can be identified with a test dose of desmopressin.

Plasma Products

Fresh-frozen plasma is too dilute for the specific treatment of VWD in most cases. Cryoprecipitate is prepared from frozen plasma by thawing at 4°C (39.2°F). The precipitate that forms is collected by centrifugation and refrozen. When thawed, cryoprecipitate from 1 unit of blood donation can be dissolved in 10 mL of saline for intravenous administration. One unit of cryoprecipitate contains approximately 100 U of factor VIII and VWF, and 200 to 250 mg of fibrinogen, representing a 10-fold concentration relative to plasma. Cryoprecipitate is not generally subjected to virus inactivation treatments and, therefore, may transmit certain infections. For this reason, virucidally treated factor VIII-VWF concentrates are preferred for therapy of VWD in countries where they are available (Table 129–5). Most of the clinical experience using such concentrates is with Humate-P (Aventis)[193] or Alphanate (Alpha Therapeutic Corp.),[194] but published results suggest that other factor VIII-VWF concentrates may be similarly effective.[195] The manufacturing process for all of these concentrates reduces the average size of the VWF multimers,[196] which could impair their adhesive function, but this has not proved to be a significant problem in practice. Most factor VIII-VWF concentrates are standardized only for factor VIII content, so that initial dosing must be based on factor VIII levels. They also differ substantially from each other in VWF content, and the VWF levels obtained during therapy must be determined by laboratory testing. Humate-P is labeled with both factor VIII and VWF:RCo

Table 129–5 Treatment with Factor VIII-VWF Concentrate

Bleeding	Initial Dose and Frequency	Target
Major surgery or bleeding	50 IU/kg daily	Trough level of VIII:C > 50 IU/dL until healing is satisfactory, typically 5–10 days
Minor surgery	40 IU/kg daily or every other day	Trough level of VIII:C > 30 IU/dL until healing is satisfactory, typically 2–4 days
Dental extractions	30 IU/kg one dose	VIII:C > 30 IU/dL for >12 hours
Minor bleeding	25 IU/kg daily	Trough level of VIII:C > 30 IU/dL until bleeding stops, typically 2–4 days
Delivery and postpartum	50 IU/kg daily starting the day of delivery	Trough level of VIII:C > 50 IU/dL until healing is satisfactory, typically 3–4 days postpartum

Initial doses of factor VIII-von Willebrand factor (VWF) concentrate have been calculated for adults with von Willebrand disease (VWD) type 3, or with VWD type 2 variants and completely dysfunctional endogenous VWF. Doses may be increased ≈ 20% for children younger than age 18 years to compensate for their relatively increased plasma volume.[194] For patients with some VWF that is normally functional (VWD type 1) or partially functional (mild type 2 variants), doses should be decreased based on the factor levels present before treatment. For concentrates labeled with VWF:RCo content, dosing may be based on VWF:RCo instead of factor VIII. Trough levels of factor VIII and VWF:RCo should be monitored at least daily. If necessary, reduced doses may be given at shorter dose intervals to decrease the range of peak and trough factor levels. If concentrates are not available locally and the risk of infection is judged to be acceptable, cryoprecipitate may be substituted assuming that one unit of cryoprecipitate contains 100 IU of factor VIII and VWF. If the patient is known to be responsive, desmopressin starting 1 hour before surgery may be substituted for factor VIII-VWF concentrates. If desmopressin is used to cover major surgery, peak and trough factor levels should be monitored and concentrates should be available in case the response to desmopressin becomes inadequate.

Primary or adjunctive therapy with antifibrinolytics, the role of platelet transfusions, and the approach to VWF inhibitors are discussed in the text.

Adapted from reference 229.

content, and initial dosing can be based on VWF level if desired.[193]

Factor VIII and VWF levels fall at different rates in patients with VWD who are treated with factor VIII-VWF concentrates,[194] and this phenomenon has important consequences when treatment is prolonged. The VWF:Ag declines with a half-time of approximately 13 hours; VWF:RCo declines more quickly with a half-time of approximately 7 hours because proteolysis in vivo converts the largest multimers into less active smaller forms more quickly than the VWF:Ag is cleared from circulation. Factor VIII levels decline slowly with an apparent half-time of approximately 24 hours that reflects both normal catabolism and stabilization of endogenously synthesized factor VIII through binding to the transfused VWF. Therefore, if dosing is adjusted to maintain the VWF:RCo level at 50 to 100 IU/dL, the factor VIII level can increase to several hundred IU/dL after a few days, which may confer a significant risk of thrombosis.[173,174,194] Excessive factor VIII levels can be avoided by laboratory monitoring and changing the concentrate dose accordingly.

Unnecessarily high factor VIII levels also could be avoided by switching to a pure VWF concentrate and relying on endogenous synthesis to maintain the factor VIII level. Such a high-purity VWF concentrate prepared from human plasma has been used successfully in Europe[197] (VWF-VHP, Biotransfusion) but is not available in the United States. Recombinant human VWF has been prepared and tested in animal models[198] but is not available for clinical use.

Pure factor VIII, plasma-derived or recombinant, is not appropriate for routine use in VWD. These preparations do not contain significant amounts of VWF and cannot correct quantitative or qualitative deficiencies of VWF. Also, when given to patients with VWD type 3 or VWD type 2N, the infused factor VIII is cleared rapidly with a half-life of less than 2 hours because there is no endogenous functional VWF to bind and stabilize it in the circulation.[199,200]

Platelets

The platelet VWF pool normally accounts for approximately 15% of total blood VWF,[201] and both plasma and platelet VWF contribute to hemostasis.[202] The transfusion of a normal platelet pheresis unit (4 to 5×10^{11} platelets) partially corrects the bleeding time of adult patients with VWD type 3, and appears to reduce the amount of cryoprecipitate necessary to fully correct the bleeding time.[203,204] Platelet transfusion could be considered for patients with VWD in whom therapy with factor VIII-VWF complex does not control serious bleeding.

Antifibrinolytic Agents

The fibrinolytic inhibitors ε-aminocaproic acid and tranexamic acid can be used in conjunction with desmopressin or factor VIII-VWF concentrates, and can be given orally or intravenously.[205] Systemic administration of either drug appears particularly effective for bleeding in the oral cavity.[206,207] Bleeding after oral surgery also was decreased by using mouth rinses containing tranexamic acid to supplement other systemic therapy.[208] Systemic antifibrinolytic agents are contraindicated in patients with bleeding in the upper urinary tract, where the formation of a stable clot may cause obstruction. Antifibrinolytics are contraindicated in patients with active thromboembolic disease and should be used with caution in patients with a history of thromboembolism.

Menstrual Cycle Bleeding

Midcycle bleeding from a hemorrhagic corpus luteum may be prevented by the use of combined oral contraceptives.[159] Menorrhagia in VWD, including VWD type 3, has been controlled with combined oral contraceptives, although the reported response rate varies among surveys from 24%[209] to 73%.[157] Estrogens at high doses can raise the plasma level of factor VIII and VWF, but current oral contraceptives do not contain sufficient estrogen and their efficacy probably depends instead on hormone-induced changes in the endometrium.

Menorrhagia also can be treated with tranexamic acid 1 g every 6 hours for 5 days,[210] or with a single dose of 4 g a day for 3 to 5 days, started at the onset of bleeding.[211] Although ε-aminocaproic acid has not been tested specifically in VWD, it has been effective for menorrhagia in otherwise healthy women at doses of 5 g three times daily for 5 days,[212] or 3 g every 6 hours for 3 to 5 days.[213] Occasional side effects include nausea, diarrhea, and orthostatic hypotension.

Desmopressin has been evaluated for the treatment of menorrhagia in two small randomized placebo-controlled trials including 22 women with VWD[214] or 20 women with unexplained prolonged bleeding times.[215] Each study reported a trend in favor of desmopressin for the reduction of menstrual bleeding, but the difference was not statistically significant. A larger open-label trial in 90 women (most with VWD) reported shortened or decreased bleeding in 88% of treated menstrual cycles.[180]

Pregnancy, Labor, and Delivery

Excessive bleeding during pregnancy is uncommon in VWD, and replacement therapy is rarely needed, even for patients with VWD type 3. Fertility is not impaired, and the rate of spontaneous abortion does not appear to be increased.[112,157] However, bleeding at delivery and postpartum may occur if the factor VIII and VWF levels are sufficiently low. Factor VIII and VWF levels normally begin to increase by the second trimester, increase approximately twofold by the end of the third trimester,[216] and decrease to baseline within a week after delivery. For patients with VWD, factor VIII and VWF levels below approximately 50 IU/dL are associated with increased risk of peripartum hemorrhage.[217] Whether factor VIII or VWF correlates best with bleeding risk has not been determined conclusively.[217,218] Severe peripartum hemorrhage has occurred in VWD patients with isolated decreases in VWF:RCo (VWD type 2A)[219] or factor VIII (VWD type 2N),[53,220] suggesting that both factors are relevant. Factor VIII and VWF levels should be checked antepartum and, if necessary, factor VIII-VWF concentrate given to increase the levels to greater than 50 IU/dL at delivery.[217] Administration of concentrate may reverse the thrombocytopenia as well as the bleeding tendency associated with VWD type 2B at delivery.[133] If factor levels are greater than 50 IU/dL, epidural anesthesia has been used without complications.[217,221] Complete evacuation and effective uterine contraction after delivery are important to prevent bleeding.[218]

In the postpartum period, desmopressin or factor VIII-VWF concentrate should be used to maintain levels greater than 50 IU/dL for 3 to 4 days.[112,217,218] Delayed bleeding may occur 2 to 3 weeks after delivery, and patients should be instructed about this risk. If hemorrhage occurs despite prophylaxis, full replacement therapy should be given using desmopressin or factor VIII-VWF concentrate as appropriate, and antifibrinolytics may be useful adjunctive treatment.

Alloantibody Inhibitors of von Willebrand Factor

Inhibitors to VWF in patients with VWD are uncommon and occur exclusively in patients with VWD type 3 who have been transfused repeatedly with plasma, cryoprecipitate, or factor VIII-VWF concentrates. Inhibitors have been identified by patient screening or physician surveys in 2.6% to 9.5% of patients with VWD type 3, although selection bias makes it difficult to know the true incidence.[112,222] Patients with large deletions of the VWF gene may be at higher risk for the development of inhibitors,[222] and a familial tendency to inhibitor formation has been noted.[223] The presence of a VWF inhibitor is suggested by the failure to respond clinically to replacement therapy, by decreased recovery of infused VWF, and by lack of correction of abnormal VWF-dependent platelet function tests. The

presence of an antibody inhibitor can be confirmed by demonstrating that patient plasma, serum or purified immunoglobulin inhibits RIPA of normal platelet-rich plasma. The inhibitors that have been characterized so far have been IgG alloantibodies and all but one were clearly polyclonal.[222] The antibodies typically inhibit the function of factor VIII-VWF complex (as in plasma) but not that of pure factor VIII, suggesting that inhibition of factor VIII-VWF is caused by steric hindrance.[223]

When transfused with a product containing VWF, patients with VWF inhibitors commonly experience serious allergic reactions with back pain, abdominal pain, and hypotension, and they may have life-threatening anaphylactic reactions.[112,170] These adverse consequences can be avoided by the use of recombinant factor VIII preparations that are free of VWF. Although the infused factor VIII is cleared rapidly, factor VIII levels of 40 to 60 IU/dL can be achieved by intravenous infusion of 700 to 900 U/kg/day, given continuously or by bolus infusion every 4 hours, and this approach has controlled bleeding after abdominal surgery or cesarian section.[224,225] Recombinant factor VIIa (NovoSeven) also has been used effectively for surgical or postpartum bleeding by continuous infusion (≈ 20 μg/kg/hour) or bolus infusion (≈ 90 μg/kg every 4 hours).[225–227]

CHAPTER 130

VITAMIN K: METABOLISM AND DISORDERS

Barbara C. Furie and Bruce Furie

INTRODUCTION

Vitamin K plays a critical role in the posttranslational modification of the blood coagulation proteins, factors VII, IX, and X, and prothrombin, and of the plasma regulatory proteins, proteins C and S. Vitamin K serves as a cofactor for an enzymatic reaction that converts glutamic acid residues in the NH_2-termini of these proteins into γ-carboxyglutamic acid (Gla) residues (Fig. 130–1).[1,2] There are three well-defined classes of Gla-containing proteins that have been isolated and extensively characterized: (1) the mammalian Gla-domain containing, vitamin K-dependent blood clotting and regulatory proteins; (2) γ-carboxyglutamic acid-containing proteins of vertebrate mineralized tissue, including osteocalcin and matrix Gla protein; and (3) conotoxins of the marine snail, *Conus*. A new class of transmembrane Gla-domain containing proteins has been identified in vertebrates and ascidians, marine invertebrates, by interrogation of gene data bases and complementary DNA (cDNA) cloning.[3–5] These proteins may suggest a role for vitamin K-dependent proteins in signal transduction.

Gla acid residues confer essential metal-binding properties on the vitamin K-dependent proteins of blood coagulation.[6] If γ-carboxylation is impaired either as a result of vitamin K deficiency or through pharmacologic intervention, the newly synthesized vitamin K-dependent proteins are secreted into the blood in their des-γ-carboxy or "abnormal" forms. The des-γ-carboxylated proteins cannot bind Ca^{2+}, and the physiologically important metal ion-mediated binding to phospholipid vesicles or cell membranes does not occur.[7,8] Because many critical enzymatic reactions of blood coagulation proceed on membrane surfaces, coagulation and its regulation are impaired. Therefore, vitamin K metabolism is essential to normal hemostatic and antithrombotic mechanisms. Indeed, inhibition of vitamin K action is the primary mechanism of oral anticoagulant therapy (see Chapter 137).

THE VITAMIN K CYCLE

In its role as a cofactor for the vitamin K-dependent carboxylase, vitamin K participates in a series of linked enzyme reactions that result in the generation of γ-carboxyglutamic acid and the regeneration of active cofactor. This series of reactions is known as the *vitamin K cycle* (Fig. 130–2). In addition to the enzyme, the reduced form of vitamin K and a glutamic acid-containing polypeptide substrate, the reactions require carbon dioxide and molecular oxygen. In the first reaction in the cycle (see Fig. 130–2), a hydrogen ion, H^+, is abstracted from the γ-carbon of the glutamyl residue and a carboxyl group is added.[9] Concomitantly, the cofactor, vitamin K, is converted from the reduced to the epoxide form.[10] The enzyme, the vitamin K-dependent carboxylase, catalyzes both carboxylation and epoxidation.[11]

THE VITAMIN K-DEPENDENT CARBOXYLASE

The vitamin K-dependent carboxylase is a single polypeptide chain of 758 amino acids.[12–15] The enzyme is found in vertebrates and invertebrates, including Drosophila,[16,17] cone snail *Conus*,[18–20] *Ciona intestinalis* (sea squirt, an *urochordates*)[3] and *Halocynthia roretzi* (a tunicate).[21] Although vertebrates and molluscs diverged on the evolutionary tree more than 500 million years ago, the vitamin K-dependent carboxylase and its gene are highly conserved.[22,23] Mice lacking the gene for the vitamin K-dependent carboxylase demonstrate a partial developmental block with only 50% of null animals surviving to term.[24] Those animals that survive to term die uniformly at birth of massive intra-abdominal hemorrhage. These data indicate that there is no redundant pathway for carboxylation of glutamic acid.[24]

The vitamin K-dependent carboxylase is an integral membrane protein that binds directly to the γ-carboxylation recognition site on the precursor forms of the vitamin K-dependent proteins.[25] The enzyme is located in both the endoplasmic reticulum and the Golgi apparatus.[26,27] However, carboxylation is an efficient process such that carboxylation of protein substrates is completed in the endoplasmic reticulum.[28] The presence of carboxylase in the Golgi apparatus is likely caused by the recycling of the membrane-bound enzyme between the endoplasmic reticulum and the Golgi apparatus.

The active site responsible for glutamate binding is located in the N-terminal one-third of the protein.[29] The complementary site on the carboxylase that binds the propeptide carboxylation recognition site also resides in part in the N-terminal one-third of the protein,[30] the C-terminal one-third of the protein[31] or perhaps both.[32] Regions around residues 234, 406, and 513 have been implicated in propeptide-binding site whereas regions around residue 359 have been implicated in catalysis.[33] The vitamin K epoxidase activity of the protein requires a C-terminal region of this enzyme for this activity.[34]

MECHANISM OF ACTION OF VITAMIN K

The most attractive hypothesis has been that an active oxygenated species of vitamin K abstracts a hydrogen from the γ-carbon of glutamic acid, with subsequent collapse of the activated vitamin K species to vitamin K epoxide and the addition of carbon dioxide to the γ-carbon of glutamic acid.[35] In support of this hypothesis, oxygen and vitamin KH_2-dependent exchange of tritium from tritiated water to the γ-carbon of a glutamic acid in a carboxylase substrate at low carbon dioxide concentrations have been taken as evidence of a carbanion mechanism.[36] Based on a nonenzymatic model, a *base strength amplification mechanism* has been proposed to explain the conversion of vitamin KH_2 into an oxygenated intermediate of sufficient basicity to abstract a hydrogen from the γ-carbon of a glutamyl residue in a carboxylase substrate.[37–39] Recent advances have been made that help resolve the conundrum of how the carboxylase active site might generate a vitamin K species of sufficient basicity. Although a vitamin K-dependent γ-glutamyl carboxylase cysteine or histidine residue was suspected of serving as the enzyme active site residue that deprotonates vitamin K,[11,40–45] more recent studies have eliminated these residues from consideration for this role.[46,47] The enzyme active site base that deprotonates vitamin K has been identified as Lys218 based on evidence that the active site base is an amine, evolutionary comparison of vitamin K-dependent carboxylases, mutagenesis studies, and chemical rescue experiments.[46,48]

The base amplification mechanism for vitamin K activation suggests that epoxidation of vitamin KH_2 by the vitamin K-

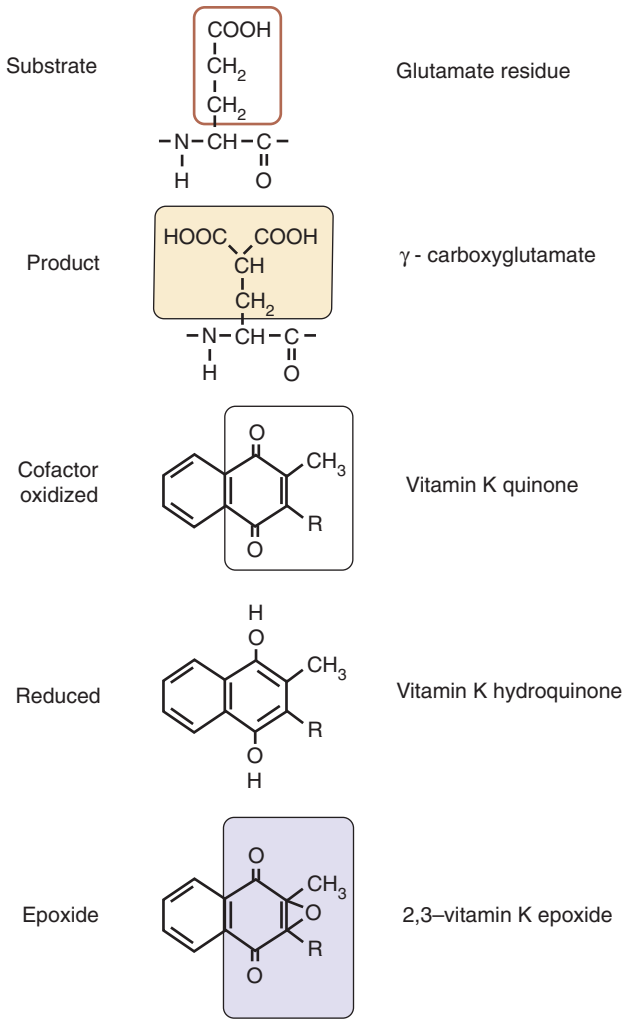

Figure 130–1 Reactants in the vitamin K-dependent carboxylation pathway.

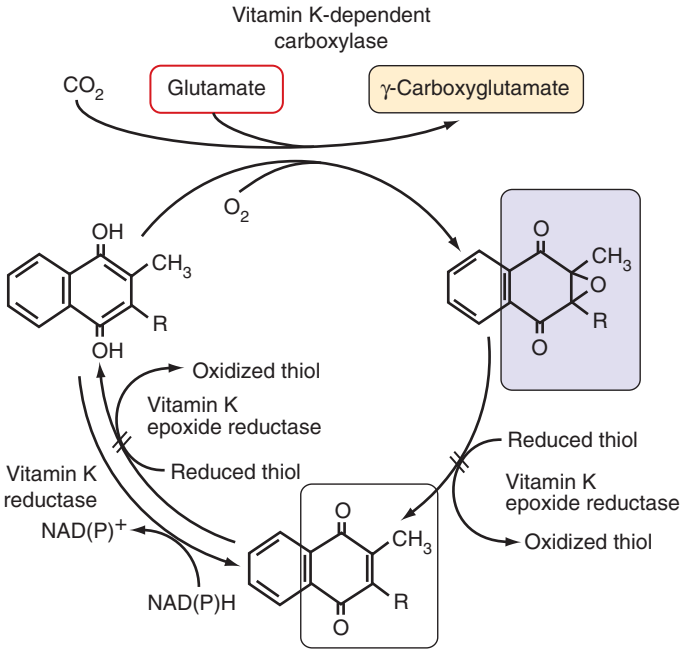

Figure 130–2 The vitamin K cycle. Reduced vitamin K, the hydroquinone form, is a cofactor for the conversion of glutamate to γ-carboxyglutamate by the vitamin K-dependent carboxylase, also known as the vitamin K epoxidase. Concomitant with conversion of glutamate to γ-carboxyglutamate, the hydroquinone is converted to 2,3-vitamin K epoxide. The epoxide can be converted to vitamin K quinone by the vitamin K epoxide reductase. Vitamin K quinone can be reduced by two pathways to the vitamin K hydroquinone, completing the cycle.

dependent carboxylase can occur in the absence of formation of γ-carboxyglutamic acid but that carboxylation cannot occur in the absence of epoxidation. However in the absence of propeptide and glutamate-containing substrate, the carboxylase lacks vitamin K epoxidase activity. When these substrates are added to the enzyme, vitamin K epoxidase activity is upregulated.[49] These results were originally interpreted to indicate that the propeptide and glutamate-containing substrate induced a conformational change in the vitamin K-dependent carboxylase that exposed a free cysteine at the catalytic site for vitamin K epoxidation.[50] In light of the observation that Lys218 is the critical active site base, an alternate hypothesis is that binding of the propeptide and glutamate substrate modify the active site environment, changing the equilibrium between the protonated state of the lysine side chain, favored at physiologic pH, and the unprotonated state required for its action as a general base.[48]

As epoxidation occurs concomitant with carboxylation and because vitamin K either from dietary sources or gut flora is in the quinone form, tissues in which γ-carboxylation takes place must have a mechanism for generating the reduced form of vitamin K. Vitamin K epoxide reductase, a dithiol-requiring enzyme, reduces vitamin K epoxide to the vitamin K quinone (see Fig. 130–2). Two enzymatic activities, including the epoxide reductase, have been identified that convert vitamin K quinone to the biologically active hydroquinone (see Fig. 130–2). The epoxide reductase activity resides in the endoplasmic reticulum. Originally thought to be part of an enzyme complex,[51,52] current evidence suggests the vitamin K epoxide reductase, capable of reducing vitamin K epoxide to vitamin K and vitamin K to the reduced form of the vitamin, is a single gene product.[53–55] However the vitamin K epoxide reductase must be recycled to its reduced form to perform another round of vitamin K reduction. Protein disulfide isomerase, an endoplasmic reticulum enzyme involved in dithiol redox exchange, has been linked to the vitamin K cycle in the endoplasmic reticulum and may be responsible for reduction of the vitamin K epoxide reductase.[56] Because both activities of the vitamin K epoxide reductase are inhibited by warfarin, an additional enzyme must be responsible for reducing vitamin K to its active cofactor form when the vitamin is given to reverse anticoagulation with warfarin.[53]

NATURE OF THE SUBSTRATE

Although many tissues contain the enzymes to carry out γ-carboxylation and the reactions of the vitamin K cycle, the primary site of synthesis of the vitamin K-dependent proteins of the blood is the liver. These proteins are synthesized with both a signal sequence and a propeptide. The canonical leader sequences provide the signal that indicates that the protein is to be secreted and thus allows the growing polypeptide chain to be translocated to the rough endoplasmic reticulum. All sequences of the propeptides of the vitamin K-dependent proteins are highly homologous and unique to this class of proteins.[57] These propeptides serve as recognition signals that designate these proteins as substrates for the vitamin K-dependent carboxylase.[58] The γ-carboxylation recognition site resides on the N-terminus of the propeptide. It is extended by a 10-residue amphipathic α-helix.[59] The propeptide of the precursor forms of the vitamin K-dependent proteins serves three functions: (1) to direct γ-carboxylation by the γ-carboxylase,[58] (2) to inhibit binding of the carboxylated precursor proteins to membranes,[60] and (3) to upregulate vitamin K epoxidase activity of the carboxylase.[49]

VITAMIN K

Forms and Distribution

The vitamin K family of chemical compounds has many members. Vitamin K_1 (2-methyl-3-phytyl-1,4-naphthoquinone) is the major form of the vitamin found in plants. Animal tissue and bacteria produce menaquinones, a series of vitamin K forms similar in structure to vitamin K_1 but with varying lengths of unsaturated polyprenyl groups at the 3 position.

Nutritional Sources

Vitamin K is an essential fat-soluble vitamin. The diet is the primary source of vitamin K in humans. Leafy green vegetables, in particular, are a good source of vitamin K_1,[61] although vitamin K_1 is widely distributed in the normal human diet. A contribution to adequate vitamin K intake in humans may be provided by the vitamin K_2 synthesized by intestinal bacteria.[62] The daily dietary requirement for the vitamin has been estimated to be 100 to 200 (μ) μg/day.[63]

Physiology

Vitamin K is absorbed in the ileum. The presence of bile salts and normal fat absorption are required for effective uptake. The storage pool of vitamin K is modest. In the absence of a dietary source of the vitamin, this storage pool can be exhausted within 1 week in an otherwise normal person. Such a deficiency does not generally lead to clinical manifestations, as the vitamin K synthesized by gut flora is available to provide suboptimal but adequate synthesis of vitamin K-dependent proteins.

VITAMIN K DISORDERS

Hemorrhagic Disease of the Newborn

Hemorrhagic disease of the newborn, because of vitamin K deficiency, develops during the first week of life, usually between days 2 and 7 (see Chapter 133).[61–66] Clinical manifestations include bleeding in the skin or from mucosal surfaces, circumcision, or venipuncture sites.[67] Rarely, internal bleeding, including retroperitoneal or intracranial hemorrhage, is the primary manifestation of hemorrhagic disease of the newborn. These ominous complications are the rationale for the use of vitamin K prophylaxis in neonates.

Almost all neonates are vitamin K deficient, presumably as a result of deficient vitamin K nutriture in the pregnant mother during the third trimester and because of the lack of colonization of the colon by bacteria that produce vitamin K in the neonate.[68] However, this deficiency is further aggravated in some patients by inadequate dietary intake of vitamin K. This disorder is more prevalent in breast-fed babies, as human milk, in contrast to cow's milk, contains only 15 μg/L of vitamin K.[67,69]

Neonates with hemorrhagic disease of the newborn have a prolonged prothrombin time and partial thromboplastin time (PTT). However, it is critical to distinguish whether the prolongation of these times is a manifestation of the deficiency of the vitamin K-dependent proteins because of vitamin K deficiency or to decreased synthetic capacity of the liver in newborns. Elevation of the abnormal (des-γ-carboxy) prothrombin (PIVKA-II) antigen level is indicative of vitamin K deficiency, as this form of prothrombin appears only when post-translational modification is impaired but not when protein synthesis is impaired.[68] Administration of vitamin K (100 μg) corrects the deficiency state and usually does not need to be repeated in the otherwise healthy infant.

Prophylactic vitamin K has been in use for in-hospital births for the past 45 years. Vitamin K (100 μg to 1 mg) is administered intramuscularly to the newborn immediately after birth. At these doses, vitamin K administration carries little morbidity and can prevent hemorrhagic disease of the newborn. Some of these vitamin K protocols are under revision[70] and have been updated.[71]

ACQUIRED VITAMIN K DEFICIENCY

Dietary Deficiency States and Antibiotics

The requirement for vitamin K is sufficiently low relative to the vitamin K content of a normal diet that clinically significant vitamin K deficiency does not occur as a result of inadequate dietary intake. Although sensitive markers of vitamin K deficiency, such as abnormal (des-γ-carboxy) prothrombin antigen,[72] indicate that diet truly depleted of vitamin K can lead to mild vitamin K deficiency, no evidence shows that an inadequate diet alone can have clinical manifestations. Bacteria in the large intestine produce functional forms of vitamin K. In the absence of dietary vitamin K, small amounts of vitamin K in the large intestine are absorbed passively and prevent severe vitamin K deficiency. In patients medicated with antibiotics that destroy the intestinal flora, this vitamin K source is eliminated. Thus, a common setting of vitamin K deficiency is the case of a patient with inadequate or minimal dietary intake treated simultaneously with antibiotics (Fig. 130–3). This form of vitamin K deficiency occurs within 1 to 3 weeks, after depletion of body stores of vitamin K.[73]

Malabsorption syndromes are commonly associated with vitamin K deficiency. Defects in the enterohepatic circulation because of biliary disease interfere with absorption of fat-soluble vitamins in the ileum. Primary biliary cirrhosis,[74] cholestatic hepatitis, and other causes of cholestasis can lead to impaired absorption of vitamin K.

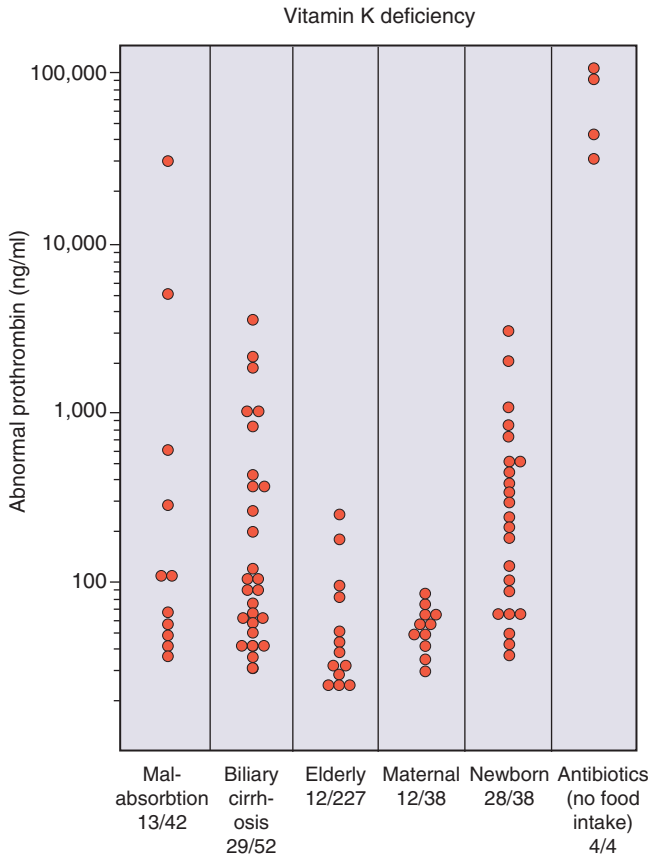

Figure 130–3 Abnormal (des-carboxy) prothrombin antigen as a marker for vitamin K deficiency. Normal subjects have no detectable abnormal prothrombin. Vitamin K deficiency arises as a result of disorders of absorption, including mild abnormalities in otherwise normal elderly subjects, or because of impaired intake.

Furthermore, intestinal malabsorption, as in sprue or regional enteritis, impairs vitamin K use. Older adults also have evidence of mild vitamin K deficiency, presumably because of intestinal malabsorption.[75]

Vitamin K Antagonists

Drugs that inhibit the reuse of vitamin K lead to a buildup of vitamin K epoxide at the expense of vitamin K hydroquinone. Warfarin and related vitamin K antagonists, whether ingested accidentally, factitiously, or as an overdose of oral anticoagulant therapy, lead to a deficiency of the vitamin K-dependent proteins, prolongation of the prothrombin time and PTT, and clinical bleeding manifestations.[76–78] Although such patients are not vitamin K deficient, the clinical and laboratory manifestations because of vitamin K antagonists are identical to those of vitamin K deficiency. Factitious warfarin ingestion may be seen as a component of a major psychiatric disturbance. Despite repeated denials of use of such medications by suspect patients, this diagnosis must be considered in all patients with *acquired* deficiency of all the vitamin K-dependent proteins. Measurement of serum warfarin level can confirm such suspicions. With the introduction of second-generation rodenticides that inhibit vitamin K action, including brodifacoum, cases of factitious ingestion and accidental poisonings have been increasingly reported.[79–87] These long-acting poisons, now widely available (eg, d-Con; see box on Reversal of Long-Acting Vitamin K Antagonists ["Superwarfarins"]), can lead to prolongation of the prothrombin time for more than 1 year after a single dose; fatalities have been reported.[88] Chemically distinct from warfarin, these compounds are not detected in serum warfarin assays. Specific serum assays have been developed.[89,90]

Other drugs cause a vitamin K deficiency-like state as well and respond to vitamin K therapy. Excessive doses of aspirin cause hypoprothrombinemia,[91] presumably because of oxidation of vitamin K. Although the mechanism is not completely understood, certain antibiotics, such as moxalactam and cefamandole, cause hypoprothrombinemia.[92–95] Malnourished patients, even those with an initially normal prothrombin time, often develop vitamin K deficiency after intravenous antibiotic therapy.[96]

Hereditary Defects of Vitamin K Use

Hereditary combined deficiencies of the vitamin K-dependent proteins, including prothrombin, factor IX, factor X, and factor VII, have been recognized for some time, although the molecular bases for the phenotype in these kindred was unknown.[97–101] Mutations in the vitamin K-dependent carboxylase and in the vitamin K epoxide reductase have been established as causes of hereditary deficiencies in the vitamin K-dependent proteins in a number of kindred. Defects in the absorption and transport of vitamin K might also be anticipated to manifest with this clinical presentation.

In kindred where hereditary combined deficiency of vitamin K-dependent proteins is caused by abnormalities in the vitamin K-dependent carboxylase point mutations in the enzyme are most often responsible. Arg394 6Leu, Trp501 6Ser, Arg485 6Pro, Trp157 6Arg, Thr591 6Lys and His404 6Pro mutations have all been linked to this disorder.[102–106] In addition a splice site mutation in carboxylase has been identified.[105] Some cases have been responsive to high daily doses of vitamin K.[101,103,107] Other cases have been resistant to vitamin K therapy, which emphasizes the heterogeneity of this disorder.

Mutations in the vitamin K epoxide reductase are causative for combined deficiency of vitamin K-dependent proteins of blood coagulation[55,106,108] and for warfarin resistance (see Chapter 137).[55,109–111] Hereditary combined deficiency of vitamin K-dependent proteins has also been shown to result from an Arg98 6Trp mutation in the vitamin K epoxide reductase.[55]

Mutations in the propeptide of factor IX render otherwise normal patients sensitive to warfarin.[112]

Therapy for Vitamin K Deficiency

Vitamin K deficiency is treated by the administration of vitamin K_1. The preferred route of administration depends on the urgency for correcting the bleeding tendency and on the risk of inducing local hematoma formation. If the bleeding is severe or life-threatening, fresh frozen plasma should be administered. Because of the risk of transmission of viral infection, the use of blood products must be weighed carefully, although this risk has been greatly reduced in recent years. (See box on Therapy for Vitamin K Deficiency.)

Reversal of Long-acting Vitamin K Antagonists ("Superwarfarins")

The long-acting vitamin K antagonists employed as rodenticides lead to pronounced bleeding syndromes following factitious or accidental ingestion of these compounds. After diagnosis and confirmation of the diagnosis, treatment can remain challenging because the inhibition of the complete synthesis of the vitamin K-dependent proteins may continue for months after initial exposure, even in the absence of reexposure. Fresh frozen plasma is used routinely to treat major bleeding complications, but this therapy is associated with a risk of blood-borne infection. Although it is desirable to correct or partially correct the prothrombin time (PT), the use of prophylactic fresh frozen plasma chronically carries significant risks and expense. Because of the potency of the second-generation rodenticides and their fat solubility, vitamin K_1 at normal doses of administration is ineffective. However, daily doses of 100 to 150 mg of vitamin K_1 administered orally have been effective in normalizing the PT. Over time, the dose of vitamin K_1 needed to correct the PT can be adjusted downward, so that only the required amounts of vitamin K are employed.

Therapy for Vitamin K Deficiency

The approach to the treatment of vitamin K deficiency depends on the clinical setting and the severity of bleeding. Except in the face of serious internal bleeding, reversal of the vitamin K deficiency by the administration of vitamin K is generally adequate. If the prothrombin time (PT) is significantly prolonged to indicate that a bleeding complication may be induced by intramuscular injection, that route of administration of vitamin K_1 (phytonadione [AquaMEPHYTON]) should be avoided. Because the delivery of vitamin K by the subcutaneous route is variable, intravenous vitamin K_1 (phytonadione [AquaMEPHYTON], 10–15 mg) is the recommended approach, as it ensures rapid delivery. However, intravenous vitamin K_1 does require monitoring, because of early reports of severe allergic reactions with the intravenous route of administration; care must be given to initiate rapid reversal of an untoward reaction. With vitamin K, the PT should return toward the normal range within 12 hours and should have corrected within 24 to 48 hours. Serious bleeding complications attributed to vitamin K deficiency, such as intracranial bleeding, must be reversed immediately. Despite the rapid action of vitamin K, administration of vitamin K should be preceded by the infusion of fresh frozen plasma. This blood component contains all the vitamin K-dependent blood-clotting proteins. In sufficient quantities, fresh frozen plasma can correct, or nearly correct, the PT, as well as the bleeding tendency.

Patients with vitamin K deficiency without bleeding manifestations can be treated with oral vitamin K or, as in patients with chronic vitamin K deficiency secondary to malabsorption syndromes, with subcutaneous vitamin K.

SUGGESTED READINGS

CHAPTER 131

LUPUS ANTICOAGULANT AND ACQUIRED INHIBITORS OF BLOOD COAGULATION

Donald I. Feinstein

Spontaneously acquired inhibitors of blood coagulation, also known as circulating anticoagulants, are pathologic macromolecules in blood that directly inhibit blood clotting proteins or reactions involving blood clotting. Most have been characterized as antibodies. These inhibitors arise secondary to transfusion of plasma or recombinant replacement proteins in patients with hereditary bleeding disorders (see Chapter 126) or arise de novo in patients with previously normal hemostatic mechanisms. This chapter will include discussion of the lupus anticoagulant and spontaneously acquired inhibitors of blood coagulation proteins. Inhibitors are usually recognized in the laboratory by prolonged coagulation tests that are subsequently found to be uncorrected by the addition of normal plasma. They may be clinically silent or may be associated with a history of excessive bleeding or paradoxically by thrombosis (see box on Diagnostic Approach to Inhibitors)

LUPUS ANTICOAGULANT AND ANTI PHOSPHOLIPID ANTIBODIES

General Considerations

The lupus anticoagulant is an antibody that prolongs phospholipid-dependent coagulation tests in vitro. It was given this name in 1972 because clear proof of its site of action was lacking, and because the anticoagulant had been recognized in patients with systemic lupus erythematosus (SLE).[1] It is a misnomer because the lupus anticoagulant is more frequently encountered in patients without lupus[1,2] and is associated with thrombosis rather than with bleeding.[1,2] Immunoglobulins reacting with other hemostatic factors, such as von Willebrand factor (VWF),[3] factor VIII,[4] factor IX, and factor XI, inhibitors of thrombin and fibrin polymerization, and factor XIII[5] have also been described in patients with SLE, but they are rare compared with the lupus anticoagulant.

Patients with the lupus anticoagulant who do not have established SLE fall into several different categories: (1) patients with "lupus-like" chronic autoimmune disorders but without findings that fit the criteria for the diagnosis of SLE;[6,7] (2) patients with other chronic systemic autoimmune disorders; (3) patients presenting with a venous or arterial thrombotic event for which no underlying cause may be apparent;[8–13] (4) patients receiving certain drugs, including procainamide[14] and phenothiazines[15] (a high prevalence of the lupus anticoagulant and a positive antinuclear antibody test are observed in psychotic patients receiving long-term chlorpromazine therapy);[15] other drugs or biologics that can induce the lupus anticoagulant include hydralazine, quinidine, and possibly α-interferon; (5) patients with a recent acute viral infection,[16] in whom the antibody is usually transient; (6) patients with human immunodeficiency virus infection;[17,18] (7) women with recurrent fetal wastage;[6,15,16,19–28] (8) occasionally in older patients with malignancies[28a] and (9) patients seeking medical attention for a variety of disorders in whom the lupus anticoagulant is discovered as an incidental finding, usually discovered because of a prolonged partial thromboplastin time (PTT) performed as a routine preoperative evaluation.

The lupus anticoagulant, and related antibodies, anticardiolipin antibody (a CL antibody) and anti-beta$_2$-glycoprotein I antibody (β_2-GPI) are antiphospholipid antibodies that are associated with the antiphospholipid antibody syndrome (APS). Criteria for the diagnosis of the antiphospholipid syndrome have been proposed and validated.[29,30] Recently, these criteria were updated.[31] The updated criteria require one or more clinical episodes of arterial, venous, or small vessel thrombosis and/or increased pregnancy morbidity plus the presence of the lupus anticoagulant, anticardiolipin antibody in medium or high titer (ie, >40 GPL or MPL units or >99th percentile, on two or more occasions, at least 12 weeks apart, measured by a standardized enzyme-linked immunoabsorbent assay [ELISA]) (Table 131–1). The syndrome may be primary when not associated with SLE and secondary when it occurs in association with SLE.[29–34]

The prevalence of lupus anticoagulant in patients with SLE in which the PTT was used for its detection is approximately 10%.[1] In other studies using various screening tests, it varied from 11% to 30%.[35] Using the kaolin clotting time—a test with increased sensitivity for detecting low-titer lupus anticoagulants because it contains no added exogenous phospholipid—evidence of inhibitor activity can be demonstrated in the plasma of 30% to 50% of randomly selected patients with SLE.[36] The percentage approximates the 42% to 44% incidence of the frequency of anticardiolipin antibodies in patients with SLE,[37] although in most other studies it varies from 17% to 39%.[35]

The prevalence of positive tests for lupus anticoagulant and anticardiolipin antibody in a normal population has been reported in several studies.[38–40] Because of the non-Gaussian distribution of anticardiolipin antibody levels in normal subjects, the cut-off points between normal and abnormal results is difficult to determine.[32,40] One study reported IgG and IgM anticardiolipin antibodies in approximately 5% of normal individuals, although only 2% had persistently elevated levels on repeat testing.[40] Shi and colleagues detected anticardiolipin antibodies in 6% of normal blood donors, respectively, and detected lupus anticoagulant activity by kaolin clotting time in 4%.[38] The prevalence of anticardiolipin antibody appears to increase with age.[35]

The prevalences of elevated levels of IgG and IgM anticardiolipin antibody in healthy pregnant women were 2% to 3% and 4%, respectively.[41–43] Most of these were low titer; only 0.2% were high titer. In other studies, the incidence of anticardiolipin antibodies in pregnant individuals ranged from 1% to 2% and lupus anticoagulant 1% to 4%.[35]

Properties, Epitope Specificity, Mechanism of Action, and Relationship of the Lupus Anticoagulant to Anticardiolipin Antibodies and Anti-β_2 Glycoprotein I Antibodies

Lupus anticoagulants and anticardiolipin antibodies are immunoglobulins that were originally thought to react only with phospholipid. However, it is now well established that these antibodies react directly with epitopes on β_2-GPI[44,45] or prothrombin,[46,47] that subsequently bind to anionic phospholipid.[46] Anticardiolipin antibodies are low-affinity monovalent antibodies to β_2-GPI when in solution, and the monovalent complexes bind weakly to anionic

Diagnostic Approach to Inhibitors

The approach to patients with abnormal coagulation tests should initially include a complete history regarding excessive bleeding, particularly as it relates to hemostatic challenges and thrombotic problems—venous or arterial. Initial laboratory studies should include a repeat of the abnormal coagulation test on a mixture of the patient's plasma and normal plasma. Correction of the abnormal test indicates a deficiency state, whereas poor correction indicates the presence of an inhibitor.

Approach to Inhibitors Associated with Bleeding

Patients who present with an acquired bleeding disorder and in whom an inhibitor is demonstrated most often have antibodies to a specific clotting factor. Subsequent laboratory evaluation should attempt to demonstrate the specific coagulation factor to which the antibody is directed and to determine the specificity of the antibody. The former is done using a specific assay for the coagulation factor suspected of being affected, and the latter is done using a specific assay for the coagulation factor of a mixture of various dilutions of patient's plasma (antibody) and normal plasma (antigen) over time. If the inhibitor is specific for a single clotting factor, procoagulant activity of that coagulation factor is neutralized over time, whereas other clothing factors assays are unaffected. For example, if an acquired inhibitor of factor VIII is suspected and the factor VIII assay is low, a factor VIII assay of a mixture of the patient's plasma and normal plasma should demonstrate a progressive decrease in factor VIII activity from immediately after the mixture was made to 1 to 2 hours later. By contrast, if factor IX and XI assays were done on the same mixture, factors IX and XI would be unaffected.

Rarely, a spontaneously acquired autoantibody reacts with a noncoagulant epitope of a specific hemostatic factor (eg, prothrombin in the lupus anticoagulant-hypoprothrombinemia syndrome) or a specific clotting factor is adsorbed to cellular surfaces (eg, VWF) or to amyloid (eg, factor X). In these patients, the addition of normal plasma to the patient's plasma results in correction of the abnormality. In these patients, the in-vivo half-life of the affected hemostatic factor is shortened significantly because of rapid clearance of the antigen-antibody complex or by adsorption of the clotting factor to a pathologic surface.

Spontaneously acquired heparin-like anticoagulants differ from the aforementioned inhibitors in that they are not immunoglobulins, and they do not specifically affect one specific clotting factor. These anticoagulants are easily recognized because their major effect is on the thrombin time, but the reptilase time is normal.

Approach to Inhibitors Not Associated with Excessive Bleeding

If the patient has a history of thrombotic disease or repeated episodes of fetal loss, he or she should be evaluated for the presence of a lupus anticoagulant and elevated levels of anticardiolipin and anti–β_2-GPI antibodies. Most commonly, patients with the former have a prolonged PTT and a normal or slightly prolonged prothrombin time. However, on occasion, the prothrombin time may be more prolonged than usual, particularly when using recombinant human tissue factor (Innovin) even in the absence of an associated prothrombin deficiency. If the patient is suspected of having a lupus anticoagulant, several relatively simple tests can be used to confirm the diagnosis. For sensitivity, the kaolin clotting time, the dilute Russell's viper venom time test, the dilute prothrombin time, or the Staclot lupus anticoagulant test are excellent tests with very good sensitivity. Some believe that more than one test should be done if a lupus anticoagulant is suspected, and a single test is negative. Correction of a prolonged clotting time by the addition of phospholipid is specific for the lupus anticoagulant. In the presence of a lupus anticoagulant with a prolonged PTT, specific intrinsic clotting factor assays are frequently low but increase with increasing dilution of test plasma. For example, assays for factor IX would be 5%; factor XI, 9%; and factor XII, 10%; and all would progressively increase with increasing dilution of the test plasma. In some cases, the factor XI or XII assay is more affected than the other assays. The lupus anticoagulant may affect all the specific assays, in contrast to an antibody to a specific clotting factor, for which a single assay shows irreversible inactivation of that clotting factor. In the latter case, dilution would not result in an increase in the level of that clotting factor.

phospholipids. However, when the antigen density is high, bivalent complexes are formed that have a high affinity for phospholipid surfaces.[48–50] The fact that β_2-GPI antibodies are polyclonal reacting with different epitopes on the β_2-GPI molecule and the increased affinity of the divalent antigen-antibody complexes for phospholipid surfaces explains why some anticardiolipin antibodies have anticoagulant activity and some do not.[50] This anticoagulant activity correlates best with the incidence of thrombosis,[51] and a subset of lupus anticoagulants caused by anti–β_2-GPI antibodies with specificity for an epitope on domain I.[52] In some patients the anticardiolipin antibody will react with immobilized cardiolipin in vitro but not prolong phospholipid-dependent coagulation tests. Similarly, some of the antiprothrombin antibodies can prolong coagulation tests and some will not.[50]

Anticardiolipin antibodies are usually IgG or IgM immunoglobulins. In some patients, for example, those in whom it arises secondary to long-term chlorpromazine therapy, it is IgM;[15] in other patients, it is IgG,[2] and in still others, it may be an IgG and IgM.[2] In addition, anticardiolipin antibodies can also be IgA but are usually associated with IgG and/or IgM isotype, and are highly prevalent in African Americans with SLE.[53]

The anti–β_2-GPI and antiprothrombin antibodies responsible for the lupus anticoagulant effect react in coagulation assay systems containing anionic phospholipids. Reducing the phospholipid component of clotting mixtures amplifies the effect of the inhibitor. The most sensitive tests for detecting the lupus anticoagulant contain only limited amounts of procoagulant phospholipid: a sensitive or dilute activated partial thromboplastin time,[54,55] the kaolin clotting time,[36] the silica clotting time,[56,57] the dilute Russell's viper venom time, the prothrombin time performed with very dilute tissue factor, the dilute prothrombin time (formerly called the tissue thromboplastin inhibition test), and the Taipan snake venom time.[58] Adding liposomes containing phosphatidylserine,[59] rabbit brain phospholipid,[60] freeze-thawed platelets[61,62] or hexagonal phospholipids[63,64] markedly shortens the prolonged PTT of plasma containing the lupus anticoagulant and is used as a confirmatory test to increase specificity for presence of a lupus anticoagulant when there is a prolonged clotting test.

Patients with antiphospholipid antibodies also frequently have evidence of anticardiolipin antibodies. These antibodies were first recognized in association with a biologic false-positive test for syphilis,[2,65] a test in which cardiolipin is the antigen. This reaction is β_2-GPI dependent, and it results from the increased binding of antigen-antibody complexes containing β_2-GPI and cardiolipin. Anticardiolipin antibody assays are measured by an ELISA using cardiolipin.[66] Bovine serum is added to block nonspecific antibody binding and to provide a source of β_2-GPI.[67] Assay results are usually reported as MPL units for IgM anticardiolipin antibody or GPL units for IgG anticardiolipin antibody. Because of assay variability, a lack of standardization of the assay and a non-Gaussian distribution in normal people, the distinction between normal and abnormal values are not clear. Although the assay is not standardized, most laboratories discriminate between normal and abnormal as 20 GPL (IgG) or MPL (IgM) units, with the cutoff values in different laboratories varying from greater than 10 GPL or MPL units[54] to 20.[68] However, in the updated Consensus Statement[31] the cutoff value has been increased to 40 GPL or MPL units. IgA anticardiolin antibodies are

Table 131–1 Updated International Consensus Statement on Classification Criteria for Definite Antiphospholipid Syndrome

Antiphospholipid antibody syndrome (APS) is present if at least one of the clinical criteria and one of the laboratory criteria that follow are met:

Clinical Criteria

1. Vascular thrombosis
   One or more clinical episodes of arterial, venous, or small vessel thrombosis, in any tissue or organ. Thrombosis must be confirmed by objective validated criteria (ie, unequivocal findings of appropriate imaging studies or histopathology). For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.
2. Pregnancy morbidity
   One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, or
   One or more premature births of a morphologically normal neonate before the 34th week of gestation because of: (i) eclampsia or severe pre-eclampsia defined according to standard definitions, or (ii) recognized features of placental insufficiency, or
   Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded.

Laboratory Criteria

Lupus anticoagulant (LA) present in plasma, on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Haemostasis (see Table 2 in Miyakis S, Lockshin MD, Atsumi T, et al.).

Anticardiolipin (aCL) antibody of IgG and/or IgM isotype in serum or plasma, present in medium or high titer (ie, >40 GPL or MPL units, or > the 99th percentile), on two or more occasions, at least 12 weeks apart, measured by a standardized enzyme-linked immunosorbent assay (ELISA).[67]

Anti–β_2-glycoprotein I antibody of IgG and/or IgM isotype in serum or plasma (in titer > the 99th percentile), present on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA, according to recommended procedures.[69,71]

Classification of APS should be avoided if less than 12 weeks or more than 5 years separate the positive antiphospholipid antibody (aPL) test and the clinical test and the clinical manifestation. Coexisting inherited or acquired factors for thrombosis are not reasons for excluding patients. A thrombotic episode in the past could be considered as a clinical criterion, provided that thrombosis is proved by appropriate diagnostic means and that no alternative diagnosis or cause of thrombosis is found. Superficial venous thrombosis is not included in the clinical criteria. Generally accepted features of placental insufficiency include: (i) abnormal or nonreassuring fetal surveillance test(s); eg, a nonreactive nonstress test, suggestive of fetal hypoxemia; (ii) abnormal Doppler flow velocimetry waveform analysis suggestive of fetal hypoxemia, eg, absent end-diastolic flow in the umbilical artery; (iii) oligohydramnios, eg, an amniotic fluid index of 5 cm or less; or (iv) a postnatal birth weight less than the 10th percentile for the gestational age.

Table 131–2 Detection of Antiphospholipid Antibodies

Lupus Anti Coagulant Antibodies

Prolongation of at least one phospholipid-dependent coagulation assay with the use of platelet-poor plasma (dilute prothrombin time, activated partial thromboplastin time (PTT), dilute activated PTT, colloidal-silica clotting time, dilute Russell's viper venom time, and kaolin clotting time).

Failure to correct the prolonged coagulation time on one of the above phospholipid-dependent tests by mixing the patient's plasma with normal platelet-poor plasma.

Confirmation by shortening or correction of the prolonged coagulation time after the addition of excess phospholipid or platelets that have been frozen or thawed.

Exclusion of the other coagulation with the use of specific factor assays if the confirmatory test is negative or if a specific factor inhibitor is suspected.

Anticardiolipin Antibodies

Enzyme-linked immunosorbent assay performed with cardiolipin-coated plates in the presence of *bovine* serum β_2-glycoprotein I. IgG and/or IgM in medium or high titer (ie, >40 GPL or MPL units or >99th percentile) on two or more occasions at least 12 weeks apart measured by a standardized enzyme-linked immunosorbent assay (ELISA).[67]

Anti-β_2-Glycoprotein I Antibodies

Enzyme-linked immunoadsorbent assay using *human* β_2-Glycoprotein I. IgG and or IgM titers >99th percentile on two or more occasions at least 12 weeks apart measured by a standardized ELISA.[69,71]

From Brandt JT, Triplett DA, Arving B, et al: Criteria for the diagnosis of lupus anticoagulants: An update on behalf of the subcommittee on Lupus Anticoagulant/Antiphospholipid Antibody of the Scientific and Substandisation Committee of the ISTH. Thromb Haemost 74(4):1185, 1995.

usually associated with increased IgM and IgG isotypes in patients with APS (Table 131–2). However, occasionally it might be the only anticardiolipin antibody that is elevated.

The recent update of the International Consensus Statement on the diagnosis of APS also included increased IgG and IgM anti–β_2-GPI antibodies[31] (see Table 131–2). These antibodies are measured by an ELISA.[69] However, although increased levels of these antibodies are independent risk factors for thrombosis[70,71] and pregnancy complications,[72,73] measurement of these antibodies also suffer from lack of standardization and lack of agreement in cutoff values. However, the Committee recommended that the cutoff value be greater than the 99th percentile of controls.[31] In 3% to 10% of patients with APS, the anti–β_2-GPI antibody might be the only one that is positive.[74]

Antiprothrombin antibodies detected by ELISA include those against prothrombin alone and those against the prothrombin-phosphatidylserine complex. The extensive review by Galli and coworkers[70] failed to find an association with these antibodies and thrombosis. However, in one study the antiphosphatidylserine prothrombin complex antibodies had a very high correlation with the presence of the lupus anticoagulant and thrombotic complications in patients with SLE.[75]

Although most patients with elevated levels of anticardiolipin antibodies also test positive for lupus anticoagulant activity, considerable data support lupus anticoagulant activity and anticardiolipin antibodies as distinct subgroups of antibodies that can be separated by affinity or physicochemical methods and have different antigenic specificities.[76,77] Antibodies to β_2-GPI can be further separated into those that have anticoagulant activity and those that do not.[78,79] Lupus anticoagulants and anticardiolipin antibodies occur concurrently in only approximately 50% to 75% of patients, and a patient may have no anticoagulant activity simultaneously with a markedly elevated anticardiolipin antibody titer by ELISA, and vice versa. Patients who are being evaluated for possible APS must have tests for lupus anticoagulant activity based on a clotting assay and anticardiolipin antibody activity by ELISA.

The mechanism by which the different antiphospholipid antibodies interfere with coagulation in vitro is not clear. However, phospholipid participates in coagulation at several steps: as a component of the prothrombinase complex, as a cofactor for factor VIIIa and factor IXa in the tenase complex, and as a cofactor for activation of factor X by factor VIIa in complex with tissue factor. The lupus anticoagulant may impede each of these reactions of blood

coagulation, and it can inhibit the binding of factor X and prothrombin to negatively charged surfaces.[36,80] Because β_2-GPI and prothrombin also bind tightly to phospholipid, it is possible that antibodies directed to epitopes on β_2-GPI and prothrombin could also interfere with phospholipid-dependent clotting reactions, particularly the tenase and prothrombinase complexes, accounting for the anticoagulant effect in vitro.

Mechanism of Hypoprothrombinemia in the Hypoprothrombinemia-Lupus Anticoagulant Syndrome

A small subset of patients with the lupus anticoagulant also have a selective deficiency of prothrombin. The plasma of these patients does not contain an antibody that neutralizes prothrombin activity,[81] and the plasma prothrombin antigen is decreased to the same extent as prothrombin activity.[82] Bajaj and colleagues[83] demonstrated that the plasma from patients with the hypoprothrombinemia-lupus anticoagulant syndrome contains antibodies that bind prothrombin without neutralizing its in-vitro coagulant activity. The decreased concentration of plasma prothrombin in patients with this syndrome results from the rapid removal of the prothrombin-prothrombin antibody complexes. Altered mobility of prothrombin antigen on crossed immunoelectrophoresis, indicative of the presence of plasma prothrombin antigen-antibody complexes, has been demonstrated in 66% to 75% of patients with the lupus anticoagulant in whom plasma prothrombin activity was not substantially decreased.[84] It is probable that the latter antibodies have less affinity for prothrombin than the antibodies found in patients with a very low prothrombin level, and that the prothrombin deficiency stems from rapid clearance of the antigen-antibody complexes.

Laboratory Evaluation

The results of screening coagulation tests usually found in patients with the lupus anticoagulant include a prolonged PTT, which is prolonged when the patient's plasma is mixed with equal parts of normal plasma (see box on Diagnostic Approach to Inhibitors). The prothrombin time is minimally to moderately prolonged (0.5 to 3 seconds), and occasionally, it is normal. However, the prothrombin time is prolonged more than normal plasma when diluted tissue factor is used, as in the dilute prothrombin time test.[85] The thrombin time is normal. The sensitivity of the PTT for lupus anticoagulant detection varies with different commercial reagents used for the test,[86,87] probably reflecting, at least in part, variation in the phospholipid composition of these reagents. Some commercial PTT reagents have been created to be very sensitive to the presence of lupus anticoagulants. The prevention of platelet activation in plasma samples is crucial because procoagulant phospholipid, in the patient plasma or in the normal plasma used for mixing studies, may neutralize weak lupus coagulant activity.[54,56,88,89] It is recommended that test plasmas and normal plasma be initially centrifuged at 2000 g for 10 minutes, followed by centrifugation at 10 to 15,000 g for 10 minutes or filtered through 0.22 μm screens to remove platelets before freezing. A normal dilute thrombin time assures that the plasma does not contain heparin.

Confirmation of the Diagnosis

The pattern of the lupus anticoagulant manifestations in coagulation testing is often indistinguishable from that of an anticoagulant directed against any one of the several clotting factors that influence the result of the PTT, but not the prothrombin time. Therefore, further tests are needed to confirm that the prolonged PTT of a mixture of the patient's plasma and normal plasma results from the lupus anticoagulant (see Table 131–2 and box on Methods for Establishing the Presence of a Lupus Anticoagulant). It is particularly important to rule out a factor VIII inhibitor, which, in contrast to the lupus anticoagulant, is associated with serious bleeding.

Methods for Establishing the Presence of a Lupus Anticoagulant

1. Platelets and platelet debris must be removed from the patient's plasma and the normal plasma used for mixed studies before any testing is carried out.
2. A screening test with very high sensitivity (eg, kaolin clotting time, dilute activated PTT, dilute Russell's viper venom time test, colloidal-silica clotting time, and dilute prothrombin time) should be used.
3. The clotting time of a mixture of test and normal plasma should be significantly longer than that of the normal plasma mixed with various non-lupus anticoagulant plasmas.
4. To increase specificity, there should be a relative correction of the defect by the addition of lysed washed platelets, phospholipid liposomes containing phosphatidylserine, or hexagonal-phase phospholipids.
5. Testing must be repeated 12 weeks apart to establish the presence of a persistent abnormality.

Various tests have been devised to increase the sensitivity to lupus anticoagulants, including examination of clotting time in systems containing reduced phospholipid, such as the kaolin clotting time,[36] the silica clotting time,[90] the dilute Russell's venom time test,[91] a modified PTT that uses polybrene to neutralize heparin and hexagonal phospholipids to correct the lupus anticoagulant effect (Staclot-LA),[54] the Taipan snake venom time,[92] and the dilute prothrombin time. The latter's sensitivity and specificity have been improved with the use of recombinant tissue factor.[93] The sensitivity and specificity of the tests vary in different reports.[54] However, there is evidence that to maximize the number of patients with lupus anticoagulants identified, more than one test should be done.[54,55] Because studies show that the lupus anticoagulant activity is the most important risk factor for thromboembolic events, it is most important to identify those patients at risk.[94,51]

Lupus anticoagulant tests should include a heparin neutralizer, or the dilute thrombin time should be done to rule out the presence of heparin. In addition, if the patient is on oral anticoagulants with an international normalized ratio (INR) greater than 3.5, the patient's plasma sample should be diluted 1:2 with normal plasma before the test is done.

Mixing studies are important in distinguishing factor deficiencies from inhibitors. One study provides evidence that β_2-GPI–dependent antibodies prolong the dilute Russell's venom time test more than the kaolin clotting time, and the prothrombin-dependent antibodies prolong the kaolin clotting time to a greater extent than the dilute Russell's venom time.[95,96]

Tests based on the observation that excess phospholipid substantially shortens the prolonged PTT of lupus anticoagulant plasma are important as a means of differentiating the lupus anticoagulant from other inhibitors. The excess phospholipid is added as freeze-thawed platelets,[62] liposomes containing phosphatidylserine,[59] platelet-derived microvesicles,[97] rabbit brain phospholipid,[60] or hexagonal phase phospholipids.[64] Correction of prolonged clotting times by excess phospholipid significantly increases specificity, and false-positive results are encountered only for heparinized patients or extremely high-titer inhibitors to other clotting factors. However, no positive results are obtained from patients with other low-titer clotting factor inhibitors, congenital factor deficiencies, hepatic insufficiency, or in patients receiving warfarin therapy. The correction of a prolonged clotting time by phospholipid is almost always confirmatory for the presence of a lupus anticoagulant.

Another novel test for the detection of lupus anticoagulants uses two different snake venoms, one that depends on the presence of

phospholipid and one that does not.[98] The ecarin time is phospholipid independent, whereas the textarin time is phospholipid-dependent. In the presence of the lupus anticoagulant the ecarin time is unaffected, but the textarin time is prolonged. Because textarin also requires factor V for prothrombin activation and ecarin does not, this test may give false-positive results in patients with factor V inhibitors.

One diagnostic approach that is helpful in ruling out other types of coagulation factor inhibitors is to perform specific one-stage clotting factor assays based on the PTT. Low values for several clotting factors and increasing values for each clotting factor with increasing dilution of the test plasma in the assay system are commonly observed test patterns. Inhibitors affecting more than one clotting factor using the PTT are usually lupus anticoagulants. In contrast, in patients with acquired factor VIII inhibitors, the factor VIII levels are lower than one sees with lupus anticoagulants and the factor VIII level does not increase with plasma dilution. The inhibitor is not neutralized by a high concentration of phospholipid. Occasionally, the factor XI and XII assays may be more affected than the other intrinsic assays, and an occasional patient will have a factor XII inhibitor associated with a lupus anticoagulant.[99] Several reviews of laboratory testing for lupus anticoagulants have been published.[54,55,100]

Laboratory Recognition of the Hypoprothrombinemia-Lupus Anticoagulant Syndrome

Although minimal to moderate prolongation of the prothrombin time, up to approximately 3 seconds beyond a control value, can be accounted for by the lupus anticoagulant, the finding of a substantially prolonged prothrombin time represents presumptive evidence of an associated specific prothrombin deficiency. Unlike the specific clotting factors assayed in modified PTT test systems, the specific clotting factors affecting the prothrombin time—factor VII, factor X, and factor V—are assayed in clotting systems that are affected only by rare, high-titer lupus anticoagulants. Therefore, the finding of a low value in a prothrombin assay may be taken as evidence of an associated prothrombin deficiency. If, however, further evidence is desired, three additional findings may be demonstrated: (1) a mixture of equal parts of the patient's plasma and normal plasma gives the expected value calculated from the mean of the levels in individual plasmas; (2) prothrombin activity and prothrombin antigen are concordantly decreased; or (3) prothrombin has abnormal mobility on crossed immunoelectrophoresis.[84,101]

CLINICAL RELATIONSHIPS OF LUPUS ANTICOAGULANT AND ANTICARDIOLIPIN ANTIBODIES: PRIMARY AND SECONDARY ANTIPHOSPHOLIPID SYNDROME

Lupus anticoagulant and anticardiolipin antibodies are associated with thrombosis or fetal wastage with or without autoimmune disorders. This clinical entity is known as the *antiphospholipid syndrome*[102,103] (see Table 131–1).[29,31] The primary antiphospholipid syndrome is defined as venous or arterial thrombotic disease, or both, or as recurrent fetal wastage associated with elevated levels of antiphospholipid antibodies in the absence of any definite autoimmune disease.[29,31] These patients do not demonstrate any other clinical or serologic evidence of autoimmune disease, except for occasional low-titer (<1:160) antinuclear antibodies. In contrast, the secondary antiphospholipid syndrome is associated with SLE and related disorders. Some patients have some evidence of a systemic autoimmune disorder but demonstrate insufficient criteria to make the diagnosis of SLE (overlap syndrome). Primary antiphospholipid syndrome rarely progresses to SLE. In one report of 128 patients with primary antiphospholipid syndrome followed for an average of 9 years only 8% developed SLE, and the presence of a positive Coombs test was a significant predictor of progression.[104] However, the recent Consensus Statement advises against using the term *secondary*, but this is controversial.[105] In addition, the Consensus Conference recognized that there are other clinical manifestations that can occur in antiphospholipid syndrome in the absence of the specific classification criteria. Such clinical manifestations include cardiac manifestations (valve disease, coronary artery disease, and ventricular dysfunction), neurologic manifestations (transient ischemic attack, stroke, dementia, cognitive dysfunction, transmyelopathy, seizures, and migraines), shin manifestations (livedo reticularis and other rare lesions), renal manifestations (thrombotic microvascular angiopathy), and thrombocytopenia.[31]

An occasional patient with high-titer anticardiolipin antibodies and/or a lupus anticoagulant can present with fulminant disease with multiorgan system involvement (eg, lung, kidney, or brain), hypertension, and microvascular and macrovascular thrombosis. This clinical presentation is known as the catastrophic antiphospholipid syndrome.[106,107] Because these patients have a high mortality rate, they require aggressive treatment.

Most patients who test positive for the lupus anticoagulant have elevated levels of anticardiolipin antibody. However, although the correlation between the two is significant, many patients showing positivity for lupus anticoagulant activity do not have elevated levels of anticardiolipin antibody or other antiphospholipid antibodies, and vice versa.[108–110]

Because anticardiolipin antibody levels can fluctuate significantly,[111] a negative test for the lupus anticoagulant and anticardiolipin antibody does not completely rule out the presence of antiphospholipid syndrome. This is particularly true during an acute thrombotic episode, when antibody titers may transiently decline to normal.[112]

Several studies[22,113] suggest that when tests for the lupus anticoagulant and anticardiolipin antibodies are performed at two separate time intervals (6 to 16 weeks), a statistically significant association can be shown between persistently positive tests and prior thromboembolic events and fetal loss. The strength of the association is much reduced when transiently positive patients are included. It is strongly recommended that repeat testing be done 12 weeks apart. In children, particularly, the antibody may persist for many months and then spontaneously disappear. These studies also showed that a combination of tests for detecting lupus anticoagulant activity is superior to a single test.

A false-positive Venereal Disease Research Laboratory test in low-titer (1:4 to 1:8) can be demonstrated in less than or equal to 30% of patients with the lupus anticoagulant or anticardiolipin antibodies. These cross-reacting antibodies differ from reagin, the antibody responsible for the Wasserman reaction in patients with syphilis and usually do not require the presence of β_2-GPI for their detection. The detergent, Tween 20, can be used in the anticardiolipin antibody assay to distinguish β_2-GPI–dependent and –independent antibodies.[114] These β_2-GPI–independent antibodies are true antiphospholipid antibodies and are frequently seen in patients with infection and usually are not associated with thrombosis.

Relationship of Lupus Anticoagulant and Anticardiolipin Antibodies to Other Antibodies

In some subjects with lupus anticoagulant, anticardiolipin antibody and/or anti–β_2-GPI antibodies that react to other anionic phospholipids, such as phosphatidylserine, phosphatidylinositol, and phosphatidic acid, have been demonstrated.[110] In some patients with lupus anticoagulant or anticardiolipin antibody, antibodies to neutral phospholipids (phosphatidylethanolamine or phosphatidylcholine) have been demonstrated.[115] Sugi and colleagues[116] have demonstrated that autoantibodies to phosphatidylethanolamine recognize a kininogen-phosphatidylethanolamine complex. Smimov and colleagues[117] have shown that inhibition of activated protein C is antibody- and phosphatidylethanolamine-dependent. However, the significance of these

antibodies in the absence of the lupus anticoagulant or anticardiolipin antibodies is unknown.

Correlation between Clinical Findings and Antiphospholipid Antibodies

Bleeding

Most patients with the lupus anticoagulant do not have a bleeding phenotype. Patients with the lupus anticoagulant have undergone needle biopsy of the kidney and the severe hemostatic challenges of major surgery,[2,8] including prostatectomy[2] and open heart surgery,[2] without excessive postoperative bleeding.

Nevertheless, patients with the lupus inhibitor may have clinically significant bleeding. In all but a few, the bleeding can be attributed to some abnormality other than the lupus inhibitor, such as depressed prothrombin activity. The combination of the lupus anticoagulant and a prothrombin coagulant activity below approximately 20% of normal has resulted in severe and even fatal bleeding. In other patients, thrombocytopenia, alone or in combination with moderate prothrombin deficiency, accounted for the bleeding tendency. The hemorrhagic manifestations may also be related to severe uremia.

Evaluation of the risk of abnormal bleeding in patients with the lupus anticoagulant includes establishing the presence or absence of prothrombin deficiency, thrombocytopenia, or uremia. Occasionally a patient may have only a prolonged bleeding time associated with excessive bleeding.[118] In the absence of these coexisting risk factors, abnormal bleeding is minimal even after trauma or surgery.[8,32] In summary, most patients with the isolated finding of lupus anticoagulant do not experience abnormal bleeding. On rare occasions, excessive postoperative bleeding has been attributed to the lupus anticoagulant.[119,120]

Thrombosis

Since the initial observation of Bowie and colleagues in 1963, it has become clear that thrombosis is a major concern in patients with the lupus anticoagulant. The reported incidence has varied from 17% to 71%, averaging approximately 30% to 40%.[6,8,37,121–123] In patients with an elevated level of anticardiolipin antibody, a high incidence (~40%) of thrombotic disease has been reported.[37,102,124] Of unselected patients with antiphospholipid antibody, 1% to 2.5% per year will develop thromboembolism,[123,125] and 10% to 25% of patients with deep venous thrombosis will be found to have antiphospholipid antibodies.[126] However, in a prospective population based study of 66,140 in Norway,[127] elevated anticardiolipin antibody levels were not a risk factor for predicting an initial venous thrombosis. Thrombosis is more frequent as the level of anticardiolipin antibody increases, and medium and high titers (>40 GPL and/or MPL units) are more frequently associated with thrombotic events. Although some investigators believe that elevated levels of IgG or IgA isotypes are more common than IgM in patients with thrombotic complications,[111,128] this has not been clearly established. The lupus anticoagulant or increased levels of anticardiolipin antibody must be persistently present on more than one occasion at least 12 weeks apart because the incidence of thrombotic complications is almost the same in patients with transiently positive tests as in patients with negative tests at two different time intervals.[21,22,113] The persistent presence of elevated levels of anticardiolipin antibody has been shown to be associated with indices of in-vivo coagulation activation. In a study of patients with SLE[129] who were persistently anticardiolipin antibody–positive versus patients who were transiently positive or persistently negative, anticardiolipin antibody–positive patients had a higher mean level of F1+2 and fibrinopeptide A than patients who were transiently positive, persistently negative, or on warfarin therapy. The differences remained significant even if patients with prior thromboembolism were excluded from the analysis. These results suggest that the presence of persistently elevated levels of anticardiolipin antibody in SLE patients is associated with an ongoing prothrombotic state. Studies suggest that the presence of lupus anticoagulants was more strongly associated with venous and arterial thrombosis than the presence of anticardiolipin antibody.[51,94,130,131] Galli and colleagues[96] have suggestive evidence that β_2-GPI antibodies that prolong the dilute Russell's viper venom time test more than the kaolin clotting time (*dilute Russell's viper venom time test phenotype*) are associated with a higher incidence of thrombosis than the prothrombin-dependent antibodies, which prolong the kaolin clotting time more than the dilute Russell's viper venom time test (*kaolin clotting time phenotype*). However, because of different commercial and noncommercial dilute Russell's viper venom time test assays, these results are difficult to reproduce in all laboratories.[132] Direct immunoassays (ELISA) for human β_2-GPI (rather than bovine β_2-GPI in the anticardiolipin assay) are also strongly associated with thrombosis and are commercially available. However, any one of these tests may be positive in patients with antiphospholipid syndrome. Studies by Galli and coworkers[51,93,123] strongly suggest that lupus anticoagulant activity is the strongest risk factor for thromboembolic events-independent of the type and site of thrombosis, the presence of SLE, and the laboratory methods used to detect them.[123] Anticardiolipin and β_2-GPI antibodies were not as strong a risk factor.

Thrombosis may be venous or arterial,[102] with events occurring nearly equally in the arterial and venous circulation[51,123,133,134] in some studies, whereas in other studies the incidence of venous thrombosis (70%) is greater than the incidence of arterial thrombosis.[95,135] Venous thrombosis is usually manifested as deep venous thrombosis of the lower extremities with or without pulmonary emboli. Unusual sites of venous thrombosis, such as hepatic veins, portal vein, inferior vena cava, mesenteric veins, renal veins, cerebral venous sinuses, retinal veins, and upper extremity veins, have been reported.[102,136,137] Arterial thrombosis is usually manifested as stroke[32,102,138] or transient ischemic attacks.[139] Nonbacterial mitral and aortic endocardial valve lesions, with or without SLE, accompanied by thromboembolic transient ischemic attacks and strokes have also been reported.[140] Some studies have suggested that stroke is most commonly an embolic event originating from cardiac vascular lesions.[141,142] In one study, 75% of patients with recurrent cerebral ischemic events had vascular thickening or vegetations found on transesophageal echocardiography.[141,142] In another study, 20% of patients admitted to a cardiology department for severe valvular heart disease had antiphospholipid antibodies.[143] Thromboembolic events were more common in the antiphospholipid antibody group. Livedo reticularis alone is common at presentation (~20%) and occasionally may be associated with cerebrovascular disease (Sneddon's syndrome). Other neurologic manifestations include epilepsy, migraine, chorea, and transverse myelitis. The association of antiphospholipid antibodies and coronary artery disease is controversial. Hamsten and colleagues[144] reported that young survivors of myocardial infarction had a high incidence of anticardiolipin antibody, and those patients with a persistently elevated anticardiolipin antibody had a higher incidence of recurrent events. Similar findings were reported in another prospective study of 133 patients who had a significant number of subsequent events compared with matched control subjects.[145] In contrast, other studies did not find elevated anticardiolipin antibody or subsequent events in patients with an acute myocardial infarction.[146,147] However, in the report from the Euro-Phospholipid Project,[136] which included the study of 1000 patients with primary or secondary antiphospholipid syndrome, 2.8% of patients presented with acute myocardial infarction and, during the evolution of the disorders, a total of 8.2% had developed a myocardial infarction or angina. Patients admitted for peripheral vascular surgical procedures also have a high incidence of phospholipid antibodies.[148]

Thromboembolic pulmonary hypertension with or without SLE can occur in association with the lupus anticoagulant or elevated levels of anticardiolipin antibody, or both.[102,149,150] Other thrombotic manifestations reported include: gangrene of extremities and digits, multi-infarct dementia, retinal arterial and venous thrombosis, renal arterial and venous thrombosis, adrenal infarction and insufficiency,

mesenteric ischemia and infarction, vascular necrosis of bone, cerebral venous thrombosis, leg ulcers, and cutaneous necrosis.[136] Patients can develop an acute or subacute microangiopathy and microvascular thrombosis with progressive loss of organ function and can be associated with a fragmentation type hemolytic anemia and thrombocytopenia (catastrophic antiphospholipid syndrome).[106] It is clear from the Euro-phospholipid Project Group who have accumulated data on 1000 patients with antiphospholipid syndrome that patients with this syndrome may have a variety of clinical manifestations that involve any organ.[136]

Although thrombosis is supposedly not associated with the lupus anticoagulant or anticardiolipin antibody induced by infection or drugs, there have been several reports of human immunodeficiency virus- or drug-associated thrombosis.[8,151] In a report of the treatment of patients with melanoma with immunotherapy, 5 of 12 patients receiving interferon-α had lupus anticoagulants and anticardiolipin antibodies within 4 to 28 days, and deep vein thrombosis developed in 4 of these 5 patients.[152] In patients with infections, anticardiolipin antibodies bind cardiolipin directly and usually do not require the presence of β_2-GPI,[32,152] except for those patients with leprosy who have β_2-GPI and prothrombin-dependent antibodies.[153,154] Despite this fact, patients with leprosy do not have an increased incidence of thrombosis.[153,154]

Patients who are persistently positive for the lupus anticoagulant or who have persistently elevated levels of anticardiolipin antibody and suffer a thromboembolic event have a recurrence rate of approximately 50% within 2 years.[133,134,155,156] Recurrences tend to occur in most of the patients on the same side of the circulation as the initial event—venous recurrences after an initial venous event and arterial recurrences after an initial arterial event.[133]

Fetal Loss, Thrombocytopenia, Hemolytic Anemias, and Other Associations

Another major clinical manifestation associated with the lupus anticoagulant or anticardiolipin antibody is fetal loss.[6,21,22,26–28,102,121,128,157] Fetal wastage may occur at any time during pregnancy.[26,27,68,102] Fetal wastage in antiphospholipid syndrome is defined as (1) any patient with three or more unexplained consecutive spontaneous abortions before the 10th week of gestation (pre-embryonic and embryonic period); (2) any patient with one or more unexplained deaths of morphologically normal fetuses at or after the 10th week of gestation; (3) one or more premature births of morphologically normal neonates before the 34th week of gestation; or (4) intrauterine growth retardation and premature birth (see Table 131–1).[31] Any patient with such a history should be tested for the lupus anticoagulant and anticardiolipin antibody. A recent study showed that increased pregnancy loss was associated with the presence of the lupus anticoagulant and elevated levels of antihuman anti–β_2-GPI antibodies, whereas it was not associated with the lupus anticoagulant and increased levels of anticardiolipin antibodies in the absence of anti–β_2-GPI antibodies.[158] Fifty percent of pregnancy losses in patients with antiphospholipid syndrome occur beyond the 10th week of pregnancy in contrast to pregnancy losses in patients without antiphospholipid syndrome, where most losses occur before the 10th week of gestation.[68] This syndrome occurs in patients with or without SLE. Thrombosis of placental vessels and placental infarction are thought to be one of the mechanisms by which fetal loss occurs.[159,102] The high incidence of thrombotic disease in these patients lends further support to this hypothesis. There is also evidence that antiphospholipid antibodies may impair trophoblastic invasion and cause embryonic loss or uteroplacental insufficiency and fetal loss.[157] The Euro Project Group identified a significantly increased incidence of preeclampsia, eclampsia, and abruptio placentae in patients with antiphospholipid syndrome.[136]

Thrombocytopenia is a frequent finding in patients with the lupus anticoagulant or anticardiolipin antibody and is seen in 30% to 50% of the patients.[157,160] Patients with SLE or related autoimmune disorders have an even higher incidence of thrombocytopenia and leukopenia.[136,161] The incidence of antiphospholipid antibodies is increased (~30%–40%) in patients with idiopathic autoimmune thrombocytopenic purpura.[157,162]

Coombs-positive hemolytic anemia has also been associated with lupus anticoagulants and/or anticardiolipin antibodies in patients with or without SLE[163,164] and occurred in approximately 10% of patients reported from the Euro-Phospholipid Project Group.[136]

CATASTROPHIC ANTIPHOSPHOLIPID ANTIBODY SYNDROME

A few patients with antiphospholipid syndrome present with an acute syndrome characterized by multiple vascular occlusions, usually affecting small vessels in several organ systems occurring over a relatively short period of time (days to weeks) and resulting in a 50% mortality.[106,107] Reviews describing the clinical characteristics of more than 230 patients with this disorder have been published.[165,166] Forty percent of the patients had SLE, 40% primary antiphospholipid syndrome, and 6% had lupus-like disease. Previous clinical findings of antiphospholipid syndrome were present in approximately 50% of the patients, most commonly venous thromboembolic disease, recurrent fetal loss, or thrombocytopenia. The most common factors that seemed to precipitate the acute syndrome were infection, trauma or invasive procedures, warfarin withdrawal, SLE flare, or the presence of a malignancy. The initial presentation was usually complex with multiorgan involvement because of thromboembolic microangiopathy. The most common systems involved were cardiorespiratory, central nervous system, and renal. Pulmonary involvement was usually caused by acute respiratory distress syndrome with or without pulmonary emboli and occasionally alveolar hemorrhage. Cardiac involvement was usually manifested as congestive heart failure with or without acute myocardial infarction or valvular lesions. The major central nervous system manifestation was ischemic stroke. Deep venous thrombosis, acute peripheral arterial occlusive disease, and skin involvement were relatively common. Manifestations of systemic inflammatory response syndrome was also common. Less common complications include hypoadrenalism because of adrenal venous occlusion and bone marrow necrosis.[106]

Laboratory findings, other than positive tests for antiphospholipid antibodies, included thrombocytopenia (60%), autoimmune hemolytic anemia (33%), and evidence of disseminated intravascular coagulation (20%). Fragmented red cells were seen in 9%.

The mortality of this large group of patients was approximately 50% with the most common cause of death being cardiac or pulmonary related. The only therapy that seemed to be of benefit was anticoagulation and corticosteroids, whereas plasmapheresis, and intravenous gammaglobulin seemed to be less effective.[106,165,166] Aggressive supportive therapy such as dialysis, mechanical ventilation, treatment of infection, and so on were important. If the patient recovered, continued anticoagulation was important. Two-thirds of patients who survive the initial catastrophic event remain symptom free, whereas approximately 25% develop noncatastrophic clinical manifestations of antiphospholipid syndrome.[166]

PATHOPHYSIOLOGIC MECHANISM(S) OF THROMBOSIS

The nature of the association between thrombosis and antiphospholipid antibodies, such as the lupus anticoagulant and anticardiolipin antibody, is uncertain. Because many people with antiphospholipid antibodies never experience thrombosis, it is not clear whether antiphospholipid antibodies are direct causative factors for thrombosis, or whether they represent secondary consequences of thrombosis with no direct pathophysiologic role. Because many of these antibodies perturb hemostasis in vitro, it has been assumed that they also directly affect the hemostatic system in vivo, so the prothrombotic-antithrombotic equilibrium is perturbed enough that it becomes unbalanced, favoring thrombosis or placental ischemia. There is evidence substantiating this in patients with SLE and elevated

anticardiolipin antibodies, in whom elevated levels of fibrinopeptide A and the prothrombin fragment F1+2 have been demonstrated.[129,167] In contrast, in the study by Ferro and coworkers,[167] F1+2 was elevated in patients with SLE who were lupus anticoagulant-positive, but patients who were positive only for anticardiolipin antibody did not have elevated levels of F1+2. In other studies of patients who were lupus anticoagulant positive, the mean level of thrombin-antithrombin complexes was higher than it was in control subjects.[99,168]

Antiphospholipid Antibodies as Direct Causative Factors for Thrombosis

There are experimental animal models that suggest that antiphospholipid antibodies directly cause thrombosis and pregnancy loss. The antiphospholipid syndrome has been produced in normal mice by passive transfer of human immunoglobulin with anticardiolipin activity[169] or by active immunization with a human monoclonal anticardiolipin antibody[170]or with β_2-GPI.[171,172] Pregnant mice that were passively[169] or actively immunized with anticardiolipin antibody IgG had increased fetal loss.[169,173] In another experimental model,[174] mice injected with purified anticardiolipin antibody from patients with antiphospholipid syndrome followed by a "pinch" injury to their femoral vein had significantly larger thrombi that persisted for a longer period of time than in appropriate control animals. A monoclonal human anticardiolipin antibody generated from a patient with the antiphospholipid syndrome caused thrombosis in mice.[175] All of these experimental models strongly suggest that antiphospholipid antibodies have a direct pathophysiologic role in thrombosis. Human anticardiolipin antibodies accelerated atherosclerosis in an low-density lipoprotein (LDL)-receptor null mouse.[176]

Mechanism of Thrombosis

The various pathophysiologic mechanisms possibly causing thrombosis have been recently extensively reviewed by Giannakopoulos and coworkers.[177] Antiphospholipid antibodies could directly contribute to thrombosis by altering platelet activity, procoagulant or anticoagulant pathways, or vascular endothelial function. Several considerations support a possible role for platelet activation in the pathogenesis of antiphospholipid antibody–associated thrombosis.[177] First, many subjects with antiphospholipid antibody–associated thrombosis have some degree of thrombocytopenia,[8,10,121] presumably immune in origin. Second, there is an association between antiphospholipid antibodies and antiplatelet antibodies.[160,161] Antiphospholipid antibodies may directly cross-react with platelets.[178,179] The third consideration is the occurrence of arterial, as well as venous, thrombotic episodes. Platelet activation is thought to play a role in the pathogenesis of arterial thrombotic disease, whereas other causes of increased thrombotic risk, such as deficiencies of antithrombin, protein C, protein S, or factor V Leiden, predispose primarily to increased venous thrombotic risk. Increased levels of a urinary metabolite of thromboxane A_2 have been demonstrated in patients with antiphospholipid antibodies.[180] However, in contrast, another study showed that although antiphospholipid antibodies could bind to circulating platelets, no evidence of measurable platelet activation was found.[178] Fourth, serum or purified IgG from subjects with antiphospholipid antibodies inhibits the release of the platelet inhibitor, prostacyclin, from vascular segments or cultured vascular endothelial cells.[181–183] This finding suggests that in some subjects with antiphospholipid antibodies, impaired prostacyclin release might lead to excessive platelet activity, resulting in thrombosis. Platelets from subjects with antiphospholipid antibody–associated thrombosis are more resistant to in-vitro inhibition by the inhibitory prostaglandin E_1, than are normal platelets. However, except for one study,[184] the correlation between in-vitro inhibition of prostacyclin release and thrombosis in subjects with antiphospholipid antibodies has been poor.[183] Shi and colleagues[185] showed that purified IgG from patients with lupus anticoagulants and anticardiolipin antibodies bound to thrombin-activated, but not resting, platelets, and antibody binding did not produce any evidence of platelet activation. There is little evidence that lupus anticoagulants or anticardiolipin antibodies directly cause platelet activation. However, Arvieux and colleagues[186] showed that murine monoclonal antibodies to β_2-GPI with lupus anticoagulant activity could activate platelets when there were subthreshold concentrations of epinephrine or adenosine diphosphate in the presence of β_2-GPI. Subsequent platelet activation was shown to depend on binding to the platelet Fc receptor, similar to the pathophysiologic process occurring in heparin-induced thrombocytopenia. As an extension of the latter hypothesis, Arnout[50] has suggested that the deposition of immune complexes (containing β_2-GPI or prothrombin) on partially activated platelets induces further cell activation by a yet to be identified signal transduction mechanism leading to full platelet activation, microvesicle generation, the formation of platelet-leukocyte aggregates, and the provision of a large anionic phospholipid surface that could generate increased thrombin.[50] The increased concentration of prothrombin on the phospholipid surface can result in the generation of excess thrombin at sites of injury.[187]

Between 30% and 70% of sera from patients with antiphospholipid antibodies contains endothelial cell-reactive antibodies.[188] Some of these antibodies bind to β_2-GPI on the endothelial cell surface and result in endothelial cell activation.[189,190] There is evidence that β_2-GPI binds with high affinity to annexin V or antibodies directly bind to annexin A_2 independent of β_2-GPI on the endothelial cell surface.[191,192] These antibodies might cause thrombosis by directly damaging endothelial cells; by impairing endothelial, antiplatelet, anticoagulant, or fibrinolytic activities; or by bringing about procoagulant changes in endothelial function, such as expression of tissue factor.[193,194] Antiphospholipid antibody–containing sera from patients with systemic lupus and thrombosis induced a small, but significant, increase of endothelial cell tissue factor activity. When added in combination with a low dose of tumor necrosis factor, a synergistic enhancement of tissue factor activity was found.[190] These antiphospholipid antibody–containing sera led to enhanced thrombosis formation in an in-vitro thrombosis model. In contrast, non–antiphospholipid antibody–containing sera from patients with systemic lupus did not generate tissue factor activity, nor did the sera produce enhanced thrombus formation.[194] Antiphospholipid antibodies stimulate tissue factor expression by human monocytes.[195,196] Simantov and coworkers[190] showed that purified IgG from lupus patients with elevated anticardiolipin antibody and antiphospholipid syndrome causes increased monocyte adhesion when reacted with endothelial cells in vitro. Monocyte adhesion depended on the presence of β_2-GPI. These data strongly suggest that anticardiolipin antibody is capable of binding to and activating vascular endothelial cells.

All of the experimental evidence at the present time suggests that anti-β_2 GPI-β_2 GPI antigen-antibody complexes binding to platelet or endothelial receptors as insufficient in themselves to activate platelets and/or endothelial cells and require a primary stimulus.[177]

Annexin V is a potent anticoagulant protein that has a high affinity for phospholipid and competes with activated coagulation factors for binding to phospholipid surfaces.[191] Thus annexin V forms a protective anticoagulant shield on endothelial cells and when disrupted by anti-β_2 GPI antibodies can result in accelerated coagulation reactions.[197] IgG fractions from patients with antiphospholipid syndrome reduce the quantity of annexin V on cultured endothelial cells and trophoblasts and accelerate the coagulation reactions of plasma clotting factors expressed on these cells.[198]

Several abnormalities of natural anticoagulant pathways have also been reported in patients with antiphospholipid antibody–associated thrombosis.[177] In one study, thrombomodulin antibodies were found in 30% of patients with the lupus anticoagulant, in 10% of patients with unexplained thromboembolism, and in 10% of control subjects.[199] However, in another study, inhibition of thrombomodulin activity was found in only 2 of 46 patients with lupus anticoagulants.[200] In that same study, plasma from 24 of 33 patients with thrombosis showed significant inhibition of activated protein C, whereas plasma from 13 patients with thrombosis showed no

inhibition. In other studies,[17,18,201] serum and purified IgG impaired activation of protein C by thrombin complexed to the endothelial cofactor, thrombomodulin,[202] and impaired the phospholipid-dependent anticoagulant action of activated protein C and its cofactor, protein S.[17] In addition, murine monoclonal anti–β_2-GPI antibodies in the presence of β_2-GPI are able to inhibit protein C anticoagulant activity in vitro.[203] Reduced plasma levels of free protein S have also been observed in subjects with antiphospholipid antibody-associated thrombosis.[151,181,204] In another study, purified IgG from seven patients with antiphospholipid antibodies reacted with the disaccharide present in the heparin-heparan pentasaccharide that binds antithrombin III, and these antibodies inhibited formation of thrombin-antithrombin complexes.[205]

It appears that plasma from some patients with antiphospholipid antibodies inhibits several natural anticoagulant pathways, and whether this inhibition stems from other antibodies has not yet been established. Although several abnormalities of the natural anticoagulant pathway have been demonstrated in patients with antiphospholipid antibodies, a close correlation between abnormalities of these pathways and thrombosis in patients with antiphospholipid antibodies has not been consistently demonstrated. A defect in natural anticoagulant pathways could not, by itself, explain the presence of arterial thromboembolism.

Because anticardiolipin antibodies are antibodies directed against β_2-GPI,[76,77] it suggests that possibly the antihemostatic effect is caused by inhibition of β_2-GPI function. Although patients with severe β_2-GPI deficiency do not have thromboembolic disease,[206] the presence of anti-β_2-GPI antibodies is associated with lupus anticoagulant activity, anticardiolipin antibodies, and thromboembolic complications in patients with systemic lupus.[207]

Impaired fibrinolysis may contribute to thrombosis in patients with antiphospholipid antibodies.[208,209] However, active systemic lupus[209,210] is independently associated with impaired fibrinolysis.[211] More recent studies of patients with antiphospholipid antibody–associated thrombosis without lupus have failed to document impaired fibrinolysis in vivo[212] or any effect of plasma-containing antiphospholipid antibodies on in-vitro endothelial secretion of tissue plasminogen activator or plasminogen activator inhibitor-1.[213] However, interference with annexin A2 function could result in impaired fibrinolysis because annexin A2 allows tissue plasminogen activator and plasminogen to bind on the endothelial cell surface.[177,192,214]

Harkko and colleagues[215] found that apolipoprotein E-deficient mice who had active atherogenesis developed high titers of autoantibodies to epitopes of oxidized LDL and to cardiolipin, and that sera or anticardiolipin antibody-IgG from patients with antiphospholipid syndrome bind to oxidized cardiolipin but does not bind to reduced cardiolipin. Antiphospholipid antibodies are directed at neo-epitopes of oxidized lipoproteins. It had been previously shown by Vaarla and colleagues[216] that binding of anticardiolipin antibody to solid-phase cardiolipin was inhibited by oxidized LDL, but not by native LDL, suggesting cross-reactivity between antiphospholipid antibodies and antibodies to oxidized LDL. Other data suggest that antiphospholipid antibodies may be pathogenic in the formation of atherosclerotic lesions and result in increased atheroma development.[217]

Although it has been proposed that fetal loss and/or growth retardation is probably also caused by placental vascular thrombosis and/or insufficiency, not all placentas show thrombosis[218] and not all patients with antiphospholipid antibodies suffer fetal loss. The passive administration of polyclonal or monoclonal antibodies from patients with antiphospholipid syndrome and healthy controls to pregnant mice does lead to adverse pregnancy outcomes. Moreover, this phenomenon appears to require complement activation.[219,220] In many patients with second or third trimester fetal loss or growth retardation, placental vascular thrombosis can be demonstrated. In addition, it has been shown that patients with β_2-GPI–dependent lupus anticoagulant activity displayed increased annexin V resistance in an in-vitro assay suggesting that anti–β_2-GPI antibodies compete with annexin V for anionic phospholipids, and thus promote thrombosis by interfering with annexin V's anticoagulant activity.[221] However, in many patients with fetal loss no placental vascular thrombosis can be found. In addition, there is evidence that trophoblast function can be disrupted because anti–β_2-GPI antibodies can inhibit trophoblast gonadotropin secretion and invasiveness in vitro.[222] Thus, there may be more than one mechanism whereby antiphospholipid antibodies may effect placental function.

THERAPY FOR PATIENTS WITH LUPUS ANTICOAGULANT AND/OR OTHER ANTIPHOSPHOLIPID ANTIBODIES

The lupus anticoagulant usually persists in the untreated adult patient. However, it frequently disappears spontaneously when it occurs in children in whom the anticoagulant develops after a viral infection and may be transient in adult patients without systemic lupus, thromboembolic disorders, or fetal loss.

When the lupus anticoagulant or elevated levels of antiphospholipid antibodies, or both, are found in patients with underlying autoimmune disease, treatment of the underlying disease with immunosuppressive therapy may result in reduction or disappearance of the antibody.[65,81] When the anticoagulant is found in association with severe prothrombin deficiency or severe thrombocytopenia (<20,000 cells/μL), treatment with corticosteroids is indicated (see preferred treatment box on Therapy for Patients with Lupus Anticoagulant or Increased Levels of Anticardiolipin or Antihuman β_2-GPI). There has been one case report of a patient with a lupus anticoagulant and hypoprothrombinemia who was resistant to corticosteroids but was responsive to intravenous gammaglobulin.[223] However, when the lupus anticoagulant or anticardiolipin antibody is discovered as an isolated finding, not associated with thrombosis or fetal loss, treatment is not indicated. Although aspirin may be effective in primary prevention of arterial thrombosis and may be effective in some patients with antiphospholipid antibodies and recurrent fetal loss, it did not show efficacy in preventing venous thrombosis and pulmonary embolism in the Physician's Health Study.[126] If low-dose aspirin is prescribed for prophylaxis, the patient should be educated about efficacy and its side effects. It is important to educate patients about the symptoms of venous thrombosis and its prophylaxis, and the symptoms of pulmonary embolism, heart attack, stroke, and in women-fetal loss. Any factors predisposing the patient to thrombosis, such as medication containing estrogen, should be discontinued. Smoking cessation should be pursued, and hypertension, hyperlipidemia, and diabetes should be aggressively treated.

Therapy for thrombosis associated with the lupus anticoagulant or elevated levels of anticardiolipin antibodies should be guided by the knowledge that recurrence is common.[126,133,134,156] In one study, patients who had discontinued oral anticoagulation had a 50% probability of recurrence in 2 years and a 78% recurrence in 8 years.[224] Similar results have been published by others with a recurrence rate of 10% to 30% per year.[123,133,134,155] Three prospective studies reported that there was an increased risk of recurrence that varied from 10% to 67% per year.[225–229] However, in many of these studies the patients did not fulfill the consensus definition of antiphospholipid syndrome.[31] In most reports the incidence of recurrence is highest in the first 6 months after discontinuing anticoagulant therapy.[225,229] Venous recurrence usually occurs in patients who have an initial venous event, whereas arterial recurrences usually occur in patients who sustain an initial arterial event.[133] Although it was initially thought that prevention of venous recurrence required high-intensity warfarin with a target INR of 3.5,[230] evidence has been accumulating from recent studies that standard intensity warfarin (INR 2 to 3) can almost completely abrogate recurrence of venous thromboembolic disease.[231,232] The pooled data from these two studies revealed no difference in recurrent thrombosis between moderate-intensity warfarin (INR 2 to 3) and high-intensity (INR 3 to 4), nor was there a greater bleeding risk.[231,232] However, it should be noted the recurrent venous events in the moderate-intensity warfarin groups were lower than expected and that patients with recurrent venous thromboembolic disease were excluded.[233–236] As the data from several studies

Therapy for Patients with the Lupus Anticoagulant or an Increased Level of Anticardiolipin Antibodies

The lupus anticoagulant persists in most untreated adults. Often it disappears spontaneously when it occurs in children in whom the anticoagulant is acquired after a viral infection, and it may be transient in adult patients without SLE, thromboembolic disorders, or fetal loss.

When the lupus anticoagulant, increased levels of anticardiolipin antibodies, or anti–β_2-GPI antibodies are found in patients with underlying autoimmune disease, treatment of the underlying disease with immunosuppressive therapy may result in reduction or disappearance of the antibody. When the lupus anticoagulant is found in association with severe prothrombin deficiency or severe thrombocytopenia (<20,000 cells/μL), treatment with adrenal corticosteroids is indicated. If the patient is actively bleeding with severe hypoprothrombinemia, adjunctive therapy with intravenous immunoglobulin (IVIg) can be given, whereas if the patient has active bleeding with only severe thrombocytopenia anti-D (if Rh+) or IVIg can be given. However, when the lupus anticoagulant, increased levels of anticardiolipin, or anti–β_2-GPI antibodies are discovered as an isolated finding and not associated with thrombosis or fetal loss, treatment is not indicated except for possibly prophylactic low-dose aspirin and/or hydroxychloroquine plus aggressive treatment of comorbid conditions such as smoking, diabetes mellitus, dyslipidemia, hypertension, and so on.

Therapy for thrombosis associated with the lupus anticoagulant or significant levels of anticardiolipin or β_2-GPI antibodies should be guided by the knowledge that recurrence is common. The site of the first event (arterial or venous) tends to predict the site of subsequent events. It is recommended that patients with acute venous thromboembolic events receive low-molecular-weight heparin subcutaneously in the usual therapeutic doses, or alternatively, intravenous unfractionated heparin in the usual therapeutic doses to achieve a plasma heparin level of 0.3 to 0.7 units using a factor Xa inhibition assay. Long-term anticoagulation with warfarin can be started simultaneously with a dose to maintain the INR between 2 and 3 using a thromboplastin insensitive to the lupus anticoagulant. If recurrent venous events occur at a therapeutic INR, then the patient should be treated with either therapeutic low-molecular-weight heparin, or alternatively, to continue with warfarin with an INR of 2.5 to 3.5.

Long-term anticoagulants are also probably efficacious in secondary prevention of arterial thrombosis depending on the vascular bed involved. In patients with ischemic coronary artery disease the target INR should be 2.5 to 3.5 or, alternatively, 2 to 3 along with low-dose aspirin (81 mg/day). If coronary ischemic events recur at an INR of 2.5 to 3.5, then low-dose aspirin (81 mg/day) can be added. In patients with cerebrovascular ischemic events aspirin alone (325 mg/day) or warfarin alone (INR of 2 to 3) are reasonable alternatives. In addition, comorbid conditions such as dyslipidemia, hypertension, diabetes, and smoking should be aggressively treated.

Because of the increased recurrence of thrombotic disease antihemostatic therapy should be continued for life, except when they occur exclusively in pregnancy. Because of the efficacy of antihemostatic therapy in preventing recurrent thrombosis, the use or corticosteroids and other immunosuppressive agents to suppress antibody production is usually not necessary in the absence of SLE. However, in patients with refractory SLE and severe manifestation of APS hematopoietic stem cell transplantation should be considered.

A pregnant patient—with or without SLE—with the lupus anticoagulant and/or a significant level of anticardiolipin or anti–β_2-GPI antibodies associated with a history of fetal wastage (see Table 123–1) should be treated with low-dose aspirin 81 mg/day plus prophylactic doses of low-molecular-weight heparin 4000 to 5000 anti-Xa units subcutaneously once every 24 hours. If fetal loss recurs on this regimen, a therapeutic dose of low-molecular-weight heparin should be tried. A pregnant patient with or without SLE with a previous thrombotic event usually is already receiving oral anticoagulants. At the time of diagnosis of pregnancy, the oral anticoagulant should be immediately replaced with low-molecular-weight heparin in full therapeutic doses (adjusted to periodically determine serum anti-Xa levels with low-molecular-weight heparin standard). Oral anticoagulants can be resumed in the postpartum period for 4 to 6 weeks.

For the patient, with or without SLE, who becomes pregnant for the first time and who has not had a prior thromboembolic event or fetal wastage, no treatment is indicated. However, the patient should be educated regarding the possibility of increased risk of fetal loss or thrombosis, the potential side effects of therapy, and the contradictory results from uncontrolled and controlled trials. After full disclosure—if the patient desires treatment—she should be given prophylactic doses of low-molecular-weight heparin and/or low-dose aspirin.

If an asymptomatic patient with persistently present antiphospholipid antibodies requires a major surgical procedure, prophylactic low-molecular-weight heparin and intermittent pneumatic compression should be used.

The patient who presents with catastrophic APS should receive anticoagulant therapy with an intravenous bolus of 80 units/kg of unfractionated heparin, followed by a continuous intravenous infusion of 18 units/kg/h or alternatively, therapeutic doses of low-molecular-weight heparin (if renal function is normal). Simultaneously, the patient should be given a pulse of high-dose methylprednisolone, 2 g intravenously daily for 3 days. If the patient's condition stabilizes within the first 24 hours, rituximab, 375 mg/m^2 should then be administered. Although plasmapheresis and/or IVIg may be helpful in some cases, these therapeutic maneuvers may interfere or make heparin and rituximab administration difficult. Because it appears that anticoagulation is much more efficacious than plasmapheresis and IVIg in this syndrome, then these therapeutic modalities could be reserved for recurrent adverse events.

noted above have demonstrated that patients with antiphospholipid syndrome have a high risk for recurrent venous thromboembolic disease after anticoagulation is discontinued, many feel that anticoagulation should be continued indefinitely.[225,229] The American College of Chest Physicians recommends treatment for 12 months and consideration of indefinite therapy after an initial event.[229,237] Because of the efficacy of warfarin therapy in preventing recurrences, the use of corticosteroids and other immunosuppressive agents to suppress antibody production in the absence of autoimmune disease is not recommended.

Monitoring anticoagulant therapy may be difficult in patients with lupus anticoagulants and a prolonged PTT. It is mandatory when using unfractionated heparin to monitor therapy using a specific heparin assay, such as the one dependent on factor Xa inhibition (therapeutic range, 0.3 to 0.7). In most instances, it is preferable to use low-molecular-weight heparin in therapeutic doses, which usually eliminates the need for monitoring. When using warfarin, the optimal INR for patients with lupus anticoagulants is controversial,[133,134,238,239] because patients with lupus anticoagulants may have a variably prolonged prothrombin time,[238,240] and various thromboplastins have a different sensitivity in the presence of a lupus anticoagulant.[238] Therefore, it is possible that in various studies of therapy in patients with lupus anticoagulants that the degree of anticoagulation is overestimated, and the target INR of 3.0 noted earlier might be an overestimate because of the presence of the lupus anticoagulant. This hypothesis is substantiated by the report by Moll and Ortel,[238] in which the prothrombin time done by the prothrombin-proconvertin test and a chromogenic factor X level correlated well with established

therapeutic ranges. The prolongation of the prothrombin time in some patients with the lupus anticoagulant is prolonged by some tissue thromboplastins, particularly recombinant tissue factor, but not the other tissue factor reagents.[241,242] A tissue factor reagent that is known to be insensitive to the effect of the lupus anticoagulant can be used. However, it is important that the specific international sensitivity index of the specific thromboplastin is used in the calculation of the INR.[241] If an insensitive tissue factor cannot be found, then a chromogenic factor X assay with a target therapeutic range of 10% to 40% (which is equal to an INR of 2 to 3) can be used. Alternatively, low-molecular-weight heparin can be used. Rarely, patients may continue to have recurrent venous thromboembolic events despite INR values in the therapeutic range. These patients can be treated with long-term low-molecular-weight heparin, warfarin with a target INR of 3.0, or aspirin in addition to warfarin.[243]

The treatment of patients with arterial thrombotic disease is less clear than in patients with venous disease. Although the recent trials with venous disease also enrolled patients with arterial thrombotic disease, there were too few patients to come to any definite conclusion.[231,232] However, in both trials there was a low recurrence rate in patients assigned to moderate-intensity warfarin (INR 2–3), and the recurrence rate was no different than with high-intensity warfarin. However, it should be noted that the patients in these two trials were patients who suffered an initial thrombotic event and excluded patients with recurrent vascular events. Thus, it is probably premature to conclude that warfarin alone with a target INR of 2 to 3 is adequate to prevent arterial thrombosis. However, it has been shown in well-controlled trials in patients with coronary artery disease that secondary prevention is effective with high-intensity warfarin (INR 2.8 to 4.8)[244–246] or moderate-intensity warfarin (INR 2.0 to 2.5) plus low-dose aspirin (75 mg).[247] In the latter study,[247] aspirin and warfarin (INR 2.2) was shown to be equivalent to high-intensity warfarin (INR 3.5) and was superior to aspirin alone. In contrast, in the antiphospholipid and stroke study (Antiphospholipid Antibodies and Stroke Study Group [APASS]),[248] aspirin alone was equivalent to warfarin (INR 1.4 to 2.8). Considering the successful trials using warfarin alone in secondary prevention in patients with coronary artery disease with a reduction in the INR to 2.5 to 3.5,[249,250] it would also be reasonable to use warfarin alone (without aspirin) with a target INR of 3.0. Thus, the treatment of arterial thrombosis in patients with associated antiphospholipid antibodies remain controversial.[225,229,231,232] However, it appears from the above studies that aspirin alone, aspirin plus moderate-intensity warfarin (INR 2–3), or moderate-intensity warfarin alone (INR 2.5–3.5) are reasonable alternatives after an initial arterial ischemic event depending on the arterial bed involved. In addition, recently it has been shown that in patients with systemic lupus with or without antiphospholipid antibodies that treatment with chloroquine and hydroxychloroquine reduced the incidence of thrombosis and prolonged survival, particularly in patients with a previous history of thrombosis and/or the presence of antiphospholipid antibodies.[251] Moreover, hydroxychloroquine has been shown to inhibit platelet activation in the presence of antiphospholipid antibodies.[252]

The optimum treatment of patients with recurrent arterial events is yet to be determined and requires either more intensive or alternative antihemostatic treatment. In addition, comorbid conditions such as diabetes, smoking, dyslipidemia, and hypertension, must be aggressively treated.

Recently it has been reported that several patients with refractory SLE with secondary antiphospholipid syndrome were treated with autologous hematopoietic stem cell transplantation with excellent results.[253] There was no treatment-related mortality, and the majority of patients remained thrombosis free without anticoagulant therapy.

A pregnant patient with or without SLE with the lupus anticoagulant or elevated levels of anticardiolipin antibody associated with a history of recurrent fetal wastage should be treated. However, the precise regimen to be followed has not been clearly established. Lubbe and colleagues[254] described a successful pregnancy outcome in a patient with the lupus anticoagulant and fetal wastage who was treated with prednisone and low-dose aspirin. Subsequently, the same regimen led to successful pregnancy outcomes in 10 of 16 pregnancies in 12 patients, some of whom had SLE.[255] Other investigators, using a similar regimen in patients without SLE, also reported a decrease in fetal wastage in a significant number of patients.[256] In a study by Silveira and associates,[256] prednisone and low-dose aspirin given to 11 patients with recurrent fetal wastage (32 previous fetal losses and 5 live-born infants) resulted in 100% live-born infants (12 pregnancies and 12 live-born infants), and no significant adverse effects to mother or infants. The levels of anticardiolipin antibody decreased in most patients. Lockshin and colleagues[257] have cast significant doubt regarding the efficacy of aspirin with or without corticosteroids in high-risk patients with high-titer anticardiolipin antibodies. In 11 pregnancies receiving corticosteroids and low-dose aspirin, there were 9 fetal losses, whereas in 10 pregnancies receiving aspirin alone or no therapy, there were 5 fetal losses. However, in a large, randomized trial in 202 patients with autoantibodies (lupus anticoagulant, anticardiolipin antibody, antinuclear antibody, anti-DNA, or antilymphocytic IgM) and unexplained loss of at least 2 fetuses, corticosteroids plus low-dose aspirin resulted in 65% viable infants, compared with 57% in the placebo group.[258] Despite these variable results with corticosteroids with or without aspirin, the formidable toxicity of corticosteroids, including hypertension, preeclampsia, gestational diabetes, and premature labor and delivery, and the lack of such toxicity with other regimens, resulted in the deletion of corticosteroids as part of the therapeutic armamentarium. However, in an occasional patient with active SLE, corticosteroids may be necessary to suppress the underlying disease.

Wallenberg and Rotmans[259] used low-dose aspirin and dipyridamole in 37 patients with obstetric histories similar to those with antiphospholipid antibodies, with a 93% success rate. Unfortunately, these patients were not systematically examined for the presence of antiphospholipid antibodies. Likewise, Elder and colleagues[159] reported similar success using low-dose aspirin alone in 42 patients, of whom 16 had SLE (13 with antiphospholipid antibodies). One other randomized double-blind trial in patients with three or more miscarriages and the presence of antiphospholipid antibodies compared low-dose aspirin 75 mg/day to placebo.[260] In this small trial of 40 patients, 85% of the placebo group and 80% of the aspirin group were delivered of live infants.

In another small, randomized trial,[261] 50 patients with at least three consecutive episodes of spontaneous pregnancy loss and positive antiphospholipid antibody were assigned low-dose aspirin alone or low-dose aspirin plus heparin with increasing doses throughout pregnancy to achieve a PTT between 1.2 and 1.5. Viable infants were delivered by 11 of 25 (44%) women receiving aspirin alone, whereas 20 of 25 women (80%) receiving aspirin plus heparin delivered viable fetuses. In another randomized trial[262] in patients with persistently positive antiphospholipid antibodies and three or more fetal losses, low-dose aspirin (75 mg) plus unfractionated heparin (5000 units twice daily) resulted in live births in 32 of 45 (71%) pregnancies, compared with 19 of 45 (42%) live births in patients receiving low-dose aspirin alone. In contrast, in a randomized trial, 98 patients with persistently positive antiphospholipid antibodies and recurrent fetal loss were assigned low-dose aspirin alone or low-dose aspirin plus 5000 units of low-molecular-weight heparin daily.[263] There was no difference in live births between the two groups with 72% fetal survival with aspirin alone versus 78% with aspirin plus heparin. This well controlled and randomized study contrasts to a large meta-analysis of several controlled trials of therapy for pregnancy loss associated with antiphospholipid antibodies, (excluding the randomized trial noted earlier).[264] Ten trials fulfilled their inclusion criteria (627 patients). Three trials of aspirin alone showed no reduction in pregnancy loss. Heparin (in prophylactic to intermediate doses) combined with aspirin resulted in a significant reduction in fetal loss compared with aspirin alone. Prednisone and aspirin resulted in a significant increase in prematurity but no significant reduction in pregnancy loss.

Rosove and colleagues[265] reported 14 successful outcomes in 15 pregnancies in 14 patients (5 with lupus) using adjusted full-dose

heparin therapy throughout pregnancy. None of the patients was treated with aspirin, and only one patient received a short course of corticosteroids for a lupus flare. Ruffatti and coworkers[266] reported 100% fetal survival in 53 patients treated with heparin alone.

Different therapeutic regimens in controlled and uncontrolled clinical trials have resulted in a decrease in fetal loss. Some trials are difficult to evaluate because the cutoff levels between normal and abnormal for anticardiolipin antibodies were lower (<20 GPL units) than the cutoff values in other studies (>20 GPL units).[68] This is obviously a reflection of the lack of standardization of the anticardiolipin assay. Despite this problem, the most efficacious regimens appear to be low- or intermediate-dose heparin plus low-dose aspirin, or adjusted-dose heparin without aspirin. Although the trials in pregnant patients with antiphospholipid antibodies used unfractionated heparin, it has been clearly shown that low-molecular-weight heparin (4000 to 5000 anti-Xa units subcutaneously every 24 hours) is safe, efficacious, and easy to use in pregnancy. Unlike unfractionated heparin, it does not cause clinically significant osteoporosis. Whether it can be used alone (without aspirin) in prophylactic doses remains to be determined in clinical trials. The only other issue regarding low-molecular-weight heparin is its use just before delivery, which may complicate the timing of epidural analgesia. However, this can be obviated by a planned delivery or switching to unfractionated heparin before delivery. The use of aspirin alone remains controversial, despite its demonstrated efficacy in some of the trials. Regimens containing corticosteroids appear in most studies to cause significant adverse events (hypertension, diabetes, and preterm labor and delivery).

Whether asymptomatic patients with antiphospholipid antibodies who desire pregnancy should be treated prophylactically is not clear. Low-titer anticardiolipin antibody occurs in up to 2% to 4% of healthy young women and high-titer antibody in approximately 0.2%.[43] Young women with antiphospholipid antibodies who wish to become pregnant may be referred for consultation. If the patient does have a high titer of IgG anticardiolipin antibody, the risk of fetal loss approximates 25%, whereas the risk of fetal loss in patients without antiphospholipid antibodies is approximately 13%. The patient should be educated regarding these data, the possibility of fetal loss, the potential side effects of therapy, and the lack of controlled trials in these patients. Because low-dose aspirin was demonstrated to be efficacious in a well-controlled clinical trial without significant side effects, its use would probably do no harm.

Treatment of Catastrophic Antiphospholipid Antibody Syndrome

In the extensive reviews of patients with catastrophic antiphospholipid syndrome, various therapeutic interventions were analyzed.[107,108,165,166] Because most patients received more than one intervention, the analysis was difficult. Recovery occurred in 62% of patients treated with anticoagulation versus 23% in those who were not.[107] The use of steroids, cyclophosphamide, plasmapheresis, or intravenous gammaglobulin did not seem to affect outcome. However, considering the various combinations, recovery occurred in 64% of patients treated with anticoagulants and steroids and only in 38% of those who were not. Other combinations did not significantly affect outcome. However, intravenous gammaglobulin or plasma exchange with fresh frozen plasma have shown some efficacy in some cases.[166] In addition, rituximab has occasionally been added to corticosteroids with positive results.[229,267,268]

An analysis of the long-term outcome of patients with catastrophic antiphospholipid syndrome that were originally reported[107] and survived the initial event revealed that 66% had no recurrence while on long-term anticoagulants, whereas 26% developed further thromboembolic events.[269] Twenty-five percent of the latter patients died from the event. Five percent of the patients died of multiorgan failure and 2% of other causes.

SPONTANEOUSLY ACQUIRED INHIBITORS OF FACTOR VIII (ACQUIRED HEMOPHILIA A)

Clinical Setting

Virtually all inhibitors of factor VIII are recognized because of their neutralization of factor VIII activity. Most occur in five clinical situations: alloantibodies in hemophilia A; postpartum; in association with various immunologic disorders; in association with various malignancies; and in older patients without any associated disorder. The last four clinical situations occur with an estimated incidence of 0.2 to 1.48/1 $\times$ 10^6 persons/year.[270–273]

In 1981, Green and Lechner[271] surveyed 215 patients with factor VIII inhibitors in an effort to gather demographic information regarding spontaneously arising inhibitors to factor VIII. The gender incidence was approximately equal, and almost 60% of the patients were older than 60 years of age. No associated disease was found in 50% of patients, but rheumatoid arthritis, SLE, drug reactions, dermatologic disorders, and different types of malignancies (solid tumors and lymphoproliferative malignancies) were each seen in 8% to 15% of the total group. In 13.5% of cases, the disorder occurred during the postpartum period. These associations have been corroborated by other reports.[272,273] Overall mortality was 22%. Approximately 38% showed eventual spontaneous disappearance of the inhibitor. The spontaneous remission rate was confirmed by Lottenberg and colleagues,[270] who reported that among 16 patients receiving no immunosuppressive therapy, 5 had spontaneous remissions.

Factor VIII Inhibitors Occurring in Patients with Immunologic Disorders, in Patients with Cancer and in Patients without Underlying Disease

Immune disorders associated with factor VIII inhibitors include rheumatoid arthritis,[274,275] SLE, and other systemic autoimmune diseases,[274–276] penicillin or other drug reactions,[1] bronchial asthma,[274,275] inflammatory bowel disease,[275] erythema multiforme,[275] dermatitis herpetiformis,[275] graft-versus-host disease,[114] and interferon-α therapy.[277,278] Occasionally, factor VIII inhibitors are associated with monoclonal gammopathies. More than 40 cases with various types of cancers have been reported.[279] Solid tumors were found in 25 patients, and 16 had hematologic malignancies.[279]

Factor VIII Inhibitors Occurring Postpartum

Factor VIII inhibitors can occur during the postpartum period,[274–276,280–283] and rarely during pregnancy.[284] Most often, the inhibitor occurs after the birth of the first or second child. Although a bleeding tendency may become evident immediately or after a prolonged interval, there is usually a 2- to 5-month delay before the diagnosis is made. The course in these patients is variable, but the inhibitor disappears spontaneously in many patients after 12 to 18 months.[280–282] In a review of 51 patients with postpartum inhibitors, the survival rate was 97% at 2 years, and Kaplan-Meier analysis revealed a probability of complete remission of almost 100%.[114] The median time to complete remission was 11 months, an interval shortened with immunosuppressive drugs.

In patients who became pregnant again after the occurrence of a postpartum factor VIII inhibitor,[281,285] only a rare patient who had achieved a remission have had a recurrence.[283,286] The cause of these postpartum inhibitors is unknown.

Properties of Spontaneously Acquired Factor VIII Inhibitors

With rare exceptions, factor VIII inhibitors are IgG antibodies. Some of these inhibitors have restricted heterogeneity because some possess

κ or λ light chains.[1,275,287–292] These inhibitors frequently contain mixtures of heavy chain subclasses. Hultin and coworkers[290] found that hemophilic and nonhemophilic inhibitors contain mixtures of IgG_1 and IgG_4 subclasses. The high incidence of factor VIII inhibitors containing a subpopulation of IgG_4 is significant because this subclass constitutes less than 5% of plasma IgG. The inhibitors are specific for factor VIII activity, and most do not interfere with the activities of VWF within the factor VIII-VWF complex. The VWF antigen and function are normal in patients with these inhibitors. Factor VIII inhibitors do not participate in complement fixation.[275,276] They show species specificity in vitro and in vivo in that human factor VIII is generally neutralized to a greater extent than is bovine or porcine factor VIII. Infusion of bovine or porcine factor VIII into a patient with an inhibitor often raises the factor VIII level.[293]

The kinetics of the reaction between factor VIII and most hemophilic inhibitors is first order with respect to factor VIII and to inhibitor (type I).[294] The inhibitor can be completely neutralized by excess factor VIII.[294] A time dependence of the neutralization of factor VIII sometimes requires 1 to 2 hours to reach equilibrium at low inhibitor concentrations.[294] Neutralization occasionally takes place in an initial rapid phase, followed by a very slow second phase.[295,296] By contrast, inhibitors arising in most nonhemophiliac patients frequently differ in their reaction kinetics from inhibitors arising in hemophiliac patients.[296,297] A linear relationship between the inhibitor concentration and the amount of factor VIII inactivated is observed with hemophilia inhibitors (type I), but not with most spontaneous inhibitors (type II). Most spontaneous inhibitors do not totally inactivate factor VIII in vitro. Although most factor VIII inhibitor patients have no factor VIII in the plasma, the occasional patient exhibits some plasma factor VIII activity.[276,297,298]

Epitope Specificity of Factor VIII Antibodies

The antigenic regions on the factor VIII molecule to which factor VIII inhibitors bind have been identified.[137,299–301] The epitopes to which alloantibodies or autoantibodies are directed are limited to certain areas of the factor VIII light or heavy chains[300,301] and interfere with factor VIII interaction with factor IX, factor X, VWF, or phospholipid.[300,301] The factor VIII molecule consists of two series of repeated homologous domains and a single B domain arranged in the following order: A1-A2-B-A3-C1-C2. Small regions rich in acidic amino acids are located between A1 and A2 (called a1), A2 and B (a2), and B and A3 (a3).[301] The heavy chain consists of A1-a1-A2-a2-B and the light chain consists of a3-A3-C1-C2.[301] The A and C domains are required for functional activity, whereas the B domain is not. A variety of immunologic techniques have been used to characterize the parts of the factor VIII molecule to which antibodies bind. These include immunoblot analysis after sodium dodecyl sulfate-polyacrylamide gel electrophoresis of purified factor VIII, immunoprecipitation assays using recombinant polypeptide fragments of factor VIII, the effects of inhibitory antibodies on functional hybrid recombinant human-porcine factor VIII peptides, enzyme-linked immunosorbent assay techniques that measure antibody binding to intact recombinant or plasma-derived factor VIII, and the use of monoclonal anti-factor VIII antibodies derived from the plasma of inhibitor patients.[300,301] The A2, A3, and C2 domains and the light chain are most immunogenic, whereas the A1 and B domains are poorly or nonimmunogenic.[300] Anti-A2 and -C2 antibodies are present in approximately 68% of plasmas tested by immunoprecipitation assays using recombinant polypeptide fragments of factor VIII.[302] Less commonly, antibodies to the different acidic regions (a_1, a_2, a_3) are also found.[302,303] The antibody or combinations of antibodies that inhibit factor VIII activity predominantly consist of those directed toward A2, A3, C2, and a3 epitopes because of the ability of polypeptides containing those epitopes to completely neutralize inhibitor activity.[300,301] Anti-C2 antibodies interfere with factor VIII function by blocking the binding of factor VIII to phospholipid or VWF[300–303] or slowing the release of VWF from factor VIII.[300,301] These antibodies interfere with the assembly of the tenase complex. Anti-A2 and anti-A3 antibodies prevent factor VIIIa interaction with factor IXa or Xa, and interfere with the function of the tenase complex.[300–303] On occasion, antibodies are generated to the a1 residues between A1 and A2, which prevents binding of factor X to factor VIII,[300,301] or more commonly anti-a3 antibodies, which interfere with the binding of VWF to factor VIII.[301]

Antibody patterns in hemophilic patients differ from those in autoantibody patients.[304] C2 antibodies were the only antibodies found in 48% of autoantibody patients, whereas this pattern occurred in only one of 34 hemophiliacs.[304] Sixty-two percent of autoantibody patterns were directed to a single epitope, in contrast to only 17% of hemophiliac patterns. Fewer autoantibody patients contained anti-A2 and anti-A3 antibodies, and the occurrence of A2 plus C2 antibodies was also less common. Hemophiliacs treated with plasma-derived factor VIII or recombinant factor VIII have equally complex patterns, but they differ in epitope specificity from one another.[304] The relative amounts of antibody to the A2 and C2 domains can vary over time, and neither level is always correlated with the other inhibitor level.[304,305]

Recognition, Identification, and Quantitation of Factor VIII Inhibitors

The presence of a factor VIII inhibitor should be suspected whenever a patient with no prior bleeding history presents with spontaneous massive bruising or with large, unexplained hematomas. For unknown reasons, patients with spontaneously acquired factor VIII inhibitors have a more severe bleeding diathesis than hemophilia A patients with inhibitors with very severe skin, mucous membrane, and soft tissue bleeding. In contrast to hemophilia A patients with inhibitors, hemarthroses are rare. Some patients will present with no or minor bleeding (see box on Diagnostic Approach to Inhibitors).[273] The PTT is prolonged, whereas the prothrombin time and thrombin time are normal. The PTT of a mixture of the patient's plasma and normal plasma is also prolonged, although inactivation of factor VIII may require preincubation for 1 to 2 hours.[40,41] Confirmation that an inhibitor acts specifically with factor VIII requires incubating the patient's plasma diluted with an equal volume of normal plasma and performing assays of factors VIII, IX, XI, and XII at 0, 60, and 120 minutes. If the inhibitor is specific for factor VIII, only factor VIII decreases over time. A technique that uses the PTT rather than a factor VIII assay detects weak inhibitors of less than 0.4 Bethesda units.[306,307] Because heparin can also prolong the PTT, it is important to exclude the presence of heparin in the sample by performing a dilute thrombin time. In addition, because the lupus anticoagulant can also present with a prolonged PTT and can also be associated with the presence of a specific factor VIII inhibitor, it is important to exclude its presence by a dilute Russell viper venom time and its correction with exogenous phospholipid.

Quantitative inhibitor measurements are important in the emergency management of hemorrhage and for evaluation of long-term therapy. A standard unit of measurement, termed the *Bethesda unit,*[308] is best suited for the measurement of inhibitors arising in hemophiliacs, but the complexity of reaction kinetics and variations in antibody affinities for factor VIII, particularly in nonhemophilic inhibitors with high residual factor VIII, limit standardization. The reason for the high residual factor VIII is not clear but Nogami[309] reported that immune complexes of autoantibody and factor VIII prevented the inactivation of factor VIII by activated protein C. The presence of factor VIII in the antigen-antibody complexes prevented its binding to phospholipid membranes where it forms the tenase complex. Despite significant residual factor VIII levels in vitro, the patient has severe bleeding. Because of the high residual factor VIII, it may be difficult to determine the inhibitor titer in nonhemophilic patients with spontaneously acquired inhibitors. The results of the Bethesda assay underestimate the actual in vivo level of human factor VIII autoantibodies. Assay results are less valuable in guiding therapy than they are in hemophiliac patients with inhibitors. There is little

correlation between the factor VIII level, titer of inhibitor, and degree of prolongation of the partial thromboplastin time with bleeding complications nor is the inhibitor titer at presentation useful for predicting the severity of bleeding. Frequently, more factor VIII must be given to obtain hemostatic levels in patients with autoantibodies to factor VIII. In the United Kingdom, the New Oxford method is used to quantitate factor VIII inhibitors,[310] with 1 Bethesda unit equaling approximately 1.21 times 1 New Oxford unit. The Bethesda assay does not ensure pH control during the incubation period, and this may result in nonantibody-mediated inactivation of factor VIII. In 1995, the Nijmegen modification of the Bethesda assay was introduced wherein the substrate plasma used in the test and control plasma is buffered to 7.4, and factor VIII-deficient plasma is substituted for imidazole buffer in the control sample.[311] Because some factor VIII-immunodepleted plasma lacks VWF, the results of the modified assay may give lower inhibitor titers compared with assay results when the factor VIII-deficient plasma in the control sample contained VWF.[312] These results were probably a result of the lack of the stabilizing effect of VWF resulting in a decrease in factor VIII level when incubated with the normal pooled plasma.[312] Recent studies suggest that 4% bovine serum albumin could be substituted for the factor VIII-deficient plasma in the control mixture without loss of specificity.[313]

Therapy of Patients with Factor VIII Inhibitors

The major objectives in the treatment of these patients are twofold: (1) the treatment of acute bleeding episodes, and (2) the elimination of the autoantibody to factor VIII (see box on Management of Spontaneously Acquired Factor VIII Inhibitors). When a patient with an inhibitor hemorrhages, conservative measures, including immobilization, compression, and possibly ε-aminocaproic acid, should be considered. The use of intramuscular injections or the use of aspirin-containing compounds is contraindicated. If the patient's bleeding is mild to moderate and the inhibitor titer is low (<3 Bethesda units) then desmopressin acetate (DDAVP) can be tried, and has been helpful in some cases.

The indication for the use of factor VIII concentrates or factor VIII bypassing agents is serious active bleeding. If the patient is not actively bleeding, transfusion is not indicated. Unlike inhibitors associated with hemophilia A, most spontaneously acquired inhibitors are usually not inducible when the patient is exposed to factor VIII. When the patient is bleeding, highly purified human factor VIII, or recombinant factor VIII is indicated in low titer inhibitor patients.

An important parameter in determining the amount of factor VIII to be infused is the titer of the inhibitor. If the titer is low (<5 Bethesda units), a large dose of human factor VIII sufficient to neutralize all the circulating inhibitor and provide enough excess factor VIII to achieve a plasma factor VIII of greater than 0.3 units/mL can be given. This can be achieved usually with the rapid infusion of human factor VIII (100 to 150 units/kg) followed by a continuous infusion of 10 units/kg/h. Alternatively, a large amount of human factor VIII can be given every 1 to 4 hours, giving 40 units of factor VIII/kg plus an additional 20 units/kg per Bethesda unit. When the inhibitor titer is slightly elevated (5–10 Bethesda units), the antibody level can be lowered by plasmapheresis or, alternatively, by one of several methods of immunoadsoprtion.[314,315] This can be followed by a bolus infusion (150–250 units/kg) followed by a continuous infusion of human factor VIII.

When factor VIII replacement is used, factor VIII levels must be assayed frequently to monitor the plasma factor VIII level achieved in vivo, particularly after the infusion of a factor VIII concentrate. The infused factor VIII may be efficacious in vivo before it is inactivated.

In the past porcine factor VIII has been used effectively in these patients because most autoantibodies have much less inhibitor activity against porcine factor VIII.[293,316,317] However, porcine factor VIII is no longer commercially available but a recombinant porcine concentrate is undergoing clinical trial.[318]

Management of Spontaneously Acquired Factor VIII Inhibitors

Conservative Measures

When a patient with an inhibitor has a hemorrhage, conservative hemostatic measures should be taken to complement whatever other therapy is used. These measures include immobilization, application of cold compresses, local application of hemostatic agents, and, on occasion, administration of ε-aminocaproic acid. The patient should not receive intramuscular injections, unnecessary venipunctures, aspirin-containing compounds, or nonsteroidal antiinflammatory drugs. If the patient has a low inhibitor level (<3 Bethesda units) then desmopressin (DDAVP) 0.3 μg/kg can be given immediately.

Selection of a Blood Product

For patients who are actively bleeding, therapeutic options include treatment with human plasma-derived or recombinant factor VIII concentrates, activated prothrombin complex concentrates, and recombinant factor VIIa. If the patient is not actively bleeding, transfusion is unnecessary. Unlike inhibitors associated with hemophilia A, most spontaneously acquired inhibitors do not increase in titer after exposure to factor VIII. This consideration should not impede transfusion therapy. If the titer is low (<5 Bethesda units), a large dose of factor VIII sufficient to neutralize all of the circulating inhibitor and provide enough excess factor VIII to achieve a plasma factor VIII of greater than or equal to 0.3 units/mL (30%) can be given. This usually can be achieved by giving a rapid infusion of giving 100 to 150 units/kg of human factor VIII concentrate followed by a continuous infusion of 10 units/kg/h. Alternatively, a large amount of human factor VIII can be given every 1 to 4 hours, giving 40 units of factor VIII/kg and an additional 20 units/kg for each Bethesda unit. If a patient has a moderately high inhibitor level of 5 to 10 Bethesda units, the inhibitor level may be lowered by approximately 50% to 65% by a 1.5-volume plasmapheresis or by using one of several methods of extracorporeal immunoadsorption. After apheresis or immunoadsorption, the patient is initially given human factor VIII (150 to 250 units/kg), followed by a continuous infusion in the dose noted previously. If plasmapheresis cannot be done promptly or if the patient has a very high titer inhibitor, it is impossible to achieve hemostatic levels of factor VIII, except by bypassing the site of inhibitor action with activated prothrombin complex concentrate (factor VIII inhibitor bypassing activity [FEIBA]) with a dose of 75 to 100 units/kg every 12 hours or recombinant factor VIIa at a dose of 90 μg/kg every 2 hours until the bleeding ceases followed by decreasing intervals of the administration of either concentrate. If factor VIII inhibitor titers are not readily available, then freeze plasma to be subsequently sent to a reference laboratory and infuse activated prothrombin complex concentrate or factor VIIa.

Immunosuppression of the Inhibitor

The long-term goal in the management of these patients should be aimed at immunosuppression of the autoantibody production. Although many immunosuppressive regimens have proved efficacious, we now initiate therapy with rituximab 375 mg/m^2 intravenously followed by weekly doses for a total of 4 weeks, immunosuppressive therapy with dexamethasone (Decadron) 40 mg/day, days 1 to 4, followed by prednisone 1mg/kg starting on day 5. Cyclophosphamide (2 mg/kg/day orally) is initiated concurrently with rituximab and dexamethasone. Inhibitor titers are determined every 1 to 2 weeks. This regimen is continued for 4 weeks. If a significant decrease in titer occurs (>50% reduction), the regimen is continued for 4 more weeks. If the preceding regimen is unsuccessful, the patient is placed on azathioprine (2 mg/kg), and serial inhibitor titers are performed. If no significant response occurs in 8 weeks, the regimen is discontinued, and cyclosporine or interferon-α therapy is tried.

If human factor VIII is ineffective, or the inhibitor level is too high, an attempt may be made to bypass the need for factor VIII by giving a prothrombin complex concentrate or recombinant factor VIIa. The prothrombin complex concentrates exhibit a procoagulant activity that bypasses the factor VIII-dependent clotting reactions. Two types of prothrombin complex concentrate have been used in the treatment of patients with factor VIII inhibitors: regular inactivated intermediate-purity prothrombin complex concentrates (eg, Bebulin VH [Baxter]); and activated concentrates, so-called anti-inhibitor coagulant complex. Both types of concentrates contain various amounts of activated factors VII, IX, and X and phospholipids, and should be distinguished from the highly purified factor IX concentrates used in the treatment of hemophilia B. The activated concentrates (FEIBA-VH [Baxter]) contain a greater amount of the factor VIII bypassing material and are specifically designed for patients with factor VIII inhibitors. Both types of concentrates have proved efficacious in hemophiliacs with inhibitors in controlled clinical trials,[319–321] but today the activated concentrates are the ones used to treat patients with inhibitors. The doses are arbitrary, but the usual initial dose of FEIBA is 75 to 100 units/kg. In a French multicenter retrospective survey of the use of FEIBA in 60 patients with factor VIII or IX inhibitors (6 of whom had spontaneously acquired inhibitors) with 433 bleeding episodes or surgical procedures, efficacy was good to excellent in 81.3% of the episodes.[322] Adverse effects were seen in only 5 of 433 episodes (12%), but an anamnestic response occurred in 17 of 54 evaluable patients (31.5%). A retrospective study of 34 patients with spontaneously acquired factor VIII inhibitors revealed a complete response rate of 86% with a dose of FEIBA of 75 units/kg every 8 to 12 hours with a median number of doses of 10 to control a severe bleed.[323] The authors emphasize that a dose of 200 units/kg/24-hour period should not be exceeded because of an increased incidence of thromboembolism.

Purified components of the prothrombin complex have been used to treat hemorrhages in patients with inhibitors. A highly purified concentrate containing factor VIIa achieved good hemostasis[324] and, subsequently, a recombinant preparation of human factor VIIa has shown significant efficacy in patients with inhibitors.[325,326] This product is designed to generate thrombin only at sites of vascular injury. In a survey of more than 240 patients, 18 of whom were patients with spontaneously acquired factor VIII autoantibodies, the recombinant factor VIIa was used successfully for critical bleeds or for surgery.[327] Dosage and interval of dosing are still being evaluated, but factor VIIa therapy is initiated with doses of 90 μg/kg, and this dose is repeated every 2 to 3 hours (half-life is 2.9 hours) for one to two times for spontaneous bleeds and every 2 to 3 hours for 48 hours for surgical procedures, followed by tapering doses over several days. Efficacy has been reported in approximately 90% of patients with spontaneous bleeds and in approximately 80% of patients undergoing surgical procedures. Treatment is not influenced by the inhibitor titer, and no specific assay reflects clinical efficacy. Antibodies to factor VII do not occur except in factor VII-deficient patients.[328] The safety profile has been excellent, and thrombotic events are rare. Continuous infusion has been evaluated and proved efficacious in some studies,[329,330] but not in others.[331]

In a recent comparison of FEIBA with recombinant factor VIIa in hemophilia patients with inhibitors with joint bleeds, both treatments were efficacious in 80% to 90% of patients.[332] However, both products did not meet statistical equivalence at the majority of time that patients were examined.

Long-term goals in the management of these patients should be aimed at immunosuppression of the autoantibody production. Assessment of immunosuppressive therapy is difficult because inhibitors occasionally disappear spontaneously, particularly in patients with postpartum inhibitors and patients with drug-induced inhibitors.[271] In patients with underlying disorders, such as systemic autoimmune disorders or cancer, treatment of the underlying disease may result in disappearance of the inhibitor. Many patients respond to corticosteroids alone; in one report of 16 patients receiving only steroids,[333] 7 were complete responders, 4 were partial responders, and 5 were nonresponders. The time to response averaged approximately 16 days. In their 1981 survey, Green and Lechner[271] found that inhibitors disappeared in 22 of 41 steroid-treated patients. In a prospective, multicenter, controlled clinical trial, antibody disappeared in 10 of 30 patients treated with prednisone alone (1 mg/kg) in the first 3 weeks, and in 3 of 4 other patients randomized to continue prednisone after the first 3 weeks of prednisone therapy.[334] In patients resistant to steroids, the use of cytotoxic agents, particularly cyclophosphamide alone or in combination with corticosteroids, can be efficacious. Antibody disappeared in three of six patients randomized to oral cyclophosphamide and prednisone after the patients were resistant to prednisone alone in the first 3 weeks. Eight patients did not respond. In this trial, the titer of antibody was significantly lower in responders than in nonresponders, and most responses occurred within 6 weeks of starting therapy.

The use of factor VIII concentrate infusion before immunosuppressive therapy was first proposed by Green.[335] The hypothesis proposed that the factor VIII concentrate infusion stimulates the abnormal clone of immune cells responsible for autoantibody synthesis and results in a greater cytotoxic effect by the immunosuppressive therapy. A combination of cyclophosphamide, vincristine, and prednisone every 3 weeks, preceded by an infusion of factor VIII concentrate (50 to 100 units/kg), resulted in complete disappearance of the inhibitor in 11 of 12 patients.[336] The responses occurred rapidly, usually within only two or three courses, and remissions in all patients were durable over 2 to 5 years. The same group reported similar response rates with a similar chemotherapeutic regimen without the infusion of human factor VIII.[337] Others have reported similar results with various combinations of prednisone, cyclophosphamide, and vincristine. The initial inhibitor titer may be an important prognostic factor in the treatment of these patients.

In one report, nine consecutive patients with a spontaneously acquired factor VIII autoantibody were treated with oral cyclophosphamide (100 to 200 mg/day) and prednisone (50 to 80 mg/day) until the inhibitor titer reached zero, followed by slowly decreasing doses.[338] All patients achieved a complete remission, with a median time of 3 weeks to resolution of all bleeding symptoms and a median time to undetectable factor VIII inhibitor of 12 weeks (range, 3 to 37 weeks). Two patients had a relapse as the immunosuppressive drugs were tapered, but the patients reattained a complete response with reinstitution of therapy. Initial titers of factor VIII inhibitor levels ranged from 2.5 to 1040 units (mean = 174), and the patients with higher inhibitor titers required a longer duration of therapy. However, in a more recent uncontrolled trial patients with spontaneously acquired factor VIII inhibitors from the United Kingdom,[273] prednisone alone (1 mg/kg) was compared to prednisone and oral cyclophosphamide (1–2 mg/kg), and there was no difference in remission rate (76% versus 78%) nor the time to remission (49 days vs. 39 days). In contrast a meta-analysis of 249 patients from 20 publications, none of which were controlled studies, found that 70% achieved remission with steroids alone and 89% with the combination of steroids and cyclophosphamide without any advantage in survival.[339] The results of these studies, along with the results of the prospective clinical trial reported by Green and associates,[334] strongly suggest but do not prove that the initial immunosuppressive treatment of choice is oral prednisone and cyclophosphamide; a preliminary dose of human factor VIII is unnecessary.

Immunosuppressive therapy should be continued as long as the inhibitor titer is decreasing because patients with high inhibitor titers respond more slowly than patients with low inhibitor titers. Patients with inhibitors who have high residual factor VIII levels in vitro (0.04 to 0.34 units/mL) respond well.[298]

If prednisone and/or cyclophosphamide are ineffective, then azathioprine in doses of 100 to 200 mg/day (or 2 mg/kg/day) has also proved effective; Green and Lechner[271] found 19 of 28 patients to respond completely. Söhngen and colleagues[340] reported five patients who responded to a combination of corticosteroids and azathioprine within 6 weeks of initiating therapy. Sallah[341] reported the use of 2-chlorodeoxyadenosine in six patients refractory to other immunosuppressive regimens. The dose used was 0.1 mg/kg/day for 7 days by continuous infusion; five patients received a single course, and one

patient received two courses of therapy. All six of the patients had a significant decrease in inhibitor titer with the median time to reach nadir being 137 days. Although no patient attained a complete remission with a zero inhibitor titer, all of them had a significant increase in factor VIII level and no further bleeding. There have also been cases reported in which cyclosporine[342,343] or interferon-α[344] resulted in a complete response.

Any response to immunosuppressive therapy generally occurs within 6 to 12 weeks. If the titer has not decreased significantly in that period, therapy should be discontinued. Although most patients who obtain a complete response do not relapse, an occasional patient relapses early at the time of tapering or withdrawal of immunosuppressive therapy, and some patients relapse several months later.[273]

Spontaneously acquired factor VIII inhibitors respond to high-dose intravenous IgG.[345] In a prospective, multicenter study of high-dose intravenous IgG, 19 patients received 1 g/kg for 2 days or 400 mg/kg for 5 days, followed by periodic maintenance doses.[346] A rapid decline in inhibitor titer occurred in 3 to 4 days in two patients, and a gradual decline occurred in four other patients, with nadirs occurring several weeks to many months after starting therapy. Concurrent therapy with prednisone could have contributed to the response in two patients. The response rate was estimated to be between 25% and 37.5%. In another report[347] seven patients were treated with intravenous IgG 0.4 gm/kg/day × 5 days, plus prednisone 1 mg/kg/day for 14 days followed by tapering of the dose. Four patients had a complete response by day 21. In a more recent report where 31 patients received intravenous IgG in addition to immunosuppressive therapy, there was no evidence of additional efficacy of intravenous IgG in patients receiving prednisone or prednisone and cyclophosphamide.[273] The mechanism by which patients with inhibitors respond to intravenous IgG is unknown. However, IgG may have a short- and long-term immunosuppressive effect.[348,349] Anti-idiotypic antibodies are present in the IgG preparations;[350–352] the emergence of anti-idiotypic antibodies may be the explanation for the occasional spontaneous remission and some instances of remission induced by immunosuppressive agents.[351]

During the past few years, the administration of anti CD-20 monoclonal antibody, rituximab, has been used in the treatment of various autoimmune disorders including spontaneously acquired factor VIII inhibitors.[353,354] Up to this time more than 50 patients with spontaneously acquired factor VIII inhibitors have been reported who have received rituximab.[355,356] Treatment with rituximab resulted in an overall rate of complete remission of approximately 75% to 80% with no difference on whether the patients had or had not received immunosuppressive drugs previously or concomitantly. The median time to complete remission was approximately 8 weeks, but some were as short as 1 to 2 weeks.[355,356] In comparison to 44 patients treated with prednisone and cyclophosphamide reported in the literature, the complete remission rate was 84% with a median time to complete remission of approximately 6 weeks.[355] Two-thirds of patients who received rituximab remained in complete remission after 2 years as compared to 94% who received prednisone/cyclophosphamide. Most patients received 4 weekly doses of rituximab, and it was less efficacious in patients with higher antibody levels[355,357] or they took longer to respond.[356]

In light of the above data, rituximab is efficacious but less so than the efficacy of prednisone and cyclophosphamide. Suggested regimens include prednisone and cyclophosphamide alone or rituximab with prednisone and cyclophosphamide.

The great majority of patients (~75%–80%) eventually attain complete remission, and approximately 20% relapsed on withdrawal of immunosuppressive therapy.[273] Thus, these patients frequently require repeat or alternative immunosuppressive therapy.

ACQUIRED INHIBITORS OF VON WILLEBRAND FACTOR

Patients with von Willebrand disease may acquire inhibitors after plasma transfusion. Usually this occurs in patients with type 3 von Willebrand disease. An acquired syndrome similar to hereditary von Willebrand disease with onset later in life has been described.[358] More than 260 cases of the acquired syndrome have been reported, several reviews have been published,[359–362] and an international registry has been established.[363] The acquired syndrome occurs in patients with systemic autoimmune disease, B-cell lymphoproliferative disorders, myeloproliferative diseases, cardiovascular disorders, Wilms tumor, hypothyroidism, and a variety of other associations.[363] The most common associations are with lymphoproliferative and myeloproliferative disorders.[363] The clinical course in these patients is extremely variable from the new onset of mild bruising and mucous membrane bleeding to severe life-threatening bleeding.

Laboratory studies in these patients are extremely variable. Screening studies of hemostasis may show a prolonged bleeding time, an abnormal platelet function analysis (PFA)-100 test, or a prolonged PTT. Analysis of VWF usually reveals low ristocetin cofactor activity or collagen binding activity, low to normal VWF antigen level, and low to normal factor VIII activity. There is frequently an increased ratio of VWF antigen to ristocetin cofactor activity and, in approximately two-thirds of the cases, high-molecular-weight multimers are missing, as in type 2 von Willebrand disease,[364–368] and in one-third the multimers are proportionally decreased as in type 1 von Willebrand disease.[364] In a few patients, their plasma could be demonstrated to impair ristocetin cofactor activity of normal plasma.[360,364–370] In some, IgG antibodies could be demonstrated by a competitive ELISA assay.[371] In contrast, in most of the patients, inhibitor activity cannot usually be demonstrated by incubating the patient's plasma with normal plasma and measuring VWF activity, VWF antigen, or factor VIII.[360,364–370,372] Although factor VIII activity levels may be low, in only a rare case can inhibitor activity against factor VIII be demonstrated.[373] The bleeding time is variable and may be normal, similar to the variable bleeding times in patients with hereditary von Willebrand disease.

Because acquired von Willebrand disease is associated with a variety of different disorders and is characterized by variable clinical and laboratory features, many different pathophysiologic mechanisms leading to low VWF levels exist. Some patients develop IgG antibodies that can impair VWF activity,[360,364–368,370] whereas in other cases the antibody does not impair VWF activity but probably binds to a nonactive site on the molecule resulting in rapid clearance of the protein from the circulation.[369,374–376] In other patients, selective adsorption of VWF by tumor cells was demonstrated.[377–380] In two cases, the mechanism of adsorption was caused by aberrant expression of the glycoprotein Ib receptor on the surface of the tumor cell.[380,381] In a case of Waldenström macroglobulinemia, selective adsorption of VWF by monomeric IgM on the lymphocyte surface was demonstrated, but there was no impairment of VWF activity by the monoclonal IgM in plasma.[377]

In patients with myeloproliferative disorders, the mechanism is thought to be caused by increased adsorption of high-molecular-weight multimers by platelets or increased proteolysis of high-molecular-weight multimers.[363,382] Other mechanisms that have been implicated as a cause of the syndrome include decreased synthesis of VWF in hypothyroidism,[383] adsorption of VWF by hyaluronic acid in patients with Wilms tumor,[384] and increased proteolysis by ADAMTS 13 of high-molecular-weight multimers because of high plasma shear rates in the area of the cardiac defect in patients with congenital heart disease or aortic stenosis.[363,385] When these various underlying disorders are abrogated by appropriate therapy, the acquired syndrome disappears.

In addition, acquired von Willebrand syndrome has occasionally been described in association with the use of certain drugs, in other systemic disorders, and in a few cases where the patient had no underlying disease and was not taking any medications.[363]

Because there are a variety of pathophysiologic mechanisms that can cause acquired von Willebrand disease, many different therapeutic approaches have been tried with varying success. Frequently, successful treatment of the underlying disease or discontinuation of a drug results in disappearance of the syndrome. In patients with lymphoproliferative disorders or systemic autoimmune disease who are bleeding, attempts can be made to increase VWF with administration

of DDAVP, cryoprecipitate, or VWF concentrate. The latter (eg, Humate-P, Alphanate, or Koate-HP) may result in a transient and blunted increase in VWF activity, VWF antigen, and factor VIII, such that effective hemostasis can be achieved.[363] Moreover, a bolus infusion followed by a continuous infusion of VWF concentrate may be more efficacious than periodic bolus infusion in the presence of an inhibitor.[386] Whenever administering DDAVP or transfusing VWF, efficacy should be measured by serial VWF and factor VIII assays. There are reports of patients with acute bleeding who failed to respond to DDAVP and VWF concentrate but responded to recombinant factor VIIa.[387,388] Several patients have been reported who responded to intravenous Ig (400 mg/kg × 5 days or 1 gm/kg × 2 days).[366,389–392] Although the response may be transient, in a few patients the response may last 2 to 3 weeks. After recurrence, repeat administration may result in repeated responses.[363,393] The patients who appear to respond to intravenous Ig are those patients with a demonstrable inhibitor in vitro and/or an associated IgG monoclonal gammopathy.[393] In patients in whom the syndrome is thought to be antibody mediated, it is conceptually possible that they respond to immunosuppressive therapy with or without the addition of rituximab, as has been reported in patients with autoantibodies to factor VIII.

ACQUIRED INHIBITORS OF FACTOR V

Rarely, factor V inhibitors occur in patients with hereditary factor V deficiency after transfusion.[394] However, most factor V inhibitors occur spontaneously in older, previously healthy patients in the absence of a common underlying disease.[394–402] The most common association seen in approximately two-thirds of the cases is a surgical procedure preceding the development of the inhibitor.[401] Other significant associations include blood transfusion, antibiotics, and malignant diseases.[401,402] Many of the cases that followed surgery were associated with the use of topical bovine thrombin or fibrin glue. Both of these substances contain a large amount of bovine thrombin and small amounts of bovine factor V. This can result in the production of antibovine thrombin antibodies or antibovine factor V antibodies that cross-react with human thrombin and factor V.[403,404] Bleeding is usually secondary to cross reactive antihuman factor V antibodies rather than to the antithrombin antibodies. Despite the various associations with factor V antibodies, in approximately 20% of cases, no associations can be identified,[401] and in these patients, true autoantibodies to factor V presumably are present.

The degree of clinical bleeding in these patients varies, in contrast to the uniformly severe bleeding in patients with factor VIII inhibitors. This extreme variability, from no clinical sequelae to fatal hemorrhage, can possibly be explained by the accessibility of platelet factor V to the antibody.[399,400] Studies by Nesheim and associates[399] on a patient with a factor V inhibitor suggest that platelet factor V is relatively protected from an antifactor V antibody in whole blood, even though plasma factor V is completely neutralized. Platelet factor V may play a key role in maintaining hemostatic competency in the presence of a factor V inhibitor. This hypothesis is supported by the efficacy of platelet concentrates in a factor V inhibitor patient.[397] Fresh frozen plasma failed to effect hemostasis, but on four separate occasions, effective hemostasis was achieved with platelet transfusions. Two other patients responded to platelet transfusions, but others were not responsive. In one recent report,[405] the amount of functional factor V was low in plasma and platelets, but the amount of factor V antigen was normal. It was subsequently shown that this was a result of the presence of factor V antigen-antibody complexes in plasma and the α granules of platelets. The course of the factor V inhibitor is short lived in most patients, disappearing within 10 weeks. Removal of the antibody by plasmapheresis or immunoadsorption resulted in decreased bleeding in some patients.[401] In one report, the administration of intravenous IgG in a patient with cross-reactive antibodies to bovine and human factor V resulted in rapid elimination of the human antibody without any effect on the titer of bovine antibody concomitant with abrogation of the hemorrhagic disorders.[403] Two other cases have been reported with a rapid response to intravenous Ig.[406] Whether steroids or other immunosuppressive agents influence the natural history of the inhibitors is unclear. The inhibitor may disappear with immunosuppressive therapy,[397] including one case with rituximab,[407] or it may disappear spontaneously without specific therapy.[394–396]

With rare exceptions the factor V inhibitors are polyclonal IgG or polyclonal IgM and IgG antibodies.[398,401,408] One study of 12 patients with factor V inhibitors showed that the IgG autoantibodies and the bovine protein-induced IgG alloantibodies immunoprecipitated the factor Va light chain, and in 9 cases the C2 domain.[408] Five of the antibodies inhibited binding of factor V to phospholipids, presumably interfering with the assembly of the prothrombinase complex.[408] Only the IgG antibodies in patients with excessive bleeding inhibited factor V in a prothrombinase assay.

The laboratory identification of a factor V inhibitor is based on coagulation assays. PTT and prothrombin time are prolonged, and normal plasma fails to correct these assays. These findings in the presence of a normal thrombin time should strongly suggest the presence of a factor V inhibitor although similar findings may also be seen in a few patients with the lupus anticoagulant.[394,398] In those patients who develop a factor V inhibitor after the use of topical thrombin, a prolonged thrombin time is a clue to the diagnosis, particularly when it is associated with a history of recent surgery. The demonstration that a mixture of the patient's plasma and normal plasma specifically lacks factor V clotting activity is required for a definitive diagnosis. The antibody can be quantitated by using an assay similar to the Bethesda assay used for the quantitation of factor VIII inhibitors.

A few patients with factor V antibodies have been reported with thrombotic manifestations rather than bleeding.[409–412] Two of the four cases had an autoimmune process in which lupus-like anticoagulant activity associated with anticardiolipin antibodies was present.[410,411,128] The third case was associated with Sjögren syndrome.[412] In three of four of these patients clotting times were prolonged, and the procoagulant function of factor V was also affected, but the patients did not have any bleeding manifestations. In the one patient, clotting times were not prolonged, but the antibody interfered with the interaction of activated protein C and factor V.[409]

ACQUIRED INHIBITORS OF FACTORS VII, IX, AND X AND PROTHROMBIN

Although prothrombin antibodies are common in patients with a lupus anticoagulant, most of the patients do not have hypoprothrombinemia (see box on Methods for Establishing the Presence of a Lupus Anticoagulant). However, in an occasional patient, the prothrombin level may be sufficiently depressed (<30%) to cause excessive bleeding. In these patients the antibody does not inactivate prothrombin activity in vitro but binds to a nonactive site on the molecule at the carboxy-terminal latent thrombin segment.[413] Consequently, the prothrombin antigen-antibody complex is rapidly cleared from the circulation, and the in-vitro laboratory findings are more consistent with a deficiency of prothrombin rather than an inhibitor of prothrombin activity (ie, the addition of normal plasma to patient plasma results in correction of the prolonged clotting time). Whether this antibody is similar to the prothrombin antibody associated with lupus anticoagulant activity (66% to 75% of patients with lupus anticoagulant) but without significant prothrombin deficiency is not clear.[100,131] It is conceptually possible that these antibodies are the same and that the rare instances of prothrombin deficiency associated with lupus anticoagulants stems from an excess of antibody or, alternatively, increased affinity of the antibodies for prothrombin, causing very rapid prothrombin antigen clearance and inadequate hepatic synthesis to compensate for the rapid clearance.

Another prothrombin antibody directed at an epitope at the amino terminal end of the prothrombin molecule has been described

in a patient without an associated lupus anticoagulant. This antibody also did not neutralize prothrombin activity in vitro and resulted in an acquired prothrombin "deficiency" state.[413] Another patient with a prothrombin antibody without a lupus anticoagulant was recently described in a patient with lymphoma in whom the antibody disappeared after treatment of the lymphoma.[414]

Several patients have been reported whose plasma contained an antibody that reacted with thrombin.[415–421] Many of these patients bleed, but some are asymptomatic. The most common cause of spontaneously acquired inhibitors to thrombin are antibodies that develop in patients exposed to bovine topical thrombin or fibrin glue preparations during surgical procedures.[403,421–426] Thirty-five percent to 50% of these patients exposed to such preparations develop antibodies to bovine thrombin and/or bovine factor Va[403,423–426] that can cross-react with their human counterparts. Other patients appeared to spontaneously develop autoantibodies to thrombin,[415–420] and some of these patients also had systemic autoimmune disorders.[418–420] Coagulation tests in these patients are distinguished by a prolonged thrombin time that does not correct on mixing with normal plasma or protamine, and the reptilase time is normal. The PTT and prothrombin times are prolonged. In contrast, a rare patient may develop a thrombin inhibitor affecting the anticoagulant function of thrombin, causing thrombosis rather than bleeding.[427,428]

Five patients in whom IgG autoantibodies to factor VII developed had a prolonged prothrombin time but a normal PTT.[429–431] Weisdorf and coworkers[432] described a patient with severe aplastic anemia who had acquired factor VII deficiency. A factor VII-binding immunoglobulin in the patient's plasma bound to factor VII, resulting in rapid clearance of the immune complex. In one patient the inhibitor was characterized as an IgG antibody that bound to the light chain of factor VIIa within or near the Gla domain and inhibited the activity of the tissue factor-factor VIIa complex.[431] There also have been several patients with hereditary factor VII deficiency who have become alloimmunized after being treated with recombinant factor VIIa.[328]

Spontaneously acquired factor IX inhibitors are extremely rare.[433–437] The clinical setting in which these inhibitors occur is similar to that associated with the development of factor VIII inhibitors. Three were associated with SLE and two with the postpartum state. Those that have been characterized are polyclonal IgG antibodies. Treatment is similar to patients with factor VIII inhibitors using factor IX concentrates, activated prothrombin complex concentrates, and recombinant factor VIIa. Most seem to disappear within 1 to 7 months of onset, but whether immunosuppressive therapy alters the natural history is unknown.

Three documented patients with a factor X inhibitor have been reported.[438,439] These patients were elderly without underlying disease who had the sudden onset of a bleeding diathesis. In two of three cases, the inhibitor was characterized as IgG antibodies and disappeared spontaneously without specific therapy.

ACQUIRED INHIBITORS OF FACTORS XI AND XII

Inhibitors directed against factors XI or XII have been reported.[440–447] Some were detected in patients with hereditary factor XI deficiency after transfusions, whereas most occurred spontaneously in patients with SLE. Many of the latter patients also had low factor XII levels. When the latter are studied with dilution, phospholipid or platelet neutralization, and dilute Russell's viper venom time tests, the diagnosis of a lupus anticoagulant becomes evident. Zucker and colleagues[443] studied several patients on long-term chlorpromazine therapy in whom asymptomatic IgM inhibitors of the intrinsic phase of blood coagulation developed. The inhibitor resulted in decreased measurements of all the plasma clotting factors in the intrinsic pathway and was shown to interfere with the coagulant activity of contact product. Some of these patients also had antibodies to various components of the contact system, including high and low-molecular-weight kininogens and factor XII.[447] Except for those with hereditary factor XI deficiency, none of the patients in whom inhibitors to the contact system developed has had excessive bleeding.

ACQUIRED INHIBITORS THAT AFFECT FIBRIN STABILIZATION, FIBRINOGEN, OR FIBRIN POLYMERIZATION

The terminal phase of blood coagulation is characterized by the cleavage of fibrinopeptides A and B from fibrinogen, polymerization of fibrin monomers, and the covalent cross-linking of the α-and γ-chains of fibrin by factor XIIIa. Spontaneously acquired inhibitors of each of these reactions have been described.

Inhibitors of fibrinogen have been reported in patients with hereditary afibrinogenemia after transfusion.[448,449] Marciniak and Greenwood[449] reported a patient in whom a polyclonal IgG antibody developed that caused a delay in the release of fibrinopeptide A from normal fibrinogen reacting with thrombin, which retarded the onset of clot formation. This patient had a prolonged PTT, prothrombin time, thrombin time, and reptilase time. The isolated inhibitor prolonged the thrombin time of normal plasma.

A high incidence of prolonged plasma thrombin time has been observed in patients with SLE. Galanakis and coworkers[450] found that two such patients had monoclonal antibodies that reacted with different parts of fibrin and fibrinogen, delaying fibrin polymerization. Autoantibodies that inhibit fibrin monomer polymerization have developed in some patients.[451,452]

Although a variety of abnormalities of hemostasis are associated with monoclonal gammopathies,[453] isolated M proteins can interfere with the conversion of fibrinogen to fibrin monomer or with the aggregation of fibrin monomers into polymers.[453–455] Coleman and associates[455] provided indirect evidence that at least some M proteins act as antibodies because Fab fragments of IgG monoclonal proteins were more inhibiting than intact protein, the isolated chains, or the Fc fragments.

Spontaneous inhibitors of fibrin stabilization can lead to severe hemorrhagic complications, some fatal.[275,456] Of the approximate 32 reported patients, several developed the inhibitor while taking isoniazid or procainamide.[5] Three other patients had SLE.[5] Non–cross-linked fibrin clots can result from neutralization of factor XIII by (1) inhibition of activation of factor XIIIa; (2) inhibition of the transamidation function of factor XIIIa; or (3) interference with the cross-linking sites on the fibrinogen substrate. Therefore, a classification scheme for the various types of factor XIII inhibitors was based on the step of the reaction sequence that is inhibited. Type I inhibitors are directed against the activation of the factor XIII zymogen but do not interfere with transamidase activity.[457] Type II inhibitors impair the transamidase activity of factor XIIIa.[5] Type III inhibitors complex with the fibrin substrate and prevent its binding by factor XIIIa. A fourth type of inhibitor was reported in which the antibody inhibits factor XIII activity by binding to the fibrin-binding site on factor XIIIa.[458] This inhibitor was characterized as an IgG antibody and disappeared with immunosuppressive therapy. Another type of IgG antibody bound the inactive and thrombin-activated factor XIII but had much greater affinity for the activated zymogen and was specific for the A subunit of factor XIII.[5] Most of the inhibitors of fibrin stabilization are IgG antibodies and usually disappear with immunosuppressive therapy or cessation of the associated drug.[5] One patient responded to rituximab.[459] Acute bleeding can sometimes be controlled by transfusion of factor XIII concentrate or cryoprecipitate.[5]

HEPARIN-LIKE ANTICOAGULANTS

The development of spontaneously acquired heparin-like anticoagulants has been reported in patients with neoplasms or those undergoing suramin therapy for the treatment of adrenocortical carcinoma.[460–465]

Reports of heparin-like anticoagulants associated with neoplastic disorders[460,461,463–466] include cases of plasma cell malignancies and a severe hemorrhagic disorder.[460,463] Coagulation studies are characterized by a prolonged thrombin time that can be corrected by the addition of protamine sulfate, toluidine blue, or heparinase to the patient's plasma. All these inhibitors possess biochemical and physicochemical properties of glycosaminoglycans. One patient treated intravenously with protamine sulfate showed an improvement in his laboratory study results, as well as decreased bleeding.[463]

A complex coagulopathy was reported in three women receiving suramin for adrenocortical carcinoma.[464] The severe hepatocellular dysfunction that developed accounted for some of the coagulopathy. Each patient acquired a potent inhibitor to the thrombin time, which increased markedly during exacerbations of hepatic injury. Anticoagulant activity was eliminated in vitro by a combination of heparitinase and chondroitinase ABC, suggesting that the activity was mediated by heparan sulfate and dermatan sulfate. Because suramin inhibits enzymes that normally degrade glycosaminoglycans, hepatic injury was hypothesized to cause the release of glycosaminoglycans, which then accumulate because of failure of degradation.

CHAPTER 132

DISSEMINATED INTRAVASCULAR COAGULATION

Howard A. Liebman and Ilene C. Weitz

Disseminated intravascular coagulation, frequently designated by its acronym DIC, is a pathologic syndrome arising from a heterogeneous group of medical disorders (Table 132–1). It is characterized by laboratory evidence of consumption and proteolytic degradation of hemostatic components. The clinical expression varies and may be manifested by laboratory abnormalities alone or in combination with hemorrhagic and thrombotic complications. Because of the variable clinical manifestations and heterogeneity of primary disorders associated with the development of DIC, the syndrome has been characterized under a number of designations, including *defibrination syndromes*, *consumptive coagulopathies*, or *consumptive thrombohemorrhagic disorders*.[1–12] Significant controversies exist in regard to the pathophysiology, diagnosis, and treatment of DIC. However, certain generally accepted clinical and laboratory observations regarding this syndrome can provide a model to assist the clinician in the diagnosis and therapy of these patients.

GENERAL PATHOGENESIS

Central to the pathogenesis of DIC is the unregulated and excessive generation of thrombin. This results in the consumption of coagulation factors that are the natural substrates of this protease, such as fibrinogen, factor V, and factor VIII. Thrombin, acting as a ligand, binds to thrombin receptors on platelets and endothelial cells[13,14] and is a potent agonist inducing platelet activation and aggregation.[15] Thrombin also induces endothelial cell release of tissue plasminogen activator (tPA).[16] In the presence of the newly formed fibrin monomer,[17] plasmin is formed from plasminogen. This results in an aggressive secondary fibrinolysis. Therefore, the clinical and laboratory manifestations of DIC result from generation of these two proteases, thrombin and plasmin. The generation of excess amounts of thrombin with relatively reduced expression of plasmin may result in large-vessel thrombosis or microvascular fibrin deposition leading to organ dysfunction and ischemic necrosis. Excessive thrombin generation with a vigorous secondary fibrinolysis may result in increased consumption of hemostatic components and bleeding. The bleeding and thrombotic manifestations of DIC are well documented in autopsy studies.[9,18–20]

INITIATION OF PHYSIOLOGIC AND PATHOLOGIC

Thrombin Generation

The physiologic formation of the hemostatic plug requires the localized and limited generation of thrombin at the site of vessel injury. DIC results from a failure of the mechanisms that limit the regulation of blood clotting and thrombin generation. This site-specific generation of thrombin is accomplished by a combination of regulatory mechanisms (Fig. 132–1). Tissue factor (TF) is expressed at the site of vessel injury. This is followed by the sequential proteolytic conversion of proenzymes to enzymes by a mechanism that involves the formation of macromolecular complexes of enzymes and cofactors on specific receptors on membrane surfaces.[21–25] The excessive generation of thrombin is limited by several natural inhibitory mechanisms. TF pathway inhibitor modulates the local effects of TF-factor VIIa expression.[26,27] The protease inhibitors, antithrombin and heparin cofactor II are bound to endothelial- and subendothelial-associated proteoglycans.[28,29] When bound to these endothelial-associated, heparin-like molecules, they become potent inhibitors of factor IXa, factor Xa, and thrombin. Thrombomodulin, a thrombin-specific receptor present on the surface of endothelial cells, binds thrombin and modifies its substrate specificity. Thrombin bound to thrombomodulin can no longer act as a procoagulant enzyme[30,31] and becomes the activator of protein C.[32] The resulting activated protein C, along with its cofactor, protein S, degrades factors Va and VIIIa, destroying their procoagulant activity.[33] The fibrin-platelet hemostatic plug is limited by a highly regulated fibrinolytic system. Plasmin, the mediator of fibrinolysis, is produced by the proteolysis of plasminogen by tPA. Plasmin rapidly degrades newly formed fibrin, reducing the size of the clot and initiating events that lead to vascular repair. DIC arises from an overwhelming of these regulatory mechanisms that leads to excessive generation of thrombin and a failure of the normal inhibitory pathways to prevent the systemic effects of the enzyme.

Although many disorders are associated with the development of DIC, initiation most often involves a common pathway (see Fig. 132–1). Initiation of DIC usually involves one or two mechanisms: mechanical tissue injury and endothelial and/or monocyte-macrophage activation and injury. Primary to both initiating pathways is the exposure of blood to excessive amounts of TF. Mechanical injury of organs rich in TF, such as brain or placenta, may result in fulminant consumption, as observed in gunshot wounds to the brain[34] or abruptio placentae.[35] A variation of tissue injury is observed in patients with malignancy-associated DIC. Malignant tissues disrupt the normal vascular hemostatic regulatory mechanisms and expose blood to tumor-associated procoagulant activity. Malignant tissues have been shown to express TF activity,[36–38] and some tumors have been shown to produce a cysteine protease capable of directly activating factor X.[36] Recent studies have shown an association between oncogenic transformation and the increased expression of tissue factor in the cancer cells.[37,38] An extreme example of malignancy-associated DIC is observed in patients with acute promyelocytic leukemia. The coagulopathy persists while the TF-rich leukemic blasts are present in blood and bone marrow.[39,40] The down-regulation of TF expression in the leukemic blasts by all-*trans*-retinoic acid, resulting in the correction of the coagulopathy, is an excellent demonstration of the importance of TF in the initiation of DIC in this disease.[41,42] Studies using sepsis or endotoxin models of DIC have clearly demonstrated the primary role of TF.[43–44] These studies have shown that the contact-phase proteins of the classic intrinsic pathway are not directly linked to the initiation of DIC and have only an ancillary role in the coagulopathy of sepsis.[45]

The intricate interactions between inflammation and coagulation have been elucidated using the model of bacterial endotoxin. Sepsis triggers a series of reactions that enhance cytokine expression and release. Levels of tumor necrosis factor (TNF), and interleukins (IL)-1, IL-6, and IL-8 are increased in response to endotoxin exposure. These cytokines, in turn, promote TF expression and thrombin generation, as well as suppression of fibrinolysis, tipping the balance in favor of the procoagulant state.[46–48] Endotoxin stimulates monocyte production of TNF. Levels of TNF increase quite early in sepsis, simultaneously with activation of coagulation. However, studies using inhibitory monoclonal antibodies to TNF show that activation

of coagulation is not inhibited by abolishing TNF activity.[49] In contrast, IL-6 has a central role in endotoxin-induced activation of coagulation because the activation could be abolished by using inhibitory monoclonal antibodies to IL-6.[50]

Resting endothelium and monocytes do not express TF.[51] Endothelial cells activated by cytokines, such as IL-1, IL-6, and TNF, or injured by endotoxin express TF activity in vitro.[52,53] Viruses and other pathogens capable of infecting endothelium are also capable of inducing increased TF expression.[54] Subsequently, TF-factor VIIa and thrombin can activate monocyte and endothelial protease-activated receptors, inducing expression of IL-6/IL-8.[55,56] Clinical studies have found elevated levels of IL-6 and IL-8 in patients with recurrent venous thrombosis, suggesting a role for these cytokines in amplifying thrombin generation.[57,58] IL-8, in conjunction with monocyte chemotactic factor, upregulates endothelial leukocyte adhesion molecules.[59,60] In murine models, blockade of leukocyte/platelet adhesion molecules combined with anticoagulants provided superior protection against the development of DIC.[61] In these circumstances, even without mechanical injury or cell death, blood is exposed to a potent procoagulant surface. The coagulation inhibitors antithrombin III, heparin cofactor II, and thrombomodulin, although highly effective in regulating the localized generation of thrombin, are overwhelmed in DIC by the more potent systemic generation of thrombin and its precursor enzymes.

The endotoxin model of sepsis-induced DIC reveals significant effects on the anticoagulant and fibrinolytic system. In addition to enhanced endothelial procoagulant activity, there is a suppression of endothelial anticoagulant properties as reflected in decreased thrombomodulin expression.[44,55,62] Levels of protein C decrease significantly in patients with sepsis-induced DIC.[63,64] Therefore, the combination of low plasma levels of protein C and decreased endothelial expression of thrombomodulin necessary for protein C activation result in a significant depression of this important antithrombotic mechanism. The physiologic importance of this protein C anticoagulant pathway is further demonstrated by the inherited deficiencies of protein C or protein S, which are associated with microvascular thrombosis and intravascular consumption, as observed in purpura fulminans of the newborn or warfarin necrosis in deficient adults.[65–68] Endotoxin has also been shown to increase plasminogen activator inhibitor synthesis and secretion, resulting in suppression of tPA-mediated activation of fibrinolysis.[69,70] In addition, thrombin-activated platelets release large amounts of plasminogen activator inhibitor-1.[70]

Antithrombin levels decrease as a result of binding to the excess thrombin generated. Significant acquired deficiencies of antithrombin are rare but can be observed in cases of overwhelming acute DIC or cases complicated by significant hepatic dysfunction.[10,71–75] Antithrombin levels of less than 60% have been associated with an

extremely high mortality rate.[74] The use of antithrombin and activated protein C concentrates has been associated with a decrease in the coagulopathy associated with severe sepsis. In vitro, antithrombin blocks the stimulatory effects of lipopolysaccharide on cultured endothelial cells and peripheral blood monocytes.[75] Induction of IL-6 and TF by lipopolysaccharide can also be blocked by antithrombin in a dose-dependent manner, independent of direct thrombin inhibition.[76] The infusion of activated protein C appears to protect against endotoxin-induced upregulation of TNF expression.[48,77] In clinical studies of patients with severe sepsis, activated protein C infusion was associated with a decrease in D-dimers and IL-6.[48] The impact of tissue factor pathway inhibitor (TFPI) in DIC associated with sepsis remains unclear. Increased, decreased, and normal levels of TFPI have been reported.[57,77]

Monocytes and neutrophils play an important ancillary role in the initiation of DIC. Monocytes activated by endotoxin or antibody-antigen complexes can express TF activity and assemble the prothrombinase complex on their membranes.[78,79] Activated monocytes also secrete the inflammatory cytokines, interleukin-1 and TNF,[80,81] which modulate endothelial procoagulant activity.[53,54]

Activated platelets expressing P-selectin also induce monocyte TF expression. Platelet-activating factor, another monocyte-derived cytokine, induces additional platelet activation and aggregation[82] and increases vascular permeability.[83] Activated neutrophils release a number of cellular enzymes that can injure endothelium and degrade subendothelial matrix.[84] Neutrophil elastase has been shown to degrade and inactivate a number of coagulation proteins and inhibitors, including factor V, factor VIII, antithrombin III, TFPI and plasminogen activator inhibitor.[85–89]

The variable clinical expressions of DIC result from this complex interaction of thrombin, plasmin, proteolytic inhibitors, platelets, endothelium, monocytes, and neutrophils. The underlying disorders that initiate DIC, such as sepsis, malignancy, or mechanical tissue injury, may trigger different hemostatic and cellular pathways for thrombin and plasmin generation, resulting in a clinical pathologic process that favors thrombosis or consumption with bleeding. The intensity and duration of hemostatic activation can result in a fulminant (acute), subacute, or chronic presentation. Fulminant DIC is usually characterized by coagulation factor consumption and bleeding. The chronic forms of DIC are more frequently characterized by thrombotic manifestations. However, in a significant number of cases, there are few or no clinical manifestations of DIC exclusive of the abnormal laboratory findings. Morbidity and mortality in these patients predominantly result from the underlying disease, and no specific treatment for the DIC is indicated.[90–93]

DIAGNOSIS OF DIC: CLINICAL AND LABORATORY FINDINGS

Clinical Features

The clinical manifestations of DIC are frequently obscured by the clinical features associated with the primary initiating illness (see Table 132–1). There is considerable variation in the frequency of specific clinical findings described in different case series, which probably reflects differences in the underlying primary disorders reported in each study.[7,9,10,91,92] Many of the clinical findings ascribed to DIC in early case series, such as adult respiratory distress syndrome (ARDS) or acute tubular necrosis, are probably a direct result of the primary illness, shock, and hypoperfusion. Their onset frequently has no direct relationship to the initiation of DIC and may precede its appearance. However, the microvascular thrombosis associated with DIC may aggravate multiorgan dysfunction, and less frequent pathologic features, such as pulmonary hemorrhage and renal cortical necrosis may be directly linked to the development of DIC.[7,9,10,18,20,91]

Bleeding is the predominant clinical manifestation observed in DIC and is reported in 70% to 90% of patients.[7,9,10,91,92] Cutaneous, gastrointestinal, genitourinary, and pulmonary bleeding, along with bleeding at surgical sites, are the most frequently reported. However, in earlier case series, the definition of DIC was based primarily on laboratory studies that clearly defined a patient population with severe consumption of hemostatic components, including fibrinogen and platelets. Studies that use laboratory criteria of DIC based primarily on markers of thrombin generation find many more cases of DIC without clinical evidence of bleeding than previously reported.[93,94,95]

Overt thromboembolic manifestations have been less frequently observed in DIC and have been reported in 10% to 40% of patients.[7,9,10,91,92] In patients with cancer, laboratory evidence of thrombin generation is frequently present without evidence of severe coagulation factor or platelet consumption.[94–100] However, activation of coagulation pathways in the patient with cancer usually results in thromboembolic manifestations.[98–100]

Laboratory Features

Laboratory studies used in the diagnosis and evaluation of patients with DIC can be characterized as tests of thrombin and plasmin generation and screening tests for hemostatic function that delineate the severity of coagulation factor consumption (Table 132–2). Although abnormalities in the screening assays, such as the prothrombin time (PT), partial thromboplastin time (PTT), or platelet count may provide important corroborative evidence of hemostatic component consumption, the diagnosis of DIC should not be made without at least one positive test indicative of excessive thrombin generation. The two most readily available studies that document the excess activity of thrombin are immunoassays for D-dimers and the protamine paracoagulation assay for fibrin monomer.[96,101–106] D-dimers are the proteolytic by-products of plasmin degradation of cross-linked fibrin monomers. In contrast, to the older assays for fibrin/ fibrinogen degradation products (FDP), which do not distinguish between the plasmin degradation by-product of fibrin or fibrinogen, the formation of D-dimers requires prior formation of fibrin monomer, which is cross-linked by factor XIIIa. The formation of fibrin monomer and the generation of factor XIIIa from its zymogen require thrombin. When using the D-dimer assay as the only laboratory marker of thrombin generation, caution must be exercised in interpreting abnormal results in patients who have had recent surgery, bleeding into tissues, cirrhotic liver disease, or renal failure. In each of these clinical circumstances, D-dimers can be moderately elevated without DIC. Therefore, patients with D-dimer levels less than 2000 ng/mL

should not be diagnosed as having DIC unless there is other corroborating evidence.[93,101,102,104]

The protamine paracoagulation test detects the presence of excess soluble fibrin monomer, which is associated with fibrinogen in plasma. The presence of fibrin monomer documents prior action of thrombin on fibrinogen. This assay can be particularly helpful in clinical circumstances when there may be other disorders that could contribute to elevations in D-dimers. However, the assay is difficult and is most reliable when the laboratory has extensive experience performing this assay. Additional assays of thrombin generation that have been used in the evaluation of patients with DIC include the ethanol gel assay for fibrin monomer,[105] immunoassays for fibrinopeptide A,[106] thrombin-antithrombin complexes,[107] and prothrombin fragment $1 \cdot 2$.[108] However, the routine clinical use of these assays is limited by their cost and complexity for simple and rapid laboratory screening. In addition, the latter three immunoassays have an excessive degree of sensitivity to thrombin generation, and positive results may not reflect clinically significant DIC.

Laboratory studies that delineate the severity of hemostatic component consumption in the patient with DIC include quantitative platelet counts and screening assays for plasma coagulation function. The screening tests include the PT, PTT, and thrombin time. Prolongations of the PT, PTT, and thrombin time assays result from the combined primary and secondary consumption of coagulation factors. Plasmin generated by secondary fibrinolysis results in the proteolytic degradation of factors, including fibrinogen and factors V, VIII, and XII. The intermediate plasmin degradation products of fibrin inhibit fibrin polymerization, which further contributes to the prolongations observed in these assays.[109] The results from these screening assays provide the information necessary for appropriate decisions regarding replacement treatment. These screening tests direct the clinician toward a diagnosis of acute DIC.

In five case studies of acute DIC, combining more than 900 patients, the most frequent laboratory abnormalities reported, in decreasing order of frequency, were thrombocytopenia, elevated fibrin degradation products, prolonged PT, prolonged thrombin time, prolonged PTT, and a low fibrinogen.[7,9,10,91,92] Although deficiencies of nearly every coagulation factor have been reported, acquired deficiencies of factor V and fibrinogen are the most frequently observed in patients with acute DIC. A fibrinogen less than 100 mg/dL, in the absence of severe liver disease, is invariably associated with acute DIC, usually associated with bleeding manifestations, and denotes a poor prognosis.[7,9,10]

In chronic DIC syndromes, the degree of clotting protein consumption may be limited and can be balanced by hepatic synthesis of coagulation factors, resulting in only minor abnormalities in the screening assays. Platelet counts may be at low normal levels and fibrinogen levels can be normal because hepatic synthesis of fibrinogen can be significantly upregulated by inflammatory cytokines.[110] In these circumstances, the presence of high levels of the markers of thrombin generation, in the appropriate clinical settings, may be sufficient to make the diagnosis of DIC.

Despite the presence of a significant secondary fibrinolysis, screening assays for increased fibrinolysis, such as the dilute whole-blood clot lysis test or euglobulin clot lysis test, usually give normal results in patients with DIC.[7,10] However, the use of these screening assays should be considered in clinical circumstances, such as DIC in association with severe liver disease,[111] in acute promyelocytic leukemia,[112,113] heat stroke,[114] amniotic fluid embolism,[115] or metastatic prostate carcinoma.[116] The clinician should be aware that there can be false-positive studies if these screening tests are performed in patients with fibrinogens less than 100 mg/dL.

The presence of thrombocytopenia, the most frequent laboratory abnormality observed in patients with DIC, should always direct the clinician to a review of the peripheral blood film. Fragmented red blood cells, although reported in patients with DIC, rarely constitute greater than 10% of the red cells.[10] However, in some cases of chronic DIC with elevated D-dimers but normal coagulation screening assay results, the presence of fragmented red cells may provide supportive evidence. In contrast, disorders, such as acute leukemia, sepsis, and thrombotic thrombocytopenic purpura can result in significant thrombocytopenia and a markedly abnormal blood film without laboratory evidence of DIC.

The diagnosis of DIC should never be made based solely on laboratory abnormalities but must include consideration for the underlying primary initiating illness and the patient's clinical presentation. Several scoring systems combining clinical and laboratory data have been devised to assist in the diagnosis and determination of prognosis of patients with DIC.[117,118,119,120] Proposed in 2001, the International Society of Thrombosist Haemostory (ISTH) scoring system uses a combination of risk assessment and simple, widely available coagulations assays. The scoring system appears to be both sensitive (93%) and specific (98%) in diagnosing patients with overt and nonovert DIC (Table 132–3).[117,118,120,121] The algorithm is similar to that used by the Japanese Ministry of Health Working group (JMHW).[119] Correlation with the Acute Physiology and Chronic Health Evaluation II (APACHE II), logistic organ dysfunction (LOD), and Sequential Organ Failure Assessment (SOFA) score have validated the usefulness of the ITSH scoring system.[122] The ISTH scoring system for DIC is only valid if the patient has a clinical syndrome that would lead to DIC.[117,118,120,122] A scoring system proposed by the Japanese Association of Acute Medicine (JAAM) expands on the JMHW by incorporating criteria for the systemic inflammatory response syndrome (SIRS), as well as the rate of decrease of the platelet count.[119] A recent prospective comparison of the algorithms used in the three scoring systems, the JAAM demonstrated a higher sensitivity rate (97%), but the specificity is unclear.[119,123] The prospective use of the ISTH scoring system is particularly useful in predicting 28-day mortality.[118,120,123] This may lead to earlier intervention and perhaps improvement in mortality.

Differential Diagnosis of Disseminated Intravascular Coagulation

A number of clinical disorders not associated with DIC can result in an acquired bleeding diathesis and significant laboratory hemostatic laboratory abnormalities. Thrombocytopenia can result from primary bone marrow failure; an infiltrative marrow process, such as leukemia; endothelial-mediated platelet activation, such as in vasculitis or thrombotic thrombocytopenic purpura; or immunologic destruction. A difficult clinical problem occurs in the patient with sepsis.[124,125] Sepsis without DIC can be associated with a variable degree of thrombocytopenia; however, sepsis with platelet counts less than 50,000 is most often associated with DIC.[124,125]

A rare syndrome of primary fibrinolysis occurs with the independent generation of plasmin without concomitant thrombin generation.[126–130] Such patients can have low fibrinogen, and elevated fibrin degradation products. In addition, patients with liver disease and primary fibrinolysis with portal hypertension may have thrombocytopenia secondary to splenic sequestration. Therefore, the differential diagnosis in these patients may prove difficult. In these patients, the dilute whole-blood clot lysis and euglobulin clot lysis tests are significantly shortened, and the protamine paracoagulation assay is negative for fibrin monomer. Despite significantly elevated fibrin degradation products, the D-dimer assay results are normal or only minimally elevated.[130]

CLINICAL PRESENTATIONS

Acute and Subacute DIC

Infection

Bacterial sepsis is a common cause of acute DIC. Thrombin generation results from bacterial or endotoxin-associated endothelial cell perturbation and monocyte activation, leading to enhanced TF activity and inflammatory cytokine secretion.[22,43,44,53,54,62] Gram-negative

organisms are more commonly associated with sepsis and DIC, although cases are associated with gram-positive sepsis.[124,125] Infection with viruses, such as varicella, rubella, rubeola, and influenza, along with intracellular pathogens, such as *Mycobacterium tuberculosis*, can also lead to DIC through enhanced endothelial and monocyte TF activity.[131–135] Fungal infections and malaria have similarly been complicated by DIC.[136–138]

There is a wide range of clinical manifestations of sepsis-associated DIC. Many cases are characterized by laboratory changes without bleeding or clinical evidence of microthrombus formation. Examples of clinical entities at the other end of the spectrum include Waterhouse-Friderichsen syndrome and purpura fulminans. The Waterhouse-Friderichsen syndrome is rare and is most often seen in association with fulminant meningococcal sepsis.[139,140] It is characterized by widespread intravascular fibrin deposition and platelet thrombi that lead to microvascular obstruction of vital organs, along with hemorrhagic necrosis of the adrenal glands. The latter leads to significant, often irreversible shock associated with a high mortality

rate. Virtually any gram-negative organism can cause DIC. The gram-positive bacterial infections associated with DIC often involve encapsulated organisms, such as pneumococci. The overwhelming infection observed in those with diminished circulatory clearance because of functional or anatomic asplenia is frequently implicated.[141] Clostridial species are also associated with severe DIC because of septic abortion, which carries a very high mortality rate.[142,143]

Purpura Fulminans

Purpura fulminans is a rare, severe skin disorder associated with DIC that primarily affects children and infants. Extensive areas of skin develop blue-black hemorrhagic necrosis, and biopsy typically reveals small-vessel microthrombi and vasculitis. Distribution of necrotic areas typically depends on the clinical setting. Patients are acutely ill with fever and hemorrhage from multiple sites, are hypotensive, and manifest typical laboratory signs of DIC.[144,145] The pathogenesis of purpura fulminans is unknown, but histologic findings have been likened to the animal model of consumptive coagulopathy, the local Shwartzman reaction.[144] It has also been suggested that the development of purpura fulminans in meningococcemia may result from acquired defects in the protein C pathway because similar lesions are seen in two other protein C deficiency states, namely, neonatal purpura fulminans and warfarin-induced skin necrosis.[145–148]

Purpura fulminans occurs in three clinical settings.[148] In acute sepsis-associated or secondary purpura fulminans, the initial presentation is one of overwhelming infection that is most commonly meningococcemia but has been reported with many other gram-positive and gram-negative organisms.[147,149,150] Patients are hypotensive with reduced peripheral perfusion contributing to skin necrosis on distal extremities; alternatively, skin necrosis can occur in a patchy distribution.[150–158] Idiopathic purpura fulminans can manifest within 10 days of an antecedent illness, most commonly scarlet fever and varicella in children. Most skin lesions are localized to the breasts or lower half of the body. Third, purpura fulminans can be seen in association with homozygous protein C deficiency in affected neonates, in whom massive intravascular thrombosis and abdominal wall gangrene can also develop.[65–68,155] Acquired inhibitors of the protein C pathway can also be associated with this presentation.[156] Patients with warfarin-induced skin necrosis may present with a similar but usually less severe form of purpura fulminans and warrant consideration of protein C or protein S deficiency.[72,157,158] The mortality rate has recently been significantly reduced in purpura fulminans, largely because of more widespread use of therapeutic heparinization in these patients and aggressive transfusion support factor replacement.[145,146,159]

Obstetric Complications

Pregnancy predisposes patients to DIC through the generation of a hypercoagulable state manifested by increased levels of most coagulation factors along with reduced fibrinolytic activity because of decreased tPA production and increased plasmin activator inhibitor levels.[160,161] Overt clinical DIC manifestations occur when these baseline conditions are complemented by the occurrence of any of a number of acute obstetric complications that lead to the release of TF or endothelial cell perturbation, followed by consumption of clotting factors and enhanced fibrinolysis.

The manifestations of DIC associated with obstetric complications are varied, with different grades of severity noted depending on the degree of hypofibrinogenemia and depletion of other clotting factors seen in each case. Because of this variation and baseline pregnancy-associated coagulation abnormalities, it is prudent to consider serial assessment of coagulation parameters when DIC is suspected to detect progressive alterations over time. Similarly, the coagulopathy may be localized to the uterus or disseminated through the blood.

Abruptio placentae, or placental detachment, has a wide range of clinical presentations—from incidental detection on pathologic examination of the placenta, to vaginal bleeding, to pronounced DIC with accompanying shock, bleeding, severe abdominal pain because of uterine contractions, and fetal death.[161,162] The exact causes of placental abruption, outside of trauma, and the subsequent processes leading to DIC remain unclear. Placenta is rich in TF activity, which likely is an important component of the DIC pathophysiologic process.[160,161] Hypofibrinogenemia has been documented in 38% of abruptio placentae cases, which implies that potentially serious and life-threatening DIC is present in a significant number of patients.[32]

Amniotic fluid embolism is a rare, usually fatal catastrophe occurring in 1 in 8000 to 1 in 80,000 deliveries. Amniotic fluid is introduced into the circulation of multiparous, postmature women with large-for-date fetuses and in those undergoing long and vigorous labor after induction.[161–165] DIC is triggered by amniotic fluid TF and an activator of factor X.[161–165] The extensive occlusion of the pulmonary arteries that causes sudden dyspnea, cor pulmonale, shock, and seizures is a result of blockage with fetal debris and meconium. This, in turn, enhances local platelet-fibrin thrombus formation. There can be secondary fibrinolysis, further contributing to defibrillation and bleeding. This is followed after a latent period of up to 3 hours by severe bleeding in 37% of cases.[166] The mortality rate associated with this condition, primarily caused by respiratory failure, is greater than 80%.[164] As with abruptio placentae, the pathogenetic mechanism for the clinical manifestations is unclear. Because of the rapid course of this complication and its infrequency, specific treatment modalities, such as heparin and fibrinolysis inhibitors have not been adequately assessed but may be considered in individual cases. Red cell and coagulation factor replacement therapy warrants consideration in patients with active bleeding, along with pulmonary and hemodynamic support.

Sepsis during pregnancy is often caused by gram-negative bacteria and *Clostridium* species, with the patient being particularly susceptible to DIC under these circumstances. Septic abortions are often associated with severe DIC, accompanied by endotoxin-mediated shock and a high mortality rate.[166] Virtually any organism can be associated with septic abortion. In addition, saline-induced abortion during the second trimester without sepsis also has a clear association with hypofibrinogenemia, thrombocytopenia, and increased fibrin degradation products.[167,168]

Malignancies

Cancer can be associated with acute or chronic DIC, depending primarily on the type of cancer. Malignancy-associated chronic DIC associated with solid tumors is reviewed later in the chapter, whereas acute DIC associated with leukemia is discussed here. DIC has been associated with acute myelocytic and lymphocytic leukemia, chronic myeloid and myelomonocytic leukemia, hairy cell leukemia, and angioimmunoblastic lymphadenopathy.[169–180] Among these diagnostic entities, acute promyelocytic leukemia is most commonly associated with life-threatening hemorrhage secondary to DIC and other hemostatic abnormalities.

The pathogenesis of DIC associated with acute promyelocytic leukemia has remained controversial; consequently, the optimal therapeutic approach associated with this condition remains unclear. Leukemic cells from patients with acute promyelocytic leukemia have been found to harbor TF, a factor X-activating protease, and to produce IL-1.[169–171,176,181,182] Increased levels of prothrombin fragment 1·2 and thrombin-antithrombin III complexes have also been described in these patients and document the excessive generation of thrombin in this leukemia.[183]

Investigators have also provided evidence for primary fibrinogenolysis as a contributing factor associated with serious bleeding seen in patients with acute promyelocytic leukemia. In this respect, urokinase-type plasminogen activator and tPA have been found in acute promyelocytic leukemia cells along with reduced plasma activity of plasminogen activator inhibitor and reduced α_2-antiplasmin plasma

levels.[109,184–193] It is likely that DIC and primary fibrinogenolysis contribute to bleeding in the patient with acute promyelocytic leukemia.

Although bleeding predominates in acute promyelocytic leukemia, thromboembolic complications have been noted in up to 5% of patients and 15% to 25% of autopsy results.[192–195] One study suggested that acute promyelocytic leukemia cells from a patient with coagulopathy did not, in fact, have procoagulant activity, but rather were capable of elaborating IL-1 that induced endothelial TF activity when mixed with endothelial cells.[190]

Acute promyelocytic leukemia-associated bleeding as a result of DIC is further exacerbated by thrombocytopenia because of marrow suppression. Once treatment is initiated, subclinical DIC often becomes clinically apparent because of chemotherapy-induced acute promyelocytic leukemia cell lysis.[195] The incidence of coagulopathy- and hemorrhage-related mortality associated with acute promyelocytic leukemia-has significantly decreased since the introduction of the differentiating agent all-*trans*-retinoic acid into induction regimens, with bleeding frequently abating within 48 hours of treatment initiation.[38,195]

Tissue Injury, Burns, and Heat Stroke

Extensive trauma and burns are often associated with localized and disseminated intravascular coagulation. This is particularly true if there is a component of head injury associated with multiple trauma because brain parenchyma is rich in TF. In this respect, laboratory-based "DIC scores" have been shown to have prognostic value in patients with head injury.[196–197] Studies have demonstrated a high mortality rate when head injuries are accompanied by bleeding and laboratory evidence of DIC, along with a correlation between time to treatment after trauma and the development and extent of DIC.[197–199]

Extensive exposure of circulating blood to TF is probably the most prevalent causative factor in trauma-associated DIC. Other possible contributions to this clinical picture may relate to dilutional coagulopathy caused by blood loss or replacement with crystalloid solutions and packed red cells alone; ischemic or trauma-associated hepatic dysfunction with reduced clotting factor and natural inhibitor synthesis; and ARDS.

Massive trauma is often accompanied by ARDS, to which hypotension followed by aggressive fluid replacement contribute. Obstruction of the pulmonary circulation secondary to multiple thrombi may also contribute to ARDS.[200,201] One study noted that among 30 patients with ARDS, 7 had evidence of additional thrombotic microangiopathy in the skin and kidneys, whereas an additional 12 had thrombocytopenia, and 4 had pulmonary vessel fibrin deposition on postmortem examination.[201]

Serious trauma cases involving multiple fractures, usually (but not always) can lead to fat embolism within the first 48 hours.[202,203] This is associated with respiratory distress and neurologic impairment secondary to marrow fat emboli from associated fractures. If the pulmonary picture is complicated by ARDS, laboratory evidence of DIC may also be present because of endothelial perturbation, TF expression, and inhibition of fibrinolysis.[203]

Burns can be associated with DIC through release into the circulation of TF from damaged tissues expressing TF, often with associated hypovolemic shock and infection, which occur later in the clinical course. In addition to DIC, significant local consumption of clotting factors has also been associated with burns.[204]

DIC and primary fibrinogenolysis have been demonstrated in association with heat stroke, a syndrome defined as a body temperature greater than 42° C (107.6°F) caused by collapse of thermoregulatory mechanisms.[205,206] Pathophysiologic mechanisms associated with the disorder include TF expression from damaged tissues and endothelial cell perturbation.[207] Extensive fibrin deposition with subsequent increased release of plasminogen activators and secondary fibrinolysis has been associated with the generalized bleeding and multiorgan failure accompanying fatal cases of heat stroke.[208]

CHRONIC DIC

Malignancies

The association between solid tumors and thrombotic and bleeding symptoms was initially described by Trousseau in 1865. *Trousseau syndrome* refers to spontaneous recurrent or migratory venous thrombosis or arterial emboli because of nonbacterial thrombotic endocarditis, or both, occurring in the setting of malignancy.[209] There is a spectrum of thrombohemorrhagic diagnostic entities seen in association with solid tumors, including low-grade DIC, venous thromboembolic disease, primary fibrinogenolysis, microangiopathic hemolytic anemia, and nonthrombotic valvular endocarditis.[210] These different disorders can present singly or multiply at any location and with any degree of acuteness or chronicity.

DIC associated with solid tumors demonstrates pathophysiologic mechanisms similar to those of the DIC seen with acute promyelocytic leukemia. These include TF secreted by tumor cells and activated monocytes.[211] A factor X-activating cysteine protease has been described in human carcinoma tissue.[36,37] Tumor cells or media conditioned by these cells induce platelet aggregation in vitro and in vivo.[212]

In a retrospective study of 1117 patients with solid tumors, a clinical and laboratory diagnosis of DIC could be made in 76 (6.8%) patients.[214] In multivariate analysis, older patients, male patients, patients with advanced-stage tumors, and patients with breast cancer were statistically more likely to develop DIC.[214] Chronic DIC is classically associated with thrombosis. Among the many studies done in the area of thrombosis and bleeding in association with solid tumors, one group documented deep venous thrombosis in 113 of 182 (62%) patients with cancer. Ninety-six of the 182 (53%) manifested migratory thrombophlebitis; 41 (23%) demonstrated nonbacterial thrombotic endocarditis, a disorder classically associated with mucin-producing carcinomas; and 75 (41%) had bleeding manifestations.[215]

Classic laboratory findings associated with chronic DIC and solid tumors include thrombocytopenia and circulating fibrin degradation products. Hypofibrinogenemia also occurs but is less common. Microangiopathic hemolytic anemia may occur in the absence of other DIC laboratory abnormalities, usually in association with disseminated mucin-secreting adenocarcinoma. Laboratory manifestations of increased thrombin generation are seen in patients with solid tumors and may not be accompanied by clinical thrombosis or bleeding.

Primary fibrinogenolysis is primarily seen in patients with prostate cancer and acute promyelocytic leukemia. These tumors are capable of producing activators of plasminogen and thrombin.[115,216] Biopsy of prostate tumors is sometimes accompanied by prolonged postoperative bleeding as a result of this phenomenon, and hemorrhagic manifestations can dominate the clinical picture.[217]

Dead Fetus Syndrome

The dead fetus syndrome occurs several weeks after intrauterine fetal death and can be accompanied by DIC.[218,219] The clinical syndrome is usually one of insidious-onset DIC mediated by TF from the placenta or dead fetus entering the maternal circulation over the ensuing days, eventually causing bleeding. Serial laboratory monitoring of the mother after diagnosis of intrauterine fetal death is warranted to detect possible progressive coagulopathy; in this event, immediate evacuation of uterine contents is indicated.

Localized Intravascular Coagulation

Aortic Aneurysm

Extensive aortic aneurysms have been associated with significant laboratory abnormalities and bleeding secondary to platelet and

fibrinogen consumption.[220] These complications are characteristically associated with extensions and enlargements of the dissecting aneurysm, which are often accompanied by sudden onset of severe pain. In one series of patients with aortic aneurysms, 40% had chronically elevated levels of fibrin split products, with 4% showing evidence of significant bleeding and laboratory findings of DIC.[220]

Hemangiomas

Kasabach and Merritt were the first to report localized intravascular coagulation in association with hemangiomas.[221] These are usually benign tumors seen mostly in infants and children that typically enlarge over time. They are associated with consumption of platelets and fibrinogen as demonstrated by radiolabeling studies showing intravascular clotting and excessive fibrinogenolysis (the latter caused by tPA release from abnormal endothelium of tumor vessels).[222–225] Microangiopathic hemolytic anemia has also been observed in this setting along with laboratory evidence of DIC.[225,226] Clinical DIC and emboli to other organs, however, usually are not seen in association with hemangiomas. Severe bleeding is normally noted only after surgery or other invasive procedures associated with the hemangioma.[226]

Liver Disease and DIC

Patients with advanced liver disease are prone to a plethora of hemostatic and thrombotic derangements that are often very difficult to classify and successfully manage. Alterations in hepatic synthesis and hepatic and renal clearance of activated coagulation, fibrinolytic, and natural inhibitor proteins, along with the thrombocytopenia and the deranged hemodynamics typically seen in this patient population, collectively contribute to the difficulties encountered.

In those with advanced or acute, severe liver disease, the clinician may expect to find decreased hepatic synthesis of most coagulation proteins, protein C, protein S, antithrombin III, and plasminogen, along with α_2-antiplasmin. The liver also demonstrates defective clearance of activated clotting proteins.[227,228] Portal hypertension leads to splenomegaly with enhanced platelet sequestration and thrombocytopenia.

Given these circumstances, the issue of whether DIC is directly associated with liver disease, as opposed to the observation that these patients may simply be more sensitive to DIC, is an unsettled one. Experimental observations suggest the existence of an association[229–235] or support the hypothesis that these hemostatic derangements may stem from disorders other than DIC.[236–239]

As is the case with the pregnancy-associated disorders, the diagnosis of DIC in patients with liver disease and generalized bleeding not caused by a local source is most readily appreciated by following serial hemostatic parameters and noting a significant reduction in these values over a short period of time. If available, tests reflecting thrombin generation, such as the protamine paracoagulation assay, the prothrombin fragment 1·2 or thrombin-antithrombin III complex levels, along with D-dimer levels, can also contribute to establishing the diagnosis.

Disseminated intravascular coagulation is also seen after the placement of peritoneovenous (LeVeen) shunts for complications associated with massive ascites. The incidence is variously quoted in different studies as ranging from 3% to 91%, and may depend on whether the primary disease is peritoneal or hepatic in origin.[240–246] Ascitic fluid possesses TF activity in association with monocytes and thrombin activity, which likely contribute to the DIC.[244,246] Clamping the shunt is the only effective treatment in severe cases because heparin and antithrombin III concentrates have not proved efficacious.[245]

Fatty liver of pregnancy has also been associated with DIC on the basis of labor-induced protein factor and platelet consumption in the presence of decreased synthesis of the clotting factors and natural inhibitors.[247] The clinical and laboratory features have been attributed to low plasma antithrombin III levels, and patients have responded to antithrombin III concentrate.[248]

TREATMENT OF DIC

General Measures and Replacement Therapy

Given the heterogeneity of the underlying disorders with which DIC is associated, the difficulties often encountered with determining the extent of consumption of clotting factors and fibrinogenolysis in each case, and the relative lack of well-controlled studies of treatment of homogeneous subgroups with DIC, many aspects of treatment of DIC are controversial. Part of the problem resides with the fact that studies are very difficult to perform in view of the variety of pathophysiologic triggers and clinical presentations associated with DIC. DIC is one disorder in which management has to be individualized, with careful attention to variables, such as the initiating illness and the presence of bleeding or thrombosis.

The cornerstones of management of DIC include aggressive basic support measures, paying close attention to circulatory volume status, gas exchange, and electrolyte balance, along with prompt, vigorous treatment of the underlying cause of the DIC. This includes, for example, intravenous antibiotics for gram-negative septicemia, prompt uterine evacuation for abruptio placentae, and restoration of hemodynamic stability for hypovolemic shock. The other management components of the disorder include determining whether replacement of depleted platelets or clotting factors is necessary and whether attempted abrogation of the DIC with heparin or natural inhibitors should be considered.

The idea that blood replacement therapy may be "fueling the fire" of DIC has never been proved (see box on Replacement Therapy for DIC). Transfusion of platelets, cryoprecipitate, and fresh frozen plasma should be reserved for those with clear laboratory evidence of DIC and bleeding or a pending invasive procedure. It is typically most effective in those with very low platelet and fibrinogen levels in whom DIC is self-limited or concluded.

Patients with head injury-associated brain tissue destruction are particularly prone to acute, limited defibrination (hypofibrinogenemia, elevated levels of serum fibrinogen-related or fibrin-related split products, and low levels of factors V and VIII or platelets), in which laboratory abnormalities often return toward normal within hours.[31] These patients benefit from rapid, optimal correction of hemostatic deficiencies to minimize the neurologic consequences of intracranial bleeding, whereas heparin therapy to prevent ongoing intravascular coagulation is not helpful because of the associated intracranial bleeding risk.

Platelets should ideally be maintained at more than 20 to 30 $\times$ 10^9/L in a bleeding patient, whereas those who are undergoing procedures or who have concurrent functional impairment or significant blood loss should have higher counts. Cryoprecipitate should be given to maintain plasma fibrinogen greater than 100 mg/dL, whereas fresh frozen plasma is indicated to correct a prolonged PT and PTT in appropriate clinical circumstances. To determine the efficacy of transfusion, platelet and fibrinogen levels should be checked 30 to 60 minutes after the transfusion and every 6 hours after that. Replacement therapy may be required every 8 hours while the underlying cause of the DIC is being addressed. Transfusions can be discontinued when the coagulation parameters are almost or fully normalized and symptoms have abated. If laboratory parameters fail to improve with transfusions because of DIC-associated bleeding, a concurrent heparin infusion may warrant consideration.

The Role of Heparin in DIC Management

Heparin should be considered in the management of DIC if (1) a patient has strong clinical and laboratory evidence of DIC and thromboembolic manifestations predominate (eg, purpura fulminans, dead fetus syndrome before induction, aortic aneurysm before

Replacement Therapy for DIC

The symptoms and abnormal laboratory findings associated with DIC are most readily addressed through the prompt recognition and treatment of the underlying disorder. Until the underlying cause can be definitively managed, blood product replacement therapy warrants consideration in the patient with significant bleeding or a planned procedure and coagulation parameters compatible with DIC. Replacement folate and vitamin K therapy also warrant consideration in any patient with prolonged DIC.

Platelet transfusions should be considered to maintain the count greater than 20 to 30 $\times$ 10^9/L in a bleeding patient, although aiming for higher values if concurrent functional impairment is present, a procedure is planned, or blood loss is significant. DIC-associated thrombocytopenia does not usually reach levels of 20 $\times$ 10^9/L, without concurrent contributing factors, such as sepsis. One unit of donor platelets is expected to contain at least 5.5 $\times$ 10^9 platelets and increases the count 6 to 8 $\times$ 10^9/L, assuming normal splenic pooling. The platelet count should be repeated 10 to 60 minutes after the first transfusion to confirm the expected increment, and every 6 hours after that. Poor postplatelet transfusion increments are often seen in consumptive thrombocytopenia, making transfusion support difficult under these circumstances.

Cryoprecipitate administration is considered in a symptomatic patient to maintain plasma fibrinogen more than 100 mg/dL. The fibrinogen content of each cryoprecipitate unit varies from 100 to 250 mg, depending on variable storage volumes and pooling methods. From 1 to 4 units/10 kg can be given, with the postinfusion increment checked 30 to 60 minutes later and followed by repeat determinations every 6 hours.[249]

Fresh frozen plasma is given if significant DIC-associated bleeding is accompanied by a prolonged PT and PTT. The aim is to reduce the PT, with the target in each case dependent on the nature and extent of bleeding, the presence and extent of coexisting hemostatic defects, and whether a procedure is planned and its attendant bleeding risk. This is accomplished by administration of 10 to 15 mL/kg of plasma.[249] Each milliliter of plasma contains 0.7 to 1 unit of activity of each clotting factor and 1 to 2 mg of fibrinogen, so an alternative formula to 10 to 15 mL/kg incorporates estimated plasma volume, desired factor level increment, and the half-life of the factor being replaced into the equation. The PT and PTT should be checked every 6 hours and plasma given as needed based on the patient's clinical response. Depending on clinical circumstances, bleeding patients with DIC given plasma transfusions can exhibit poor clinical and laboratory responses, particularly if advanced liver disease with coexistent diminished clotting factor synthesis and altered hemodynamics complicate the picture.

Heparin in the Management of DIC

The circumstances under which a trial of heparin should be considered in the management of a patient with clinical and laboratory evidence of DIC are outlined in the text. In general, if the clinical setting is more compatible with chronic DIC (eg, secondary to solid tumor), the picture is more likely to be complicated by thromboembolic phenomena rather than bleeding, which necessitates consideration of heparin therapy.

If an initial heparin bolus is indicated, one nomogram suggests 80 units/kg intravenously can be given, followed by an 18 units/kg/h infusion.[250] Heparin has variable sensitivity to different thromboplastin reagents incorporated in individual laboratory PTT assays. Therefore, any laboratory nomogram used in heparin dosing needs to have its dosing recommendations based on the therapeutic range for the local PTT reagent tailored to corresponding heparin levels of 0.2 to 0.4 units/mL by protamine titration or anti-factor Xa levels of 0.3 to 0.7 units/mL. If no bolus is indicated, patients can be started on an 18 units/kg/h infusion. The PTT, heparin level, or anti-factor Xa level should be checked 6 hours after the start of therapy, and dosage adjustments made accordingly.[250]

For long-term outpatient therapy (eg, for solid tumor-associated chronic DIC), it is also possible to achieve therapeutic heparin levels through subcutaneous injection, with its anticoagulant effect occurring 1 hour later and peak levels after 3 hours. Typically, 35,000 units are given daily, divided into two doses 12 hours apart, with a PTT drawn 6 hours after a dose, and subsequent dosage adjustments made based on the result. Serial heparin or anti-factor Xa levels may be preferable for monitoring if the baseline PTT is prolonged. If an initial rapid effect is desired, a 5000 unit intravenous heparin bolus can be given before the initial subcutaneous dose. Efficacy of heparin treatment can be monitored by changes in D-dimer, fibrinogen, and platelet levels.

Early evidence suggests a potential role for low-molecular-weight heparin in the prevention and management of DIC in association with acute promyelocytic leukemia and Trousseau syndrome.[251,252,253] In this case, low-molecular-weight heparin may be administered subcutaneously in prophylactic doses, enoxaparin 30 mg every 12 hours, or therapeutically at 1 mg/kg every 12 hours, dalteparin doses are 5000 units daily or 200 units/kg every 24 hours, or tinzaparin 75 units/kg to 175 units/kg daily.

surgery); or (2) intensive blood replacement therapy fails to alleviate excessive bleeding and increase the level of coagulation proteins. These circumstances notwithstanding, it is important to consider that heparin is less likely to lead to clinical improvement in DIC once it is established and ongoing, which is usually the case by the time it is diagnosed. Heparin is also capable of exacerbating DIC-associated bleeding in these populations and should be used very cautiously. For these reasons, heparin usually has a limited role, if any, in acute DIC.

In chronic DIC associated with solid tumors, the dead fetus syndrome, or hemangiomas, continuous heparin infusion without a loading bolus can be given with blood products if the clinical picture warrants treatment (eg, deteriorating coagulation parameters in dead fetus syndrome, thrombosis, or before chemotherapy). Patients with solid tumors can be given long-term, adjusted-dose subcutaneous unfractionated heparin or low-molecular-weight heparin rather than oral anticoagulants, which are ineffective in this circumstance (see box on Heparin in the Management of DIC).[251,252] Because the baseline PTT is often prolonged in these patients, the antithrombotic effect of heparin may be monitored by serial heparin or anti-factor Xa levels.

The role of heparin in the treatment of the complex coagulopathy associated with acute promyelocytic leukemia remains controversial.[253–256] Supportive care aimed at maintaining the platelet count above 50,000 and replacing fibrinogen is critical in preventing bleeding complications. Because of the rapid improvement of the DIC in patients receiving all-*trans*-retinoic acid as part of the induction therapy, the role heparin has in acute promyelocytic leukemia is likely to be limited to patients with overt thrombotic complications.[41,42,195] Similarly, the use of heparin in DIC associated with advanced liver disease remains unclear.[257–259] It is contraindicated in abruptio placentae because of bleeding complications associated with delivery and hysterectomy, if these are carried out, and controlled trials have not been done in acute DIC associated with septic abortion.

The role of heparin in management of aortic aneurysms depends on whether the patient is a surgical candidate. Although a nonsurgical patient with only laboratory evidence of DIC does not need heparin, it is prudent to obtain a DIC screen on any patient with an aortic

aneurysm in whom surgery is contemplated to avoid serious intraoperative and postoperative bleeding. Preoperative correction of any hemostatic defects with replacement therapy and continuous heparin infusion is in order.[260] These maneuvers should also be considered in patients with bleeding aortic aneurysms. Those with evidence of an aneurysmal leak associated with factor consumption require transfusion of platelets and cryoprecipitate and emergency surgery, and they should not receive heparin.

The use of low-molecular-weight heparins in prophylaxis and treatment of DIC has recently been described in several case reports.[252,253] Although no control trials have yet been reported, these early reports suggest that low-molecular-weight heparins may be as efficacious as adjusted-dose heparin, providing reproducible anticoagulation with less frequent dosing. In one study, six patients with acute promyelocytic leukemia received enoxaparin from the day of admission until presenting skin and mucous membrane bleeding resolved, and the coagulation values returned to normal (11 to 23 days). Three had laboratory evidence of DIC on presentation, and significant bleeding complications developed in two patients while on low-molecular-weight heparin, and in a third, bleeding occurred 3 days after its discontinuation.[253]

Antithrombin and Protein C Concentrates

Antithrombin concentrate has been used in the management of subsets of patients with DIC on the premise that systemic consumptive coagulopathies often lead to a relative plasma deficiency of natural inhibitors, such as antithrombin, that contributes to a procoagulant state. Antithrombin deficiency would also be expected to decrease the effect of any therapeutic heparin used to treat DIC, and so antithrombin concentrates warrant consideration in any heparinized patient with DIC, particularly if heparin resistance is encountered.

Exogenous antithrombin neutralizes thrombin generated in DIC and potentially ameliorates thrombosis, particularly if there is hepatic insufficiency with its associated decrease in antithrombin synthesis. In this respect, antithrombin shortens the duration of DIC in some patients with fatty liver of pregnancy, and its use should be considered in this setting.[261] Except for hepatic insufficiency, other studies have shown improved hemostatic function in most patients with DIC given antithrombin, but no effect on mortality.[262,263] A phase III randomized placebo-controlled trial of antithrombin concentrate failed to demonstrate any statistically significant benefit in survival at any point during the study period.[261]

Activated protein C has been given to animals in concert with infusion of *Escherichia coli* with the subsequent prevention of DIC and gram-negative septicemia.[264] Conversely, when these infusions were supplemented with anti-protein C antibody, inhibition of protein C led to enhanced *E. coli*-associated lethality. Additional studies suggested activated protein C concentrates ameliorated DIC in a rabbit model, with less bleeding than was associated with heparin.[265] This was confirmed in humans in a prospective, double-blind study comparing the safety and efficacy of activated protein C and unfractionated heparin in the treatment of DIC.[266] The death rate at 28 days was significantly reduced in the activated protein C arm.[266,267] Studies of protein C concentrate replacement in infants with purpura fulminans because of severe protein C deficiency and in infants, children, and adults with meningococcemia appear promising.[268–270] A phase III, randomized placebo-controlled trial of activated protein C concentrate was performed in patients with severe sepsis and demonstrated a statistically significant reduction in absolute risk of death of 6.1% and a relative risk reduction of 19.4%.[271] The benefit was seen early and maintained throughout the study period. The risk reduction was independent of the baseline protein C level. Analysis of IL-6 and D-dimer levels showed statistically significant decreases in the activated protein C compared with controls. Bleeding complications were described but were manageable in the antithrombin and activated protein C trials. Activated protein C concentrate has been approved for clinical use in patients with severe sepsis. A case series of pediatric patients with meningococcemia and DIC managed with plasma or whole-blood exchange led to survival of seven of eight patients, with no associated bleeding or cardiovascular complications during the procedure.[271] A prospective, randomized study should be performed to see if activated protein C concentrate can substitute for plasma exchange in the management of meningococcal sepsis.

Fibrinolysis Inhibitors

Under most circumstances, patients with DIC should not be treated with fibrinolytic inhibitors. These agents act by blocking the secondary fibrinogenolysis that accompanies DIC to various extents and may prevent tissue perfusion.[272–275]

The DIC setting in which fibrinolytic inhibitors may warrant consideration includes (1) when intense primary fibrinogenolysis can be demonstrated in association with disease states, such as acute promyelocytic leukemia,[115] Kasabach-Merritt syndrome,[276,277] prostate cancer; and (2) when the patient is bleeding profusely and is not responding to replacement therapy. In the latter case, factor degradation products may be contributing to bleeding, and the use of fibrinolytic agents should be considered only after the continuously bleeding patient has received replacement therapy for depleted hemostatic factors, and intravenous heparin infusions ε-aminocaproic acid or tranexamic acid may be useful in these cases in concert with heparin for the coexisting DIC.[278–281]

An approach to treatment of Kasabach-Merritt syndrome entails administering a fibrinolytic inhibitor alone or in combination with cryoprecipitate.[115,276] The result has been tumor shrinkage and correction of hemostatic defects through induction of thrombosis within the tumor.

CHAPTER 133

DISORDERS OF COAGULATION IN THE NEONATE

Cameron Trenor, III and Ellis J. Neufeld

Neonates experience rapid physiologic changes after birth, some of which impact the hemostatic system. Evaluation of disorders of coagulation in the neonate requires an understanding of the evolution of physiologic normal values for age, the congenital disorders that present in early life, and the clinical settings common in neonatology that affect hemostasis and thrombosis risks. The rapid evolution of the blood coagulation system after birth leads to a dynamic group of age-dependent reference ranges in factors that should be considered physiologically normal. Developmental hemostasis is the term applied to the evolution of the hemostatic and fibrinolytic systems through infancy and childhood.

DEVELOPMENTAL HEMOSTASIS

The hemostatic system evolves throughout childhood and most rapidly during the neonatal period. Changing plasma concentrations of proteins involved in blood coagulation lead to a dynamic group of reference ranges for preterm and term infants. Although discrepant from adult values, these reference ranges are neither "abnormal" nor pathologic. The relative rarity of hemorrhagic or thrombotic complications in this population argues that the neonatal coagulation system is physiologically replete.

Laboratory Evaluation

Laboratory evaluation of thrombosis or bleeding in a neonate requires recognition that reference ranges for healthy newborns are age-dependent and differ from adult values. The concept of developmental hemostasis was pioneered by Maureen Andrew, and her seminal papers describing reference ranges for healthy premature and full-term neonates are still widely referenced.[1,2] However, recent data suggest that reference ranges for coagulation assays in infants vary with analyzer and reagents systems used.[3] As current instrumentation for coagulation testing has evolved since age-specific normal ranges were defined, reference laboratories should develop their own age-related reference ranges specific for their own testing systems. Neonatal samples should be drawn by experienced staff, ideally from free-flowing veins. Samples are processed in 1 mL tubes containing 0.1 mL of 3.2% buffered sodium citrate, aiming for a final ratio of one part citrate to nine parts blood.

The prothrombin time, expressed in seconds, is usually similar between full-term neonates and adults despite relative deficiencies of vitamin K-dependent coagulation factors.[2] However, premature infants and cord blood samples exhibit a prolonged prothrombin time[1,4] compared to adults. Activated partial thromboplastin time (PTT) is prolonged in newborns, attributed to relative deficiencies in contact factors.[5] Thrombin time is similar to adult values when measured in the presence of calcium to compensate for the unique fetal form of fibrinogen with increased sialic acid content.[6] The template bleeding time is reportedly preserved in neonates, but this is an unreliable technique in neonatology and is not recommended for bleeding evaluations.

Blood Coagulation Proteins

The synthesis of fetal and neonatal coagulation proteins begins at approximately 10 weeks of gestation, and plasma concentrations of these proteins increase with gestational age. Maternal coagulation proteins cannot cross the placenta.[7] However, the impact of maternal drug use on fetal vitamin K-dependent coagulation protein synthesis has been described, with warfarin, phenytoin, barbiturates, and antibiotics as examples.

The study of coagulation factors in neonates is confounded by a dynamic group of age-dependent reference ranges. Physiologic ranges for coagulation factors in healthy newborns having received intramuscular vitamin K after delivery have been established and are shown in Table 133–1. Plasma levels of fibrinogen and factors V, VIII, and XIII are present at adult levels at birth. Levels of von Willebrand factor (vWF), particularly high-molecular-weight multimers, are higher than adult levels from birth until 3 months of age,[8] in part because of maternal estrogen and despite adult levels of the vWF processing enzyme, ADAMTS-13.[9] Vitamin K-dependent factors (prothrombin and factors VII, IX, and X) are present at significantly lower levels than in adults, as are the four contact factors (factor XI, factor XII, prekallikrein, and high molecular weight kininogen). Both the contact factors and the vitamin K-dependent factors approach adult levels by approximately 6 months of age.

Regulation of Thrombin

Direct thrombin inhibition occurs via α_2-macroglobulin, antithrombin, and heparin cofactor II. Unlike in adults, α_2-macroglobulin is the dominant thrombin inhibitor in neonates, with twice the plasma concentration and thrombin binding of antithrombin.[10] Thrombin inhibition through heparin cofactor II is catalyzed by a fetal proteoglycan anticoagulant produced by the placenta and found in both maternal and fetal circulation.[11,12]

Inhibition of thrombin generation is also accomplished by upstream inhibition of the clotting proteins in the prothrombinase and *tenase* complexes (see Chapter 118). Thus, protein C, its cofactor protein S, and tissue factor pathway inhibitor (TFPI) serve as they do in adults. Circulating levels of proteins S and C are substantially lower than adult levels, requiring 6 to 12 months respectively to reach adult levels. Despite lower total protein S, free protein S levels are preserved because of low levels of C4b-binding protein in newborn plasma. The interaction of protein S with activated protein C in neonatal plasma may be limited by elevated levels of α_2-macroglobulin.[13] Free TFPI levels are lower than in adults, despite total TFPI levels being similar in neonatal and adult plasma.[14]

Thrombin regulation in neonatal plasma is similar to the plasma from therapeutically anticoagulated adults.[15] The amount of thrombin generated in neonates is proportional to available prothrombin concentrations,[16] whereas the rate of thrombin generation is dependent on other procoagulant protein concentrations. The capacity of neonatal fibrin clots to bind thrombin is lower than in adults because of lower plasma prothrombin levels.[17] This observation implies that

Table 133–1 Reference Values (Ranges) for Common Coagulation Tests and Blood Coagulation Protein Levels by Age, Comparing Two Comprehensive Prospective Studies with Different Methodologies†

decreased plasma prothrombin levels may suppress thrombus propagation in neonates when compared to adults.

The Fibrinolytic System

Although some components of the neonatal fibrinolytic system are distinct from adult proteins, their clinical relevance is probably minimal. The fibrinolytic system functions to control thrombus size by influencing clot lysis through the actions of plasminogen. Fetal plasminogen circulates at substantially lower levels than in adults yet has increased receptor affinity because of a relative increase in mannose and sialic acid side chains.[18] Whereas a healthy neonate has decreased plasmin-generating potential than an adult,[19] the stress of illness can increase depressed baseline levels of tissue plasminogen activator (tPA) up to eightfold. Neonates with severe plasminogen deficiency have only a minimal increased risk of thrombosis, and most of their clinical findings result from poor extravascular fibrinolysis.[20] The major plasmin inhibitors are found at near adult levels in the neonate. In sum, this implies relatively increased thrombus stability in healthy newborns that is normalized under physiologic stress.

Platelets

Neonatal platelet count and mean platelet volume are similar to adult values. Thrombocytopenia is common in neonates. Thrombocytosis is rare in neonates but is associated with prematurity and occurs 4 to 6 weeks after delivery. This correlates with evidence of increased megakaryocytopoiesis in the third trimester.[21]

Platelet function is altered at birth. Platelets are activated to a degree during the birth process, hypothesized to be a result of temperature change, hypoxia, acidosis, adrenergic stimulation, and amniotic fluid exposure. In contrast, platelet adhesion and aggregation may be inhibited by the transient perinatal release of nitric oxide.[22] Consistent with this, both bleeding times[23] and platelet function analyzer (PFA)-100 closure times are shorter in neonates than adults, perhaps mediated by increased neonatal high multimeric vWF.[24] If

available, PFA-100 is preferred to bleeding time for testing platelet-related hemostasis. The bleeding time is inconsistent in neonates, and this test is to be discouraged in nearly every clinical circumstance. The PFA-100 is not a perfect surrogate for clotting status in vivo so that mild defects in platelet function might provide false negative results.[25] As a practical matter, it is not often clinically necessary to diagnose mild congenital platelet disorders in the neonate because severe neonatal bleeding is rare with mild defects.

The Vessel Wall

Animal models and in-vitro systems provide evidence that young blood vessels possess greater antithrombotic potential than adult vessels. In both rabbit venous and aortic models, increased heparin sulfate glycosaminoglycans are associated with increased antithrombin-mediated anticoagulant activity in rabbit pups compared to adults.[26,27] Circulating levels of endothelial cell adhesion markers vary with age, implying that expression or secretion of these proteins from the vessel wall may be dynamic in neonates.[28]

NEONATAL HEMORRHAGIC DISORDERS

Significant bleeding in neonates should prompt a hemostasis evaluation. In sick infants, acquired factor deficiencies or thrombocytopenia are frequently to blame, but rare congenital factor deficiencies often present with neonatal bleeding. Attention to maternal contributing factors (eg, infection, thrombocytopenia, drugs) is critical when evaluating neonates. Initial empirical therapy consists of platelet and/or factor supplementation, often while diagnostic studies are underway.

Evaluation of the Bleeding Neonate

Neonatal, peripartum, maternal, and family histories are each important in the evaluation of a newborn with hemorrhagic complications. Documentation of vitamin K administration in the delivery room should be confirmed. Maternal factors that can directly lead to neonatal thrombocytopenia include infection, immune thrombocytopenia, or drugs. Maternal vitamin K deficiency or drugs impairing vitamin K metabolism can lead to severe deficiencies of vitamin K-dependent blood coagulation proteins at birth. On physical examination, the location and characteristics of bleeding (eg, procedural, mucosal, cutaneous, intraventricular), whether diffuse or localized and the general appearance of the baby as sick or well will help predict the underlying etiology of hemorrhage. Ill-appearing newborns are prone to disseminated intravascular coagulation or liver disease as reasons for acquired factor deficiencies. These disorders tend to present with diffuse bleeding. Well-appearing newborns are more likely to have localized bleeding or ecchymoses because of thrombocytopenia from a transplacental antibody, vitamin K deficiency, or a rare inherited factor deficiency.

Laboratory evaluation of the hemorrhage in newborns should include sepsis evaluation, platelet count, prothrombin time, PTT, thrombin time, fibrinogen, and if other causes are not identified, consideration of a PFA-100. In male infants with a positive family history of hemophilia or strong clinical suspicion, factors VIII and IX should be measured regardless of a PTT prolongation. Deficiencies of factor XIII, α_2-antiplasmin or plasminogen activator inhibitor-1 will not be detected by standard screening, and specific testing should be obtained if suspected. Further evaluation of this laboratory screening approach is summarized in Fig. 133–1, modified from Blanchette and Rand.[29]

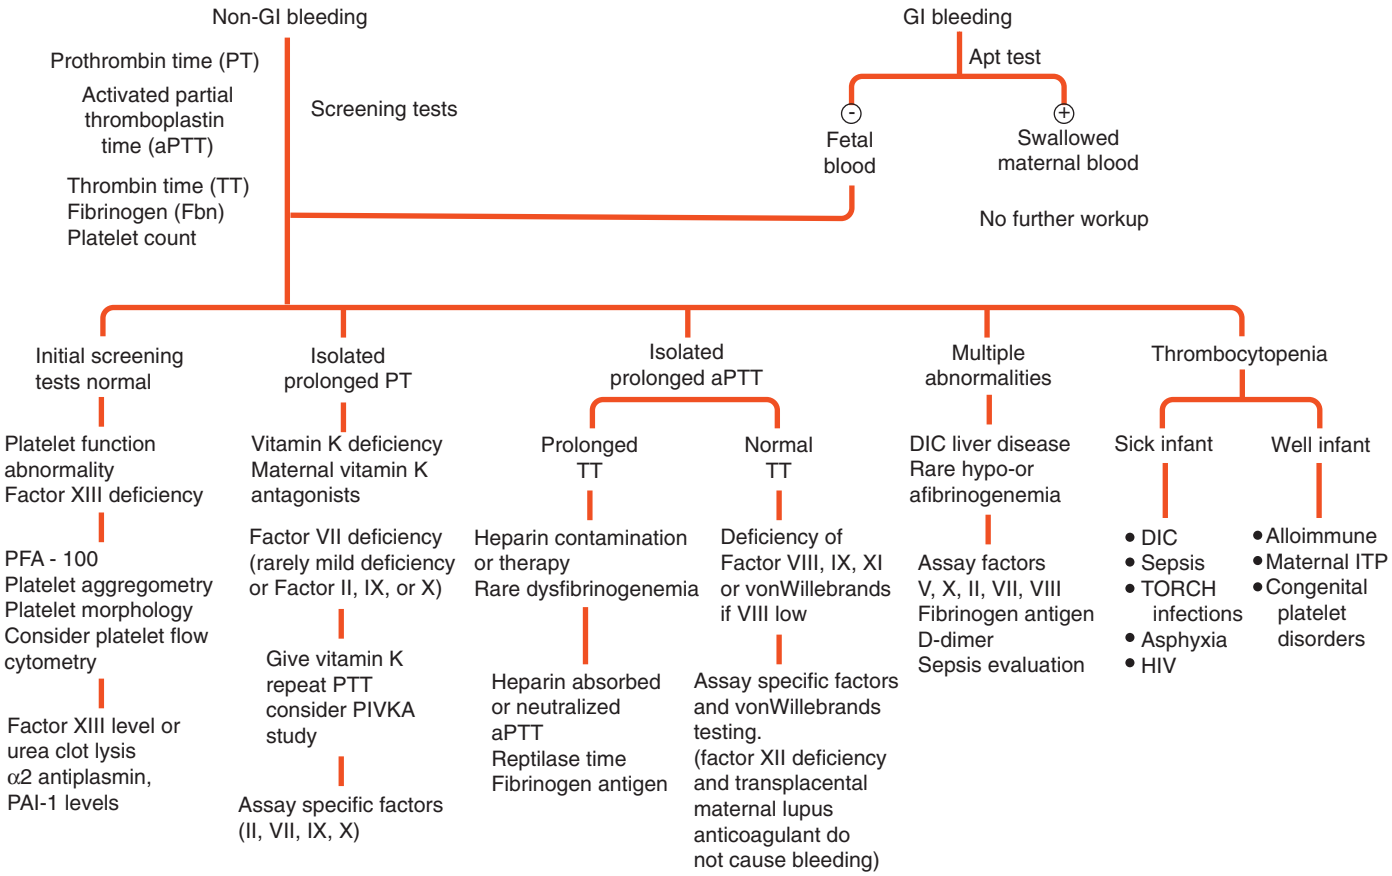

Figure 133–1 Diagnostic approach to the bleeding neonate.

Neonatal Thrombocytopenia

The following factors are important to consider when evaluating neonatal thrombocytopenia: congenital or acquired, sick or well, maternal antibody or drug, and platelet size. Platelet number and size in healthy neonates is equivalent to adults and thrombocytopenia is defined as less than 150,000 cells/μL. Significant thrombocytopenia (less than 50,000 cells/μL) in neonates rarely manifests with bleeding, particularly in the absence of maternal antiplatelet antibodies.[30] In the absence of maternal thrombocytopenia, fewer than 1% of healthy newborns have thrombocytopenia,[30] compared to more than 20% of newborns requiring intensive care.[31]

The majority of causes of neonatal thrombocytopenia involve increased platelet destruction. In well-appearing newborns, thrombocytopenia is usually an immune-mediated phenomenon related to maternal transplacental IgG antibodies or drugs (eg, quinine, hydralazine, thiazides, tolbutamide). In sick newborns, platelet destruction is often related to infection, disseminated intravascular coagulation, extracorporeal membrane oxygenation (ECMO), thrombosis, or mechanical ventilation performed for hyaline membrane disease. Significant localized thrombosis in large vessels can also lead to thrombocytopenia, as can specific recognizable syndromes including renal vein thrombosis, necrotizing enterocolitis, or vascular anomalies (Kasabach-Merritt syndrome).

Platelet production is impaired after significant hypoxic-ischemic injury, perhaps because fetal megakaryocytes are particularly sensitive to hypoxia. Newborns from pregnancies complicated by intrauterine growth restriction or pregnancy-induced hypertension frequently have transient mild to moderate thrombocytopenia. Other causes of decreased platelet production in neonates include rare primary congenital platelet or marrow disorders and infiltrative disorders. These are summarized in Table 133–2.

Table 133–2 Syndromic, Genetic, and Acquired Etiologies of Neonatal Thrombocytopenia

Inborn Errors of Metabolism
Isovaleric acidemia
Methylmalonic acidemia (with acute acidosis) and cobalamin metabolic defects
Holocarboxylase deficiency
Mitochondrial disorders
Pearson syndrome
Kearns-Sayer syndrome
Genetic Marrow Failure Syndromes
Amegakaryocytic thrombocytopenia
Fanconi anemia
Other Syndromic Thrombocytopenias
Thrombocytopenia-absent radius syndrome
Paris-Trousseau syndrome
X-linked thrombocytopenias
Wiskott-Aldrich syndrome
GATA-1 mutations
Aneuploidy
Trisomy 21, 13, or 18
Genetic Macrothrombocytopenias
May-Hegglin, Sebastian, Fechtner syndromes
Bernard Soulier syndrome
Acquired Marrow Disorders
Oncologic
Neonatal leukemia
Neuroblastoma
Histiocytic Lymphohistiocytosis (HLH)

Platelet Abnormalities

Qualitative platelet disorders are only rarely associated with overt neonatal bleeding. Clinical suspicion should be aroused in patients with clinical bleeding in the setting of normal coagulation screening and platelet counts. Bleeding may include mucocutaneous sites, heelsticks for capillary blood sampling, cephalohematoma, umbilical stump bleeding, or postprocedural bleeding. Neonatal presentation usually involves only the most severe genetic disorders of platelet function, because of defects of platelet fibrinogen receptor, integrin glycoproteins IIb and IIIa, (Glanzmann thrombasthenia), and von Willebrand receptor glycoprotein Ib (Bernard-Soulier syndrome) (see Chapter 141). Maternal medications may affect platelet function, most notably aspirin, although low-dose aspirin does not appear to significantly alter neonatal platelet function.[32] Neonatal medications may also affect platelet function. Common offenders include nitric oxide, prostaglandin E2, indomethacin, and aspirin. Suspected platelet disorders should be evaluated by platelet morphology and direct platelet aggregation studies after initial screening by PFA-100. Additional flow cytometry for specific surface glycoproteins or electron microscopy studies for granule morphology by an expert consultant should be considered. Evaluation of the bleeding time is rarely more helpful than clinical assessment and direct tests on blood. Treatment with platelet infusion is standard if bleeding is present. The potential risk of allosensitization from normal platelets in congenital deficiencies of platelet surface antigens must be weighed against the severity of bleeding when functional defects are suspected.

Vitamin K Deficiency Bleeding

Vitamin K is a necessary cofactor for γ-glutamyl carboxylase, the enzyme required for posttranslational carboxylation of prothrombin, factors VII, IX, and X, and proteins C, S, and Z. Many newborns are significantly deficient in vitamin K, whether measured in cord blood[33] or indirectly through activity levels of vitamin K-dependent blood coagulation proteins.[34] Despite this, bleeding is relatively rare even in the absence of empiric vitamin K supplementation. Risk factors for bleeding include maternal malabsorption, maternal drugs impairing vitamin K metabolism, exclusive breast-feeding, and neonatal malabsorption.

Classical *hemorrhagic disease of the newborn* because of vitamin K deficiency occurs from days 2 to 7 of life. Gastrointestinal bleeding is the most common presentation, but procedural bleeding, bruising, or intracranial hemorrhage can occur. Early bleeding in the first 24 to 48 hours of life is usually associated with maternal drugs (phenytoin, barbiturates, antibiotics) crossing the placenta and impairing fetal/neonatal vitamin K synthesis. Occurring up to 12 weeks of age, late onset vitamin K-related bleeding is typically associated with exclusive breast-feeding or with neonatal fat malabsorption and often manifests as catastrophic bleeding, including intracranial hemorrhage.

Vitamin K prophylaxis with a single dose of 0.5 to 1 mg IM (SC or IV are also sufficient) in the delivery room prevents early and classic onset bleeding. Oral dosing may be effective as well but is potentially limited by absorption, regurgitation, and compliance and is therefore not recommended presently. Initial reports of an association with IM vitamin K and leukemia[35,36] have not been corroborated.[37] In addition to a prolonged prothrombin time, the PTT is prolonged in severe vitamin K deficiency, whereas platelet count, thrombin time, and fibrinogen are normal. Treatment with vitamin K for recognized deficiency should be through either slow infusion intravenously (to minimize anaphylactoid reactions) or subcutaneously. Intramuscular injection in the setting of severe vitamin K deficiency bleeding can lead to large hematomas and should be avoided. Significant bleeding should be treated with fresh frozen plasma, as vitamin K will take 12 hours or more to act to a significant degree. The addition of blood product concentrates enriched for vitamin K-dependent proteins (prothrombin complex concentrates)

should be reserved for life-threatening bleeding, given concerns about precipitating thrombosis.[38]

Inherited Coagulation Disorders

Prolonged PTT

Hemophilia is the most common inherited coagulation disorder, as discussed in detail in Chapter 125. Evaluation for factor VIII, IX, and XI deficiencies should be undertaken immediately in any neonate with an isolated prolonged PTT and bleeding or positive family history. Male newborns with a positive (maternal) family history of hemophilia should be evaluated prior to intramuscular injections, including vitamin K. Typically, newborns with hemophilia and bleeding are well-appearing. Male infants far outnumber females, given the location of both factor VIII and factor IX genes on the X chromosome. However, severe factor VIII or factor IX deficiency can, albeit rarely, present in females. Factor XI deficiency is an autosomal recessive disorder, so female newborns with bleeding and isolated prolonged PTT should also be tested. Evaluation of hemophilia carrier status in mothers of unknown status (eg, single prior affected child or positive history in maternal grandmother) can be performed genetically, as factor levels in carriers range widely and overlap with normal levels. Most bleeding episodes in newborn males occur after circumcision or occasionally umbilical stump separation, although intracranial hemorrhage is reported in approximately 3.5% of hemophiliac newborns,[39] and cephalhematomas are common. Joint bleeding is very rare in the neonatal period. For patients with known or suspected hemophilia or severe deficiencies of factors VII, X, or XIII, screening for intracranial bleeding should be considered. Although head ultrasound is often used for screening, head computed tomography (CT) is more sensitive than ultrasound for small parafalcine bleeds, which can also occur in a small percentage of normal infants with no sequelae.

Isolated Prolonged Prothrombin Time

Inherited factor VII deficiency is a rare, autosomal recessive condition with a strong gene dosage effect. Neonatal bleeding can occur in severe cases (ie, homozygosity or compound heterozygosity for two mutations in the factor VII gene). Factor VII deficiency is rarely reported to be associated with microcephaly or midline defects because of loss of adjacent genes in disruptions on chromosome 13q. Additionally, factor VII deficiency is found in combined factor defects associated with abnormalities of the vitamin K pathways. Replacement with fresh frozen plasma or recombinant factor VIIa at very low doses is used to correct the deficiency.

Prolonged Prothrombin Time and PTT

The association of bleeding with prolongation of both the prothrombin time and PTT in a healthy newborn may indicate vitamin K deficiency or congenital deficiencies of prothrombin, factors V or X, and also rare combined deficiencies. More commonly, combined prothrombin time and PTT prolongation occurs in sick newborns with disseminated intravascular coagulation (DIC) pathophysiology or severe perturbed liver synthetic function. Any of these factor deficiencies may present with postprocedure, umbilical stump, intracranial, or gastrointestinal bleeding.

Combined factor deficiencies are rare but must be considered when laboratory evaluation or clinical course are confusing. Autosomal recessive mutations in the LMAN1 (ERGIC-53) or MCFD2 result in combined factor V and VIII deficiency,[40] because of defective intracellular processing of both factors. Mutations in γ-glutamyl carboxylase are associated with inherited combined deficiencies of all vitamin K-dependent proteins.[41] Factor VII deficiency has rarely been reported in combination with factors V, VIII, IX, X, XI, and protein C defects, as reviewed by Girolami.[42]

Factor XIII

Factor XIII is a transpeptidase that crosslinks fibrin strands and is required for clot stability. Severe factor XIII deficiency may present with neonatal bleeding and is not detected by screening prothrombin time, PTT, or thrombin-time assays. Specific factor XIII levels or urea clot solubility testing are used for diagnosis, and treatment is replacement with factor XIII concentrate or by cryoprecipitate. Intracranial bleeding in a child with no other risk factors should prompt a search for factor XIII deficiency.

Other Inherited Deficiencies Associated with Neonatal Bleeding

Von Willebrand disease (vWD) is the most common inherited bleeding diathesis and is discussed in Chapter 129. vWD has been associated with neonatal bleeding, although very rarely, and generally with severe subtypes. The largest case series of 55 newborns with vWD reports no bleeding complications,[43] although individual cases of scalp hematomas and bleeding after vitamin K injection or umbilical stump detachment are reported. Acquired forms of vWD also occur rarely and may complicate obstetric management of afflicted patients and affect their newborns. Family history of vWD, especially type 2 (dominant, qualitative defects), should prompt vWD evaluation in the neonate prior to circumcision, and possibly before intramuscular injections. There is possible association of vWD and acute idiopathic pulmonary hemorrhage.[44] Children with new diagnoses of type 3 vWD should be genetically tested for mutations predisposing for inhibitory alloantibody formation prior to aggressive replacement with exogenous vWF.[45] Treatment in neonates for prophylaxis or bleeding is with plasma-based factor VIII:vWF concentrates that contain von Willebrand factor (e.g., Humate-P or Alphanate), dosed initially at 40 to 60 ristocetin cofactor units/kg.

Afibrinogenemia can be associated with neonatal bleeding. Severe deficiency of fibrinogen is rare and can manifest as bleeding in soft tissue, after circumcision, or after umbilical stump detachment. Diagnosis is evident by standard fibrinogen assays, and treatment involves replacement with cryoprecipitate or, if available, fibrinogen concentrate.

Even complete deficiencies of the contact factors, high-molecular-weight kininogen, prekallikrein, and factor XII, are not associated with bleeding phenotypes. Autosomal recessive deficiencies of the fibrinolytic proteins α_2-antiplasmin[46] and plasminogen activator inhibitor-1[47] have been associated with case reports of pediatric bleeding, but no cases are reported in the neonatal period.

Liver Disease

Coagulopathy and bleeding because of inadequate hepatic synthetic function is not unique to neonates. Liver disease in neonates may be caused by viral hepatitis, parenteral nutrition, cholestasis, hypoxic injury, or metabolic disease. Rare disorders presenting with liver failure in neonates include hereditary tyrosinemia, neonatal hemochromatosis, and hemophagocytic lymphohistiocytosis.

Because of synthetic deficiencies of multiple coagulation proteins, laboratory workup typically reveals prolonged prothrombin time and PTT. Platelet count may be depressed, especially if hypersplenism is present, and platelet dysfunction is often present. Hypofibrinogenemia is a late effect of liver disease and elevated fibrin degradation products and D-dimer occur because of delayed hepatic clearance.

Diagnostically, measurement of factors V, VII, and VIII can help distinguish liver disease, vitamin K deficiency, and consumptive coagulopathy (eg, DIC or large vascular malformations). Factors V and VIII are not vitamin K-dependent, are made by the liver and multiple cell types respectively, and have neonatal concentrations similar to adult levels. Deficiency of all three implies consumption, whereas decreased levels of factors V and VII with normal factor VIII is consistent with liver disease.

Treatment should include factor replacement with fresh frozen plasma or cryoprecipitate and platelet transfusion. Patients with biliary atresia or other cholestatic liver failure syndromes may also benefit from parenteral administration of vitamin K. Successful therapy is predicated on treatment of the underlying cause of liver disease.

Intraventricular Hemorrhage

Intraventricular hemorrhage carries significant morbidity and mortality in the newborn period. With improvements in neonatal care, the incidence of intraventricular hemorrhage is decreasing despite its association with prematurity. The etiology of intraventricular hemorrhage is multifactorial but includes prematurity of cerebral vasculature and ischemia-reperfusion injury related to ventilatory support, blood pressure lability, or extracorporeal membrane oxygenation. The role of coagulopathy or thrombocytopenia is unclear. One study reports hypofibrinogenemia, thrombocytopenia, or prolonged clotting time in 11 of 15 neonates with intraventricular hemorrhage whereas only in 5 of 35 control newborns.[48] Hemorrhage after thrombosis may explain some cases (especially in full-term infants), with factor V Leiden heterozygosity identified in 18% of neonates with grade 2 to 4 intraventricular hemorrhage compared to 3% of controls.[49] Multiple trials have analyzed antenatal vitamin K administration, indomethacin, antithrombin, fresh frozen plasma, factor XIII, tranexamic acid, or ethamsylate for prevention of intraventricular hemorrhage. Studies to date have drawn mixed conclusions or lack long-term developmental outcomes, thus preventing a consensus recommendation. Cerebellar hemorrhage should raise suspicion for an organic acidemias, such as methylmalonic, propionic, or isovaleric acidemia.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation is occasionally used in neonates with severe persistent pulmonary hypertension or in conjunction with cardiac surgery for patients with severe cardiomyopathy. The extracorporeal membrane oxygenation pump, oxygenation membrane, and large-bore catheters in the patients all pose thrombotic risk, whereas the requirement for long-term high-dose systemic anticoagulation can pose a severe bleeding risk in sick neonates. Protocols that strike a balance between too little and too much anticoagulation have been worked out empirically over the last 20 years, following activated clotting time assays. With extracorporeal membrane oxygenation anticoagulation, prothrombin time and PTT assessments of coagulation status may give results that do not correlate with activated clotting time assays. Complicating this, there is evidence that heparin dose is prognostic of extracorporeal membrane oxygenation survival independent of the activated clotting time, implying that an activated clotting time of 180 to 220 seconds may not represent adequate anticoagulation.[50] Further, prolonged use of extracorporeal membrane oxygenation reliably causes a state of depleted clotting factors and high levels of fibrin degradation products. However, this depletion does not mean patients are adequately anticoagulated. The laboratory hallmark of this state is a very prolonged PTT or moderately long activated clotting time and high D-dimers, at very low heparin doses (compared to those used at initiation of extracorporeal membrane oxygenation). In neonates with thrombosis or specific high-risk situations, daily fresh frozen plasma infusion is sometimes used as a source of plasminogen and anticoagulant proteins. Data supporting specific regimens for this purpose are lacking.

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS), also known as hyaline membrane disease, is an acute pulmonary process common in premature neonates. Part of the pathophysiology of RDS includes hyaline membrane formation and fibrin deposition through diffuse areas of atelectasis. Although increasing thrombin generation and decreased antithrombin levels correlate with the severity of RDS, therapeutic interventions addressing the coagulation system have been inconclusive. Studies using plasmin[51] or plasminogen[52] demonstrated a survival benefit; heparin is controversial, and antithrombin supplementation may lead to increased mortality.[53] Further clinical studies are needed to address possible benefits of antithrombotic or thrombolytic therapies in RDS. The generation of thrombin and deposition of fibrin leads to a laboratory profile consistent with mild DIC or thrombosis. Low fibrinogen and elevated D-dimer are present in RDS and may mask the laboratory evaluation of thromboembolic disease. Doppler ultrasound should be relied on for diagnosis of deep venous thrombosis or suspected pulmonary embolism. Unexpected increase in ventilatory support should raise suspicion for pulmonary embolism in this population.

NEONATAL THROMBOEMBOLIC DISORDERS

Thrombosis in neonates is uncommon, but more than half of pediatric thromboembolic events occur in the neonatal period. The incidence of neonatal thromboembolic events is increasing because of improved neonatal survival and an increased use of thrombogenic surfaces (eg, catheters, extracorporeal membrane oxygenation circuits) for advanced neonatal care. Approximately 80% of neonatal thrombi are associated with indwelling catheters. However, rare severe congenital thrombophilias present in the newborn period and deserve special consideration in this population. Positive family history or prior miscarriages may indicate a hereditary thrombophilia. Heparin remains the mainstay of therapy, but newer agents have been successfully employed in special circumstances, such as heparin-induced thrombocytopenia.

Incidence

Current estimates of the incidence of neonatal thrombosis are provided by three international registries with different inclusion criteria. German, Dutch, and Canadian registries have independently reported the incidence of neonatal thromboembolic events at 15 to 51 events per 10,000 patients.[54–56] Two-thirds of thromboembolic events were venous, and 80% were either catheter-associated or followed a severe illness.[57] Arterial thromboembolic events in neonates usually involve either stroke or emboli to limbs from catheter-associated thrombi.

Acquired Thrombophilia

Indwelling Catheters

Central venous and arterial access is required for the advanced care provided in modern neonatology. The most common acquired thrombotic risk factor in neonates is the presence of an indwelling vascular catheter. Awareness of the prothrombotic biases of catheter location, size, material, duration of placement, and type of fluid delivered is important in this population. Symptomatic venous thrombosis presents with swelling, discoloration, and temperature decrease of an affected limb. Loss of catheter patency, evidence of collateral circulation and/or unexplained thrombocyto-

penia should raise clinical suspicion for thrombosis. Importantly, prospective imaging prior to indwelling central access catheter removal find high rates of asymptomatic thrombi (up to 86%)[55] with an unknown potential for long-term morbidity. Treatment often begins with removal of the catheter, although consideration of anticoagulation prior to catheter removal is warranted, especially in infants with right to left intracardiac or intrapulmonary shunting. Small catheter-mediated thrombi may resolve without specific therapy.[58] Larger thrombi or those in locations associated with greater morbidity (eg, sinovenous, renal, portal) may warrant short courses of heparin or thrombolytic agents. Platelets should never be administered through arterial catheters because of the potential risk of embolisms.

Disseminated Intravascular Coagulation

Neonates are susceptible to DIC because of immature anticoagulant and fibrinolytic pathways. Most cases of neonatal DIC are associated with tissue ischemia and acidosis secondary to sepsis, low output cardiac failure, perinatal asphyxia, severe respiratory distress syndrome, or necrotizing enterocolitis.[59] Other causes of consumption coagulopathy include large vascular anomalies (the nidus for consumption being the abnormal vascular endothelium of the lesion), severe liver disease, massive hemolysis, or hereditary thrombophilia. DIC may present with hemorrhage and/or thrombosis. Laboratory evaluation reveals prolonged prothrombin time, PTT and thrombin clotting time, decreased fibrinogen, thrombocytopenia, and increased D-dimer and fibrin split products. Sepsis-induced DIC in premature infants may be predicted by elevation of serum interleukin (IL)-6 and IL-10 without elevation of regulated on activation, normal T-cell expressed and secreted (RANTES).[60] Definitive therapy for DIC requires identification and reversal of the trigger for coagulation activation. Treatment of bleeding or prophylaxis for procedures is provided by infusion of fresh frozen plasma, platelets (if bleeding is severe) and, if needed for hypofibrinogenemia, cryoprecipitate. A reasonable target range for bleeding in neonatal DIC is to maintain fibrinogen greater than 100 mg/dL, platelets greater than 50,000 cells/μL, and a prothrombin time that is only modestly elevated. Heparin should be given in thrombotic DIC with antithrombin repletion by concentrate when indicated and attention to the high risk of bleeding complications. Animal models have demonstrated reversal of DIC and improved mortality with replacement of antithrombin, activated protein C, tissue factor pathway inhibitor, and tPA,[61,62] but confirmatory studies in neonates have not been performed to date.

Congenital Thrombophilia

Healthy newborns with spontaneous thrombi are rare, and this presentation should prompt an evaluation for congenital thrombophilia. Heterozygosity at a single thrombophilia locus is generally insufficient to promote neonatal thrombus formation without an additional inciting event (eg, central access catheter placement). However, rare homozygous and compound heterozygous mutations in multiple genes can present with thrombophilia in the neonatal period. Congenital thrombophilia should be considered in patients with spontaneous or extensive thrombosis, ischemic skin lesions or purpura fulminans or a family history of purpura fulminans.[63] It is difficult to promptly distinguish acquired deficiencies from heterozygous inherited deficiencies, so thrombophilia evaluations other than for homozygous states should be deferred from the acute setting. Amongst the several known causes of congenital thrombophilia, only homozygous or compound heterozygous protein C and/or protein S deficiencies are clearly sufficient for neonatal thrombosis. However, antithrombin deficiency, mutations in the prothrombin gene (G20210A), factor V Leiden, elevated lipoprotein (a), and maternal anticardiolipin or lupus anticoagulant have all been associated with thrombosis in neonates.

Specific Neonatal Thrombotic Syndromes

Renal Vein Thrombosis

The renal vein is one of the most common sites of neonatal thrombotic events. Renal vein thrombosis is more common in males[54] and in the left renal vein, although 28% to 44% occur bilaterally.[64,65] Renal vein thrombosis presents with hematuria, thrombocytopenia, and a palpable abdominal mass and may include proteinuria, edema, hypertension, renal failure, anuria, adrenal hemorrhage, or anemia. Diagnosis is reliably confirmed by Doppler ultrasound. Renal vein thrombosis is associated with prematurity, umbilical venous catheters, diabetic mothers, asphyxia, and infections. Factor V Leiden and prothrombin mutation G20210A and elevated lipoprotein(a) have also been found in association with renal vein thrombosis. However, these are very common traits, and it would be inaccurate to say they are proven to be causal, despite the associations.[64,66] Although no clear treatment guidelines exist, supportive care is reasonable for unilateral renal vein thrombosis. Treatment with heparin, either unfractionated or low-molecular-weight, and fibrinolytics are considered for renal insufficiency or involvement of bilateral renal veins or the inferior vena cava. Neonates with renal vein thrombosis should be followed closely for persistent hypertension and chronic renal insufficiency.[67]

Portal Vein Thrombosis

The true incidence of portal vein thrombotic events is unknown but is at least 36 cases per 10,000 neonatal intensive care unit admissions.[68] Prospective ultrasonography revealed 43% of neonates with umbilical venous catheters harbor a clinically silent portal venous thrombus.[58] Most cases are asymptomatic and are identified incidentally by abdominal ultrasound. Major risk factors for occurrence are umbilical venous catheter placement and severe illness; correlation with inherited thrombophilias is controversial.[68,69] The long-term complications of portal venous thrombi are lobar atrophy and portal hypertension with associated gastrointestinal bleeding. These complications are distinctly associated with ectopic umbilical venous catheter placement (below or in the liver) or with occlusive thrombi concurrent with ultrasonographic liver parenchymal changes. Neonates with umbilical venous catheters should be monitored with ultrasound and catheter removal and/or anticoagulation should be considered for portal venous thrombosis.

Purpura Fulminans

Purpura fulminans is a catastrophic presentation of disseminated purpuric lesions, often associated with bullae and necrosis. The histopathology of these lesions reveals diffuse cutaneous microthrombi with surrounding hemorrhage. Diffuse thrombosis including stroke, retinal infarcts, arterial infarction with gangrene, and disseminated intravascular coagulation is often associated with purpura fulminans. Neonatal presentation is associated with severe protein C,[70] antithrombin or protein S[71] deficiency, either acquired in sepsis or inherited as homozygous or compound heterozygous conditions. Some infants with severe protein C deficiency do not develop thrombosis until adulthood,[72] implying that additional factors influence neonatal presentation. Treatment with heparin and replacement with protein C concentrate or fresh frozen plasma is indicated, and successful long-term anticoagulation has been reported.[73]

Arterial Ischemic Stroke

Perinatal arterial ischemic stroke is an important cause of cerebral palsy, epilepsy, and cognitive impairment. Perinatal arterial ischemic stroke is predominantly diagnosed in full-term neonates[74] and has a prevalence of 20 cases per 100,000 live births.[75] In the neonatal

period, perinatal arterial ischemic stroke often presents with focal or generalized seizure, although pathologic hand preference before 1 year of age is most common if the stroke was asymptomatic in the newborn period.[76] Ischemic injury is usually detected by magnetic resonance imaging (MRI) or magnetic resonance angiography, and unilateral lesions favor the left hemisphere.[75] It is now accepted that perinatal arterial ischemic stroke risk factors differ from those of older infants and children, as maternal and placental factors are probably often involved, and some events even occur in utero.[77] The most common acquired risk factors for perinatal arterial ischemic stroke are perinatal asphyxia, fetal distress, chorioamnionitis or other infections, preeclampsia, congenital heart disease, and dehydration. The contribution of congenital thrombophilia to perinatal arterial ischemic stroke risk in unclear, although the transient presence of maternal anticardiolipin antibodies may be common.[76] The majority of perinatal ischemic strokes have no detectable hypercoagulable states on subsequent analysis. One possible explanation is embolic arterial occlusion from placental thrombi through the umbilical vein and across the physiological right to left shunts of the fetus and neonate. Evaluation of placental pathology is important because demonstration of placental thrombi or abruption may indicate maternal prothrombotic states. Furthermore, if placental thrombi can be proven histologically, the recurrence risk for infants is especially low. No controlled trials have been performed to date involving anticoagulation in perinatal arterial ischemic stroke, and such studies are needed. One current guideline suggests 10 to 14 days of therapeutic heparin (unfractionated or low-molecular-weight heparin [LMWH]) for perinatal stroke.[78] Because of a low risk of recurrence, long-term anticoagulation or antiplatelets agents are not routinely recommended. Long-term developmental outcomes depend on stroke size, with poorer outcomes for large strokes, especially those involving Broca and Wernicke areas, the internal capsule, and basal ganglia.[79] Cerebral palsy is particularly associated with delayed presentation of symptoms[79] and quantified diffusion restriction of descending corticospinal tracts on MRI.[80]

Sinovenous Thrombosis

The Canadian Pediatric Ischemic Stroke Registry identified 0.67 cases of cerebral venous sinus thrombosis per 100,000 children, with 43% occurring in the neonatal period.[81] Risk factors for neonatal sinovenous thrombosis include perinatal asphyxia, dehydration, infection, congenital heart disease, and severe illness, with ECMO now recognized as a specific risk factor.[82,83] The frequencies of congenital thrombophilias are estimated at 20% to 40% of neonates with venous sinus thrombosis, with factor V Leiden and methyltetrahydrofolate reductase C677T mutation occurring most commonly.[82,83] The latter is so common in the general population that it is not believed to be causally related to thrombosis. In contrast to purpura fulminans, no cases of congenital deficiencies of protein C, protein S or antithrombin have been reported. Clinical presentation ranges from silent or subtle to diffuse neurologic changes, seizures, and intraventricular hemorrhage. Up to 31% of full-term neonates with intraventricular hemorrhage are found to have associated venous sinus thrombosis.[84] This suggests a different pathophysiology than intraventricular hemorrhage in premature infants. Diagnosis in neonates is frequently made by transcranial Doppler ultrasound. However, MRI with magnetic resonance venogram is the most sensitive diagnostic technique.[81] The Canadian Pediatric Ischemic Stroke Registry reports that 42% of neonatal sinovenous thrombi have associated cerebral parenchymal infarcts, and 83% of these are hemorrhagic infarcts.[81] Treatment recommendations for neonatal venous sinus thrombosis are not standardized, aside from treatment of underlying conditions, when relevant (eg, infection, congenital heart disease, dehydration). The high rate of associated hemorrhage increases the risk of treatment with heparin, either unfractionated or LMWH, so treatment plans should be individualized. In older patients, punctate hemorrhage behind a cerebral venous infarct is not an absolute contraindication to anticoagulation, but studies in neonates are lacking. Nevertheless, in the Canadian registry, 36% of neonates were treated with heparin, unfractionated or LMWH, most for 3 months, and no cases of death or neurologic compromise from hemorrhage were reported.[81] Overall outcomes from the Canadian registry reveal neurologic impairment in up to two-thirds of cases and approximately 2% mortality.[82] Associated parenchymal infarction is associated with prolonged neurologic deficits.

Principles of Therapy

As with other age groups, therapeutic modalities available to neonates include supportive care, anticoagulation, thrombolytic agents, and surgical thrombectomy. The British Haemostasis and Thrombosis Task Force has proposed guidelines for the management of neonatal thrombosis.[63] Supportive therapy is recommended for clinically silent thrombi, including catheter-mediated events. As soon as practical, catheters associated with thrombi should be removed, and all documented thrombi should be followed closely with serial imaging.

Anticoagulation with unfractionated or LMWH is described in neonates and is the mainstay of anticoagulant therapy. Oral vitamin K antagonists are not recommended in the acute settings for management of neonatal thrombosis. Anticoagulation with heparin in neonates often requires supplementation of physiologically low levels of antithrombin with concentrate or fresh frozen plasma, especially for

Treatment of Neonatal Thrombosis

Unfractionated Heparin
Bolus: 75 unites/kg UFH over 10 minutes
Maintenance: 28 units/kg/h, therapeutic goal = 0.3–0.7 U/ml
Prophylaxis: 10 U/kg/h
Follow platelet count q2d to detect 2–5% chance of HIT

Enoxaparin
1.5 mg/kg SC q12h (with normal renal function)
Check anti-Factor Xa level by peripheral venipuncture 4–6 hours after 2nd or 3rd dose therapeutic goal 0.5–1 U/ml (goal 0.4–0.6 U/ml if concurrent thrombocytopenia or other bleeding risk factor)
Hold for 12 hours prior to minor procedures, 24 h prior to major procedures
Follow platelet count q2d to detect 2–5% chance of HIT

Prophylaxis with Enoxaparin
0.75 mg/kg SC q12h
If checked, anti-Factor Xa level 4–6 hours after 2nd or 3rd dose should be <0.4 U/ml
Hold for 12 hours prior to procedures

Purpura Fulminans
Concurrent unfractionated heparin (as above); goal = 0.3–0.7 U/ml and replacement with FFP or protein C concentrate.
FFP: 15 ml/kg BID until specific diagnosis is clear
Protein C concentrate for severe protein C deficiency
Load with 100–120 U/kg, then 60–80 U/kg q6h × 3 doses (goal protein C activity 100%). Once therapeutic anticoagulation is achieved, maintenance therapy with 45–60 U/kg q6–12h (goal protein C activity >25%)

Antithrombin III Repletion
Antithrombin III (functional) should be maintained at >35% of normal levels for effective heparin-based anticoagulation
Dose in International Units = (desired – current ATIII*) × weight (kg)

*expressed as % normal level based on functional ATIII level.

tPA Thrombolysis in Neonatal Thrombosis

Concurrent Heparin (Unfractionated Heparin or Enoxaparin) Should Be Considered at Prophylactic Dosing

- Non-life or limb-threatening thrombi:
  0.05 mg/kg h × 2 h
  If no improvement 0.1 mg/kg/h × 6 hours
  Discontinue after 8 hours
- Life or limb-threatening thrombi:
  0.1 mg/kg/h for up to 6 hours
  If no response, consider increase by 0.1 mg/kg/h increments to max 0.5 mg/kg/h
  Maintain fibrinogen >150 mg/dL
  Reversal of severe bleeding with aminocaproic acid at 100 mg/kg IV q6h

Recommended Dosing for Transfusion in Neonatal Hemorrhage

PRBCs: 10–15 cc/kg single donor PRBCs infused over 4 hours
Platelets*: 10 ml/kg raises platelet count by 75 K (goal >50 K if bleeding, >20 K if not)
FFP: 10 ml/kg raises factor levels 0.1–0.2 U/ml; 15 ml/kg BID for purpura fulminans
Cryoprecipitate: 0.15 U/kg raises fibrinogen about 100 mg/dL (goal >150 mg/dL if bleeding, >50 mg/dL if not bleeding)
Von Willebrand Factor: 40–69 "ristocetin cofactor units"/kg of plasma-derived FVIII/VWF preparations
Factor VIII: for hemophilia A—50 U/kg load, then 25 U/kg q12h. Recombinant factor preferred.
Factor IX: for hemophilia B—80–100 U/kg daily. Recombinant factor preferred.
Factor VIIa: for severe factor VII deficiency—20–30 mcg/kg q6–12h

*Volume limits transfusion of platelets by the "unit" in small neonates. Practices vary—follow institutional guidelines for volume dosing or volume reduction.

apparent heparin resistance. The starting doses for heparin (unfractionated and LMW) are outlined in the Treatment of Neonatal Thrombosis box. Management of heparin anticoagulation in neonates requires special consideration for physiologically low antithrombin levels and prolonged PTT. Antithrombin should be corrected in laboratory evaluation of anti-Xa levels. Therapeutic anticoagulation is defined by therapeutic anti-Xa levels (0.3–0.7 units/mL for unfractionated heparin and 0.5–1 units/mL for LMWH). Unfractionated heparin dosing may also be adjusted according to the PTT that correlates to anti-Xa levels of 0.3 to 0.7 units/mL. Three LMWHs have been studied in neonates,[85] and the most experience lies with enoxaparin. Prophylactic heparin administration is recommended for umbilical arterial lines (0.5 units/h) and for cardiac catheterization (bolus 100–150 units/kg with catheter insertion, repeat for prolonged procedures).

The antibodies that cause heparin-induced thrombocytopenia (HIT) are found in neonates with an estimated incidence as high as 1.5%,[86] particularly in patients following cardiac surgery. Overt HIT with thrombosis is apparently much more rare, although it has been observed in neonates and can be life-threatening. Mothers with HIT can passively transfer this antibody to their fetus. Diagnostic criteria for HIT include platelet count decrease by more than 50%, timing 5 to 10 days after heparin initiation (neonates cannot exhibit an anamnestic response) and new thrombosis with a positive HIT antibody. Treatment includes cessation of heparin therapy and anticoagulation with argatroban or lepirudin. Data supporting use of these agents is sparse in neonates but is reviewed by Risch and colleagues.[87] Fondaparinux might be a reasonable option in selected cases, but experience in neonates is limited.

Guidelines for thrombolytic management of neonatal thrombi have been reported by the British Haemostasis and Thrombosis Task Force[63] and the Perinatal and Pediatric Subcommittee of the International Society of Thrombosis and Haemostasis.[88] Both groups agree that thrombolysis should be considered for extensive thrombosis, organ dysfunction, limb-threatening ischemia, and low-dose thrombolysis for catheter-occluding thrombi. Tissue plasminogen activator is the most studied thrombolytic reagent in pediatric patients. Transfusion support for hypofibrinogenemia and thrombocytopenia should be provided to minimize bleeding risk. Contraindications for thrombolytic therapy include active bleeding and major surgery or bleeding within 10 days, whereas relative cautions include severe asphyxia within 7 days, seizures within 48 hours, sepsis or prematurity of less than 32 weeks of gestation. When required, heparin given concomitantly with tPA should be given at prophylactic dosing (0.75 mg/kg every 12 hours for LMWH or 10 units/kg/h for unfractionated heparin). Surgical thrombectomy is reserved for organ, limb, or life-threatening thrombi when tPA is impractical or predicted to be ineffective or too slow.

CHAPTER 134

HYPERCOAGULABLE STATES

Kenneth A. Bauer

INTRODUCTION

Improved understanding of the molecular basis of the coagulation mechanism coupled with clinical investigation has facilitated the identification of hemostatic risk factors in substantial numbers of patients presenting with venous thrombosis. Persons with a tendency to thrombosis are defined as having thrombophilia, and the term *inherited thrombophilia* is applied to persons with genetic defects that predispose them to the development of venous thromboembolism.

This chapter describes the hereditary thrombotic disorders or primary hypercoagulable states (Table 134–1), as well as some of the major acquired or secondary hypercoagulable states (malignancy, nephrotic syndrome, paroxysmal nocturnal hemoglobinuria [PNH], hyperviscosity syndromes, drug-induced thrombosis, and antiphospholipid antibody syndrome).

CLINICAL APPROACH

Differential Diagnosis

A clinically useful approach to patients with an active thrombotic process is to categorize the underlying disorder as either a primary or an acquired hypercoagulable state. Thus, one group of patients will have features that suggest the presence of an inherited thrombotic disorder or a primary hypercoagulable state (see Table 134–1). Such disorders result from mutations in single genes encoding a plasma protein component of one of the major natural anticoagulant mechanisms. The anticoagulant systems most frequently involved in the inherited hypercoagulable states include antithrombin III in the heparan sulfate-antithrombin III mechanism and protein C, protein S, and factor V Leiden in the protein C anticoagulant pathway (Fig. 134–1). An elevation in the plasma prothrombin level in association with a G to A transversion at position 20210 in the 3′-untranslated region of the prothrombin gene also is a risk factor for venous thrombosis.

A second group of patients have an acquired or secondary hypercoagulable state. The underlying disorder may be any of a heterogeneous group of disorders characterized by an increased risk for the development of thrombotic complications compared with that in the general population (Table 134–2).

The inherited thrombotic disorders (see Table 134–1) have been associated almost exclusively with *venous thrombosis*. Hereditary deficiencies of antithrombin III, protein C, or protein S will be found in less than 10% of unselected individuals presenting with venous thromboembolism (Table 134–3). Resistance to activated protein C because of the factor V Leiden mutation and the prothrombin G20210A mutation are more prevalent defects that can also be found in significant numbers of persons with first episodes of idiopathic venous thrombosis older than age 50 in the absence of a positive family history.[1–3]

A significant percentage of women with thrombosis in association with oral contraceptive use or pregnancy will have an inherited disorder, especially the factor V Leiden[4,5] and prothrombin G20210A mutations.[6] Hereditary thrombophilia has also been identified as a risk factor in patients with venous thrombosis in uncommon sites such as the portal, hepatic, mesenteric, axillary, and cerebral veins. The presence of indwelling venous catheters however, is the most common risk factor today for upper extremity venous thrombosis, and this complication generally does not warrant evaluation of the patient for an underlying hypercoagulable state.

Although classification of patients as having either a hereditary or an acquired disorder is useful in directing the laboratory evaluation for hypercoagulability, thrombosis frequently results from the interplay of genetic and acquired factors. Patients with hereditary defects are at lifelong risk of developing thrombosis, and stimuli such as pregnancy, estrogen use, or surgery trigger thrombotic episodes in perhaps 50% of affected persons. Also, defects in more than one coagulation protein can be identified in some patients who have experienced venous thrombosis, reflecting the high background frequency in the general population of abnormalities such as factor V Leiden[2] and the prothrombin G20210A mutation.[8] Such patients have a more severe thrombotic tendency than those with a single identifiable mutation.[9–15] Thus, thrombosis can be viewed as a multigene disorder in which susceptible persons will have one or more genetic mutations, with clinical events occurring when they are exposed to exogenous prothrombotic stimuli (Fig. 134–2).[16] In many cases, however, the inciting precipitant to thrombosis is not reported by the patient and presumably is subclinical.

History and Physical Examination

In the evaluation of patients with a recent or remote history of thrombosis, historical details should be obtained regarding the age of onset, location of prior thrombotic lesions, and results of objective diagnostic studies documenting thrombosis. Such diagnostic studies are critical, because the clinical diagnosis of deep vein thrombosis, in particular, is notoriously inaccurate (see Chapter 135). The patient should be carefully questioned about circumstances proximate to the time of thrombosis that might have precipitated the event. Possible inciting factors include surgical procedures, trauma, pregnancy, immobility, and estrogen administration. Women should be carefully questioned regarding prior use of oral contraceptives or hormone replacement therapy and obstetric history. An increased risk of recurrent fetal loss is associated with the presence of lupus anticoagulants or antiphospholipid antibodies, as well as with the hereditary thrombotic disorders.[17–21] A family history is particularly important because a well-documented history of venous thrombosis in one or more first-degree relatives strongly suggests the presence of a hereditary defect. The initial manifestation of a malignancy can be a thrombotic event, so inquiry should be made regarding the presence of constitutional symptoms (eg, diminished appetite, weight loss, fatigue), pain, hematochezia, hemoptysis, or hematuria. It also should be ascertained whether the patient has an underlying disease, such as cancer, collagen-vascular disease, a myeloproliferative disorder, atherosclerotic disease, or nephrotic syndrome, or takes synthetic or natural estrogens, or drugs that can induce lupus anticoagulants, such as hydralazine, procainamide, or phenothiazines. Recurrent thrombosis despite therapeutic anticoagulation with oral anticoagulants is common in patients with an occult neoplasm or an established diagnosis of cancer.

In the physical examination, special attention should be directed to the vascular system, extremities to look for signs of superficial or

Table 134–1 Differential Diagnosis of the Patient Presenting with Thrombosis or Thrombotic Diathesis

Inherited (Primary) Hypercoagulable States
- Activated protein C resistance caused by factor V Leiden Mutation
- Prothrombin gene mutation (G to A transition at position 20210 in the 3′-untranslated region)
- Antithrombin III deficiency
- Protein C deficiency
- Protein S deficiency
- Dysfibrinogenemias (rare)

Acquired (Secondary) Hypercoagulable States

In association with physiologic or thrombogenic stimuli
- Pregnancy (especially the postpartum period)
- Estrogen use (oral contraceptives, hormone replacement therapy)
- Immobilization
- Trauma
- Postoperative state

Advancing age

Obesity

Prolonged air travel

Lupus anticoagulant or antiphospholipid antibody syndrome

In association with other clinical disorders (see Table 134–2)

Mixed/Unknown
- Activated protein C resistance in the absence of factor V Leiden
- Elevated factor VIII level
- Elevated factor XI level
- Elevated factor IX level
- Elevated thrombin activatable fibrinolysis inhibitor (TAFI) level
- Decreased free tissue factor pathway inhibitor (TFPI) level
- Decreased plasma fibrinolytic activity

deep vein thrombosis, chest, heart, abdominal organs, and skin to detect skin necrosis or livedo reticularis. Because venous thromboembolism may be the first manifestation of an underlying malignancy, rectal examination and stool testing for occult blood should be done, and women should undergo a pelvic examination.

The hereditary thrombotic disorders include deficiencies of antithrombin III, protein C, or protein S; the factor V Leiden and prothrombin G20210A mutations; and rarely, dysfibrinogenemias. The most common sites of thrombosis in such patients are the deep leg veins, iliac veins, and pulmonary arteries. Thrombosis in mesenteric, portal, and cerebral veins as well as superficial thrombophlebitis has been described in patients with these disorders. Typical precipitating

Table 134–2 Acquired Conditions and Disorders Associated with Hypercoagulable States

Systemic lupus erythematosus in association with the presence of a lupus anticoagulant or antiphospholipid antibodies

Malignancy
- Disease-related: includes migratory superficial thrombophlebitis (Trousseau syndrome), nonbacterial thrombotic endocarditis, thrombosis associated with chronic DIC, thrombotic microangiopathy
- Treatment-related: associated with the administration of various chemotherapeutic agents (L-asparaginase, mitomycin, some adjuvant chemotherapeutic agents for treatment of breast cancer, thalidomide or lenalidomide in conjunction with high doses of dexamethasone

Infusion of prothrombin complex concentrates

Nephrotic syndrome

Heparin-induced thrombocytopenia

Myeloproliferative disorders

Paroxysmal nocturnal hemoglobinuria

DIC, disseminated intravascular coagulopathy

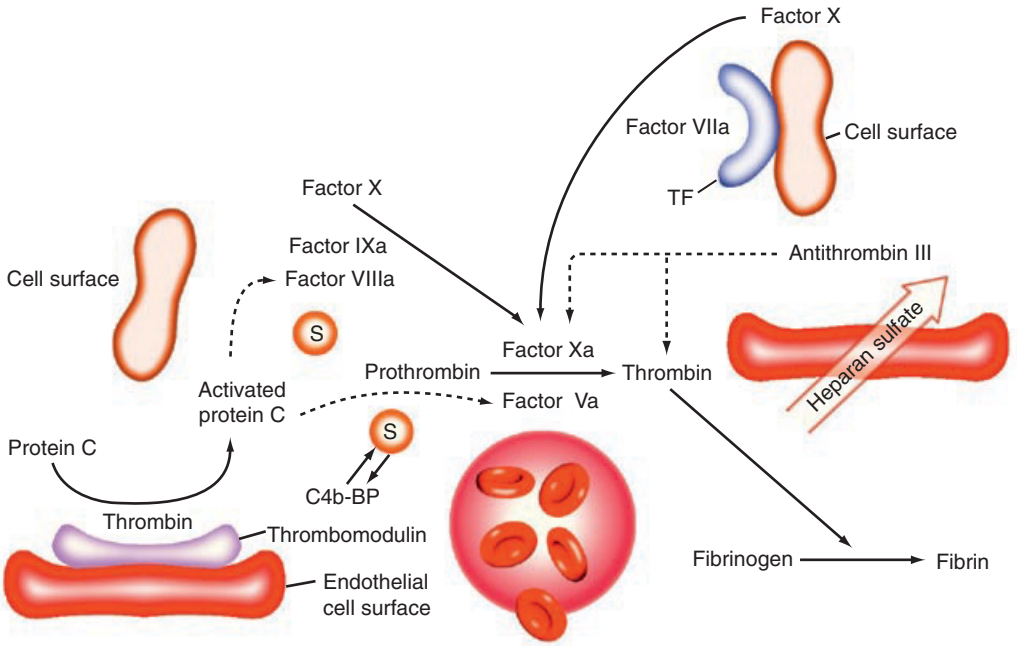

Figure 134–1 A SCHEMATIC DIAGRAM OF THE PATHWAYS THAT GENERATE FACTOR XA AND THROMBIN, AND THE NATURAL ANTICOAGULANT MECHANISMS THAT REGULATE THE ACTIVITY OF THESE ENZYMES. Factor X can be activated by factor VIIa-tissue factor (TF) complex or the factor IXa-VIIIa-activated cell surface complex. Factor Xa binds to the factor Va on activated platelets and mediates the conversion of prothrombin to thrombin under physiologic conditions. Thrombin is then able to act upon fibrinogen to form a fibrin clot. Thrombin and factor Xa are inactivated by antithrombin III bound to heparan sulfate molecules associated with the vascular endothelium, resulting in the formation of factor Xa-antithrombin III and thrombin-antithrombin III complexes. Protein C is activated by thrombin bound to the endothelial cell receptor thrombomodulin. Once activated, protein C functions as a potent anticoagulant by inactivating factors VIIIa and Va. Protein S enhances the binding of activated protein C to phospholipid-containing membranes and is able to accelerate the inactivation of factors VIIIa and Va by this enzyme. The complement component, C4b-binding protein (C4b-BP), forms complexes with protein S, which neutralizes its ability to serve as a cofactor for activated protein C in inactivating factors VIIIa and Va.

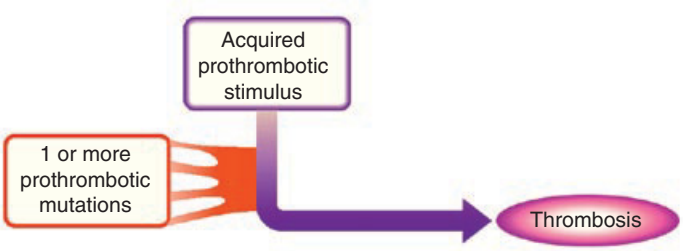

Figure 134–2 Venous thrombosis can be viewed as a multigene disorder in which susceptible persons will have one or more genetic mutations. Clinical events often occur when they are exposed to exogenous prothrombotic stimuli. *(Modified from Schafer AI: Hypercoagulable states: Molecular genetics to clinical practice. Lancet 344: 1739, 1994, with permission. © by the Lancet, Ltd.)*

Table 134–3 Prevalence of Defects in Patients with Venous Thrombosis

Activated protein C resistance (factor V Leiden)	12–40%[a]
Prothrombin gene mutation (G to A transition at position 20210 in the 3′-untranslated region)	6–18%[a]
Deficiencies of antithrombin III, protein C, protein S	5–15%
Antiphospholipid antibody syndrome	5–10%

[a]Prevalence restricted to white populations.

factors for thrombosis in such patients are the postoperative state, immobilization, trauma, pregnancy, oral contraceptive use, and advancing age.

Patients with thrombosis should be questioned regarding their ethnic background. The factor V Leiden and prothrombin G20210A mutations are not found in aboriginal African, Native American, or Asian populations.[22,23] The two mutations arose approximately 30,000 years ago in whites in Europe.[24,25] The carrier frequency of the factor V Leiden in the U.S. population with African, Native American, or Asian ancestry is 1.23%, 1.25%, and 0.45%, respectively.[26]

Laboratory Evaluation

Routine Tests

The initial laboratory evaluation for patients with thrombosis should include a complete blood count, review of the peripheral blood smear, and serum chemistries including liver and renal function tests, and urinalysis.

Elevations in the hematocrit, white blood cell count, or platelet count should lead to consideration of polycythemia vera and essential thrombocythemia in the differential diagnosis. These myeloproliferative disorders predispose patients to venous as well as arterial thrombotic events, particularly when the hematocrit or platelet count is not controlled by therapy. In addition, secondary polycythemia or secondary thrombocytosis may provide a clue to an underlying occult neoplasm that may itself be the predisposing factor to thrombosis. Leukopenia and thrombocytopenia often are found in PNH, a hematologic disorder characterized by chronic intravascular hemolysis with episodes of gross hematuria and a unique constellation of thrombotic complications. These occur almost exclusively in the abdominal venous network, including the mesenteric, hepatic, portal, splenic, and renal veins, and the cerebral venous circulation. The development of thrombosis and thrombocytopenia concurrent with heparin administration should always prompt consideration of the diagnosis of heparin-induced thrombocytopenia.

If the blood smear shows evidence of red-cell fragmentation or schistocytes, the differential diagnosis includes disseminated intravascular coagulation (see Chapter 132) and the thrombotic microangiopathies (thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome). Although bleeding is the most common coagulation problem in disseminated intravascular coagulation, patients with malignancy can have a low-grade consumptive coagulopathy leading to the development of venous or arterial thrombosis. The latter can result from emboli arising from fibrin vegetations on the mitral or aortic valves (ie, nonbacterial thrombotic endocarditis). A leukoerythroblastic picture with nucleated red blood cells or immature white cells on the peripheral smear should suggest the possibility of bone marrow involvement by tumor.

Patients with Budd-Chiari syndrome, which occurs when there is obstruction of the hepatic venous circulation, have ascites and hepatomegaly along with abnormal liver function tests. The nephrotic syndrome is characterized by large amounts of protein in the urine, hypoalbuminemia, and hyperlipidemia. Renal vein thrombosis can complicate the clinical course in up to one-third of such patients, but patients with nephrotic syndrome are prone as well to venous thrombosis in sites such as leg veins and pulmonary arteries.

Patients with thrombosis should routinely undergo baseline coagulation tests, including prothrombin time and partial thromboplastin time (PTT). For the latter test, use of a reagent sensitive to the presence of lupus anticoagulants will provide an initial screen for this acquired abnormality. If the PTT is normal, the use of additional specialized clotting assays such as the dilute Russell viper venom time, kaolin clotting time, and the tissue thromboplastin inhibition test, may facilitate making this diagnosis in patients suspected on clinical grounds of having a lupus anticoagulant (see Chapter 131). Some, but not all, individuals with lupus anticoagulants have elevated titers of cardiolipin or β_2-glycoprotein-I antibodies. Patients with abnormal test results should be periodically reevaluated, because lupus anticoagulants or elevated cardiolipin antibody levels are considered to be risk factors for thrombosis only if the abnormalities persist over several months.

In patients who present with idiopathic venous thromboembolism, the available data do not support an extensive search (eg, computed tomography scans of the chest, abdomen, and pelvis) for occult malignancy. It is however important to pursue symptoms or findings on physical examination that suggest an underlying malignancy and to ensure that age-appropriate screening tests have been performed (ie, mammography, colonoscopy).

Tests for Specific Biologic Risk Factors

Based on the history and physical examination, a decision must be made as to whether testing should be performed to identify specific biologic risk factors predisposing to thrombosis. Clinical judgement must be exercised with regard to the scope of the evaluation as well as the optimal time for its performance. The decision as to which tests should be ordered is determined partly by the type of thrombotic event (Table 134–4). Hereditary deficiencies of antithrombin III, protein C, and protein S, and the factor V Leiden mutation and the prothrombin G20210A mutations are risk factors for venous thrombosis. Although there are reports of an association with arterial thrombosis in select populations, such as children and young women with myocardial infarction, it is generally not recommended to test for these defects in most such patients. The presence of a lupus anticoagulant is a risk factor for venous as well as arterial thrombosis. Therefore, performance of these tests is warranted in the latter group of patients, particularly when other factors predisposing to arterial thrombosis are absent.

Additional factors will guide the extent of the laboratory evaluation. Clinical features that increase the likelihood of identifying individuals with deficiencies of antithrombin III, protein C, and protein

Table 134–4 Sites of Thrombosis According to Coagulation Defect

Abnormality	Arterial	Venous
Factor V Leiden	–	+
Prothrombin gene mutation	–	+
Antithrombin III deficiency	–	+
Protein C deficiency	–	+
Protein S deficiency	–	+
Lupus anticoagulant	+	+

S include an initial venous thrombotic event younger than the age of 50 years, recurrent thrombosis, and positive family history.[27] These features also increase the chances of identifying individuals with factor V Leiden and the prothrombin gene mutation, although these genetic defects also can frequently be identified in older individuals with an initial episode of deep venous thrombosis who do not have acquired risk factors or a positive family history. Screening for all of these defects and lupus anticoagulant/antiphospholipid antibodies also is warranted in patients with thrombosis in unusual vascular beds (eg, mesenteric vein thrombosis, cerebral venous thrombosis).

Some clinical features have been associated with individual hereditary thrombotic disorders. Approximately one-third of individuals who sustain the rare complication of warfarin-induced skin necrosis will prove to have protein C deficiency; however, this syndrome has also been reported in patients with protein S deficiency[28] and factor V Leiden.[29] In newborn infants, the development of skin necrosis and visceral thrombosis (eg, neonatal purpura fulminans) indicates a likely diagnosis of severe hereditary protein C deficiency, although cases have been reported in association with homozygous protein S deficiency as well. Both conditions require emergent therapy if major morbidity or mortality are to be averted. Although the presence of resistance to heparin's anticoagulant effect, as measured by the PTT, often leads to consideration of antithrombin III deficiency, congenital antithrombin III deficiency is infrequently diagnosed in such individuals.

Table 134–5 gives a list of tests useful in screening patients suspected of having a biologic defect predisposing to thrombosis. Coagulation assays with high sensitivity and specificity for the factor V Leiden mutation are available and are based on the resistance of the mutant factor Va molecule to inactivation by activated protein C. Positive results are confirmed by genetic testing of DNA obtained from peripheral blood mononuclear cells. Initial testing for the factor V Leiden mutation can also be done genetically; testing for the prothrombin G20210A mutation must be done genetically. The best screening tests for deficiencies of antithrombin III, protein C, and protein S are functional assays that detect both quantitative and qualitative defects. Immunologic assays detect only quantitative deficiencies of these proteins. For antithrombin III, convenient functional assays are available that measure the heparin cofactor activity of the molecule. Among protein C assays, coagulation assays provide a more complete evaluation of the functional activity of the molecule than is possible with amidolytic assays. However, coagulation assays for protein C as well as protein S can give falsely low values if the factor V Leiden mutation is present,[30] and reliable application of these assays requires initial assessment as to whether this mutation is present. To screen for a dysfibrinogenemia, the thrombin time is recommended along with measurements of plasma fibrinogen by clotting and immunologic assay.

Timing of Laboratory Testing

An important consideration in the laboratory evaluation of patients with a suspected deficiency of antithrombin III, protein C, or protein S is the timing of testing. Erroneous diagnoses can be made because of the influence of acute thrombosis, comorbid illness, or anticoagulant therapy on the levels of these plasma proteins. Table 134–6 provides a list of some of the common causes of acquired deficiencies of antithrombin III, protein C, or protein S.

Acute thrombosis by itself can result in transiently reduced levels of antithrombin III and, occasionally, protein C and protein S. Heparin therapy can be associated with up to a 30% decline in plasma antithrombin III levels over several days, whereas warfarin produces a marked drop in the functional activity of protein C and protein S and a lesser decline in immunologic levels. Warfarin has also been shown to rarely elevate antithrombin III levels significantly, sometimes into the normal range, in patients with a hereditary deficiency of this inhibitor. For these reasons, it is optimal to test for

Table 134–5 Screening Laboratory Evaluation for Patients Suspected of Having a Biologic Defect Predisposing to Thrombosis

Test for presence of factor V Arg506Gln
Screen with clotting assay using factor V-deficient plasma[a] and confirm with genetic test for factor V Arg506Gln (factor V Leiden) or obtain genetic test for factor V Arg506Gln (factor V Leiden) only
Genetic test for prothrombin gene mutation (G to A transition at position 20210 in the 3′-untranslated region)
Functional assay of antithrombin III (heparin-cofactor assay)[a]
Functional assays of protein C[a]
Functional assay of protein S/immunological assays of total and free protein S[a]
Screen for dysfibrinogenemias (immunologic and functional assays of fibrinogen, thrombin time)[a]
Clotting assay for lupus anticoagulant[a]/serologic tests for antiphospholipid antibodies

[a]Coagulation assays are performed on platelet-poor plasma obtained from blood samples drawn into a solution containing 3.8% (wt/vol) sodium citrate. The ratio of anticoagulant to blood is 0.1:0.9 (vol/vol). In the absence of an accompanying clinical history for the patient, determination of the prothrombin time will help to exclude the ingestion of warfarin, which will affect the measurements of protein C and protein S. Determination of the thrombin time as well as the PTT will help to exclude the administration of heparin.

PTT, partial thromboplastin time.

Table 134–6 Causes of Acquired Deficiencies in Antithrombin III, Protein C, or Protein S

Antithrombin III	Protein C	Protein S
Neonatal period	Neonatal period	Neonatal period
Pregnancy		Pregnancy
Liver disease	Liver disease	Liver disease
DIC[a]	DIC[a]	DIC
Nephrotic syndrome	Chemotherapy (CMF)

Acute thrombosis	Acute Thrombosis	Acute thrombosis
Treatment with:		
Heparin	Warfarin	Warfarin
L-asparaginase	L-asparaginase	L-asparaginase
Estrogens		Estrogens

CMF, cyclophosphamide, methotrexate, 5-fluorouracil; DIC, disseminated intravascular coagulation.

these deficiency states at least 2 weeks after the patient has completed the initial course of oral anticoagulant therapy following a thrombotic event. If, however, levels of antithrombin III, protein C, or protein S are obtained on acute presentation and are well within the normal range, these findings will effectively exclude the diagnosis of these deficiency states. The finding of a low level during this period will need to be confirmed by repeat testing after anticoagulation is discontinued.

The investigation of first-degree family members is useful to document the hereditary nature of the deficiency. Confirmation of a deficiency state in first-degree family members is particularly helpful diagnostically in patients in whom the risks of recurrent thrombosis are too great to temporarily discontinue anticoagulation. In such patients, a diagnosis of protein C or protein S deficiency can be confirmed by carrying out testing after warfarin has been discontinued for 2 weeks under the cover of heparin or low-molecular-weight heparin at therapeutic doses.

Other Coagulation Abnormalities

Elevations in the levels of several coagulation factors, including factor VIII,[31–33] factor XI,[34] factor IX,[35] thrombin activatable fibrinolysis inhibitor,[36] and decreased levels of free tissue factor pathway inhibitor[37] and plasma fibrinolytic activity[38] have been implicated as risk factors for a first episode of venous thrombosis. The molecular basis for these abnormalities has not been elucidated. For factor VIII, high plasma activity levels cannot be attributed to overt inflammation because patients with levels greater than 150% did not have elevations in acute phase reactants such as C-reactive protein, fibrinogen, and erythrocyte sedimentation rate.[39] Austrian investigators found that the probability of recurrent venous thrombosis at 2 years in persons with factor VIII levels greater than 234% of normal (the 90th percentile of the values for the study sample) was 37% compared with 5% in patients with levels less than 120% of normal. This observation has not however been corroborated by other groups.[40,41]

In the absence of the factor V Leiden mutation, a significantly increased risk for venous thrombosis is associated with a reduced sensitivity to activated protein C, as measured by a clotting assay that does not mix patient's plasma with factor V-deficient plasma.[42] However, this risk is lower than in carriers of the factor V Leiden mutation. This increased risk remains after adjustment for elevated levels of factor VIII and oral contraceptive use, both of which are known to lead to a reduced response to activated protein C.

Many other hemostatic gene polymorphisms have been investigated and suggested to be risk factors for venous and arterial thrombosis; most of these associations have not been substantiated by subsequent studies.[43–46]

There have been reports of thrombosis in association with abnormalities in other coagulation or fibrinolytic system proteins. These include heparin cofactor II deficiency, plasminogen deficiency (either hypo- or dysplasminogenemias), factor XII deficiency, and elevations in plasminogen activator inhibitor type 1 (PAI-1). Causal associations between these abnormalities and an increased risk of thrombosis have not been clearly defined, however.

INHERITED HYPERCOAGULABLE DISORDERS

Antithrombin III Deficiency

In 1965, Egeberg[47] described a Norwegian family in which certain members who had a history of thrombosis had plasma concentrations of antithrombin III that were 40% to 50% of normal. Subsequently, other investigators described additional families with a similar constellation of clinical and laboratory abnormalities.[48,49]

Antithrombin III deficiency is inherited in an autosomal dominant fashion and thus affects both sexes equally. Two major types of inherited antithrombin III deficiency have been delineated (Table 134–7). The type I deficiency state is a result of reduced synthesis of biologically normal protease inhibitor molecules.[50] In these cases, the antigenic and functional activity of antithrombin III in the blood is reduced in parallel. The molecular basis of this disorder is either a deletion of a major segment of the antithrombin III gene or, more commonly, the occurrence of small deletions/insertions, or single base substitutions. These mutations will introduce a frameshift, a direct termination codon, a change in messenger RNA (mRNA) processing, or unstable translation products. The antithrombin III mutation database includes more than 100 distinct mutations in patients with a type I deficiency.[51] The second type of antithrombin III deficiency is produced by a discrete molecular defect within the protease inhibitor (type II). The plasma levels of antithrombin III are greatly reduced as judged by functional activity, whereas antithrombin III immunologic activity is essentially normal.

Table 134–7 Assay Measurements in Heterozygous Antithrombin (ATIII) Deficiency

	Activity		
Types	**Antigen**	**Heparin Cofactor**	**Progressive ATIII**
I	Low	Low	Low
II			
Active site defect	Normal	Low	Low
Heparin-binding site defect	Normal	Low	Normal

The prevalence of type I antithrombin III deficiency in the adult population is approximately 1:2000.[52,53] Studies of healthy blood donors employing functional assays that measure heparin cofactor activity have found that the prevalence of antithrombin III deficiency in the general population is 1:250 to 1:500;[54,55] a substantial number, however, have a type II defect with mutations at the heparin-binding site that are associated with a lower risk of thrombosis.[53] The best single screening test for the disorder is the antithrombin III-heparin cofactor assay that measures factor Xa inhibition.

The thrombotic risk associated with antithrombin III deficiency depends on population selection. In older reviews of antithrombin III deficiency including families with a high penetrance of thrombosis, more than 50% of affected patients experience venous thrombotic episodes.[56,57] The initial clinical manifestations occur apparently spontaneously in approximately 42% of subjects but are related to pregnancy, parturition, oral contraceptive ingestion, surgery, or trauma in the remaining 58% of patients.[56] The most common sites of disease are the deep veins of the leg and the mesenteric veins. Recurrent thrombotic episodes occur in approximately 60% of affected persons, and clinical signs of pulmonary embolism are evident in 40%.[56] Although cases have been reported in which antithrombin III-deficient infants sustained cerebral venous thrombosis,[58–60] thrombotic episodes are rare in affected children before puberty. After puberty, thrombotic events occur with some frequency and the risk of thrombosis increases substantially with advancing age.[56] First-degree relatives of symptomatic individuals with antithrombin III deficiency have an 8- to 10-fold increased risk of thrombosis over that in noncarriers.[61,62] In the Leiden Thrombophilia Study, a case-control study of 474 consecutive patients following an initial episode of deep vein thrombosis,[63] the prevalence of antithrombin III deficiency was only 1.1%, and the odds ratio for thrombosis was only 5.0.[64]

The first family with type II antithrombin III deficiency was described in 1974.[65] Many families with this type of deficiency state have been reported, and they have been further subcategorized on the basis of two different functional assays of antithrombin III activity. The first is the antithrombin III-heparin cofactor assay, which measures the ability of heparin to bind to lysyl residues on the inhibitor and catalyze the neutralization of coagulation enzymes such as thrombin and factor Xa. This assay, based on factor Xa inhibition,

is currently the most widely used functional antithrombin III assay. The second test is the progressive antithrombin III activity assay, which quantitates the capacity of this inhibitor to neutralize the enzymatic activity of thrombin in the absence of heparin.

Heparin cofactor II is another protein in human plasma that exhibits heparin cofactor activity.[66,67] In contrast to antithrombin III, this inhibitor does not inhibit factor Xa or other serine proteases and requires concentrations of heparin of at least 1 unit/mL in the reaction mixture to function as an efficient inhibitor of thrombin; it therefore probably plays a minimal role when heparin is used clinically as an anticoagulant.[67] Because some functional antithrombin III assays employ heparin concentrations greater than 1 unit/mL, an assay based on factor Xa inhibition is more specific than one based on thrombin inhibition to identify patients with congenital antithrombin III deficiency.[68] Heparin cofactor II can also interact with another glycosaminoglycan, dermatan sulfate, and this binding dramatically accelerates the neutralization of thrombin by this inhibitor. Several patients have been described with inherited deficiencies of heparin cofactor II and thrombotic phenomena,[69,70] but the causal relationship is uncertain.[71]

Many mutant antithrombin III molecules have been identified with reductions in heparin cofactor activity without a concordant reduction in progressive antithrombin III activity.[51] These variants generally have mutations at a heparin-binding site at the N-terminal end of the molecule. Variants with decreased activity in both antithrombin functional assays generally have mutations near the Arg393-Ser394 site at the C-terminal end of the molecule. Another type of mutation has been described at the C-terminal end of the antithrombin III molecule between amino acids 402 and 429. These type II variants are termed *pleiotropic* because they exhibit multiple functional defects.[72] Mutations at positions 402 to 407 can lead to the presence of trace amounts of an electrophoretically and functionally abnormal antithrombin III molecule.[72] The similarity of characteristics of these mutations indicates that the region of residues 402 to 407 is important for the maintenance of normal plasma levels of antithrombin III antigen.[73]

A case-control study of 1,018 Spanish patients with venous thromboembolism recently reported that the antithrombin A348S mutation was present in 1.7% and 0.2% of cases and controls, respectively.[74] Presence of the mutant allele was associated with an adjusted odds ratio of 9.75 (95% confidence interval [CI], 2.2–42.5) for venous thrombosis. This mutation did not decrease antithrombin III antigen or anti-factor Xa activity in a heparin cofactor assay, and it only slightly reduced anti-thrombin activity. As only six cases were identified as having antithrombin III deficiency by anti-factor Xa activity assay, this antithrombin variant represented the primary cause of antithrombin III deficiency in this population.

The risk of thrombosis is substantially less in heterozygous patients with type II defects at the heparin-binding site as compared to the thrombin-binding site.[75] Persons with plasma antithrombin III-heparin cofactor activity measurements of approximately 50% and normal progressive antithrombin III activity (ie, heparin binding site defects) have infrequent thrombotic episodes.[76,77] Several of these cases came to clinical attention when severe venous or arterial thrombosis, or both, accompanied by plasma antithrombin III-heparin cofactor levels below 10%, developed in young children of these heterozygous subjects.[78,79] There often was a history of parental consanguinity, and these children were homozygous for an antithrombin molecular defect. In contrast with this subgroup of patients, heterozygous type II patients with both diminished progressive antithrombin III activity and antithrombin III-heparin cofactor activity (ie, thrombin-binding site defects) sustain venous thromboembolism as often as type I patients do.

The mean concentration of antithrombin III in normal pooled plasma is approximately 140 μg/mL. Most laboratories report a normal range between 75% and 120% of normal pooled plasma for antithrombin III-heparin cofactor determinations, and a somewhat wider range for immunoassay results.

Healthy newborns have approximately one-half the normal adult concentration of antithrombin III;[80] levels gradually reach those in adults by 6 months of age.[81] The levels may be considerably lower in infants born after 30 to 36 weeks of gestation[81] and are even further reduced in infants with respiratory distress, necrotizing enterocolitis, sepsis, or disseminated intravascular coagulation (DIC). Thromboembolic events are rare in children with hereditary antithrombin III deficiency. In the absence of heparin, antithrombin III contributes approximately 80% of the thrombin-neutralizing capacity of normal adult plasma. The levels of a second thrombin inhibitor, α_2-macroglobulin, are higher during the first two decades of life than in adults, which may lessen the risk of thromboembolic complications in antithrombin III-deficient patients during childhood.[82]

A variety of pathophysiologic conditions can reduce the concentration of antithrombin III in the blood (see Table 134–6). Acute thrombosis infrequently lowers antithrombin III levels substantially, but DIC usually reduces the level of this inhibitor. Lowered antithrombin III concentrations occur in patients with liver disease as a result of decreased protein synthesis. Decreased antithrombin III levels are also observed in individuals with the nephrotic syndrome as a consequence of urinary excretion.[83] Furthermore, modest reductions in plasma antithrombin III concentration are found in users of oral contraceptives as well as in women receiving hormone replacement therapy.[56,84] The levels of antithrombin III do not change substantially during normal pregnancy but may decrease significantly in women with pregnancy-induced hypertension, preeclampsia, or eclampsia. Infusions of L-asparaginase can substantially lower the plasma concentration of this inhibitor. In addition, the administration of heparin decreases plasma antithrombin III levels,[85] presumably on the basis of accelerated in-vivo clearance. Evaluation of plasma samples from patients during a period of heparinization can therefore potentially lead to an erroneous diagnosis of antithrombin III deficiency.

Owing to the number of clinical disorders that can be associated with reductions in the plasma concentration of antithrombin III, definitive diagnosis of the hereditary deficiency state is often difficult. Although an antithrombin III level in the normal range usually is sufficient to exclude the disorder, low levels should be confirmed by obtaining another sample at a subsequent time point. This determination is ideally performed when the patient is no longer receiving oral anticoagulants, because these medications have occasionally been reported to increase plasma antithrombin III concentrations into the normal range in patients with the hereditary deficiency state.[48] Confirmation of the hereditary nature of the disorder requires the investigation of other family members. Diagnosis of other affected family members also allows for appropriate counseling regarding the need for prophylaxis against venous thrombosis.

Protein C Deficiency

In 1981, Griffin and colleagues[86] described the first kindred in which several persons had plasma levels of protein C antigen of approximately 50% of normal and a history of recurrent thrombotic events. Subsequently, others[87–89] reported families with heterozygous protein C deficiency.

Heterozygous protein C deficiency is inherited in an autosomal dominant fashion; a more severe form of protein C deficiency is an autosomal recessive disorder. The phenotype of patients with heterozygous protein C deficiency is similar to that of persons with hereditary antithrombin III deficiency. In severely affected families, approximately 75% of protein C-deficient individuals experienced one or more thrombotic events. The initial episode occurs apparently spontaneously in approximately 70% of those experiencing such events. The remaining 30% have typical associated risk factors, such as pregnancy, parturition, contraceptive pill use, surgery, or trauma, at the time they develop acute thrombotic events. Patients are infrequently symptomatic until their early 20s, but increasing numbers experience thrombotic events by the time that they reach the age of 50 years.

The most common sites of disease are the deep veins of the legs, the iliofemoral veins, and the mesenteric veins. Approximately 63%

of affected patients develop recurrent venous thrombosis, and approximately 40% exhibit signs of pulmonary embolism.[90] Superficial thrombophlebitis of veins in the lower extremity as well as cerebral venous thrombosis can occur in protein C-deficient patients.[87] There have been reports of nonhemorrhagic arterial stroke in young adults with hereditary protein C deficiency, but a causal relationship is uncertain.

The prevalence of protein C deficiency in outpatients presenting with an initial episode of venous thromboembolism ranges from 0.5% to 4%.[27,64,91] In earlier reports of more selected patient populations, protein C deficiency was more frequently identified, ranging from 2% to 9%. Initial estimates placed the prevalence of protein C deficiency between 1 : 16,000 and 1 : 32,000 within the general population, based on the assumption that protein C was an autosomal dominant disorder with high penetrance and that at least one-half of the individuals with the deficiency would demonstrate symptomatic thrombosis. However, it was difficult to reconcile this figure with the infrequent history of thrombosis in parents of infants presenting with purpura fulminans, which is caused by the homozygous or doubly heterozygous form of protein C deficiency. This disparity led to studies of healthy blood donors, which found a much higher prevalence of heterozygosity for protein C deficiency than was previously estimated, ranging from 1 : 200 to 1 : 500.[92,93]

The risk of thrombosis initially attributed to protein C deficiency was subject to selection bias, being overestimated from familial reports. Data from the Leiden Thrombophilia Study indicate that heterozygous protein C deficiency is associated with about a sevenfold increased risk for an initial episode of deep vein thrombosis over that in normal persons.[64] Among Italian patients, protein C deficiency is associated with a similar sevenfold increase in venous thrombotic risk.[61] In asymptomatic carriers of protein C deficiency, the incidence of thrombosis is fairly low at 0.4 to 1.0% annually.[94]

Two major subtypes of heterozygous protein C deficiency have been delineated using immunologic and functional assays (Table 134–8). The type I deficiency state is the most common form and is characterized by a reduction in both the immunologic and biologic activity of plasma protein C to approximately 50% of normal. Studies of the genetic defects in patients with protein C deficiency have led to the identification of 195 different mutations.[95] In persons with a type I deficiency, missense and nonsense mutations are most common. Other types of mutations resulting in type I protein C deficiency include promoter mutations, splice-site abnormalities, in-frame deletions, frameshift deletions, in-frame insertions, and frameshift insertions. In families with a type II deficiency state, affected persons have normal protein C levels on immunologic examination yet possess lowered functional levels of the zymogen. Point mutations in the protein C gene result in the presence of dysfunctional protein C molecules in the affected patient's plasma.

Warfarin-induced skin necrosis has been associated with the presence of heterozygous protein C deficiency.[96,97] This syndrome typically occurs during the first several days of warfarin therapy, often in association with the administration of large loading doses of the medication. The skin lesions occur on the extremities, breasts, and trunk, as well as the penis, and extend over a period of hours from an initial central erythematous macule. If protein C is not rapidly administered, the affected cutaneous areas become edematous, develop central purpuric zones, and ultimately become necrotic. Biopsies demonstrate fibrin thrombi within cutaneous vessels with interstitial hemorrhage. The dermal manifestations of warfarin-induced skin necrosis are clinically and pathologically similar to those seen in infants with purpura fulminans because of severe protein C deficiency.

The pathogenesis of warfarin-induced skin necrosis is attributable to the emergence of a transient hypercoagulable state. The initiation of the drug at standard doses leads to a decrease in protein C anticoagulant activity levels to approximately 50% of normal within 1 day.[98] Although factor VII activity measurements follow a pattern similar to that of protein C, the levels of the other vitamin K-dependent factors decline at slower rates, consistent with their longer half-lives (Fig. 134–3). During this period, it therefore appears that the drug's suppressive effect on protein C has a greater influence on the hemostatic mechanism than that caused by its reduction in factor VII. These effects are augmented when greater than 10 mg of warfarin daily is administered to initiate oral anticoagulation or if the patient has an underlying hereditary deficiency of protein C. Only approximately one-third of patients with warfarin-induced skin necrosis, however, have an inherited deficiency of protein C, and this complication is only infrequently reported in individuals with the heterozygous deficiency state. This syndrome has also been reported in association with an acquired functional deficiency of protein C.[99]

A rare disorder exists in which newborns develop a syndrome described as *purpura fulminans* and exhibit laboratory evidence of DIC in association with protein C antigen levels less than 1% of normal.[100–102] In some instances, there was a history of consanguinity in the family, making it highly likely that the affected infants were homozygous for the deficiency state.[101,102] These newborns can also be double heterozygotes, as was demonstrated in a Chinese patient who had a 5-nucleotide deletion in one protein C allele and a missense mutation in the other.[103] The heterozygous parents of these infants only infrequently had thromboses, in contrast to patients with thrombotic histories and a hereditary partial deficiency of protein C. There have also been a number of reported cases of older patients with homozygous or doubly heterozygous protein C deficiency who do not present with lesions resembling purpura fulminans. These individuals generally had protein C levels less than 20% of normal in the absence of oral anticoagulant therapy, and their clinical presentation was similar to that of severely affected persons from thrombophilic kindreds with the heterozygous deficiency state.[104,105] Genotyping of such homozygous individuals identified several missense mutations in the protein C gene; the variant protein C molecules produced by these individuals are either synthesized at a decreased rate or rapidly cleared from the circulation. The parents of these patients and infants with purpura fulminans have a type I deficiency state.

The nature of the molecular defect in the protein C gene per se does not explain the marked phenotypical variability in heterozygous type I protein C deficiency. A mutation common among symptomatic Dutch patients has also been found in an asymptomatic Swedish parent[106] of a doubly heterozygous child.[107] Also 4 of the 11 mutations observed in homozygotes, whose parents frequently are asymptomatic, have been found in symptomatic heterozygotes.[108] As in other inherited thrombotic disorders, the variable penetrance of thrombosis in heterozygous protein C deficiency reflects a complex interaction with other modulating factors.

A variety of immunologic and functional techniques have been developed to measure protein C levels in plasma samples. Enzyme-linked immunosorbent assays are commonly used to determine protein C antigen levels. Functional assays initially used either thrombin or the thrombin-thrombomodulin complex to activate protein C. Enzymatic activity is then assessed using either a chromogenic substrate or by measuring its anticoagulant activity in a clotting assay.[98] The development of simpler functional assays was facilitated by the observation that the venom of the Southern copperhead snake (*Agkistrodon contortrix*) activates protein C in plasma. After activation of protein C by this venom, the enzyme's amidolytic activity can be

Table 134–8 Assay Measurements in Heterozygous Protein C Deficiency

	Activity		
Types	**Antigen**	**Amidolytic**	**Coagulant**
I	Low	Low	Low
II	Normal	Low	Low
	Normal	Normal	Low

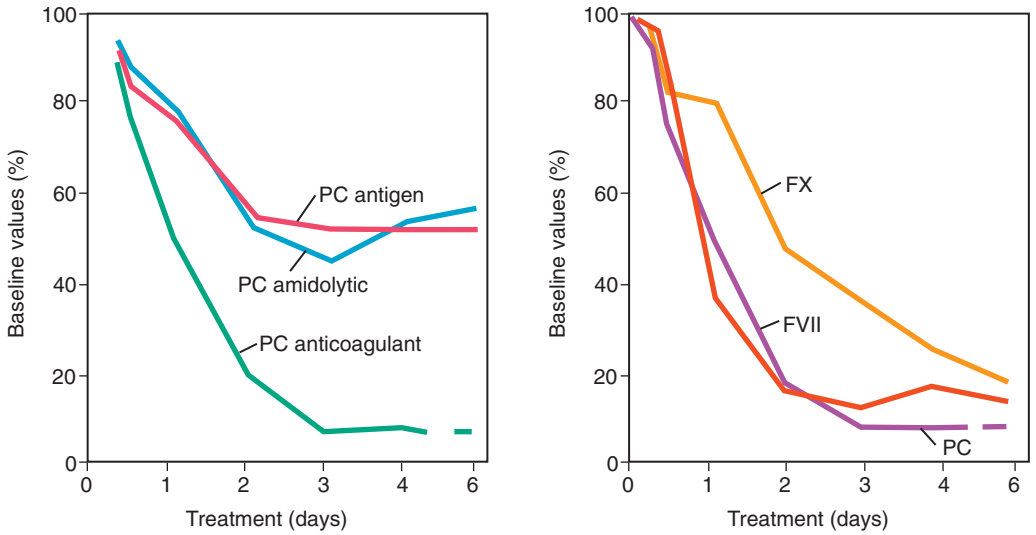

Figure 134–3 Mean levels of protein C (PC) anticoagulant activity, PC amidolytic activity, and PC antigen (left graph), and of PC anticoagulant activity and factor VII activity and factor X activity (right graph), following the initiation of warfarin therapy in patients with deep venous thrombosis. Patients were maintained on heparin infusions, and 10 mg of warfarin were administered for the first three days. Dosages were subsequently adjusted on the basis of the prothrombin time. Measurements are expressed as percentages of prewarfarin levels. *(From D'Angelo SV, Comp PC, Esmon CT, D'Angelo A: Relationship between protein C antigen and anticoagulant activity during oral anticoagulation and in selected disease states. J Clin Invest 77:416, 1986, with permission).*

measured using a suitable chromogenic substrate, or its anticoagulant activity can be measured in a clotting assay.

Functional assays using amidolytic and clotting endpoints may give useful information about the nature of the molecular defect in patients with type II protein C deficiency. Several persons have been described with normal protein C antigen measurements who have substantial reductions in protein C anticoagulant activity, but normal or near normal amidolytic activity.[98] These defects potentially reflect a reduced ability of activated protein C to interact with platelet membranes or with its substrates such as factor V and factor VIII. Thus, the protein C anticoagulant activity assay should have greater sensitivity than the amidolytic assay in screening for molecular defects resulting in type II protein C deficiency. Most clinical laboratories, however, prefer to use a chromogenic assay for initial screening, because it is technically easier to perform and has a smaller coefficient of variation than that of the clotting assay. "Global" coagulation assays also have been developed to screen for any major abnormality in the entire protein C pathway (eg, protein C deficiency, protein S deficiency, the factor V Leiden mutation).[109] The usefulness of these assays has been limited, however, by a poor sensitivity for protein S deficiency.

Protein C normally circulates in human plasma at an average concentration of 4 μg/mL. The levels of protein C antigen in healthy adults are log-normal distributed, with 95% of the values ranging from 70% to 140%.[92] There is no significant gender dependence, but mean protein C concentrations increase by approximately 4% per decade. The relatively wide normal range of protein C measurements in the general population occasionally makes it difficult to identify a given person as having heterozygous protein C deficiency. If medical and pharmacological causes of low levels are excluded, patients with a protein C value of less than 55% of normal are very likely to have the genetic abnormality, whereas levels from 55% to 65% are consistent with either a deficiency state or the lower end of the normal distribution.[92] To document the presence of protein C deficiency with confidence, it is therefore useful to obtain repeat laboratory determinations as well as to perform family studies to identify an autosomal dominant inheritance pattern.

Protein C levels in newborns are 20% to 40% of normal adult levels.[110] Preterm infants have even lower levels, and babies with significant perinatal thrombosis can have levels suggestive of the homozygous deficiency state. Acquired protein C deficiency (see Table 134–6) occurs in liver disease, severe infection and septic shock, DIC, adult respiratory distress syndrome, the postoperative state,[110] breast cancer patients receiving cyclophosphamide, methotrexate, and 5-fluorouracil,[111] and in association with L-asparaginase. A particularly severe form of acquired protein C deficiency has been described in association with purpura fulminans and DIC in patients with acute viral or bacterial infections, in particular meningococcemia.[112] In contrast to antithrombin III, the antigenic concentrations of vitamin K-dependent plasma proteins, including protein C, often are elevated in patients with the nephrotic syndrome.[113]

Warfarin therapy reduces functional[98] and, to a lesser extent, immunologic measurements of protein C,[86,114] making it difficult to diagnose heterozygous protein C deficiency in this setting. Research laboratories have used a reduced ratio of protein C antigen to prothrombin or factor X antigen to identify patients with a type I deficiency state.[86,114] This approach, however, can be used only in persons in a stable phase of oral anticoagulation, and the diagnostic criteria for the disorder vary with the intensity of warfarin therapy.[114] Therefore, evaluation in patients suspected of having the deficiency state should be delayed until after oral anticoagulation has been discontinued for at least 2 weeks, and family studies should also be performed. If warfarin cannot be discontinued because of the severity of the thrombotic diathesis, such patients can be studied while receiving unfractionated or low-molecular-weight heparin therapy, which does not alter plasma protein C levels.

An acquired inhibitor of protein C has been documented in an Australian patient.[115] This patient had a bleeding diathesis for several years, with the development of purpura fulminans before his death. An autopsy showed arterial and venous thrombi in many organs. Laboratory evaluation demonstrated the presence of chronic DIC. The immunoglobulin G (IgG) fraction of the patient's plasma completely inhibited the functional anticoagulant activity of activated protein C.

Protein S Deficiency

In 1984, members from several kindreds who exhibited reduced levels of protein S were described who had a striking history of recurrent venous thrombotic disease.[116,117] Subsequently, many additional families with this disorder have been reported.

Heterozygous protein S deficiency is inherited in an autosomal dominant fashion, with a reported frequency of approximately 10% in families with inherited thrombophlia.[61] However, the prevalence is less (between 1% and 7%) among consecutive outpatients with

deep vein thrombosis.[27,64] Protein S deficiency generally is considered to confer a risk of thrombosis similar to that in protein C deficiency, although the association has been complicated by considerable phenotypical variability. A more severe form of protein S deficiency is an autosomal recessive disorder.

The clinical presentation of patients with heterozygous protein S deficiency is similar to that outlined for deficiencies of antithrombin III and protein C. Of 71 protein S-deficient members from 12 Dutch pedigrees,[118] 74%, 72%, and 38% of the individuals sustained deep vein thrombosis, superficial thrombophlebitis, and pulmonary emboli, respectively. The mean age of the first thrombotic event was 28 years, with a range of 15 and 68 years; 56% of the episodes were apparently were spontaneous, and the remainder were precipitated by an identifiable factor. Thrombosis also has been reported in the axillary, mesenteric, and cerebral veins. Although there have been case reports of young patients with arterial thrombosis and protein S deficiency, current data do not support an association between hereditary protein S deficiency and an increased risk of arterial thrombosis.[119]

Under normal conditions, approximately 60% of the total protein S antigen in plasma is complexed to a complement component, C4b-binding protein. Only the free 40% is functionally active as a cofactor in mediating the anticoagulant effects of activated protein C. This observation has led to the development of methods for measuring total[117] and free protein S antigen.[120] Total protein S antigen can be reliably measured by enzyme-linked immunosorbent assay techniques following dilution of plasma samples to allow dissociation of the protein S-C4b-binding protein complexes. After removal of protein S-C4b-binding protein complexes from plasma by polyethylene glycol precipitation,[120] free protein S can be quantitated by immunoassay of the supernatant fractions. It is also possible to measure free protein S specifically by a monoclonal antibody-based immunoenzymatic assay that uses antibodies specific for the free form.[121] Functional assay methods are based on the ability of protein S to serve as a cofactor for the anticoagulant effect of activated protein C. Some of the original coagulation assays developed to measure the functional activity of plasma protein S were later found to be sensitive to abnormalities associated with resistance to activated protein C (factor V Leiden),[122] which has led to the development of more accurate assays.[123]

Three types of protein S deficiency states can be identified on the basis of measurements of total and free antigen as well as functional activity (Table 134–9). Type I deficiency is associated with approximately 50% of the normal total protein S antigen level,[117] and decrements in free protein S antigen and protein S functional activity to less than approximately 40% of normal.[120] Another type of hereditary deficiency (type II) has been described in which the functional activity of protein S is decreased, but with normal total and free antigen levels. A type III deficiency state is characterized phenotypically by a decreased concentration of free and functional plasma protein S, but a normal level of total protein S antigen.

The analysis of mutations in patients with protein S deficiency was complicated by the presence of a protein S pseudogene.[124] Mutations, however, were subsequently identified in approximately 70% of thrombophilic families with protein S deficiency using mutation screening strategies.[125] Type I deficiency most often is secondary to missense mutations, base pair insertions or deletions, premature stop codons, or mutations affecting a splice site. There have been a few cases of large deletions of the gene. Of the more than 130 different mutations documented in patients with various types of protein S deficiency, only 7 different nucleotide substitutions have been identified with a type II deficiency.[126] Several of these mutations are located in the N-terminal end of the protein S molecule, which includes the domains that interact with activated protein C.

The biologic basis of type III protein S deficiency state is uncertain. Furthermore, the coexistence of the type I and type III deficiencies has been reported in some protein S-deficient families, which has led to the proposal that the two types of protein S deficiency are phenotypical variants of the same genotype and are not the product of distinct genetic mutations.[127] In a followup analysis of one large family with a high prevalence of both type I and type III deficiencies, total protein S antigen, but not free protein S antigen levels, were shown to directly correlate with age.[128] These findings were independent of gender and also seen in non-deficient family members. A single point mutation in the protein S gene was responsible for the quantitative type I deficiency, but the type III phenotype was actually caused by an age-dependent free protein S deficiency; with increasing age, the relative concentrations of free protein S to total protein S decreased. However, a Dutch cohort study of first-degree family members with protein S deficiency found that affected relatives of probands with type I deficiency were at increased risk for venous thromboembolism, whereas affected relatives of probands with type III deficiency were not.[119]

Young patients with recurrent venous thromboembolic disease associated with doubly heterozygous or homozygous protein S deficiency have been identified.[116] The parents of the patients were asymptomatic and had laboratory studies consistent with type I protein S deficiency. Neonatal purpura fulminans has been described in association with homozygous protein S deficiency.[129,130]

The average concentration of total protein S antigen in normal adults is 23 μg/mL, but there is considerable overlap between "low normals" and individuals with heterozygous protein S deficiency. Levels increase with advancing age and are lower and more variable in females than males. These factors have confounded the reliable estimation of the prevalence of heterozygous protein S deficiency in the normal population as well the relative risk for thrombosis conferred by the disorder.[64] Thus, it is difficult to make the diagnosis of heterozygous protein S deficiency by performing only a single assay; repeat sampling and family studies usually are required to establish the diagnosis firmly.

Acquired protein S deficiency occurs during pregnancy[131] and in association with the use of oral contraceptives.[132] Reduced protein S levels also have been noted in patients with DIC and acute thromboembolic disease.[133] C4b-binding protein is an acute phase protein, and the decline in protein S activity in the latter two conditions as well as in other inflammatory disorders is attributable to a shift of the protein to the complexed, inactive form.[133] The levels of total and especially free protein S are significantly reduced in men with human immunodeficiency virus infection.[134] Total protein S antigen measurements are generally increased in patients with the nephrotic syndrome,[113] although functional assays give reduced values. This is caused in part by the loss of free protein S in the urine and by elevations in C4b-binding protein levels. Total and free protein S antigen levels are moderately decreased in liver disease[133] and in association with L-asparaginase chemotherapy. An acquired severe deficiency of protein S also has been reported in association with cutaneous necrosis.[135] Several studies have noted an association between antiphospholipid antibodies and acquired protein S deficiency, especially in severe cases of varicella complicated by purpura fulminans.[136]

Interpretation of protein S measurements in patients receiving oral anticoagulants is complicated inasmuch as the antigenic and functional levels of the protein drop substantially with vitamin K antagonists. In stably anticoagulated patients, research investigators used reductions in the ratio of total protein S antigen to prothrombin antigen to infer a diagnosis of type I protein S deficiency; the strategy employed was similar to that described for the diagnosis of protein C deficiency.[117]

TABLE 134–9 Assay Measurements in Heterozygous Protein S Deficiency

Types	Protein S Total Antigen	Protein S Free Antigen	Protein S Activity
I (classic)	Low	Low	Low
II	Normal	Normal	Low
III	Normal	Low	Low

Total protein S antigen values in healthy newborns at term are 15% to 30% of normal, whereas C4b-binding protein is markedly reduced to less than 20%. Thus, the free form of the protein predominates in this setting, and functional levels are only slightly reduced compared with those in normal adults.[137]

Activated Protein C Resistance and the Factor V Leiden Mutation

In 1993, Dahlbäck[138] identified a novel mechanism for familial thrombophilia: the plasmas of persons with unexplained personal and familial histories of venous thromboembolism exhibited a poor response to activated protein C (APC) in a PTT assay. The observations of Dahlbäck facilitated the development of a PTT-based assay to screen for APC resistance, which demonstrated the abnormality in 33% of Swedish patients referred for evaluation of venous thrombosis.[139] Precipitating factors for thrombosis, such as pregnancy and the use of oral contraceptives, were identified in 60% of the patients. Family studies revealed that relatives with APC resistance had a significantly higher frequency of thrombosis than that in relatives without the defect. In a U.S. referral population of patients younger than age 50 years with unexplained venous thromboembolic disease, approximately 50% were found to have APC resistance.[140] Investigators in Italy and Austria confirmed that APC resistance was a frequent laboratory abnormality in patients with unexplained venous thrombosis.[122,141]

Major contributions to our understanding of the molecular basis and clinical relevance of APC resistance were made by Dutch investigators from Leiden. In 1987, they initiated the Leiden Thrombophilia Study, a large case-control study to investigate risk factors for first episodes of venous thrombosis in the general population of The Netherlands. The rationale for undertaking this study was, in part, to define the true risk of venous thrombosis associated with protein C deficiency. There was a seeming paradox in that referred patients from families with protein C deficiency had a high frequency of venous thrombosis, but the deficiency state is present in 1:200 to 1:500 healthy blood donors. The selection criteria for accruing subjects into these studies turns out to be a major factor underlying this difference.

Following the initial observations of Dahlbäck, patients entering the Leiden Thrombophilia Study were screened for APC resistance after the completion of anticoagulant therapy.[1] Entry criteria were a first episode of deep venous thrombosis in outpatients younger than 70 years and confirmation of the diagnosis by objective evaluation. Patients with malignancy were excluded. Each thrombosis patient was assigned a healthy age- and gender-matched control. APC resistance was found in 21% of thrombosis patients and 5% of controls. Patients with APC resistance were calculated to have a sevenfold increased relative risk of venous thrombosis over that in controls. This corresponds to an incidence for an initial episode of deep venous thrombosis among carriers in the general Dutch population of approximately 0.06 episodes per 100 person-years (Table 134–10). A lower frequency of APC resistance in this study compared with that in studies of referral populations is attributable to different selection criteria for the thrombosis cohorts.

It subsequently was shown that a defect in factor V involving the mutation of arginine 506 to glutamine (Arg506Gln or factor V Leiden) is most often the cause of APC resistance.[142] This is the site at which APC cleaves factor Va, and this sequence alteration makes the mutant factor Va molecule biochemically resistant to inactivation by the activated protein C.[142,143] The Arg506Gln substitution was found to be the cause of APC resistance in about 90% of Dutch patients with APC resistance in the PTT assay,[142] and the mutation was found in 2% to 4% of healthy Dutch controls. Most patients with APC resistance are heterozygous for the factor V Leiden mutation, but a number of homozygous patients with heightened APC resistance in PTT assays have been identified.[142,144] Homozygotes are at higher thrombotic risk than that noted for heterozygotes (see Table 134–10),[145] as are patients with heterozygous resistance to APC combined with mutations in the genes for protein C, antithrombin III, and probably protein S.[10,13,146] The genes for factor V and antithrombin III both are located on the long arm of chromosome 1, thereby allowing for coinheritance of the factor V Leiden mutation and an antithrombin III mutation within all affected members of a family. This situation is expected to lead to an even more severe thrombotic diathesis.[13]

Table 134–10 The Leiden Thrombophilia Study Data: Relative and Absolute Risks of an Initial Episode of Deep Venous Thrombosis in the General Population Because of Common Risk Factors

Factors	Risk	Incidence*	Reference
Normal	–	0.008	
Prothrombin gene mutation	2.8 × ↑	0.022	(3)
Oral contraceptives	4 × ↑	0.03	(212)
Factor V Leiden heterozygotes	7 × ↑	0.057	(1)
Oral contraceptives + Factor V Leiden	35 × ↑	0.285	(212)
Factor V Leiden Homozygotes	80 × ↑	0.5–1	(145)

*Episodes per 100 person-years.

The U.S. Physicians' Health Study also has provided valuable data regarding factor V Leiden as a risk factor for venous as well as arterial thrombosis. In a retrospective case-control study of 14,916 healthy men older than age 40 years with a mean followup period of 8.6 years, heterozygosity for the factor V Leiden mutation was identified in 12% of patients with a first episode of deep vein thrombosis or pulmonary embolism and in 6% of controls.[2] The relative risk of venous thromboembolism was increased 3.5-fold in those persons with no other concomitant risk factors but was reduced to 1.7-fold in those with preexistent cancer or recent surgery. This study also showed that elderly patients with venous thrombosis frequently have the mutation.[2] Among men older than 60 years with initial episodes of venous thrombosis and no identifiable triggering factors, 26% were heterozygotes for factor V Leiden.

A cohort study of more than 9000 randomly selected adults in Denmark found that the simultaneous presence of smoking, obesity (body mass index greater than 30 kg/m^2), older age (older than 60 years), and the factor V Leiden mutation resulted in absolute 10-year venous thromboembolism rates of 10% in heterozygotes and 51% in homozygotes.[147]

A prospective cohort study determined the incidence of venous thromboembolism in asymptomatic carriers of the factor V Leiden mutation identified through family studies of symptomatic probands. Nine events occurred in 1564 observation-years resulting in an annual incidence of 0.58%. It was concluded that the absolute annual incidence of venous thromboembolism in asymptomatic carriers of the mutation is low.[148]

A number of studies have examined whether factor V Leiden, a prevalent abnormality in white populations, leads to an increased risk for arterial thrombotic events. There are no convincing data that other thrombophilic states such as deficiencies of antithrombin III, protein C, and protein S confer an increased risk of arterial thrombosis, but evaluation of these associations is complicated by the relative infrequency of these defects. In a cohort of men older than age 40 years in which there was a low prevalence of smoking, the U.S. Physicians' Health Study did not find an association between the factor V Leiden mutation and myocardial infarction or stroke.[2] In a younger cohort of Italian patients with myocardial infarction occurring younger than age 45 years, an increased incidence of the factor V Leiden mutation relative to that in controls also was not found.[149] Furthermore, a report of 36 French homozygous patients with the mutation did not identify a tendency for the development of arterial thrombosis.[150]

Data from a case-control study, however, suggest that heterozygosity for factor V Leiden is a risk factor for a myocardial infarction in young women (18 to 44 years old), but only in the presence of other cardiac risk factors.[151] The presence of the factor V Leiden mutation was associated with a 2.4-fold increased risk of myocardial infarction after adjustment for age (9.5% of patients with myocardial infarction, compared with 4.1% in controls). The risk of myocardial infarction associated with factor V Leiden was observed only among current cigarette smokers, in whom the mutation conferred a threefold increased risk. Compared with women who did not smoke and did not carry the factor V Leiden mutation, women who smoked and carried the mutation had a 30-fold increased risk of myocardial infarction. Although other cardiac risk factors such as older age, obesity, hypercholesterolemia, hypertension, diabetes, family history of ischemic heart disease, and postmenopausal status that is surgically induced were associated with cardiac events, the use of low-dose oral contraceptives was not. Data from this cohort indicate that the prothrombin gene mutation is also a risk factor for myocardial infarction, but only in current cigarette smokers.[152]

Obstetric complications, such as severe preeclampsia, abruptio placentae, fetal growth retardation, and stillbirth, are associated with intervillous or spiral artery thrombosis and consequent placental insufficiency. Factor V Leiden as well as other hereditary thrombophilias is associated with an approximate tripling of the risk of late fetal loss.[17,21] An increased incidence of factor V Leiden, as well as other thrombophilias, also was reported in women in association with other obstetric complications;[153] associations with preeclampsia and intrauterine growth restriction/retardation have, however, not been corroborated.[154,155]

The prevalence of heterozygosity for the factor V Leiden mutation in whites, including European, Jewish, Israeli Arab, and Indian populations, ranges between 1% and 8.5%. The mutation apparently is not present in African blacks or in Chinese, Japanese, or Native American populations.[22] In Europe, the mutation has been found to be more prevalent in northern countries such as Sweden than in southern countries such as Spain and Italy. Using dimorphic sites in the factor V gene to do haplotype analysis, data have been provided supporting the existence of a founder effect among whites of differing ethnic background.[24] It also was estimated that the mutation originated approximately 30,000 years ago, which came after the evolutionary divergence of white, African, and Asian populations.

Two mutations at the Arg306 residue in factor V, the second APC cleavage site in the activated cofactor, have been described in patients with a history of thrombosis. These mutations involve substitutions of Arg306 with threonine (factor V Cambridge)[156] or glycine (in Hong Kong Chinese).[157] The latter mutation, however, evidently has no clinical relevance because it is not associated with APC resistance, and the mutation is as common in healthy Chinese blood donors as in patients with thrombosis (4.5% and 4.7%, respectively).[158] The factor V Cambridge mutation is extremely rare among whites with venous thromboembolic disease.

Cosegregation of heterozygous APC resistance caused by the factor V Leiden mutation and type I factor V deficiency has been reported in some patients.[159,160] The plasma of these individuals manifests severe APC resistance in PTT assays, as found in patients homozygous factor V Leiden patients (ie, the patients with such cosegregation are pseudo-homozygous). These patients were seemingly more thrombosis-prone than were heterozygous relatives with factor V Leiden alone, suggesting that their clinical phenotype is similar to homozygous factor V Leiden patients.

Several polymorphisms are present in the factor V gene.[161,162] An extended factor V gene haplotype (HR2) containing the R2 polymorphism (His1299Arg) is associated with mild APC resistance and occurs with increased frequency in heterozygous patients with the factor V Leiden mutation with the lowest APC resistance ratios.[162] Although one case-control study found that the R2 allele was a risk factor for venous thromboembolism with an odds ratio of 2.0 after excluding subjects with genetic defects such as factor V Leiden,[163] another case-control study found no significant increase in risk.[164]

The initial observations of Dahlbäck[138] facilitated the development of a PTT-based assay that serves as a screening test for APC resistance. The PTT assay is performed in the presence or absence of a standardized amount of APC, and the two clotting times are converted to an APC ratio. Results can be interpreted by comparing the ratio with the normal range, or by normalizing it to the APC resistance ratio obtained using normal pooled plasma. Although this first generation APC resistance assay was conceptually quite simple and easy to perform in a coagulation laboratory, it required careful standardization and determination of the normal range in at least 50 controls. The level of APC, the PTT reagent, and the instrumentation used for clot detection affected the performance characteristics of the assay. Some assays using this format, therefore, had inadequate sensitivity and specificity for the factor V Leiden mutation. Also, patients receiving anticoagulants or with an abnormal PTT caused by other coagulation defects could not be evaluated with this assay, and the test was not validated in patients with acute thrombosis or in pregnant women.

The discovery that factor V Leiden is the dominant genetic defect responsible for APC resistance facilitated the development of second-generation coagulation tests. With proper standardization, this assay is characterized by nearly 100% sensitivity and 100% specificity for the mutation. For these tests, patient plasma is diluted in a sufficient volume of factor V-deficient plasma, and then a PTT-based assay is performed. This modification also permits the evaluation of plasmas of patients receiving anticoagulants or with abnormal PTT results caused by coagulation factor deficiencies other than factor V.

The fact that the dominant mutation underlying APC resistance is factor V Leiden makes it attractive to diagnose this defect by analyzing genomic DNA in peripheral blood mononuclear cells. This can be readily accomplished by amplifying a DNA fragment containing the factor V mutation site by polymerase chain reaction and analyzing the cleavage products on ethidium bromide-stained agarose gels after restriction enzyme digestion with MnlI.[142] The substitution of an A for a G at nucleotide 1691 in the factor V cDNA (CGA to CAA) results in the Arg506Gln mutation and the loss of a MnlI cleavage site. Other diagnostic approaches include hybridization with allele-specific oligonucleotide probes.

Some patients with APC resistance without the factor V Leiden mutation can be identified using the first generation PTT-based assay. The Leiden Thrombophilia Study demonstrated that this abnormality is a significant independent risk factor for an initial venous thrombotic event.[42] Performance of this assay is not recommended, however, as part of the routine laboratory evaluation, because the commercially available APC resistance assays using undiluted plasma do not replicate the performance characteristics of the assay used in the Leiden Thrombophilia Study, and the clinical implications of this type of APC resistance are uncertain.

Prothrombin Gene Mutation

In 1996, investigators from Leiden reported that a G to A substitution at nucleotide 20210 in the 3′-untranslated region of the prothrombin gene is associated with elevated plasma prothrombin levels and an increased risk of venous thrombosis.[3] This mutation, which was discovered by sequencing the prothrombin gene of selected patients with venous thrombosis, is located at the last position of the 3′-untranslated region at the cleavage site for polyadenylation of prothrombin mRNA. The prothrombin 20210A mutation changes the position of the 3′-cleavage/polyadenylation reaction in prothrombin mRNA, thereby leading to increased prothrombin biosynthesis by the liver.[165] This finding is in contrast to previous data that the mutation changes mRNA stability by increasing mRNA 3′-end formation.[166]

Investigation of a referral population with a personal and family history of venous thrombosis demonstrated that 18% had the mutation in the 3′-untranslated region of the prothrombin gene, whereas it was present in only 1 of 100 healthy controls.[3] Among these thrombosis patients, 40% also carried the factor V Leiden

mutation, again emphasizing the current view of venous thrombosis as a multigene disorder.

In the Leiden Thrombophilia Study, 6.2% of venous thrombosis patients and 2.3% of healthy matched controls had the prothrombin gene mutation.[3] This mutation independently confers a 2.8-fold increased risk of venous thrombosis (see Table 134–10) and the effect is operative in both genders and all age groups. Among heterozygotes with the prothrombin gene mutation, 87% of thrombosis patients and controls in the study had prothrombin activity levels that were greater than 1.15 units/mL, whereas only 23% of those with a normal prothrombin genotype were elevated to this degree.

In subsequent studies, the prothrombin G20210A mutation was found at significantly higher frequency in patients with venous thrombosis than healthy controls.[167,168] As with the factor V Leiden mutation, the risk of venous thrombosis among carriers of the prothrombin mutation is substantially increased by the use of oral contraceptives.[6] Large population studies have shown that the prevalence of the mutation is approximately 2% in the general white population, albeit with significant geographic variation. Among southern Europeans the prevalence was approximately 3%, but it was only very rarely identified in individuals of Asian or African descent.

Polymerase chain reaction methods are used to detect the prothrombin G20210A mutation in genomic DNA[3] and methods are available to detect both the prothrombin G20210A mutation and factor V Leiden in the same reaction. Although plasma prothrombin activity and antigen levels are significantly higher in individuals with the prothrombin G20210A mutation, concentrations cannot be used to screen for the defect due to significant overlap with values in the normal population.[3]

Dysfibrinogenemias

Qualitative abnormalities of fibrinogen are inherited in an autosomal dominant manner. The dysfibrinogenemias are a heterogeneous group of disorders that may be asymptomatic or manifest with a bleeding diathesis or recurrent venous or arterial thromboembolism (see Chapter 127). A small number of variant fibrinogens have been reported to be associated with thrombotic complications. These defects can be detected with thrombin and reptilase times, which often are prolonged. Functional fibrinogen measurements usually are substantially lower than antigenic measurements in the plasmas of affected patients. An occasional patient with a dysfibrinogemia may have a prolonged prothrombin time or PTT, and the inability of some abnormal fibrinogens to clot completely in vitro can result in false-positive results in fibrin(ogen) degradation product tests.

The functional and biochemical defects of a number of abnormal fibrinogens associated with thromboembolic disease have been characterized (see Chapter 127).[169,170] The conversion of fibrinogen to fibrin by thrombin results in the proteolytic cleavage of fibrinopeptides A and B from the molecule. Defects in the release of these two peptides or abnormalities in fibrin polymerization have been reported. Such functional defects do not, however, offer a ready explanation for the thrombotic diathesis seen in these subjects. Abnormalities in the binding of thrombin to fibrin also have been found in some dysfibrinogenemias.[171,172] In one of these kindreds, three homozygous siblings with a Bβ chain substitution of Ala by Thr at position 68 had a severe clinical phenotype sustaining both arterial and venous thrombosis at a young age.[171] Decreased binding of thrombin by this mutant fibrinogen has been suggested to lead to the presence of excessive thrombin in the circulation and the occurrence of thrombosis. Other fibrinogen mutants have been shown to cause abnormal fibrin polymerization. Some of the abnormal fibrinogens have been evaluated for their ability to resist or promote fibrinolysis on incorporation into a fibrin clot. The fibrin formed from fibrinogen *Chapel Hill III* has been demonstrated to be abnormally resistant to lysis by plasmin.[173] Plasminogen activation is decreased in the presence of the fibrin formed from fibrinogen Dusart, despite normal tissue-type plasminogen activator binding to the substrate.[174] These abnormalities have the potential for decreasing fibrinolytic activity in vivo, which results in a familial thrombotic diathesis in biochemically affected persons.

Inherited Abnormalities of Fibrinolysis

Although investigators have identified a few individuals with inherited abnormalities of the fibrinolytic mechanism and recurrent venous thromboembolism, the clinical association is considerably less striking than that in many kindreds with deficiencies of antithrombin III, protein C, or protein S, or with the factor V Leiden mutation and the prothrombin gene mutation. Dysplasminogenemia or hypoplasminogenemia has been reported in a number of individuals with thromboembolic disease; the first case of an abnormal plasminogen was identified in Japan.[175] The propositus had a history of recurrent thrombosis, and family studies demonstrated that the biochemical abnormality followed an autosomal dominant inheritance pattern. Despite the hereditary nature of the defect, none of the other biochemically affected members of the kindred had experienced a thrombotic event. Other Japanese pedigrees without thrombosis have since been described with the same biochemical defect; the gene frequency of this variant in the Japanese population was 0.018.[176] Population studies in the United States have not uncovered any cases of this dysplasminogenemia. The non-Japanese cases of dysplasminogenemias and hypoplasminogenemias also have been characterized by the absence of thrombotic episodes in biochemically affected family members other than the propositi.

Severe type 1 plasminogen deficiency is associated with a rare chronic inflammatory disease of the mucous membranes. The disorder is characterized by the presence of fibrin-rich pseudomembranous lesions and the most common clinical manifestations are ligneous conjunctivitis (80%) and ligneous gingivitis (34%). Less common sites of involvement are the vagina, respiratory tract, ears, and gastrointestinal tract.[177] Patients with this disorder have been found to be homozygous or compound heterozygous for a number of different mutations in the plasminogen gene.[177] Although this disorder occasionally can be life-threatening, venous and thrombosis was not observed among these patients. A severely affected infant with ligneous conjunctivitis has been treated successfully with a purified plasminogen concentrate,[178] but this product is not commercially available.

There were reports documenting the existence of thrombophilic families in association with impaired fibrinolysis.[179,180] Reevaluation of several of these families demonstrated the presence of hereditary protein S deficiency and no association between elevations in PAI-1 activity and a history of thrombosis.[181,182]

Immunochemical methods for the measurement of tissue-type plasminogen activator and functional assays for its inhibitors have been applied to the study of patients with documented venous thromboembolism. These studies suggested that defective synthesis or release of tissue-type plasminogen activator, as well as increased levels of PAI-1, may be important pathogenetic factors in as many as one-third of these individuals.[183–185] Subsequent studies however have not found a relationship between impaired fibrinolytic activity and venous thromboembolism.[186,187]

Factor XII Deficiency

Factor XII is the zymogen of a serine protease that initiates the contact activation reactions and intrinsic blood coagulation in vitro but probably plays no physiologic role in hemostasis in vivo. Persons with severe factor XII deficiency (factor XII activity less than 1% of normal) have markedly prolonged PTTs but do not exhibit a bleeding disorder. The absence of a hemostatic defect in patients with a severe deficiency of factor XII, prekallikrein, or high-molecular-weight-kininogen indicates that these factors are not required for in-vivo hemostasis. A number of cases of venous thromboembolism or myocardial infarction in factor XII-deficient patients,[188] including the

initial patient described with the abnormality,[189] have been reported, however.

A literature review of 121 patients with factor XII deficiency found an 8% incidence of thromboembolism, including several myocardial infarctions in relatively young persons.[188] Interpretation of such data is difficult, because such complications are likely to be reported in the literature, whereas the asymptomatic patient with factor XII deficiency may go unrecognized. This problem has led some groups to perform cross-sectional analyses of thromboembolic events in larger numbers of unselected families with factor XII deficiency.[190,191] In Swiss families with factor XII deficiency, 2 of 18 homozygous or doubly heterozygous patients had sustained deep vein thrombosis, although each occurred at a time when other predisposing thrombotic risk factors were present.[190] Among heterozygotes with factor XII deficiency, only 1 of 45 had a possible history of venous thrombosis. These investigators concluded that heterozygous factor XII deficiency does not constitute a major thrombotic risk factor, whereas a severe deficiency may predispose some affected persons to venous thrombosis. Other groups of investigators have found a 10% to 20% incidence of thrombotic episodes in heterozygotes.[191,192] Thus, it remains uncertain whether an increased thrombotic risk is associated with factor XII deficiency.

Hyperhomocysteinemia

Homocysteine is a sulfur-containing amino acid that is formed from methionine (Fig. 134–4). It is converted back to methionine by one of two remethylation pathways or undergoes transsulfuration to cysteine. In remethylation catalyzed by the enzyme methionine synthase, homocysteine acquires a methyl group from 5-methyltetrahydrofolate and vitamin B_{12} (cobalamin) acts as a cofactor. In a secondary pathway, betaine is the methyl donor in a reaction catalyzed by betaine-homocysteine methyltransferase. In transsulfuration, homocysteine condenses with serine to form cystathionine in a reaction catalyzed by cystathionine-β-synthase followed by hydrolysis by the enzyme γ-cystathionase to cysteine and α-ketobutyrate. Vitamin B_6 (pyridoxine) is a cofactor in both of these reactions. The normal plasma homocysteine concentration is 5 to 16 μM.

Homocystinuria is a rare autosomal recessive inborn error of metabolism presenting in childhood. The most frequent cause is homozygous cystathionine-β-synthase deficiency, which has a frequency in the general population of approximately 1:250,000. As a result of impaired intracellular metabolism of homocysteine, increased amounts of the amino acid accumulate in the blood and are excreted in the urine. Children with homocystinuria exhibit premature atherosclerosis and venous thromboembolism, along with mental retardation, ectopic lenses, and skeletal abnormalities. A small number of cases are caused by homozygous defects encoding 5,10-methylenetetrahydrofolate reductase (MTHFR), and persons so affected are similarly afflicted with premature vascular disease and thrombosis along with neurologic problems. The mechanisms by which hyperhomocysteinemia act as an atherogenic and thrombogenic risk factor have been only partially elucidated.[193,194]

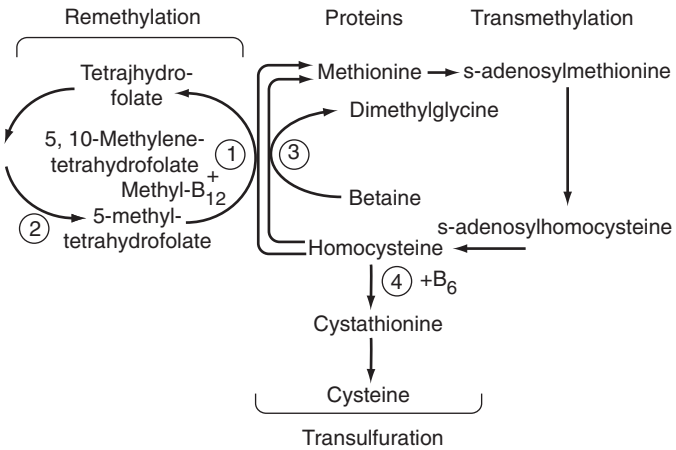

Figure 134–4 Intracellular metabolism of homocysteine occurs through remethylation to methionine or transsulfuration to cysteine. Numbered circles indicate the enzymes involved: 1, methionine synthase; 2, methylenetetrahydrofolate reductase (MTHFR); 3, betaine-homocysteine methyltransferase; 4, cystathionine beta-synthase. *(From De Stefano V, Finazzi G, Mannucci PM: Inherited thrombophilia: Pathogenesis, clinical syndromes, and management. Blood 87:3531, 1996, with permission).*

During the last two decades, mild or moderate hyperhomocysteinemia was identified as a seemingly independent risk factor for venous and arterial thrombotic events.[195–197] Mild (16–24 μmol/L) or moderate (25–100 μmol/L) hyperhomocysteinemia results from genetic and acquired abnormalities. Although heterozygous cystathionine-β-synthase deficiency is found in only approximately 0.3% of the general population, a MTHFR variant with an alanine to valine substitution at amino acid 677 is common[198] and can be present in 1.4 to 15% of the population, depending on their origin.[197] This mutation causes thermolability of MTHFR and a 50% reduction in its specific activity. The most common causes of acquired hyperhomocysteinemia are deficiencies of vitamin B_{12}, folate, or vitamin B_6, which are cofactors in homocysteine metabolism. There is a strong inverse correlation between hyperhomocysteinemia and folate levels and, to a lesser extent, with vitamin B_{12} and B_6 concentrations. Elderly patients frequently have elevated plasma homocysteine concentrations even in the absence of vitamin deficiencies, as do patients with renal failure. Cigarette smoking is also associated with acquired hyperhomocysteinemia.

Although patients with homocystinuria because of cystathionine-β-synthase deficiency have levels greater than 100 μmol/L, individuals with heterozygous defects in this gene or inadequate vitamin B_6 levels may have normal or only slightly elevated levels of fasting homocysteine. The discrimination of such patients from normal individuals can be improved by demonstrating an abnormal increase in plasma homocysteine 4 hours after an oral methionine load. Defects in the remethylation pathway because of MTHFR gene defects or inadequate folate or vitamin B_{12} levels tend to cause elevated homocysteine levels under fasting conditions. The prevalence of hyperhomocysteinemia is almost twice as high when based on homocysteine measurements performed after methionine loading as when based on fasting levels.

As folic acid, vitamin B_6, and vitamin B_{12} supplementation can decrease plasma homocysteine levels, it was hypothesized that treatment with these supplements would reduce the risk of arterial and venous thrombosis. Large randomized placebo-controlled clinical trials, however, reported that clinical outcomes are not improved by providing supplements of these vitamins to patients with histories of ischemic stroke,[199] myocardial infarction,[200] vascular disease,[201] or venous thrombosis.[202]

Because there are currently no data that persons with mild hyperhomocysteinemia and a history of venous or arterial thrombosis should be managed any differently than those with normal homocysteine levels, there is no longer justification for routinely obtaining homocysteine levels in such patients. In addition, results from the Leiden MEGA study indicate that presence of homozygosity for the MTHFR C677T polymorphism, which mildly increases homocysteine levels, is not associated with an increased risk for venous thrombosis.[203] These testing for this polymorphism should not be performed. It should furthermore be noted that the prevalence of hyperhomocysteinemia in the U.S. population has declined since the wheat supply was fortified with folic acid in the late 1990s. Although there were previous reports that hyperhomocysteinemia significantly increased the risk for a first venous thrombotic event in patients with the factor V Leiden mutation,[204] a recent publication found no additive or multiplicative interaction between these abnormalities for the risk of venous thrombosis.[205]

ACQUIRED THROMBOTIC DISORDERS

Pregnancy, Oral Contraceptives, and Hormone Replacement Therapy

Pregnancy is associated with an approximately sixfold increased risk of venous thromboembolism. Although the incidence of deep vein thrombosis and pulmonary embolism has been estimated to be as high as 1%, the true incidence is unknown because of difficulties in performing screening radiologic studies in pregnant women. Although relatively rare, pulmonary embolism causes 12 deaths per 1 million pregnancies in the state of Massachusetts and is estimated to account for 12% of fatalities during pregnancy.[206]

The puerperium, defined as the 6-week period following delivery, is associated with a higher rate of thrombosis than that associated with pregnancy itself. Risk factors for thrombosis in pregnancy include increasing age, Cesarean delivery, prolonged immobilization, obesity, and previous thromboembolism. Coexistent thrombophilia represents a major risk factor.[207] Factor V Leiden and the G20210A prothrombin gene mutation individually are associated with an increased risk of venous thromboembolism during pregnancy and the puerperium, and the risk among women with both mutations is disproportionately higher than that among women with only one mutation.[208]

Thrombosis during pregnancy and the puerperium is attributable to pregnancy-induced alterations in hemostasis as well as venous stasis in the lower extremities caused by the gravid uterus. Trauma to the pelvic veins during vaginal delivery or tissue injury during Cesarian section also contributes to the hypercoagulable state. Compression of the left iliac vein by the crossing right iliac artery is a local, mechanical factor that is believed to underlie the threefold higher incidence of deep vein thrombosis in the left leg compared to the right.

Marked changes in the coagulation mechanism occur during pregnancy. Increased levels of markers of coagulation system activation can be detected in the systemic circulation by the end of the first trimester. The elevations in thrombin generation probably arise from the uteroplacental circulation because the placenta is rich in tissue factor. The vasculature of the placenta is unique from other tissues in that it is lined by chorionic villi that are covered by trophoblast tissue, rather than endothelium, which is in direct contact with maternal blood.

The levels of most procoagulant factors increase during pregnancy, with fibrinogen increasing markedly from a normal level of 250 to 400 mg/dL to 600 mg/dL in late pregnancy. Among the natural anticoagulant proteins, there is a significant decline in the level of free and total protein S in the second trimester.[131] At the same time, fibrinolytic system activity declines progressively during pregnancy. Platelet activation and increased platelet turnover also probably occur during pregnancy; mild thrombocytopenia, possibly as a result of increased consumption, occurs in 8.3% of healthy women at term.[209] The net effect of these hemostatic changes is to promote blood coagulation so as to provide adequate hemostasis at the time of placental separation. The altered levels of hemostatic proteins return to normal within 4 weeks after delivery. Fibrinolytic activity rapidly returns to nonpregnant levels within hours after placental separation.

Oral contraceptive use is associated with an increased risk of venous and arterial thrombosis.[4] The risk of venous thrombosis is related to the estrogen dose, and most oral contraceptives prescribed in the United States contain less than 50 μg of ethinylestradiol in combination with a progestational agent (ie, combined oral contraceptives). The use of low dose-estrogen preparations containing older progestational agents (levonorgestrel, lynoestrenol, and norethisterone), however, still confers approximately a fourfold increased risk of venous thromboembolism, compared with that in nonusers (see Table 134–10). The risk of myocardial infarction and stroke is less. Oral contraceptives affect lipid profiles by lowering low-density lipoprotein cholesterol and raising high-density lipoprotein cholesterol levels. Unexpectedly, newer progestogens (desogestrel, gestodene, and norgestimate) with less deleterious effects on lipid profiles are associated with a higher risk of venous thromboembolism than that noted for the previous generation of combined oral contraceptives.[210,211] This risk is particularly high among carriers of the factor V Leiden mutation[212,213] and women with a family history of thrombosis. It is not yet known whether oral contraceptives containing the newer progestogens are associated with any increase in risk of myocardial infarction, which is a rare event in young women.

The mechanism by which oral contraceptives are prothrombotic is complex and uncertain. Prothrombotic effects include modest increases in the levels of procoagulant factors (factor VII, factor VIII, factor X, prothrombin, fibrinogen) and decreases in the levels of anticoagulant proteins (antithrombin III, protein S). The development of *acquired* APC resistance has been demonstrated, by means of a thrombin generation assay, in women taking oral contraceptives. Although the molecular basis for this phenomenon is unknown, it provides a plausible explanation for the greatly increased thrombotic risk among oral contraceptive users who are carriers of the factor V Leiden mutation.[4]

Although the thrombogenicity of oral contraceptives was recognized shortly after their introduction in the 1960s, convincing evidence that the lower estrogen dose used for hormone replacement therapy leads to an increased risk of venous thromboembolism was conclusively reported only in 1996. The estrogens commonly prescribed for hormone replacement are chemically different than those in oral contraceptives and are considered to have substantially lower biologic potency. Venous thrombotic risk associated with hormone replacement therapy is increased two- to fourfold, an effect similar in magnitude to that noted for oral contraceptives. The use of hormone replacement therapy, however, leads to a considerably larger number of excess cases of thrombosis, as a result of an overall age-related increase in the incidence of thrombosis. Carriers of the factor V Leiden mutation receiving hormone replacement therapy have a significantly increased risk of venous thromboembolism.[214,215] Data from the Heart and Estrogen Replacement Study (HERS) and the Estrogen Replacement and Atherosclerosis Trial indicate that heterozygous carriers of factor V Leiden on hormone replacement therapy had an odds ratio that was 14.1-fold higher for venous thromboembolism, as compared to noncarriers receiving placebo.[215]

Raloxifene, a selective estrogen receptor modulator that has antiestrogenic effects on breast and endometrial tissue but estrogenic effects on bone, lipid metabolism, and coagulation, is also associated with an increased risk of venous thromboembolic disease.[216]

Postoperative State, Trauma, and Immobility

Deep vein thrombosis and pulmonary embolism occur with increased frequency in postoperative patients. The thrombotic risk, however, is dependent on the type of surgery performed. Deep vein thrombosis in this population is usually asymptomatic, so that the use of reliable noninvasive tests or lower limb venography is required to establish the diagnosis. Based on patient characteristics and the type of surgery, the postoperative thrombotic risk can be estimated and an assessment made of the need for prophylactic anticoagulation. Risk factors associated with higher rates of thrombosis include older age, previous venous thromboembolism, the coexistence of malignancy or medical illness (eg, cardiac disease), thrombophilia, and longer surgical and immobilization times. In patients older than age 40 years not receiving thromboprophylaxis, the incidence of deep vein thrombosis following general or gynecologic surgical procedures is approximately 20% to 25%, and clinically significant pulmonary embolism occurs in 1% to 2% of these patients. For urologic surgery, the incidence of deep vein thrombosis ranges from 10% for transurethral procedures to up to 40% for radical prostatectomies. Orthopedic procedures on the hip and lower extremities are among the most thrombogenic surgical procedures. In the absence of prophylaxis, the risk of deep vein thrombosis following total knee replacement is 45% to 70%, and fatal pulmonary embolism has been reported to occur in 1% to 3% of patients undergoing hip surgery. The increased thrombotic

risk is not confined to the immediate postoperative period and continues for several weeks.

Deep vein thrombosis and pulmonary embolism also are commonly encountered following major trauma. A study of patients admitted to a Canadian regional trauma unit demonstrated that 58% of patients had lower extremity deep vein thrombosis, which usually was asymptomatic.[217] Risk factors for thrombosis in this setting were older age, the need for surgery or blood transfusions, and the presence of lower extremity fractures or spinal cord injury. Pulmonary embolism occurs in 2% to 22% of trauma patients, and is the third most common cause of death in those who survive the first 24 hours.[218]

The mechanism of activation of the coagulation system following surgery or trauma has not been elucidated, but the exposure of tissue factor from injured tissue or activated monocytes is the most likely pathway for increased thrombin generation in these settings. In postoperative patients, the occurrence of thrombosis is also influenced by fibrinolytic system activity. Minor alterations in a number of hemostatic parameters have been reported in postoperative patients, including elevated levels of fibrinogen and von Willebrand factor and decreased levels of antithrombin III and protein C. Decreased venous blood flow in the lower extremities also contributes to postoperative hypercoagulability. In hip replacement surgery, the femoral vein in the operated leg may kink, thereby stimulating proximal venous thrombosis in the absence of preexistent calf vein thrombosis.

Venous stasis can be a precipitating cause of venous thromboembolism, particularly in hospitalized patients. An increased risk for venous thromboembolism also has been observed with prolonged air travel, particularly when the distance is greater than approximately 3000 miles.[219–221] Venous stasis secondary to immobilization is likely the major mechanism underlying this risk, which is increased in the presence of other predisposing thrombotic risk factors.[222,223]

Malignancy

The incidence of clinical thromboembolic disease in the cancer population has been estimated to be as high as 11%.[224] Autopsy series have described even higher rates of thrombosis for certain tumor types. One autopsy study found a 30% incidence of thrombosis in patients who died of pancreatic cancer and more than 50% in patients with tumors in the body or tail of the pancreas. Other tumor types commonly associated with thromboembolic complications are carcinomas of the gastrointestinal tract, ovary, prostate, and lung.

Patients with malignancy also have a higher rate of postoperative venous thrombotic complications than the general population, with an incidence of approximately 40%. Careful attention should therefore be paid to prophylaxis of deep vein thrombosis in such patients undergoing major abdominal or pelvic surgical procedures.

In some instances thrombosis manifests itself before the diagnosis of an underlying malignancy. Prandoni[225] investigated 250 consecutive patients with symptomatic deep vein thrombosis that was objectively documented by venogram. Cancer was identified at the time of diagnosis of the thrombotic event in 3.3% of patients with idiopathic venous thrombosis (ie, those with no other known risk factors), but no cases were found in patients with secondary venous thrombosis (those with documented additional risk factors such as prolonged immobilization, leg trauma, or hereditary thrombotic disorder). During a 2-year followup period, cancer was diagnosed in 7.6% of the patients with idiopathic venous thrombosis and in 1.9% of the patients with secondary venous thrombosis. The incidence of cancer was considerably higher in patients with recurrent idiopathic venous thrombosis.

The probability of detecting an occult neoplasm in patients with a documented thrombotic event also was evaluated by Monreal and colleagues,[226,227] who found a malignant lesion in 22.6% of patients with idiopathic deep vein thrombosis in contrast to 6.1% of patients with secondary thrombosis and in 11.5% patients with pulmonary embolism. The higher incidence of cancer reported by these investigators probably is because of a more aggressive diagnostic approach, which included chest radiography, upper gastrointestinal endoscopy, abdominal ultrasound study, and computed tomography scan.

Nonbacterial thrombotic endocarditis, characterized by sterile vegetations composed of platelets and fibrin on heart valves, is highly associated with malignant disorders. In autopsy series, cancer was found in as many as 75% of cases of nonbacterial thrombotic endocarditis. The majority of cases of nonbacterial thrombotic endocarditis occur in patients with adenocarcinomas, and its incidence among lung cancer patients may run as high as 7%. Laboratory evidence for DIC is often present. The aortic and mitral valves are most commonly affected. The diagnosis of nonbacterial thrombotic endocarditis can be difficult to make ante mortem, because less than 50% of patients have audible cardiac murmurs, and small lesions may not be identified by echocardiography.

The major clinical manifestations of nonbacterial thrombotic endocarditis are caused by systemic emboli from the vegetations on the heart valve(s) rather than from valvular dysfunction itself. Common sites of embolization include the spleen, kidney, and extremities, with the most significant morbidity arising from emboli to the central nervous system and coronary arteries. Nonbacterial thrombotic endocarditis should be considered in all cancer patients who develop an acute stroke syndrome, as well as in others who have cerebral embolism with an unknown etiology.

DIC is the cardinal coagulopathy associated with malignancy and results from generalized activation of the coagulation system. Malignancy is the third most common cause of DIC after infection and trauma and accounts for 7% of cases. DIC is a common coagulopathic complication in cancer patients and has been reported in as many as 15% of patients with malignancy. DIC occurs in virtually all patients with acute promyelocytic leukemia. The leukemic promyelocytes contain procoagulants that can trigger DIC, as well as fibrinolytic activators. The cell lysis that results from conventional chemotherapy releases these enzymes and can exacerbate the coagulopathy. Other disease entities, particularly sepsis, which in itself may be responsible or may contribute to the development of DIC in cancer patients, should be ruled out.

Various patterns of DIC are seen in association with malignancy. Acute forms of DIC are rare and usually present with minor bleeding from mucosal or cutaneous surfaces or extensive life-threatening hemorrhage involving visceral sites. Laboratory evaluation demonstrates prolongation of the prothrombin time, PTT, thrombin time, and reptilase time; decreased fibrinogen concentration; thrombocytopenia; and elevated levels of fibrin degradation products. More common in cancer patients are chronic forms of DIC. Many patients with chronic DIC are asymptomatic, and laboratory data often show modest reductions in fibrinogen and platelet count, elevated fibrin degradation products, and minimal changes in the prothrombin time or PTT. Others may have more obvious evidence of platelet, fibrinogen, and coagulation factor consumption. These latter patients often demonstrate hypercoagulability and can manifest deep vein thrombosis, Trousseau syndrome (ie, migratory superficial phlebitis involving the upper or lower extremities), or nonbacterial thrombotic endocarditis.

Thrombotic microangiopathy is the descriptive term for a syndrome characterized by hemolytic anemia, thrombocytopenia, pathognomonic microvascular thrombotic lesions, and the involvement of various specific organs (see Chapter 139). Depending on the differences in organ involvement, thrombotic microangiopathy is commonly called *thrombotic thrombocytopenic purpura* or *hemolytic uremic syndrome*. Severe thrombotic microangiopathy associated with thrombocytopenia may occur in as many as 5.7% of patients with metastatic carcinomas, most frequently with gastric, breast, or lung primary sites. Despite the classical manifestations of a Coombs-negative hemolytic anemia and severe thrombocytopenia, patients usually present with neurologic abnormalities, including headache, confusion or paresis, and occasionally signs of DIC. Renal failure is an uncommon feature of carcinoma-associated thrombotic microangiopathy. The goal of treatment of malignancy-related thrombotic microangiopathy is to decrease the tumor burden, because other treatment modalities, such as corticosteroids, plasma exchange or

plasma infusion, result in only moderate and transient clinical improvement.

Probably contributing to the thrombotic tendency in cancer patients are clinical factors such as vascular stasis because of obstruction of blood flow by the tumor or patient immobility, hepatic involvement and dysfunction, sepsis, advanced age, other comorbid conditions, and certain antineoplastic agents. Thus, the exact details of the mechanisms underlying coagulation activation in malignancy remain uncertain, and a complex interaction of several of the above mechanisms, as well as others yet to be identified, may be responsible.

Nephrotic Syndrome

The nephrotic syndrome results from a variety of pathologic processes that cause excessive kidney glomerular leakage of plasma proteins into the urine. It is clinically characterized by edema, proteinuria, hypoalbuminemia, and hyperlipidemia. Thrombosis is a major cause of morbidity in patients with the nephrotic syndrome; the renal veins are the most commonly affected sites.[228] Renal vein thrombosis occurs in approximately 35% of cases, but the incidence varies considerably based on the underlying renal pathology and on the severity and duration of the proteinuria. The incidence of thrombosis in other sites is approximately 20%.[228,229] In adults, deep vein thrombosis and pulmonary embolism are the most common thrombotic complications. Arterial thrombosis is seemingly more common in children with nephrotic syndrome, resulting in stroke, mesenteric infarction, or limb ischemia.

Alterations in many blood coagulation parameters have been reported in patients with the nephrotic syndrome, although some abnormalities are inconsistently reported, of relatively minor magnitude, and poorly correlated with thrombotic events. The variability in findings is attributable to the complex nature of the nephrotic syndrome itself and the resultant marked stimulation of hepatic protein biosynthesis.

Among the natural anticoagulant proteins, plasma antithrombin III levels often are decreased, owing at least in part to urinary excretion. The antigenic levels of protein C and protein S generally are increased.[113] Plasma levels of several components of the coagulation cascade—factors XII, XI, and X—are reported to be decreased as a result of urinary excretion, whereas factors XIII, X, VIII, VII, and V characteristically are elevated in these patients. Some data suggest that platelet hyperreactivity, increased whole blood viscosity, and abnormal fibrin clot architecture related to hypofibrinolysis may contribute to the thrombotic diathesis in the nephrotic syndrome.

Hemolytic Anemias

PNH is a rare acquired clonal disorder of bone marrow stem cells. Patients generally manifest chronic intravascular hemolysis, with episodes of gross hemoglobinuria accompanied by leukopenia and thrombocytopenia. Many have a prior history of aplastic anemia. Despite the presence of thrombocytopenia, thrombosis is more commonly encountered than bleeding. Indeed, thrombosis can be a presenting feature of PNH, as well as an important cause of morbidity and mortality in this disorder. A diagnosis of PNH should be suspected in patients with a negative family history of thrombosis but with evidence of pancytopenia, an elevated reticulocyte count, or results of iron studies consistent with iron deficiency.

A unique feature of PNH is the predilection for thrombosis to occur in the intraabdominal venous network (mesenteric, hepatic, portal, splenic, and renal veins) and cerebral vessels, as opposed to deep vein thrombosis or pulmonary embolism. Arterial events such as myocardial infarction, stroke, and aortic thrombosis have rarely been reported. Acute thrombotic episodes should be treated with heparin or low-molecular-weight heparin. Fibrinolytic agents have been used successfully to treat acute intraabdominal venous thrombosis. Long-term oral anticoagulation should be considered in patients with thrombosis in association with PNH.

The abnormality of PNH erythrocytes that leads to hemolysis is their increased sensitivity to complement-mediated lysis. Deficiencies of a number of membrane proteins have been observed in PNH, including acetylcholinesterase, leukocyte alkaline phosphatase, *decay accelerating factor*, CD59 (membrane inhibitor of reactive lysis) antigen, homologous restriction factor, CD58, 5′-ectonucleotidase, CD16, urokinase-type plasminogen activator, and CD14 antigen. These proteins all are attached to the cells by a glycosylphosphatidylinositol anchor, and PNH appears to be the consequence of somatic mutations in the X-linked PIG-A (phosphatidylinositol glycan class A) gene, which participates in an early step in glycosylphosphatidylinositol anchor synthesis. Several of the membrane abnormalities involve proteins that modulate complement function, and the absence of CD59 antigen on erythrocytes appears to be the most critical defect. Granulocytes and platelets, like red cells, show increased sensitivity to complement-mediated lysis. Shed circulating platelet microparticles in PNH result in the dissemination of procoagulant phospholipids in the blood flow, possibly contributing to the thrombotic tendency in these patients. Although it has been suggested that the membrane abnormalities in PNH may lead to increased platelet activation by complement, there is not currently an adequate explanation for the thrombotic tendency in this disease. There is no apparent association between hemolytic and thrombotic episodes, nor does the onset of thrombosis correlate with the duration or degree of hemolysis.

Thrombosis is also a serious complication in patients with other types of hemolytic anemias, including sickle cell disease and thalassemia. In sickle cell disease, increased blood viscosity because of sickled erythrocytes contributes to microvascular occlusion. Asymptomatic patients with sickle cell disease also exhibit ongoing platelet activation, thrombin generation, and, fibrinolysis that increases during episodes of pain. These changes have been noted to be predictive of frequency of pain and interval to next pain episode, thereby implicating thrombogenic activity in the development of sickle cell pain crises. There is evidence for endothelial activation and increased numbers of circulating microvascular endothelial cells (CD36+) overexpressing intercellular adhesion molecule 1, vascular cell adhesion molecule 1, E-selectin, P-selectin, and tissue factor in patients with sickle cell disease.[230] Although much of the morbidity in sickle cell disease is a result of tissue ischemia and infarction (sickle cell crisis) caused by sickle cell occlusion of the microvasculature, both children and adults with sickle cell disease also have an increased risk of thrombosis of large blood vessels.

As standards of care for thalassemic patients have improved in recent years, resulting in an almost doubling of life expectancy, previously undescribed complications of the disease are being recognized, particularly thromboembolic complications.[231] These include cerebral thrombosis, deep vein thrombosis, pulmonary embolism, and recurrent arterial occlusions. Venous thrombosis develops following splenectomy in some patients with thrombocytosis. Associated with these clinical thromboembolic complications, profound hemostatic abnormalities have been observed in patients with β-thalassemia major, β-thalassemia intermedia and hemoglobin H disease.[231]

Hyperviscosity

Thrombosis can be a manifestation of diseases associated with hyperviscosity. Hyperviscosity of the blood may be caused by increased plasma viscosity, an increased number of red or white blood cells, or decreased deformability of cells.

Increased plasma viscosity can result from hypergammaglobulinemia or hyperfibrinogenemia. Hypergammaglobulinemia associated with the hyperviscosity syndrome is most commonly encountered in patients with Waldenström's macroglobulinemia or multiple myeloma. Presenting manifestations of the hyperviscosity syndrome include bleeding because of platelet dysfunction, visual disturbances,

and neurologic defects. Thrombosis in hypergammaglobulinemic states is attributable to abnormal rheology.

Hyperviscosity plays an important role in the pathogenesis of thrombosis in polycythemia vera, which is a major complication of this disorder. Patients with elevated hematocrits have increased whole blood viscosity, and this abnormality has been inversely correlated with cerebral blood flow. Acquired qualitative platelet defects also have been implicated in the pathogenesis of the hemostatic defects in polycythemia vera. Common thrombotic complications in this disorder include cerebrovascular accidents, myocardial infarction, peripheral arterial occlusion, deep vein thrombosis, pulmonary embolism, and portal and hepatic vein thrombosis (Budd-Chiari syndrome).

In the myeloid and monocytic leukemias, the presence of very elevated white blood counts (generally greater than 100,000 cells/mm^3) can increase the viscosity in the microcirculation, which can play a role in the pathogenesis of thrombosis. Small vessels in the lungs, brain, and less commonly, other organs may be obstructed by large numbers of immature leukocytes.

In sickle cell disease, the increase in blood viscosity secondary to sickling of erythrocytes may contribute to the occlusion of small blood vessels. Enhanced adhesion of sickle erythrocytes to vascular endothelium, along with increased coagulation and platelet activation, promotes vascular occlusion.

Drug-Induced Thrombosis

The contribution of cancer therapies to the development of thrombotic events can be difficult to evaluate, because the neoplasm itself and other risk factors predispose cancer patients to thromboembolic complications.

Thrombotic events have been reported with induction chemotherapy regimens for acute lymphoblastic leukemia (ALL) that include L-asparaginase. Intracranial thrombosis with hemorrhage is observed most frequently, but deep venous thrombosis and pulmonary embolism can also occur. The incidence of thrombotic complications in children receiving L-asparaginase as part of induction chemotherapy for ALL is approximately 1%. Generalized bleeding episodes have only rarely been observed.

The inhibition of protein synthesis by L-asparaginase causes deficiencies of numerous plasma proteins, including albumin, thyroxine-binding globulin, and various coagulation proteins. Decreased levels of prothrombin, factors V, VII, VIII, IX, X, XI, fibrinogen, antithrombin III, protein C, protein S, and plasminogen have all been described secondary to L-asparaginase chemotherapy. Decreased levels of procoagulant factors lead to prolongation of the prothrombin time, PTT, and thrombin time. These coagulation abnormalities resolve within 1 to 2 weeks after cessation of the drug.

It is difficult to assess the role of the substantial reductions in the levels of natural anticoagulant proteins such as antithrombin III, protein C and protein S in the pathogenesis of the thrombotic events. Both procoagulant and anticoagulant protein synthesis in the liver are decreased by L-asparaginase, leading to uncertainty about whether there is an alteration in the balance of the opposing forces of the hemostatic mechanism. In one study of children with ALL receiving L-asparaginase, prednisone, and vincristine, no correlation was found between protein C, protein S, or antithrombin III levels and the presence or absence of thrombosis.[232] Other clinical factors may contribute to the pathogenesis of thrombotic complications that are observed in these patients, including immobility and concurrent sepsis.

Women with breast cancer receiving certain chemotherapy regimens are at increased risk for developing thrombosis. The availability of large numbers of patients receiving standard adjuvant chemotherapy programs as well as appropriate matched, untreated control populations has facilitated studies of this association. One study found a 5% incidence of symptomatic venous thrombosis among patients with stage II breast cancer treated with chemotherapy regimens that included cyclophosphamide, methotrexate, and 5-fluorouracil (CMF).[233] All of the thrombotic events occurred while the patients were receiving chemotherapy. In the post-treatment followup period, no clinically evident thromboses were observed. Goodnough[234] reported a 17.6% incidence of thrombosis in a series of patients with metastatic breast cancer receiving chemotherapy, with pulmonary embolism or deep vein thrombosis accounting for a majority of the thrombotic events. Levine[235] randomized 205 patients receiving adjuvant chemotherapy for stage II breast cancer to either a 12-week or a 36-week course of chemotherapy after primary surgical treatment. During the first 12 weeks of chemotherapy, there were similar numbers of thrombotic events; however, during the following 24 weeks, there were 5 additional thrombotic events in the 36-week treatment group, whereas no further thromboses were seen in the 12-week treatment group who had already completed therapy. Thus, 6.8% of the patients had a thromboembolic event while on chemotherapy, but no further thrombotic events were detected during the postchemotherapy followup period of more than 2400 patient-months. No relationships were found in this study between the development of thrombosis and estrogen or progesterone receptor status, age, number of involved lymph nodes, or subsequent tumor recurrence.

The association of arterial thrombosis and cancer therapy was shown in studies by Wall[236] and Saphner.[237] The Cancer and Acute Leukemia Group B study[236] found a 1.3% incidence of arterial thrombosis, either peripheral arterial or cerebrovascular, in 1014 patients during treatment for stage II or III breast cancer on two separate chemotherapy protocols. All except one of the thrombotic events occurred while patients were receiving chemotherapy. In the study by Saphner,[237] which included 2352 patients, a significant increase in arterial thrombosis was found in premenopausal women who received combined chemohormonal therapy, whereas no higher risk for arterial thrombosis was seen in postmenopausal women receiving tamoxifen either alone or in combination with chemotherapy. In both studies, arterial thrombotic events tended to occur early in the course of treatment.

The pathophysiologic basis for the thrombogenicity of chemotherapy in breast cancer patients is not well understood. In a prospective study of patients receiving adjuvant chemotherapy for breast cancer, no alterations in antithrombin III levels were detected. Rogers[111] found a statistically significant decrease in protein C and protein S levels during CMF chemotherapy. Some of these patients had decrements in protein C and S levels that fell below the range of values seen in hereditary thrombotic disorders. Decreases in factor VII and fibrinogen levels also were reported. None of the patients in this small study, however, had clinically evident thrombosis. Other investigators have observed significant declines in protein C concentration during CMF chemotherapy, which returned to baseline values after the completion of therapy.[238] Possible explanations for these chemotherapy-induced abnormalities include impairment of vitamin K metabolism, inhibition of DNA/RNA synthesis leading to a decrease in protein synthesis by the liver, and initiation of intravascular coagulation.

Hormonal therapies, such as estrogen therapy for prostate carcinoma, have clearly been linked to an increased incidence of thromboembolic disease. In the Veterans Administration Cooperative Urologic Research Group's studies of estrogen therapy in patients with prostate cancer, death rates from cardiovascular events were higher in those on 5 mg of diethylstilbestrol daily than in those on a 1 mg daily dose.[239] The antitumor effect of these two dosages was similar.

The use of tamoxifen, an antiestrogen with some proestrogenic activity for the prevention and treatment of breast cancer, is associated with an increased risk of venous thromboembolic events.[240,241] The factor V Leiden and prothrombin G20210A mutations are not associated with thrombosis in women on tamoxifen.[242,243]

For the treatment of multiple myeloma, thalidomide or lenalidomide, particularly when given in protocols that include high doses

of dexamethasone, is associated with a high incidence of venous thromboembolism.[244]

Lupus Anticoagulants and the Antiphospholipid Syndrome

A diagnosis of antiphospholipid antibody syndrome requires an initial thrombotic event in association with a persistent lupus anticoagulant and/or persistently elevated levels of cardiolipin (IgG or IgM) or β_2-glycoprotein I antibodies (see Chapter 131). Clinical manifestations include venous or arterial thrombosis and recurrent fetal loss. Thrombocytopenia and livedo reticularis may also be found in patients with the syndrome. Antiphospholipid antibody syndrome frequently occurs in patients with systemic lupus erythematosus but also occurs in patients with cancer and with some infections and with the administration of certain drugs. Lupus anticoagulants result from the presence of immunoglobulins, which bind to phospholipids and plasma proteins (β_2-glycoprotein 1, prothrombin) and prolong phospholipid-dependent clotting assays in vitro (see Chapter 131). Persons with lupus anticoagulants do not suffer from a bleeding diathesis unless other hemostatic defects are present (eg, severe thrombocytopenia, prothrombin deficiency). Paradoxically, a persistent lupus anticoagulant and/or a high level of cardiolipin or β_2-glycoprotein-I antibodies identifies thrombotic patients at substantially increased risk for recurrence. However, asymptomatic patients with transient lupus anticoagulants in association with infections or drugs may not be at increased risk for thrombosis.

The management of acute venous thromboembolism in patients with lupus anticoagulants is similar to that in other patients without this laboratory abnormality. The initial treatment of patients with a prolonged PTT at baseline, however, is complicated by the fact that the PTT cannot reliably be used to monitor unfractionated heparin dosage unless proper in-vitro calibration studies are done by adding known amounts of heparin into plasma samples and measuring the response of the PTT. Thus, it is preferable to monitor anticoagulant therapy in these individuals by performing plasma heparin measurements using factor Xa and a suitable chromogenic substrate. These problems are obviated by the use of low-molecular-weight heparin, which does not require coagulation monitoring. The presence of lupus anticoagulants also can interfere with heparin monitoring during cardiac surgery.

Warfarin is effective in preventing recurrent thrombosis, although retrospective studies indicated that an international normalized ratio (INR) greater than 3 is required.[245,246] Randomized clinicals trial in patients with the antiphospholipid antibody syndrome have shown that an INR of 2 to 3 is as effective as an INR of 3 to 4 in preventing recurrent venous thrombosis.[247,248]

The clinical heterogeneity of the individual populations in which lupus anticoagulants develop makes it difficult to generalize regarding their long-term antithrombotic management. Persons in whom transient lupus anticoagulants develop in association with infections do not experience thromboembolic episodes, and it is unclear whether drug-associated lupus anticoagulants are associated with thrombosis. Thus, the presence of persistent lupus anticoagulant or a high-titer antiphospholipid antibody, or both, in an asymptomatic subject with no prior thrombotic history is not an indication for anticoagulant or antiplatelet medications. Inasmuch as it is not currently possible to determine reliably the risk of thrombosis in an asymptomatic individual with these laboratory abnormalities, however, all such individuals should receive appropriate prophylaxis in conjunction with major surgical procedures, prolonged immobilization, pregnancy, and the postpartum period, unless there is a strong contraindication to such treatment. Corticosteroids can normalize clotting assay times or reduce antiphospholipid antibody titers in persons with lupus anticoagulants. These and other immunosuppressive medications have not been proved to prevent recurrent thrombosis, however.

MANAGEMENT

Acute Thrombosis

The acute management of venous thrombosis or pulmonary embolism in patients with biologic risk factors for thrombosis generally is not different from that in other individuals. Massive acute venous thrombosis and pulmonary embolism are strong indications for thrombolytic therapy. The usual treatment consists of unfractionated heparin or low-molecular-weight heparin followed by long-term anticoagulation with warfarin (or other vitamin K-antagonists). Warfarin can be started within the first 24 hours. Heparin or low-molecular-weight heparin is continued for at least 5 days or until the prothrombin time is in the therapeutic range, namely, until an INR of 2.0 to 3.0 is achieved. Special considerations may apply to selected patients with antithrombin III deficiency and hereditary protein C deficiency. The principles of anticoagulation are described in further detail in Chapter 137.

Antithrombin III Deficiency

Persons with antithrombin III deficiency can usually be managed successfully with low-molecular-weight heparin or intravenous heparin, although in some situations, higher than usual doses are required to achieve adequate anticoagulation. In antithrombin III-deficient individuals receiving heparin for the treatment of acute thrombosis, the adjunctive role of antithrombin concentrate purified from human plasma is not clearly defined because controlled trials have not been performed. Antithrombin III concentrate has been used safely and effectively in patients with antithrombin deficiency and acute venous thrombosis. It is recommended in those patients who have unusually severe thrombosis, have difficulty achieving adequate anticoagulation, or experience recurrent thrombosis despite adequate anticoagulation. It can also be used for antithrombotic prophylaxis in antithrombin III-deficient patients in whom anticoagulation is contraindicated. The use of antithrombin concentrate as adjunctive therapy or as an alternative to heparin, however, has not been studied in a controlled trial.[249]

Antithrombin concentrate is prepared from pooled normal human plasma. The manufacturing processes used to prepare antithrombin concentrate result in a product that is greater than 95% pure; this process inactivates the hepatitis B virus and human immunodeficiency virus-I. It is preferable to administer antithrombin concentrate rather than fresh frozen plasma. A human antithrombin concentrate has also been produced from the milk of transgenic goats using recombinant DNA technology[250] and is commercially available in Europe.

The infusion of 50 units of plasma-derived antithrombin concentrate per kilogram of body weight (1 unit is defined as the amount of antithrombin in 1 mL of pooled normal human plasma) usually will increase the plasma antithrombin III level to approximately 120% in a congenitally deficient individual with a baseline level of 50%. Plasma levels should be monitored to ensure that they remain above 80%. The administration of 60% of the initial dose at 24-hour intervals is recommended to maintain inhibitor levels in the normal range.[251] Recovery of plasma-derived antithrombin concentrate in vivo in patients with antithrombin deficiency is 1.4% to 2.7% per unit per kilogram of body weight. Recovery is lower in patients with acute thrombotic events and those receiving heparin therapy. The biologic half-life approximates 2.8 to 4.8 days.

Oral anticoagulants are highly effective in the management of patients with antithrombin III deficiency. Warfarin should be continued indefinitely in patients with recurrent venous thrombosis. Asymptomatic antithrombin III-deficient persons from thrombophilic kindreds are not generally given prophylactic anticoagulation unless they are exposed to situations that predispose them to the development of thrombosis (eg, prolonged immobilization, surgery, pregnancy).

Protein C Deficiency

Hereditary protein C deficiency can rarely be associated with warfarin-induced skin necrosis because of the induction of a transient hypercoagulable state by warfarin. Despite this risk, routine measurement of plasma protein C concentrations in all individuals with thrombosis before the initiation of oral anticoagulants is not recommended. This conclusion is based on three observations: the infrequent occurrence of warfarin-induced skin necrosis even among patients with hereditary protein C deficiency; the frequency of asymptomatic hereditary protein C deficiency in the general population (1:200 to 1:500); and the diagnostic difficulty in making a rapid and definitive laboratory diagnosis of the deficiency state.

Conversely, oral anticoagulation in a patient who is known or likely to be protein C deficient should be started under the cover of full heparinization. The dose of warfarin should be increased gradually, starting from a relatively low level (eg, 2 mg for the first 3 days and then in increasing amounts of 2 to 3 mg/day until therapeutic anticoagulation is achieved). Patients with heterozygous protein C deficiency and a history of warfarin-induced skin necrosis have been successfully retreated with oral anticoagulants. Administration of protein C, in the form of either fresh frozen plasma or protein C concentrate derived, can provide protection against recurrent skin necrosis until a stable level of anticoagulation is achieved. A highly purified protein C concentrate derived from human plasma is commercially available.

Long-Term Therapy to Prevent Recurrent Venous Thromboembolism

After initial heparinization, standard therapy for patients with deep venous thrombosis or pulmonary embolism typically includes anticoagulation with warfarin for 3 to 12 months at a target INR of between 2 and 3; this regimen results in more than a 90% reduction in recurrence risk. In patients presenting with a first episode of symptomatic venous thromboembolism, Prandoni[252] found the cumulative incidence of recurrent venous thrombosis after the cessation of anticoagulant therapy to be 24.8% at 5 years and 30.3% at 8 years. Other investigators have confirmed that this risk is approximately 5% to 15% per year for the first several years after a first or even a second episode of unprovoked venous thrombosis.

Recurrences are less common when the initial event is associated with a transient risk factor (eg, surgery, trauma, pregnancy). Despite the relatively high recurrence risk in patients with a first episode of unprovoked venous thrombosis, anticoagulation with warfarin has not proved to have sufficient benefit, compared with the bleeding risk, to support long-term prophylaxis for all patients at substantial recurrence risk. For example, one controlled trial evaluated the efficacy of long-term warfarin therapy (INR 2 to 2.85) for 6 months or indefinitely in 227 patients with a second venous thrombotic episode, but not specifically inherited thrombophilia.[253] Long-term warfarin was highly effective in preventing recurrences as compared with 6 months of therapy (2.6% vs. 21% over 4 years). This benefit was partially counterbalanced by a trend toward an increased incidence of major hemorrhage (8.6% vs. 2.3%), and there was no difference in mortality rate between the two groups.

Owing to the relatively high frequency of the factor V Leiden mutation in patients with a first episode of venous thromboembolism, there is a substantial amount of data on the risk of recurrence. Although two groups initially reported that patients with factor V Leiden who had a first venous thrombotic event were more than twice as likely to have a recurrent episode than those without the mutation,[204,254] several other groups have not found that heterozygosity for this defect or the prothrombin G20210A mutation confers a higher recurrence risk.[14,40,255–257] Thus, the consensus view is that neither of these defects alone is predictive of recurrence, and several studies have argued against the use of long-term warfarin therapy after a first thromboembolic episode in these patient populations. As an example, the recurrence rate after discontinuation of oral anticoagulant therapy was assessed in 62 patients with factor V Leiden.[258] None of the patients had a recurrent event while taking warfarin. The median time to recurrence after stopping warfarin was 9 years; the period was shorter (3.5 years) among patients who suffered an idiopathic rather than precipitated first event. It was estimated that, even in the latter group, death from hemorrhage would probably exceed the number of fatal pulmonary emboli prevented with chronic warfarin therapy. A decision analysis model concerning the value of extended anticoagulation in patients with factor V Leiden who had a first deep vein thrombosis concluded that the number of major induced hemorrhages would exceed the number of clinical pulmonary emboli that would be prevented, and that extension of oral anticoagulation beyond 1 year would not produce clinical benefit.[259] There is no increase in mortality among patients with the factor V Leiden mutation,[260] further supporting the argument that the mortality risk of chronic warfarin therapy at a target INR of 2 to 3 in the average thrombophilic patient may exceed the potential benefit.

The recurrence risk appears to be significantly higher in the small subset of patients who are heterozygous for both mutations, homozygous for factor V Leiden, or have another thrombophilic defect.[10–15]

The presence of antiphospholipid antibody syndrome[246] or cancer[261,262] are also important risk factors for recurrence. A randomized clinical trial of patients with venous thromboembolism in the setting of active cancer demonstrated that chronic low-molecular-weight heparin leads to a significantly lower recurrence rate than that with standard therapy (low-molecular-weight heparin for 5–7 days followed by warfarin at a target INR between 2 and 3).[263]

Owing to the relatively low frequency of antithrombin, protein C, or protein S deficiency in unselected cohorts with an initial episode of venous thromboembolism, randomized clinical trials have included too few patients with these deficiencies to draw firm conclusions. A literature review and retrospective cohort study suggested that they have a high annual incidence of recurrent venous thromboembolism during the years immediately following a first episode and that this incidence declines thereafter.[264] The application of decision analysis to this problem indicates that optimal anticoagulant treatment duration will vary depending on the type of initial event (spontaneous or secondary; deep vein thrombosis or pulmonary embolism), patient age, and time passed since the initial thromboembolic episode.[265] Of interest, retrospective studies are unable to demonstrate an increase in mortality in patients with antithrombin III[266] or protein C deficiency.

For the individual patient, the decision to continue anticoagulation indefinitely requires estimation of the quantitative risk of recurrent thrombosis, including fatal pulmonary embolism, and major bleeding, including fatal bleeding over time. Patient compliance has a major impact on the success of therapy, and patient preferences must be factored into the decision. Many clinicians with experience managing these disorders recommend indefinite anticoagulation for patients with heterozygous antithrombin III deficiency. Some also recommend such an approach for patients with heterozygous deficiencies of protein C and protein S.

In summary, the decision whether to undertake extended or indefinite anticoagulation must be tailored to the individual patient based on several factors (Table 134–11). Commonly cited criteria for indefinite anticoagulation include the following:

Two or more spontaneous venous thrombotic events that are separated by a relatively short period of time (less than 2 years)

One spontaneous thrombosis in the case of antithrombin III deficiency, the antiphospholipid antibody syndrome, and active cancer

A single unprovoked venous thrombotic event in the presence of more than one genetic abnormality (eg, combined heterozygosity

Table 134–11 Long-Term Management of Patients with Venous Thromboembolism

Risk Classification	Management
High-Risk	Indefinite anticoagulation
2 or more spontaneous events for all high-risk patients	
1 spontaneous life-threatening thrombosis	
1 spontaneous thrombosis at unusual sites (mesenteric or cerebral venous)	
1 spontaneous thrombosis in association with the antiphospholipid antibody syndrome, active cancer, antithrombin III deficiency, or more than one genetic or allelic abnormality	
Moderate-Risk	Vigorous prophylaxis in
1 thrombosis with a known provocative stimulus	High-risk settings in asymptomatic patients

for the factor V Leiden mutation and the prothrombin G20210A mutation)

A single spontaneous pulmonary thromboembolic event that is massive or submassive

One spontaneous thrombosis at an unusual site (eg, mesenteric, portal, or cerebral veins)

Management of Pregnancy

The management of pregnancy in women with a history of thrombosis or hereditary thrombotic disorders poses special problems. The incidence of thrombotic complications during pregnancy and the postpartum period appears to be greater in women with antithrombin III deficiency than in those with deficiencies of protein C or protein S.[267] During pregnancy, adjusted-dose unfractionated heparin or low-molecular-weight heparin administered by the subcutaneous route is the anticoagulant of choice, because its efficacy and safety for the fetus are established. Low-molecular-weight heparin is an attractive alternative to unfractionated heparin in these women because of its better bioavailability and longer half-life. There is a low risk of venous thromboembolism antepartum without prophylactic anticoagulation in women with a history of thrombotic episodes[268] in association with transient risk factors; the risk appears to be higher in women with the factor V Leiden mutation. Treatment, however, should be administered during the postpartum period. Affected women with antithrombin III deficiency with or without previous thrombotic events probably should receive treatment. Treatment for asymptomatic women with other hereditary thrombotic disorders should be considered on an individual basis, but asymptomatic women with heterozygosity for factor V Leiden or the prothrombin G20210A mutation are at low risk and generally will not require prophylactic anticoagulation.

The dose and duration of heparin or low-molecular-weight heparin therapy in pregnancy are uncertain, because appropriately designed clinical trials have not been performed. Women considered to be at high risk should receive therapeutic doses by subcutaneous injection every 12 hours for the duration of pregnancy. The dose of unfractionated heparin should be adjusted to maintain the 6-hour postinjection PTT at 1.5 times the control value. In women considered to be at intermediate risk, lower doses of heparin (5000 to 10,000 units subcutaneously every 12 hours), or low-molecular-weight heparin can be started during the second or third trimester and continued for approximately 6 weeks into the postpartum period. Low-risk patients can be observed closely throughout the pregnancy.

In women who are planning pregnancy while receiving long-term oral anticoagulant therapy, several approaches can be taken to minimize the risk of both thrombotic complications and warfarin embryopathy. One is to stop warfarin and commence subcutaneous heparin or low-molecular-weight heparin therapy. This approach potentially exposes the patient to many months of heparin therapy while she is trying to conceive. Alternatively, warfarin therapy could be continued with the performance of pregnancy tests on a frequent basis. As soon as pregnancy is diagnosed and before the sixth week of gestation, oral anticoagulants must be discontinued and heparin therapy initiated. The risk of warfarin embryopathy appears to be quite small during the first 6 weeks of pregnancy.

Management of Warfarin-Induced Skin Necrosis and Neonatal Purpura Fulminans

As warfarin-induced skin necrosis is a rare complication, therapy has been guided primarily by knowledge regarding its pathogenesis. The diagnosis should be suspected in individuals with painful, red skin lesions developing within a few days after the initiation of the drug, and immediate intervention is required to prevent rapid progression and reduce complications. Therapy should consist of immediate discontinuation of warfarin, administration of vitamin K, and infusion of heparin at therapeutic doses. Lesions have been reported to progress despite adequate anticoagulation with heparin.

In persons with hereditary protein C deficiency, the administration of a source of protein C should be considered. This measure also may be appropriate in other patients with warfarin-induced skin necrosis, because they invariably have reduced plasma levels of functional protein C when the skin lesions first appear. Fresh frozen plasma has been used, but improved results can be expected with the administration of a highly purified protein C concentrate, which facilitates the rapid and complete normalization of plasma protein C levels.

The management of neonatal purpura fulminans in association with homozygous or doubly heterozygous protein C deficiency is more complicated, and heparin therapy has not been shown to be effective. The administration of a source of protein C appears to be critical in the initial treatment for these patients. Fresh frozen plasma has been used with success in affected infants. However, the half-life of protein C in the circulation is only approximately 6 to 16 hours, and the administration of plasma on a frequent basis is limited by the development of hyperproteinemia or hypertension, loss of venous access, and the potential for exposure to infectious viral agents. Protein C concentrate is efficacious in treating neonatal purpura fulminans.[269] Warfarin has been administered to these infants without the redevelopment of skin necrosis during the phased withdrawal of fresh frozen plasma infusions, and this medication has been used chronically to control the thrombotic diathesis. Successful liver transplantation was performed in a child with liver failure and homozygous protein C deficiency, which resulted in normalization of the plasma protein C level and resolution of the thrombotic diathesis.[270]

CHAPTER 135

VENOUS THROMBOEMBOLISM

Wendy Lim, Mark A. Crowther, and Jeffrey S. Ginsberg

Venous thrombosis remains a common medical condition that is associated with significant morbidity. This condition is largely preventable, and recent advances have further reduced the risk of venous thrombosis and simplified its therapy.

Although venous thrombosis can occur in any vein, it most commonly occurs in the leg veins. Superficial venous thrombosis occurs most frequently in varicosities and usually is benign and self-limiting. Occasionally, and particularly with thrombosis of the long saphenous vein, superficial vein thrombosis can grow and extend into the deep veins. Deep vein thrombosis, in contrast to superficial vein thrombosis, is a more serious condition. Thrombi localized to the calf veins often are small and therefore less commonly associated with clinically important pulmonary embolism or postphlebitic syndrome. In contrast, proximal deep vein thrombosis involving the popliteal, femoral, or iliac venous system is commonly complicated by pulmonary embolism. Extensive damage to venous valves may lead to postphlebitic syndrome in some patients.

Venous thrombosis and its major complication, pulmonary embolism, are important causes of morbidity and mortality in hospitalized patients. Venous thromboembolism also occurs spontaneously in otherwise well, ambulatory outpatients. The diagnosis of acute venous thromboembolism in outpatients is now being made more frequently because of increased diagnostic suspicion and the availability of reliable, noninvasive diagnostic tests.

PATHOGENESIS OF VENOUS THROMBOEMBOLISM AND CLINICAL RISK FACTORS

Venous thrombi are composed predominantly of fibrin and red cells[1] and usually arise in the large venous sinuses in the calf, in valve cusp pockets in the deep veins of the calf, or at sites of vessel damage. Pathologic or physiologic venous thrombosis occurs when activation of blood coagulation exceeds the ability of the natural anticoagulant mechanisms and the fibrinolytic system to prevent clot formation.[1] More than 150 years ago, our current understanding of the pathogenesis of venous thromboembolism was first described by Virchow. He proposed that thrombotic disorders were associated with the triad of stasis, vascular injury, and hypercoagulability,[2] and that abnormalities in this triad are found in patients with arterial or venous thromboembolism. Over the next 100 years, the roles of stasis and vascular injury in the pathogenesis of thrombosis were studied extensively, leading to the development of effective treatments for thromboembolic disorders. Stasis and vascular injury, with activation of blood coagulation, are the most frequent precipitants of venous thromboembolism. In addition to activating coagulation, tissue damage can also impair fibrinolysis by reducing synthesis of tissue plasminogen activator (tPA) and by increasing endothelial cell production of plasminogen activator inhibitor type 1 (PAI-1), the major inhibitor of the fibrinolytic pathway.[3]

Under normal circumstances, activated coagulation factors are diluted in the flowing blood and are neutralized by inhibitors on the surface of endothelial cells or by circulating antiproteinases.[4] Activated clotting factors that escape regulation, as a result of either reduced levels of inhibitors or sudden generation of overwhelming amounts of these enzymes, trigger the coagulation system, thereby leading to fibrin formation. Homeostatic mechanisms, including activation of the fibrinolytic system with release of tPA[5] and urokinase, are immediately invoked to reduce the likelihood of pathologic thrombus formation.

THROMBOGENIC FACTORS

Activation of Blood Coagulation

With the exception of small amounts of factor VII, the coagulation proteins circulate as inactive precursors, or zymogens. Each zymogen is converted into an active enzyme that then activates the next zymogen in the coagulation pathway (see Chapter 118).[6] Traditionally, the coagulation cascade has been divided into an intrinsic and an extrinsic pathway. Although these pathways reflect the way coagulation is measured in the laboratory, they do not reflect how coagulation occurs in vivo. In vivo, coagulation is initiated exclusively by the tissue factor pathway. In this pathway, a proportion of the circulating activated factor VII—factor VIIa—binds to tissue factor at sites of vascular injury. The tissue factor-factor VIIa complex then activates both factor IX and factor X.[7] Levels of factor VIIa can be increased by factor Xa; however, this reaction is rapidly downregulated by tissue factor pathway inhibitor (TFPI). TFPI renders factor Xa inactive by complexing with it; the TFPI-factor Xa complex then binds the factor VIIa-tissue factor complex and prevents further activation of factor X.[8]

In the presence of activated factor V, phospholipid, and calcium, factor Xa completes the coagulation cascade by converting prothrombin to thrombin. Thrombin then converts fibrinogen to fibrin, activates platelets, and activates factor XIII, which, in the presence of calcium, cross-links the fibrin, thereby stabilizing the clot. To ensure continuous generation of thrombin, thrombin and factor Xa activate factor VIII and factor V, markedly accelerating the coagulation reactions involving these two cofactors, and thrombin activates factor XI, which in turn activates additional factor IX, establishing a positive feedback loop.[6]

Coagulation may be activated by contact of factor XII with collagen on exposed subendothelium of damaged vessels or by contact with prosthetic surfaces, but this does not appear to be an important pathway in vivo. Coagulation is further augmented by activated platelets. Coagulation also may be initiated by the exposure of blood to tissue factor made available locally as a result of vascular wall damage,[7] by activation of endothelial cells, and by activated monocytes that migrate to areas of vascular injury.[9] Factor X can be activated directly by extracts of malignant cells that contain a cysteine protease,[10] which may be one of the mechanisms by which thrombosis is induced in patients with malignant disease. A factor elaborated by hypoxic endothelial cells also can directly activate factor X,[11] potentially leading to thrombosis in patients with severe venous stasis in whom stagnant hypoxia occurs in the valve cusps.

Clinical risk factors that predispose patients to venous thromboembolism by activating blood coagulation include malignancy, extensive surgery, trauma, burns, myocardial infarction, and possibly local hypoxia produced by venous stasis.[11]

Venous Stasis

Venous return from the legs is enhanced by venous valves, which prevent blood from pooling in the lower legs, and by contraction of the calf muscles, which propels blood upward from the extremities. Venous stasis may contribute to thrombogenesis by allowing stagnation of the blood with associated local hypoxia, which stimulates endothelial cell release of an activator of blood coagulation.[11] Venous stasis is produced by immobility, venous obstruction, increased venous pressure, venous dilation, and increased blood viscosity.

Immobility

Venous thrombosis occurs in immobilized persons because blood pools in the intramuscular sinuses of the calf, which are dilated during recumbency. Many clinical examples highlight the role of stasis in the pathogenesis of venous thrombosis. For example, the prevalence of venous thrombosis found at autopsy is markedly increased in persons who were confined to bed for more than 1 week before death. Furthermore, preoperative immobility is associated with a higher frequency of perioperative venous thrombosis. After surgery, patients remain at risk for venous thromboembolism for as long as they are immobile. Finally, immobility contributes to the high incidence of postoperative venous thrombosis in patients who have undergone hysterectomy, transabdominal prostatectomy, hip surgery, knee surgery, or surgery for fractures of the lower limb. The effect of immobility on thrombosis is well illustrated by comparing the location of thrombosis in paraplegics with that in stroke patients. Whereas thrombosis occurs with equal frequency in both legs in paraplegics, it occurs more frequently in the paralyzed limb in stroke patients.

Venous Obstruction and Increased Venous Pressure

Venous obstruction contributes to the risk of venous thrombosis in patients with pelvic tumors, and to recurrent venous thrombosis in patients with persistent obstruction because of proximal vein thrombosis. Raised central venous pressure produces venous stasis in the extremities, which may explain the high prevalence of venous thrombosis in patients with heart failure. A similar mechanism may underlie the propensity for thrombosis in the left leg during pregnancy, presumably from obstruction of the left common iliac vein by the right common iliac artery accentuated by the presence of the gravid uterus.[12]

Increased Blood Viscosity and Venous Dilation

Venous stasis can be caused by increased blood viscosity or venous dilation. The blood viscosity can be increased by polycythemia, hypergammaglobulinemia, dysproteinemias, or an increased fibrinogen concentration. Stasis because of venous dilation may contribute to the increased risk of thrombosis in patients with varicose veins and in elderly patients, particularly if they are bedridden. The ability of estrogen to cause venous dilation may contribute to the increased prevalence of thrombosis during pregnancy,[13] in patients taking estrogen-containing oral contraceptive pills,[13] and in women taking postmenopausal estrogen replacement therapy.[14–16]

Vessel Wall Damage

Although the normal endothelium is nonthrombogenic, damage or injury to the endothelium can trigger the activation of platelets and coagulation. Vascular injury leads to the expression of tissue factor. In addition, the exposure of blood to subendothelium leads to platelet adhesion, activation and aggregation.

The vascular endothelium can be damaged by direct trauma, or it can be perturbed by exposure to endotoxin, inflammatory cytokines such as interleukin-1 and tumor necrosis factor, thrombin, or low oxygen tension. Perturbed endothelial cells synthesize tissue factor and PAI-1 and internalize thrombomodulin-changes that promote thrombogenesis.[17] Furthermore, damaged endothelial cells produce less tPA, the principal activator of fibrinolysis.

Direct venous damage may lead to venous thrombosis in patients undergoing hip surgery, knee surgery, or varicose vein stripping and in patients with severe burns or lower-limb trauma. Perturbation of vascular endothelium by exposure to thrombin or inflammatory mediators probably contributes to the thrombosis that occurs after tissue damage, such as surgery or trauma, and in patients with acute or chronic inflammatory states.

PROTECTIVE MECHANISMS

Endothelial Protective Mechanisms

Normal vascular endothelium is nonthrombogenic to flowing blood. Endothelial cell-surface glycosaminoglycans and thrombomodulin are potent inhibitors of coagulation, and vessel wall generation of prostacyclin and nitric oxide and synthesis of plasminogen activators limit platelet aggregation and fibrin deposition.

Thrombomodulin and heparan sulfate present on the luminal surface of endothelial cells are important modulators of thrombin activity. Heparan sulfate, a glycosaminoglycan similar to heparin, catalyzes the inhibition of thrombin and factor Xa by antithrombin.[4] Thrombomodulin serves as a surface-bound receptor for thrombin.[17] Once complexed with thrombomodulin, thrombin undergoes a conformational change that markedly alters its substrate specificity such that thrombin is no longer capable of activating platelets, of converting fibrinogen to fibrin, or of activating factors V, VIII, and XIII.[4] Rather, complexed thrombin acquires enhanced ability to activate protein C, which in turn proteolytically inactivates factors Va and VIIIa. This reaction requires protein S as a cofactor. Thus, once bound to thrombomodulin, thrombin not only loses its procoagulant activity but, by activating protein C, triggers a potent anticoagulant pathway.

Generation of plasminogen activators[18] by vascular wall cells limits fibrin deposition, and platelet aggregation is inhibited by the release of prostacyclin (prostaglandin I_2) and endothelium-derived nitric oxide.[19] Endothelial cell affinity for tPA, plasminogen, and activated protein C and protein S also may contribute to the thromboresistance of the vessel wall.[4] Plasminogen binds to the cell surface, where it can be activated to plasmin by tPA, thereby promoting local fibrinolytic activity. Bound activated protein C and protein S have a potent anticoagulant function.

Endothelial cells also have properties that are potentially procoagulant. Perturbed endothelial cells also synthesize endothelins, which cause local vasoconstriction.

Inhibitors of Blood Coagulation

Activated coagulation factors are serine proteases, and their activity is modulated by several naturally occurring plasma inhibitors. The most important inhibitors of the blood coagulation system are antithrombin III, protein C, and protein S.[4] An inherited deficiency of one of these three proteins was found in 11% of patients enrolled in a prospective evaluation of the prevalence of hypercoagulable states in 2132 consecutive patients presenting with venous thrombosis.[20] Any of several congenital dysfibrinogenemias also can predispose the affected person to thrombosis, as can congenital deficiency of plasminogen.

HYPERCOAGULABLE STATES

Other potential causes of venous thromboembolism are hypercoagulable states, including those associated with deficiencies of

antithrombin and proteins C and S, the factor V Leiden and prothrombin G20210A mutations, hyperhomocysteinuria, and the presence of antiphospholipid antibodies. Hypercoagulable states are the subject of Chapter 134.

NATURAL HISTORY OF VENOUS THROMBOEMBOLISM

Most thrombi are asymptomatic and confined to the intramuscular veins of the calf. These calf vein thrombi often undergo spontaneous lysis and rarely, if ever, produce long-term sequelae.[21] By contrast, complete lysis of proximal vein thrombosis is uncommon even when heparin treatment is given.[22]

The symptoms and signs of venous thromboembolism are caused by obstruction to venous outflow, inflammation of the vessel wall or perivascular tissues, or embolization of thrombus into the pulmonary circulation. Asymptomatic pulmonary embolism is detected by perfusion lung scanning in approximately 50% of patients with documented proximal vein thrombosis.[23] Most clinically significant and fatal pulmonary emboli probably arise from thrombi in the proximal veins of the legs. Although pulmonary embolism also may complicate calf vein thrombosis, these emboli tend to be smaller in size, and pulmonary embolism occurs less commonly than in patients with proximal vein thrombosis.[23] Asymptomatic venous thrombosis is found in 70% of patients who present with confirmed pulmonary embolism.[24] These thrombi usually are large and involve the proximal veins.

Extensive venous thrombosis causes venous valvular damage, which leads to the postphlebitic syndrome.[25] Patients with a previous history of venous thrombosis are at increased risk of further episodes of venous thrombosis, particularly when patients are exposed to high-risk situations.[26]

PROGNOSIS WITH VENOUS THROMBOSIS

Untreated or inadequately treated venous thrombosis is associated with a high complication rate, which can be decreased markedly by adequate anticoagulant therapy. Approximately 20% of untreated silent calf vein thrombi and 20% to 30% of untreated symptomatic calf vein thrombi extend into the popliteal vein. When extension occurs and is untreated, it is associated with a 40% to 50% risk of clinically detectable pulmonary embolism.[21] Patients with proximal vein thrombosis who receive inadequate treatment[27] have a 47% frequency of recurrent venous thromboembolism over 3 months, and patients with symptomatic calf vein thrombosis who receive a 5-day course of intermittent intravenous unfractionated heparin without continuing oral anticoagulants have a recurrence rate greater than 20% over the next 3 months.[28]

By contrast, clinically detectable recurrence occurs in less than 2% of patients with proximal vein thrombosis during the initial period of unfractionated heparin therapy[23] if an adequate anticoagulant response is achieved, and the recurrence rate during the subsequent 3 months of treatment with oral anticoagulants or moderate doses of subcutaneous unfractionated heparin is 2% to 4%.[27,29,30] After 3 months of anticoagulant therapy, the recurrence rate is 5% to 10% in the subsequent year.[27,29,30] Patients whose first episode of venous thrombosis was idiopathic and those who have ongoing risk factors, such as prolonged immobilization or cancer, have a higher risk of recurrence.

The significance of asymptomatic calf deep vein thrombosis discovered incidentally by screening venography after orthopedic surgery is unclear although the risk of clinical sequelae from these thrombi is low.[31] As a result, if adequate perioperative deep vein thrombosis prophylaxis is given, it probably is not necessary to perform screening tests for deep vein thrombosis in asymptomatic patients at the time of hospital discharge.

POSTPHLEBITIC SYNDROME

The postphlebitic syndrome is caused by venous hypertension, usually resulting from valve destruction. Valve destruction results in malfunction of the muscular pump mechanism, which leads to increased pressure in the deep calf veins during ambulation. The high pressure ultimately renders the perforating veins of the calf incompetent, so that blood flow is directed from the deep veins into the superficial venous system during muscular contraction. This leads to edema and impaired viability of subcutaneous tissues and, in its most severe form, to venous ulceration. Outflow obstruction initially may be bypassed by the development of collateral veins, but with time, the veins distal to the obstruction become dilated and their valves become incompetent.

In patients whose thrombosis extends into the iliofemoral veins, the leg swelling at initial presentation may not resolve entirely. This is in contrast to patients with less extensive proximal vein thrombosis, where the swelling may subside after initial treatment but recur months or years later. Other symptoms and signs of the postphlebitic syndrome may be delayed for 5 to 10 years after the initial thrombotic event. These symptoms include pain in the calf that is relieved with rest and leg elevation, pigmentation and induration around the ankle and lower one-third of the calf, and ulceration, which usually occurs in the region of the medial malleolus.

Patients with extensive thrombosis involving the iliofemoral vein frequently have greater disability and may even have venous claudication, which is characterized by incapacitating, bursting pain with exercise.[32] This complication rarely occurs in patients with thrombosis involving the more distal veins.

The frequency with which postphlebitic syndrome occurs after venous thromboembolism is controversial. Prandoni and colleagues[33] demonstrated that 29% of patients with acute deep vein thrombosis will develop the syndrome after 8 years of followup; however, other investigators have found a much lower rate.[34] The development of ipsilateral recurrent thrombosis was associated with a large increase in risk for the development of postphlebitic syndrome.

Whether therapy for acute venous thrombosis reduces the long-term risk of postphlebitic syndrome is unclear. In practical terms, therapy that reduces thrombus extension or prevents the development of profound outflow obstruction from the limb is likely to reduce the long-term risk of postphlebitic syndrome. In addition, the use of below-knee graduated compression stockings has been shown to reduce the risk of postphlebitic syndrome in patients with deep vein thrombosis.[35]

DIAGNOSIS OF VENOUS THROMBOSIS

The approach to the diagnosis of venous thrombosis has changed radically over the past 2 decades. It is now accepted that the clinical diagnosis of venous thrombosis is unreliable and that objective tests are necessary to confirm the diagnosis.

In symptomatic patients, venous ultrasonography has a sensitivity and specificity for detection of proximal (femoral or popliteal vein) deep vein thrombosis of more than 95%.[36] However, ultrasonography is insensitive for detection of calf vein thrombosis and of any deep vein thrombosis occurring after orthopedic surgery.[37] Ultrasound examination can be repeated 7 days after the initial study to increase its sensitivity for detection of clinically important calf vein thrombosis and to improve the safety of diagnostic strategies that do not include venography in patients with suspected calf vein thrombosis. This strategy will detect the 10% to 30% of calf vein thrombi that extend proximally. If examination findings remain negative after 7 days, the risk of clinically important proximal extension is negligible, and it is safe to withhold antithrombotic treatment.[38–41]

CLINICAL DIAGNOSIS

Although clinical diagnosis is unreliable, careful documentation of clinical symptoms and signs is helpful in ruling out venous thrombosis when an alternative cause is identified. The conditions that most frequently mimic venous thrombosis are a ruptured Baker cyst, cellulitis, sciatica, muscle or tendon tear, muscle cramp, muscle hematoma, external venous compression, superficial thrombophlebitis, and the postphlebitic syndrome. In assessing patients for suspected venous thrombosis, patients can be reliably classified into high-, intermediate-, and low-probability groups based on their clinical manifestations and the presence or absence of risk factors such as recent immobilization, hospitalization within the past 6 months, or malignancy.[42] In one series, patients with the classic symptoms and signs of deep vein thrombosis such as localized pain, tenderness, swelling, and discoloration, and who had at least one risk factor had an 85% probability of venous thrombosis, whereas those with atypical symptoms and no risk factors had only a 5% probability of venous thrombosis. These low- and high-pretest probabilities can be combined with the results of objective noninvasive tests to make clinical decisions (Fig. 135–1). A low clinical pretest probability and a negative result on noninvasive testing can be used to exclude a diagnosis of venous thrombosis and obviate further testing, whereas a high clinical pretest probability and a negative noninvasive test result should prompt further investigation with venography.

In approximately 70% of patients referred for clinically suspected venous thrombosis, the diagnosis will be excluded by objective tests.[38,39] Of the 30% who have venous thrombosis, approximately 85% will have proximal vein thrombosis, and the remainder will have thrombosis confined to the calf.[38,39]

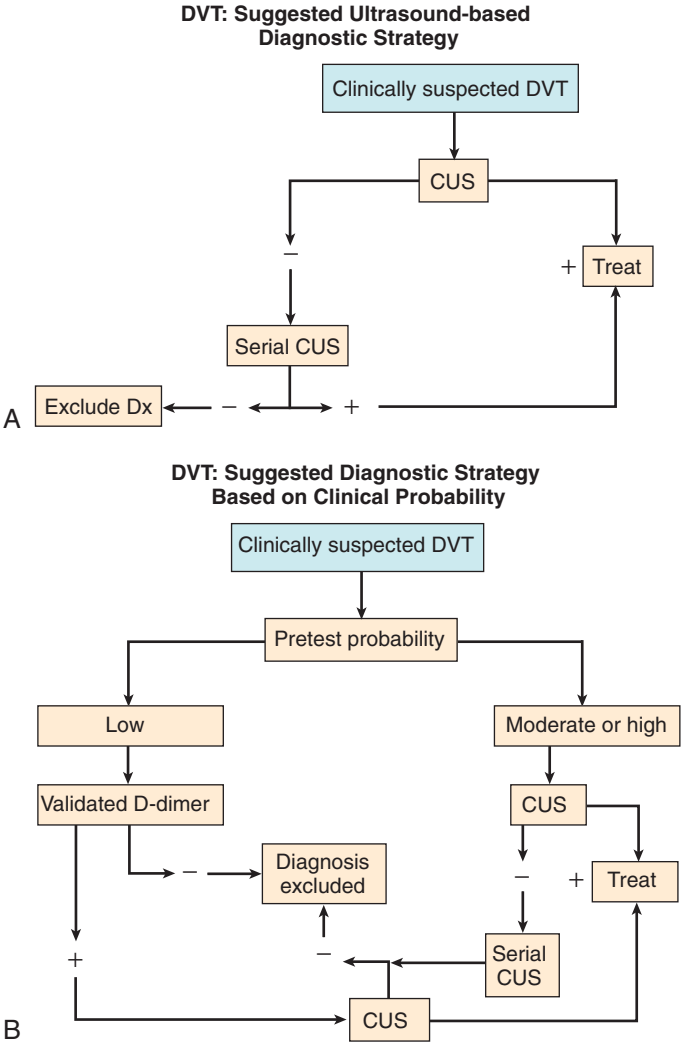

Figure 135–1 Diagnostic algorithms for the management of patients with suspected deep vein thrombosis (DVT). (**A**) Ultrasound examination-based strategy. (**B**) Clinical probability-based strategy. CUS, compression ultrasound.

OBJECTIVE DIAGNOSTIC TESTS

Both invasive and noninvasive tests are useful for the diagnosis of venous thrombosis. Venography is the only invasive test of proven value; the noninvasive test that has been most widely studied is venous ultrasonography. Unlike venography, ultrasonography lacks sensitivity for detection of calf vein thrombosis.

Venography

Venography remains the reference standard for the diagnosis of venous thrombosis.[43] It is technically difficult, and its proper execution and interpretation require considerable experience. Venography may produce superficial phlebitis and can cause deep vein thrombosis,[43] but with good technique, ascending venography outlines the entire deep venous system of the lower extremities, including the calf and iliac veins.

Venous Ultrasonography

Venous ultrasonography is performed using a high-resolution real-time scanner equipped with a 5-MHz electronically focused linear array transducer. The common femoral vein and femoral artery are first located in the groin, with the patient in a supine position. The superficial femoral vein is then examined along its course. Next, the popliteal vein is located and examined down to the level of its trifurcation into the peroneal and tibial veins. At each of these locations, the vein being examined is compressed gently but firmly with the transducer probe, and the results are observed on the monitor. Hard copies from freeze-frame images of both stages of the procedure are obtained and serve as a permanent record.

Venous ultrasonography is very accurate for the detection of proximal vein thrombosis in symptomatic patients but relatively insensitive for detection of calf vein thrombosis. If the field of examination is extended to the distal popliteal vein and the proximal deep calf veins, venous ultrasonography detects approximately 50% of calf vein thrombi in symptomatic patients.[44,45] Although there are reports that ultrasound examination of the calf can detect thrombi reliably, most such reports have not used venography as their reference standard. Furthermore, whether the value of this test is maintained when it moves from highly specialized vascular laboratories into community ultrasonography laboratories is unknown. A potential limitation of venous ultrasonography is its inability to visualize the iliac veins and the segment of the superficial femoral vein within the femoral canal. This is not a serious limitation, because isolated thrombi within the femoral canal or the iliac vein are rare.[46] Furthermore, the obstruction produced by iliac vein thrombi often limits the compressibility of the common femoral vein segment and hence will be detected indirectly.

D-Dimer Assays

D-dimer assays use mono- or polyspecific antibodies against D-dimer to provide quantitative or qualitative data on the concentration of D-dimer in whole blood or plasma. D-dimer is a product of fibrin lysis and is increased in patients with acute venous thromboembolism. However, the test is nonspecific because the level of D-dimer also is increased in a variety of conditions including malignancies and

infections. Therefore, the D-dimer assay is most useful as a tool to rule out suspected deep vein thrombosis.[47,48]

D-dimer assays have two principal limitations: (1) A positive test is nonspecific and should not be used as the sole criterion for diagnosis of venous thrombosis; and (2) numerous test kits are available that have different sensitivities for deep vein thrombosis. Thus, D-dimer results are not interchangeable between kits. This has led to significant confusion regarding the use of D-dimer assays, and this confusion is exacerbated by the fact that the use of an insensitive D-dimer assay to rule out venous thrombosis could result in omission of required diagnostic testing, placing patients at risk for pulmonary embolism and death.

The optimal setting for use of a D-dimer assay is in the assessment of patients with a low clinical pretest probability of deep vein thrombosis. The combination of a low pretest probability (determined using a validated scoring system) and a negative result on a validated D-dimer assay essentially rules out the diagnosis of acute deep vein thrombosis, obviating the need for additional testing. Some D-dimer kits have been studied in patients with low and moderate pretest probabilities of deep vein thrombosis and have been shown to reliably exclude deep vein thrombosis in both patient groups.[49,50] Evaluation of the levels of D-dimer may be of particular value in patients with suspected recurrent venous thrombosis, and it may assist in decision making about optimal duration of anticoagulation.[51]

DIAGNOSTIC STRATEGIES

Diagnostic algorithms for the noninvasive diagnosis of clinically suspected venous thrombosis are presented in Fig. 135–1. If ultrasonography is not immediately available, patients can receive a therapeutic dose of low molecular weight heparin and return for diagnostic testing on the subsequent day. Patients with a high pretest likelihood of deep vein thrombosis and negative findings on ultrasound examination require an additional diagnostic test; either venography or serial ultrasonography (with two repeat tests, the first on day 3 to 5 and the second on day 7 to 14) must be performed.

PULMONARY EMBOLISM

Clinical Manifestations

In most instances, pulmonary embolism is clinically silent. Dyspnea is the most frequently reported symptom.[52,53] Chest pain is common and typically pleuritic in nature but may be substernal and compressing. Hemoptysis is a less frequent feature of pulmonary embolism.[24,52,53]

The physical signs of pulmonary embolism are nonspecific. Syncope usually is associated with massive pulmonary embolism and is caused by a reduction in cardiac output. This in turn results in hypotension and transient impairment of cerebral blood flow.

Although 70% of patients with pulmonary embolism have venographic evidence of thrombosis at presentation, less than 20% of these patients have leg symptoms.[24] Massive pulmonary embolism causes tachypnea, tachycardia, cyanosis, and hypotension. In these patients, cardiac examination may reveal a right ventricular heave, a loud pulmonary second sound, and a gallop rhythm. Physical examination of the chest may be normal, or nonspecific abnormalities may be detected. Patients with pulmonary infarction or atelectasis may have reduced movement of the affected portion of the chest. There may be signs of pulmonary consolidation or atelectasis, a pleural friction rub, crackles, or a pleural effusion, and a low-grade fever may be present.

Differential Diagnosis

The differential diagnosis of dyspnea and pleuritic chest pain, in addition to pulmonary embolism, includes pneumonia, pleurisy, chest wall pain from trauma, pericarditis, atelectasis, pneumothorax, acute bronchitis, acute bronchiolitis and acute bronchial obstruction as a result of mucous plugging or bronchoconstriction.

Diagnosis

The clinical diagnosis of pulmonary embolism is as unreliable as the diagnosis of venous thrombosis. Consequently, objective tests are necessary. The chest radiograph is not specific for pulmonary embolism and usually does not show any diagnostic abnormality. Nevertheless, it is useful in excluding other causes for the presenting symptoms (eg, pneumothorax) and is essential for interpreting the lung scan findings. Like the chest radiograph, the electrocardiogram frequently is normal or shows nonspecific abnormalities. However, in the appropriate clinical setting, electrocardiograph evidence of right ventricular strain is strongly suggestive of pulmonary embolism. Similarly, elevated levels of cardiac troponin frequently are seen in patients with massive pulmonary embolism as a result of right ventricular strain and associated myocardial ischemia.[54]

Diagnostic Tests for Pulmonary Embolism

Pulmonary Angiography

Pulmonary angiography is the reference standard for establishing the presence or absence of pulmonary embolism. Selective angiography and magnification views improve resolution and reduce the risk of the procedure. When pulmonary angiography is adequately performed, a negative result excludes the diagnosis of pulmonary embolism. Unless the tertiary pulmonary arteries are visualized in a patient with a small perfusion defect, however, the diagnosis of pulmonary embolism cannot be excluded.[55]

Arrhythmias, cardiac perforation, cardiac arrest, and hypersensitivity reactions to contrast material occur in 3% to 4% of patients undergoing pulmonary angiography.[56] Patients with a history of allergy to radiopaque dye should not undergo pulmonary angiography.

Ventilation-Perfusion Lung Scan

The lung scan consists of a perfusion and a ventilation component. For the perfusion component, particles of isotopically labeled microaggregates of human albumin are injected intravenously and become trapped in the pulmonary capillary bed. Their distribution reflects lung blood flow and is recorded with an external photoscanner. A normal perfusion scan excludes pulmonary embolism, but an abnormal perfusion scan is nonspecific.[24,53,57]

Ventilation lung scanning is performed using either radioactive gases or aerosols that are inhaled and exhaled by the patient while a gamma camera records the distribution of radioactivity within the alveolar gas exchange units. The purpose of ventilation imaging is to improve the specificity of perfusion scanning for the diagnosis of pulmonary embolism. A high-probability ventilation-perfusion scan (in which a segmental or greater area is ventilated but not perfused) has a positive predictive value for pulmonary embolism of more than 90%, obviating the need for angiography.

Helical Computed Tomography Scanning

Helical or spiral computed tomography (CT) scanning of the chest has emerged as a preferred test for the diagnosis of pulmonary embolism. This test is relatively insensitive, particularly for detection of emboli that lodge in the peripheral pulmonary vasculature. However, when performed in experienced clinical centers with use of validated scanning protocols, helical CT scanning is a useful tool to rule out pulmonary embolism in patients with compatible clinical symptoms.

For example, in one study where patients with suspected pulmonary embolism were evaluated with single-detector helical CT scanning and those with negative or inconclusive findings on CT scanning underwent ultrasonographic evaluation of their legs on the day of presentation and on days 4 and 7 after scanning, 124 of 510 enrolled patients had pulmonary embolism.[58] In 130 patients, an alternate diagnosis for their chest symptoms was found with the CT scan, 10 patients either could not have a CT performed or had a uninterpretable scan, and 248 patients had normal scans. Two of these 248 patients had proximal deep vein thrombosis on their initial ultrasound study, and all other patients had normal findings on serial ultrasound examinations. This and other similar studies suggest that if used correctly, helical CT scanning is a useful test in patients with suspected pulmonary embolism. In fact, systematic reviews suggest that a correctly done spiral CT effectively rules out pulmonary embolism in patients suspected to be at low or moderate risk of this complication.[59]

Diagnostic Strategy

Patients with large perfusion defects (involving one or more segments, or more extensive defects) and a ventilation-perfusion mismatch have a 90% probability of pulmonary embolism. Similarly, patients with a normal perfusion scan have less than a 2% probability of having pulmonary embolism, excluding the diagnosis. However, most patients who have ventilation-perfusion scanning performed will have neither of these findings; rather, they will have either matched defects or small perfusion defects.[24,53,57] Patients with these findings require further investigation with either pulmonary angiography or objective tests for venous thrombosis. A patient with suspected pulmonary embolism, an indeterminate ventilation-perfusion scan, and positive findings on leg ultrasound examination can be assumed to have pulmonary embolism. A patient with suspected pulmonary embolism, an indeterminate ventilation-perfusion scan, and a negative result on leg ultrasound examination requires additional testing, because the thrombus may have completely embolized to the lungs.[24,53]

A diagnostic algorithm for the management of clinically suspected pulmonary embolism is shown in Fig. 135–2. After a history and physical examination, electrocardiograph , and chest radiography, all patients with suspected pulmonary embolism should undergo helical CT scanning or ventilation-perfusion lung scanning. A negative result on perfusion lung scan, or a negative helical CT, rules out clinically significant pulmonary embolism, and anticoagulant therapy can be withheld. If the perfusion scan demonstrates one or more segmental (or larger) defects and ventilation to these regions is normal, or if an intraluminal filling defect is seen on helical CT, a diagnosis of pulmonary embolism is made. Although a ventilation-perfusion mismatch supports a diagnosis of pulmonary embolism, a ventilation-perfusion "match" does not exclude pulmonary embolism, and further objective testing is required in these patients. Similarly, the diagnosis of pulmonary embolism cannot be excluded in patients with small perfusion defects (one or more subsegmental defects) or those with indeterminate lung scan findings (in which the perfusion defects correspond with abnormalities on the chest radiograph). In these patients, venous ultrasonography should be performed. If deep vein thrombosis is documented, a diagnosis of pulmonary embolism can be assumed, and anticoagulant therapy should be started, thereby obviating the need for pulmonary investigations.

However, if results on these tests are negative, additional objective investigations (including, perhaps, pulmonary angiography) are required in patients with a high clinical suspicion. For those with a lower pretest probability of pulmonary embolism, an alternative strategy is to withhold anticoagulants and to perform serial noninvasive tests to detect ongoing venous thrombosis. In patients with a low or low-to-moderate pretest probability of pulmonary embolism, a D-dimer test may prove useful. If the D-dimer assay result is negative, further testing could be avoided, whereas if it is positive (increasing the likelihood of acute thrombosis), further testing is warranted.[60,61]

MANAGEMENT OF PATIENTS WITH SUSPECTED RECURRENT VENOUS THROMBOEMBOLISM AND POSTPHLEBITIC SYNDROME

A majority of patients with a history of venous thrombosis who develop new onset leg pain do not have recurrent deep vein thrombosis when investigated with the appropriate diagnostic tests. Some of these patients have the postphlebitic syndrome; in others, the pain is unrelated to venous thrombosis.[62] Misdiagnosis of postphlebitic syndrome as acute deep vein thrombosis has immediate consequences for patients, because many such patients will be treated with life-long warfarin. In these patients, who in fact did not experience recurrent thrombosis, this treatment is unneeded, costly, and associated with significant risk.

DIAGNOSIS OF ACUTE RECURRENT VENOUS THROMBOSIS

The diagnosis of acute recurrent venous thrombosis is difficult to make, because the clinical manifestations of recurrence are nonspecific. In addition, all of the validated diagnostic tests for acute venous thrombosis have limitations in this setting, because the venous occlusion produced by the initial episode of venous thrombosis makes it difficult to identify new abnormalities.

The most appropriate diagnostic strategy for suspected recurrent venous thrombosis has yet to be determined. The patient's history may be helpful in determining the likelihood of recurrent thrombosis. Leg pain with ambulation and leg swelling that is relieved with overnight rest is typical of the postphlebitic syndrome. New, clinically significant and persistent leg swelling, particularly if the symptoms do not abate overnight, is consistent with recurrent thrombosis and should prompt diagnostic evaluation. It may also be useful to obtain a measurement of the international normalized ratio (INR) at the time of presentation, and to assess the INR measurements in recent weeks. Warfarin is a very effective antithrombotic; thus, the risk of recurrent thrombosis in therapeutically anticoagulated patients irrespective of their symptoms is very low. Nevertheless, recurrent thrombosis despite therapeutic anticoagulation occasionally

is seen in patients with cancer or those with antiphospholipid antibodies.

Many patients with a history of venous thrombosis will have a heightened level of concern about the risk of recurrent thrombosis. This heightened concern will lead these patients to seek testing for recurrent thrombosis even with incompatible symptoms. Such patients require careful clinical and radiologic evaluation. If there is no evidence of acute recurrence, they may require counseling and significant education about their condition.

The best test for recurrent thrombosis is the demonstration of a new thrombus in a previously unaffected venous segment. Thus, lack of compressibility on ultrasonography or an intraluminal filling defect on venography is diagnostic of recurrent thrombus, if the lesion involves an area that was previously documented to be free of thrombus. Similarly, a normal venogram rules out recurrence, and normal findings on ultrasound examination rule out proximal thrombus. A normal result on ultrasound study does not rule out calf vein thrombosis, and requires that additional testing with serial ultrasonography be performed if this is suspected. Other findings, such as lack of compressibility of the veins or an intraluminal filling defect with flow seen on Doppler ultrasound studies, are not sufficiently reliable to either confirm or rule out acute thrombosis. In these cases, serial testing (to detect extension) may be useful.

D-dimer–based testing strategies are very attractive in patients with suspected recurrence, because they may obviate the need for additional diagnostic testing. Until such strategies are carefully studied, however, they should not be used in these patients.

Magnetic resonance imaging may be of use in some patients with suspected recurrence as it appears that selected magnetic resonance protocols may be able to reliable classify the age of the thrombus.

DIAGNOSIS OF THE POSTPHLEBITIC SYNDROME

The clinical spectrum of the postphlebitic syndrome varies from a course that may mimic acute venous thrombosis to one of persistent leg pain that is worse at the end of the day and is associated with dependent edema, stasis pigmentation, and, in its most severe form, skin ulceration.[63] Rarely, patients may complain of venous claudication on walking.[64] When symptoms are acute or subacute in onset, a diagnosis of postphlebitic syndrome should be considered only after recurrent venous thrombosis has been excluded by objective tests. There is no single definitive diagnostic test for the postphlebitic syndrome, but a history of objectively documented deep vein thrombosis, appropriate clinical findings, and evidence of venous reflux or outflow obstruction on venous ultrasonography constitute sufficient evidence to make this diagnosis.

Other causes of recurrent leg pain or swelling include recurrent muscle strain, internal derangement of the knee or hip, recurrent cellulitis, extrinsic compression of the vein, lumbosacral disk disease, sciatic pain, and factitious causes of leg pain and swelling.

PROPHYLAXIS OF VENOUS THROMBOEMBOLISM

Pulmonary embolism is a common preventable cause of death in hospitalized patients.[65] Hospitalized patients can be classified as at low, moderate, or high risk for developing venous thromboembolism. Effective prophylaxis is cost-effective and is available for most high-risk groups.[66]

Low-Dose Unfractionated Heparin

Low doses of unfractionated heparin prevent thrombosis by catalyzing the inhibition of thrombin, factor Xa, and the other serine proteases by antithrombin. Unfractionated heparin is usually given subcutaneously at a dose of 5000 units 2 hours before surgery and continued postoperatively at a dose of 5000 units every 8 to 12 hours. Low-dose unfractionated heparin prophylaxis does not require laboratory monitoring and is simple and convenient to administer. It is the method of choice for moderate risk general surgical and medical patients, and it reduces the risk of venous thromboembolism by 50% to 70%.[65,67–69] When used in these doses, unfractionated heparin is both highly effective and associated with only a small increase in the risk of bleeding. Although low-dose unfractionated heparin is effective in patients undergoing elective hip surgery and reduces the incidence of venous thrombosis by approximately 40%, it is less effective than other current prophylactic strategies and thus should not be used as the sole form of prophylaxis in such patients. Low-dose unfractionated heparin has not been shown to be effective in patients with hip fractures or those undergoing major knee surgery. In addition, use of subcutaneous heparin may be associated with heparin induced thrombocytopenia, particularly in the postoperative period.

Intermittent Pneumatic Compression

Intermittent pneumatic compression of the legs enhances blood flow in the deep veins and increases blood fibrinolytic activity.[65] Although there are few methodologically rigorous studies that support the effectiveness of intermittent pneumatic compression for venous thrombosis prophylaxis, this modality is virtually free of clinically important side effects and is particularly useful in patients who have a high risk of bleeding. It also is frequently used, albeit with little supporting evidence, during the operative procedure in patients undergoing extended-duration surgery and in patients after trauma. Intermittent compression is the prophylactic measure of choice in selected patients undergoing neurosurgical procedures;[70] however, most of these patients should eventually receive low molecular weight heparin as well.[71]

Graduated Compression Stockings

Graduated compression stockings also reduce venous stasis in the legs and are effective for preventing postoperative venous thrombosis in low- and moderate-risk general surgical patients[68] and in medical or surgical patients with neurologic disorders, including paralysis of the lower limbs.[70] In surgical patients, the combination of graduated compression stockings and low-dose unfractionated heparin is significantly more effective than low-dose unfractionated heparin alone.[72,73] Use of graduated compression stockings alone, however, constitutes inadequate prophylaxis in patients undergoing surgery associated with a very high risk of thromboembolism.[74] Graduated compression stockings are inexpensive and should be considered for use in all high-risk surgical patients, even if other forms of prophylaxis are used.

Oral Anticoagulants

When administered in doses that prolong the prothrombin time to an INR of 2.0, oral anticoagulants effectively prevent postoperative venous thromboembolism in patients in all risk categories.[65,69] Oral anticoagulants can be given preoperatively, at the time of surgery, or in the early postoperative period. When these agents are started at the time of surgery or in the early postoperative period, the anticoagulant effect is not achieved until the third or fourth postoperative day. Nevertheless, when used in this fashion, oral anticoagulants are effective in very high-risk patient groups, including patients with hip fractures.[75] Prophylaxis with oral anticoagulants is relatively inconvenient, however, because careful laboratory monitoring is necessary.

Low-Molecular-Weight Heparins and Fondaparinux

When used in prophylactic doses, once or twice daily, low-molecular-weight heparin is an effective and safe agent for prophylaxis in the

following high-risk groups: patients undergoing elective hip surgery, those with hip fractures, patients undergoing major general surgery or major knee surgery, those with spinal injury, and those who have sustained a stroke. Low-molecular-weight heparin is more effective than standard low-dose unfractionated heparin in general surgical patients, patients undergoing elective hip surgery, and patients with stroke or spinal injury. In addition, low-molecular-weight heparin also has been shown to be more effective than warfarin in patients undergoing hip or major knee surgery, better than adjusted-dose unfractionated heparin in preventing proximal vein thrombosis after elective hip surgery, and superior to dextran or aspirin after hip surgery.[76] Recently, concern about the coadministration of epidural anesthesia or analgesia and low-molecular-weight heparins has led to recommendations against the coincident use of these modalities. Recent evidence suggests that once-daily low-molecular-weight heparin may be safer than twice-daily low-molecular-weight heparin, allowing coincident use.[77]

Low-molecular-weight heparins produce their anticoagulant effect by preferentially catalyzing the inactivation of factor Xa by antithrombin. This effect is produced by a *pentasaccharide based on* a conserved sequence in the heparin molecule. The pentasaccharide moiety, fondaparinux, has been synthesized chemically and has been studied for the prevention and treatment of venous thromboembolism. Fondaparinux has been shown to be superior to low-molecular-weight heparin for the prevention of venous thrombosis after high-risk orthopedic surgery and is the only agent to demonstrate clear efficacy in patients undergoing surgical repair of a fractured hip. Extended use of fondaparinux in this patient population significantly reduces the risk of clinical venous thromboembolism over an extended followup period.[78] Fondaparinux has also been shown in clinical trials to be as effective and safe as unfractionated intravenous heparin for the treatment of acute symptomatic pulmonary embolism,[79] as effective and safe as twice-daily low-molecular-weight heparin for the treatment of deep vein thrombosis[80] and as effective as therapeutic dose enoxaparin in patients with unstable coronary syndromes. In this latter study fondaparinux was also safer than enoxaparin.

Choice of Prophylaxis in Different Patient Groups

General Surgical and Medical Patients

Early ambulation should be encouraged, and use of graduated compression stockings should be considered for all general surgical and medical patients. Moderate-risk patients should be given prophylaxis with low-dose unfractionated heparin. If anticoagulants are contraindicated because of an unusually high risk of bleeding, intermittent pneumatic compression should be used. Patients at very high risk, such as those with recent venous thrombosis, should receive low-molecular-weight heparin, oral anticoagulants, or adjusted-dose unfractionated heparin.

Hip Surgery

Low-molecular-weight heparin, oral anticoagulants, fondaparinux, or adjusted-dose unfractionated heparin are all effective in preventing venous thrombosis in patients undergoing hip surgery. In direct comparisons, fixed-dose low-molecular-weight heparin was more effective than warfarin in preventing thrombosis and was better than adjusted-dose unfractionated heparin in preventing proximal vein thrombosis. Fondaparinux is more effective than low-molecular-weight heparin. Extended duration anticoagulation is now recommended by consensus conferences for such patients; as a result extended prophylaxis after hospital discharge should be considered in all such patients.

Major Knee Surgery

Low-molecular-weight heparin or fondaparinux is the prophylactic agent of choice in patients undergoing major knee surgery. Early mobilization should be encouraged. Extended duration anticoagulation is now recommended by consensus conferences for such patients; as a result extended prophylaxis after hospital discharge should be considered in all such patients.

Genitourinary Surgery, Neurosurgery, and Ocular Surgery

In patients undergoing genitourinary surgery, neurosurgery, or ocular surgery, intermittent pneumatic compression, with or without the use of static graduated compression stockings, is effective and does not increase the risk of bleeding. Selected patients undergoing neurosurgery should receive low-molecular-weight heparin. Some patients undergoing surgery for urogenital cancer are at very high risk of venous thrombosis; there is increasing enthusiasm for prolonging prophylaxis after hospital discharge in such patients particularly if they are discharged from the hospital early in their postoperative course.

Stroke and Spinal Injury

Low-molecular-weight heparin is more effective than low-dose standard unfractionated heparin in patients who have suffered stroke or spinal injury and is the prophylactic method of choice for prevention of venous thrombosis. Extended prophylaxis with warfarin (target INR 2.0 to 3.0) should be used in patients who remain at high risk for venous thrombosis because of paralysis. Whether such prophylaxis should be continued after hospital discharge is unknown; in most centers, prophylaxis is discontinued at the time of discharge.

Trauma

Most trauma patients should receive low-molecular-weight heparin prophylaxis. In patients deemed to be at very high risk of bleeding, intermittent compression can be used until the bleeding risk has declined. Routine interruption of the inferior vena cava with a filter device has never been studied and will be associated with an increased risk of subsequent venous thrombosis.

Extending Prophylaxis after Hospital Discharge

Venographic studies suggest that approximately 1 of 5 (20%) patients undergoing elective orthopedic surgery who receive standard antithrombotic prophylaxis will have asymptomatic deep vein thrombosis found by venography at the time of hospital discharge. However, in the 3 months after hospital discharge, symptomatic nonfatal venous thromboembolism occurs in only approximately 1 of 42 (2.4%) patients, and fatal pulmonary embolism occurs in approximately 1 of 1250 (0.08%) patients.[81] Thus, treatment with a short, 5- to 10-day course of anticoagulant therapy after hip or knee arthroplasty is associated with a low risk for the development of subsequent clinically important symptomatic venous thromboembolism. Nevertheless, some authorities advocate extended-duration anticoagulation after hospital discharge. This treatment is designed to further reduce this low risk by providing additional prophylaxis during the period when patients are returning to a normal level of mobility.

A variety of treatment strategies have been used for extended prophylaxis, including use of aspirin, low-molecular-weight heparin, warfarin, and fondaparinux. Each of these strategies has been shown to reduce the risk of both venographic and clinically apparent deep vein thrombosis, suggesting that extended duration anticoagulation

should be considered in all patients undergoing very high-risk surgery. Extended duration prophylaxis may be particularly important in patients who are discharged soon after surgery, at which time they have markedly reduced mobility.

To further refine post-discharge prophylaxis, it would be helpful to identify high-risk patient groups. This approach would allow therapy to be administered to those most in need, rather than exposing all patients to the costs, bleeding risk, and inconvenience of 3 to 4 weeks of anticoagulant therapy. For example, it may be reasonable to limit extended duration anticoagulation to high-risk patients, such as those with limited postoperative mobility, patients with a noncemented hip prosthesis who are non–weight-bearing, those with previous venous thromboembolism or morbid obesity, and those with cancer. This approach has not been tested in prospective clinical trials.

TREATMENT OF VENOUS THROMBOEMBOLISM

The objectives of treatment for venous thromboembolism are to prevent death from pulmonary embolism, to reduce morbidity from the acute event, to minimize postphlebitic symptoms, and to prevent chronic thromboembolic pulmonary hypertension. All of these goals can be achieved with adequate anticoagulant therapy.

PREVENTING DEATH CAUSED BY PULMONARY EMBOLISM

Anticoagulants are effective in reducing mortality from pulmonary embolism.[82] However, some patients have relative or absolute contraindications to anticoagulant therapy. Such patients can be broadly divided into two groups. The first group consists of patients with a transient risk factor for bleeding, such as surgery for resection of a bowel tumor or active ulcer disease. Although not formally studied in randomized trials, insertion of a temporary vena cava filter, followed by its removal and subsequent therapeutic anticoagulation when the bleeding risk is diminished, should be considered for such patients. This strategy reduces the initial risk of bleeding while eliminating the long-term increase in the risk of deep vein thrombosis associated with permanent caval interruption.

The second group of patients consists of those with a persistent, major risk factor for bleeding; because the mortality rate for major bleeding occurring during therapeutic anticoagulation is approximately 20%, such patients should be considered for insertion of a permanent vena cava filter. This procedure is associated with a significant risk of immediate worsening of leg symptoms because of blockage of the inferior vena cava by thrombus and a long-term increase in the risk of recurrent deep vein thrombosis.

Thrombolytic therapy with streptokinase, urokinase, or tPA is more effective than unfractionated heparin alone in correcting the angiographic defects produced by pulmonary embolism[82] and may be better than unfractionated heparin in preventing death in patients with massive pulmonary embolism associated with shock.[83,84] Based on these findings, thrombolytic therapy is the treatment of choice for patients with massive pulmonary embolism, or in those with underlying cardiac or pulmonary disease, in whom even a small or moderate-sized embolus may be life-threatening.

Thromboendarterectomy is effective in selected cases of chronic thromboembolic pulmonary hypertension with proximal pulmonary arterial obstruction.[85] Urgent pulmonary embolectomy is usually reserved for patients with a saddle embolism lodged in the main pulmonary artery or for those with massive embolism whose blood pressure cannot be maintained despite thrombolytic therapy and vasopressor agents.[82] Although this procedure can be successfully performed by experienced surgical teams, in inexperienced hands it is associated with high complication and mortality rates. Patients with repeated episodes of pulmonary embolism and significant chronic pulmonary hypertension with right ventricular compromise should be carefully anticoagulated and monitored. If pulmonary pressures do not decrease, they should be evaluated for surgical fitness. If deemed necessary, surgery should be carried out in expert centers, within which the likelihood of success of the procedure is high.[85]

ANTICOAGULANT THERAPY TO REDUCE MORBIDITY FROM THE ACUTE EVENT

The first principle of treatment for acute venous thrombosis is to deliver effective doses of a parenteral anticoagulant as soon as the diagnosis is confirmed (or, if testing is delayed and the clinical likelihood of disease is moderate or high, before confirmation of the diagnosis). The second principle is that the initial anticoagulant should be a fast-acting parenteral drug, because currently available oral anticoagulants have a delayed onset of action. Third, patients should receive a full course of therapeutic-dose anticoagulants because use of subtherapeutic drug doses are associated with a high risk of recurrent thrombosis.

Traditionally, patients with acute venous thrombosis were admitted to the hospital and given intravenous unfractionated heparin, administered to achieve a therapeutic partial thromboplastin time (PTT). Warfarin was then started, and the heparin continued until the INR was more than 2.0. This treatment strategy remains a practice standard. However, recent work has confirmed that the vast majority of patients with acute venous thrombosis are safely and effectively managed as outpatients with therapeutic doses of low-molecular-weight heparin and warfarin.

Treatment should consist of weight-adjusted, once- or twice-daily subcutaneous low-molecular-weight heparin. Monitoring of the anticoagulant effect of the low-molecular-weight heparin is not required. If anticoagulant-related complications develop, or if the patient is at extremes of weight (less than 40 kg or greater than 100 kg), or has severe renal insufficiency, then the anticoagulant effect of the low-molecular-weight heparin can be assessed using an antifactor Xa assay. The target factor Xa assay target is 0.5 to 1.0 unit/mL measured 4 hours after a subcutaneous injection using a twice-daily dosing schedule. Low-molecular-weight heparin does not have a predictable effect on the PTT; thus, this test cannot be used for monitoring low-molecular-weight heparin. Warfarin should be initiated on the same day as the institution of unfractionated heparin. The low-molecular-weight heparin should be continued for at least 4 days and until the INR has been between 2.0 and 3.0 on two consecutive days.

Patients with comorbid conditions that preclude outpatient treatment, those with significantly symptomatic pulmonary embolism, or those in whom thromboembolism develops during hospitalization should receive either unfractionated heparin or low-molecular-weight heparin in the hospital.[86] Prospective randomized trials have compared the safety and effectiveness of unfractionated heparin given by either continuous intravenous infusion, intermittent intravenous injection, or subcutaneous injection. Although continuous intravenous unfractionated heparin infusion produces less bleeding than occurs with intermittent intravenous injections, unfractionated heparin delivery by intermittent subcutaneous injections appears to be as safe and efficacious as continuous intravenous unfractionated heparin infusion in the treatment of venous thrombosis.[82,87]

Unfractionated heparin has a half-life that varies considerably among different people.[88] After a single intravenous injection, there is an initial rapid disappearance owing to a saturable clearance mechanism, followed by a more gradual linear clearance,[89] with a mean heparin half-life of approximately 60 minutes. Whereas intravenous unfractionated heparin produces an immediate anticoagulant effect, peak heparin levels are not achieved until 3 hours after subcutaneous injection, but the levels will remain therapeutic for up to 12 hours, depending on the dose.

Unfractionated heparin therapy can be monitored using the activated clotting time and the PTT, or by heparin assays that measure the ability of heparin to accelerate the inactivation of factor Xa or thrombin. It is important to give adequate doses of unfractionated

heparin at initial presentation because the risk of recurrent venous thromboembolism probably is increased if insufficient doses are given. Accordingly, the PTT should be maintained above a level equivalent to a heparin level of 0.3 unit/mL as determined by measuring the antifactor Xa activity. For most currently used PTT reagents, this is equivalent to a PTT ratio of 1.8 times the control value. Thus, the recommended therapeutic range is a PTT ratio of 1.8 to 2.5.[90] Higher unfractionated heparin doses may be associated with an increase in the risk of bleeding.[89]

In the past, heparin was administered for a period of 7 to 10 days, and oral anticoagulants were started after 3 to 5 days and overlapped with heparin for 4 to 5 days. The period of overlap is necessary because the antithrombotic effects of oral anticoagulants are delayed and because the initial increase in the INR is attributable to a decrease in the level of factor VII, which has a short half-life, and not to reductions in the levels of prothrombin and factor X, which have longer half-lives and therefore must be reduced to produce therapeutic anticoagulation.[91,92] Two studies have demonstrated that 9 to 10 days of unfractionated heparin therapy are no better than a 4- to 5-day course of unfractionated heparin with overlapping warfarin.[93] Because neither study included many patients with major pulmonary embolism or extensive iliofemoral vein thrombosis, it would be prudent to use heparin for at least 7 days in these patients.

Recent evidence suggests that unfractionated heparin can be used without laboratory monitoring, similar to low-molecular-weight heparin; in a study of more than 700 patients, unfractionated heparin was administered using a fixed, weight adjusted dose without PTT monitoring. The risk of bleeding and recurrent thrombosis was found to be similar to that seen in patients treated with twice daily dalteparin or enoxaparin.[94]

After an initial course of heparin therapy, patients with venous thromboembolism require continuing anticoagulant therapy for several months to prevent recurrence.[27,28] Both therapeutic doses of subcutaneous heparin or low-molecular-weight heparin and oral anticoagulants are effective for this indication. Some patients will require long-term anticoagulation: patients with multiple previous episodes of venous thrombosis; those with a persistent, major risk factor for venous thrombosis; and those in whom the consequences of recurrence would be dire. Other patients, particularly those with an episode of venous thrombosis that occurred in the absence of a clear cause should receive a minimum of 6 months of therapeutic anticoagulation.

Fondaparinux is as effective as low-molecular-weight heparin in patients with acute deep vein thrombosis or pulmonary embolism.

PREVENTING MORBIDITY FROM THE POSTPHLEBITIC SYNDROME

The postphlebitic syndrome is a major cause of morbidity. The risk of postphlebitic syndrome in patients with symptomatic deep vein thrombosis may be as high as 29% after 8 years if the definition of this syndrome includes symptoms such as occasional leg pain or swelling.[33] The ability of thrombolytic therapy to prevent the postphlebitic syndrome has been evaluated to a limited extent. Streptokinase treatment produces complete lysis of acute venous thrombi in 30% to 40% of cases and causes partial lysis in an additional 30%.[82] By contrast, complete lysis of venous thrombi occurs in less than 10% of patients given unfractionated heparin. It is estimated that thrombolysis occurs 3.7 times more often in patients who receive streptokinase than in those given unfractionated heparin, but major bleeding occurs 2.9 times more frequently with streptokinase. Although five randomized studies have reported that the frequency of the postphlebitic syndrome is significantly higher in patients who receive unfractionated heparin than in those given streptokinase,[82] one trial[95] reported that patients given streptokinase and those given unfractionated heparin had similar manifestations of the postphlebitic state after 5 years of followup. Two studies reported that the incidence of the postphlebitic syndrome was reduced by the early use of graduated compression stockings, a finding disputed by another study.[82] In view of their low cost and lack of toxicity, most experts recommend that patients with persistent leg swelling after deep vein thrombosis wear compression stockings.

Catheter-directed lysis of deep vein thrombosis is widely practiced in the United States. Using a variety of techniques, with the usual lytic agent being tPA, rapid and near complete resolution of thrombus can be demonstrated in many patients. Unfortunately, neither the immediate or long-term benefit of such expensive and potentially toxic therapy has been demonstrated in controlled clinical trials. In particular, there is no good quality evidence of improved venous valvular function after catheter-directed lysis.

PREVENTION OF LATE EFFECTS OF PULMONARY EMBOLISM

Clinically significant pulmonary hypertension is an uncommon complication of pulmonary embolism. In randomized trials comparing unfractionated heparin with either streptokinase or urokinase for the treatment of acute pulmonary embolism, thrombolytic therapy produced greater improvement in lung scan-detected perfusion defects than that obtained with unfractionated heparin during the first week. However, there were no apparent differences in the lung scan findings at 2 weeks, 3 months, and 1 year.[96] Subsequent long-term followup in small subgroups of patients indicated that pulmonary capillary blood volume and both pulmonary vascular resistance and functional status were significantly better in patients who received fibrinolytic therapy than in those given unfractionated heparin.[82] As a result, thrombolysis is reserved in most centers for patients with massive pulmonary embolism causing cardiovascular collapse.

Moser and colleagues[85] have reported their experience with surgical pulmonary endarterectomy in carefully selected patients with chronic thromboembolic pulmonary hypertension. Most patients with obstruction of the proximal pulmonary arteries show impressive improvement after endarterectomy. These investigators stress the importance of careful patient selection and expert perioperative management.

SIDE EFFECTS, COST, AND CLINICAL USEFULNESS OF THROMBOLYTIC THERAPY

Bleeding occurs more frequently with thrombolytic therapy than with unfractionated heparin.[82,97] The risk of hemorrhage increases with the duration of thrombolytic infusion and usually occurs at a site of previous surgery or trauma. Intracranial hemorrhage occurs in approximately 1% of patients at risk, approximately twice as frequently as with unfractionated heparin treatment.

PRACTICAL RECOMMENDATIONS

A majority of patients with proximal deep vein thrombosis, calf vein thrombosis, and minimally symptomatic pulmonary embolism should receive outpatient low-molecular-weight heparin. Selected patients may be admitted for intravenous unfractionated heparin although there is no evidence that this therapy is superior to low-molecular-weight heparin in any clinical setting.

Warfarin should be started at the same time as for initiation of the heparin, considering patient age and gender in selecting a warfarin dose. An initial dose of 5 to 10` mg can be given to most individuals, and initial doses less than 5` mg should be used for elderly patients. Women generally require lower warfarin doses than men. The duration of warfarin therapy is variable. Patients with a persistent, major risk factor for recurrence, such as malignancy, should receive warfarin for as long as the risk factor persists. Those with a secondary thrombosis (such as after orthopedic surgery) who have

returned to normal mobility may need warfarin for as little as 6 weeks, although a 3-month treatment period probably is preferable. Patients with idiopathic deep vein thrombosis (ie, those without a clear precipitant) should receive a minimum of 6 months, although consideration may be given for longer duration of therapy. The optimal duration of warfarin therapy for these patients is unknown and some of these patients receive indefinite anticoagulant therapy. Two potential tests that may prove of value are compression ultrasonography when anticoagulant discontinuation is being considered, and D-dimer assays. A persistent intraluminal filling defect seen on ultrasonography and/or a persistently positive D-dimer may predict recurrent thrombosis and mandate extended duration anticoagulant therapy.

A large randomized trial has suggested that patients with venous thrombosis in the setting of ongoing or recently treated cancer have a lower risk of recurrent thrombosis when given extended-duration low-molecular-weight heparin than when given warfarin.[98] This treatment should probably be considered in all patients with acute venous thrombosis occurring in the setting of cancer.

The dose of unfractionated heparin should be adjusted to maintain the PTT at 1.8 to 2.5 times control. To monitor unfractionated heparin given by continuous intravenous infusion, the PTT should be measured 6 hours after the bolus dose so that it reflects the anticoagulant effects of the infusion. If twice-daily subcutaneous unfractionated heparin is given, a mid-interval PTT should be measured 6 hours after the injection.

The INR is used to monitor oral anticoagulant therapy, and the dose of warfarin should be adjusted to achieve an INR of 2.0 to 3.0. Heparin can be discontinued when the INR has been therapeutic for 2 successive days.

VENOUS THROMBOSIS IN UNUSUAL SITES

Subclavian or Axillary Vein Thrombosis

Although thrombosis of the subclavian or axillary veins most frequently occurs as a complication of a chronic indwelling catheter, it also may occur as a consequence of local malignancy and is a well-documented complication of mastectomy and radiation therapy.[99] Subclavian vein thrombosis is particularly common in children with indwelling central venous catheters; this complication develops in up to 20% of children who have catheters placed for cancer chemotherapy or parenteral nutrition. In adults, the cause of subclavian or axillary vein thrombosis is frequently uncertain, and idiopathic subclavian or axillary vein thrombosis often occurs in young patients preceded by repetitive, strenuous activity that involves the affected arm. Occasionally, subclavian or axillary vein thrombosis can occur in patients with activated protein C resistance or congenital deficiency of antithrombin, protein C, or protein S, or in patients with antiphospholipid antibodies. Finally, thrombosis of the axillary or subclavian vein or the superior vena cava is a rare complication of perivenous endocardial pacing using an implantable system.[100,101] Upper extremity deep vein thrombosis is associated with pulmonary embolism, a complication seen frequently in children with catheter-related thrombosis. In adults, however, such emboli are predominately small and minimally symptomatic.

Patients with subclavian or axillary thrombosis usually experience pain in the axilla and edema and cyanosis of the arm. If thrombosis extends into the superior vena cava, edema and cyanosis of the face, neck, and upper extremities may develop. Dilated superficial veins on the chest and arms may appear after a number of days. Occasionally, asymptomatic thrombosis of the internal jugular vein accompanies subclavian vein thrombosis. The definitive diagnosis is made with venography, although venous ultrasonography is frequently used as the first-line diagnostic test. Patients with a negative ultrasound and a high clinical suspicion for upper extremity thrombosis should undergo venography.

Subclavian or axillary vein thrombosis usually is treated with anticoagulants. Thrombolytic therapy also is effective and should be considered, because it is estimated that greater than two-thirds of the patients with subclavian vein thrombosis will have persistent symptoms in the affected arm. Subclavian vein stenosis that persists after thrombolytic therapy may predispose to recurrence and may limit the benefits of thrombolysis.[102] In some settings, stenting of subclavian vein stenosis after venous thrombosis may reduce symptoms, particularly in patients requiring dialysis in whom outflow obstruction from the arm may cause major morbidity.

Mesenteric Vein Thrombosis

Mesenteric vein thrombosis is uncommon. This disorder occurs most commonly in the sixth and seventh decades of life and affects segments of the small bowel, leading to hemorrhagic infarction rather than gangrene. Bowel infarction often produces bloody ascites, and adhesions frequently develop between the involved bowel and the omentum. Many of the affected patients have associated disorders, such as thrombosis at other sites, inflammatory bowel disease, recent abdominal surgery, malignant disease, and portal hypertension. Mesenteric vein thrombosis also may complicate hypercoagulable states (such as antithrombin, protein C, or protein S deficiencies), polycythemia vera, or the use of oral contraceptives, and it also has been reported in late pregnancy. In approximately 20% of cases, no underlying cause is found. The clinical manifestations of mesenteric vein thrombosis include intermittent abdominal pain, abdominal distention in the later stages of the disorder, vomiting, diarrhea, and melena. Although the diagnosis often is difficult to make, blood-stained ascitic fluid on abdominal paracentesis and hemorrhagic bowel infarcts at peritoneoscopy are characteristic findings. Management includes supportive care and surgical resection followed by anticoagulant therapy. The mortality rate is approximately 20%, and recurrence is seen in up to 20% of cases.

Renal Vein Thrombosis

Renal vein thrombosis can occur as a complication of the nephrotic syndrome, possibly because antithrombin is lost in the urine, and is commonly seen in association with membranous glomerulonephritis. Patients may be asymptomatic, may present with mild symptoms of abdominal or back pain, or may have severe flank pain and tenderness. Pulmonary embolism has been described as a relatively common complication of renal vein thrombosis. With anticoagulant therapy there is a gradual improvement in renal function tests, although patients may suffer from long-standing proteinuria. Thrombolytic therapy has been used successfully in a small number of patients with renal vein thrombosis.

Cerebral Vein Thrombosis

Spontaneous venous thrombosis of the cerebral veins is an uncommon manifestation of thrombophilia. Patients may present with signs and symptoms of raised intracerebral pressure: headache, nausea, vomiting. Many patients with spontaneous cerebral vein thrombosis will be found to have a hypercoagulable state (see Chapter 134).[103] A relationship among cerebral vein thrombosis, oral contraceptive use, and the prothrombin gene 20210A mutation has been described.[183] Patients with cerebral vein thrombosis should be given therapeutic doses of heparin followed by warfarin and monitored for development of symptomatic intracerebral hemorrhage.[104]

CHAPTER 136

ARTERIAL THROMBOEMBOLISM

Elizabeth F. Krakow, Jeffrey S. Ginsberg, and Mark A. Crowther

INTRODUCTION

Arterial thrombosis usually occurs as a complication of atherosclerosis. Atherosclerosis is the most common underlying cause of coronary heart disease, cerebrovascular disease, and peripheral arterial disease and as such is the single most common cause of mortality and morbidity in Western populations. Arterial narrowing caused by atherosclerosis limits blood flow and causes ischemic symptoms when the oxygen requirements are increased by exercise. For example, angina pectoris occurs when the coronary arteries cannot supply sufficient blood flow to meet the demands of the myocardium. Similarly, intermittent claudication reflects ischemia of the leg muscles as a result of an imbalance between arterial blood supply and the demands of the exercising muscles, whereas intestinal angina typically occurs after a large meal when the blood supply to the gut is insufficient to meet the requirements.

Tissue infarction occurs when the arterial supply is completely occluded for a critical period of time. Arterial occlusion usually is the result of the rupture or fissuring of an atherosclerotic plaque, which exposes thrombogenic material and triggers the formation of a platelet-fibrin thrombus.

PATHOGENESIS OF ATHEROSCLEROSIS

The term *atherosclerosis* was introduced by Marchand, who recognized the association of fatty degeneration and vessel stiffening.[1] Atherosclerosis affects medium and large-sized arteries and is characterized by patchy intramural thickening of the subintima that encroaches on the arterial lumen and eventually leads to vascular obstruction. The earliest lesion of atherosclerosis is the fatty streak, which is caused by an accumulation of lipid-laden foam cells in the intimal layer of the artery. With time, the fatty streak evolves into a fibrous plaque, the hallmark of established atherosclerosis.

Atherosclerotic lesions are composed of three major components. The first is a cellular component with increased numbers of intimal smooth muscle cells and an accumulation of macrophages. The second component is the connective tissue matrix, large amounts of which are produced by the proliferating smooth muscle cells, and extracellular lipid. The third component is lipid that accumulates within the smooth muscle cells and the macrophages, thereby converting them into foam cells. Thus, the development of atherosclerotic lesions involves proliferation of smooth muscle cells, synthesis of connective tissue matrix, and accumulation of macrophages and lipid.

Over the years, two main hypotheses have been proposed to explain the pathogenesis of the atherosclerotic process: the lipid hypothesis[2,3] and the chronic endothelial injury hypothesis.[4] Experimentally, atherosclerosis can be produced by cholesterol feeding or by chronic endothelial injury.

The Lipid Hypothesis

The lipid hypothesis postulates that with increased levels of low-density lipoproteins (LDLs), lipid accumulates in smooth muscle cells and macrophages as the LDL penetrates the arterial wall. LDL is oxidized in the presence of endothelial cells. In its oxidized form, LDL becomes more atherogenic. Thus, oxidized LDL causes endothelial damage[5] and is chemotactic for monocyte-macrophages. Monocytes first adhere to the altered endothelium by interacting with surface adhesion molecules (eg, vascular cell adhesion molecule 1 [VCAM-1]), and then migrate through the endothelium and basement membrane by elaborating hydrolases that degrade connective tissue matrix (matrix metalloproteinases). As these cells accumulate, they take up lipid and are converted to foam cells. Macrophages bind intra-intimal LDL through a family of novel receptors, known as scavenger receptors, which recognize LDL only after it has been oxidized. Oxidation affects both lipid and apoprotein moieties of the LDL molecule; the lecithin component of LDL phospholipid undergoes conversion to lysolecithin, which is chemotactic for monocytes.[6] In addition, uptake of oxidized LDL renders the macrophages less mobile, thereby promoting the accumulation of these lipid-laden cells in the intima (Fig. 136–1).

An experimental model of atherosclerosis has been developed in monkeys fed a diet rich in cholesterol.[2] Within 2 weeks of induction of hypercholesterolemia, monocytes become attached to the surface of the arterial endothelium, migrate into the subendothelium, and accumulate lipid, which gives them the appearance of foam cells. Proliferating smooth muscle cells then emerge, and they also accumulate lipid. As the fibrous plaque enlarges, the endothelial cells retract, exposing the subendothelium to the blood and triggering the formation of platelet-fibrin thrombi. The release of platelet-derived growth factor leads to further smooth muscle proliferation, as described in the response-to-injury hypothesis. Support for the important role of oxidized LDL in atherogenesis comes from several sources. Administration of antioxidants to hyperlipidemic rabbits inhibits the formation of fatty streaks. Oxidized LDL can be extracted from human lesions, and many humans have circulating antibodies that are specific for epitopes of oxidized LDL.[6]

The Chronic Endothelial Injury Hypothesis

The response-to-injury hypothesis was proposed by Russell Ross.[4,7] It postulates that endothelial injury results in loss of endothelium, adhesion of platelets to subendothelium, aggregation of platelets, release of platelet-derived growth factors and elaboration of chemotactic factors that attract leukocytes, which in turn release other growth factors. The growth factors induce replication and migration of smooth muscle cells into the intima and result in the formation of a fibrous plaque. The smooth muscle cells synthesize and secrete connective tissue matrix containing collagen, proteoglycans, and elastic fibers, which contributes to the mass of the lesion. Plaque fissure or rupture may trigger the formation of a platelet-fibrin plug, which is then incorporated into the lesion. With repeated injury there is further intimal proliferation and progressive narrowing of the lumen.

The earliest stages of atherosclerosis are mediated by the inflammatory cascade. This cascade is initiated as the response to the injury caused by turbulent blood flow in the setting of an unfavorable serum lipid profile. Animals fed an atherogenic diet rapidly overexpress VCAM-1. VCAM-1 expression on endothelial surfaces is an early and necessary step in the pathogenesis of atherosclerosis.[8] VCAM-1

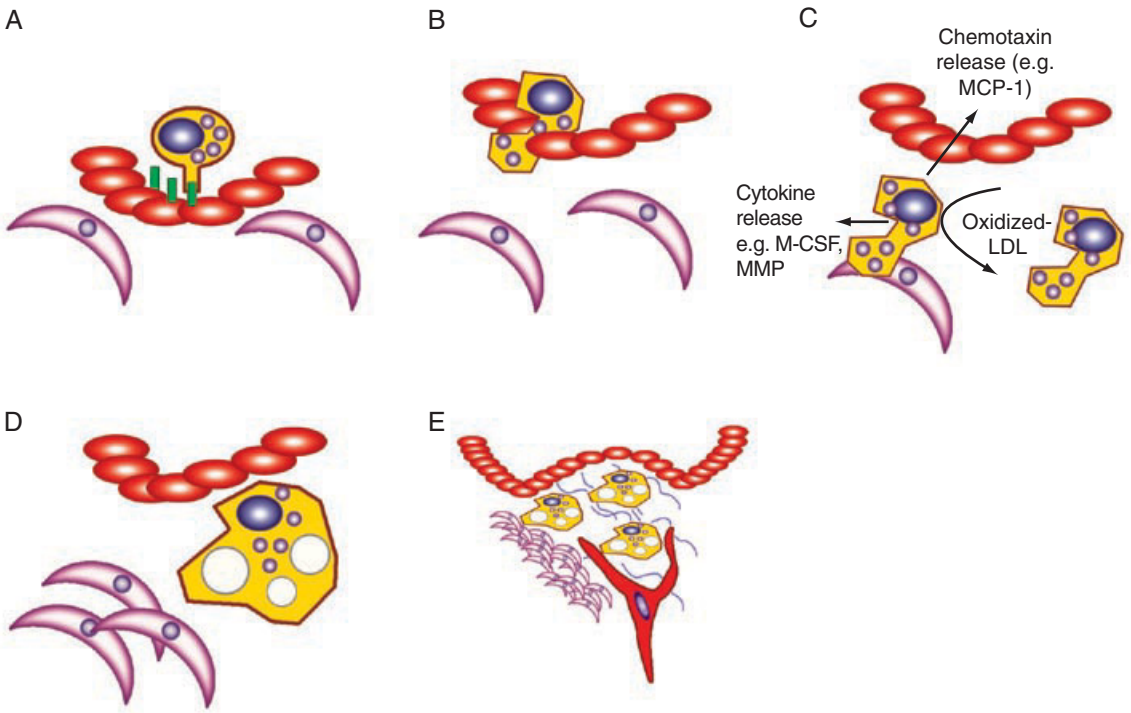

Figure 136–1. Atherosclerosis is initiated when adhesive proteins are expressed by the endothelium, causing leukocytes to adhere to the endothelium (Panel A). Leukocytes then cross the endothelial barrier (B). Monocytes within the subendothelial space "orchestrate" the development of atherosclerosis through cytokine release (C). The first clinically apparent lesion is the accumulation of foam cells (D). The clinically important lesion is characterized by intimal narrowing, many foam cells, neovascularization and flow-limiting stenosis (E). LDL, low density lipoprotein. MCP-1, monocyte chemoattractant protein 1; M-CSF, monocyte-colony stimulating factor; MMP, matrix metalloproteinase. *(Adapted with permission from Crowther M, Pathogenesis of atherosclerosis. Hematology Am Soc Hematol Educ Program 436, 2005.)*

expression increases recruitment of monocytes and T-cells to sites of endothelial injury. Subsequently, monocyte chemoattractant protein 1 (MCP-1) and other chemokines (eg, leukotactin-1[9,10]) released by leukocytes and stimulated monocytes magnify the inflammatory cascade by recruiting additional leukocytes, activating leukocytes in the media, and causing proliferation and migration of smooth muscle cells. The smooth muscle cells in turn elaborate a monocyte chemotactic factor and synthesize connective tissue matrix. Locally-elaborated monocyte-colony stimulating factor causes monocyte proliferation, and local activation of monocytes leads to both cytokine-mediated progression of atherosclerosis and oxidation of LDL. Oxidized LDL is cytotoxic to cultured endothelial cells.

The molecular mechanisms by which oxidized LDL may cause or perpetuate endothelial injury, attract monocytes, stimulate smooth muscle growth and promote arterial thrombosis are now being elucidated. Specifically, oxidation of LDL upregulates genes involved in the inflammatory cascade, such as a ligand in the tumor necrosis factor receptor superfamily 14 (LIGHT). LIGHT may in turn promote further lipid accumulation by upregulating a scavenger receptor and enhance macrophage expression of tissue factor and plasminogen activator inhibitor 1, creating a prothrombotic cell phenotype.[11] Through these molecular pathways, the lipid hypothesis and the endothelial injury hypothesis are closely linked.

Once initiated, many mediators of inflammation have been described to influence mitogenesis, intracellular matrix proliferation, angiogenesis, foam cell development and thrombosis. For example, CD40 ligand (CD40L) elaborated within the plaque increases the local expression of tissue factor, and thus, presumably, increases the likelihood of thrombosis. Anti-CD40L abrogates evolution of established atherosclerotic lesions in animal models.[12] Inflammatory mediators expressed by smooth muscle cells within the atherosclerotic plaque include, but are not limited to, interleukin (IL)-1β, tumor necrosis factor α and β, IL-6, monocyte-colony stimulating factor, MCP-1, IL-18, and CD40L.

Functional and Structural Consequences of Early Lesions

With the development of atherosclerosis, there is impaired regulation of vascular tone. This is caused in part by decreased production of endothelial-derived nitric oxide. The impaired release of nitric oxide is associated with increased vascular tone and may be associated with increased platelet activation and intimal proliferation.[13]

Atherosclerotic lesions can develop in the absence of endothelial denudation and without the involvement of platelet-derived growth factors.[2] Thus, smooth muscle hyperplasia occurs in hypertension without associated endothelial cell loss[14–17] and persists long after platelet interaction with the vessel wall has ceased.[18–20] Cells other than platelets produce growth factors,[7] including macrophages,[21] endothelial cells,[22] and arterial smooth muscle cells,[23] and these may contribute to the growth of the atherosclerotic plaque.[4] In this context, local synthesis of platelet-derived growth factor has been demonstrated in human atherosclerotic plaques.[24]

Growth of the Atherosclerotic Plaque

The atherosclerotic plaque grows slowly over a period of years and can produce severe stenosis or even total vascular occlusion. The mature plaque consists of a fibrous cap composed of collagen, a lipid core containing intracellular and extracellular lipid, and areas of calcification. Lipid-rich plaques are prone to spontaneous fissuring or rupture when exposed to high shear stress at sites of stenosis and arterial branching. Two forms of plaque injury are recognized: superficial and deep. Superficial injury produces areas of focal endothelial denudation that can enlarge and lead to the formation of mural or even occlusive thrombi. Plaques that are capped with superficial collagen fibers separated by large number of lipid-filled macrophages predispose to superficial injury.[25,26]

Deep intimal injury is characterized by a split or tear that extends from the luminal surface of a plaque deep down into the plaque substance. This type of injury, which tends to occur in plaques that contain a large lipid-rich pool, exposes blood to the highly thrombogenic contents of the plaque. In particular tissue factor is elaborated within the plaque, a process exacerbated by local expression of CD40L, and leads to intraluminal and extraluminal thrombosis. Intraluminal thrombi become incorporated into, and increase the size of, the atherosclerotic plaque, whereas extraluminal thrombi can be partly or completely occlusive.[27]

Angiogenesis within the Plaque

Angiogenic signaling and proliferation of microvessels within the plaque is incompletely understood. Plaque hemorrhage is likely attributable to bleeding from fragile microvessels that proliferate within the plaque itself, presumably in response to local angiogenic stimuli. Kockx and colleagues proposed that intraplaque microhemorrhage may initiate platelet and erythrocyte deposition, lead to iron deposition, activate macrophages, and contribute to foam cell formation.[28] Support for this hypothesis lies in the finding that intraplaque microvessels are an independent predictor of plaque rupture.[29] The potential importance of angiogenesis in the development of atherosclerosis is found in experiments demonstrating that thalidomide reduced atherosclerotic lesion development in a placebo-controlled trial in atherosclerosis-prone mice.[30] However, thalidomide and its analogs have pleiotropic effects, including anti-inflammatory and matrix stabilizing effects. For example, in early pilot studies in humans with chronic heart failure, it is unlikely that the prompt improvement in ejection fraction was caused by the anti-angiogenic properties of thalidomide.[31]

Anti-Atherogenic Pathways

Understanding of the pathogenesis of atherosclerosis on the molecular level will lead to new therapeutic targets. For example, peroxisome proliferator-activated receptors (PPARs)[32] have numerous potential anti-atherogenic activities. PPAR-α can inhibit adhesion molecules including VCAM-1, increase endothelial nitric oxide release, reduce foam cell formation, and reduce uptake of glycated LDL and triglyceride-rich remnant lipoproteins. PPAR-γ is expressed on endothelial cells, smooth muscle cells, macrophages, and T-cells in the atherosclerotic lesion. The functions attributed to this receptor include:[1] increased nitric oxide synthesis and release,[2] decreased recruitment of T cells,[3] reduced angiogenesis,[4] inhibition of smooth muscle cell migration,[5] decreased smooth muscle cell expression of matrix degrading enzymes,[6] decreased macrophage-dependent expression of matrix metalloproteinase 9 and osteopontin,[7] enhanced release of the IL-1 receptor antagonist, and[8] enhanced reverse cholesterol transport. The thiazolidinedione oral hypoglycemic medications (commonly called *glitazones*) are PPAR-γ agonists. They might also activate PPAR-α. Glitazones reduce serum C-reactive protein (CRP), matrix metalloproteinase 9, and tumor necrosis factor-a in humans.[33,34] PPAR agonists might prove effective in treating atherosclerosis in nondiabetic patients.[35]

PATHOGENESIS OF ARTERIAL THROMBOSIS

Arterial thrombi form under conditions of high blood flow and are composed mainly of platelet aggregates held together by fibrin strands. Thrombosis is initiated by rupture of the atherosclerotic plaque, which exposes thrombogenic material in the subendothelium to the blood.[27,36] If the thrombus is nonocclusive and blood flow remains rapid, the thrombi may organize and become incorporated into the atherosclerotic plaque.[36] With more marked arterial narrowing, shear rates increase and promote more extensive platelet and fibrin deposition, which can result in the formation of an occlusive thrombus.

Thrombogenic Factors

Thrombosis occurs when the balance between thrombogenic factors and protective mechanisms is perturbed. The protective mechanisms include the nonthrombogenic properties of intact endothelial cells, fluid-phase antiproteases, and the dissolution of fibrin by the fibrinolytic system. Thrombogenic stimuli include injury or loss of endothelial cells and activation of platelets and blood coagulation.

Nonthrombogenic Properties of Endothelial Cells

The fluidity of blood *in vivo* is enhanced by the thromboresistant properties of intact vascular endothelium and is threatened by damage to the vessel wall.[37] Endothelial cell-surface glycosaminoglycans and thrombomodulin are potent inhibitors of coagulation. Vessel wall generation of prostacyclin and nitric oxide limits platelet aggregation. Finally, plasminogen activators limit fibrin deposition.[38]

Damage to the Vessel Wall

Thrombogenesis is promoted by loss of endothelium, which may be caused by direct physical damage such as occurs with angioplasty, hemodynamic stress, use of tobacco products, high blood cholesterol levels, or enzymes released from platelets and leukocytes.[7] The shedding of endothelial cells exposes the subendothelium to platelets and blood coagulation proteins. Platelets that adhere to the subendothelium undergo a shape change, aggregate, and secrete their granular contents, thereby recruiting more platelets. At physiologic shear rates, platelet adhesion to subendothelial collagen is mediated by von Willebrand factor, glycoprotein VI, and glycoprotein Ib on the platelet surface[39] as well as to subendothelial components.

Although endothelial cell loss represents the most severe form of vascular damage, more subtle injury may also promote thrombogenesis. Thus, endothelial cells exposed to endotoxin, cytokines such as IL-1 and tumor necrosis factor, thrombin, hypoxia, or increased shear stress synthesize tissue factor and internalize thrombomodulin, thereby promoting coagulation. In addition, these perturbed cells also produce plasminogen activator inhibitor type 1, which impairs fibrinolysis, and acquire receptors to which leukocytes and platelets adhere.[38] Finally, the altered endothelial cells synthesize factors that regulate local blood flow. These include vasoconstrictors known as *endothelins*, as well as vasodilators such as prostacyclin and nitric oxide.[13,38]

Platelet Activation

Platelets adhering to collagen undergo a shape change, secrete their granular contents, and aggregate. In addition to collagen, a variety of other agonists, including thrombin, epinephrine, and thromboxane A_2 (TXA_2), also promote platelet aggregation.[40] Whereas all of these agents stimulate the synthesis of TXA_2, collagen, thrombin, and TXA_2 also induce the release of adenosine diphosphate from platelet granules, which amplifies the aggregation process. In addition to these pathways, thrombin-induced platelet aggregation occurs through a third mechanism that may involve the activation of platelet calpain.[41]

Activated platelets contribute to chronic lesional development. They secrete vascular endothelial growth factor, its relative vascular endothelial growth factor-C, and fibroblast growth factor, which might promote or sustain neoangiogenesis within the plaque.[42] They also elaborate tumor growth factor β and platelet-derived growth factors. These two mitogenic cytokines act at the site of the thrombus to promote the development of atherosclerotic lesions.

Virtually all agonists that induce platelet aggregation act through a common pathway that involves the increase in ionized calcium within the platelet cytoplasm either by mobilization of calcium from the dense tubular system or by increased transport across the membrane. This in turn results in the functional expression of the platelet glycoprotein GPIIb/IIIa, which serves as a receptor for fibrinogen and other Arg-Gly-Asp–containing adhesive proteins such as fibronectin, von Willebrand factor, and thrombospondin.[41] Binding of fibrinogen to GPIIb/IIIa is essential for platelet aggregation because fibrinogen bridges the platelets together.

An increase in platelet cyclic adenosine monophosphate levels reduces the calcium-mobilizing effect of all agonists. Prostacyclin produced by endothelial cells inhibits platelet aggregation by activating platelet adenylate cyclase, thereby elevating cyclic adenosine monophosphate levels.[43]

Activation of Coagulation

Damage to the vessel wall activates the blood coagulation pathway by exposing blood to tissue factor or collagen in the subendothelial matrix, thus activating platelets. Thrombin formed as a result of these processes then serves to convert fibrinogen to fibrin, which stabilizes the platelet aggregates.

EPIDEMIOLOGY AND PREVENTION OF ATHEROSCLEROSIS

The most effective means of preventing arterial thrombosis is to prevent atherosclerosis. The proven risk factors for atherosclerosis are abnormal lipids, hypertension, cigarette smoking, obesity, physical inactivity, diabetes, age, family history, and male gender. The first five of these risk factors are potentially reversible, and there is evidence that their reversal reduces the complications of atherosclerosis. At least 90% of the risk for myocardial infarction is attributable to modifiable risk factors.[44] In general, compliance with recommendations for lifestyle modification is poor.

Cholesterol and Lipids

The plasma level of cholesterol is determined by genetic factors, by the type and amount of fat in the diet, and by other factors such as obesity, physical activity, and disease states. Based on the results of animal studies, epidemiologic data, and interventional studies, there is good evidence for an association between hypercholesterolemia and atherosclerosis.

Of the three major classes of lipoproteins, very-low-density lipoproteins, LDL, and high-density lipoproteins (HDLs), LDL contain 60% to 70% of the total serum cholesterol and are the most atherogenic. In contrast, the levels of HDL are inversely correlated with the risk of coronary heart disease.

The association between serum cholesterol levels and the risk of coronary heart disease is continuously graded.[45,46] Familial hypercholesterolemia, a disorder caused by an absent or defective LDL receptor, causes premature coronary heart disease.[47,48] In the heterozygous form of this disorder, which occurs in 1 in 500 in the population, the total cholesterol concentration is usually in excess of 300 mg/dL. Approximately 5% of all patients who present with acute myocardial infarction younger than the age of 60 years have heterozygous familial hypercholesterolemia. The homozygous form of familial hypercholesterolemia occurs in approximately 1 in 1 million individuals and presents with cholesterol levels ranging from 600 to 1,000 mg/dL. Patients usually develop severe coronary heart disease younger than the age of 20 years.

Reduced levels of HDL cholesterol are associated with an increased risk of coronary heart disease. The main causes of reduced HDL cholesterol include cigarette smoking, obesity, physical inactivity, androgenic and related steroids (including anabolic steroids), beta-blocking agents, hypertriglyceridemia, and genetic factors. In contrast, weight reduction, exercise, and some medications elevate HDL cholesterol levels.

Both the cholesterol level and the prevalence of coronary heart disease are influenced by environmental factors, including diet. Thus, individuals who immigrate from countries where the prevalence of coronary heart disease and the serum cholesterol levels are low to a country with a high prevalence of coronary heart disease will often have increases in both serum cholesterol levels and rates of coronary heart disease.

The evidence that decreasing serum cholesterol levels with cholesterol-lowering drugs or dietary modification slows and even reverses the progression of coronary atherosclerosis[49–52] and reduces coronary events[53] comes from many randomized trials.[49,53–55] Lowering the serum cholesterol level with diet or drug therapy also slows the progression of angiographically documented coronary atherosclerosis in patients with arterial bypass grafts.[49] Modifying several risk factors, such as lowering the serum cholesterol level, the blood pressure, and the levels of LDL cholesterol and cessation of smoking, reduces the risk of ischemic heart disease.[56,57] Individuals with several risk factors benefit most from these measures (see box on Clinical Controversy).[58]

Despite the enthusiasm for a lower target LDL to prevent cardiovascular events (including coronary death), the effect of statins on overall mortality is debated. A large meta-analysis of standard-dose statin therapy found a 12% relative reduction in all-cause mortality that was driven by the reduction in coronary deaths; there was no significant reduction in other vascular causes of death or in noncardiovascular mortality.[68] Despite the apparent safety of most statins, intensive statin therapy has not lowered all-cause mortality.[60–63] In recent trials, overall mortality was essentially the same in standard and intensive therapy arms. Although these trials involved 27,548 patients, even in aggregate they may be underpowered to detect a difference in this endpoint.[59] Although one trial showed a trend toward more noncardiovascular deaths associated with intensive therapy,[60] in pooled analyses, it does not appear that intensive therapy increases the risk of noncardiovascular death over standard-dose therapy.[59]

Another specific modifiable risk factor for atherosclerosis has recently emerged. Trans fats are unsaturated fats with at least one double bond in the *trans* configuration. Industrially-produced trans fats are found in partially hydrogenated vegetable oils common in baked goods, margarines, and other manufactured food products. As

Clinical Controversy

How low should cholesterol levels for secondary prevention of cardiovascular events be reduced? Meta-analysis[59] has confirmed that aggressive lowering of the serum cholesterol level in patients with stable coronary artery disease[60,61] or recent acute coronary syndrome or myocardial infarction[62,63] results in a rapid decrease in the risk of subsequent ischemic cardiac complications, the need for surgical revascularization, stroke, and coronary death rates. This effect occurs even in patients with minimal risk factors, (such as hypertensive patients older than 65 years but without evidence of coronary heart disease), and whose LDL cholesterol level falls within the normal range (2.6–3.4 mmol/L, 100–130 mg/dL).[64] Clinical trials have demonstrated that each incremental reduction of LDL achieved with hydroxymethylglutaryl-coenzyme A reductase inhibitors (*statins*) leads to an incremental reduction of cardiovascular events, across LDL levels.[60–66] Target LDL values for secondary prevention have been revised accordingly: Although a target of less than 100 mg/dL (2.6 mmol/L) is mandated, treating to less than 70 mg/dL (1.8 mmo/L) is considered reasonable.[67]

compared with an equal number of calories from saturated or *cis*-unsaturated fatty acids, trans fats increase LDL, decrease HDL, increase lipoprotein(a) levels, and reduce LDL particle size. In prospective studies, the relation between trans fats and coronary events has been even greater than predicted from these deleterious effects on the lipid profile. In randomized controlled trials, trans fats were shown to promote inflammation and induce endothelial cell dysfunction. In meta-analyses, a 2% increase in trans fat consumption was associated with greater than 20% increase in incident coronary heart disease. In individual epidemiologic studies, they have been linked to sudden cardiac death. It has been estimated that 6% to 22% of cardiac events could be averted if intake of trans fats were broadly reduced.[69] Many countries are now regulating the elimination of trans fats from commercial products.

Tobacco

Cigarette smoking increases the risk of coronary heart disease, peripheral arterial disease, cerebrovascular disease, and graft occlusion after reconstructive arterial surgery. It is particularly hazardous in those with a poor cardiovascular risk profile and in women taking estrogens, and there is a dose relationship between the risk of coronary heart disease and the number of cigarettes smoked daily.[70] Within 1 year of abstinence, those who stop smoking have only half the risk of those who continue to smoke, regardless of how long they smoked. After 15 years of abstinence, their risk of dying from coronary heart disease is similar to that of persons who have never smoked.[71] Smoking cessation also reduces mortality after coronary artery bypass graft surgery, reduces morbidity and mortality in patients with peripheral vascular disease, and decreases mortality after myocardial infarction.[72]

Although the mechanism by which smoking increases the risk of atherosclerosis is uncertain, there are several possibilities. Cigarette smoking decreases the levels of HDL, increases LDL cholesterol, and, by raising levels of carbon monoxide, leads to hypoxia, thereby perturbing the anticoagulant properties of the endothelium. In addition, smoking increases platelet reactivity and, by elevating the plasma fibrinogen and the hematocrit, also increases blood viscosity.

Hypertension

Hypertension is a risk factor for stroke, myocardial infarction, and cardiac and renal failure.[73] Beginning at 115/75 mm Hg, cardiovascular disease risk doubles for each increment of 20/10 mm Hg.[74] Treatment of hypertension reduces the incidence of stroke and lowers overall mortality, but there is less convincing evidence that it affects coronary events.[75] Thus, pooled analysis of all studies examining the effects of lowering the blood pressure shows a 10% risk reduction for mortality and a 40% risk reduction for stroke. However, there is only an 8% risk reduction for fatal and nonfatal myocardial infarction, a difference that is not statistically significant.

Diabetes

Patients with diabetes have twice the risk of incident myocardial infarction and stroke as the general population.[76] Asymptomatic patients with diabetes may have the same atherosclerotic burden as nondiabetic persons with symptomatic coronary artery disease.[77] Persons with diabetes and no prior history of myocardial infarction have as high a risk of myocardial infarction and of fatal myocardial infarction as nondiabetic patients who previously suffered a myocardial infarction.[78] Therefore, national guidelines for cholesterol and hypertension management recommend the same treatment targets for diabetic patients without known cardiovascular disease as for patients with established cardiovascular disease.[74,79–81]

The mechanisms by which insulin resistance and hyperglycemia promote atherosclerosis and endothelial dysfunction are complex.[82] For example, hyperglycemia induces procoagulant proteins and inhibits fibrinolysis. Advanced glycation end products produce reactive oxygen species and increase oxidative stress by activating nicotinamide adenine dinucleotide phosphate oxidase through specific receptors. Reactive oxygen species stimulate expression of procoagulant and proinflammatory genes, leading to apoptosis of endothelial cells and decreased endothelial cell proliferation. Advanced glycation end products also modify extracellular matrix proteins, resulting in decreased vessel elasticity. Intermolecular cross-linking by advanced glycation end products impairs the function of endothelial proteins. Endothelial cells express specific receptors, which in turn promote inflammation through activation of NF-κB and through interactions with macrophages in the vessel wall. These macrophages become foam cells and contribute to progression of the atherosclerotic lesion.

Physical Inactivity

Individuals who exercise regularly have less cumulative disability[83] and a lower incidence of myocardial infarction and death,[84–92] but it is uncertain whether the association is causal or whether it merely reflects the fact that healthier individuals are more likely to exercise. In patients who have recovered from an acute myocardial infarction, exercise produces approximately 20% reduction in the risk of recurrent infarction or death.[93,94] Regular exercise may exert these protective effects by increasing the levels of HDL cholesterol and lowering the blood pressure.[95,96]

Obesity

Although some observational studies[97] have suggested that obesity is an independent risk factor for coronary heart disease, this has not been a universal finding. Obesity is linked to the development of insulin resistance, type 2 diabetes, hypertension, obstructive sleep apnea, and dyslipidemia.[98] Whether obesity confers a substantial risk of cardiovascular events independent of these risk factors is debated. Even among patients with established coronary artery disease, it has been difficult to show an independent effect of obesity on mortality.[99] However, weight loss ameliorates the risk factors cited and is currently considered an important therapeutic goal.

Emerging Risk Factors

Evidence is increasing that a variety of additional risk factors for atherosclerotic disease exist.

Inflammation

Given the importance of the inflammatory cascade in the pathogenesis of atherosclerosis, clinical interest has focused on the development of markers of risk attributable to inflammation. Predominant among these is C reactive protein (CRP). CRP is a pentraxin that is central to the human innate immune response.[100] CRP is predominantly produced by the liver as an acute phase reactant. Arterial smooth muscle cells can express CRP in response to inflammatory cytokines.[101] Whether CRP is causally related to atherogenesis is controversial. Even experimental work reached differing conclusions about whether a direct association between CRP and the pathogenesis of atherosclerosis exists. For example, Danenberg and colleagues evaluated the proinflammatory and prothrombotic effects of CRP on monocytes and endothelial cells in vivo by subjecting wild-type mice, which do not express CRP, and human CRP-transgenic mice to models of arterial injury. In one model, complete thrombotic occlusion of the femoral artery at 28 days was seen in 17% of wild-type mice compared with 75% of CRP-transgenic mice.[102] However, Hirschfield and colleagues found transgenic expression of CRP in

mice prone to atherosclerosis had no effect on the development, progression, or severity of spontaneous atherosclerosis.[103]

Regardless of whether it has any pathogenic role in atherosclerosis, in humans CRP is a mild-to-moderate biomarker of atherosclerotic complications.[104–108] Many large, prospective, primary prevention studies have shown that highly-sensitive CRP measurement is an independent predictor of stroke,[109] peripheral arterial disease,[108] acute myocardial infarction, and cardiovascular death even after adjustment for traditional cardiac risk factors such as serum LDL or the composite Framingham risk score.[110–116] Studies in populations experiencing stable angina or acute coronary syndromes,[104,117–119] undergoing elective or acute percutaneous[120–122] or surgical[123] coronary revascularization, or who have established coronary artery disease[124] have reached similar conclusions.

Whether the success of statin therapy is attributable only to its LDL-lowering effects, or whether it is also attributable to antiinflammatory effects, is unknown.[125,126] Outcome trials designed to evaluate this question have found that lowering CRP is at least as important as lowering LDL and that patients with the lowest levels of LDL but elevated levels of CRP carry a substantial risk for atherosclerotic progression (as measured by intravascular ultrasound[127]) and for cardiac events[128] compared with patients with the lowest levels of both LDL and CRP (see box on Who Should Be Screened with CRP?). Other clinical evidence that systemic inflammation contributes to the progression of atherosclerosis comes from the increased rate of cardiac events in patients with connective tissue diseases, such as systemic lupus erythematosus[131] or rheumatoid arthritis.[132,133]

Lipoprotein(a)

Lipoprotein(a) [Lp(a)] is composed of a lipoprotein attached to apolipoprotein B-100. Its physiologic role is not known but it might mediate transport of oxidized LDL. Elevated levels of Lp(a) have also emerged as a potential risk factor for atherosclerosis.[134–137] However, the data are inconsistent,[138] and it is unclear that focusing on Lp(a) over and above LDL has any therapeutic benefit[139] even if the two molecules are under separate metabolic control. Genetically determined elevation of Lp(a) may play a larger role in young patients with premature atherosclerosis.[135,140] Interest in this biochemical abnormality is heightened by the observation that niacin therapy reduces Lp(a) levels. There are limited data showing that niacin reduces the risk of atherothrombotic complications in the setting of secondary prevention,[141] but niacin has not been adequately evaluated for primary prevention.

Homocysteine

Congenital or acquired hyperhomocysteinemia is associated with an increase in the risk of both arterial and venous thromboembolism.[142,143] Genetic studies of polymorphisms in the methylenetetrahydrofolate reductase gene corroborate results from observational studies linking hyperhomocysteinemia to stroke.[144] In most cases, homocysteine levels may be reduced with the administration of folic acid or vitamins B_6 or B_{12}.[145,146] Although one randomized, placebo-controlled trial suggested that aggressive lowering of homocysteine levels reduces the risk of stenosis after percutaneous coronary interventions,[147] other studies have not found this association[148] or even found increased rates of in-stent restenosis.[149] Three large randomized controlled trials focused on secondary prevention found no benefit to lowering homocysteine levels. High-dose folate therapy showed no ability to prevent ischemic stroke in the Vitamin Therapy for Prevention of Stroke trial,[150] and two studies actually demonstrated possible harm.[151,152] In the Norwegian Vitamin Trial, although B_6, folate, B_{12}, or all three effectively lowered homocysteine levels by 27%, the group taking B_6 alone or folate and B_{12} alone suffered roughly the same rate of stroke and myocardial infarction as the placebo group, although the group randomized to combination therapy had an absolute increase in stroke or myocardial infarction of approximately 5% over the placebo and other treatment arms when followed for 3 years.[151] The Heart Outcomes Prevention Evaluation II found a protective effect on stroke (possibly because of uncorrected statistical testing of multiple endpoints), no effect on myocardial infarction or cardiovascular death, and a slight increase in hospitalization for unstable angina.[152] The role of hyperhomocysteinemia in atherosclerosis is debated; it is not thought to be directly responsible for initiating or propagating whatever processes confer an increased risk of arterial thromboses to such patients.[153]

Who Should Be Screened with CRP?

At present, guidelines from the American Heart Association/Centers for Disease Control recommend against screening the entire adult population with CRP. The guidelines endorse measurement of CRP at the discretion of the physician, particularly in persons deemed an intermediate risk by the Framingham criteria, where the finding of an elevated CRP might prompt further intensification of therapy. However, low-risk individuals are unlikely to be reclassified as high-risk based solely on elevation of the CRP, although high-risk persons and patients with established atherosclerotic disease should be treated intensively regardless of the CRP value.[129,130] Serial monitoring of the CRP or treating to particular CRP targets has not been evaluated.

Impaired Endothelial Progenitor Cell Production or Function

Early endothelial cell dysfunction is manifested by impaired nitric oxide production and poor vascular responses to vasodilators. These changes predict progression of atherosclerosis and confer an increased risk of cardiac events.[154,155] Endothelial injury manifests as changes at the luminal surface of the cell and eventually apoptosis occurs. In this way, a functional and presumably reversible impairment progresses to permanent structural damage.[156] As in other organs, repair of these lesions and regeneration of a healthy endothelium might depend on stem cell proliferation and local engraftment.

Endothelial progenitor cells (EPCs) are derived from the bone marrow (Fig. 136–2) and circulate throughout adult life.[157,158] Preliminary evidence for this phenomenon came from two observations. In canines, bone-marrow derived cells were shown to "endothelialize" Dacron grafts rendered impervious to capillary ingrowth.[158] In humans, endothelial cells from male heart transplant recipients were observed to have engrafted in the blood vessels in female donor hearts.[159] EPCs are thought to serve two roles: endothelialization and neovascularization. A putative hematopoietic/angiopoietic stem cell that gives rise to EPCs has been postulated. Other sources for circulating EPCs have been postulated as well. These include myeloid cells (which can be coaxed to differentiate into endothelial cells *in vitro*), mature endothelial cells that have shed from the vessel wall, and tissue stem cells in the myocardium. Agreement on the cell markers that define an EPC and the most accurate methods of quantifying EPC number and biologic functionality is lacking.[156,160,161] Like T-cells, EPCs may be a heterogeneous population of closely related cells with highly specialized functions.

Decreased numbers and decreased proliferative potential of circulating EPCs predict cardiovascular events.[162–164] These relationships hold true even after adjustment for traditional cardiac risk factors.[164] Three possible explanations exist: Poor EPC mobilization and engraftment may be a primary mechanism of atherosclerosis; it may be caused by the same underlying etiology as atherosclerosis (eg, impaired nitric oxide synthesis); or it may be an epiphenomenon. These competing hypotheses do not detract from the potential usefulness of EPCs as a biomarker of cardiovascular risk.

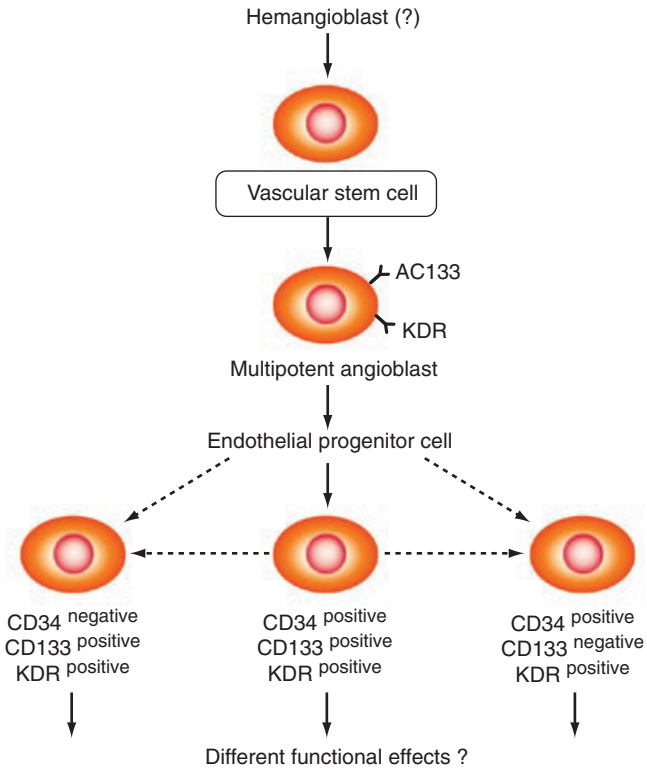

Figure 136–2. Endothelial progenitor cells are putatively derived from the hemangioblast, circulate in peripheral blood, and have the potential to differentiate into mature endothelial cells. The surface markers CD34, KDR (VEGFR2), and CD133 define circulating endothelial progenitor cells. Different subpopulations display different functional activities concerning angiogenesis and endothelial cell repair. The CD34 negative, CD133 and VEGFR2 positive EPC subpopulation may be a precursor of the CD34/CD133 positive EPC population and preferably homes to sites of ischemia. *(Adapted with permission from Werner N, Nickenig G. Clinical and therapeutical implications of EPC biology in atherosclerosis. J Cell MolMed Apr-Jun;10(2):318, 2006.)*

Many modifiable factors influence circulating EPC levels and function. These include physical activity,[165] smoking,[166] estrogen,[167] and inflammation.[168] The capacity of EPCs to differentiate may influence recovery following acute myocardial infarction.[169] Early studies have explored pharmacologic approaches to increase circulating EPCs,[170] stents impregnated with "EPC-capturing" antibodies or peptides[171,172] or seeded with EPCs themselves,[173,174] vascular endothelial growth factor gene transfer,[175] and autotransplantation.[176–179] Sources of autologous EPCs include peripheral blood[176,178] and bone marrow.[177–179] Different cell preparations yield differing amounts of EPCs, hematopoietic cells, and mesenchymal cells. The EPCs may be expanded by culture *ex vivo*.[176,178] The timing of transplant in relation to myocardial infarction varies among studies. Intracoronary infusion of marrow[176,180–182] and peripheral blood[176,183] presumed to contain functional EPCs is feasible in the early period after acute myocardial infarction. Similar studies have been performed in patients with chronic myocardial ischemia.[178,183–185] Granulocyte colony-stimulating factor has occasionally been used for progenitor cell mobilization.[183,185] Most of these early trials assessed surrogate endpoints, such as change in left ventricular ejection fraction or myocardial perfusion. Follow-up has been short. The improvements have been modest at best and inconsistent. Only one randomized study detected a clinical benefit.[179]

Four classes of drugs already known to benefit patients at risk for cardiovascular events may increase circulating EPCs. Angiotensin II accelerates EPC senescence such that their proliferation is impaired, but valsartan (an angiotensin I receptor blocker) attenuates this process.[186,187] In small studies in humans, olmesartan, irbesartan, and ramipril increased the number of circulating EPCs.[188,189] Ramipril (an angiotensin-converting enzyme inhibitor) was also shown to increase their functional activity.[189] Preclinical data suggest that hydroxymethylglutaryl coenzyme A reductase inhibitors can also augment circulating EPCs.[190–193] Erythropoietin can mobilize EPCs,[194–196] but it might have deleterious cardiovascular effects for other reasons, such as increasing blood viscosity and blood pressure, particularly in patients who are not anemic. Whether elevation of circulating EPCs persists with chronic pharmacologic treatments and whether achieving a given level of circulating EPCs can be considered a surrogate marker for decreasing clinical events—and hence an important therapeutic target—has not been validated.

Nonsteroidal Anti-inflammatory Drugs

Cyclooxygenases (COX) 1 and 2 form prostaglandins from arachidonic acid. Prostaglandins are lipid mediators of pain, fever, inflammation, vasodilation, smooth muscle function, and gastric mucus secretion. Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandin synthesis by inhibiting COX enzymes. Traditional NSAIDs inhibit both COX isoforms reversibly, whereas aspirin inhibits both irreversibly. The original but oversimplified "COX-2 hypothesis" stated that the prostaglandins formed by constitutively-expressed COX-1 have a homeostatic role, whereas those formed by inducible COX-2 are primarily responsible for inflammation. Available NSAIDs have a spectrum of COX-2:COX-1 selectivity: Indomethacin, ibuprofen, and naproxen are essentially nonselective; celecoxib and diclofenac have similar but only moderate COX-2 selectivity; rofecoxib and valdecoxib are more COX-2 specific; whereas lumiracoxib is the most COX-2 specific.[197] COX-2 selectivity can be lost at high drug concentrations.[197] Relative selectivity may also be affected by polymorphisms of the COX-1 and COX-2 genes themselves and of the enzymes involved in NSAID metabolism.[198]

It was proposed that selective COX-2 inhibitors would be as effective as traditional NSAIDs with a lower incidence of gastrointestinal ulceration and bleeding. However, the biology of COX-1 and COX-2 predicts that selective COX-2 inhibition could promote cardiovascular events. Mature platelets express only COX-1, which is responsible for TXA_2 production. COX-2 selective inhibitors substantially impair vascular biosynthesis of prostaglandin I_2 (prostacyclin) without impairing platelet production of TXA_2.[199,200] Normally, prostaglandin I_2 opposes various mediators of platelet aggregation, vasoconstriction and attendant blood pressure elevation, and atherogenesis—including TXA_2. In animal models, unopposed TXA_2 effects accelerate initiation and progression of atherosclerosis.[201,202] Indeed, several clinical trials designed to address the gastrointestinal safety,[203–205] colorectal adenoma prevention,[206,207] and analgesia in the immediate post–coronary bypass period[208,209] detected a higher incidence of myocardial infarction among patients allocated to COX-2 inhibitors versus placebo or nonselective NSAIDs. This risk appeared not only among populations considered at high risk of myocardial infarction[208,209] but also among those whose baseline risk of myocardial infarction was probably intermediate[203] or low.[206] Duration of exposure seems to increase the risk of cardiovascular endpoints, in line with the hypothesis that selective COX-2 inhibition promotes atherogenesis. Meta-analysis suggests the overall risk for myocardial infarction in chronic users of COX-2 inhibitors is approximately twofold compared to placebo (corresponding to an excess of 1 to 4 myocardial infarctions in 1000 person-years).[210] Accordingly, rofecoxib and valdecoxib have been withdrawn from the market. The incidence of serious vascular events seems similar between COX-2 inhibitors and traditional NSAIDs (ibuprofen and diclofenac—although one caveat in interpreting these results is that diclofenac has relatively more COX-2 selectivity).[210] It is unknown whether the risk associated with the high doses of traditional NSAIDs employed as comparators in the COX-2 inhibitor trials may overrepresent the risk associated with more moderate doses (see box on Do All NSAIDs Increase the Risk of Cardiac Events?).

Do All NSAIDS Increase the Risk of Cardiac Events?

Whether certain traditional NSAIDs may not impact cardiovascular risk, or may even be cardioprotective, is a matter of debate. For example, in small, short-term studies, flurbiprofen was effective in reducing reinfarction and the need for secondary revascularization after a first myocardial infarction[211] and indobufen reduced cardioembolic events.[212] High-dose naproxen does not appear to carry the same cardiovascular risks as other NSAIDs.[210] To account for this finding, it has been suggested that the long half-life of naproxen (14 hours) compared to other NSAIDs might promote more sustained inhibition of platelet aggregation. However, whether naproxen offers cardioprotection compared to aspirin has not been prospectively evaluated, and early experiments indicate that aspirin is probably the better choice for two reasons. First, naproxen's pharmacodynamic effect is strictly tied to its systemic bioavailability, so missing one or two doses allows prompt recovery of platelet COX-1 activity within 24 hours. Second, naproxen inhibits prostacyclin production to a substantial degree whereas aspirin does not,[213] raising the possibility that long-term use of naproxen could be atherogenic.

Finally, the interaction between NSAIDs and aspirin remains far from clear. *In vitro* and human studies suggest that ibuprofen negates the beneficial antiplatelet effects of aspirin.[214–216] Such a negative interaction was not found to hold for rofecoxib or diclofenac.[216] Studies examining clinical outcomes of combined NSAID-aspirin therapy have been conflicting.[217–219] This is likely caused by differences in study design, difficulty accounting for nonprescription use of these medications, and difficulty in estimating adherence to therapy. A very large case-control study sought to overcome these limitations. The authors concluded that there in no increased risk of myocardial infarction among patients simultaneously taking aspirin and ibuprofen chronically, compared with those taking aspirin alone.[219]

At this time, sufficient evidence does not exist to recommend concurrent use of aspirin to mitigate cardiovascular effects of long-term NSAID use. Similarly, some patients choose long-term COX-2 specific NSAID therapy over nonselective NSAIDs for noncardiovascular indications, either to minimize gastrointestinal effects or because anecdotally occasional patients may experience superior analgesia with COX-2 inhibitors. In this instance, some clinicians prescribe concurrent low-dose aspirin therapy. However, it is crucial to realize that low-dose aspirin negates the gastrointestinal benefits of the COX-2 inhibitor[204] and that this approach has not been prospectively evaluated with a cardiovascular endpoint.

Other Risk Factors

Impaired fibrinolysis has been linked to atherosclerotic vascular disease in some but not all studies. Antiphospholipid antibodies are clearly associated with premature arterial thromboembolism and may be associated with accelerated atherosclerosis. Both thoracic radiation therapy and heart transplantation are associated with accelerated atherosclerosis and ischemic cardiac syndromes.

NONINVASIVE TREATMENT OF ARTERIAL THROMBOEMBOLISM

Treatment of atherosclerosis and its thromboembolic complications includes interventional procedures such as endarterectomy, embolectomy, arterial bypass surgery, and angioplasty with or without stenting, as well as medical management. The three forms of medical therapy that have proven effective in the treatment of arterial thrombosis are antiplatelet drugs, thrombolytic agents, and anticoagulants.

Optimal nonsurgical management of the complications of atherosclerosis is a rapidly evolving field. Additionally, "standard" nonsurgical practice will vary based on local facilities and health care expertise. Current resources and consensus panel recommendations are available.[67,220–223]

Antiplatelet Agents

Three antiplatelet agents—aspirin, ticlopidine, and clopidogrel—have been shown to be effective in the prevention and treatment of arterial thrombosis.[224,225] In addition, agents that inhibit the interaction between fibrinogen and its receptors on platelets reduce the risk of acute ischemic cardiac syndromes after coronary angioplasty.[226]

Aspirin

The antithrombotic effects of aspirin reflect its ability to inhibit the synthesis of TXA_2, a potent inducer of platelet aggregation and vasoconstriction, by inactivating platelet cyclooxygenase. Aspirin is rapidly absorbed from the gastrointestinal tract and peak levels are reached 15 to 20 minutes after ingestion. Despite its rapid clearance from the circulation, the inhibitory effects of aspirin persist for the life span of the platelets because the drug irreversibly acetylates cyclooxygenase. A dose as small as 80 mg of aspirin per day is sufficient to inhibit TXA_2 synthesis. Aspirin therapy is inexpensive, widely available, and largely nontoxic; thus it should be used in all patients with evidence of atherosclerotic disease unless a specific contraindication exists.

The side effects of aspirin are primarily gastrointestinal, and gastrointestinal hemorrhage can occur in some patients. These complications are dose-related and are reduced if enteric-coated aspirin is used. Aspirin is contraindicated in patients with active peptic ulcer disease or aspirin-induced asthma, and it should be discontinued if gastrointestinal side effects are severe.

In most randomized studies, patients with a history of active peptic ulcer disease were excluded, and the beneficial effects of aspirin occurred without hemorrhagic complications.[227] However, in a U.S. Physicians Study the use of aspirin was associated with an increased incidence of cerebral hemorrhage, a finding not observed in symptomatic patients treated with aspirin to prevent the complications of atherosclerosis.[227,228]

Dipyridamole

Dipyridamole interferes with platelet function by inhibiting adenosine deaminase and phosphodiesterase, causing accumulation of adenosine, adenine dinucleotides, and cyclic adenosine monophosphate. It also causes vasodilation. In studies in which aspirin alone was compared with the combination of aspirin and dipyridamole for cardiovascular events, no additional benefit was observed from the addition of dipyridamole.[227,229] However, two trials showed that the combination of aspirin and dipyridamole is somewhat more effective than aspirin alone for patients who suffer transient ischemic attacks or minor ischemic strokes.[230,231] Like aspirin, dipyridamole also augments the antithrombotic effect of oral anticoagulants in patients with mechanical prosthetic valves.[232]

Ticlopidine and Clopidogrel

Ticlopidine and clopidogrel are thienopyridine derivatives that inhibit adenosine diphosphate-dependent platelet aggregation by antagonizing the $P2Y_{12}$ adenosine diphosphate receptor. They are metabolized by the liver, producing active metabolites. Because the production of intermediate active metabolites is required, the

inhibitory effects of ticlopidine and clopidogrel on platelet function are delayed after administration.

Ticlopidine is more effective than aspirin in reducing stroke in patients with transient cerebral ischemia or minor stroke. Ticlopidine is also effective in 1) reducing the risk of the combined outcome of stroke, myocardial infarction, or vascular death in patients with thromboembolic stroke, 2) decreasing vascular death and myocardial infarction in patients with unstable angina, 3) reducing acute occlusion of coronary bypass grafts, and 4) improving walking distance and decreasing vascular complications in patients with peripheral vascular disease.[224]

The most common side effects of ticlopidine are diarrhea and skin rash; the most serious complications are neutropenia and thrombotic thrombocytopenic purpura. Nevertheless, ticlopidine should be considered in place of aspirin in patients who are allergic to or intolerant of aspirin, or who have had a vascular event despite the use of aspirin.

Clopidogrel and ticlopidine are more effective than aspirin for the prevention of ischemic stroke, myocardial infarction, or vascular death in patients at high risk of these complications.[225] Compared to ticlopidine, clopidogrel poses a much lower risk for the development of neutropenia or thrombotic thrombocytopenic purpura.

Combined use of aspirin and clopidogrel is of established benefit in the acute setting, especially to maintain patency of intraluminal arterial stents. Long-term combined use of aspirin and clopidogrel in patients with established coronary artery disease may marginally reduce the risk of recurrent arterial thrombosis.[233] Whether the added cost of clopidogrel is worth this marginal benefit is unclear. Furthermore, the same trial studied combined use of aspirin and clopidogrel for primary prevention in patients with a high risk for atherothrombotic events but no known coronary artery disease and found both cardiovascular death and all-cause mortality were increased in the primary prevention group.[233] Caution must be exercised in interpreting these results as they are derived from subgroup analysis. Combined treatment can be considered for many patients with established atherosclerosis (especially for those patients who recently suffered myocardial infarction, who have unstable angina, or have undergone percutaneous coronary intervention), but it is not currently advocated for primary prevention, even in high-risk patients. At what time point the risk-benefit balance in patients who had indications for using clopidogrel in an acute setting, for secondary prevention, approaches the increased risk seen in patients who have no such indications is unknown.

Platelet Glycoprotein IIb/IIIa Blockade

Blockade of the platelet fibrinogen receptor (glycoprotein IIb/IIIa [GPIIb/IIIa]) using humanized monoclonal antibodies (abciximab) or small molecule inhibitors (eptifibatide, tirofiban) reduces the risk of clinically significant ischemic events in patients undergoing coronary angioplasty. Large studies have demonstrated that GPIIb/IIIa antagonists reduce the risk of death, myocardial infarction, or urgent coronary artery bypass grafting in the first 30 days after percutaneous coronary intervention in patients with acute or chronic coronary syndromes. The absolute risk reduction for death or myocardial infarction at 30 days is on the order of 3%.[234–242] Demonstration that GPIIb/IIIa antagonists reduce the risk of ischemic events after percutaneous coronary intervention led to their use in other settings.

In ST-elevation myocardial infarction, there is a need for reperfusion strategies that improve on the outcomes of fibrinolytic therapy. Fibrinolytic therapy may achieve adequate epicardial blood flow, but distal plaque embolization may nonetheless compromise myocardial reperfusion. Early dose-finding trials found that adding a GPIIb/IIIa inhibitor to full-dose fibrinolytic therapy may be beneficial,[243,244] but in at least one such trial, the enthusiasm for this approach was tempered by increased bleeding.[245] Likewise, large trials of high-dose and low-dose fibrinolytic therapy combined with GPIIb/IIIa inhibition have not found clear reductions in long-term mortality and the risk of major bleeding persists.[246,247]

In non–ST-elevation myocardial infarction and unstable angina, GPIIb/IIIa antagonists have a larger role. In patients not scheduled for percutaneous coronary intervention (PCI), trials involving greater than 31,000 patients have demonstrated an absolute risk reduction of death or myocardial infarction of approximately 1% at 30 days after the index event.[248] Platelet fibrinogen receptor blockade is now a standard component of the treatment of refractory acute coronary syndromes while awaiting resolution or definitive therapy.

Abciximab produces an immediate and profound inhibition of platelet activity that persists for 6 to 12 hours after termination of its infusion. Administration of abciximab is associated with an increase in the risk of hemorrhage, although this risk can be moderated with the judicious use of heparin and careful patient selection. Eptifibatide and tirofiban have shorter half-lives, and platelet function normalizes within 4 to 8 hours of termination of the infusion. Drug-induced thrombocytopenia is more common with abciximab than with the small molecule inhibitors, but severe thrombocytopenia is rare (0.9%–1.6%), usually transient, and generally responds to platelet transfusions. A thrombogenic syndrome analogous to heparin-induced thrombocytopenia has not been observed.

Thrombolytic Therapy

Thrombolytic therapy is useful in the treatment of arterial thrombosis because rapid clot lysis and restoration of blood flow prevent permanent tissue damage. More than 80% of patients with acute myocardial infarction have thrombotic occlusion of the infarct-related coronary artery, and thrombolytic agents produce rapid lysis of these thrombi in 50% to 75% of cases.[220] Tissue plasminogen activator (tPA) is more effective than streptokinase in achieving early coronary lysis, but both agents improve left ventricular function and reduce mortality.[249] Thus, streptokinase and tPA decrease mortality by approximately 25% when used without adjunctive aspirin or intravenous heparin, and reduce mortality by 40% to 50% when either agent is combined with aspirin.[53,250] In the Global Utilization of Streptokinase and t-PA for Occluded Coronary Arteries-I (GUSTO-I) study, an accelerated tPA regimen combined with high-dose intravenous heparin produced a 14% greater reduction in mortality than streptokinase. This difference was most evident in patients treated within 4 hours of onset of symptoms. Unfractionated heparin or low-molecular-weight heparin is usually advised in conjunction with the so-called "fibrin-specific" fibrinolytics (reteplase, alteplase, tenecteplase). Recent American College of Chest Physicians guidelines emphasize the importance of using unfractionated heparin in conjunction with the non–fibrin-specific streptokinase as well.[220]

Following successful thrombolysis there is a 10% to 20% reocclusion rate and a 3% to 4% reinfarction rate.[250] Aspirin reduces the incidence of reinfarction.[220,251] Reocclusion is less common with streptokinase than with tPA. The traditional explanation is that streptokinase induces extensive plasma proteolysis and release of fibrinogen degradation products. However, at pharmacologic doses used for acute myocardial infarction, all thrombolytic agents cause a high degree of systemic fibrinolysis and hence systemic anticoagulation. Direct thrombin inhibitors, such as bivalirudin (Hirulog) and hirudin, are more effective than heparin at preventing reocclusion after coronary thrombolysis. However, large-scale clinical trials have been disappointing.[251–253]

Recent developments in thrombolytic medications have focused both on improving efficacy and increasing the convenience of thrombolytic therapy. Thus, agents that can be administered by rapid intravenous bolus, oftentimes outside the hospital setting, have recently been the focus of research studies. In general, these agents are either not, or only marginally, more effective than traditional thrombolytic medications, but are more convenient to use.

Anticoagulants

Heparin

The role of anticoagulant therapy in the treatment of arterial thrombosis is controversial.[254,255] When used alone, heparin is effective in the short-term treatment of unstable angina,[254] but a rebound effect is seen when the drug is stopped.[256] Aspirin appears to prevent the cluster of ischemic events that occur when heparin is discontinued. There is some suggestion that the addition of heparin to aspirin improves the short-term outcome in patients with unstable angina, but it is uncertain whether this effect is sustained. Moderate doses of heparin (12,500 units subcutaneously every 12 hours) also reduce the incidence of mural thrombosis detected by two-dimensional echocardiography, which is a particular problem in patients with anterior infarction.

Heparin prevents early reocclusion of the infarct-related artery after successful thrombolysis with tPA. However, a meta-analysis has suggested that routine administration of heparin to patients with acute myocardial infarction is not indicated.[257] Heparin therapy reduced mortality by 6% (95% confidence intervals: 0%–10%), and the rate of reinfarction by 1.3%. However, heparin was associated with a clinically important increase in the risk of major hemorrhage that outweighed its observed benefit. A more recent meta-analysis could not detect a beneficial effect of heparin on reinfarction or death in patients treated with thrombolysis. A trend toward bleeding complications with heparin was noted. However, there are limitations among the studies of patients receiving thrombolytics for acute myocardial infarction. These limitations include a serious lack of power to detect even a modest benefit of heparin and lack of routine aspirin prescription.[258]

Low-Molecular-Weight Heparin

In patients with ST-elevation myocardial infarction, the most recent meta-analysis concluded that at 30 days, subcutaneous low-molecular-weight heparin given for 4 to 8 days after thrombolysis reduces reinfarction by approximately one-quarter and death by approximately 10% compared with placebo and, when directly compared with heparin, low-molecular-weight heparin reduces reinfarction by almost one-half.[258] Whether the various low-molecular-weight heparins differ in efficacy from one another in terms of clinical endpoints is not known. Reviparin compared to placebo showed a slight benefit on reinfarction and mortality in patients with ST-elevation myocardial infarction.[259]

In patients with unstable angina or non–ST-elevation myocardial infarction, the benefit of low-molecular-weight heparin over heparin is not clear. Both had a similar risk of mortality, recurrent angina, and major bleeding, but low-molecular-weight heparin decreased the risk of myocardial infarction.[260]

There is limited experience with intravenous low-molecular-weight heparin during percutaneous intervention, but one meta-analysis suggests that employed without monitoring of the anticoagulant effect, it may be comparable to heparin and may even carry a lower risk of hemorrhage.[261]

Fondaparinux

Fondaparinux is a synthetic pentasaccharide that binds antithrombin and catalyzes its inhibition of factor Xa.

The Sixth Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS-6) trial studied patients presenting with ST-elevation myocardial infarction.[262] Patients underwent PCI or thrombolysis. In subjects without a clear indication for anticoagulation, fondaparinux was compared to placebo or heparin. Subjects with a clear indication for anticoagulation (ie, those destined for primary PCI or receiving so-called fibrin-specific thrombolytics) were randomized to fondaparinux or heparin. There was no benefit to adjunctive therapy with fondaparinux in patients undergoing primary PCI. However, in those receiving thrombolytics or no reperfusion therapy at all, fondaparinux yielded an absolute risk reduction of approximately 1.5% in the incidence of reinfarction or death, whether compared to placebo or to heparin.

OASIS-5 studied patients presenting with acute coronary syndromes (unstable angina or non–ST-elevation myocardial infarction).[263] Fondaparinux was not inferior to enoxaparin in the early postinfarction period in terms of death, progression to myocardial infarction, or refractory ischemia. Fondaparinux led to an absolute reduction in mortality of 0.7% up to 180 days after the index event. In both OASIS-5 and OASIS-6, fondaparinux was associated with less major bleeding compared to heparin or low-molecular-weight heparin. The reduction in major bleeding has been postulated to contribute to the observed mortality difference. Whether it results from an intrinsic property of the drugs, or whether the commonly employed doses of heparin and low molecular weight heparin are in fact too high, is a matter for debate. Fondaparinux is also attractive because it is administered in a fixed dose (2.5 mg daily) without monitoring in patients with creatinine clearance as low as 30 mL/min.

Warfarin

Oral anticoagulants are effective for the treatment of arterial thrombosis. Two studies have shown that oral anticoagulants are effective for long-term treatment of patients with myocardial infarction, an observation confirmed in a meta-analysis.[264–266] This meta-analysis also confirmed that low-dose warfarin (1 or 3 mg) combined with 80 mg of aspirin per day does not provide benefit beyond that achieved with 160 mg of aspirin/day.[267] Therapeutic doses of warfarin are not commonly administered for primary or secondary prophylaxis of myocardial infarction because of the inconvenience associated with international normalized ratio (INR) monitoring.

Direct Thrombin Inhibitors

The role of bivalirudin and other direct thrombin inhibitors, which have been licensed in some jurisdictions for the treatment of acute coronary syndromes, is currently evolving.[268] To date, there does not appear to be any benefit to using direct thrombin inhibitors in lieu of heparin for acute coronary syndromes. Also, direct thrombin inhibitors have not been evaluated for this indication in the era of aggressive antiplatelet therapy with clopidogrel, aspirin, and GPIIb/IIIa inhibitors. For patients undergoing percutaneous coronary intervention, bivalirudin may be safer than heparin because of reduced bleeding.[269]

Atrial Fibrillation

Patients with nonvalvular atrial fibrillation have an increased risk of stroke, which occurs at a frequency of 5% per year.[270–274] The risk of stroke is similar for persistent and paroxysmal atrial fibrillation. The risk of stroke increases with age,[275,276] and is increased by a number of associated cardiac disorders, including a history of myocardial infarction, angina, heart failure, and previous thromboembolic event, and the presence of left atrial dilation, left ventricular dysfunction, mitral calcification, or hypertension. In such patients, warfarin (INR 2.0–3.0) produces a 60% to 80% reduction in the risk of stroke, with only a modest increase in bleeding complications.[270–274] Therefore, warfarin (target INR 2.0–3.0) should be administered to all patients with persistent or paroxysmal nonvalvular atrial fibrillation who do not have a contraindication to anticoagulant therapy. This recommendation applies particularly to those patients with nonvalvular atrial fibrillation who have an additional risk factor for stroke,[277] such as hypertension, impaired left ventricular function and/or congestive heart failure, diabetes, previous cerebral ischemia or systemic

embolization. In these patients, warfarin therapy (target INR 2.0–3.0) is more effective than either fixed low-dose warfarin,[278] aspirin,[278] or aspirin and clopidogrel in combination.[279] Aspirin should be used in patients with nonvalvular atrial fibrillation who are at high risk for stroke when warfarin is contraindicated. Low-risk patients (ie, those who are younger than 65 years old and without a history of cerebral ischemia, diabetes, hypertension, left ventricular dysfunction, or structural heart defects) should receive aspirin, 325 mg/day. Such patients who are between 65 and 75 years of age should receive either aspirin or warfarin. Several scoring systems to stratify the risk of stroke in atrial fibrillation patients have been developed.[277]

Mechanical and Bioprosthetic Valves

Patients with prosthetic heart valves have an increased risk of systemic embolism, which most often manifests as a stroke. The embolic risk is greater with mechanical than with bioprosthetic valves, with prosthetic mitral rather than aortic valves, and when there is associated atrial fibrillation.[232] For patients with tissue prosthetic valves who are in sinus rhythm, the risk of embolism is largely confined to the first 3 months after valve insertion, whereas patients with mechanical prosthetic valves have a lifelong risk of systemic embolism. The general consensus is that patients with tissue valves but no other risk factors for thrombosis should receive warfarin for 3 months after valve placement, with a goal INR of 2.0 to 3.0, followed by lifelong low-dose aspirin.[232,280]

Randomized trials in patients with mechanical prosthetic valves have shown that warfarin is effective in reducing the risk of systemic embolism, even when given at a lower intensity than that used in the past.[281,282] Current American College of Chest Physician recommendations are for a target INR of 2.5 (range 2.0–3.0) with a St. Jude Medical bileaflet valve in the aortic position, a target INR of 3.0 (range 2.5–3.5) with a tilting disk or bileaflet valve in the mitral position, and a target INR of 3.0 (range 2.5–3.5) in combination with low-dose aspirin for patients with caged ball or caged disk valves in either position.[232] Current American College of Cardiology/American Heart Association recommendations are to increase the target INR to the 2.5 to 3.5 range for patients with mechanical aortic valves who have additional risk factors for thromboembolism (atrial fibrillation, left ventricular dysfunction, prior thromboembolism, or a hypercoagulable condition). The American College of Cardiology/American Heart Association also strongly recommends adding low-dose aspirin to warfarin in all patients with risk factors for thromboembolism, unless aspirin is contraindicated for reasons such as gastrointestinal bleeding.[280]

CHAPTER 137

ANTITHROMBOTIC DRUGS

Jeffrey I. Weitz

Arterial and venous thromboses are major causes of morbidity and mortality. Arterial thrombosis is the most common cause of acute myocardial infarction, ischemic stroke and limb gangrene, whereas deep vein thrombosis leads to pulmonary embolism, which can be fatal, and to the postphlebitic syndrome. Most arterial thrombi are superimposed on disrupted atherosclerotic plaque because plaque rupture exposes thrombogenic material in the plaque core to the blood. This material then triggers platelet aggregation and fibrin formation, which results in the generation of a platelet-rich thrombus that can temporarily or permanently occlude blood flow.[1] In contrast to arterial thrombi, venous thrombi rarely form at sites of obvious vascular disruption. Although they can develop after surgical trauma to veins, or secondary to indwelling venous catheters, venous thrombi usually originate in the valve cusps of the deep veins of the calf or in the muscular sinuses,[2] where they are triggered by stasis. Sluggish blood flow in these veins reduces the oxygen supply to the avascular valve cusps.[3] Endothelial cells lining these valve cusps become activated and express adhesion molecules on their surface. Tissue factor-bearing leukocytes and microparticles adhere to these activated cells and induce coagulation.[4] Local thrombus formation is exacerbated by reduced clearance of activated clotting factors as a result of impaired blood flow. If the calf vein thrombi extend into more proximal veins of the leg, thrombus fragments can dislodge, travel to the lungs, and produce a pulmonary embolism.[5]

Arterial and venous thrombi are composed of platelets and fibrin, but the proportions differ. Arterial thrombi are rich in platelets because of the high shear in the injured arteries. In contrast, venous thrombi, which form under low-shear conditions, contain relatively few platelets and are predominantly composed of fibrin and trapped red cells.[6] Because of the predominance of platelets, arterial thrombi appear white, whereas venous thrombi are red in color, reflecting the trapped red cells.

Antithrombotic drugs are used for prevention and treatment of thrombosis. Targeting the components of thrombi, these agents include (a) antiplatelet drugs, which inhibit platelets; (b) anticoagulants, which attenuate coagulation; and (c) fibrinolytic agents, which induce fibrin degradation (Fig. 137–1). With the predominance of platelets in arterial thrombi, strategies to inhibit or treat arterial thrombosis focus mainly on antiplatelet agents, although, in the acute setting, they often include anticoagulants and fibrinolytic agents. Anticoagulants are the mainstay of prevention and treatment of venous thromboembolism because fibrin is the predominant component of venous thrombi. Antiplatelet drugs are less effective than anticoagulants in this setting because of the limited platelet content of venous thrombi. Fibrinolytic therapy is used in selected patients with venous thromboembolism. For example, patients with massive or submassive pulmonary embolism can benefit from systemic or catheter-directed fibrinolytic therapy. Catheter-directed fibrinolytic therapy also can be used as an adjunct to anticoagulants for treatment of certain patients with extensive iliofemoral vein thrombosis.[7]

ANTIPLATELET DRUGS

Role of Platelets in Arterial Thrombosis

In healthy vasculature, circulating platelets are maintained in an inactive state by nitric oxide (NO) and prostacyclin released by endothelial cells lining the blood vessels. In addition, endothelial cells also express ADPase on their surface which degrades ADP released from activated platelets. When the vessel wall is damaged, release of these substances is impaired and the subendothelial matrix is exposed.[8] Platelets adhere to exposed collagen, von Willebrand factor, and fibronectin via receptors constitutively expressed on the platelet surface. Adherent platelets undergo a change in shape, secrete ADP from their dense granules, and synthesize and release thromboxane A_2. Released ADP and thromboxane A_2, which are platelet agonists, activate ambient platelets and recruit them to the site of vascular injury.

Disruption of the vessel wall also exposes tissue factor-expressing cells to the blood. Tissue factor initiates coagulation. Activated platelets potentiate coagulation by binding clotting factors and may support the assembly of activation complexes that enhance thrombin generation. In addition to converting fibrinogen to fibrin, thrombin also serves as a potent platelet agonist and recruits more platelets to the site of vascular injury.

When platelets are activated, GPIIb/IIIa, the most abundant receptor on the platelet surface, undergoes a conformational change that enables it to ligate fibrinogen. Divalent fibrinogen molecules bridge adjacent platelets together to form platelet aggregates. Fibrin strands, generated through the action of thrombin, then weave these aggregates together to form a platelet/fibrin mesh.

Antiplatelet drugs target various steps in this process (Fig. 137–2). The commonly used drugs include aspirin, thienopyridines (clopidogrel and ticlopidine), dipyridamole, and GPIIb/IIIa antagonists.

Aspirin

The most widely used antiplatelet agent worldwide is aspirin. As an inexpensive and effective antiplatelet drug, aspirin serves as the foundation of most antiplatelet strategies.

Mechanism of Action

Aspirin produces its antithrombotic effect by irreversibly acetylating and inhibiting platelet cyclooxygenase (COX)-1 (Fig. 137–2), a critical enzyme in the biosynthesis of thromboxane A_2. At high doses (approximately 1 g/day), aspirin also inhibits COX-2, an inducible COX isoform found in endothelial cells and inflammatory cells.[8,9] In endothelial cells, COX-2 initiates the synthesis of prostacyclin, a potent vasodilator and inhibitor of platelet aggregation.

COX-2 inhibitors were developed to block the production of inflammatory prostaglandins without affecting platelet function. The

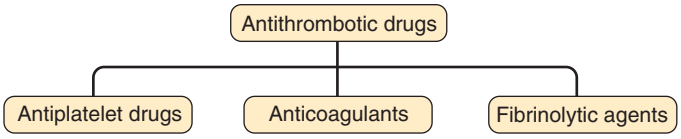

Figure 137–1 Classification of antithrombotic drugs.

various COX-2 inhibitors differ in their selectivity for COX-2 relative to COX-1. By blocking prostacyclin synthesis without concomitant inhibition of thromboxane A_2 production, highly selective inhibitors of COX-2 increase the risk of cardiovascular events. Thus, long-term rofecoxib therapy increases the risk of myocardial infarction three- to fivefold,[10,11] a finding that led to the withdrawal of this drug from the market.

Indications

Aspirin is widely used for secondary prevention of cardiovascular events in patients with coronary artery disease, cerebrovascular disease, or peripheral vascular disease. Compared with placebo, aspirin produces a 25% reduction in the risk of cardiovascular death, myocardial infarction or stroke in these patients.[12] Aspirin also is used for primary prevention in patients whose estimated annual risk of myocardial infarction is in excess of 1%, a point where its benefits are likely to outweigh harms.[13] This includes patients older than 40 with two or more major risk factors for cardiovascular disease, or those older than 50 with one or more such risk factor.[9] Aspirin is equally effective in men and women. In men, aspirin mainly reduces the risk of myocardial infarction, whereas in women aspirin lowers the risk of stroke.[14]

Dosages

Aspirin is usually administered at doses of 75 to 325 mg once daily. There is no evidence that higher doses of aspirin are more effective than lower doses, and some analyses suggest reduced efficacy with higher doses.[9] Because the side effects of aspirin are dose-related, daily aspirin doses of 75 to 150 mg are recommended for most indications. When rapid platelet inhibition is required, an initial aspirin dose of at least 160 mg should be given.[9]

Side Effects

Most common side effects are gastrointestinal and range from dyspepsia to erosive gastritis or peptic ulcers with bleeding and perforation.[9] These side effects are, at least to some extent, dose-related. Use of enteric-coated or buffered aspirin in place of plain aspirin does not eliminate the risk of gastrointestinal side effects. The overall risk of major bleeding with aspirin ranges from 1% to 3% per year.[9,15] The risk of bleeding is increased when aspirin is given in conjunction with anticoagulants, such as warfarin. When dual therapy is used, low-dose aspirin should be given (75–100 mg daily). Eradication of *Helicobacter pylori* infection and administration of proton pump inhibitors may reduce the risk of aspirin-induced gastrointestinal bleeding in patients with peptic ulcer disease.

Aspirin should not be administered to patients with a history of aspirin allergy characterized by bronchospasm. This problem occurs in approximately 0.3% of the general population, but is more common in those with chronic urticaria or asthma, particularly in subjects with coexisting nasal polyps or chronic rhinitis.[16] Hepatic and renal toxicity are observed with aspirin overdose.

Aspirin Resistance

The term *aspirin resistance* has been used to describe both clinical and laboratory phenomena.[17] Clinical aspirin resistance is defined as the failure of aspirin to protect patients from ischemic vascular events. This is not a helpful definition because it is made after the event occurs. Furthermore, it is not realistic to expect aspirin, which only blocks thromboxane A_2-induced platelet activation, to prevent all vascular events.

Aspirin resistance also has been described biochemically as failure of the drug to produce its expected inhibitory effects on tests of platelet function, such as thromboxane A_2 synthesis[18] or arachidonic acid-induced platelet aggregation.[19] However, the tests of platelet function used for diagnosis of biochemical aspirin resistance have not been well standardized.[17] Furthermore, there is no definitive evidence that these tests identify patients at risk of recurrent vascular events, or that resistance can be reversed either by giving higher doses of aspirin or by adding other antiplatelet drugs.[17] Until this information is available, testing for aspirin resistance remains a research tool.

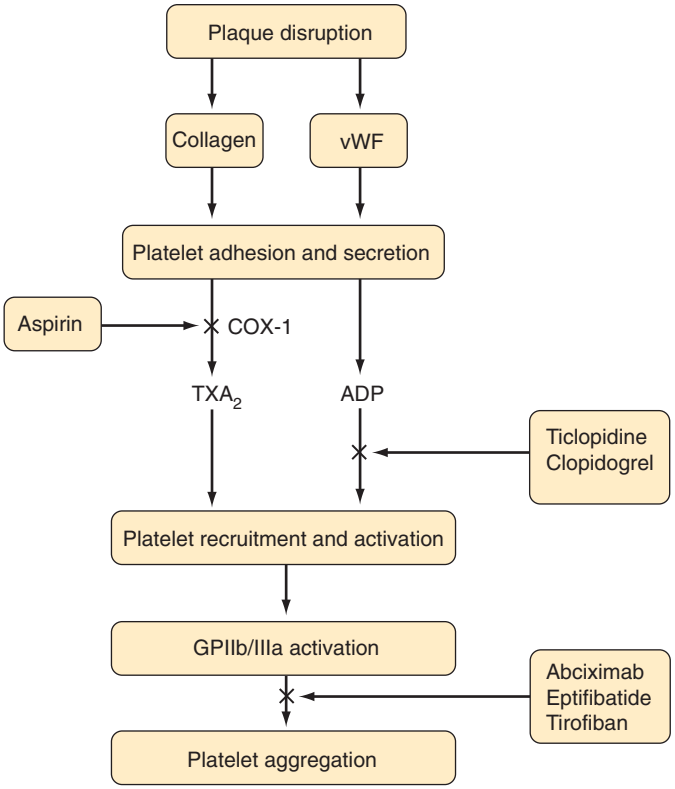

Figure 137–2 Site of action of antiplatelet drugs. Aspirin inhibits thromboxane A_2 (TXA_2) synthesis by irreversibly acetylating cyclooxygenase-1 (COX-1). Reduced TXA_2 release attenuates platelet activation and recruitment to the site of vascular injury. Ticlopidine and clopidogrel irreversibly block $P2Y_{12}$, a key ADP receptor on the platelet surface. Therefore, these agents also attenuate platelet recruitment. Abciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking fibrinogen binding to activated glycoprotein (GP) IIb/IIIa.

Thienopyridines

The thienopyridines include ticlopidine (Ticlid) and clopidogrel (Plavix), drugs that target $P2Y_{12}$, a key ADP receptor on platelets.

Mechanism of Action

The thienopyridines are structurally related drugs that selectively inhibit ADP-induced platelet aggregation by irreversibly blocking $P2Y_{12}$ (Fig. 137–2). Ticlopidine and clopidogrel are both prodrugs that must be metabolized by the hepatic cytochrome P450 (CYP) enzyme system to become biologically active. Consequently, when

given in usual doses, their onset of action is delayed for several days.[20]

Indications

Like aspirin, ticlopidine is effective at reducing the risk of cardiovascular death, myocardial infarction, and stroke in patients with atherosclerotic disease.[21] Because of its delayed onset of action, ticlopidine is not recommended in patients with acute myocardial infarction. Ticlopidine was used routinely as an adjunct to aspirin after coronary artery stenting and as an aspirin substitute in those intolerant to aspirin.[20] Because clopidogrel is more potent than ticlopidine and has a better safety profile, clopidogrel has replaced ticlopidine.[20]

When compared with aspirin in patients with recent ischemic stroke, myocardial infarction or peripheral arterial disease, clopidogrel reduced the risk of cardiovascular death, myocardial infarction, and stroke by 8.7%.[22] Therefore, clopidogrel is more effective than aspirin but also is more expensive. In some patients, clopidogrel and aspirin are combined to capitalize on their capacity to block complementary pathways of platelet activation. For example, the combination of aspirin plus clopidogrel is recommended for at least 4 weeks after implantation of a bare metal stent in a coronary artery and longer in those with a drug-eluting stent.[20] Recent concerns about late in-stent thrombosis with drug-eluting stents have led some experts to recommend long-term use of clopidogrel plus aspirin for this indication.[23,24]

The combination of clopidogrel and aspirin also is effective in patients with unstable angina. Thus, in 12,562 such patients, the risk of cardiovascular death, myocardial infarction or stroke was 9.3% in those randomized to the combination of clopidogrel and aspirin and 11.4% in those given aspirin alone. This 20% relative risk reduction with combination therapy was highly statistically significant.[25] However, combining clopidogrel with aspirin increases the risk of major bleeding to approximately 2% per year. This bleeding risk persists even if the daily dose of aspirin is 100 mg or less.[26] Therefore, the combination of clopidogrel and aspirin should only be used when there is a clear benefit. For example, this combination has not proven to be superior to clopidogrel alone in patients with acute ischemic stroke,[27] or to aspirin alone for primary prevention in those at risk for cardiovascular events.[28]

Dosing

Ticlopidine is given twice daily at a dose of 250 mg. The more potent clopidogrel is given once daily at a dose of 75 mg.[20] Because its onset of action is delayed for several days, loading doses of clopidogrel are given when rapid ADP receptor blockade is desired. For example, patients undergoing coronary stenting are often given a loading dose of 300 mg, which effects inhibition of ADP-induced platelet aggregation in approximately 6 hours. Loading doses of 600 or 900 mg produce an even more rapid effect.[20]

Side Effects

The most common side effects of ticlopidine are gastrointestinal. More serious are the hematologic side effects, which include neutropenia, thrombocytopenia, and thrombotic thrombocytopenic purpura. These side effects usually occur within the first few months of starting treatment. Therefore, blood counts must be carefully monitoring when initiating therapy with ticlopidine. Gastrointestinal and hematologic side effects are rare with clopidogrel.[20]

Thienopyridine Resistance

There is subject variability in the capacity of the thienopyridines to inhibit ADP-induced platelet aggregation.[29] This variability reflects, at least in part, genetic polymorphisms in the CYP isoenzymes involved in the metabolic activation of the drugs. For example, subjects with the *CYP2C19*2* allele exhibit decreased responsiveness to clopidogrel as do those with reduced CYP3A4 activity.[30,31] These findings raise the possibility that pharmacogenomic profiling may help identify clopidogrel-resistant patients. Point-of-care devices that assess the extent of platelet inhibition may also help to identify these patients.[32] It is currently unknown, however, whether patients with biochemical evidence of clopidogrel resistance have a poorer outcome and whether administration of higher doses of clopidogrel to these patients overcomes this problem.

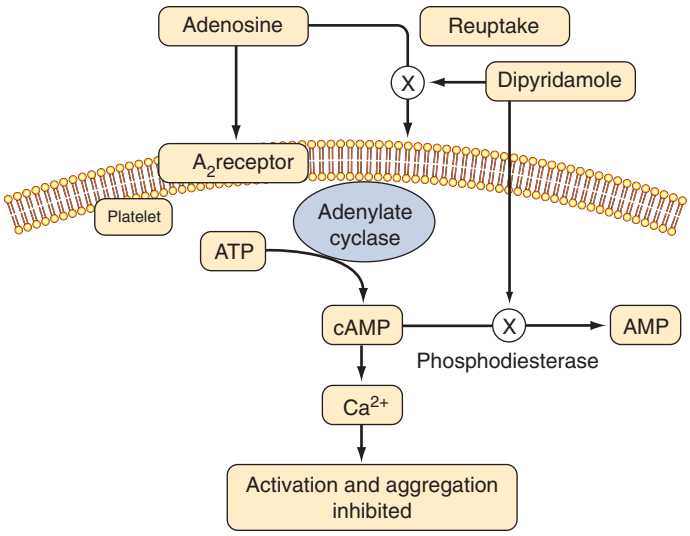

Figure 137–3 Mechanism of action of dipyridamole. Dipyridamole increases levels of cAMP in platelets by (**A**) blocking the reuptake of adenosine and (**B**) inhibiting phosphodiesterase-mediated cAMP degradation. By promoting calcium uptake, cAMP reduces intracellular levels of calcium. This, in turn, inhibits platelet activation and aggregation.

Dipyridamole

A relatively weak antiplatelet agent on its own,[20] an extended release formulation of dipyridamole combined with low-dose aspirin, a preparation known as Aggrenox, is used for prevention of stroke in patients with transient ischemic attacks.[33]

Mechanism of Action

By inhibiting phosphodiesterase, dipyridamole blocks the breakdown of cAMP. Increased levels of cAMP reduce intracellular calcium and inhibit platelet activation. Dipyridamole also blocks the uptake of adenosine by platelets and other cells. This produces a further increase in local cAMP levels because the platelet adenosine A_2 receptor is coupled to adenylate cyclase (Fig. 137–3).

Dosing

Aggrenox is given twice daily. Each capsule contains 200 mg of extended release dipyridamole and 25 mg of aspirin.[33]

Side Effects

Because dipyridamole has vasodilatory effects, it must be used with caution in patients with coronary artery disease. Gastrointestinal complaints, headache, facial flushing, dizziness, and hypotension also can occur. These symptoms often subside with continued use of the drug.[33]

Indications

Dipyridamole plus aspirin was compared with aspirin or dipyridamole alone, or with placebo, in patients with an ischemic stroke or

Table 137–1 Features of GPIIb/IIIa Antagonists

Feature	Abciximab	Eptifibatide	Tirofiban
Description	Fab fragment of humanized mouse monoclonal antibody	Cyclical KGD-containing heptapeptide	Nonpeptidic RGD mimetic
Specific for GPIIb/IIIa	No	Yes	Yes
Plasma half-life	Short (minutes)	Long (2.5 hours)	Long (2.0 hours)
Platelet-bound half-life	Long (days)	Short (seconds)	Short (seconds)
Renal clearance	No	Yes	Yes

KGD, Lys–Gly–Asp; RGD, Arg–Gly–Asp.

transient ischemic attack. The combination reduced the risk of stroke by 22.1% compared with aspirin and by 24.4% compared with dipyridamole.[34] A second trial compared dipyridamole plus aspirin with aspirin alone for secondary prevention in patients with ischemic stroke. Vascular death, stroke, or myocardial infarction occurred in 13% of patients given combination therapy and in 16% of those treated with aspirin alone.[35] On the basis of these data, Aggrenox is often used for stroke prevention. However, because of its vasodilatory effects and the paucity of data supporting the use of dipyridamole in patients with symptomatic coronary artery disease, Aggrenox should not be used for stroke prevention in such patients.

GPIIb/IIIa Receptor Antagonists

As a class, parenteral GPIIb/IIIa receptor antagonists have an established niche in patients with acute coronary syndromes. The three agents in this class are abciximab (ReoPro), eptifibatide (Integrilin), and tirofiban (Aggrestat).

Mechanism of Action

A member of the integrin family of adhesion receptors, GPIIb/IIIa, is found on the surface of platelets and megakaryocytes.[36] With approximately 80,000 copies per platelet, GPIIb/IIIa is the most abundant receptor. Consisting of a noncovalently linked heterodimer, GPIIb/IIIa is inactive on resting platelets. When platelets are activated, inside–outside signal transduction pathways trigger a conformational activation of the receptor. Once activated, GPIIb/IIIa binds adhesive molecules, such as fibrinogen and, under high-shear conditions, von Willebrand factor. Binding is mediated by the Arg–Gly–Asp (RGD) sequences found on the α chains of fibrinogen and on von Willebrand factor, and by the Lys–Gly–Asp (KGD) sequence located within a unique dodecapeptide domain on the γ chains of fibrinogen. Once bound, fibrinogen and/or von Willebrand factor bridge adjacent platelets together to induce platelet aggregation.[36]

Although abciximab, eptifibatide, and tirofiban all target the GPIIb/IIIa receptor, they are structurally and pharmacologically distinct (Table 137–1). Abciximab is a Fab fragment of a humanized murine monoclonal antibody directed against the activated form of GPIIb/IIIa.[37] Abciximab binds to the activated receptor with high affinity and blocks the binding of adhesive molecules. In contrast to abciximab, eptifibatide and tirofiban are synthetic small molecules.[37] Eptifibatide is a cyclic heptapeptide that binds GPIIb/IIIa because it incorporates the KGD motif, whereas tirofiban is a nonpeptidic tyrosine derivative that acts as an RGD mimetic. Abciximab has a long half-life and can be detected on the surface of platelets for up to 2 weeks. Eptifibatide and tirofiban have shorter half-lives.[37]

In addition to targeting the GPIIb/IIIa receptor, abciximab also inhibits the closely related $a_v\beta_3$ receptor, which binds vitronectin, and $a_M\beta_2$, a leukocyte integrin. In contrast, eptifibatide and tirofiban are specific for GPIIb/IIIa. Inhibition of $a_v\beta_3$ and $a_M\beta_2$ may endow abciximab with antiinflammatory and/or antiproliferative properties that extend beyond platelet inhibition.[37]

Dosing

All of the GPIIb/IIIa antagonists are given as an intravenous bolus followed by an infusion. Because they are cleared by the kidneys, the doses of eptifibatide and tirofiban must be reduced in patients with renal insufficiency.[37]

Side Effects

In addition to bleeding, thrombocytopenia is the most serious complication. Thrombocytopenia is immune-mediated and is caused by antibodies directed against neoantigens on GPIIb/IIIa that are exposed upon antagonist binding.[38] With abciximab, thrombocytopenia occurs in up to 5% of patients, and is severe in approximately 1% of these individuals. Thrombocytopenia is less common with the other two agents, occurring in approximately 1% of patients.

Indications

Abciximab and eptifibatide are used in patients undergoing percutaneous coronary interventions, particularly those with acute myocardial infarction.[39] Tirofiban is used in high-risk patients with unstable angina. Eptifibatide also can be used for this indication.[40]

New Antiplatelet Agents

Thienopyridines that produce more predictable suppression of ADP-induced platelet aggregation are under investigation.[41,42] Direct acting reversible $P2Y_{12}$ antagonists also have been developed. These agents can be given orally or parenterally and have a rapid onset of action because they are not prodrugs.[42] Finally, orally active inhibitors of the type 1 protease-activated receptor (PAR-1), the major thrombin receptor on platelets, also are entering clinical trials.

ANTICOAGULANTS

There are both parenteral and oral anticoagulants. Currently avail-able parenteral anticoagulants include heparin, low-molecular-weight heparin (LMWH) and fondaparinux, a synthetic pentasaccharide. The only available oral anticoagulants are the vitamin K antagonists, of which warfarin is the agent most often used in North America.

Parenteral Anticoagulants

Heparin

A sulfated polysaccharide, heparin is isolated from mammalian tissues rich in mast cells. Most commercial heparin is derived from porcine intestinal mucosa and is a polymer of alternating D-glucuronic acid and *N*-acetyl-D-glucosamine residues.[43]

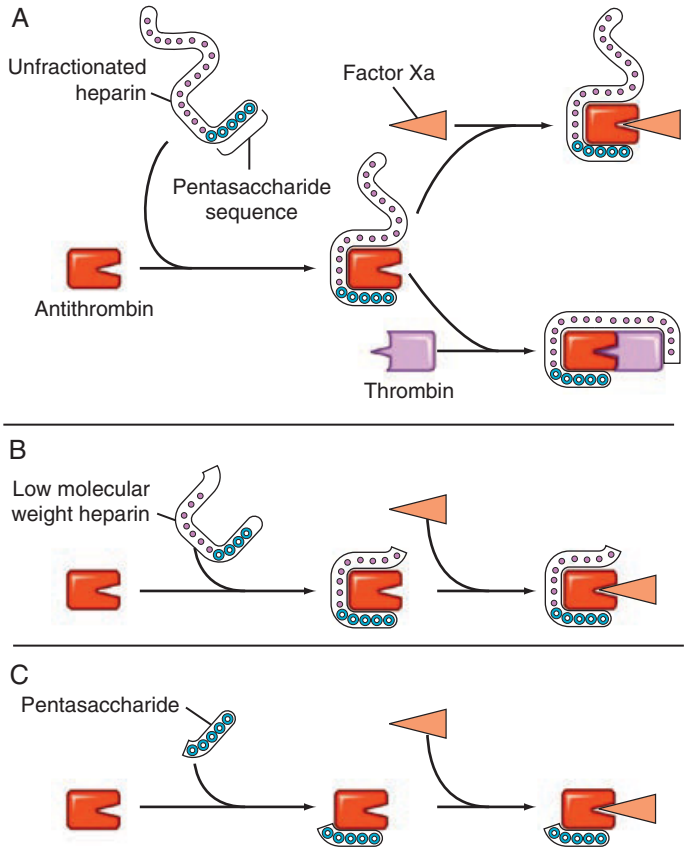

Figure 137–4 Mechanism of action of heparin, low-molecular-weight heparin, and fondaparinux, a synthetic pentasaccharide. (**A**) Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units, which corresponds to a molecular weight of 5400, are of sufficient length to perform this bridging function. With a mean molecular weight of 15,000, all of the heparin chains are long enough to do this. (**B**) Low-molecular-weight heparin (LMWH) has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin because, with a mean molecular weight of 4500 to 5000, at least half of the LMWH chains are too short to bridge antithrombin to thrombin. (**C**) The pentasaccharide only accelerates factor Xa inhibition by antithrombin because the pentasaccharide is too short to bridge antithrombin to thrombin.

Figure 137–5 Comparison of the stimulatory effects of pentasaccharide and unfractionated heparin on catalysis of antithrombin-mediated inhibition of thrombin (IIa), factor IXa (IXa), and factor Xa (Xa). Second-order rate constants of inhibition of IIa, IXa, or Xa by antithrombin, measured in the presence of heparin (open bars) or fondaparinux (closed bars) were divided by those determined in the absence of glycosaminoglycan and are plotted as fold increase over the uncatalyzed rate of inhibition (reprinted with permission from Wiebe EM, Stafford AR, Fredenburgh JC, et al: Mechanism of catalysis of inhibition of factor IXa by antithrombin in the presence of heparin or pentasaccharide. J Biol Chem 278(37):35767, 2003.

Mechanism of Action

Heparin acts as an anticoagulant by activating antithrombin and accelerating the rate at which antithrombin inhibits enzymes involved in blood coagulation, particularly thrombin and factor Xa.[44] Antithrombin, the obligatory plasma cofactor for heparin,[44] is a 58,000 molecular weight single-chain polypeptide that is a member of the serine protease inhibitor (serpin) superfamily. Synthesized in the liver and circulating in plasma at a concentration of 2.6 μM, antithrombin acts as a suicide substrate for its target enzymes.

To activate antithrombin, heparin binds to the serpin via a unique pentasaccharide sequence that is found on one-third of the chains of commercial heparin (Fig. 137–4). The remainder of the heparin chains that lack this pentasaccharide sequence have little or no anticoagulant activity.[45] Once bound to antithrombin, heparin induces a conformational change in the reactive center loop of antithrombin that renders it more readily accessible to its target proteases. This conformational change enhances the rate at which antithrombin inhibits factor Xa by at least two orders of magnitude, but has little effect on the rate of thrombin inhibition by antithrombin.[46] To catalyze thrombin inhibition, heparin serves as a template that binds antithrombin and thrombin simultaneously.[47] Formation of this ternary complex brings the enzyme in close apposition to the inhibitor, thereby promoting the formation of a stable covalent thrombin–antithrombin complex.[47,48]

Only pentasaccharide-containing heparin chains composed of at least 18 saccharide units (which correspond to a molecular weight of 5400) are of sufficient length to bridge thrombin and antithrombin together.[49] With a mean molecular weight of 15,000, and a range of 5000 to 30,000, almost all of the chains of unfractionated heparin are long enough to effect this bridging function.[44] Consequently, by definition, heparin has equal capacity to promote the inhibition of thrombin and factor Xa by antithrombin and is assigned an anti–factor Xa to anti–factor IIa (thrombin) ratio of 1 : 1.[44]

Although current dogma states that heparin catalysis of factor Xa inhibition by antithrombin is mediated solely by the conformational changes evoked by pentasaccharide binding to antithrombin, recent studies have challenged this concept. Thus, in the presence of calcium, a heparin-binding site on factor Xa is exposed.[50,51] By binding simultaneously to this site on factor Xa and to antithrombin, longer pentasaccharide-containing heparin chains accelerate the rate of factor Xa inhibition by antithrombin more than shorter chains. The same is true for heparin catalysis of factor IXa inhibition by antithrombin.[52,53] Thus, maximum enhancement in the rate of factor Xa or factor IXa inhibition by antithrombin requires heparin chains that are of sufficient length to bridge the enzymes to antithrombin (Fig. 137–5).

In addition to activating antithrombin, heparin also can catalyze heparin cofactor II. This 66,000 molecular weight serpin, which is found in plasma at a concentration of 1.2 M, is a specific inhibitor of thrombin.[54] Two features account for the specificity of heparin cofactor II. First, the reactive site of heparin cofactor II contains the sequence Leu444–Ser445, a peptide bond that is not readily susceptible to cleavage by coagulation proteases other than thrombin.[55] Second, heparin cofactor II possesses a unique anionic sequence at its N-terminal. In its unactivated state, this sequence forms an intramolecular bond with the positively charged glycosaminoglycan-binding site located on the body of heparin cofactor II. When heparin or dermatan sulfate, a glycosaminoglycan that interacts only with

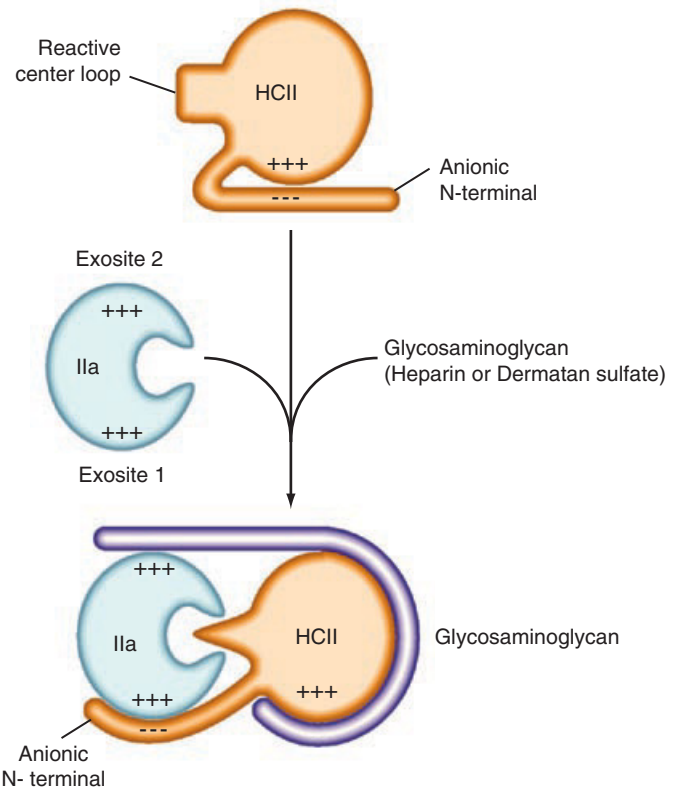

Figure 137–6 Catalysis of heparin cofactor II (HCII) by glycosaminoglycans. In its inactivated form, the acidic N-terminal tail of HCII is tethered to the positively charged glycosaminoglycan-binding site on the body of the serpin. The binding of heparin or dermatan sulfate to this binding site displaces the N-terminal tail, thereby facilitating the interaction of this anionic domain with exosite 1 on thrombin. Glycosaminoglycan binding also evokes a conformational change in the reactive center loop of HCII that contributes to the formation of the HCII–thrombin complex. Longer heparin chains not only bind to HCII, but also bind to the heparin-binding domain on thrombin, so-called exosite 2. Heparin-mediated bridging of HCII to thrombin enhances the rate of inhibition. Consequently, longer heparin chains that contain at least 26 saccharide units promote thrombin inhibition by HCII to a greater extent than shorter chains. Unlike heparin, dermatan sulfate does not need to bind to thrombin for maximal enhancement in the rate of thrombin inhibition because shorter dermatan sulfate fragments are just as active as longer ones.

heparin cofactor II, binds to heparin cofactor II, this N-terminal sequence is displaced, which enables its tethering to a positively charged domain on thrombin, exosite 1.[56–59] This tethering interaction occurs only with thrombin and facilitates thrombin inhibition by heparin cofactor II (Fig. 137–6).

Maximum catalysis of heparin cofactor II by heparin requires heparin chains composed of at least 26 saccharide units, which corresponds to a molecular weight of 7800.[60,61] Longer heparin chains activate heparin cofactor II to a greater extent than shorter chains because the longer chains are of sufficient length to not only bind to heparin cofactor II, but to also bind to thrombin to form a ternary complex.[62] Formation of this complex brings thrombin and heparin cofactor II into close apposition.

The interaction of heparin with heparin cofactor II is not mediated by the antithrombin-binding pentasaccharide sequence.[63] Because heparin lacks a specific heparin cofactor II-binding domain, heparin's affinity for heparin cofactor II is lower than that for antithrombin. Consequently, 10-fold higher heparin concentrations are needed to accelerate thrombin inhibition by heparin cofactor II in plasma than are necessary to enhance thrombin's inactivation by antithrombin.[64] Therefore, it is likely that heparin cofactor II contributes to the anticoagulant activity of heparin only when the drug is given in high doses.

Heparin causes the release of tissue factor pathway inhibitor (TFPI) from the endothelium.[65,66] A factor Xa-dependent inhibitor of tissue factor-bound factor VIIa,[67] TFPI may contribute to the antithrombotic activity of heparin. Longer heparin chains induce the release of more TFPI than shorter chains.[65,66]

Pharmacology of Heparin

Heparin must be given parenterally. It is usually administered subcutaneously or by continuous intravenous infusion. When used for therapeutic purposes, the intravenous route is most often employed. If heparin is given subcutaneously for treatment of thrombosis, the dose of heparin must be high enough to overcome the limited bioavailability associated with this method of delivery.[44]

After entering the circulation, heparin binds to a variety of plasma proteins other than antithrombin, which decreases the anticoagulant activity of heparin. The levels of heparin-binding proteins vary between patients because some of these proteins are acute-phase reactants whose levels are elevated in ill patients,[68,69] whereas others, such as high-molecular-weight multimers of von Willebrand factor, are released when platelets or endothelial cells are activated by thrombin.[70,71] Activated platelets also release platelet factor 4 (PF4), a highly cationic protein that binds heparin with high affinity.[72] The large amount of PF4 found in the vicinity of platelet-rich arterial thrombi has the potential to locally neutralize the anticoagulant activity of heparin.[73]

Because the levels of heparin-binding proteins are so variable between patients, the anticoagulant response to fixed or weight-adjusted doses of heparin is unpredictable. Consequently, coagulation monitoring is essential to ensure that a therapeutic response is obtained when heparin is administered for treatment purposes.

Heparin is cleared through a combination of a rapid saturable and a much slower first-order mechanism.[74–76] The saturable phase of heparin clearance is thought to be due to binding to endothelial cell receptors[77,78] and macrophages.[79] Bound heparin is internalized and depolymerized.[80,81] The slower nonsaturable mechanism of clearance is largely renal. At therapeutic doses, a large proportion of heparin is cleared through the rapid saturable, dose-dependent mechanism. The complex kinetics of clearance make the anticoagulant response to heparin nonlinear at therapeutic doses, with both the intensity and duration of effect rising disproportionately with increasing dose. Thus, the apparent biological half-life of heparin increases from approximately 30 minutes after an intravenous bolus of 25 U/kg, to 60 minutes with an intravenous bolus of 100 U/kg, to 150 minutes with a bolus of 400 U/kg.[74–76]

Monitoring

Heparin therapy can be monitored using the activated partial thromboplastin time (aPTT) or anti–factor Xa level. Although the aPTT is the test most often employed for this purpose, there are problems with this assay. aPTT reagents vary in their sensitivity to heparin, and the type of instrumentation used for testing can influence the results.[82] Consequently, laboratories must establish a therapeutic aPTT range with each reagent–instrument combination by measuring the aPTT and anti–factor Xa level in plasma samples collected from heparin-treated patients. For most of the aPTT reagents and instruments in current use, therapeutic heparin levels are achieved with a two- to threefold prolongation of the aPTT.[83]

Anti–factor Xa levels also can be used to monitor heparin therapy. With this test, therapeutic heparin levels range from 0.3 to 0.7 units/mL. Although this test is gaining in popularity, anti–factor Xa assays have yet to be standardized, and results can vary widely between laboratories.

Up to 25% of heparin-treated patients with venous thromboembolism require more than 35,000 units/day to achieve a therapeutic aPTT. These patients are considered heparin resistant.[84] It is useful

to measure anti–factor Xa levels in these patients because many will have a therapeutic anti–factor Xa level despite a subtherapeutic aPTT. This dissociation in test results occurs because elevated plasma levels of fibrinogen and factor VIII, both of which are acute-phase proteins, shorten the aPTT but have no effect on anti–factor Xa levels.[85] Heparin therapy in patients who exhibit this phenomenon is best monitored using anti–factor Xa levels instead of the aPTT.[84] Patients with congenital or acquired antithrombin deficiency and those with unusually high levels of heparin-binding proteins often require very high doses of heparin to achieve a therapeutic aPTT or anti–factor Xa level. If there is good correlation between the aPTT and the anti–factor Xa levels, either test can be used to monitor heparin therapy.

Dosing

For prophylaxis, heparin is usually given in fixed doses of 5000 units subcutaneously two or three times daily. With these low doses, coagulation monitoring is unnecessary.[86] In contrast, monitoring is essential when heparin is given in therapeutic doses because a subtherapeutic anticoagulant response has been associated with a higher risk of recurrent thrombosis.[87–90] Fixed-dose or weight-based heparin nomograms are used to standardize heparin dosing and to shorten the time required to achieve a therapeutic anticoagulant response. At least two heparin nomograms have been validated in patients with venous thromboembolism and reduce the time required to achieve a therapeutic aPTT.[91,92] Weight-adjusted heparin nomograms also have been evaluated in patients with acute coronary syndromes.[93,94]

A recent study indicates that unmonitored twice daily subcutaneous heparin is as effective and safe as once-daily low-molecular-weight heparin for initial treatment of venous thromboembolism. High doses of heparin were used; treatment was started with a dose of 333 units/kg followed by 250 units/kg twice daily thereafter.[95] Based on these findings, unmonitored high-dose subcutaneous heparin is a viable treatment option in patients with renal insufficiency where low-molecular-weight heparin or fondaparinux is problematic.

Limitations of Heparin

Heparin has pharmacokinetic and biophysical limitations (Table 137–2). The pharmacokinetic limitations reflect heparin's propensity to bind in a pentasaccharide-independent fashion to cells and plasma proteins. Heparin binding to cells explains its dose-dependent clearance, whereas binding to plasma proteins results in a variable anticoagulant response and can lead to heparin resistance.

The biophysical limitations of heparin reflect the inability of the heparin-antithrombin complex to (a) inhibit factor Xa when it is incorporated into the prothrombinase complex,[96,97] the complex that converts prothrombin to thrombin, and (b) to inhibit thrombin bound to fibrin.[98,99] Consequently, factor Xa bound to activated platelets within platelet-rich thrombi has the potential to generate thrombin, even in the face of heparin.[100] Once this thrombin binds to fibrin, it too is protected from inhibition by the heparin–antithrombin complex.[98,99] Clot-associated thrombin can then trigger thrombus growth by locally activating platelets and amplifying its own generation through feedback activation of factors V, VIII, and XI.[101–103] Further compounding the problem is the potential for heparin neutralization by the high concentrations of PF4 released from activated platelets within the platelet-rich thrombus.[73]

Table 137–2 Pharmacokinetic and Biophysical Limitations of Heparin

Limitations	Mechanism
Poor bioavailability at low doses	Limited absorption of long heparin chains
Dose-dependent clearance	Binds to endothelial cells
Variable anticoagulant response	Binds to plasma proteins whose levels vary from patient to patient
Reduced activity in the vicinity of platelet-limited activity against factor Xa incorporated in the prothrombinase complex and thrombin bound to fibrin	Neutralized by platelet factor 4–released rich thrombi from activated platelets Reduced capacity of heparin-antithrombin complex to inhibit factor Xa bound to activated platelets and thrombin bound to fibrin

Side Effects

The most common side effect of heparin is bleeding. Other complications include thrombocytopenia, osteoporosis, and elevated levels of transaminases.

Bleeding

The risk of heparin-induced bleeding increases with higher heparin doses. Concomitant administration of drugs that affect hemostasis, such as antiplatelet or fibrinolytic agents, increases the risk of bleeding, as does recent surgery or trauma.[104] Heparin-treated patients with serious bleeding can be given protamine sulfate to neutralize the heparin. Protamine sulfate, a mixture of basic polypeptides isolated from salmon sperm, binds heparin with high affinity, and the resultant protamine–heparin complexes are then cleared. Typically, 1 mg of protamine sulfate, administered intravenously, neutralizes 100 units of heparin. Anaphylactoid reactions to protamine sulfate can occur, and drug administration by slow intravenous infusion is recommended to reduce the risk of these problems.[105,106]

Thrombocytopenia

Heparin can cause thrombocytopenia. Heparin-induced thrombocytopenia (HIT) is an antibody-mediated process that is triggered by antibodies directed against neoantigens on PF4 that are exposed when heparin binds to this protein.[107] These antibodies, which usually are of the IgG class, bind simultaneously to the heparin-PF4 complex and to platelet Fc receptors. Such binding activates the platelets and generates platelet microparticles. Circulating microparticles are prothrombotic because they express anionic phospholipids on their surface and can bind clotting factors, thereby promoting thrombin generation.[108]

The features of HIT are illustrated in Table 137–3. Typically, HIT occurs 5 to 14 days after initiation of heparin therapy, but it can manifest earlier if the patient has received heparin within the past 3 months.[109] It is rare for the platelet count to fall below 100,000/μL in patients with HIT, and even a 50% decrease in the platelet count from the pretreatment value should raise the suspicion of HIT in those receiving heparin.[107] HIT is more common in surgical patients

Table 137–3 Features of Heparin-Induced Thrombocytopenia

Features	Details
Thrombocytopenia	Platelet count of 100,000/μL or less or a decrease in platelet count of 50% or more
Timing	Platelet count falls 5–10 days after starting heparin
Type of heparin	More common with unfractionated heparin than low-molecular-weight heparin
Type of patient	More common in surgical patients than medical patients. More common in women than in men
Thrombosis	Venous thrombosis more common than arterial thrombosis

Management of Heparin-Induced Thrombocytopenia

Stop all heparin
Give an alternative anticoagulant, such as lepirudin, argatroban, bivalirudin, danaparoid or fondaparinux
Do not give platelet transfusions
Do not give warfarin until the platelet count returns to its baseline level. If warfarin was administered, give vitamin K to restore the INR to normal
Evaluate for thrombosis, particularly deep vein thrombosis

Advantages of Low-Molecular-Weight Heparin over Heparin

Advantage	*Consequence*
Better bioavailability and longer half-life after subcutaneous injection	Can be given subcutaneously once or twice daily for both prophylaxis and treatment
Dose-independent clearance	Simplified dosing
Predictable anticoagulant response	Coagulation monitoring is unnecessary in most patients
Lower risk of heparin-induced thrombocytopenia	Safer than heparin for short or long-term administration
Lower risk of osteoporosis	Safer than heparin for extended administration

than in medical patients and, like many autoimmune disorders, occurs more frequently in females than in males.[110]

HIT can be associated with thrombosis, either arterial or venous. Venous thrombosis, which manifests as deep vein thrombosis and/or pulmonary embolism, is more common than arterial thrombosis. Arterial thrombosis can manifest as ischemic stroke or acute myocardial infarction. Rarely, platelet-rich thrombi in the distal aorta or iliac arteries can cause critical limb ischemia.[107]

The diagnosis of HIT is established using enzyme-linked assays to detect antibodies against heparin–PF4 complexes or with platelet activation assays. Enzyme-linked assays are sensitive but can be positive in the absence of any clinical evidence of HIT.[107] The most specific diagnostic test is the serotonin release assay. This test is performed by quantifying serotonin release when washed platelets loaded with labeled serotonin are exposed to patient serum in the absence or presence of varying concentrations of heparin. If the patient serum contains the HIT antibody, heparin addition induces platelet activation and subsequent serotonin release.[107]

Management of HIT is outlined in the box below. Heparin should be stopped in patients with suspected or documented HIT, and an alternative anticoagulant should be administered to prevent or treat thrombosis.[107,111] The agents most often used for this indication are parenteral direct thrombin inhibitors, such as lepirudin, argatroban or bivalirudin, or factor Xa inhibitors, such as fondaparinux or danaparoid.

Patients with HIT, particularly those with associated thrombosis, often have evidence of increased thrombin generation that can lead to consumption of protein C. If these patients are given warfarin without a concomitant parenteral anticoagulant to suppress thrombin generation, the further decrease in protein C levels induced by warfarin can trigger skin necrosis.[112,113] To avoid this problem, patients with HIT should be treated with a direct thrombin inhibitor or fondaparinux until the platelet count returns to normal levels. At this point, low-dose warfarin therapy can be introduced, and the thrombin inhibitor or fondaparinux can be discontinued when the anticoagulant response to warfarin has been therapeutic for at least 2 days.[107]

Osteoporosis

Treatment with therapeutic doses of heparin for over a month can cause a reduction in bone density. This complication has been reported in up to 30% of patients given long-term heparin therapy,[114–117] and symptomatic vertebral fractures occur in 2% to 3% of these individuals.

Studies in vitro[118] and in laboratory animals[119–121] have provided insights into the pathogenesis of heparin-induced osteoporosis. These investigations suggest that heparin causes bone resorption both by decreasing bone formation and by enhancing bone resorption. Thus, heparin affects the activity of both osteoblasts and osteoclasts.

Elevated Levels of Transaminases

Therapeutic doses of heparin frequently cause modest elevation in the serum levels of hepatic transaminases, without a concomitant increase in the level of bilirubin.[122,123] The levels of transaminases rapidly return to normal when the drug is stopped. The mechanism responsible for this phenomenon is unknown.

Low-Molecular-Weight Heparin

Consisting of smaller fragments of heparin, low-molecular-weight heparin is prepared from unfractionated heparin by controlled enzymatic or chemical depolymerization. The mean molecular weight of low-molecular-weight heparin is approximately 5000, one-third the mean molecular weight of unfractionated heparin.[124] Low-molecular-weight heparin has advantages over heparin and has replaced heparin for most indications.

Mechanism of Action

Like heparin, low-molecular-weight heparin exerts its anticoagulant activity by activating antithrombin. With a mean molecular weight of 5000, which corresponds to approximately 17 saccharide units, at least half of the pentasaccharide-containing chains of low-molecular-weight heparin are too short to bridge thrombin to antithrombin (Fig. 137–4). However, these chains retain the capacity to accelerate factor Xa inhibition by antithrombin because this activity is largely the result of the conformational changes in antithrombin evoked by pentasaccharide binding. Consequently, low-molecular-weight heparin catalyzes factor Xa inhibition by antithrombin more than thrombin inhibition.[125] Depending on their unique molecular weight distributions, low-molecular-weight heparin preparations have anti–factor Xa to anti–factor IIa ratios ranging from 2:1 to 4:1.

Pharmacology

Although usually given subcutaneously, low-molecular-weight heparin also can be administered intravenously if a rapid anticoagulant response is needed. Low-molecular-weight heparin has pharmacokinetic advantages over heparin.[124,125] These advantages reflect the fact that shorter heparin chains bind less avidly to endothelial cells, macrophages, and heparin-binding plasma proteins.[126–128] Reduced binding to endothelial cells and macrophages eliminates the rapid, dose-dependent, and saturable mechanism of clearance that is a characteristic of unfractionated heparin. Instead, the clearance of low-molecular-weight heparin is dose-independent and its plasma half-life is longer.[85,86] Based on measurement of anti–factor Xa levels, low-molecular-weight heparin has a plasma half-life of approximately 4 hours. Low-molecular-weight heparin is cleared almost exclusively by the kidneys and the drug can accumulate in patients with renal insufficiency.[124,125]

Low-molecular-weight heparin exhibits approximately 90% bioavailability after subcutaneous injection.[124,125] Because low-

molecular-weight heparin binds less avidly to heparin-binding proteins in plasma than heparin, low-molecular-weight heparin produces a more predictable dose response and resistance to low-molecular-weight heparin is rare. With a longer half-life and more predictable anticoagulant response, low-molecular-weight heparin can be given subcutaneously once or twice daily without coagulation monitoring, even when the drug is given in treatment doses.[124] These properties render low-molecular-weight heparin more convenient than unfractionated heparin. Capitalizing on this feature, studies in patients with venous thromboembolism have shown that home treatment with low-molecular-weight heparin is as effective and safe as in-hospital treatment with continuous intravenous infusions of heparin.[129–131] Out-patient treatment with low-molecular-weight heparin streamlines care, reduces health care costs, and increases patient satisfaction.

Monitoring

In the majority of patients, low-molecular-weight heparin does not require coagulation monitoring. If monitoring is necessary, anti–factor Xa levels must be measured because most low-molecular-weight heparin preparations have little effect on the aPTT. Therapeutic anti–factor Xa levels with low-molecular-weight heparin range from 0.5 to 1.2 units/mL when measured 3 to 4 hours after drug administration. When low-molecular-weight heparin is given in prophylactic doses, peak anti–factor Xa levels of 0.2 to 0.5 units/mL are desirable.[132]

Indications for low-molecular-weight heparin monitoring include renal insufficiency and obesity. Low-molecular-weight heparin monitoring in patients with a creatinine clearance of 50 mL/minute or less is advisable to ensure that there is no drug accumulation. Although weight-adjusted low-molecular-weight heparin dosing appears to produce therapeutic anti–factor Xa levels in patients who are overweight, this approach has not been extensively evaluated in those with morbid obesity. It may also be advisable to monitor the anticoagulant activity of low-molecular-weight heparin during pregnancy because dose requirements can change, particularly in the third trimester.[132] Monitoring also is important in high-risk settings, such as in patients with mechanical heart valves who are given low-molecular-weight heparin for prevention of valve thrombosis.

Dosing

The doses of low-molecular-weight heparin recommended for prophylaxis or treatment vary depending on the low-molecular-weight heparin preparation. For prophylaxis, once-daily subcutaneous doses of 4000 to 5000 units are often used, whereas doses of 2500 to 3000 units are given when the drug is administered twice daily. For treatment of venous thromboembolism, a dose of 150 to 200 units/kg is given if the drug is administered once daily. If a twice-daily regimen is employed, a dose of 100 units/kg is given. In patients with unstable angina, low-molecular-weight heparin is given subcutaneously on a twice-daily basis at a dose of 100 to 120 units/kg.[124]

Side Effects

The major complication of low-molecular-weight heparin is bleeding. Recent meta-analyses suggest that the risk of major bleeding may be lower with low-molecular-weight heparin than with unfractionated heparin.[133,134] HIT and osteoporosis are less common with low-molecular-weight heparin than with unfractionated heparin.[124]

Bleeding

Like the situation with heparin, bleeding with low-molecular-weight heparin is common in patients receiving concomitant therapy with antiplatelet or fibrinolytic drugs. Recent surgery, trauma, or underlying hemostatic defects also increase the risk of bleeding with low-molecular-weight heparin.[104]

Although protamine sulfate can be used as an antidote for low-molecular-weight heparin, protamine sulfate incompletely neutralizes the anticoagulant activity of low-molecular-weight heparin because it only binds the longer chains of low-molecular-weight heparin.[135] Because longer chains are responsible for catalysis of thrombin inhibition by antithrombin, protamine sulfate completely reverses the antithrombin activity of low-molecular-weight heparin. In contrast, protamine sulfate only partially reverses the anti–factor Xa activity of low-molecular-weight heparin because the shorter pentasaccharide-containing chains of low-molecular-weight heparin do not bind to protamine sulfate. Consequently, patients at high risk for bleeding may be more safely treated with continuous intravenous unfractionated heparin than with subcutaneous low-molecular-weight heparin. In addition to the potential for complete reversal with protamine sulfate, the short half-life of intravenous heparin also is an advantage if major bleeding occurs.

Thrombocytopenia

The risk of HIT is approximately fivefold lower with low-molecular-weight heparin than with heparin.[136,137] Low-molecular-weight heparin binds less avidly to platelets and causes less PF4 release. Furthermore, with lower affinity for PF4 than heparin, low-molecular-weight heparin is less likely to induce the conformational changes in PF4 that trigger the formation of HIT antibodies.

Low-molecular-weight heparin should not be used to treat HIT patients[107,111] because most HIT antibodies exhibit cross reactivity with low-molecular-weight heparin.[138,139] This in vitro cross reactivity is not simply a laboratory phenomenon because there are case reports of thrombosis when HIT patients are treated with low-molecular-weight heparin.

Osteoporosis

The risk of osteoporosis is lower with long-term low-molecular-weight heparin than with heparin.[140] For extended treatment, therefore, low-molecular-weight heparin is a better choice than heparin because of the lower risk of both osteoporosis and HIT.

Fondaparinux

A synthetic analog of the antithrombin-binding pentasaccharide sequence, fondaparinux differs from low-molecular-weight heparin in several ways (Table 137–4). Fondaparinux is licensed for (a) thromboprophylaxis in medical, general surgical and high-risk orthopedic patients, and (b) as an alternative to heparin or low-molecular-weight heparin for initial treatment of patients with established venous thromboembolism. In some countries, fondaparinux also is approved for treatment of patients with acute coronary syndromes.

Table 137–4 Comparison of Low-Molecular-Weight Heparin and Fondaparinux

Features	LMWH	Fondaparinux
Molecular weight	4500–5000	1728
Catalysis of factor Xa inhibition	Yes	Yes
Catalysis of thrombin inhibition	Yes	No
Bioavailability after subcutaneous administration (%)	90	100
Plasma half-life (hours)	4	17
Renal excretion	Yes	Yes
Induces release of tissue factor pathway inhibitor	Yes	No
Neutralized by protamine sulfate	Partially	No

LMWH, low-molecular-weight heparin.

Mechanism of Action

As a synthetic analog of the antithrombin-binding pentasaccharide sequence found in heparin and low-molecular-weight heparin, fondaparinux has a molecular weight of 1728. Fondaparinux binds only to antithrombin (Fig. 137–4) and is too short to bridge thrombin to antithrombin. Consequently, fondaparinux catalyzes factor Xa inhibition by antithrombin and does not enhance the rate of thrombin inhibition.[141]

Pharmacology of Fondaparinux

Fondaparinux exhibits complete bioavailability after subcutaneous injection. With no binding to endothelial cells or plasma proteins, the clearance of fondaparinux is dose independent and its plasma half-life is approximately 17 hours.[142] The drug is given subcutaneously once daily. Because fondaparinux is cleared unchanged via the kidneys, it is contraindicated in patients with a creatinine clearance less than 30 mL/minute and it should be used with caution in those with a creatinine clearance less than 50 mL/minute.[141]

Fondaparinux produces a predictable anticoagulant response after administration in fixed doses because it does not bind to plasma proteins. The drug is given at a dose of 2.5 mg once daily for prevention of venous thromboembolism. For initial treatment of established venous thromboembolism, fondaparinux is given at a dose of 7.5 mg once daily. The dose can be reduced to 5 mg once daily for those weighing less than 50 kg and increased to 10 mg for those more than 100 kg. When given in these doses, fondaparinux is as effective as heparin or low-molecular-weight heparin for initial treatment of patients with deep vein thrombosis or pulmonary embolism and is associated with similar rates of bleeding.[143,144]

Fondaparinux is used at a dose of 2.5 mg once daily in patients with acute coronary syndromes. When this prophylactic dose of fondaparinux was compared with treatment doses of enoxaparin in patients with non-ST-segment elevation acute coronary syndromes, there was no difference in the rate of cardiovascular death, myocardial infarction, or stroke at 9 days.[145] However, the rate of major bleeding was 50% lower with fondaparinux than with enoxaparin, a low-molecular-weight heparin preparation—a difference that likely reflects the fact that the dose of fondaparinux was lower than that of enoxaparin. In acute coronary syndrome patients who require percutaneous coronary interventions, there is a risk of catheter thrombosis with fondaparinux unless adjunctive heparin is given.[146]

Side Effects

Fondaparinux does not cause HIT and, in contrast to low-molecular-weight heparin, there is no cross reactivity of fondaparinux with HIT antibodies. Fondaparinux can induce the formation of HIT antibodies to the same extent as low-molecular-weight heparin, however.[147] In contrast to heparin or low-molecular-weight heparin, fondaparinux is too short to cluster PF4 tetramers together, which is a prerequisite for HIT antibody binding.[148] This phenomenon not only explains why HIT antibodies do not cross-react with fondaparinux, but also explains why fondaparinux does not cause HIT despite the fact that it induces the formation of HIT antibodies. Fondaparinux has been successfully used for HIT treatment.[149] However, large clinical trials supporting the use of fondaparinux for this indication are lacking.

The major side effect of fondaparinux is bleeding. There is no antidote for fondaparinux. Protamine sulfate has no effect on the anticoagulant activity of fondaparinux because it fails to bind to the drug. Recombinant activated factor VII reverses the anticoagulant effects of fondaparinux in volunteers,[150] but it is unknown whether this agent will control fondaparinux-induced bleeding.

Parenteral Direct Thrombin Inhibitors

Heparin and low-molecular-weight heparin are indirect inhibitors of thrombin because their activity is mediated by antithrombin. In contrast, direct thrombin inhibitors do not require a plasma cofactor; instead, these agents bind directly to thrombin and block its interaction with its substrates. Approved parenteral direct thrombin inhibitors include lepirudin (Refludan), argatroban (Novastan), and bivalirudin (Angiomax) (Table 137–5). Lepirudin and argatroban are licensed for treatment of patients with HIT, whereas bivalirudin is approved as an alternative to heparin in patients undergoing percutaneous coronary interventions, including those with HIT.[151]

Table 137–5 Comparison of the Properties of Hirudin, Bivalirudin, and Argatroban

	Hirudin	Bivalirudin	Argatroban
Molecular mass	7000	1980	527
Site(s) of interaction with thrombin	Active site and exosite 1	Active site and exosite 1	Active site
Renal clearance	Yes	No	No
Hepatic metabolism	No	No	Yes
Plasma half-life (minute)	60	25	45

Lepirudin

A recombinant form of hirudin, lepirudin is a bivalent direct thrombin inhibitor that interacts with both the active site and exosite 1, the substrate-binding site, on thrombin.[151] For rapid anticoagulation, lepirudin is given by continuous intravenous infusion, but the drug can be given subcutaneously for thromboprophylaxis. Lepirudin has a plasma half-life of 60 minutes after intravenous infusion and is cleared by the kidneys. Consequently, lepirudin accumulates in patients with renal insufficiency.[152] A high proportion of lepirudin-treated patients develop antibodies against the drug.[153] Although these antibodies rarely cause problems, in a small subset of patients they can delay lepirudin clearance and prolong its anticoagulant activity. Serious bleeding has been reported in some of these patients.[153]

Lepirudin is usually monitored using the aPTT and the dose is adjusted to maintain a aPTT that is 1.5 to 2.5 times the control. The aPTT is not an ideal test for monitoring lepirudin therapy because the clotting time plateaus with higher drug concentrations. Although the ecarin clotting time provides a better index of lepirudin dose than does the aPTT, the ecarin clotting time has yet to be standardized.

Argatroban

A univalent inhibitor that targets the active site of thrombin, argatroban is metabolized in the liver.[151] Consequently, this drug must be used with caution in patients with hepatic insufficiency. Argatroban is not cleared via the kidneys so this drug is safer than lepirudin for HIT patients with renal insufficiency.

Argatroban is administered by continuous intravenous infusion and has a plasma half-life of approximately 45 minutes. The aPTT is used to monitor its anticoagulant effect and the dose is adjusted to achieve a aPTT 1.5 to 3 times the baseline value, but not to exceed 100 seconds. Argatroban also prolongs the international normalized ratio (INR), a feature that can complicate the transitioning of patients from argatroban to warfarin.[154] This problem can be circumvented by using the levels of factor X to monitor warfarin in place of the INR. Alternatively, the argatroban infusion can be stopped for 2 to 3 hours prior to INR determination.

Bivalirudin

A synthetic 20-amino acid analog of hirudin, bivalirudin is a divalent thrombin inhibitor.[151] Thus, the N-terminal portion of bivalirudin interacts with the active site of thrombin, whereas its C-terminal tail binds to exosite 1, the substrate-binding domain on thrombin. Bivali-

rudin has a plasma half-life of 25 minutes, the shortest half-life of all the parenteral direct thrombin inhibitors.[151] Bivalirudin is degraded by peptidases and is partially excreted via the kidneys. When given in high doses in the cardiac catheterization laboratory, the anticoagulant activity of bivalirudin is monitored using the activated clotting time. With lower doses, its activity can be assessed using the aPTT.

Studies comparing bivalirudin with heparin suggest that bivalirudin produces less bleeding.[155,156] This feature plus its short half-life make bivalirudin an attractive alternative to heparin in patients undergoing percutaneous coronary interventions,[157] and it is licensed for this indication. Bivalirudin also is approved for management of HIT patients who require percutaneous coronary interventions.[158]

ORAL ANTICOAGULANTS

Current oral anticoagulant practice dates back almost 60 years to when the vitamin K antagonists were discovered as a result of investigations into the cause of hemorrhagic disease in cattle. Characterized by a decrease in prothrombin levels, this disorder is caused by ingestion of hay containing spoiled sweet clover. Hydroxycoumarin, which was isolated from bacterial contaminants in the hay, interferes with vitamin K metabolism, thereby causing a syndrome similar to vitamin K deficiency. A variety of coumarin derivatives are available. The agent most widely used in North America is warfarin.

Warfarin

A water-soluble vitamin K antagonist, warfarin was initially developed as a rodenticide. Like other vitamin K antagonists, warfarin interferes with the synthesis of the vitamin K-dependent clotting proteins, which include prothrombin and factors VII, IX, and X. The synthesis of the vitamin K-dependent anticoagulant proteins, proteins C and S, also is reduced by vitamin K antagonists.

Mechanism of Action

All of the vitamin K-dependent clotting factors possess glutamic acid residues at their N-termini. A posttranslational modification adds a carboxyl group to the γ-carbon of these residues to generate γ-carboxyglutamic acid.[159] This modification is essential for expression of the activity of these clotting factors because it permits their calcium-dependent binding to negatively charged phospholipid surfaces.[160,161] The γ-carboxylation process is catalyzed by a vitamin K-dependent carboxylase. Thus, vitamin K from the diet is reduced to vitamin K hydroquinone by vitamin K reductase (Fig. 137–7). Vitamin K hydroquinone serves as a cofactor for the carboxylase enzyme, which in the presence of carbon dioxide replaces the hydrogen on the γ-carbon of glutamic acid residues with a carboxyl group. During this process, vitamin K hydroquinone is oxidized to vitamin K epoxide, which is then reduced to vitamin K by vitamin K epoxide reductase.[162]

Warfarin inhibits vitamin K epoxide reductase (VKOR), thereby blocking the γ-carboxylation process.[162,163] This results in the synthesis of vitamin K-dependent clotting proteins that are only partially γ-carboxylated.[164] Warfarin acts as an anticoagulant because these partially γ-carboxylated proteins have reduced or absent biological activity. The onset of action of warfarin is delayed until the newly synthesized clotting factors with reduced activity gradually replace their fully active counterparts.

The antithrombotic effect of warfarin depends on a reduction in the functional levels of factor X and prothrombin, clotting factors that have half-lives of 24 and 72 hours, respectively.[165] Because of the delay in achieving an antithrombotic effect, initial treatment with warfarin is supported by concomitant administration of a rapidly acting parenteral anticoagulant, such as heparin, low-molecular-weight heparin, or fondaparinux, in patients with established thrombosis or at high risk for thrombosis.[126]

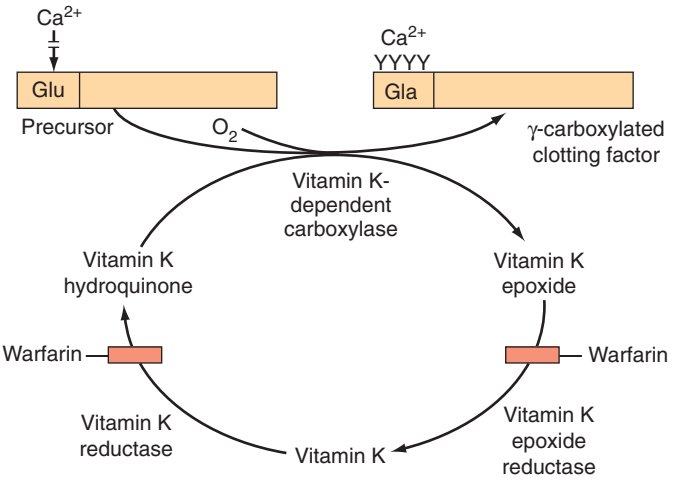

Figure 137–7 The vitamin K cycle and its inhibition by warfarin. Dietary vitamin K is reduced by vitamin K reductase to generate vitamin K hydroquinone. Vitamin K hydroquinone serves as a cofactor for the vitamin K-dependent carboxylase that converts glutamic acid residues at the N-termini of the vitamin K-dependent precursors to γ-carboxyglutamic acid residues, thereby creating the so-called Gla-domain. By binding calcium, the Gla-domain is critical for the interaction of the vitamin K-dependent clotting factors with negatively charged phospholipid membranes. During vitamin K-dependent carboxylation, vitamin K is oxidized to vitamin K epoxide. Vitamin K epoxide is then converted to vitamin K by vitamin K epoxide reductase. Vitamin K antagonists, such as warfarin, interfere with this cycle by inhibiting vitamin K epoxide reductase and vitamin K reductase. Of these two enzymes, vitamin K epoxide reductase is more readily blocked by vitamin K antagonists than vitamin K reductase. Consequently, supplemental vitamin K can overcome the inhibitory effects of vitamin K antagonists.

Pharmacology

Warfarin is a racemic mixture of *R* and *S* isomers. Of these, the *S* isomer is more active. Warfarin is rapidly and almost completely absorbed from the gastrointestinal tract. Levels of warfarin in the blood peak approximately 90 minutes after drug administration.[165] Racemic warfarin has a plasma half-life of 36 to 42 hours, and more than 97% of circulating warfarin is bound to albumin. It is only the small fraction of unbound warfarin that is biologically active.[165]

Warfarin accumulates in the liver, where the two isomers are metabolized via distinct pathways. Oxidative metabolism of the *S* isomer is effected by CYP2C9. Two relatively common variants, *CYP2C9*2* and *CYP2C9*3*, have reduced activity. Patients with these variants require lower maintenance doses of warfarin. Polymorphisms in *VKORC1* also can influence the anticoagulant response to warfarin.[166,167] These findings have prompted a recommendation that patients starting on warfarin should be tested for these polymorphisms and that this information should be incorporated into their warfarin-dosing algorithms. Whether this approach will increase the efficacy and/or safety of warfarin therapy is unproven.

In addition to genetic factors, the anticoagulant effect of warfarin is influenced by diet, drugs, and various disease states. Fluctuations in dietary vitamin K intake affect the activity of warfarin. A wide variety of drugs can alter absorption, clearance, or metabolism of warfarin.[165] Because of the variability in the anticoagulant response to warfarin, coagulation monitoring is essential to ensure that a therapeutic response is obtained.

Monitoring

Warfarin therapy is most often monitored using the prothrombin time, a test that is sensitive to reductions in the levels of prothrombin,

factor VII, and factor X.[165] The test is performed by adding thromboplastin, a reagent that contains tissue factor, phospholipid, and calcium, to citrated plasma and determining the time to clot formation. Thromboplastins vary in their sensitivity to reductions in the levels of the vitamin K-dependent clotting factors. Consequently, less sensitive thromboplastins will prompt the administration of higher doses of warfarin to achieve a target prothrombin time. This is problematic because higher doses of warfarin increase the risk of bleeding.

The international normalized ratio (INR) was developed to circumvent many of the problems associated with the prothrombin time assay. To calculate the INR, the patient's prothrombin time is divided by the mean normal prothrombin time and this ratio is then multiplied by the international sensitivity index (ISI), an index of the sensitivity of the thromboplastin used for prothrombin time determination to reductions in the levels of the vitamin K-dependent clotting factors. Highly sensitive thromboplastins have an ISI of 1.0. Most current thromboplastins have ISI values that range from 1.0 to 1.4.[165]

Although the INR has helped standardize anticoagulant practice, problems persist. The precision of INR determination varies depending on reagent–instrumentation combinations. This leads to variability in the INR results. Also complicating INR determination is unreliable reporting of the ISI by thromboplastin manufacturers.[165] Furthermore, every laboratory must establish the mean normal prothrombin time with each new batch of thromboplastin reagent. To accomplish this, the prothrombin time must be measured in fresh plasma samples from at least 20 healthy volunteers using the same instrumentation that is used for patient samples.[165]

For most indications, warfarin is administered in doses that produce a target INR of 2.0 to 3.0. An exception is patients with mechanical heart valves where a target INR of 2.5 to 3.5 is recommended.[165] Vitamin K antagonists have a narrow therapeutic window. Thus, studies in atrial fibrillation demonstrate an increased risk of cardioembolic stroke when the INR falls below 1.7 and an increase in bleeding with INR values greater than 4.5.[168] Likewise, a study in patients receiving long-term warfarin therapy for unprovoked venous thromboembolism demonstrated a higher rate of recurrent venous thromboembolism when the warfarin dose was adjusted to achieve a target INR of 1.5 to 1.9 than with a target INR of 2.0 to 3.0. Rates of major bleeding were similar.[169]

Dosing

Warfarin is usually started at a dose of 5 to 10 mg. The dose is then titrated to achieve the desired target INR. Because of its delayed onset of action, patients with established thrombosis or those at high risk for thrombosis are given concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, low-molecular-weight heparin, or fondaparinux. Initial prolongation of the INR reflects reduction in the functional levels of factor VII. Consequently, concomitant treatment with the parenteral anticoagulant should be continued until the INR has been therapeutic for at least 2 consecutive days. A minimum 5-day course of parenteral anticoagulation is recommended to ensure that the levels of prothrombin have been reduced into the therapeutic range with warfarin.[165]

Because warfarin has a narrow therapeutic window, frequent coagulation monitoring is essential to ensure that a therapeutic anticoagulant response is obtained. Even patients with stable warfarin dose requirements should have their INR determined every 2 to 4 weeks. More frequent monitoring is necessary when new medications are introduced because so many drugs enhance or reduce the anticoagulant effects of warfarin.

Side Effects

Like all anticoagulants, the major side effect of warfarin is bleeding. A rare complication is skin necrosis. Warfarin crosses the placenta and can cause fetal abnormalities. Consequently, warfarin is contraindicated during pregnancy.

Bleeding

At least half of the bleeding complications with warfarin occur when the INR exceeds the therapeutic range. Bleeding complications may be mild, such as epistaxis or hematuria, or more severe, such as retroperitoneal or gastrointestinal bleeding. Life-threatening intracranial bleeding also can occur.[165]

To minimize the risk of bleeding, the INR should be maintained in the therapeutic range. In asymptomatic patients whose INR is between 3.5 and 4.5, warfarin should be withheld until the INR returns to the therapeutic range. If the INR is greater than 4.5, a therapeutic INR can be achieved more rapidly by administration of low doses of sublingual vitamin K.[170,171] A sublingual vitamin K dose of 1 mg usually is adequate for patients with an INR between 4.9 and 9, whereas 2 to 3 mg can be used for those with an INR greater than 9. Higher doses of vitamin K can be administered if more rapid reversal of the INR is required or if the INR is excessively high.

Patients with serious bleeding need more aggressive treatment. These patients should be given 10 mg of vitamin K by slow intravenous infusion. Additional vitamin K should be given until the INR is in the normal range. Treatment with vitamin K should be supplemented with fresh frozen plasma as a source of the vitamin K-dependent clotting proteins. For life-threatening bleeds, or if patients cannot tolerate the volume load, recombinant factor VIIa or prothrombin complex concentrates can be used.

Warfarin-treated patients who experience bleeding when their INR is in the therapeutic range require investigation into the cause of the bleeding. Those with gastrointestinal bleeding often have underlying peptic ulcer disease or a tumor. Similarly, investigation of hematuria or uterine bleeding in patients with a therapeutic INR may unmask a tumor of the genitourinary tract.

Skin Necrosis

A rare complication of warfarin, skin necrosis usually is seen 2 to 5 days after initiation of therapy. Well-demarcated erythematous lesions form on the thighs, buttocks, breasts, or toes. Typically, the center of the lesion becomes progressively necrotic. Examination of skin biopsies taken from the border of these lesions reveals thrombi in the microvasculature.

Warfarin-induced skin necrosis is seen in patients with congenital or acquired deficiencies of protein C or protein S.[172,173] Initiation of warfarin therapy in these patients produces a precipitous fall in plasma levels of proteins C or S, thereby eliminating this important anticoagulant pathway before warfarin exerts an antithrombotic effect through lowering of the functional levels of factor X and prothrombin. The resultant procoagulant state triggers thrombosis. Why the thrombosis is localized to the microvasculature of fatty tissues is unclear.

Treatment involves discontinuation of warfarin and reversal with vitamin K, if needed. An alternative anticoagulant, such as heparin or low-molecular-weight heparin, should be given in patients with thrombosis. Protein C concentrates or recombinant activated protein C can be given to protein C-deficient patients to accelerate healing of the skin lesions; fresh frozen plasma may be of value for those with protein S deficiency. Occasionally, skin grafting is necessary when there is extensive skin loss.

Because of the potential for skin necrosis, patients with known protein C or protein S deficiency require overlapping treatment with a parenteral anticoagulant when initiating warfarin therapy. Warfarin should be started in low doses in these patients and the parenteral anticoagulant should be continued until the INR is therapeutic for at least 2 to 3 consecutive days.

Pregnancy

Warfarin crosses the placenta and can cause fetal abnormalities or bleeding. The fetal abnormalities include a characteristic embryopathy, which consists of nasal hypoplasia and stippled epiphyses. The risk of embryopathy is highest if warfarin is given in the first trimester of pregnancy.[174] Central nervous system abnormalities also can occur with exposure to coumarins at any time during pregnancy. Finally, maternal administration of warfarin produces an anticoagulant effect in the fetus that can cause bleeding. This is of particular concern at delivery when trauma to the head during passage through the birth canal can lead to intracranial bleeding. Because of these potential problems, warfarin is contraindicated in pregnancy. Instead, heparin, low-molecular-weight heparin, or fondaparinux can be given during pregnancy for prevention or treatment of thrombosis.

Warfarin does not pass into the breast milk. Consequently, warfarin can safely be administered to nursing mothers.[174]

Special Problems

Patients with a lupus anticoagulant or those who need urgent or elective surgery present special challenges. Although observational studies suggested that patients with thrombosis complicating the antiphospholipid antibody syndrome required higher-intensity warfarin regimens to prevent recurrent thromboembolic events, two recent randomized trial demonstrated that targeting an INR of 2.0 to 3.0 is as effective as higher-intensity treatment and produces less bleeding.[175,176] Monitoring warfarin therapy can be problematic in patients with antiphospholipid antibody syndrome if the lupus anticoagulant prolongs the baseline INR.

If patients receiving long-term warfarin treatment require an elective invasive procedure, warfarin can be stopped 5 days prior to the procedure to allow the INR to return to normal levels. Those at high risk for recurrent thrombosis can be bridged with once- or twice-daily subcutaneous injections of low-molecular-weight heparin when the INR falls below 2.0. The last dose of low-molecular-weight heparin should be given 12 to 24 hours prior to the procedure, depending on whether low-molecular-weight heparin is administered twice or once daily, respectively. After the procedure, treatment with warfarin can be restarted.

New Oral Anticoagulants

New oral anticoagulants that target thrombin or factor Xa are under development.[177] These drugs have a rapid onset of action and have half-lives that permit once- or twice-daily administration. Designed to produce a predictable level of anticoagulation, these new oral agents can be given in fixed doses without coagulation monitoring. Therefore, these drugs will be more convenient to administer than warfarin. The results of ongoing phase II and III clinical trials will determine the role of these new oral anticoagulants in the prevention and treatment of thrombosis.

FIBRINOLYTIC DRUGS

Role of Fibrinolytic Therapy

Used to degrade thrombi, fibrinolytic drugs can be administered systemically or they can be delivered via catheters directly into the substance of the thrombus. Systemic delivery is used for treatment of acute myocardial infarction, acute ischemic stroke and most cases of massive pulmonary embolism. The goal of therapy is to produce rapid thrombus dissolution, thereby restoring antegrade blood flow. In the coronary circulation, restoration of blood flow reduces morbidity and mortality by limiting myocardial damage, whereas in the cerebral circulation, rapid thrombus dissolution decreases the neuronal death and brain infarction that produce irreversible brain injury. For patients with massive pulmonary embolism, the goal of fibrinolytic therapy is to restore pulmonary artery perfusion.

Peripheral arterial thrombi and thrombi in the proximal deep veins of the leg are most often treated using a catheter-directed approach. Catheters with multiple side holes can be utilized to deliver fibrinolytic drugs. In some cases, intravascular devices that fragment and extract the thrombus are used to hasten treatment. Although these devices can be used alone, they are often used in conjunction with fibrinolytic agents.

Mechanism of Action

Currently approved fibrinolytic agents include streptokinase, acylated plasminogen streptokinase activator complex (anistreplase), urokinase, recombinant tissue-type plasminogen activator (rt-PA) (Alteplase; Activase), and two recombinant derivatives of rt-PA, tenecteplase (TNKase) and reteplase (Retaplase). All of these agents act by converting the proenzyme, plasminogen, to plasmin, the active enzyme (Fig. 137–8). Plasmin then degrades the fibrin matrix of thrombi, thereby producing soluble fibrin degradation products.[178]

Endogenous fibrinolysis is regulated at two levels. Plasminogen activator inhibitors, particularly the type 1 form, known as PAI-1,[179] prevent excessive plasminogen activation by regulating the activity of t-PA and urokinase-type plasminogen activator (u-PA). Once plasmin is generated, it is regulated by plasmin inhibitors, the most important of which is α_2-antiplasmin. The plasma concentration of plasminogen is twofold higher than that of α_2-antiplasmin. Consequently, with pharmacological doses of plasminogen activators, the concentration of plasmin that is generated can exceed that of α_2-antiplasmin.[180] In addition to degrading fibrin, unregulated plasmin also can degrade fibrinogen and other clotting factors. This process, which is known as the systemic lytic state, reduces the hemostatic potential of the blood and increases the risk of bleeding.

The endogenous fibrinolytic system is geared to localize plasmin generation to the fibrin surface. Both plasminogen and *t*-PA bind to fibrin to form a ternary complex that promotes efficient plasminogen activation.[181–183] In contrast to free plasmin, plasmin generated on the fibrin surface is relatively protected from inactivation by α_2-antiplasmin, a feature that promotes fibrin dissolution.[184,185] Furthermore, C-terminal lysine residues exposed as plasmin degrades fibrin serve as binding sites for additional plasminogen and t-PA molecules. This creates a positive feedback that enhances plasmin generation. When used pharmacologically, the various plasminogen activators capitalize on these mechanisms to a lesser or greater extent.

There are two pools of plasminogen: circulating plasminogen and fibrin-bound plasminogen (Fig. 137–9). Plasminogen activators that preferentially activate fibrin-bound plasminogen are considered fibrin-specific. In contrast, nonspecific plasminogen activators do not

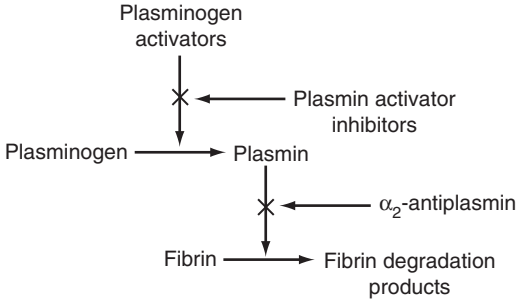

Figure 137–8 Fibrinolytic system and its regulation. Plasminogen activators convert plasminogen to plasmin. Plasmin then degrades fibrin into soluble fibrin degradation products. The system is regulated at two levels. Type 1 plasminogen activator inhibitor (PAI-1) regulates the plasminogen activators, whereas α_2-antiplasmin serves as the major inhibitor of plasmin.

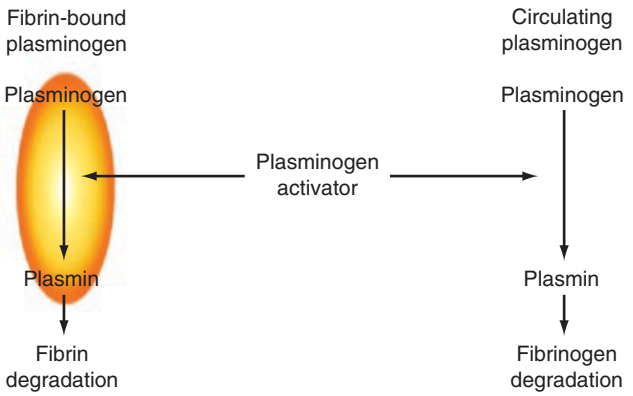

Figure 137–9 Consequences of activation of fibrin-bound or circulating plasminogen. The fibrin specificity of plasminogen activators reflects their capacity to distinguish between fibrin-bound and circulating plasminogen. This, in turn, reflects their affinity for fibrin. Plasminogen activators with high affinity for fibrin preferentially activate fibrin-bound plasminogen. This results in the generation of plasmin on the fibrin surface. Fibrin-bound plasmin, which is protected from inactivation by α_2-antiplasmin, degrades fibrin to yield soluble fibrin degradation products. In contrast, plasminogen activators with little or no affinity for fibrin do not distinguish between fibrin-bound and circulating plasminogen. Activation of circulating plasminogen results in systemic plasminemia and subsequent degradation of fibrinogen and other clotting factors.

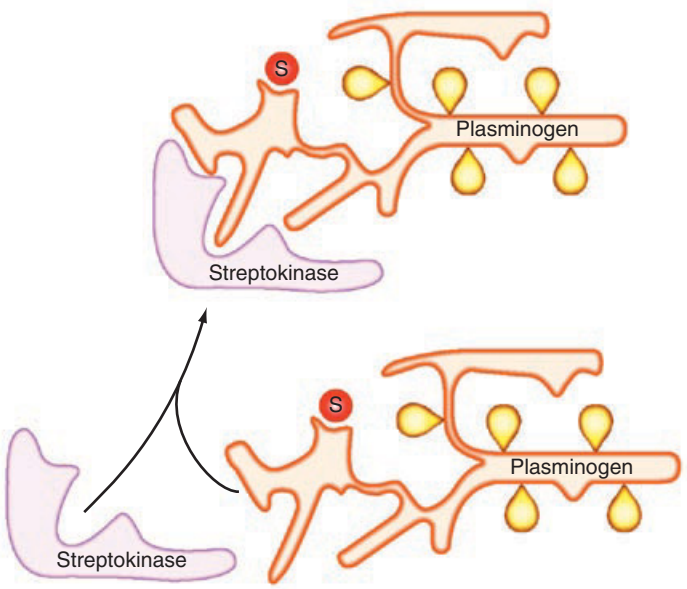

Figure 137–10 Mechanism of action of streptokinase. Streptokinase binds to plasminogen and induces a conformational change in plasminogen that exposes its active site. The streptokinase/plasmin(ogen) complex then serves as the activator of additional plasminogen molecules.

discriminate between fibrin-bound and circulating plasminogen. Activation of circulating plasminogen results in the generation of unopposed plasmin that can trigger the systemic lytic state. Alteplase and its derivatives are fibrin-specific plasminogen activators, whereas streptokinase, anistreplase, and urokinase are nonspecific agents.

Streptokinase

Unlike other plasminogen activators, streptokinase is not an enzyme and does not directly convert plasminogen to plasmin. Instead, streptokinase forms a 1 : 1 stoichiometric complex with plasminogen. Formation of this complex induces a conformational change in plasminogen that exposes its active site (Fig. 137–10). This conformationally altered plasminogen then converts additional plasminogen molecules to plasmin.[186]

Streptokinase has no affinity for fibrin and the streptokinase–plasminogen complex activates both free and fibrin-bound plasminogen. Activation of circulating plasminogen generates sufficient amounts of plasmin to overwhelm α_2-antiplasmin. Unopposed plasmin not only degrades fibrin in the occlusive thrombus but also induces a systemic lytic state.[187]

When given systemically to patients with acute myocardial infarction, streptokinase reduces mortality.[188,189] For this indication, the drug is usually given as an intravenous infusion of 1.5 million units over 30 to 60 minutes. Patients who receive streptokinase can develop antibodies against the drug as can patients with prior streptococcal injection. These antibodies can reduce the effectiveness of streptokinase.

Allergic reactions occur in approximately 5% of patients treated with streptokinase.[190] These may manifest as a rash, fever, chills, and rigors. Although anaphylactic reactions can occur, these are rare. Transient hypotension is common with streptokinase and has been attributed to plasmin-mediated release of bradykinin from kallikrein.[191] The hypotension usually responds to leg elevation and administration of intravenous fluids and low doses of vasopressors, such as dopamine or norepinephrine.[192]

Anistreplase

To generate this drug, streptokinase is combined with equimolar amounts of Lys-plasminogen, a plasmin-cleaved form of plasminogen with a lysine residue at its N-terminal. The active site of Lys-plasminogen that is exposed on combination with streptokinase is then masked with an anisoyl group. After intravenous infusion, the anisoyl group is slowly removed by deacylation, giving the complex a half-life of approximately 100 minutes. This allows drug administration via a single bolus infusion.

Although it is more convenient to administer, anistreplase offers few mechanistic advantages over streptokinase. Like streptokinase, anistreplase does not distinguish between fibrin-bound and circulating plasminogen. Consequently, it too produces a systemic lytic state. Likewise, allergic reactions and hypotension are just as frequent with anistreplase as they are with streptokinase.[193]

When anistreplase was compared with ateplase in patients with acute myocardial infarction, reperfusion was obtained more rapidly with alteplase than with anistreplase.[194] Improved reperfusion was associated with a trend toward better clinical outcomes and reduced mortality with alteplase. These results and the high cost of anistreplase have dampened the enthusiasm for its use.

Urokinase

Derived from cultured fetal kidney cells, urokinase is a two-chain serine protease with a molecular weight of 34,000.[195] Urokinase directly converts plasminogen to plasmin by cleaving the Arg560–Val561 bond. Unlike streptokinase, urokinase is not immunogenic and allergic reactions are rare. Urokinase produces a systemic lytic state because it does not discriminate between fibrin-bound and circulating plasminogen.

Despite many years of use, urokinase has never been systemically evaluated for coronary fibrinolysis. Instead, urokinase is often employed for catheter-directed lysis of thrombi in the deep veins or the peripheral arteries. Because of recent production problems, the availability of urokinase is limited.

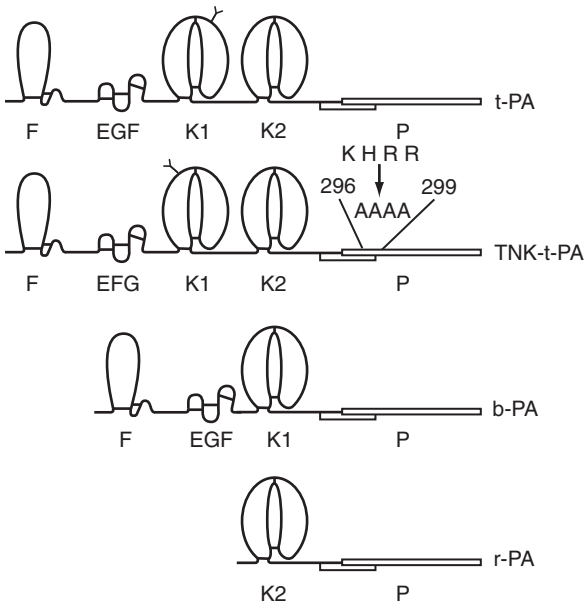

Figure 137–11 Domain structures of alteplase (*t*-PA), tenecteplase (TNK-*t*-PA), desmoteplase (b-PA), and reteplase (r-PA). The finger (F), epidermal growth factor (EGF), first and second kringles (K1 and K2, respectively), and protease (P) domains are illustrated. The glycosylation site (Y) on K1 has been repositioned in tenecteplase to endow it with a longer half-life. In addition, a tetra-alanine substitution in the protease domain renders tenecteplase resistant to PAI-1 inhibition. Desmoteplase differs from alteplase and teneteplase in that it lacks a K2 domain. Reteplase is a truncated variant that lacks the F, EGF, and K1 domains.

Alteplase

A recombinant form of single-chain t-PA, Alteplase has a molecular weight of 68,000.[196] Alteplase is rapidly converted into its two-chain form by plasmin. Although single- and two-chain forms of t-PA have equivalent activity in the presence of fibrin, in its absence, single-chain t-PA has 10-fold lower activity.[197,198]

Alteplase consists of five discrete domains (Fig. 137–11). The N-terminal A-chain of two-chain Alteplase contains four of these domains; residues 4 through 50 make up the finger domain, a region that resembles the finger domain of fibronectin, resides 50 through 87 are homologous with epidermal growth factor, whereas residues 92 through 173 and 180 through 261, which have homology to the kringle domains of plasminogen, are designated as the first and second kringle, respectively. The fifth Alteplase domain is the protease domain; it is located on the C-terminal B-chain of two-chain Alteplase.

The interaction of Alteplase with fibrin is mediated by the finger domain, and to a lesser extent, by the second kringle domain.[199,200] The affinity of Alteplase for fibrin is considerably higher than that for fibrinogen.[200] Consequently, the catalytic efficiency of plasminogen activation by Alteplase is two to three orders of magnitude higher in the presence of fibrin than in the presence of fibrinogen. This phenomenon helps to localize plasmin generation to the fibrin surface.

Although Alteplase preferentially activates plasminogen in the presence of fibrin, Alteplase is not as fibrin-selective as was first predicted. Its fibrin specificity is limited because like fibrin, the fibrin fragments (DD)E, the major soluble degradation product of cross-linked fibrin,[201] binds Alteplase and plasminogen with high affinity.[200] Consequently, (DD)E is as potent as fibrin as a stimulator of plasminogen activation by Alteplase. Whereas plasmin generated on the fibrin surface results in thrombolysis, plasmin generated on the surface of circulating (DD)E degrades fibrinogen.[202] Fibrinogenolysis results in the accumulation of fragment X, a high molecular weight clottable fibrinogen degradation product. Incorporation of fragment X into hemostatic plugs formed at sites of vascular injury renders them susceptible to lysis.[203–205] This phenomenon may contribute to Alteplase-induced bleeding.

A trial comparing Alteplase with streptokinase for treatment of patients with acute myocardial infarction demonstrated significantly lower mortality with Alteplase than with streptokinase,[206] although the absolute difference was small. The greatest benefit was seen in patients less than 75 years of age with anterior myocardial infarction who presented less than 6 hours after symptom onset.

For treatment of acute myocardial infarction or acute ischemic stroke, Alteplase is given as an intravenous infusion over 60 to 90 minutes. The total dose of Alteplase usually ranges from 90 to 100 mg. Allergic reactions and hypotension are rare and Alteplase is not immunogenic.[190]

Tenecteplase

A genetically engineered variant of t-PA, tenecteplase was designed to have a longer half-life than t-PA and to be resistant to inactivation by PAI-1.[207] To prolong its half-life, a new glycosylation site was added to the first kringle domain (Fig. 137–11). Because addition of this extra carbohydrate side chain reduced fibrin affinity, the existing glycosylation site on the first kringle domain was removed. To render the molecule resistant to inhibition by PAI-1, a tetra-alanine substitution was introduced at residues 296–299 in the protease domain, the region responsible for the interaction of t-PA with PAI-1.[207–209]

Tenecteplase is more fibrin-specific than t-PA. Although both agents bind to fibrin with similar affinity, the affinity of tenecteplase for (DD)E is significantly lower than that of t-PA.[210] Consequently, (DD)E does not stimulate systemic plasminogen activation by tenecteplase to the same extent as t-PA. As a result, tenecteplase produces less fibrinogenolysis than t-PA.

For coronary fibrinolysis, tenecteplase is given as a single intravenous bolus. In a large phase III trial that enrolled more than 16,000 patients, the 30-day mortality rate with single bolus tenecteplase was similar to that with accelerated dose t-PA.[211] Although rates of intracranial hemorrhage also were similar with both treatments, patients given tenecteplase had fewer noncerebral bleeds and a reduced need for blood transfusions than those treated with t-PA.[211] The improved safety profile of tenecteplase likely reflects its enhanced fibrin specificity.

Reteplase

A recombinant *t*-PA derivative, reteplase is a single-chain variant that lacks the finger, epidermal growth factor, and first kringle domains (Fig. 137–11). This truncated derivative has a molecular weight of 39,000.[212] Reteplase binds fibrin more weakly than t-PA because it lacks the finger domain.[213] Because it is produced in *Escherichia coli*, reteplase is not glycosylated. This endows it with a plasma half-life longer than that of t-PA. Consequently, reteplase is given as two intravenous boluses, which are separated by 30 minutes.[214] Clinical trials have demonstrated that reteplase is at least as effective as streptokinase for treatment of acute myocardial infarction,[214] but the agent is not superior to t-PA.[215]

New Fibrinolytic Agents

Several new drugs are under investigation. These include desmoteplase (Fig. 137–11), a recombinant form of the full-length plasminogen activator isolated from the saliva of the vampire bat,[216,217] and alfimeprase, a truncated form of fibrolase, an enzyme isolated from the venom of the southern copperhead snake.[218] Desmoteplase, which is more fibrin-specific than t-PA,[200,219,220] is being investigated for the treatment of acute ischemic stroke. With a potential for enhanced safety, desmoteplase may extend the window for treatment beyond 3 hours. An ongoing phase III clinical trial is exploring this possibility.

Alfimeprase is a metalloproteinase that degrades fibrin and fibrinogen in a plasmin-independent fashion.[218] In the circulation, alfimeprase is inhibited by α_2-macroglobulin.[179] Therefore, the drug must be delivery to the thrombus via a catheter. Once localized on the thrombus, alfimeprase produces rapid fibrin degradation.

Arterial and venous thrombosis reflect a complex interplay among the vessel wall, platelets, the coagulation system, and the fibrinolytic pathways. Activation of coagulation also triggers inflammatory pathways that may contribute to thrombogenesis. A better understanding of the biochemistry of blood coagulation and advances in structure-based drug design have identified new targets and resulted in the development of novel antithrombotic drugs. Well-designed clinical trials have provided detailed information on which drugs to use and when to use them. Despite these advances, however, arterial and venous thromboembolic disorders remain a major cause of morbidity and mortality. Therefore, the search for better targets and more potent or more convenient antiplatelet, anticoagulant, and fibrinolytic drugs continues.

IMMUNE THROMBOCYTOPENIC PURPURA, NEONATAL ALLOIMMUNE THROMBOCYTOPENIA, AND POSTTRANSFUSION PURPURA

James Bussel and Douglas B. Cines

IMMUNE THROMBOCYTOPENIC PURPURA

Introduction

Immune thrombocytopenic purpura (ITP) is the most common cause of acquired severe thrombocytopenia. ITP has been estimated to affect approximately 1 in 10,000 in the general population, about half of whom are children, and to account for 0.18% of hospital admissions (reviewed in reference 1). The clinical presentation varies from severe thrombocytopenia and bleeding to the discovery of mild asymptomatic thrombocytopenia during evaluation of another illness or during routine annual checkup.[2] ITP can occur as an isolated condition or it may accompany other systemic disorders, requiring separate or integrated management. ITP in pregnant women has more limited therapeutic options and is infrequently complicated by severe neonatal thrombocytopenia. ITP is caused by autoreactive antibodies that bind to platelets and shorten their lifespan. Substantial strides have been made toward understanding the pathophysiology of ITP, including the role of persistent infection in certain cases and the understanding that platelet production may be impaired. Important new treatment modalities, each with their own efficacy, side effects, tolerability, and cost, have been introduced. Practice guidelines were developed in the United States in 1996[3] and the United Kingdom in 2003,[4] but require updating. The intent of this chapter is to review the clinical features of ITP, consider new developments in diagnosis and in management, and provide the practitioner with our view of how these are best incorporated into patient care. The discussion of ITP in adults and children is separated to emphasize the issues pertinent to each population, but general concerns common to both are covered in the section on adults.

Immune Thrombocytopenic Purpura in Adults

Presentation

It had long been thought that in adults, ITP occurs most commonly in women during the second and third decades of life.[5] Recent surveillance studies indicate that ITP may actually be more common in older individuals of both sexes in some settings.[6,7] Patients may come to medical attention with platelet counts between 10,000 and 20,000/μL because they develop petechiae, purpura or ecchymoses, and/or epistaxis over the course of several days. Those with platelet counts between 30,000 and 50,000/μL often give a history of easy bruising. Patients with platelet counts below 10,000/μL are more likely to have widespread cutaneous bruising accompanied by bleeding from mucosal sites, including epistaxis, gingival bleeding, hematuria, menorrhagia or, less commonly, melena. Rarely, the presentation is intracranial hemorrhage or significant bleeding at other internal sites. Platelet counts above 50,000/μL are likely to be discovered incidentally.[8] Most patients are otherwise in their usual state of health, although chronic fatigue, inability to focus, and similar protean complaints are not uncommon.[9] Few adults give a history of a viral illness in the preceding weeks. A few show evidence of another systemic disorder associated with immune thrombocytopenia. However, the typical patient is well with the exception of bleeding and possibly fatigue.

Differential Diagnosis

ITP is the most common cause of severe thrombocytopenia in otherwise healthy young adults. ITP remains a diagnosis of exclusion.[3,4] Other disorders that need to be considered are divided into those that cause isolated thrombocytopenia and those usually associated with additional hematologic abnormalities. The former include inherited thrombocytopenia (Chapter 32), drug-induced thrombocytopenia (Chapter 140), and secondary immune thrombocytopenias (see below), including HIV and hepatitis C infection (Chapter 158). During pregnancy, the differential diagnosis also includes gestational thrombocytopenia, preeclampsia and HELLP, and less commonly other disorders. Other causes of thrombocytopenia are generally evident from the initial presentation (Chapter 121). Among elderly adults, the major additional consideration is myelodysplasia in which thrombocytopenia can precede other manifestations by months to years.[10] Myelodysplasia with a relatively normal-appearing bone marrow and refractory ITP can be virtually indistinguishable on presentation. Thrombocytopenia with additional hematologic abnormalities has multiple causes, including hypersplenism, leukemia, aplastic anemia, and the thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS) or disseminated intravascular coagulation (DIC), among others (Chapters 139 and 140).

Initial Evaluation

The physical examination reveals only signs of bleeding, typically petechiae and purpura unless there are comorbid conditions. Splenomegaly or lymphadenopathy suggests another diagnosis or an underlying illness with secondary thrombocytopenia. The blood counts are normal except for the platelet count unless there has been significant bleeding, in which case normocytic or, if chronic bleeding has led to iron deficiency, microcytic anemia may be seen. Thrombocytopenia determined by automated analyzer must be confirmed by examination of the peripheral blood smear to exclude pseudothrombocytopenia (see below) and hematologic conditions that affect multiple cell lines (Fig. 138–1). Platelet size is increased in many patients; however, the mean platelet volume determined by automated counter is inaccurate at very low platelet counts and platelets consistently approaching the size of erythrocytes are more typical of hereditary macrothrombocytopenias. Conversely, unusually small platelets are associated with Wiskott–Aldrich syndrome. Schistocytes should suggest TTP, HUS, or DIC (Chapters 132 and 139) and

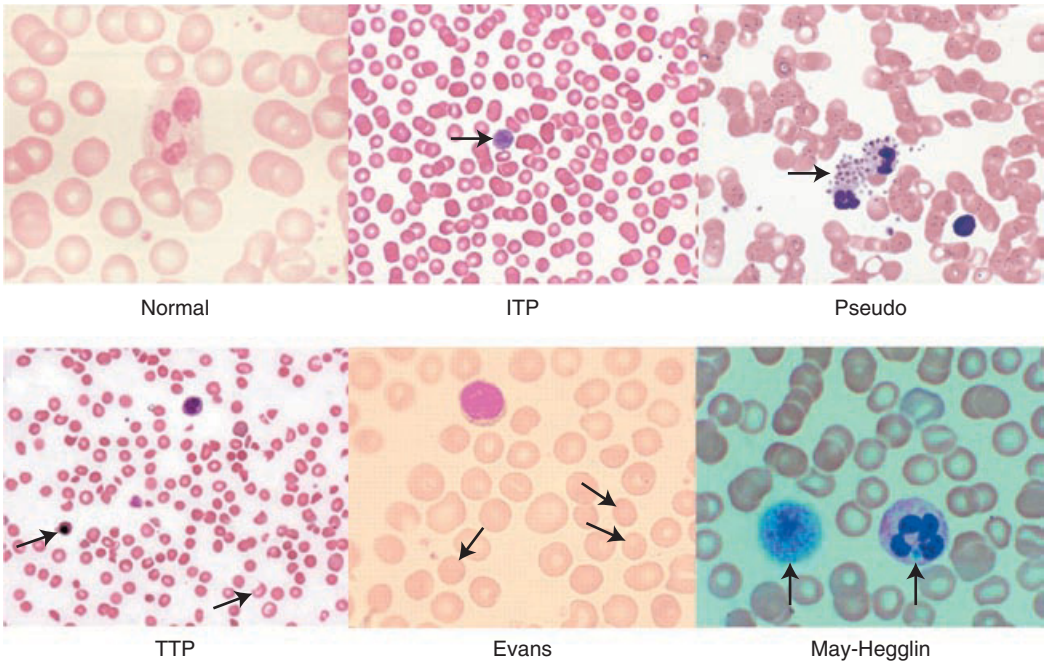

Figure 138–1 Peripheral blood smear in immune thrombocytopenic purpura (ITP) and other conditions. Normal: Blood smear from healthy individual showing normal number and size distribution of platelets. ITP: Blood smear confirms low platelets count and shows a megathrombocyte (arrow) but no other abnormalities. Pseudo: Pseudothrombocytopenia. Blood smear shows platelet clumping and rosetting around leukocyte (arrow). TTP: Thrombotic thrombocytopenia purpura. Arrows point to a schistocyte and a nucleated red blood cell. Evans: Evans syndrome refers to concurrent ITP and autoimmune hemolytic anemia as suggested by spherocytes (arrows). May-Hegglin: Inherited thrombocytopenia characterized by giant platelets and leukocyte inclusion bodies (arrows).

polychromasia with spherocytes might indicate Evans syndrome (see below).

No additional diagnostic studies are required to make a diagnosis of ITP in the typical cases. Testing for platelet antibodies is not recommended. The marrow, if performed, reveals normal erythroid and myeloid development, normal to increased numbers of megakaryocytes, and no marked dysplastic features such as megakaryocyte clumping or bare nuclei. Even when the presentation is typical, bone marrow aspiration and biopsy are probably indicated in older individuals.[3] The initial history, course, and response to therapy provide important diagnostic clues,[3] including those suggesting secondary ITP. Serological evaluation for HIV and/or hepatitis C infection is indicated in at-risk populations because of the potential adverse effect of prolonged corticosteroid usage on viral replication and the utility of antiviral therapy in treating the accompanying thrombocytopenia.[11] Quantification of immunoglobulins and immunoelectrophoresis may be appropriate in the elderly, those with hepatosplenomegaly or lymphadenopathy, and in patients with a history of recurrent infections. Both hypothyroidism and hyperthyroidism are common. The role of testing for antiphospholipid antibodies (APLA) is uncertain. Testing for a lupus anticoagulant should be performed if there is a history of a thromboembolic event, recurrent miscarriages, a prolonged aPTT or other suggestion of a systemic autoimmune disease. APLA are common[12] but do not affect response to ITP-directed therapy.[13,14] On the other hand, there is divergence in the literature as to the risk of thrombosis in patients with APLA during or after recovery.[13,14]

The role of testing for infection with *Helicobacter pylori* or the empiric use of antibiotics on presentation remains controversial because the outcome of this approach has been highly variable (reviewed in reference 15). Patients are often asymptomatic, in which case the best way to establish the diagnosis is by using ^{13}C-breath urea or the stool antigen tests rather than serology; false positive serology has been reported after treatment with IVIG. Antibiotic therapy is least likely to be effective in patients with severe ITP of long-standing duration.[16]

Pseudothrombocytopenia

Pseudothrombocytopenia is an in vitro artifact of automated cell counting that occurs with a frequency of between 1 in 1000 and 1 in 10,000 blood specimens collected in EDTA.[17] The phenomenon involves platelet agglutination by autoantibodies that bind to a conformer of the platelet glycoprotein IIb-IIIa complex induced by low concentrations of ionized calcium only attained in vitro. The diagnosis is suspected when platelet clumping is observed on a blood smear made from EDTA-anticoagulated blood.[17] The diagnosis is confirmed by demonstrating that the platelet count is substantially higher when measured in citrated or heparinized blood, or in blood obtained without an anticoagulant and analyzed by blood smear. Platelet clumping occurs at body temperature, distinguishing it from cold agglutinins, although the two may coexist. Falsely low platelet counts may also occur when giant platelets are excluded from automated analysis. The blood smear of all patients with ITP must be analyzed to confirm the automated platelet count before therapy is initiated or changed.

Pathogenesis and Laboratory Diagnosis

Eluates from ITP platelets contain autoantibodies to platelet glycoproteins IIb/IIIa (integrin αIIbβ3), Ib/IX, and Ia/IIa (integrin α2β1), among other determinants (see references 18 and 19 for review). It is common to find antibodies to multiple platelet antigens.[20] Detecting antibodies in platelet eluates is estimated to have a sensitivity of between 49% and 66%, a specificity of 79% to 92% and a positive predictive value of 78% to 92%.[21,22] However, interlaboratory agreement is only 55% to 67%, and detection of circulating antibody is less useful and reproducible. A negative test does not exclude the diagnosis of ITP.[21,23] The sensitivity and specificity for using these tests to distinguish ITP from thrombocytopenia associated with myelodysplasia, systemic lupus, chronic hepatitis, and other conditions have not been determined in a systematic way. Therefore, ITP

remains a clinical diagnosis made by excluding other diseases and it is still premature to rely on platelet antibody tests to confirm or to exclude the diagnosis.[3] The most reliable diagnostic criterion continues to be a response to "ITP specific" therapies, especially IVIG and IV anti-D.

Platelet life span is reduced in almost all patients[24,25] because of accelerated clearance of antibody-coated platelets by Fcγ receptors expressed on tissue macrophages. In most patients, an increased percentage of young, large (>20 fL) or reticulated platelets is seen suggesting an attempt to compensate by increasing platelet production.[26] However, in up to two-thirds of patients, platelet production is impaired[27,28] because nascent antibody-coated platelets are destroyed or damaged by intramedullary macrophages,[29] autoantibodies impede megakaryocyte differentiation and platelet release,[30–32] and/or because cytotoxic $CD8^+$ T cells damage megakaryocytes. Thrombopoietin levels are normal or minimally elevated in contrast to the marked elevations seen in hypomegakaryocytic disorders.[33] Although most identified autoantibodies bind to glycoproteins that serve important hemostatic functions, only a few patients note easy bruising at platelet counts above 50,000/μL as a result of antibody-induced storage pool deficiency or other qualitative defects.[34] In rare cases, platelet autoantibodies cause an acquired thrombasthenia or Bernard–Soulier-like disorder.[35,36]

Initial Treatment of Adults With Immune Thrombocytopenic Purpura

Management is predicated on the platelet count and severity of bleeding (Panel 1; top panel).[37] The primary short-term goal is to provide the minimal therapy needed to attain a hemostatic platelet count (>20,000–30,000/μL) and then to temporize until the disease improves or remits.[38] Because few adults with ITP remit spontaneously soon after diagnosis (reviewed in reference 39), treatment is indicated for the typical patient who presents with platelet counts lower than 20,000 to 30,000/μL, especially those over the age of 60 or with a previous history or ongoing bleeding, who are at greatest risk for life-threatening hemorrhage.[40] Treatment may be required at higher presenting platelet counts in patients with medical conditions that predispose to bleeding, in need of surgery, on mandated antiplatelet agents or anticoagulation, or who are at high risk of trauma owing to employment or difficulty in self-care as a result of physical, mental, or emotional disturbance, among other reasons.[37] In the absence of hemorrhage or other medical emergency, such as concurrent trauma or surgery, or another issue as indicated above, treatment is generally initiated with prednisone 1 to 2 mg/kg/day. IV anti-D (especially at a dose of 75 μg/kg) is a suitable alternative in Rh(D)-positive individuals with a negative direct antiglobulin test (DAT) and is less toxic, but considerably more expensive (Fig. 138–2B).[41] Approximately 50% of patients show sustained improvement with repeated infusions.[42] Intravenous immunoglobulin (IVIG; 1 g/kg for 1–2 days) should be used with IV methylprednisolone (30 mg/kg up to 1 g) when platelet counts remain below 5000/μL despite several days of corticosteroids or when bleeding is more widespread (see below). Others advocate basing initial therapy on the severity of bleeding.[43] Recent studies indicate that initiating therapy with one to four 4-day courses of high-dose dexamethasone may lead to sustained hemostatic responses in approximately 50% of patients.[44,45] Therapy is generally not required at platelet counts above 30,000/μL in the absence of bleeding or predisposing comorbid conditions.[3,37]

Glucocorticoids impair the clearance of antibody-coated platelets by tissue macrophages,[46] inhibit antibody production[47] and/or may increase platelet production,[29] possibly by inhibiting phagocytosis of platelets by bone marrow macrophages. Petechiae and purpura may resolve before the platelet count rises through a direct effect on vascular integrity and because newly formed platelets are preferentially recruited to sites of bleeding. Sixty to 90% of patients respond to prednisone depending on the intensity and duration of treatment,[3,48] most within 3 to 4 weeks[49,50] by which time considerable toxicity is usually evident. Although there is little consensus on the appropriate duration of therapy,[3] our opinion is that there is no compelling evidence that prolonging treatment further will alter the natural history and that it will clearly increase toxicity. Alternative forms of management should be sought if the platelet count does not increase sufficiently or falls below hemostatic levels during tapering rather than resuming prednisone or increasing the dose. Long-term remission rates of 9% to 32% are reported with prednisone alone.[3,48–50] Therefore, it is likely that most patients, including initial responders, will require additional forms of treatment.

Emergent Treatment

Consideration should be given to hospitalizing all patients who present with platelet counts lower than 10,000 to 20,000/μL until a beneficial effect of treatment can be documented, unless the patient is known to have shown a good response previously to a specific agent. Emergency treatment is indicated for internal or profound mucocutaneous bleeding (Fig. 138–2A) (reviewed in reference 37). General measures to reduce the bleeding risk should be instituted, including avoidance of drugs that interfere with platelet and hemostatic function, control of blood pressure, measures to minimize the risk of trauma, and treatments that have beneficial local effects on bleeding, for example, Amicar for epistaxis and oral bleeding and progesterone for vaginal bleeding. Treatment is initiated with IVIG (1 g/kg/day for 1–3 consecutive days) or IV anti-D (75 μg/kg) and intravenous methylprednisolone (1–2 g/day for 1–3 consecutive days) unless the platelet exceeds 30,000 to 50,000/μL sooner.[3,51,52] Platelet transfusions are indicated for life-threatening bleeding and are often surprisingly effective,[53] especially when given continuously after an initial bolus and preceded by other therapies, such as IVIG.[54] Multimodality therapy with corticosteroids, IVIG and/or anti-D and/or vincristine has recently been shown to be effective in patients with poor outcomes to individual agents.[55] Splenectomy is reserved for the rare patient who fails to respond and requires immediate additional treatment, for example, prior to emergency craniotomy for intracranial hemorrhage. A bone marrow documenting a normal-appearing marrow with active megakaryocytopoiesis should be performed if there is any question regarding the diagnosis. Experience with plasmapheresis is limited (reviewed in reference 56). Recombinant factor VIIa can be administered if bleeding remains uncontrolled while awaiting a response to treatment; dosing is not well established, but a minimum of 40 U/kg has been used successfully in patients with thrombocytopenia of diverse etiologies.[57]

Management of First Relapse—Medical Therapy and Splenectomy

Prednisone is generally tapered over 1 to 4 months, at which time most adults relapse. For those who do not respond or fail to sustain a response (platelet count <30,000–50,000/μL) (Fig. 138–2C), either splenectomy (Fig. 138–2E) or medical therapy (Fig. 138–2D) can be pursued. Prolonged reliance on corticosteroids to maintain a hemostatic platelet count should be avoided whenever possible. A trial of steroid-sparing agents or alternatives to steroids (see below) should be implemented. More patients and physicians are waiting for at least 6 to 12 months before proceeding to splenectomy even in the face of persistent thrombocytopenia. The argument for medical therapy is based on recent evidence that a substantial fraction of patients treated repetitively with anti-D or with a course of dexamethasone or rituximab (see below) can postpone or avoid splenectomy.[58] The decision to defer or proceed with splenectomy is predicated on disease severity, side effects of therapy, desired level of physical activity, travel (eg, exposure to malaria and poor access to medical care), compliance, and, importantly, patient and physician preference.

Response to splenectomy cannot be predicted from results of prior treatment, though patients totally refractory to several prior

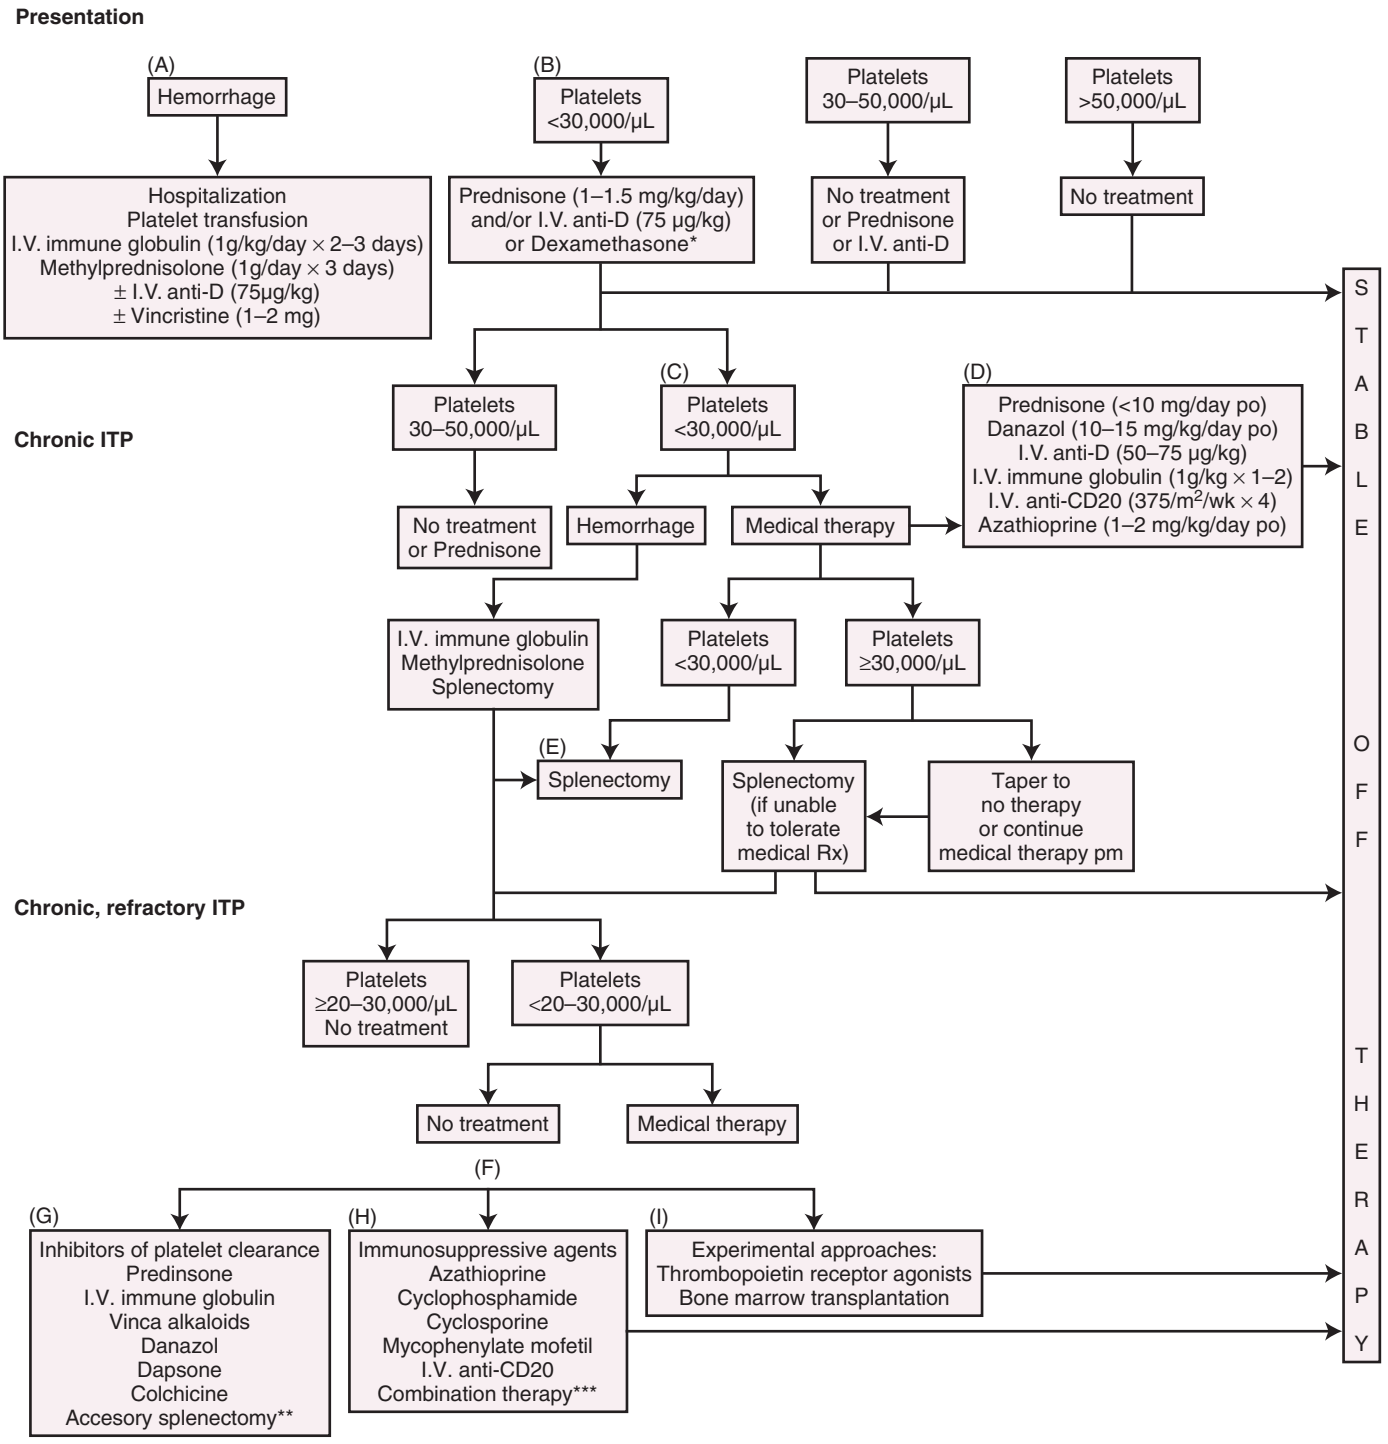

Figure 138–2 Treatment algorithm for management of adult-onset ITP. Letters refer to specific aspects of management cited in text. *Presentation.* Some advocate the use of 20,000/μL as a guideline for therapy. The decision to treat patients with platelet counts lower than 50,000/μL is based in part on evidence of bleeding, a history of bleeding, comorbid risk factors, life-style and tolerance of therapy. There is no consensus as to duration of steroid therapy. The use of anti-D as initial therapy is appropriate only for Rh^+, DAT^- individuals who are not markedly anemic or hemolyzing. *Chronic ITP.* The goal of medical therapy is to attain a hemostatic platelet count, generally greater than 20,000 to 30,000/μL. The threshold for treatment depends on comorbid risk factors for bleeding and risk of trauma. Higher platelet counts may be appropriate for surgery or after trauma. Medications can be used individually but combinations of azathioprine and danazol (or corticosteroids) may provide added benefit and allow lower doses to be utilized. IVIG and anti-D is generally reserved for severe thrombocytopenia unresponsive to oral agents. The decision to proceed to splenectomy depends on intensity of therapy required, tolerance to side effects, risk of surgery and patient preference. IVIG and/or methylprednisolone may help to increase the platelet count immediately prior to splenectomy. Laparoscopic and open splenectomy have comparable outcomes. *Chronic, refractory ITP.* The decision to treat patients who have platelet counts lower than 20,000 to 30,000/μL after splenectomy involves an assessment of the risk of hemorrhage versus the side effects of each form of therapy (see text). *Accessory splenectomy is reserved for those who have had a durable remission from splenectomy. **Drugs are often used in combination (e.g. azathioprine and danazol). Patients receiving protracted courses of corticosteroids should be monitored for osteopenia and cataracts. Modified from the New England Journal of Medicine 364:995, 2002.

approaches to management fair less well. IVIG, anti-D, and/or pulse doses of corticosteroids are used to boost the platelet count above 50,000/μL preoperatively. Prophylactic platelet transfusions are discouraged as bleeding is rare even in the face of severe thrombocytopenia and the platelet count typically rises rapidly once the splenic artery is ligated. Approximately 85% attain a stable hemostatic response initially (reviewed in reference 59), of whom approximately 20% relapse within 5 to 10 years.[38,59] The short- and long-term outcomes of laparoscopic and conventional transabdominal approaches are comparable[60] and the former hastens recovery. Splenic irradiation is less effective and is reserved for the elderly and others in whom splenectomy is indicated but hazardous.[61] The major known risks of splenectomy are overwhelming bacterial sepsis and reduced ability to control certain infections such as malaria and babesiosis. Sepsis occurs in less than 1% of otherwise healthy adults with uncomplicated ITP managed appropriately.[62] Immunization with polyvalent pneumococcal, *Haemophilus influenzae* type B, and quadrivalent meningococcal polysaccharide vaccines, depending on age and immunization history, should be given at least 2 weeks prior to splenectomy.[63,64] Our experience is that immunizations can be given successfully 6 or more weeks postoperatively in those receiving immunosuppression, that is, rituximab or azathioprine prior to splenectomy. Evidence is lacking to suggest any benefit of prophylactic antibiotics in otherwise healthy adults or even in children more than 5 years of age. Pneumococcal vaccination should be readministered at 5- to 10-year intervals; the conjugated vaccine, effective in infants under the age of 2 when Pneumovax is not, can be tried in patients not responding to Pneumovax. Any febrile illness demands careful evaluation and IV antibiotics should be instituted immediately at the onset of a systemic illness with fever higher than 101°F even when a specific bacterial etiology is not evident.

Chronic Immune Thrombocytopenic Purpura: Splenectomy Failures

As many as 50% of adults require therapy after splenectomy (Fig. 138–2F).[3] Response to splenectomy is lower in elderly patients, and probably in those with Evans syndrome or secondary immune thrombocytopenias. The incidence of major hemorrhage in patients failing splenectomy is in the range of 2% to 3% per year in referral practices.[38,72] The initial approach to patients with bleeding or severe thrombocytopenia after splenectomy is generally the same as at presentation: the diagnosis should be reevaluated, alternative reasons for thrombocytopenia and bleeding must be excluded, measures to limit bleeding instituted, and treatment with corticosteroids and/or IVIG reinstituted depending on the severity. IV anti-D is the one treatment that is much less effective after splenectomy.[73] Once the platelet count has increased to a safe level, steroids are tapered. An occasional patient can be managed with alternate-day corticosteroids or sufficiently low daily doses of prednisone (5–10 mg) to permit long-term use, but most will require one or more of the treatments described below (Fig. 138–2E). Osteoporosis and cataracts should be monitored on a regular basis and prophylactic measures instituted to mitigate accelerated bone loss in patients continuing to be maintained on corticosteroids.

The goal of therapy for those who fail or relapse after splenectomy may differ from the initial presentation because fewer patients attain a durable unmaintained remission. In guidelines issued by the American Society of Hematology and by others, a platelet count of 30,000/μL is recommended as a surrogate endpoint.[37,48] However, some experts recommend using a platelet count as low as 10,000 to 20,000/μL in the absence of bleeding.[39] Treatment must be individualized as the tolerance for severe thrombocytopenia varies considerably and somewhat unpredictably, and unnecessary or prolonged steroid treatment increases mortality due to infection.[74] The risk of bleeding is influenced by the patient's age, bleeding history, and comorbid conditions,[40] which must be balanced against an individualized estimate of potential complications of each treatment modality. Elderly patients are more likely to bleed and to be exposed to medications that impair platelet function, but also are more likely to suffer debilitating side effects of therapy. Therefore, no treatment paradigm is applicable to all patients and intangibles such as level of physical activity, other medical conditions, tolerance to the side effects of therapy, and life expectations must be taken into consideration (Fig. 138–2F).

Place of Splenectomy in the Management of Adults with Immune Thrombocytopenic Purpura

For more than 50 years, splenectomy has been the treatment of choice for adults with ITP whose platelet counts have fallen after a course of prednisone, generally given at a dose of 1 to 1.5 mg/kg/day. The initial response to splenectomy exceeds 70% and most responding patients remain in clinical remission indefinitely (reviewed in reference 65). The efficacy and safety of laparoscopic splenectomy further enhanced patient acceptance. However, concerns about overwhelming sepsis postsplenectomy remain and recent studies have raised questions about pulmonary hypertension, atherosclerosis and thromboembolic complications, albeit generally in patients undergoing the procedure for other indications. The development of new drugs to treat ITP and the use of the internet have combined to increase patient concerns about undergoing surgery to remove a "normal" organ. However, until recently, there has been no indication that any treatment favorably alters the natural history of ITP, permitting splenectomy to be deferred without unacceptable medication-related toxicity.

Studies by Cooper et al using repeated injections of IV anti-D,[42] a study by George et al comparing repeated infusions of IV anti-D to prednisone,[66] a single course of rituximab (reviewed in reference 67), and three recent studies using short courses of dexamethasone as initial treatment[44,45,68] suggest that one-third to 50% of patients may attain hemostatic platelet counts without additional therapy and without splenectomy. Follow-up is short and it is now clear that some initial responders to rituximab relapse at later times.[69] Moreover, not all patients can tolerate the effects of dexamethasone on mood, rituximab may alter the T- and B-cell repertoire even after peripheral B-cell numbers have returned to normal, and rare cases of severe intravascular hemolysis and disseminated intravascular coagulation have occurred in patients who tolerated an initial course of anti-D.[70,71] Moreover, a platelet count that is generally adequate for hemostasis (>30,000/μL) may be unsuitable for patients with an active lifestyle, comorbid risk factors for bleeding, or settings where use of drugs that interfere with platelet function are deemed mandatory. Lastly, the treatment landscape may be altered soon by the introduction of thrombopoietin receptor agonists. Therefore, the proper timing of splenectomy has become a matter of considerable discussion between patients and their hematologists and the verdict is by no means "in."

Accessory Spleens

Residual splenic tissue is identified using either radionucleotide, MR imaging or CT scan. Response rates to removing an accessory spleen vary considerably (see reference 75 for review), but success appears more likely if the duration of initial response to splenectomy exceeded 2 years (Fig. 138–2G).[75]

Agents That Impair Platelet Clearance

Most postsplenectomy patients require maintenance doses of corticosteroids that are intolerable in order to maintain adequate platelet

counts. Although the options for treatment are discussed below as if each is to be used as a single agent, benefits are often at least additive when agents are used in combination and the toxicity is reduced because lower doses may suffice (Fig. 138–2G).

Intravenous Immunoglobulin

Approximately 85% of adults respond to IVIG given by intermittent intravenous infusion at a dose of 1 g/kg/day for 2 consecutive days with an increase in platelet count to higher than 50,000/μL and in approximately 65% the peak platelet count exceeds 100,000/μL,[76] although the response rate may be lower in patients failing splenectomy. Single infusions are repeated as needed every 7 to 28 days. IVIG impairs the clearance of IgG-coated platelets,[77] perhaps indirectly by activating the inhibitory receptor FcRγIIb.[78]

There is no evidence that commercial preparations of IVIG differ in efficacy but they may differ in toxicity in certain subpopulations, for example, IgA content in the rare patient with IgA deficiency and anti-IgA antibodies and high osmolarity due to sucrose in elderly, diabetic patients at risk for renal failure. Toxicity is generally mild and self-limited. However, many patients complain of postinfusion headaches that, in a few, are unusually severe because of aseptic meningitis.[79] Positive antiglobulin tests after infusion due to isohemagglutinins are common but are typically short-lived and overt hemolytic anemia is very rare.[80] Other side effects in order of frequency include thrombosis,[81] pulmonary or renal failure,[82] and anaphylactoid reactions in IgA-deficient patients with IgE anti-IgA antibodies (in whom IgA-depleted preparations should be used).[83,84] Antiviral antibodies[85] can be passively acquired but there are no documented cases of HIV, hepatitis A, B, or C, HTLV1, or parvovirus transmission with currently available preparations. The major limitations of IVIG are the need for frequent infusion, availability, duration, and severity of postinfusion headaches, time of infusion, and cost. Approximately one-third of patients who respond initially ultimately may become refractory.[86] The major indications for IVIG are (a) treatment of hemorrhagic emergencies; (b) preparation for splenectomy or other surgical procedures in patients intolerant of or resistant to corticosteroids who are Rh- or have a positive direct antiglobulin test, precluding the use of anti-D; (c) to defer splenectomy in debilitated adults; (d) during pregnancy when potentially teratogenic drugs must be avoided; and (e) chronic management of patients who are either refractory to other modalities or who are awaiting response to slower-acting agents.

Anti-D

The response rate of Rh(D)+ individuals given IV anti-D at a dose of 75 μg/kg intravenously is comparable to IVIG.[41,87] Treatment takes approximately 5 minutes, is less expensive than IVIG, the product is not currently in short supply, and the systemic side effects of the latter are avoided. The most common toxicity of anti-D is hemolytic anemia. The mean decrease in hemoglobin is 1 to 2.0 g/dL, which may be accompanied by chills and nausea notwithstanding premedication with acetaminophen, antihistamines, and steroids, or, in less than 1% of cases, by intravascular hemolysis (IVH).[70] Disseminated intravascular coagulation, renal failure, and even death has been reported in a few patients with IVH.[71] Anti-D should probably be avoided in patients with ongoing hemolysis or positive direct antiglobulin tests not attributable to prior anti-D treatment, and in those with comorbidities such as cirrhosis or renal insufficiency that may predispose to these serious complications of IVH. Other limitations of anti-D treatment include its inapplicability to Rh(D)– individuals and very limited efficacy postsplenectomy. The indications for use of anti-D are essentially the same as for IVIG. However, anti-D appears to work through a different mechanism than IVIG, that is, by blocking FcγRIIA and/or FcγRIIIA,[88] suggesting the two agents may provide additive benefits in urgent situations. Anti-D has been especially useful in HIV-positive individuals and those needing chronic treatment, in whom it is desirable to avoid long-term use of corticosteroids and splenectomy.[89]

Danazol

Approximately 20% to 40% of pre- and postsplenectomized patients respond to the attenuated androgen, danazol, at a dose of 10 to 15 mg/kg/day for 4 to 6 months (Fig. 138–2-D, G).[90,91] However, danazol is generally less effective in refractory patients.[92,93] Part of the variation in reported response is due to differences in the duration of treatment,[90] because some individuals require up to 6 months for a benefit to be seen. Danazol impairs macrophage-mediated clearance of antibody-coated platelets initially[94] and may inhibit antibody production with prolonged use.[90,95] The major indications for danazol are to defer splenectomy and as a corticosteroid-sparing drug. Most patients require continued treatment at low daily doses to maintain remission.[96] Danazol shares with other androgens the potential to increase cholesterol, and to cause masculinization, mood and menstrual changes, and hepatic injury, including cholestatic hepatitis, peliosis hepatis,[97] and neoplasia.[98] We have found the combination of danazol and azathioprine (see below) to be more effective than either drug alone, using IV steroids and IVIG as supplements until a stable response is seen.[37]

Agents that Impair Antibody Production

Rituximab

Rituximab is being used more frequently as second-line therapy before as well as after splenectomy. Rituximab is a chimeric anti-CD20 monoclonal antibody that depletes B cells. When given at a dose of 375 mg/m^2 once weekly for 4 weeks, durable complete responses lasting at least 1 year are seen in 25% to 40% of patients, whereas others may attain relatively brief partial responses lasting weeks to months.[99–101] Response rates are not influenced by splenectomy status. However, in one study, 40% of 47 patients in CR at 1 year relapsed by year 5.[69] Patients with a durable initial complete response often respond to a second course if they relapse (reviewed in reference 102) but the duration is rarely longer than the initial response. Complete responses to a single dose have been reported in children.[103] The mechanism of response continues to defy simple categorization. An early-response phase, possibly due to macrophage inhibition by opsonized B-cells, and a late response phase, presumably resulting from inhibition of antibody synthesis and other B-cell functions, are both seen.[104] Recent work suggests that depletion of B cells removes an important source of stimulation for autoreactive T cells.[69] To date, patients with ITP have experienced few side effects other than transient serum sickness in children[104] provided that appropriate premedication is used and that the initial infusion rate is slow and increased gradually. Reactivation of hepatitis B in carriers has been seen and there have been a few cases of progressive multifocal leukoencephalopathy in patients with systemic lupus who were receiving additional immunosuppressants at the time they were treated with rituximab. As of now, no long-term clinical sequelae of immunosuppression have been demonstrated in the approximately 700,000 patients treated for a variety of indications although there is evidence for prolonged perturbation in the B-cell and T-cell repertoire in patients treated for other autoimmune disorders.[105]

Azathioprine

Twenty to 40% of patients respond to azathioprine (1–3 mg/kg/day as tolerated to maintain an absolute neutrophil count of approximately 1500/μL) depending on intensity and duration of treatment.[106–108] As with all modalities, responses are less frequent in refractory patients. The median time to response in one study was 4 months, and maximal benefit was not attained in some until 7 to 8

months. Complete responses tend to be durable and, on occasion, persist after treatment is discontinued. Serious side effects are rare and predominantly limited to reversible elevations of serum transaminases; some patients experience diarrhea, nausea, and depression that can be avoided by ingestion at bedtime.

Cyclophosphamide

Comparable response rates have been reported using cyclophosphamide as a single agent (1–2 mg/kg/day titrated based on the neutrophil count or 1–2 courses given intravenously at a dose of 1–1.5 g/m^2 every 3 weeks).[108,109] Cyclophosphamide can cause alopecia, hemorrhagic cystitis, and bladder fibrosis and should be used cautiously in younger patients because of its potential to cause infertility and leukemia. The combination of cyclophosphamide, prednisone, and other agents, for example, vinca alkaloids, may be effective in some refractory patients with acceptable toxicity and lasting efficacy.[110]

Other Immunosuppressants

Patients have been treated successfully with cyclosporine[111,112] or mycophenolate mofetil.[113] The former has been effective but its toxicity would appear to preclude long-term use if other modalities were available. The latter is best used as part of a combination approach. Other patients have been treated by incubating their plasma with columns coated with staphylococcal protein A, but this approach has been largely discontinued because of toxicity and lack of efficacy.

Additional Approaches

Dapsone (75 mg qd)[114] is effective in some patients, presumably by impeding macrophage function as a result of oxidant-mediated hemolysis; screening for G6PD deficiency may be advisable in males prior to use. Response rates in refractory patients are low.[115] Vinca alkaloids bind avidly to platelets and are released slowly into the plasma, which allows antibody-coated platelets to target the drug to tissue macrophages, inhibiting phagocytosis.[94,116] Vincristine (0.03 mg/kg or 1–1.5 mg/m^2; not to exceed 2 mg) and vinblastine (4–6 mg/m^2; not to exceed 10 mg) can be administered either by IV push or by slow infusion.[117] The response rate to either drug is approximately 10% in patients with chronic refractory ITP when used as a single agent and sustained complete remissions are uncommon.[118] Treatment generally has to be given every 2 to 4 weeks for an indefinite period and patients often become refractory or treatment has to be stopped because of neurologic toxicity. Vinca alkaloids are most effective when used as part of combination treatment.

Chronic Refractory Immune Thrombocytopenic Purpura

Approximately 20% of patients either do not respond to these approaches, relapse when the medications are stopped, or are unable to tolerate them (Fig. 138–2H). At this point, there must be a reassessment as to whether any therapy is needed, as some patients tolerate low platelet counts without bleeding.[39] However, the mortality rate from bleeding ranges from 2.2% for those younger than 40 years of age to more than 40% in those older than 60 in this subpopulation.[72,119] Therefore, almost all refractory patients with platelet counts lower than 20,000 to 30,000/μL will ultimately require treatment. The use of experimental approaches is to be considered in this setting.

High-dose immunosuppression followed by autologous bone marrow or peripheral stem cell transplantation has been used by several groups in this setting (Fig. 138–2I). In the largest reported series, 6 of 14 patients developed a complete or partial remission; however, some of the 6 suffered other complications.[120] Studies using a humanized monoclonal antibody to the T-cell costimulatory molecule CD154[121] have shown success even in previously refractory patients but its use has been discontinued because of the advent of thromboembolic complications.

Investigational trials using thrombopoietin-receptor agonists have shown great success in most patients, even those with severe disease. Dose-dependent increases in platelet counts have been reported in the majority of even refractory patients with few serious side effects.[122–124] In one study of AMG531, patients maintained their platelet counts for more than 2 years with weekly treatment with good drug tolerance and minimal toxicity. With more protracted usage, reticulin fibrosis has been seen in a small number of patients, which resolved on discontinuation of the agent; it is not yet known if this is a class effect. A high response rate has also been seen in two randomized, placebo-controlled studies of eltrombopag given for 6 weeks.[125] If these agents continue to show high response rates without serious unforeseen toxicities, it is anticipated that they will be incorporated into the management of patients at many stages of the disease and have the potential to be especially useful in refractory patients.

SECONDARY THROMBOCYTOPENIAS

Introduction

Secondary immune thrombocytopenias comprise as many as 40% to 50% of cases of ITP in some series.[126,127] The reason for the increased recognition of secondary ITP is not apparent other than the spread of HIV-1 and hepatitis C infections and increasingly effective therapy for chronic lymphoid malignancies (Chapters 83). This incidence needs to be considered in determining which patients with ITP should be investigated for an underlying disorder and whether to treat a patient with a systemic illness for presumed ITP when other causes of thrombocytopenia may coexist.

Systemic Lupus Erythematosus

An estimated one-third of patients with SLE develop thrombocytopenia sometime during their illness, although not all require treatment.[128–130] Thrombocytopenia may precede the diagnosis of SLE by months to years, but this occurs in only 2% to 5% of patients with classic ITP.[5,131,132] Therefore, serologic evaluation should be restricted to those with additional clinical or laboratory evidence consistent with lupus[3] rather than an isolated positive ANA.[132]

The pathogenesis of thrombocytopenia in SLE is multifactorial. Antibodies to platelet glycoproteins, like those seen in ITP, to DNA,[133,134] to phospholipids and phospholipid-binding proteins[135–137] to CD40 ligand,[138] to thrombopoietin[139] and immune complexes of diverse composition[140,141] have been identified, but bear an inconstant relationship to thrombocytopenia. When severe thrombocytopenia is part of a systemic relapse, platelet deposition may occur in vessels involved by inflammation,[142] as part of the hemophagocytic syndrome or a systemic thrombotic microangiopathy, in which cases ITP-directed approaches are often ineffective. The distinction may be difficult.[143] Evidence of marrow damage not found in ITP has been reported,[139] but amegakaryocytic thrombocytopenia is rare.[144]

The significance of thrombocytopenia depends on the clinical context. Thrombocytopenia has been associated with increased disease activity and mortality in some but not in all studies.[130,145] However, the clinical course of thrombocytopenia in the absence of other disease manifestations is similar to primary ITP,[128,146] whereas severe thrombocytopenia that develops during a systemic exacerbation of vasculitis may carry a poorer prognosis.[128,129,147] Treatment decisions should be predicated on the extent to which thrombocytopenia per se is the predominant reason for treatment and the likelihood that systemic vasculitis will necessitate treatment in the future.

Because patients with persistent SLE often experience repeated episodes of thrombocytopenia, treatment should only be used when there is a risk of bleeding in order to avoid excessive use of corticosteroids or other medications in these heavily treated patients. Patients with severe thrombocytopenia and no evidence of active SLE should be treated as if they had primary ITP, in which case the initial response to corticosteroids, danazol, IVIG, and immunosuppression is comparable.[130,148–151] There is less published experience with other medical approaches although rituximab has activity in SLE and the thrombopoietic agents may be useful in the future. The role of splenectomy remains controversial. Variation in the response rates reflects differences in disease severity.[152,153] Reliance on splenectomy should be tempered by the knowledge that patients may often require corticosteroids or immunosuppressants to control the underlying disease. In our opinion splenectomy is indicated when thrombocytopenia is severe and persistent, is the predominant reason for treatment, when other tolerable options are ineffective, and when the SLE is otherwise well controlled.[154] Profound thrombocytopenia occurring during the course of a systemic exacerbation of SLE requires control of the underlying disease.[155]

Common Variable Immunodeficiency and IgA Deficiency

ITP occurs with increased frequency in patients with common variable immunodeficiency (CVID) and other forms of immunodeficiency. Approximately 10% of patients with CVID develop ITP and a similar proportion autoimmune hemolysis. Conversely, approximately 1% of adults with otherwise typical ITP meet criteria for CVID.[156] The average age at diagnosis was 28 years in one large series.[157] CVID should be suspected in patients with even mild recurrent infections and allergies, as should IgA deficiency. A higher than expected incidence of mutations in the transmembrane activator and calcium modulator and cyclophilin ligand [CAML] interactor (TACI) have been reported in patients with CVID with ITP and Evans syndrome.[158] Splenectomy and immunosuppressive agents should be avoided to the extent possible and treatment with IVIG is preferable. IgA deficiency also occurs in at least 1% of ITP patients although anti-IgA antibodies are rare.

Lymphoproliferative Disorders

Chronic Lymphocytic Leukemia

Thrombocytopenia caused by marrow and splenic infiltration is a common feature of advanced CLL; these patients have a mean survival of about 19 months. By contrast, ITP occurs in more than 10% patients with CLL,[159] may precede the diagnosis of CLL or develop at any stage and does not necessarily confer a poor prognosis.[160–162] The diagnosis of ITP becomes progressively more difficult as the CLL progresses. ITP should be suspected in early-stage disease when the bone marrow contains "adequate" numbers of megakaryocytes or in advanced stages when the severity of thrombocytopenia is disproportionate to the extent of marrow infiltration or splenomegaly. The concurrent development of autoimmune hemolytic anemia may suggest the diagnosis as well.[161] Several cases have been associated with the use of fludarabine.[163] When ITP is difficult to diagnose, a course of therapy with IVIG may be indicated for therapeutic and diagnostic purposes, although most patients with CLL and immune thrombocytopenia respond to corticosteroids or splenectomy.[160–162] Rituximab has been useful to inhibit both B-cell proliferation and antibody production, although additional agents are necessary to treat the CLL itself. IVIG prophylaxis (400 mg/kg/month) should be considered in patients postsplenectomy and in those with a history of infection or who require chronic immunosuppressive therapy.

Hodgkin Disease and Non-Hodgkin Lymphomas

ITP occurs in up to 1% of patients with Hodgkin disease. The clinical course of approximately 50 patients has been reported.[164–166] In three-quarters of these, ITP was diagnosed an average of 52 months (1 month–22 years) after the Hodgkin disease was diagnosed,[167] whereas it was discovered at the time of splenectomy for ITP in a few.[5] In the rest, ITP preceded the diagnosis of Hodgkin disease, although in some the interval was so long as to place the association in doubt.[167–169] In approximately one-third of the reported cases, ITP heralded a recurrence.[164,166,167,170,171] Most patients without evidence of recurrent Hodgkin disease responded to corticosteroids,[167,171] splenectomy,[170] and/or azathioprine,[171] whereas chemotherapy treatment of the underlying disease was effective in others.[161]

The association between immune thrombocytopenia and non-Hodgkin lymphoma appears almost coincidental[164,170,172–174]; however, autoimmune hemolysis occurs in some patients as well. In most cases, thrombocytopenia proved difficult to manage unless the underlying malignancy responded to chemotherapy.

Leukemia of Large Granular Lymphocytes

The term LGL leukemia is applied to two disorders distinguished by the phenotype of the clonally expanded cell population.[175] In more than 90%, there is a clonal expansion of $CD3^+CD16^+$ T cells (T-LGL) and the natural history is typically one of stability or slow progression. In the remaining patients, the LGL cells express an NK phenotype ($CD3^-CD16^+CD57^+$), the disorder is more aggressive, and severe thrombocytopenia caused by marrow replacement and splenic infiltration may develop over months.[175] Most patients with T-LGL present with recurrent infections secondary to neutropenia. Five to 20% develop thrombocytopenia, which is generally mild and secondary to splenomegaly. An occasional patient presents with severe thrombocytopenia and the clinical picture of ITP.[176] The diagnosis should be suspected when thrombocytopenia is accompanied by neutropenia, arthralgia, splenomegaly, and/or a positive test for rheumatoid factor, similar to Felty syndrome. On occasion, the number of LGL cells is only slightly increased,[175] making it hard to distinguish from severe ITP in which an increase in $CD56^+D3^-$ cells[177] may also be observed.[178] Insufficient patients have been reported to determine whether the response to treatment in T-LGL differs from that of primary ITP.

Posttransplantation

Persistent thrombocytopenia develops in 3% to 5% of recipients of allogeneic bone marrow and solid organ transplants as a result of allo- or autoimmune or nonimmune causes, including partial reconstitution, graft versus host disease, CMV infection, venoocclusive disease, sepsis, and microangiopathic processes, among others.[179–181] Alloimmune thrombocytopenia may result from residual host B-cell reactivity against donor platelets.[182] Autoimmune thrombocytopenia, which has also been reported after autologous bone marrow or peripheral blood stem cell transplantation, is presumed to result from immune dysregulation or, rarely, donation by patients with compensated ITP.[183,184] Thrombocytopenia is often mild and transient, but in others is persistent, severe, and occasionally refractory and fatal. In the latter cases, patients do not respond to typical ITP therapies and careful exploration for infections and GVHD is warranted. In general, the treatment options are the same as those for primary ITP including, on occasion, splenectomy and retransplantation, but response rates are low (reviewed in reference 180). Thrombopoietic agents may prove useful in the future.

Miscellaneous Disorders

An increased incidence of immune thrombocytopenia is reported in patients with autoimmune thyroid disease.[185,186] Also, mild

thrombocytopenia may be caused by hypersplenism that responds slowly to control of the hyperthyroid state.[185] The incidence of hypothyroidism also appears to be increased in ITP patients. In patients with sarcoidosis, immune platelet destruction may be superimposed on thrombocytopenia caused by splenic and marrow infiltration with granulomas.[187,188] ITP is also reported in association with myasthenia gravis,[189] multiple sclerosis,[1] and in patients with a variety of benign and malignant neoplasms, most of whom respond to conventional treatment for ITP.[174,190,191] Evans syndrome is the combination of autoimmune hemolysis and ITP. Response rates to medical therapy and splenectomy are lower than in primary ITP, especially in children. Severe ITP and other cytopenias also occur in patients with autoimmune lymphoproliferative syndrome caused by mutations in the Fas gene, Fas, caspase-8, or caspase-10; the disorder may present in adults and occasionally without marked lymphadenopathy (reviewed in reference 192).

IMMUNE THROMBOCYTOPENIC PURPURA IN CHILDHOOD

Introduction

The child with ITP differs from adults with ITP with respect to the differential diagnosis, the higher frequency of earlier spontaneous remission, and the greater reluctance to proceed to splenectomy. Potential long-term effects of treatment require careful consideration in a population with a greater-than-50-year life expectancy. There is as yet no pathophysiological explanation that explains the differences in ITP between these two age groups.

Presentation

Children with acute ITP typically present with the sudden onset of petechiae and purpura and platelet counts lower than 20,000 to 30,000/μL. The relationship between the bleeding risk and platelet count appears to be similar to that found in adults. Intracranial hemorrhage (ICH) has been reported in approximately 0.1% to 1% of children.[193] This may be higher than the incidence in adults and may occur earlier in the course. Both sexes up to teen age are affected with equal frequency. The peak incidence of ITP occurs between the ages of 3 and 5 but it may occur at any age after 2 to 3 months.[194] Many children have a history of nonspecific viral infection or vaccination with live virus[195] in the week(s) prior to developing symptoms. However, causality is hard to prove. The parents and pediatrician are often more concerned than the child, who usually feels well. As in adults, the physical examination is notable only for signs of bleeding, absence of hepatomegaly or lymphadenopathy, and a normal uvula and radial rays; minimal splenomegaly is detectable in less than 10% of children. The CBC should be within normal limits for age with the exception of the platelet count; if anemia is due to chronic bleeding, microcytosis and hypochromia may be present. The white blood cell differential, which normally has more lymphocytes than neutrophils in children less than 4 to 5 years of age,[194] is also expected to be normal, although some young, activated cells may be seen on smear.

Evaluation

To experienced pediatric hematologists, this constellation of findings (ie, an otherwise healthy child with the apparent rapid onset of isolated thrombocytopenia and a physical examination notable only for bleeding) is sufficient to make a diagnosis of ITP, which is by far the most common (>95%) cause of isolated, especially severe, thrombocytopenia in childhood. No additional testing, including a bone marrow, is required if the presentation is typical irrespective of choice of therapy.[3,196,197] Red blood cell typing for the presence of the Rh(D) antigen, a reticulocyte count, and direct antiglobulin test is appropriate if use of anti-D is contemplated.[3,196,197] Cooperative childhood cancer study group trials, which included thousands of children with leukemia, demonstrated that none presented with isolated thrombocytopenia, an otherwise normal blood count and smear, and the absence of hepatosplenomegaly or lymphadenopathy.[193,198] Moreover, although some pediatricians are more comfortable if a bone marrow examination is performed prior to treatment with corticosteroids, in a study of more than 100 thrombocytopenic children with a classical presentation of ITP, only one child was found to have another diagnosis (aplastic anemia, not leukemia).[197] Finally, as in adults, a substantial response to IVIG or anti-D is diagnostic of ITP.[199] Additional testing should be performed, e.g., HIV, only if the appropriate signs, symptoms, or history are present.[200]

Differential Diagnosis

Once thrombocytopenia is documented, three questions arise: (a) Is the thrombocytopenia isolated? (b) If isolated, is it immune? and (c) If immune, is it primary? Additional diagnoses must be considered if other cytopenias or abnormalities on physical examination are present.

1. Severe anemia, even if there has been significant epistaxis or metromenorrhea, should lead to an investigation of alternative diagnoses, for example, aplastic anemia and dysplastic marrow disorders occasionally characterized by an elevated MCV (>90 in preteens), microangiopathic hemolytic disorders (Chapter 139) and Evans syndrome (see above). Orthopedic abnormalities are common in children with Fanconi anemia (thumbs) and with Thrombocytopenia and Absent Radius syndrome (TAR) syndrome. Neutropenia may be caused by an associated neutrophil antibody (analogous to anemia in Evans syndrome) or a sign of an underlying marrow disorder.
2. In a healthy child with an otherwise normal CBC and no abnormalities other than bleeding manifestations on physical examination, the next consideration is to exclude other nonimmune inherited disorders that account for 2% to 10% of the children presenting with isolated thrombocytopenia.[201] A bone marrow examination will not usually help to differentiate ITP from these syndromes. The diagnosis of a familial disorder may be difficult for many reasons. Affected family members may be asymptomatic or the disorder may be inherited in an autosomal recessive manner. Commonly, an inherited cause of thrombocytopenia is suspected only after the child has failed to respond to treatment for ITP. Fortunately, most children with inherited thrombocytopenias have mild to moderate thrombocytopenia (20,000–100,000/μL) and do not have symptoms or require treatment other than prior to surgery or when the platelet count is further decreased by infection. Small platelets should raise a suspicion of Wiscott–Aldrich syndrome, the XLT form may present with thrombocytopenia alone. The Bernard–Soulier syndrome should be suspected if there is moderate thrombocytopenia and giant platelets, as should the group of MHY9-RD macrothrombocytopenias, such as May–Hegglin, which are characterized by mutations in the heavy chain of nonmuscle myosin (Chapter 32). Non-TAR, congenital amegakaryocytic thrombocytopenia may be indistinguishable from ITP on presentation. The diagnosis is often first considered in a child less than 1 to 3 years of age when thrombocytopenia only responds to platelet transfusions. Testing for a c-mpl mutation will identify most patients, although bone marrow biopsy remains the definitive diagnostic test.
3. Underlying disorders associated with ITP should be excluded. HIV as a cause of ITP in childhood is usually the result of in utero transmission; effective antiretroviral therapy almost always suppresses clinical manifestations in the infant. Hepatitis C and *H pylori* need to be considered, as in adults, although there is far less information in this age group. SLE (with or without antiphospholipid syndrome) may develop in 2% to 5% of female adolescents

who present with ITP. Testing for antinuclear antibodies should only be performed if suggestive symptoms or laboratory findings are present. Humoral immunodeficiency is found in 1% to 2% of children with ITP, most commonly due to CVI or IgA deficiency. Almost 10% of ITP patients were IgG_2 deficient in one study[157]; the incidence may be sufficient to warrant measuring immunoglobulin and subclass levels and/or documenting response to polyvalent pneumococcal vaccine prior to splenectomy.[202] Immunoglobulin measurements may also be indicated in children who are to receive IVIG.[203] Autoimmune lymphoproliferative syndrome is characterized by marked hepatosplenomegaly and/or lymphadenopathy beginning in childhood[192,204]; autoimmune hemolysis is common. Most cases have an abnormality in CD95 (Fas), resulting in persistence of autoreactive T cells that fail to undergo timely programmed cell death.

Management at Presentation

Which children with acute ITP should be treated and which treatment should be used remain controversial.[3,196,205,206] Treatment is intended to prevent ICH and to improve quality of life. However, the incidence of ICH is too low[207] to perform a controlled study of treatment. The risk of ICH is higher in children with platelet counts lower than 10,000/μL,[208] those presenting with extensive "wet" purpura or additional sites of bleeding, with coexisting coagulopathies, or with a history of significant head trauma. However, as ICH can occur in the absence of bleeding at other sites, our approach is to treat all children with platelet counts below 15,000 to 20,000/μL. It should be emphasized that no trial has demonstrated a reduction in ICH with treatment, and other experienced pediatric hematologists use more (or less) restrictive criteria. At least 80% of affected children recover spontaneously, approximately half within the first 2 months.[209,210] Chronicity is more likely to develop in teenagers, and in children with SLE or Evans syndrome. However, children of any age can develop chronic ITP even with an otherwise typical presentation, and there is as yet no evidence that the natural history of childhood ITP is altered by early treatment.[211]

Prednisone (2–4 mg/kg/day),[212] IV or oral methylprednisolone (30 mg/kg/day for 3 days),[213] IVIG (1 g/kg/day for 2 days)[214] and IV anti-D (75 μg/kg)[73,87] shorten the duration of severe thrombocytopenia compared with observation alone. IVIG increased the platelet count by an average of 54,000/μL within the first 24 hours in one study.[199] The combination of IVIG and corticosteroids may be synergistic. Platelet transfusions should be reserved for ongoing or imminent, (e.g., post head trauma), major hemorrhage.[53] We recommend that all children with acute ITP, platelet counts lower than 20,000/μL, and wet purpura, hematuria, hematochezia, or metromenorrhagia, be treated with a combination of IVIG (1 g/kg/day) and intravenous methylprednisolone (30 mg/kg/day), both for 1 to 3 days, with the goal of increasing the platelet count to exceed 30,000/μL and cessation of bleeding. If bleeding continues and the platelet count does not increase, adding IV anti-D (75 μg/kg in an Rh+, DAT– patient) and/or vincristine (0.03 mg/kg) is almost always effective. The diagnosis of ITP should be reconsidered if a child fails to respond to therapy, in which case a bone marrow should be performed or repeated.[55]

Management of Acute Immune Thrombocytopenic Purpura After the First Week

The goal of treatment is to maintain a platelet count higher than 20,000 to 30,000/μL with a minimum of toxicity, allowing normal or near normal activity until further improvement occurs spontaneously. Drugs that impair platelet function, such as aspirin, nonsteroidal antiinflammatory agents, and glycerol guaiacolate, should be avoided. Guidelines must be set for physical activity. Our policy is to interdict only high-contact sports such as football, lacrosse, and hockey at platelet counts lower than 30,000/μL, but not to restrict other physical activities, including basketball, soccer, track, swimming, bicycling, baseball, and tennis, although such decisions need to be individualized.[37]

Primary reliance may be placed upon prednisone because it is relatively inexpensive, given orally, and toxicity is not intolerable as long as treatment duration is limited. The dose is usually tapered over 2 to 6 weeks, although there is no evidence in favor of any specific duration. If prednisone is continued, an attempt should be made to administer it on alternate days to minimize toxicity, especially osteoporosis, the most significant, long-term side effect of corticosteroids in children. The utility of high-dose dexamethasone in children with chronic ITP has been disappointing.[211]

We recommend IVIG[217] or IV anti-D (Winrho-SD)[73] either as initial treatment or for children who require more than 0.1 to 0.2 mg/kg/day of prednisone as continued treatment. Both IVIG and anti-D are generally administered on an "as needed" basis rather than at fixed intervals. Treatment may be continued for at least 12 months if a response is seen, as spontaneous improvement may be delayed. In general, few children will require splenectomy. Treatment with rituximab[104,218] or, less commonly, azathioprine[219] may be used on occasion to defer splenectomy. Although short-term treatment results may mimic those seen in adults, the long-term outcome is not known. Evidence of special toxicity is not present, but some clinicians give IVIG to young children treated with rituximab to avoid potential hypogammaglobulinemia.[220] Danazol is reserved for peri- and postpubertal ITP because of its effect on bone age.

The advantage of IVIG in managing children includes the high response rate and lack of serious long-term toxicity.[199,206] The disadvantages are that IVIG must be infused over hours, depending upon the platelet count, postinfusion headaches are common and often marked, and the cost is high.[217] In contrast to adults, few pediatric patients become refractory even with prolonged treatment. There is no evidence that any of the commercially available products differ in clinical effectiveness. Anti-D appears to be equally safe as and comparably effective to IVIG in Rh+ patients who have not undergone splenectomy[73] and infusion is complete within minutes. Whether early treatment with IVIG or anti-D will alter the incidence of chronic ITP remains to be determined. Children have been treated with each modality for years without evidence of cumulative toxicity.

Chronic Immune Thrombocytopenic Purpura in Children: Management After 6 to 12 Months

Durable clinical remission occurs in 70% to 90% of children with typical ITP after splenectomy.[221] Laparoscopic splenectomy has less long-term impact on physical activity and child-bearing than an open procedure. Yet, pediatric hematologists delay recommending splenectomy for at least 1 year after diagnosis for two reasons. First, children who have platelet counts higher than 20,000 to 30,000/μL and are asymptomatic can be followed safely with little or no treatment. Virtually all children can be managed with IVIG or anti-D if the platelet count falls below 20,000 to 30,000/μL; low doses of prednisone (<0.2 mg/kg/qod) can be added, as needed. Our experience and those of others is that the platelet count often improves over time, although on occasion a previously stable patient will develop thrombocytopenia and menorrhagia at puberty. Second, the risk of postsplenectomy sepsis may be as high as 2% over 10 years in children. Indeed, there have been deaths reported from postsplenectomy sepsis as well as from bleeding in this age group. The risk appears to be reduced substantially by administering pneumococcal, H Flu B, and meningococcal vaccines in conjunction with prophylactic antibiotics, which is the current standard of care. How often to revaccinate and the value of prophylactic antibiotics in this setting remain unsettled. We currently recommend that Pneumovax be readministered every 5 to 10 years, but do not readminister H Flu B vaccine unless a specific risk is identified. Meningococcal vaccine is typically

Initial Management of Immune Thrombocytopenic Purpura in Childhood

It is well known that children with newly diagnosed immune thrombocytopenic purpura (ITP) often improve on their own, with or without treatment. A recent study suggests that the rate of spontaneous improvement may be as high as 90% by 1 year, with half of the children showing improvement within 2 months.[215] This high rate of spontaneous improvement has led to the evolution of two distinct schools of thought regarding the approach to the initial management of children who present with acute ITP.

Proponents of one school believe that if patients are likely to get better on their own, little is to be gained by intervention until at least 3 to 6 months has passed from diagnosis. Even then therapy is not indicated unless the platelet count is very low and there is significant bleeding, as the prognosis for eventual improvement or resolution is still good. The rationale is that intracranial hemorrhage (ICH) is a very rare event, that all therapies have toxicities, and the entire process of providing treatment, including doctor's visits and obtaining blood counts, generates more distress than benefit.

In contrast, advocates of the other school believe that it is appropriate to provide treatment to a child if the platelet count is very low, that is, less than 15,000 to 20,000/μL, in order to minimize the risk of bleeding. This approach takes into account parental anxiety regarding low counts, risk of nonfatal but serious bleeding in addition to ICH, and the need to restrict physical activities until the count improves.

Observational studies are underway that may provide insight into this controversy, but an unequivocal answer may remain elusive because too many unmeasurable variables contribute to the risk of bleeding, especially when the incidence of severe bleeding is low. In the absence of such information, one clear change in medical practice has been that the cutoff platelet count for intervention even among "treaters" has decreased from 30,000–50,000/μL to 10,000–20,000/μL in children with no bleeding or only scattered petechiae or minimal bruising. Also, there is more emphasis on basing treatment decisions on the extent of bleeding, although there is neither precision nor uniformity in approach among even the most experienced pediatric hematologists.

Even in settings where there is reasonable consensus that treatment is indicated, considerable variation remains in practice patterns. Some assume that in the most severely affected patients,[216] any of the most effective treatments (IVIG 1 g/kg, IV anti-D 75 μg/kg, and very high-dose corticosteroids), each of which have their own kinetics, cost and toxicity profile, can be used supplemented by platelet transfusions as needed. Recent data indicate that the combination of IVIG (1 g/kg), IV methylprednisolone (30 mg/kg), IV anti-D (75 μg/kg), and/or vincristine (0.03 mg/kg) is often effective when single agents are not.[55]

Whatever criteria for instituting treatment are used and whatever treatment is instituted, the most important clinical message is the need to monitor the patient very closely for new signs of bleeding and the readiness to provide additional treatment within 12 to 72 hours if there is no response to the first agent chosen. Additional studies of acute ITP in children are needed to predict risk of bleeding and chronicity that would permit more rational intervention in a disorder that is generally benign but that is rarely occasioned by catastrophic bleeding complications or by severe thrombocytopenia lasting for years.

(re)administered prior to starting college. Intravenous antibiotics should be initiated urgently for children with a fever higher than 102°F. Most pediatric hematologists prefer waiting until a child has reached 5 years of age before recommending splenectomy because of the frequency of infection and high fevers in this population, although there is insufficient data on the risk of sepsis after the age of 2 to make firm recommendations in difficult-to-manage patients. In younger children, it may be wise to document protective titers of antibody to the most common serotypes of pneumococcus prior to splenectomy. No other long-term health risks have been identified in children who have been splenectomized for ITP to date although this has received little study and pulmonary hypertension has been reported after splenectomy, primarily to treat or as a result of hemolytic disorders.

Among the few children refractory to splenectomy, alternate diagnoses should be reinvestigated. Few children have significant bleeding problems even if they remain thrombocytopenic, an observation that must be borne in mind when recommending potentially toxic forms of treatment for platelet counts higher than 20,000/μL. The rare, symptomatic, refractory pediatric patient should be approached in the same manner as the comparable adult, although the potential side effects of various drugs may differ depending on the age of the child. The efficacy of treatment in this setting is entirely anecdotal.

IMMUNE THROMBOCYTOPENIC PURPURA DURING PREGNANCY

Diagnosis

The incidence of ITP is reported to be 1 to 2 per 1000 deliveries.[222] Proper management involves not only careful attention to the mother but also an awareness of the incidence and consequences of neonatal thrombocytopenia caused by transplacental passage of maternal autoantibodies. This includes the risks and benefits to the fetus of maternal therapy, invasive monitoring, and surgical delivery. Comprehensive reviews of the differential diagnosis and management of thrombocytopenia in pregnancy have been published.[223,224]

The most common condition confused with ITP is gestational thrombocytopenia, which occurs in 4% to 8% of pregnancies. Gestational thrombocytopenia is likely when an otherwise healthy woman with a previously documented normal platelet count develops mild thrombocytopenia (>70,000–100,000/μL) in the third trimester of an uncomplicated pregnancy.[225] Severe maternal or neonatal thrombocytopenia is rare and there is no indication for additional diagnostic or therapeutic interventions other than following the maternal platelet count until term when epidural anesthesia becomes an issue (see below). Because gestational thrombocytopenia and ITP are both diagnoses of exclusion, it may be difficult to make the distinction in an asymptomatic woman with no previous platelet count who presents with moderate to severe thrombocytopenia earlier in pregnancy.[226,227] Although the incidence of gestational thrombocytopenia far exceeds all other causes combined, previously healthy women can present for the first time during gestation with ITP, early preeclampsia, type IIb von Willebrand disease, a microangiopathic disorder, or hereditary thrombocytopenia.

Therapy of Immune Thrombocytopenic Purpura in Pregnancy

Most women are managed through pregnancy without major difficulty, although a severe exacerbation may occur on occasion. The only contraindication to pregnancy is the (inadvertent) use of cyto-

toxic drugs with teratogenic potential during the first trimester. Pregnancy does not alter the threshold for maternal treatment in ITP, as platelet counts higher than 20,000 to 30,000/μL are adequate for otherwise uncomplicated pregnancy until term.[3] Prednisone has been the mainstay of therapy and appears to pose little risk to the human fetus owing to placental metabolism.[228] However, protracted use of prednisone is associated with a higher rate of premature labor and pregnancy-induced hypertension[227] and may exacerbate gestational diabetes. For these reasons, refractory patients and those requiring more than 20 mg of prednisone daily are generally managed with IVIG. Laparoscopic splenectomy has been performed successfully during the second trimester,[229] but is rarely needed and should be avoided unless absolutely necessary. There is limited experience with azathioprine for ITP, although it has been used to suppress renal transplant rejection without evidence of teratogenicity.[228] We have reported on the treatment of eight women with anti-D (1–7 courses) without evidence of fetal hydrops by ultrasound or of neonatal anemia or jaundice in the seven Rh+ neonates.[230] Rituximab can be detected in serum for 3 to 6 months after completion of treatment and in theory can be transported across the placenta and cause B-cell depletion in the fetus. Other drugs, for example, vinca alkaloids, should also be avoided if at all possible.

The major therapeutic challenge generally comes at delivery. Maternal platelet counts greater than 50,000/μL suffice for cesarean section[227,231] and this level is a useful goal as term approaches when emergent obstetrical indications are more common. Cesarean sections have been performed safely at lower platelet counts when necessary.[226] Anesthesiologists require higher platelet counts for epidural anesthesia, although studies to support any minimal threshold are lacking.[226] Severe bleeding after vaginal delivery is uncommon even at very low platelet counts.[226,227] A second major goal of management is to prevent neonatal ICH. However, there is no noninvasive means to identify neonates at risk, and the best approach to managing delivery remains unsettled.[232] The risk of neonatal thrombocytopenia lower than 50,000/μL is estimated to be 9% to 15%, the incidence of platelet counts below 20,000/μL is approximately 5%,[226] and the risk of ICH is below 1%.[231] Antenatal ICH is extremely rare,[226] arguing against maternal treatment of the fetus (in contrast to alloimmune thrombocytopenia) except for very special cases, for example, the mother's previous child was born with an ICH or a platelet count lower than 10,000/μL.

The risk of severe neonatal thrombocytopenia appears to be substantially greater if a previous fetus has been severely affected[226,233] and perhaps if the mother is more severely affected.[226,234] Otherwise, there is at best a weak correlation between fetal and maternal platelet counts.[222,226,227,235,236] Severely thrombocytopenic neonates have been born to mothers with normal platelet counts,[237] including those who responded to splenectomy, corticosteroids, or IVIG.[238]

There is no noninvasive means to predict the fetal platelet count. Although prenatal platelet counts can be measured by fetal scalp or percutaneous umbilical blood sampling (PUBS), neither is in widespread use. Too often fetal scalp sampling platelet counts are falsely low because of clumping, which leads to unnecessary emergency cesarean sections, and the risk of hemorrhage after PUBS exceeds that of ICH even in skilled hands. Although there is no direct evidence that cesarean section prevents ICH in ITP,[231] we consider the procedure if severe neonatal thrombocytopenia is documented or expected[3,239] or if there is a difficult delivery. Neonatal platelet counts often fall transiently in the first few days postpartum, possibly related to the maturation of the reticuloendothelial cell system. Treatment with IVIG and steroids is indicated at platelet counts lower than 30,000/μL in view of the vulnerability of neonates to ICH. A head sonogram, CT, and/or MRI should be obtained as soon as possible after birth to exclude ICH. Emergent management of the neonate with platelet transfusions and IVIG with or without corticosteroids[240] should be instituted if there is any suspicion of bleeding, even in the absence of overt neurologic impairment or documented hemorrhage until ICH can be excluded on radiologic grounds. Close monitoring should continue until a normal platelet count is documented.

Neonatal Alloimmune Thrombocytopenia

Clinical Presentation

Alloimmune thrombocytopenia (AIT) is the platelet analog of hemolytic disease of the newborn, although there are important differences in natural history and management. AIT is identified clinically in approximately 1 in 5000 term pregnancies (approximately 800–4000 cases per year in the United States),[241,242] accounting for as many as 50% of the cases of severe neonatal thrombocytopenia.[241,243] Large screening studies have documented that AIT actually occurs as often as 1 in 1000 deliveries based on both systematically performed neonatal platelet counts and screening of HPA-1a negative families.[244–246] Neonates with moderate thrombocytopenia are now being identified more often as a result of greater awareness and the wider availability of recently developed serologic techniques. However, in contrast to hemolytic disease of the newborn, routine screening is still not performed.[241,247] Typically, the diagnosis is suspected when bleeding and severe thrombocytopenia occur unexpectedly in a neonate born after an otherwise uneventful pregnancy. A platelet count lower than 50,000/μL, unknown etiology of the thrombocytopenia, and possibly a family history of transient neonatal thrombocytopenia point to the diagnosis of AIT.[245] ICH is common (10%–20%) and is fatal in 1% to 5% of cases.[241,248] Hydrocephalus or porencephaly due to ICH in utero occurs in up to 10% of severely thrombocytopenic fetuses.[248–251] Thrombocytopenia typically persists for up to 3 weeks.[243]

Pathogenesis

AIT is caused by the transplacental passage of maternal alloantibodies against platelet antigens shared by the father and fetus. Shed fetal platelet antigens can pass into the maternal circulation by the end of the first trimester,[252] by which time the placenta has developed the capacity to transport maternal IgG antibodies to the fetus. Serologic diagnosis involves demonstrating parental platelet antigen incompatibility and antiplatelet antibody in maternal serum of matching specificity. Diverse biallelic antigen systems have been implicated. Most cases identified in non-Asian populations occur in homozygous HPA-1b (Pl(A2)/Pl(A2)) mothers.[241] Most neonates are severely affected as are the few cases attributable to alloantibodies against other determinants on platelet glycoprotein IIIa, for example, anti-HPA-1b[253] and anti-HPA-4 (Yuk(a)/Pen) in Asian populations[254] and glycoprotein IIb, for example, anti-HPA-3a (Bak(a)/Lek) and anti-HPA-9(Max).[255] Br(a)/Br(b) incompatibility, which accounts for 15% to 20% of the cases of AIT in Europe,[241,256] is generally milder and is more likely to occur during subsequent pregnancies, presumably because platelets express fewer copies of the glycoprotein Ia/IIa complex on which the HPA-5 alleles are located. Too few cases of AIT due to antibodies to other antigens[257–259] have been reported to estimate the severity or prevalence because a severe clinical presentation is the usual reason to initiate an investigation. There is debate regarding the frequency of Gov (HPA-15a and 15b) incompatibility as a cause of AIT. ABO- and HLA antibodies rarely, if ever, cause AIT. Additional alloantibodies with novel specificities will likely be identified in the future. These advances place additional demands on referral laboratories to acquire and maintain the appropriate roster of typed controls, reference sera, and DNA-based techniques for haplotyping.

Neonatal thrombocytopenia develops in 1% to 6% of women who are homozygous for the HPA-1b allele and carry an HPA-1a fetus.[241,242] Production of anti-HPA-1a antibodies occurs almost exclusively in women who carry the HLA haplotype DRB30101 also known as Dw52a[260–263]; the incidence of AIT in this subpopulation exceeds 25%,[242] a relative risk 10- to 100-fold above HPA-1b/1b women with other HLA haplotypes. Genetic restriction in the development of anti-HPA-5a antibodies may exist as well.[264] These genetic linkages have important implications in managing relatives of affected women. Because fetal blood sampling may induce sensitization, it is our policy to test previously unsensitized HPA-1b/1b, DRB30101 positive women for circulating anti-HPA-1a antibodies monthly, and

at 36 to 38 weeks if the child's father is HPA-1a positive. A PUBS is performed only if antibodies are detected. Amniocentesis is performed for fetal platelet typing if the father is unavailable, uncertain, or a heterozygote.

Management of the Affected Child

The index case can be devastating and typically occurs without warning. ICH is identified in approximately 10% of neonates during the peripartum period, making immediate diagnosis and treatment mandatory. A normal maternal platelet count should be documented, although AIT can occur coincidentally with ITP or other causes of maternal thrombocytopenia, especially gestational.[265] A neonate born with a platelet count lower than 50,000/μL should be presumed to have AIT even if there is evidence of another etiology such as bacterial sepsis, disseminated intravascular coagulation, congenital viral (herpes, CMV, varicella, rubella) or toxoplasma infection. AIT should also be considered in any neonate with parenchymal ICH. If AIT is suspected, treatment followed by testing should be initiated.

The urgency of treatment should be governed by the likelihood of ICH and the severity of the thrombocytopenia. If the ultrasound or CT is normal and there is no clinical evidence of ICH, transfusion of random donor platelets, which has been shown to be effective in most cases of neonatal AIT in two recent studies, should also be started.[266,267] IVIG should also be started[241,268,269] although responses can take 1 to 3 days. Therefore, corticosteroids may provide added benefit but should not be used as the sole modality.[241,270] If ICH has occurred, then random donor platelets should be given immediately, and repeated as needed to maintain the count higher than 50,000 to 100,000 along with IVIG (with or without corticosteroids) while antigen-negative, often maternal, platelets are procured.[271] Although in theory maternal platelets should be washed to remove circulating alloantibody and resuspended in AB-positive plasma, in actual practice they can be administered safely after centrifugation alone. The platelets should be irradiated to lessen the risk of graft-versus-host disease.[272] A rise in the platelet count should be verified. Serologic studies of the parents should be performed to confirm the diagnosis because of the implications for subsequent pregnancies and the possible need for genetic counseling of other family members. Maternal antibodies that react with paternal platelets are not detected in up to 15% of otherwise typical cases.[241]

Management of Subsequent Pregnancies

An aggressive approach is warranted, especially in cases of HPA-1a incompatibility[273] for several reasons: (a) Severe thrombocytopenia recurs in more than 99% of subsequent pregnancies. (b) Most will be more severely affected than their previously affected sibling. (c) Severe fetal thrombocytopenia occurs early, with 40% of fetuses having platelet counts lower than 20,000/μL by 24 weeks. (d) Neither the presence nor the absence of alloantibody in the mother nor a change in antibody titer predicts the fetal platelet count.[242,274] (e) At least one-half of ICH occurs antenatally and, therefore, would not be prevented by elective cesarean section at term. (f) When treatment is withheld, fetal platelet counts often fall rapidly or remain very low during gestation.[275] (g) Effective antenatal treatment is available.[275,276]

Antenatal management has changed over the past several years as newer studies have enabled better informed therapeutic decisions to be made. Two approaches to antenatal management of thrombocytopenic fetuses have been studied. The more aggressive approach, pursued primarily in several European centers, involves weekly transfusion of maternal or antigen-matched platelets in utero starting as early as 20 to 26 weeks' gestation.[275,277] Each procedure carries a risk of fetal exsanguination and side effects from transfusion[278] and the long-term outcomes reflect the high risk to the fetus of repeated procedures. More recent studies have added to the concerns regarding fetal blood sampling.[279,280] In the United States, initially IVIG (1 g/kg/week) was administered weekly to the mother once it was clear that she was carrying an HPA-1a-positive fetus and thrombocytopenia was documented or could be assumed based on paternal homozygosity.[273,275,281–284] One randomized study clarified that IVIG alone at 1 g/kg/week was not sufficient if there had been an antenatal ICH or if the pretreatment fetal count was lower than 10,000 to 20,000/μL. Therefore a second dose of 1 gm/kg/week has been explored, as has the addition of prednisone (0.5–1 mg/kg/day).

We currently initiate therapy at 12 weeks of gestation with IVIG at a dose of 2 g/kg/week if an antenatal ICH occurred during a prior pregnancy. Otherwise IVIG either at 1 to 2 g/kg/week or at 1 g/kg/week together with 0.5 mg/kg/day of prednisone can be started at 20 to 26 weeks of gestation without fetal blood sampling. Whether to sample at 32 to 34 weeks of gestation in order to augment treatment for persisting fetal thrombocytopenia, continue treatment until term without sampling, or increase treatment without sampling at 32 weeks remains unsettled. Avoiding the initial fetal sampling has sufficed to provide good control of the fetal platelet count while substantially minimizing the number of invasive procedures.[285] Long-term outcome studies suggest that antenatal treatment does not result in residual complications for the fetus and may even preserve immunologic and neurologic development.[286,287]

POSTTRANSFUSION PURPURA

Clinical Presentation

Posttransfusion purpura (PTP) is an uncommon (1/7000 transfusions),[288] acquired thrombocytopenia that develops approximately 1 week after blood transfusion. The typical patient is a multiparous, middle-aged or elderly female who presents with the acute onset of bleeding due to severe thrombocytopenia a mean of 6 to 8 days (range 1–14 days) after receiving a blood product containing platelet material.[289] Almost all other affected patients have a history of prior transfusion, making PTP exceptionally rare in males and in previously untransfused nulliparous females.[247,290] In such cases, the onset may be delayed.[291] Subclinical cases have been reported,[292,293] but the incidence of asymptomatic, milder forms is unknown. PTP after bone marrow[294] or solid organ transplantation[295] has been described. On rare occasions, thrombocytopenia develops within hours after transfusion of a blood product containing alloantibodies to recipient platelets.[296,297]

Pathogenesis

The pathogenesis of PTP remains unclear. Alloantibodies are found in essentially all patients. However, the enigma is whether the alloantibodies are responsible for destroying autologous platelets, which appear to lack the relevant antigen. Any proposed explanation must also account for the low incidence in genetically susceptible individuals exposed to products known to contain the provoking antigen, the absence to date of the PTP syndrome in women whose pregnancies are complicated by AIT due to alloantibodies with same apparent specificity, the prolonged duration of the thrombocytopenia, the occasional failure to respond to transfusion of "antigen-negative" platelets,[298] and the fact that the syndrome may not recur after inadvertent or deliberate reexposure to antigen-mismatched products.[247,292,299] Indeed, in at least one instance, reinfusion of plasma obtained during the period of severe thrombocytopenia did not reproduce the syndrome.[300]

Sera from more than 90% of patients with PTP contain antibodies to the Pl(A1) antigen (HPA-1a), which is expressed on the platelets of 97% to 98% of the Caucasian population. In the remaining cases, antibodies to the Pl(A2) (HPA-1b) allele,[289] other epitopes on platelet glycoproteins IIb-IIIa or, less commonly, other platelet antigens are responsible. Although only anti-HLA antibodies were detected in several patients, their role is unclear.[289,301] Another unanswered question is why PTP is a rare disorder. On the basis of

the prevalence of HPA-1b homozygosity, it would be expected that anti-HPA-1a antibodies would develop in 1% to 3% of all recipients of random donor transfusions. The lower-than-expected frequency may result in part from genetic restriction on antibody production. PTP and NAIT are both closely linked to HLA B8 and DRB30101.[242,260,263] Yet, only single instances of PTP occurring in sisters[302] or in a woman with a history of AIT have been reported.[303] Three theories to explain the clinical features of PTP have been proposed.

It was initially suggested that the alloantibodies cause complement-dependent lysis of donor platelets, releasing antigen–antibody complexes that bind to HPA-1a-negative host platelets via Fcγ receptors, perpetuating the destructive process.[300] Antigen-independent platelet destruction could explain why transfusing HPA-1a negative platelets may be ineffective as well as the failure to detect autoantibodies. Platelet eluates collected as long as 100 days after the acute episode may contain immunoglobulin with anti-HPA-1a reactivity[304,305] that also binds to autologous and other HPA-1 negative platelets.[304] However, it has not been proven that these sera or eluates contain immune complexes composed of HPA-1a and anti-HPA-1a, or that they volley between rapidly destroyed platelets and their replacements for several weeks without themselves being cleared from the circulation.

An interrelated hypothesis is that the immune complexes bind to HPA-1a-negative platelets through the antigen, followed by the formation of immune complexes in situ. Only during an anamnestic response would sufficient alloantibody and donor antigen be present coincidentally to initiate PTP. PTP plasma has been reported to contain HPA-1a antigen, both soluble and in the form of microparticles,[306,307] capable of binding to antigen-negative platelets in vitro.[308] It is estimated that binding of less than 5% of the amount of soluble HPA-1a antigen potentially present in a single unit of blood may suffice to destroy all circulating platelets.[309,310] The remaining antigen–antibody complexes could perpetuate sensitization of the markedly reduced number of residual platelets left after the initial round of destruction.[309] Although measurable amounts of HPA-1a antigen have been detected in PTP plasma during the acute syndrome,[309,310] it remains to be proven that HPA-1 antigen complexed with anti-HPA-1a antibody is present on host platelets in vivo.

A more compelling case can be made for the hypothesis that a subset of anti-HPA-1a antibodies cross-react with undefined determinants on HPA-1b platelets.[311] Although the HPA-1a and 1b antigens differ at a single amino acid, it is likely that the conformation of the gpIIb-IIIa complex diverges sufficiently that only a small proportion of anti-HPA-1a antibodies cross-react with host protein or that autoantibodies directed at entirely different epitopes are generated.[312] Sera and platelet eluates from some individuals with PTP have been found to contain immunoglobulin with anti-HPA-1a reactivity that also bind to autologous platelets and platelets lacking gpIIb-IIIa.[313,314] The hypothesis that a subset of antibodies cross-reacts with autologous platelets would be consistent with (a) the infrequent occurrence of overt PTP in HPA-1 negative patients (re)exposed to blood products containing the antigen; (b) the absence of PTP in HPA-1a negative mothers with AIT; (c) the prolonged course in the absence of treatment; and (d) the presence of anti-HPA-1a reactivity in eluates from autologous platelets and those congenitally lacking gpIIIa.

Diagnosis

PTP should be suspected in any patient, especially older multiparous or previously transfused women, who develop severe thrombocytopenia approximately 1 week after transfusion. Suspicion is heightened if the patient's plasma lyses platelets from random normal donors, because there are few other conditions (eg, quinidine and heparin-associated purpura) in which this occurs. Treatment must be initiated immediately based on clinical criteria, because it may take several days before the results of confirmatory tests become available. The sine qua non of diagnosis is the demonstration of platelet-specific alloantibodies to determinants that are not present on the patient's own platelets determined by genotyping.[315] Alloantibodies to HPA-1a/1b and HPA-5/5b are readily detected using a commercial ELISA but may be missed if the patient has received multiple platelet transfusions.[316] Detection of antibodies to other, less common antigens requires co-ordination with a reference center.

Treatment

The clinical course of untreated patients is typically prolonged. In one series, bleeding lasted a mean of 10.2 days.[289] It took a mean of 14.6 days until the platelet count exceeded 50,000/μL (range 3–90), and 19.5 days until it exceeded 100,000/μL (range 3–130). Thrombocytopenia can persist for 60 to 120 days[292] and fatality rates approach 10%.[247,298,317] Therefore, intervention must be initiated once the disorder is suspected clinically. The treatment of choice is intravenous immunoglobulin (IVIG) 1 g/kg/day for 2 days; a second course may be required.[318] More than 90% of patients respond, generally beginning within 2 to 3 days.[289,318] Corticosteroids have an adjunctive role, if any. A response to splenectomy in a refractory patient has been reported.[319] Thrombocytopenia may recur within days of stopping treatment; relapses are generally milder and more easily managed than was the initial episode.[289,310] The role of prophylactic platelet transfusions in patients with profound thrombocytopenia but non–life-threatening bleeding is unclear. Sera from affected patients often contain antibodies to many HLA determinants, making provision of antigen-matched platelets problematic. Administration of random donor platelets is commonly associated with moderate to severe transfusion reactions, including bronchospasm and hypotension, rarely succeeds in raising the platelet count, and theoretically may perpetuate the disease.[300,318,320,321] Even when antigen-matched platelets can be procured in time, they may or may not suffer the same fate as the patient's own "antigen-negative" cells (reviewed in reference 322).

Anti-HPA-1a antibodies may persist for more than a year[323] and PTP may recur.[292,299,324] Although reexposure to blood products containing the relevant antigen does not invariably provoke PTP,[300,310] antigen-matched or autologous blood products should be used whenever possible.[289] It is unknown whether washing or using frozen and thawed red cells removes sufficient antigen to prevent recurrence.[324,325] The increased use of leukodepletion may have contributed to the apparent decreased incidence of PTP.[288] There is no data as to the risk of PTP developing in unaffected multiparous or in previously transfused siblings who share HLA haplotypes. The risk of women with pregnancies complicated by NAIT developing PTP is sufficiently low that only awareness and close monitoring of platelet counts after transfusion appears warranted.

CHAPTER 139

THROMBOTIC THROMBOCYTOPENIC PURPURA AND THE HEMOLYTIC UREMIC SYNDROME

Keith R. McCrae, J. Evan Sadler, and Douglas B. Cines

INTRODUCTION

In 1925, Moschowitz described a 16-year-old girl who died of a previously undescribed illness characterized by microangiopathic hemolytic anemia, petechiae, hemiparesis, and fever.[1] Postmortem examination revealed numerous hyaline thrombi, most prevalent in the terminal arterioles and capillaries of the heart and kidneys. In 1936, four similar cases were reported by Baehr et al, who proposed that the hyaline thrombi were secondary to agglutinated platelets,[2] and in 1947 Singer suggested that the term *thrombotic thrombocytopenic purpura* be used to describe this disorder.[3] In 1955 Gasser used the term *hemolytic uremic syndrome* (HUS) to describe a related syndrome that consisted of Coombs-negative hemolytic anemia, thrombocytopenia, and renal failure.[4] When considered together, these disorders are referred to as thrombotic microangiopathies, based on their shared features of microangiopathic hemolytic anemia, thrombocytopenia, and microvascular thrombotic lesions.[5–7]

The clinical and pathologic features of TTP and HUS often overlap.[6,8–10] However, these disorders appear to have a different pathogenesis as demonstrated by the high incidence of severe deficiency of the von Willebrand factor (VWF)-cleaving protease ADAMTS13 in patients with clinically diagnosed TTP, but not HUS.[11–13] Similarly, deficiency of complement regulatory proteins, particularly factor H or membrane cofactor protein, appears to be a unique characteristic of some familial and sporadic cases of HUS.[14–16] Moreover, although TTP and HUS affect many of the same organ systems, the frequency with which they do so differs, and the histopathologic features of the lesions of TTP and HUS are also distinct.[17] Finally, plasma exchange is a highly effective therapy for idiopathic TTP[10,18–21] but is usually ineffective for sporadic HUS or *Escherichia coli* verotoxin-associated HUS.[21,22] Based on these considerations, a better understanding of these disorders may be facilitated by continuing to distinguish them, while recognizing that extensive overlap in clinical features may prevent an unambiguous diagnosis of TTP or HUS in some patients. The measurement of ADAMTS13 levels is still not standardized among laboratories, and its utility in diagnosing or distinguishing between these disorders remains uncertain.[10,23–25] Given the growing number of clinical situations that may be associated with thrombotic microangiopathies, a simplified classification scheme that provides a practical framework for classifying these syndromes has been proposed (Table 139–1).[21]

GENETIC ASSOCIATIONS AND FAMILIAL THROMBOTIC MICROANGIOPATHY

Over the last 5 years an abundance of information concerning the genetics and pathogenesis of thrombotic microangiopathies has emerged. These data are considered in two primary categories—the role of complement regulatory factor deficiencies in the hemolytic uremic syndrome, and that of VWF cleaving protease (ADAMTS13) deficiency in TTP.

Complement Regulatory Factor Deficiencies in Familial Hemolytic Uremic Syndrome

The term *HUS* is generally used to encompass several diverse disorders discussed in detail below. By far the most common is the epidemic, or "typical" form of HUS that is associated with diarrhea caused by verotoxin-producing *E coli* (VTEC). VTEC-associated HUS accounts for at least 95% of all cases in children[7,26] and most nonsporadic cases in adults. The remaining "atypical" forms of HUS often exhibit autosomal dominant or recessive inheritance,[27] and have been associated with deficiencies in proteins that regulate the alternative pathway of complement activation.[28–30]

Diagnosis and Pathophysiology

Loss of function mutations in complement regulatory proteins, factor H (FH), factor I (FI) and membrane complement protein (MCP, CD46) have been identified in approximately 15% to 30%, 5% to 12%, and 10% to 13% of patients with atypical HUS, respectively.[31–33] Antibodies to FH have been identified in a few affected children.[34] Deletion of factor H-related molecules 1 and 3 (FHR1 and FHR3)[35] also has been described. Conversely, gain of function mutations in complement factor B[36] and complement factor C3[37] have been reported.

Factor H acts in concert with plasma cofactor I[14,38] and the transmembrane cofactor protein MCP[15] to downregulate C3b-mediated amplification of the alternative complement pathway by promoting the decay of C3bBb, the alternative pathway C3 convertase, and by cleaving and inactivating C3b.[16] HUS-associated mutations in FH cluster primarily in the C-terminal region, leading to impaired binding to cell-surface or subendothelial C3b, whereas binding to fluid phase C3b is preserved.[39,40] Thus, plasma levels of C3 are only reduced in 30% to 50% of affected patients at diagnosis.[41] A Web site for genotypic, phenotypic, and structural information on FH, FI, and MCP mutations has been developed (http://FH-HUS.org/).[42,43]

The mechanism(s) by which complement activation leads to the clinical manifestations of HUS remains uncertain. Moreover, approximately one-half of patients with familial HUS have not had mutations identified in complement regulatory proteins, implicating other pathways in pathogenesis.

Clinical Course

Inherited HUS associated with deficiency of complement regulatory proteins typically runs a chronic relapsing course, often complicated by hypertension and renal insufficiency.[14,44,45] Exacerbations may be preceded by infection, but occasionally are associated with pregnancy or seemingly incidental events. Penetrance is approximately 60% in families with heterozygous mutations in FH; thus HUS may occur in siblings with identical genetic abnormalities at different times, or not at all.[46] The prognosis of patients with FH and IF deficiencies is especially poor, with a high rate of recurrence and progression to end-stage renal disease or death approaching 70% in the former, whereas MCP deficiency carries a better prognosis.[31] Aggressive treat-

Table 139–1 Proposed Classification Scheme for Thrombotic Microangiopathics

Category	Clinical Features*	Mechanism	Treatment
Idiopathic TTP	Coombs negative, without DIC or other conditions† associated with secondary TTP. Severe renal failure is uncommon.	Autoimmune ADAMTS13 deficiency in a majority of patients	>80% respond to plasma exchange. May benefit from immunosuppression.
Secondary TTP	Associated conditions include cancer, infection, hematopoietic stem cell transplantation, chemotherapy, specific drugs such as cyclosporine, quinine, ticlopidine.	Mechanisms are mostly unknown. ADAMTS13 deficiency is uncommon.	With occasional exceptions, responses to plasma exchange are unlikely. Treatment and prognosis are dictated by the specific associated conditions.
Verotoxin-associated HUS (usually accompanied by diarrhea; D^+ HUS)	Acute renal failure, often oliguric, preceded by bloody diarrhea	Endothelial damage by Shiga toxin-producing *Escherichia coli*. ADAMTS13 deficiency is extremely rare.	Usually self-limited though extensive support required. No demonstrated efficacy of plasma exchange.
Atypical HUS	Acute renal failure, often oliguric, without a preceding diarrheal illness.	Complement regulatory protein deficiencies in at least 50% of patients; ADAMTS13 deficiency is extremely rare.	No demonstrated efficacy of plasma exchange, except possibly for factor H deficiency.

*Clinical features listed are in addition to microangiopathic hemolytic anemia and thrombocytopenia.
†Conditions associated with autoimmune ADAMTS13 deficiency and idiopathic TTP include certain autoimmune disorders, pregnancy, and ticlopidine.

ment with plasma exchange[45] or plasma infusions of 15 to 20 mL/kg weekly or biweekly[47,48] may slow the progression of renal failure in some patients. However, the evidence that plasma-based therapy or immunosuppression affects the clinical course in most patients is limited.

Affected patients have a high risk of recurrence after renal allografting[31,49,50] and HUS has been reported in related donors after surgery. Factor H is a soluble blood protein made in the liver. Therefore Factor H deficiency is not corrected by renal allografting, and HUS often recurs in the transplanted kidney, especially living-related donors.[27,28] One patient appears to have been cured by combined kidney and liver transplantation.[51] HUS recurs rarely in renal allografts of patients with MCP deficiency, suggesting that local expression of MCP is protective.[15,32]

ADAMTS13 Deficiency in Familial Thrombotic Thrombocytopenic Purpura

Schulman[52] and Upshaw[53] described a distinct form of autosomal recessive TTP, referred to as Upshaw–Schulman syndrome. Patients often have neonatal jaundice without maternal blood type incompatibility, and experience repeated episodes of thrombotic microangiopathy during early childhood.[54–57] Exacerbations often occur in association with minor respiratory infections, tonsillitis, sinusitis, otitis media, surgery, or routine vaccinations.[52,53,58,59] A substantial fraction of patients, perhaps one-half, are asymptomatic until early adulthood.[55] Affected women may present with thrombotic microangiopathy during pregnancy. Rare asymptomatic males have been identified in their fourth or fifth decade of life.[55]

The patients frequently present with microangiopathic hemolytic anemia, severe thrombocytopenia and neurologic defects that may range from mild alterations in mental status or visual disturbances to paralysis, seizures, or coma. Renal involvement causes proteinuria and hematuria, with granular and red cell casts. In contrast to familial HUS, serum creatinine usually is only modestly elevated, although patients may occasionally have severe acute renal insufficiency and some develop chronic renal failure requiring dialysis.[56,57] Symptomatic gastrointestinal involvement appears to be rare but may include abdominal pain, nausea, and vomiting.[60] One patient was reported to reproducibly develop pulmonary infiltrates during relapses.[61] These clinical and laboratory abnormalities resolve promptly with plasma replacement, and patients usually can be maintained symptom-free by small transfusions of plasma, typically 5 to 20 mL/kg every 2 to 3 weeks,[54] although some patients require larger volumes of plasma.[56]

The defect in Upshaw–Schulman syndrome was first linked to VWF by Moake,[62] who found "unusually large" VWF multimers in the plasma of patients with chronic relapsing TTP. He proposed that the patients lacked a plasma protease or reductase that normally cleaves "unusually large" VWF multimers, and that the abnormal multimers then cause uncontrolled intravascular platelet aggregation, thrombosis, and tissue infarction. Subsequently, a plasma metalloprotease was discovered that degrades VWF multimers by cleaving the Tyr (1605) Met (1606) bond in the VWF subunit,[63,64] and patients with Upshaw–Schulman syndrome were shown to lack this enzyme,[58] supporting Moake's model for the pathogenesis of VWF-dependent thrombotic microangiopathy.

The VWF protease was purified from plasma, cloned, and found to be a member of the ADAMTS family of metalloproteases, where "ADAMTS" stands for "a disintegrin-like and metalloprotease (reprolysin type) with thrombospondin type 1 motif" (Fig. 139–1). Simultaneously, genome-wide linkage analysis showed that Upshaw–Schulman syndrome is caused by mutations in the *ADAMTS13* gene on chromosome 9q34.[65] Like other members of the family, ADAMTS13 has a metalloprotease domain followed by a disintegrin domain, a thrombospondin-1 repeat, and a cysteine-rich and spacer domain characteristic of the family. These domains are followed by seven additional thrombospondin-1 repeats and two CUB domains. Several of the structural domains distal to the metalloprotease domain participate in the recognition of VWF.[66]

ADAMTS13 is synthesized mainly in the liver by hepatic stellate cells but also in vascular endothelial cells[67] and renal glomerular podocytes.[68] Small amounts of functional ADAMTS13 are present in platelets.[69]

Deletion, splice site, frameshift, and missense mutations that cause Upshaw–Schulman syndrome have been found in almost all structural domains of ADAMTS13, and there is no obvious hot spot for such mutations. Expression studies have shown that the missense mutations almost always prevent the secretion of ADAMTS13 protein, although some also impair catalytic activity.[66,70,71]

ACQUIRED THROMBOTIC MICROANGIOPATHIES

Idiopathic Thrombotic Thrombocytopenic Purpura

Clinical Manifestations

The classic pentad of symptoms that comprise the syndrome of TTP include microangiopathic hemolytic anemia (MAHA), thrombocytopenia, neurologic symptoms, fever, and renal dysfunction.[10,72–77] In

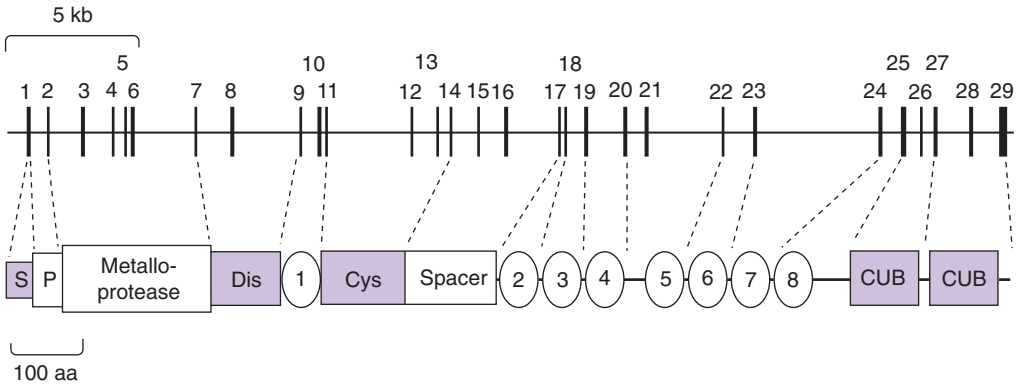

Figure 139–1 Structure of ADAMTS13. The *ADAMTS13* gene contains 29 exons and spans 37 kb on chromosome 9q34. Dashed lines show the relationship between the gene structure and domains of the ADAMTS13 protein. The ADAMTS13 precursor contains 1427 amino acid residues and includes a signal peptide (S), propeptide (P), metalloprotease, disintegrin domain (Dis), thrombospondin type 1 repeats (numbered 1–8), cysteine-rich domain (Cys), spacer domain, and CUB domains. Adapted with permission from Zheng X, Chung D, Takayama TK, et al: Structure of von Willebrand factor-cleaving protease (ADAMTS13), a metalloprotease involved in thrombotic thrombocytopenic purpura. J Biol Chem 276:41059, 2001.

earlier studies, approximately 75% of patients presented with a triad of MAHA, neurologic symptoms, and thrombocytopenic purpura[75,76]; however earlier recognition of TTP[78] and the established therapeutic efficacy of plasma exchange had led to a gradual appreciation that MAHA and thrombocytopenia alone in the absence of an obvious precipitating condition are sufficient diagnostic criteria for diagnosis of TTP.[6,23] Indeed, the evolution of this diagnostic approach has led to a sevenfold increase in the use of plasma exchange for TTP.[23,79]

TTP occurs with an estimated annual incidence of 3.7 to 11 cases per million,[80,81] is more common in females (female/male ratio of 3 : 2),[75,76,82,83] and has a peak incidence in the fourth decade.[75,76,83] Other risk factors appear to include African ancestry[80,84] and obesity.[84,85] Ten to 40% of patients complain of an upper respiratory tract infection or flu-like syndrome in the weeks preceding the diagnosis. Occasional patients present with malaise, fatigue, fever, or other nonspecific symptoms of days' to weeks' duration that are unresponsive to antibiotics or symptomatic management. The diagnosis of TTP may be overlooked until these prodromal symptoms become unrelenting or neurologic dysfunction develops. Neurologic symptoms ranging from headache and confusion to somnolence, seizures, aphasia, or coma often dominate the clinical picture in TTP[75–78,86] and may fluctuate in severity, a characteristic attributed to the repetitive formation and dissolution of microthrombi in the cerebral microvasculature.[87,88] Thrombocytopenia may be severe, with platelet counts below 20,000/μL, and mucocutaneous bleeding is common.[75–77,86] The prothrombin time, partial thromboplastin time, and fibrinogen levels are usually normal or only mildly perturbed; mild elevations in fibrinogen degradation products occur in 50% of patients[89] although more sensitive assays, such as those for prothrombin fragment 1+2, thrombin–antithrombin and plasmin–antiplasmin complexes often demonstrate subtle activation of coagulation and fibrinolytic pathways.[90] Evidence of renal involvement may include hematuria, proteinuria, granular or red cell casts, and mild azotemia, though anuria and renal failure are uncommon presenting features.

MAHA, resulting from fragmentation of red blood cells in the microvasculature[89,90] is a sine qua non of this disorder. The presence of schistocytes on the peripheral blood smear is the most characteristic laboratory finding of thrombotic microangiopathy (Fig. 139–2), although these may not be apparent in rare patients at the onset of their disease.[91,92] The markedly elevated levels of plasma lactate dehydrogenase (LDH) that are typically seen in patients with TTP, once believed to result primarily from hemolysis, also reflect a contribution from tissue ischemia.[93] Nucleated red blood cells are present in many patients, and their number may be disproportionately increased in comparison to the degree of reticulocytosis.[75] With rare exceptions, the direct antiglobulin test is negative.[76] Other less common symptoms may include abdominal pain and respiratory distress. The differential diagnosis of TTP is broad.[23,77] Although a severe deficiency (<5%) of ADAMTS13 is consistent with a diagnosis of TTP, it is not diagnostic. Similarly, TTP cannot be excluded by a normal or only moderately decreased level of ADAMTS13.[94]

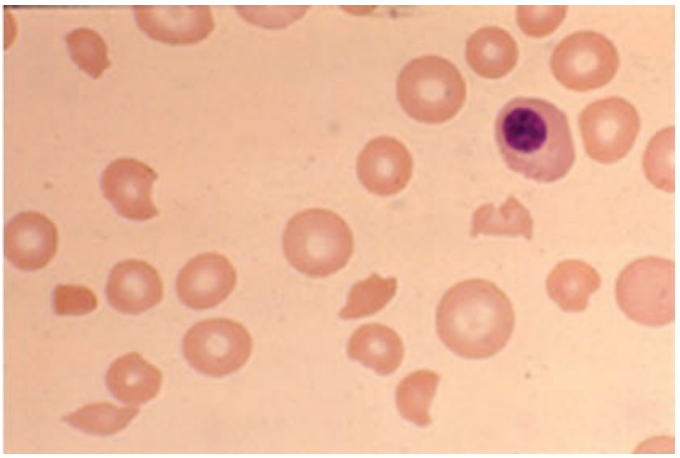

Figure 139–2 This peripheral blood film was obtained from a 28-year-old woman who presented with fever, epistaxis, and altered mental status. Note the absence of platelets and the presence of a nucleated erythrocyte and schistocytes (*arrows*), consistent with a microangiopathic process.

Pathogenesis

The cloning and biochemical characterization of ADAMTS13 has provided new insight into its role in the pathogenesis of TTP,[95,96] and facilitated the development of a model for how VWF and ADAMTS13 regulate platelet adhesion.[97] Endothelial cells secrete "unusually large" VWF multimers that may remain adherent to the cell surface and promote platelet attachment, or enter the circulation and promote intravascular platelet aggregation. Under high shear, vWF multimers elongate along the endothelium and promote platelet adhesion as well as susceptibility to vWF enzymatic cleavage.[64] ADAMTS13 regulates the activity of vWF by cleaving the most hemostatically active high-molecular-weight multimers; failure of this feedback mechanism may lead to the microvascular thrombosis, tissue ischemia, and infarction that are characteristic of TTP. However, many questions yet remain concerning the pathogenesis of this disorder.[21,98] For example, the factors that trigger sporadic episodes of TTP remain undefined. Although endothelial damage or

Approach to the Patient with Thrombotic Microangiopathy

The diagnosis of thrombotic microangiopathy must be made in a timely manner because delay carries with it the attendant risk of sudden death. The disorder should be considered when prodromal symptoms such as malaise, fatigue, gastrointestinal distress, or low-grade fever persist or progress in the face of symptomatic therapy, and a complete blood count and an analysis of the peripheral blood film should be performed. Suspicion should be heightened in women who are or were recently pregnant, in patients who are infected or are at risk for infection with the human immunodeficiency virus (HIV), in allograft recipients, and in those with a history of underlying vasculitis or exposed to specific drugs described in the text. Patients with early, idiopathic TTP frequently present without the classic triad or pentad of signs and symptoms. Thus, a provisional diagnosis of a primary thrombotic microangiopathy should be made, and plasma-based therapy instituted, in any patient with microangiopathic hemolytic anemia and thrombocytopenia, unless an alternative cause is evident. We consider an average of one or more schistocytes per high-power field to be of concern, especially when accompanied by thrombocytopenia and nucleated red blood cells, or a markedly increased serum LDH level. The differential diagnosis of microangiopathic hemolytic anemia (MAHA) and thrombocytopenia is extensive, and diagnosing a primary thrombotic microangiopathy can be difficult. Vascular damage secondary to systemic lupus erythematosus, scleroderma, septic or tumor emboli, immune complex-mediated vasculitis (eg, infective endocarditis), malignant hypertension, cryoglobulinemia, or infection with rickettsial or, more rarely, hemorrhage-inducing viral organisms, may all mimic thrombotic microangiopathy. Thrombotic microangiopathy may also be superimposed on preexisting immune vascular disorders such as systemic lupus erythematosus or the antiphospholipid syndrome; in such patients, plasma exchange should be added to existing antiinflammatory and immunosuppressive therapy. Occasional patients with disseminated intravascular coagulation secondary to malignancy or sepsis present with occlusive microangiopathy of sufficient severity to be confused with primary thrombotic microangiopathy. In the setting of renal transplantation, a biopsy may be required to distinguish thrombotic microangiopathy from allograft rejection or recurrence of a preexisting renal vascular disorder. Occasional patients with thrombotic microangiopathy may present with acute pancreatitis, acute respiratory distress syndrome, memory and personality changes, or other poorly defined neurologic symptoms that themselves have a broad differential diagnosis. Again, the finding of MAHA and thrombocytopenia provides important clues to the underlying problem and the urgent need for intervention with plasma-based therapy.

ADAMTS13 in the Management of Thrombotic Thrombocytopenic Purpura

A role for von Willebrand factor (vWF) in the pathogenesis of thrombotic thrombocytopenic purpura (TTP) has been suspected since the early 1980s, when reports describing the presence of ultralarge vWF multimers in the plasma of affected patients first appeared. This finding led to the hypothesis that TTP might result from deficiency of a protease responsible for vWF cleavage, and almost 20 years later the vWF-cleaving protease was isolated and found to be deficient in most patients with TTP. This protease was subsequently cloned, found to be a member of the ADAMTS metalloprotease family, and denoted ADAMTS13. This tremendous progress raised expectations that a simple and accurate diagnostic test would soon be available for the diagnosis of TTP. However, the utility of ADAMTS13 testing remains undefined, due in part to issues such as a lack of assay standardization and different inclusion criteria in studies that have assessed the relevance of ADAMTS13 measurements. Despite these obstacles, areas where this assay may or may not be useful have begun to emerge. *First*, ADAMTS13 measurements may be useful but are not sensitive for the diagnosis of TTP and specificity depends on the clinical setting. The incidence of severe ADAMTS13 deficiency (defined as <5% activity) has been reported to be as low as 33% in some series of patients with apparently idiopathic thrombotic microangiopathy. However, for patients with thrombotic microangiopathy, severe ADAMTS13 deficiency is very specific for idiopathic TTP, but may also occur, uncommonly, in other disorders such as sepsis-induced DIC or severe liver failure. Thus, although a severe ADAMTS13 deficiency is consistent with TTP, it is not diagnostic in the absence of other clinical information. Moreover, normal or moderately reduced ADAMTS13 levels (20%–40%) do not exclude TTP. *Second*, there is insufficient evidence at present to demonstrate a clear relationship between the levels of ADAMTS13 and/or anti-ADAMTS13 antibodies in acute TTP with short-term outcomes. Though two prospective studies suggest a higher first remission rate in patients with severe deficiencies of ADAMTS13, these findings require validation in larger, prospective studies. There is also no evidence that real-time monitoring of ADAMTS13 or anti-ADAMTS13 antibodies during initial treatment improves outcomes; both the diagnosis and initial management of TTP should be based on clinical and laboratory parameters, such as the platelet count and LDH. *Third*, patients with severe deficiencies of ADAMTS13, or detectable levels of anti-ADAMTS13 antibodies obtained either at diagnosis or during initial remission, are at markedly increased risk for subsequent TTP relapse, which may occur in 30% to 55% of patients with TTP. Thus, patients in this category might be considered for additional immunosuppressive therapy with anti-CD20 or other agents during remission, although the benefit of such intervention on long-term outcomes remains uncertain.

activation has been suggested as one such factor, exactly what may initiate such insults is uncertain. Moreover, some patients develop TTP despite normal levels of circulating ADAMTS13, whereas patients with congenital deficiencies of ADAMTS13 may not develop TTP until adulthood, and sometimes not at all.[55] The latter observations emphasize that factors other than ADAMTS13 deficiency contribute to the development of TTP, and suggest that ADAMTS13 deficiency should be considered an important risk factor, though perhaps not always a sufficient cause of this syndrome. This concept has been borne out in studies of ADAMTS13-deficient mice; the risk of developing a TTP-like syndrome depends strongly on the genetic background, and in some mice ADAMTS13 deficiency causes disease only after exposure to agents like Shigatoxin that induce endothelial cell dysfunction.[99]

Pathology

The prototypic vascular lesions of TTP are characterized by platelet-rich thrombi within or beneath a damaged endothelium.[54] Involved microvascular endothelial cells are swollen and in some cases detached. The subendothelium contains hyaline material that is relatively poor in fibrin but consists instead largely of von Willebrand factor (VWF) and platelet remnants.[17,100] In contrast, the lesions of HUS are rich in fibrin and contain comparatively little VWF.[17] Involved vessel walls characteristically display a paucity of mononuclear leukocytes; fibrinoid necrosis, aneurysm formation, and other evidence of vasculitis are absent in primary or idiopathic cases. Medium- and large-sized arteries show less extensive involvement and the venous system

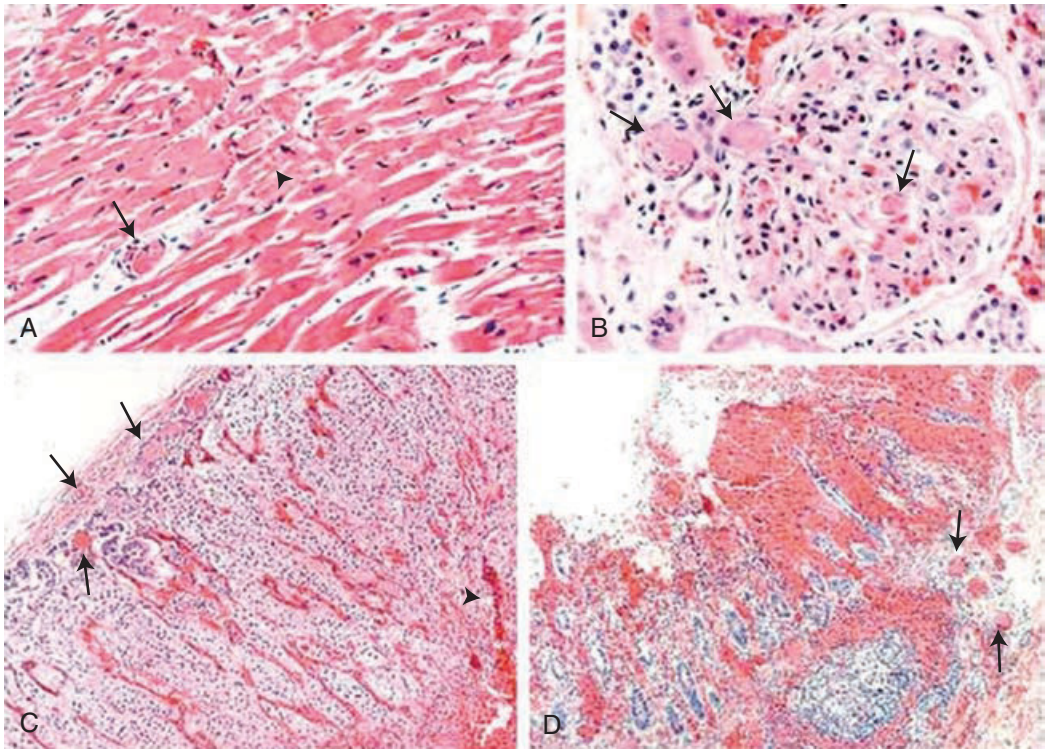

Figure 139–3 Tissue specimens obtained at autopsy from a patient with abnormalities characteristic of TTP. A specimen from the heart (*Panel A*) shows multiple intramyocardial microthrombi (*arrow*), hemorrhage, and early ischemic changes, with scattered foci of contraction-band necrosis (*arrowhead*). A specimen from the kidney (*Panel B*) shows characteristic microthrombi in an afferent arteriole, the glomerular hilum, and glomerular capillaries (*arrows*), with vascular congestion and parenchymal hemorrhage in the surrounding interstitium. A tissue specimen from the adrenal gland (*Panel C*) shows characteristic subcapsular microthrombi (*arrows*), with congestion of cortical arterioles and medullary parenchymal hemorrhage (*arrowhead*). A specimen from the cecum (*Panel D*) shows submucosal microthrombi (*arrows*) and hemorrhagic mucosal ulceration and necrosis. Microthrombi were also present in the pancreas, thyroid gland, and other organs. Photographs and interpretation by Patrick Stangeby. (Reproduced from George JN: Thrombotic thrombocytopenic purpura. N Engl J Med 354:1927, 2006, with permission).

is typically spared. The most commonly affected organs include the brain, pancreas, heart, and adrenal glands.[17,75] Involvement of other sites such as the kidney, spleen, gingiva, bone marrow, and skin (Fig. 139–3) may occur as well.[17,86] A characteristic pathologic lesion involving adjacent areas of vascular dilatation and constriction accompanied by segmental hyaline change may occur in the placenta of pregnant patients with TTP.[101]

von Willebrand Factor and ADAMTS13

Shortly after the congenital absence of ADAMTS13 was discovered to cause familial TTP, almost all patients with nonfamilial, idiopathic TTP were found to have acquired absence of ADAMTS13 activity, usually associated with autoantibody IgG inhibitors of the protease.[12,102] These initial findings have been confirmed repeatedly, although the prevalence of ADAMTS13 deficiency in TTP has not always been as high. Some of this variation may reflect the inclusion or exclusion of patients with acute renal failure or other preexisting conditions. For example, one study found ADAMTS13 deficiency in 18 of 48 adults with idiopathic thrombotic microangiopathy unselected for renal function,[84] whereas another study reported ADAMTS13 deficiency in 22 of 22 patients without acute anuric renal failure.[103] Conversely, acquired severe ADAMTS13 deficiency is extremely rare in patients without thrombotic microangiopathy,[13] with the possible exception of sepsis. For example, a retrospective study of 109 patients with sepsis-induced DIC found ADAMTS13 levels lower than 5% in 17 of them (16%).[104] Severe liver failure is another setting in which rare patients may have severe ADAMTS13 deficiency. Modest decreases in plasma ADAMTS13 activity have been reported in newborns and among adults with cirrhosis, chronic renal insufficiency, pregnancy, connective tissue diseases, and various inflammatory conditions, but the mean ADAMTS13 levels in all of these groups were higher than 40% and none of the patients had levels lower than 6%.[105,106] Therefore, severe ADAMTS13 deficiency (<5%) appears to be quite specific for TTP, although its sensitivity depends on how patients are identified and whether they have other conditions that may predispose to thrombotic microangiopathy.[13,107]

Antibodies against ADAMTS13 have been demonstrated in 59% to 100% of patients with acquired severe ADAMTS13 deficiency.[12,84,102,103,108,109] This variability probably reflects the relative insensitivity of certain assays for detecting inhibitors.[110] In addition, some IgG and IgM antibodies may cause ADAMTS13 deficiency by promoting its clearance from the circulation without inhibiting activity.[111]

Plasma exchange is effective for patients with or without inhibitors, and clinical responses frequently occur despite the persistence of both the inhibitor and severe ADAMTS13 deficiency, although patients with high-titer inhibitors may respond more slowly and relapse more often.[55,103,112] Both congenital and acquired ADAMTS13 deficiency are characterized by unpredictable periods of stability between relapses, which probably reflects a role of stress in exacerbating the disease by activating or damaging endothelium, increasing the release of unusually large VWF multimers, and triggering microvascular platelet thrombosis. An interaction between ADAMTS13 deficiency and stress would account for the frequent occurrence of thrombotic microangiopathy in association with pregnancy, surgery, infections, and various other inflammatory conditions that raise VWF levels.

Other Mechanisms

ADAMTS13 levels are normal in some cases of idiopathic TTP, and in almost all cases of thrombotic microangiopathy associated with stem cell or organ transplantation, cancer, infections, severe hypertension, and certain drugs. Therefore, as discussed above, mechanisms other than ADAMTS13 deficiency can cause thrombotic microangiopathy, and various studies have implicated endothelial injury, platelet activation, and alterations in blood clotting as contributory factors.

Plasma from patients with TTP and other forms of thrombotic microangiopathy often contain elevated concentrations of endothelial-derived proteins such as thrombomodulin, P-selectin, plasminogen activator inhibitor type 1 (PAI-1), and VWF.[88,113,114] Elevated levels of endothelial cell microparticles,[115] some of which may bind vWF[116] and induce platelet aggregation,[117] and decreased levels of tissue factor pathway inhibitor[118] have also been reported. The production and stability of endothelial cell prostacyclin, a vasodilator and inhibitor of platelet activation, may be decreased.[119,120] Impaired renal generation of prostacyclin has been observed in children with *Escherichia coli*-associated HUS.[121] However, treatment of patients with intravenous prostacyclin has met with inconsistent responses.[122–124]

Antiplatelet and endothelial cell antibodies of diverse specificity have been identified in TTP, and may bind preferentially to microvascular endothelial cells.[125,126] Some antiendothelial cell antibodies recognize CD36[125,127] and might inhibit the binding of thrombospondin-like domains in ADAMTS13 to microvascular endothelium.[18] However, the pathophysiological significance of these antibodies has not been established.

Plasma from patients with idiopathic and human immunodeficiency virus (HIV)-associated TTP and sporadic HUS, but not *E coli* verotoxin-associated HUS, induce apoptosis of dermal microvascular, renal and cerebral, but not pulmonary or hepatic endothelial cells. Apoptosis involves the induction of Fas (CD95)[128,129] and upregulation of caspases 1 and 3, and is inhibited by overexpression of Bcl-X_L or the Bcl-2 homolog A1.[130] DNA array analysis suggests that the resistance of pulmonary endothelial cells to apoptosis induced by TTP plasma may reflect increased expression of survival factors such as the TRAIL antagonist osteoprotegerin and vascular endothelial cell growth factors and their receptors.[131] Ticlopidine and plasma from patients with ticlopidine-associated TTP also induced apoptosis of microvascular endothelial cells in vitro, possibly related to altered interactions of endothelial cells with the extracellular matrix.[132]

In addition to alterations in endothelial cell function, TTP plasma may promote platelet aggregation directly.[133] Platelet microparticles have been detected in essentially all patients with thrombotic microangiopathy, their number correlating inversely with the platelet count and their disappearance with clinical improvement.[134] Circulating endothelial microparticles may directly bind vWF, and aggregate platelets through a vWF-dependent pathway.[135] Though several additional platelet-activating moieties have been identified,[136–139] their role in the pathogenesis of TTP has not been defined. Indeed, recent thought concerning the pathogenesis of TTP has evolved toward a model in which platelet aggregation occurs primarily in response to high-molecular-weight vWF multimers bound to the surface of stimulated endothelial cells and not appropriately cleaved in the absence of ADAMTS13, rather than on spontaneous aggregation of platelets in plasma.[140]

Some reports suggest a role for increased procoagulant activity in the pathogenesis of thrombotic microangiopathy. Acquired deficiencies of proteins C and S have been described in some patients.[141,142] Analysis of a small case series suggested that the prevalence of Factor V Leiden was increased in patients with TTP and normal ADAMTS13 activity,[143] though this was not observed in a larger study.[144] In patients with verotoxin-producing *E coli* infection (see section on Verotoxin-Associated Thrombotic Microangiopathy), evidence for activation of the coagulation system, as documented through the measurement of prothrombin fragment 1+2 and thrombin–antithrombin complexes,[145,146] closely follows the onset of bloody diarrhea and precedes the development of the hemolytic uremic syndrome.[145]

Several reports have focused on characterization of the fibrinolytic abnormalities in patients with thrombotic microangiopathies, particularly HUS. Plasminogen activator activity was reportedly absent from vessels occluded by microthrombi.[147] Plasma levels of PAI-1 are increased in both primary[90,148] and bone marrow transplant-associated TTP,[149] as well as in VTEC-associated HUS.[141,150–152] Plasma concentrations of PAI-1 may have prognostic significance in children with the latter, and the recovery of renal function in a cohort of children with thrombotic microangiopathy may correlate with the removal of PAI-1 by peritoneal dialysis.[152] Others, however, argue that the elevated concentrations of PAI-1 result primarily from renal insufficiency,[153,154] and that corresponding increases in t-PA, t-PA:PA1-1 complexes and fibrinogen D-dimers suggest that fibrinolysis is stimulated rather than impaired.[153,155]

Vasoregulators such as endothelin[156] may also contribute to microvascular constriction and increased shear stress in thrombotic microangiopathy, particularly within the renal vasculature. Nitric oxide metabolites may be involved in the generation of lipid peroxides, superoxide anions, peroxynitrite and hydroxyl radicals, though increased production of nitric oxide diminished renal injury in a rat model of thrombotic microangiopathy.[157] Nitric oxide depletion as a result of binding to free hemoglobin has been postulated to mediate vasoconstriction in patients with TTP.[158] Products of activated leukocytes, such as elastase and cathepsin G may also contribute to tissue damage.[159]

Therapy

The mortality rate of TTP exceeds 90% without therapy. Through the mid-1970s, splenectomy remained the only modality with more than an anecdotal response rate.[76] Since that time, there has been a dramatic reversal of this prognosis with the advent of plasma-based therapy, such that long-term survival now approaches 80%.[6,20,160,161] Moreover, with the appreciation that TTP may in many cases be an immune-mediated disorder, the use of immune-based approaches is expanding.

Plasma Therapy

Anecdotal responses to whole blood infusion were reported after Moschowitz's initial description of TTP, in which he noted that a colleague had seen four similar patients who recovered promptly after transfusion of whole blood.[1] Yet the remarkable benefit of plasma therapy was not appreciated until 1976, when Bukowski et al reported a 50% survival rate in 16 patients with thrombotic microangiopathy treated by exchange transfusion.[162] The next year, Byrnes and Khurana reported that the active component in whole blood was contained in plasma, an observation that led to the widespread use of plasma infusion.[163] The same year, Bukowski et al[164] demonstrated the efficacy of plasma exchange, which suggested that the response rate might be improved by removing a toxic substance from patient plasma.

The results of a prospective trial reported in 1991 appeared to resolve the long-debated issue of the relative efficacy of plasma exchange versus infusion in favor of the former. At 6 months, complete remissions were seen in 78% of patients treated with exchange versus 31% in those treated with plasma infusion.[165] This study did not resolve the question of whether removal of a disease-inciting agent or replacement of a missing factor accounted for the superior response observed with plasma exchange, particularly because patients in the exchange arm received a threefold greater volume of plasma. Indeed, a retrospective study demonstrated no significant difference in outcome in patients with acquired TTP who received equal volumes of plasma by exchange or infusion.[166] However, the current model for the pathogenesis of acquired idiopathic TTP suggests that plasma exchange is superior because it both removes an IgG inhibitor of ADAMTS13 and replaces the deficient protein, and the benefit of

plasma exchange over infusion has also been suggested by a recent systematic review.[167] In contrast, plasma infusion may be sufficient for patients with a genetic cause of ADAMTS13 deficiency, or perhaps acquired deficiency due to a low-titer inhibitor.[164,168] From a practical perspective, large volumes of plasma are more easily administered by plasma exchange, and unless a genetic deficiency of ADAMTS13 has been documented, plasma infusion should be reserved for situations in which exchange is not immediately available.[169] It is worth noting that plasma exchange is highly effective even in patients who do not have a severe deficiency of ADAMTS13,[84] suggesting that this modality may have additional therapeutic mechanisms. This observation highlights the belief that monitoring of ADAMTS13 and/or anti-ADAMTS13 levels during plasma therapy for acute TTP does not improve outcomes (see box on ADAMTS13 in the Management of Thrombotic Thrombocytopenic Purpura).

Plasma exchange is generally initiated with the goal of exchanging 1 to 1.5 plasma volumes (40–60 mL/kg) daily although the optimal regimen has not been determined.[20,23] Patients begun on a regimen of 1 plasma volume daily may be increased to 1.5, or in some cases, 2 plasma volumes daily if their initial response is poor. Neurologic improvement occurs most rapidly, often within hours to days.[78] The serum LDH level typically falls by 50% within 3 days in responders, and the platelet count begins to rise in a mean of 5 days, although normalization may take several weeks.[78] Impaired renal function is generally the last to improve. Several prognostic factors at the time of presentation have been suggested through multivariate analysis, including an age greater than 40 years, hemoglobin less than 9.0 g/dL, and the presence of a fever greater than 38.5°C.[170]

Fresh frozen plasma remains the most commonly used replacement product. An advantage to the use of cryosupernatant, which is depleted of von Willebrand factor, was suggested by a retrospective study in which 50% of patients seemingly refractory to exchange with FFP responded to subsequent exchange with cryosupernatant (cryopoor plasma, CPP).[165] However, a small prospective study found no difference in outcomes between patients treated with these products as initial therapy.[171] These findings are consistent with a recent study in which similar concentrations and stability of ADAMTS13 during storage at 1 to 5°C were observed in CPP and fresh frozen plasma.[172] Experience with solvent-detergent treated plasma has been increasing, and in a recent pilot study this product appeared to have similar efficacy as standard fresh frozen plasma with a lowered incidence of allergic/urticarial and citrate reactions; an increased risk of thrombosis was not observed.[173] Solvent-detergent treated plasma contains ADAMTS13 at concentrations approximately 20% below those observed in fresh-frozen plasma.[174]

Daily plasma exchange should be continued until neurologic symptoms have resolved and both a normal serum LDH and platelet count have been maintained for at least 2 to 3 days[10,20,23,72,175]; a shorter duration of therapy risks immediate and occasionally fatal relapse. Approximately 85% to 90% of patients will show a clinical and laboratory response to plasma exchange within 3 weeks, most often within 10 days (mean 15.8; range 3–36 days).[165] However, at least 30% of patients experience one or more relapses, the exact frequency depending on the definition used; recurrence within 30 days of discontinuing plasma exchange is considered exacerbation of existing disease.[6] The decision to switch from FFP to cryosupernatant or to introduce another form of therapy remains a matter of clinical judgment but has historically not been considered until the patient has received a minimum of 10 to 14 days of daily exchange with FFP, unless extraordinary circumstances intervene. There is little data to support an approach of either abrupt discontinuation of plasma exchange after remission is achieved or "tapering" the frequency of therapy; thus, this decision must be empiric. The benefit of using other modalities with plasma exchange in the treatment of TTP is unproven, although the addition of rituximab and other agents has been proposed based on anecdotal results from small studies.[176–179]

Contemporary studies have highlighted the complications of plasma exchange therapy. Complication rates may approach 30%, mostly related to central venous catheter insertion or infection.[180–182] Thrombosis has also been reported, and some, but not all reports have suggested a higher incidence when solvent-detergent (S/D) treated plasma, which contains reduced amounts of protein S, is used as a replacement fluid.[183,184]

Corticosteroids

Corticosteroids are often used as part of initial therapy or in those who fail to show a brisk response to plasma-based therapy.[6] Corticosteroids are of little benefit on their own[87,160] and retrospective studies do not provide compelling evidence that they improve the response to plasma exchange.[160] However, the antiinflammatory and immunosuppressive effects of corticosteroids make them attractive adjunctive therapy for autoimmune idiopathic TTP and they have been recommended for routine use for patients receiving plasma exchange.[20]

Splenectomy

Before the introduction of plasma therapy, splenectomy was considered first-line treatment for TTP, inducing remission in up to 50% of patients when used in conjunction with other agents.[160] In the plasma exchange era splenectomy has generally been reserved for refractory patients, with variable response rates.[43,119,120] Recent reports demonstrate that laparoscopic splenectomy may be safely performed in TTP patients with minimal morbidity,[185] and that excellent responses occur in some refractory patients.[121,122] Some series suggest that splenectomy induces an enhanced response to plasma exchange in patients initially refractory.[78,87] Splenectomy during hematologic remission may reduce the incidence of relapses in patients with chronic relapsing TTP.[186] Therefore, splenectomy may be considered in patients refractory to large-volume plasma exchange or immunosuppression (see below). Plasma exchange should be continued after surgery and until the thrombotic microangiopathy remits.

Other Modalities

The response rate to *antiplatelet agents* such as aspirin, dipyridamole, sulfinpyrazone, or ticlopidine as single agents approximates 10%,[87,160] essentially indistinguishable from the natural history of thrombotic microangiopathy. Antiplatelet agents have not been convincingly shown to increase the response to plasma exchange[6,165,187,188] and may promote bleeding in the setting of severe thrombocytopenia and invasive procedures.[6,189] Hence, their use as first-line therapy cannot be recommended, though a potential role in preventing relapse has been reported.[190] The use of *intravenous immunoglobulin* is predicated on a report that IgG from healthy individuals inhibits the capacity of TTP plasma to agglutinate platelets in vitro,[191] a finding that has not been reproduced. Most reports supporting the efficacy of intravenous immunoglobulin[192] are compromised by the delay in the initiation of treatment or concomitant administration of other agents, and others have failed to demonstrate responses to intravenous immunoglobulin after failure of plasma exchange. A recent study described a response to the combination of plasma exchange and intravenous immunoglobulin in a patient who was refractory to plasma exchange alone.[179] There are anecdotal reports of favorable responses to *vincristine*[87,160,193–195] as well as other immunosuppressive therapies such as azathioprine, cyclophosphamide, cyclosporine, and staphylococcal protein A immunoadsorption.[196,197]

With numerous reports documenting its efficacy[92,198–200] the anti-CD20 monoclonal antibody, rituximab, has been used with increasing frequency in TTP.[201] The bulk of rituximab use has been in patients refractory to plasma exchange, in whom it has been used alone[202] or in conjunction with additional plasma exchange.[177,178,203] In some individuals, rituximab has been employed in the treatment of one or more relapses.[204,205] Rituximab administration has been associated with a decrease in the level of inhibitory ADAMTS13 IgG antibodies,[202,203,206] which has led to its use in patients with TTP in remission in whom decreasing levels of ADAMTS13 activity with recurrence of inhibitors has been noted during follow-up.[207] However, there have been no prospective, randomized trials of rituximab in

Transfusion Therapy in Thrombotic Microangiopathy

Patients with TTP often develop symptomatic anemia because of bleeding and partially compensated hemolytic anemia. Packed red blood cells can be transfused safely in this setting. In elderly patients and in those with an impaired cardiovascular system, it may be prudent to provide an additional margin of safety when choosing a threshold for transfusion. In contrast, platelet transfusions are relatively contraindicated in TTP. Though no controlled studies have addressed this issue, there are several published reports of patients under treatment for TTP whose clinical situation deteriorated markedly within 1 to 24 hours of receiving allogeneic platelets; the authors are aware of similar experiences. Clinical deterioration after platelet transfusion can also occur in patients with HUS, as well as VTEC-associated and drug-induced thrombotic microangiopathies. Postmortem examination of such patients has revealed widespread microthrombi involving the brain, heart, lung, kidney, and multiple other organs. Many of these appeared "fresh," in that they showed no evidence of overgrowth by proliferative endothelial cells. Sudden death has also been reported on rare occasions in patients who responded to plasma therapy with a rapid rise in the platelet count. Thus, we consider platelet transfusions to be relatively contraindicated in patients with TMA in the absence of overt major bleeding or a comparable hemostatic challenge.

either primary or relapsed TTP, and thus its efficacy and optimal application in TTP remain uncertain. A randomized, prospective trial of plasma exchange alone compared to plasma exchange and rituximab is under development through the NIH-sponsored Transfusion Medicine and Hemostasis Clinical Trials Network.[208]

Cyclosporine is another immunotherapy that has been used anecdotally in TTP, with studies showing promise both in reducing the incidence of relapse,[209] and treating early relapse.[210] Responses correlate with improvements in ADAMTS13 activity and decreases in anti-ADAMTS13 antibody titer.[211] As with rituximab, the role of cyclosporine in the treatment of TTP remains uncertain because of the paucity of information derived from prospective, randomized trials.[212] Anecdotal success with mycophenolate mofetil has also been reported.[213]

The use of low-dose aspirin (81 mg daily) commenced on platelet recovery (platelet count >50,000/μL) has been recommended by some, particularly in patients who experience a rapid rise in the platelet count.[20,87] Folate supplementation and administration of the hepatitis B vaccine should be considered routine components of supportive care.[20] Platelet transfusion is relatively contraindicated in patients with TTP.

THE HEMOLYTIC UREMIC SYNDROME

The hemolytic uremic syndrome is considered as two primary syndromes that differ in cause and outcome, though each of these may have several variations (Table 139–1).

Verotoxin-Associated Thrombotic Microangiopathy

Epidemiology

This variant of thrombotic microangiopathy has been referred to as "typical," "epidemic," "childhood," diarrheal D^+, verotoxin *E coli*-associated (VTEC), and Shiga-like toxin (Stx)-related HUS. The incidence is highest in children below the age of 5 years,[214] but the disorder can occur at any age.[7,214–217] In one epidemiologic study conducted in the United States, the median age of patients with D^+ HUS was 4 years; 55% of patients were less than 5 years of age, 33% between 5 and 17 years, 6% between 18 and 44 years, and 6% older than 45 years of age.[218] The pathogenesis, and in particular its association with verotoxin-producing *E coli*,[26] has been established; these organisms account for 80% to 86% of HUS in the United States and Europe.[216] The major reservoir of verotoxin-producing *E coli* is domestic cattle; approximately 2% to 3% harbor enteropathic *E coli* in their gastrointestinal tract at the time of slaughter,[219] and meat becomes contaminated with *E coli* during processing. The organism has also been isolated from deer, sheep, goats, horses, dogs, birds, and flies.[214] Outbreaks are most often associated with ingestion of inadequately cooked ground beef,[214,218,220] though contamination of poultry, cheese, fruits, and vegetables has also been reported. Other cases have been attributed to ingestion of contaminated water[221] or unpasteurized apple cider or milk.[222] The incidence of Stx-HUS may be increasing as a result of developments in food production methods.[219] Meat is now more likely to be prepared from hundreds or thousands of grain-fed cows. Industrial farming also generates large quantities of potentially contaminated manure that periodically enters streams where it can contaminate feed and uncooked vegetables.[219] Carriage may be asymptomatic[223] and fecal–oral transmission may contribute to spread in settings such as day care centers[224] and nursing homes,[225] whereas aerosolization in barns has been implicated in outbreaks at fairs. Petting zoos have also been a source of pathogenic *E coli*.[226]

The relationship of Stx-producing organisms to human disease was first recognized in 1983 based on the identification of *E coli* strain O157:H7 as the probable cause of two outbreaks of hemorrhagic gastroenteritis.[227] VTEC were implicated in the development of HUS after the organisms were detected in stools from 11 of 15 Canadian children with HUS.[228] Subsequent studies demonstrated an association between HUS and additional verotoxin-producing strains of *E coli*,[218,229] of which more than 100 have now been identified.[148,152] In one outbreak, toxigenic *E coli* were detected in 68% of children with HUS; 46% of cases were due to *E coli* O157:H7, 25% to *E coli* O26, and the rest due to other serogroups.[230,231] VTEC are also associated with sporadic, nonepidemic cases of HUS,[214,220,232] although molecular subtyping may be required for documentation.[233] The disease occurs more frequently during summer and autumn in temperate climates,[26] with approximately 50% of cases occurring between June and September.[216] In addition to *E coli*, infection by Shigatoxin-producing *Shigella dysenteriae* serotype 1 is associated with HUS in developing countries, particularly in Asia and Africa, though *S dysenteriae* is a very uncommon cause of HUS in industrialized countries.[217] The mortality of *S dysenteriae*-associated HUS is significantly higher than that of *E coli*-associated disease despite a similar pathogenesis.[216] Cases resulting from verotoxin-producing *Citrobacter freundii* have also been reported.[230]

Clinical Manifestations

Stx-induced HUS occurs most commonly after *E coli* O157:H7-induced gastroenteritis,[234,235] with rare cases reported after infection of the urinary tract or skin, or infection with non-*E coli* organisms.[216,217,230,236,237] The disease begins with the sudden onset of abdominal pain and watery diarrhea a mean of 3.7 (range 2–12) days after toxin exposure.[151,238,232] Abdominal pain may be severe and precede the onset of diarrhea. This presentation, particularly in the absence of fever, may be difficult to differentiate from inflammatory bowel disease, appendicitis, ischemic colitis, or intussusception. Bloody diarrhea generally ensues on the second day accompanied in some cases by nausea and vomiting,[7,218,238] though up to one-third of patients do not report blood in the stool.[239] Fever is typically absent or mild. Colonoscopy reveals edematous colonic mucosa, with occasional ulceration and pseudomembrane formation. Thumbprinting in the distal ascending and proximal transverse colon, suggesting an ischemic colitis, may be seen on barium enema and is attributed to exotoxin-induced thrombi in the microvasculature of the bowel wall.[7,232]

It is estimated that *E coli*-associated hemorrhagic gastroenteritis is complicated by HUS in 8% to 18% of sporadic cases, and more than

20% in certain epidemic outbreaks.[7,240] Young children and the elderly are at greatest risk,[238] perhaps due in part to slower clearance of the organism from the gastrointestinal tract. HUS typically develops 1 to 3 days after the onset of bloody diarrhea, with oliguria or other evidence of renal impairment[7,216,218,241]; 50% of patients require dialysis, at least temporarily.[235] The severity of MAHA varies considerably, but many affected individuals require red cell transfusions.[238] Thrombocytopenia is common, with a median platelet count of 30,000/μL in one study,[218] but may be mild or absent in up to 30% of cases at presentation. Twenty-five percent of patients develop neurologic manifestations, which may include irritability and somnolence, and less commonly, confusion, paresis, and seizures.[7,218,242]

The disease should be suspected in a patient who presents with the characteristic clinical manifestations after an episode of bloody diarrhea, although the prototypic history of a preceding hemorrhagic gastroenteritis may be absent in up to 30% of cases.[7,218,238,243] Stool cultures are positive in approximately 50% of those whose diagnosis is confirmed serologically.[218,235] *E coli* O157:H7 ferment sorbitol slowly, appearing as colorless overnight colonies on sorbitol–MacConkey agar; sorbitol-negative cultures may be characterized further using commercially available O157:H7-specific antisera.[218,244] Methods to detect Stx or their structural genes[232] improve diagnostic sensitivity, and a point-of-care card that detects *E coli* O157:H7 by immunodiffusion has been developed.[245]

The risk of developing HUS when Stx is associated with non-O157:H7 species of *E coli* varies.[246,231] A fourfold or greater rise in antibody titer to either Stx or O157 lipopolysaccharide confirms the diagnosis.[232] Serologic assays are more sensitive than stool cultures and may remain positive for up to 8 weeks.[218,247] Algorithms developed to diagnose Stx-HUS have recently been developed.[248]

Pathology

Renal biopsy, though rarely required for diagnosis in endemic areas, suggests that endothelial damage is central to the pathogenesis of Stx-HUS. Involved glomeruli show widening of the subendothelial space, which is filled with cellular debris and fibrin (Fig. 139–3). Concurrent thickening of the capillary wall results in a "double contour" appearance.[249] In some specimens, infiltration of glomeruli by monocytes and, to a lesser extent, neutrophils has been observed, perhaps as a result of elevated urinary levels of monocyte chemoattractant protein-1 and interleukin 8.[250] Glomerular capillary endothelial cells are swollen and occasionally detached, leading to obliteration of the capillary lumens.[251] Thrombi in glomerular capillaries may be sparse,[120] though thrombotic occlusion of afferent arterioles may be present. Glomerular involvement with sparing of larger arterioles and arteries is generally associated with a better prognosis.[252] In older children and adults (who primarily develop sporadic, D^- HUS), involvement of arterioles and interlobular arteries, with relative sparing of glomeruli, is observed more commonly. Lesions are characterized by edema and myointimal proliferation, necrosis of the vascular wall, and patchy renal cortical necrosis. Glomeruli exhibit ischemic changes, characterized by collapse, retraction, and wrinkling of the capillary loops. This pattern is associated with a poor prognosis and a high incidence of chronic renal insufficiency.[252]

Toxins

Enteropathic *E coli* are generally noninvasive. These organisms create a tight zone of attachment to the intestinal wall through the actions of intimin, and express several other virulence factors that enhance their proliferation locally.[22,253,254] Their capacity to cause HUS is attributed to two 70-kd bacterial exotoxins[255] named verotoxins for their cytotoxicity against African green monkey kidney (Vero) cells. The toxins are transported across the intestinal epithelium through specific para- and intercellular mechanisms[256] and then circulate, most likely by binding with low affinity to the surface of neutrophils, before being transferred to receptors expressed on glomerular endothelial cells that are upregulated by proinflammatory cytokines (see below).[257,258] Verotoxins also bind to platelets, red cells, and activated monocytes; however, the majority of transport appears to result from neutrophil binding because toxin incubated with whole blood binds preferentially to the latter.[217,257]

Verotoxin-1 is homologous to a Shigella toxin[214,255] and is therefore generally referred to as Shiga-like toxin 1 (SLT-1 or Stx1). Most strains of pathogenic *E coli* produce a second toxin, Stx2, which is 30-fold more potent[259] and associated with a higher risk of developing HUS.[260] The toxins are carried on a lysogenic bacteriophage that is capable of infecting other strains of *E coli*. The intact, 70-kd Stx holotoxins consist of a 32-kd A subunit and five 7.7-kd B receptor-binding subunits.[259] The toxin binds to terminal Gala1-4Galb (galabiose) residues primarily on globosyltriaosylceramide (Gb_3; also known as CD77 and the human blood group P(k) antigen)[261] that are highly expressed on capillary endothelium in the glomerulus and brain; the expression of these receptors is upregulated by TNF released as a consequence of toxin-induced leukocyte activation.[262] Receptor-bound holotoxin is internalized[263] and transported in a retrograde manner to the endoplasmic reticulum and then to the nucleus.[262,264] The A subunit is proteolyzed to a 27-kd A1 subunit that binds the 60s ribosomal subunit and cleaves adenosine from ribosomal RNA and RNA-free chromatin and DNA.[265] This prevents elongation factor 1-dependent binding of aminoacyl tRNA, which inhibits protein synthesis and leads to caspase-mediated endothelial cell apoptosis.[266] Signal transduction through cross-linked B-unit–CD77 complexes may also contribute to its cytotoxicity.[256,267] Recently, additional virulence factors, such as cytolethal distending toxin, which may interfere with the endothelial cell cycle, have been described, though their specific role in disease pathogenesis has yet to be fully defined.[268]

Pathophysiology

HUS is caused by endothelial cell damage initiated by Shiga toxins and the inflammatory cytokines they induce. The subytpe and amount of Stx, as well as other virulence factors, contribute to risk.[269] Stx promotes bacterial adhesion to the intestinal epithelium and stimulates a local inflammatory response that recruits neutrophils and monocytes, leading to toxic and ischemic intestinal inury. Stx translocates across the epithelium where it binds to and activates leukocytes, and is then transported via leukocytes to target organs such as the kidney. There, Stx upregulates expression of high-affinity Gb3 receptors on renal capillary endothelium, mesangial and tubular epithelial cells.[270] Increased expression of Gb3 on glomerular microvascular and cerebral endothelium compared with other vascular beds[271] contributes to their heightened sensitivity to apoptosis, cytotoxicity, upregulation of integrins, and procoagulant activity.[271,272] The predilection of children to develop HUS may relate to the higher levels of Gb_3 expression compared with adults.[271] *E coli* lipopolysaccharide and Stx also stimulate leukocyte and intrarenal expression of diverse proinflammatory cytokines including IL-1, -6 and -8, MCP-1, interleukin-1β, and interferon-γ that exacerbate toxin- and leukocyte-induced endothelial dysfunction.[270,273,274] Interactions between endothelial cell fractalkine and mononuclear leukocytes expressing the fractalkine receptor, CX3R1, may play a particularly important role in the renal damage characteristic of HUS.[275] Stx also acts in concert with lipopolysaccharide to trigger a procoagulant state early in the course of the disease that involves platelet activation,[276,277] expression of tissue factor, release of unusually large von Willebrand factor multimers,[278] and elaboration of plasminogen activator-1,[145] promoting thrombosis at sites of damaged endothelium.

Management

Stx-associated HUS is the most common cause of acute renal failure in children[26,243] and its management has been recently reviewed.[248,279]

Patients with acute bloody diarrhea, especially in the absence of fever, and those with very painful diarrhea should be considered to have *E coli* O157:H7 infection and be admitted for hydration and infection control.[248,280] Aggressive hydration has been shown to be nephroprotective,[281] though careful attention to fluid and electrolyte status is essential.[282] Although approximately 60% of children require dialysis initially, the disorder is typically self-limited and mortality has been reduced to 3% to 5%[283] with appropriate supportive care[266,218] with death usually due to severe involvement of the central nervous system, intestine or myocardium.[283] Renal insufficiency generally resolves within 2 to 3 weeks, although some patients have prolonged anuria, requiring several months before return to normal, and renal recovery after up to 40 months of dialysis has been reported.[284] Though angiotensin converting enzyme inhibitors (ACEI) may diminish renal blood flow in acute HUS, they may have a renoprotective effect in patients with persistent proteinuria following the disease.[281] Despite a favorable short-term outcome, many children with Stx-associated HUS develop chronic renal insufficiency over time.[285] In one report of 29 patients with "typical" childhood HUS followed for 15 to 28 years, 7 developed chronic renal failure and 12 developed hypertension, proteinuria, or reduced glomerular filtration rate, whereas only 10 showed no residual abnormalities.[252] Thus, approximately 50% to 60% of patients have complete recovery with long-term preservation of renal function.[283,286] Long-term outcome is worse in those presenting with prolonged anuria,[287] an elevated leukocyte count,[288] elevated levels of prothrombin fragment 1+2, tissue type plasminogen activator and plasminogen activator 1[145] and older age.[22,225,289] There is also a correlation between the extent of histological damage on presentation and eventual outcome; virtually all patients with cortical necrosis are left with significant chronic renal disease.[252] Proteinuria persisting for more than 1 year after the initial episode of thrombotic microangiopathy is likewise associated with progressive renal disease.[243,283]

In randomized trials, neither plasma infusion nor exchange has been of benefit in children or adults with Stx-associated HUS.[20,286,290] A trial of pheresis is indicated only in the adult with episodic HUS that cannot be distinguished from TTP on presentation.[6] Corticosteroids, heparin, urokinase, aspirin, and dipyridamole have been ineffective.[216] A silicon dioxide particle covalently linked to a trisaccharide, designed to bind toxin in the intestine and block systemic effects, has not shown benefit in clinical trials.[291] Antimotility agents and narcotics delay clearance of *E coli* and toxin from the GI tract and may increase the risk of progression to thrombotic microangiopathy.[292,293] Nonsteroidal antiinflammatory agents may reduce renal blood flow. Most experts believe that antibiotics increase the risk of progression to HUS by lysing bacteria, releasing Stx and inducing bacteriophages on which *stx* genes are expressed,[248,294] though this was not confirmed in a recent metanalysis.[295]

Sporadic (D^-) Hemolytic Uremic Syndrome

"Sporadic" HUS is a form of systemic thrombotic microangiopathy in which renal failure developing in the absence of an obvious precipitating factor is the predominant feature. This disorder may be referred to as the "adult" or "atypical" HUS, but also accounts for up to 10% of cases in the pediatric population. Sporadic HUS is not associated with a prodrome of bloody diarrhea and therefore is also referred to as D^- or $VTEC^-$ HUS to contrast with HUS associated with verotoxin-producing *E coli* or other bacteria.[28] However, D^+ cases do occur in adults, often in epidemics associated with a contaminated food source.[219] "Sporadic" cases occurring in more than one family member[296] may follow an autosomal recessive or dominant pattern, and many are associated with a mutation in complement regulatory proteins (vide supra).[14,38,200] The course of thrombotic microangiopathy that complicates bone marrow transplantation, immunosuppressive medication, pregnancy, and chemotherapy most closely resembles that of D^- HUS.[28] Although D^- HUS is significantly less common than TTP, the fact that up to 16% of patients in large TTP series have required dialysis demonstrates that these disorders can be indistinguishable on clinical gounds.[6,10,23,297]

Patients with sporadic HUS often experience a prodrome suggestive of an upper respiratory tract infection or nonspecific symptoms of malaise and fatigue, but severe abdominal pain and bloody diarrhea as observed in D^+ HUS is notably absent. Neurologic manifestations are typically less common and severe than in TTP and are less likely to dominate the clinical course.[298] MAHA is universal, and the reticulocyte count and LDH concentration are elevated,[299] but severe thrombocytopenia is less common than in TTP.[299,300] Sporadic HUS does not display the seasonal variability characteristic of verotoxin-associated HUS.[26] Renal involvement is more severe than in TTP, with up to 60% of patients requiring dialysis.[301]

Because of its rarity, lack of clear diagnostic criteria, and the inclusion of patients with HUS in series consisting primarily of patients with TTP, the responsiveness of patients with atypical HUS to therapy is ill defined. This disorder is also frequently grouped with pregnancy, cancer, and chemotherapy-associated thrombotic microangiopathies that may have similar clinical presentations but different natural histories. Nevertheless, overt sporadic HUS is associated with a poor prognosis, especially in the elderly and those with severe renal dysfunction.[299] The mortality rate approaches 25%, and 50% of surviving patients develop chronic renal insufficiency.[26,216,217,285,302] Responses to plasma exchange have been reported, but their frequency is difficult to assess.[302,303] Likewise, it is not clear whether this disorder responds to the above-mentioned ancillary agents appropriate for use in TTP. Nevertheless, and despite a lack of definitive evidence that plasma exchange prevents the progression of sporadic HUS to chronic renal insufficiency, a trial of plasma exchange is appropriate in patients able to undergo the procedure safely.[6,20,302,303] Recurrences during pregnancy have been reported.[304,305] Renal transplantation is associated with a high risk of recurrence.[49,50] Guidelines for transplantation have been published (http://espn.cardiff.ac.uk/hus_guideline_2005.pdf).

Cyclosporine A–Associated and Posttransplantation Thrombotic Microangiopathy

Thrombotic microangiopathies occur most commonly in three transplant-related settings: (a) in association with the use of cyclosporine A (CyA), (b) as recurrent disease after transplantation for a thrombotic microangiopathy-related disorder, and (c) after bone marrow transplantation.

Cyclosporine:

Cyclosporine A is the most common cause of drug-induced thrombotic microangiopathy.[306] Thrombotic microangiopathy occurs in 1% to 5% of renal transplant recipients,[307–312] as well as in occasional solid organ recipients (reviewed in reference 308) treated with CyA or FK506. CyA-induced thrombotic microangiopathy typically develops insidiously with progressive, otherwise unexplained renal insufficiency.[307] MAHA or thrombocytopenia develops in only half the patients and is usually mild.[307,310] The appearance of the glomerular capillary and arteriolar thrombotic lesions is similar to de novo cases of thrombotic microangiopathy.[313] The distinction of CyA-induced thrombotic microangiopathy from acute tubular necrosis or rejection can often be made only by biopsy, and not in every case can an unequivocal distinction be established.[314] Broad alloantibody reactivity[307] and coinfection with cytomegalovirus[311] may predispose to CyA-associated thrombotic microangiopathy.

CyA is cytotoxic to cultured endothelial cells at concentrations similar to the peak plasma levels and tissue concentrations achieved in vivo.[315] CyA acts synergistically with IL-1α, IL-1β, and TNF-α to induce endothelial cell tissue factor expression[316] and inhibit thrombomodulin activity.[317] CyA also enhances the secretion of thromboxane by cultured endothelial cells[315] and inhibits the produc-

tion or activity of a putative plasma prostacyclin stimulating factor.[318] Plasma levels of VWF[319] and endothelin-1[320] are elevated during episodes of nephrotoxicity, consistent with endothelial cell injury. CyA also enhances platelet aggregation and thromboxane release.[321]

CyA-induced thrombotic microangiopathy often responds to a reduction of the dose or temporary discontinuation of CyA. The prognosis is generally good, although some patients develop permanent renal failure.[306] In many patients, CyA can be reintroduced at a lower dose[307,322]; in others, FK 506 has been substituted successfully,[323] although the latter may also precipitate thrombotic microangiopathy.[324] The utility of plasma exchange is uncertain.

Renal Transplantation:

Approximately 50% of patients with idiopathic HUS develop end-stage renal insufficiency, thus becoming candidates for renal transplantation. Thrombotic microangiopathy can recur in the transplanted kidney, even in the absence of CyA. The reported frequency of this complication varies widely,[325–327] with the lowest incidence (approximately 10%) in young children with a history of Stx-associated HUS.[328–330] The incidence approaches 50% in older children and adults with atypical presentations in whom a familial etiology is likely.[328–330] Recurrence rates are lower in those with a longer duration between the initial episode of HUS and transplantation, and perhaps in those who have had bilateral nephrectomy.[330] A careful, multigenerational history must be taken to exclude the possibility of familial thrombotic microangiopathy when a living related donation is being considered.[200,329,330] The management of HUS associated with deficiencies in complement regulatory proteins is discussed above.

Bone Marrow Transplantation:

Thrombotic microangiopathy occurs in approximately 6% of patients who undergo allogeneic marrow transplantation; the incidence is estimated to be 0.1% to 1% after autologous marrow or stem cell transplantation.[83,331–337] The incidence is difficult to determine and diagnostic criteria are somewhat arbitrary as schistocytes and thrombocytopenia are nearly universal findings after bone marrow transplantation,[333,338] and the differential diagnosis of fever, renal failure, and neurologic complications is extensive. Indeed the utility of considering thrombotic microangiopathy to be a specific disorder in this setting has been questioned.[339] The clinical manifestations typically begin months after transplantation.[335,340] The pathophysiology is assumed to reflect systemic endothelial cell injury from a variety of causes. VWF protease activity may fall after transplantation,[341] but severe deficiency as occurs in TTP is uncommon (reviewed in references 308 and 342). Risk factors include use of an unrelated or mismatched donor,[336–338] total body irradiation as part of the pretransplant conditioning regime,[343] CyA or FK506 posttransplant,[331,333,344] systemic cytomegalovirus or other infection, older age,[336] female gender,[335] and graft-versus-host disease.[334,336,339,342,344] Systemic microangiopathy is rare,[339] but an intestinal biopsy may be needed to distinguish thrombotic microangiopathy from GVH in patients with refractory diarrhea.[345]

Withdrawal or substitution of another immunosuppressive for cyclosporine, if possible, and aggressive therapy with plasma exchange is often considered.[335,346] Discontinuing CyA may worsen underlying GVH and the benefit of plasma exchange has not been established; plasma exchange has also been associated with transfusion-related acute lung injury.[49] Alternative causes should be sought and aggressive treatment of infection and graft-versus-host disease be employed first in all but the most overt cases.[337] It is difficult to establish the prognosis because of variable inclusion criteria. Although patients may show an initial response to plasma therapy, the effectiveness of exchange has not been established and mortality exceeds 50%, often due to complications of graft-versus-host disease or opportunistic infection.[83,308,336,337,339,342] Defibrotide has been used with reported success in a few cases.[347]

Cancer and Chemotherapy-Associated Thrombotic Microangiopathy

Thrombotic microangiopathies may terminate the course of some patients with disseminated malignant neoplasms and large tumor burdens, most commonly adenocarcinoma of the gastrointestinal tract, breast, and lung.[77,348,349] Patients generally present with the abrupt onset of moderate to severe MAHA and thrombocytopenia. Renal insufficiency and neurologic dysfunction occur less commonly than in idiopathic or chemotherapy-induced thrombotic microangiopathy,[350,351] and may result from concurrent metabolic disturbances, central nervous system metastases, or hemorrhage.

The pathogenesis of cancer-associated thrombotic microangiopathy remains poorly understood.[77] Laboratory evidence of disseminated intravascular coagulation (DIC) is found in 25% to 80% of patients based on findings of elevated fibrin split products[348,350,352] or more sensitive measures of fibrinogen turnover.[77,348,350] However, the observation that thrombotic microangiopathy occurs in only 5% of patients with disseminated malignancy and DIC[349] suggests that additional factors, such as microvascular occlusion or intimal proliferation induced by tumor emboli within the pulmonary vasculature,[350,353,354] or formation of an incompletely endothelialized tumor vasculature that predisposes to platelet adhesion, must be involved. Severe deficiency of ADAMTS13 is not typical.[355] Survival is generally measured in weeks. The only effective therapy is reduction of the tumor burden, a goal that is often not attainable. A role for plasma exchange has not been established.

Specific cancer chemotherapeutic agents have also been implicated in the development of thrombotic microangiopathy.[351,356] Many patients were receiving therapy for an adenocarcinoma at the time thrombotic microangiopathy developed,[357,358] making the risk attributable to the neoplasm versus the therapy difficult to determine.[349,357,359,360] However, unlike cancer-associated thrombotic microangiopathy, most patients with chemotherapy-associated thrombotic microangiopathy do not carry a large tumor burden, and some may be in remission.[77,353] Mitomycin-C, a known nephrotoxin[357] is the most commonly reported cause, though other agents, including gemcitabine, *cis*-platininum, bleomycin, docetaxel, 5-fluourouracil, deoxycoformycin, carboplatin, and interferon-α, either alone or in combination, have been implicated.[77,308,358–362] Most patients who develop thrombotic microangiopathy due to mitomycin-C do so after having received a cumulative dose in excess of 60 mg,[357] but the syndrome has been reported after minimal exposure.[359] Most (77%) cases occur within 4 months of the last exposure to chemotherapy, and it is uncommon for cases to develop beyond 1 year.

Patients with chemotherapy-associated thrombotic microangiopathy generally present with moderate to severe MAHA, thrombocytopenia, and renal insufficiency (median creatinine value of 4.2 mg/dL).[349,357] Approximately 15% to 20% develop neurologic dysfunction, which may include confusion, headache, and seizures. A unique feature in some series is noncardiogenic pulmonary edema in more than 50% of patients.[358] Pulmonary function may deteriorate rapidly after red blood cell or platelet transfusion,[357] which should be used with caution.

Chemotherapy-associated thrombotic microangiopathy is presumed to result from direct toxicity to the endothelium. Mitomycin inhibits the production of prostacyclin by umbilical vein endothelium, and the infusion of mitomycin-C into the rat kidney induces histological changes similar to those of chemotherapy-induced thrombotic microangiopathy.[363] ADAMST13 levels are not severely depressed.[84] Chemotherapy-induced thrombotic microangiopathy confers a grave prognosis. Fewer than 20% of affected patients respond to plasma exchange and corticosteroids, and more than 50% die within 2 months.[349,353,357,364] Anecdotal responses to immunophoresis with staphylococcal protein A columns have been reported in approximately 50% of patients, typically those with no clinically evident tumor, though these reports require confirmation.[357,365,366]

Miscellaneous, Drug-Associated Thrombotic Microangiopathy

In addition to chemotherapeutic agents, thrombotic microangiopathy has been associated uncommonly with more than 50 drugs, including penicillins,[77] ciprofloxacin[367] and clarithromycin,[368] histamine H_2-receptor antagonists,[369] the norplant contraceptive,[370] and thienopyridines,[371–373] among others.[77,374] Interestingly, the mechanisms by which each of these agents induce the thrombotic microangiopathy may differ, as may the natural history and response to therapy. Although mitomycin C, gemcitabine, and cyclosporine appear to induce TMA in a cumulative dose-dependent manner, quinidine[375] and thienopyridines (ticlopidine and clopidogrel) induce thrombotic microangiopathy through either idiosyncratic, immune-mediated mechanisms or acute endothelial toxicity.[371,374,376]

An association of quinine with thrombotic microangiopathy was first reported by Gottschall et al in 1991, who described the course of three patients with a syndrome resembling idiopathic HUS.[377] Patients generally present with severe MAHA, platelet counts lower than 50,000/μL and renal insufficiency, usually requiring dialysis.[375] Neurologic dysfunction occurs in a minority of patients, but can be severe; granulocytopenia and lymphopenia have been reported.[378] In earlier reports, the prognosis was favorable once quinine was withdrawn and plasma exchange instituted.[375] However, in a recent series, 17 of 225 patients with HUS had quinine-associated thrombotic microangiopathy; 4 of these died, and 7 survivors were left with chronic renal failure.[379] Although this disorder occurs most commonly after the ingestion of quinine tablets, cases have been reported after exposure to quinine in beverages such as tonic water, and the syndrome may recur rapidly upon reexposure.[379,380] The pathogenesis may involve idiosyncratic, quinine-dependent antibodies reactive with platelet glycoproteins IIb/IIIa and Ib/IX and related antigens on endothelial cells and neutrophils[375,377,378,381] that promote neutrophil aggregation and binding to endothelial cells in a drug-dependent manner.[375,378,381]

The thienopyridines ticlopidine and clopidogrel are another common cause of drug-induced TTP. TTP occurs in a higher percentage of patients exposed to ticlopidine, with an incidence ranging from 1:600 to 1:4814 patient exposures[373,376,382,383] in contrast to an estimated incidence of 4 per 1,000,000[384] to 1 per 8,500 to 26,000[385] exposures in patients taking clopidogrel.[372] No cases of clopidogrel-associated TTP were encountered in the CAPRIE and CURE studies, each of which enrolled more than 6200 patients.[376] Despite the low frequency of cases in patients treated with clopidogrel, the fact that this drug is the second most commonly prescribed drug in the United States renders it the most commonly reported drug associated with TTP in the FDA's MedWatch database, accounting for more than 30% of all drug-associated TTP cases. Interestingly, the pathogenesis and natural history of TTP associated with ticlopidine and clopidogrel may differ in many cases.[371] Reductions in ADAMTS13 activity below 15% occur in 85% of patients with ticlopidine-exposed patients, but in only 15% of patients with clopidogrel-associated TTP. These reductions reflect the development of anti-ADAMTS13 antibodies.[112] TTP generally develops within 2 to 12 weeks of starting the drug,[376] and responds relatively quickly to plasma exchange, which reduces mortality and should be initiated promptly on diagnosis.[386] Spontaneous relapses may occur in these patients.[371,373] In contrast, 90% of patients exposed to clopidogrel, but only 10% of patients exposed to ticlopidine, develop a syndrome characterized primarily by microangiopathic hemolytic anemia and renal insufficiency, without severe thrombocytopenia[371,387]; these individuals have normal levels of ADAMTS13, usually develop disease within the first 2 weeks of drug treatment, and may require several weeks of plasma exchange to achieve remission. Whether plasma exchange actually improves the clinical outcome is uncertain.[371] Spontaneous relapses are uncommon in these individuals.[372,376,385,386]

HIV-Associated Thrombotic Microangiopathy

An association between HIV infection and thrombotic microangiopathy has been recognized since 1984.[388–390] The incidence of HIV infection in patients with thrombotic microangiopathy varies from 15% to 50% in endemic areas.[389–391] The presentation of HIV-associated thrombotic microangiopathy and TTP in non–HIV-infected individuals are similar,[77,78,391,392] although some patients with HIV present with acute renal failure.[393] Thrombotic microangiopathy may occur at any time during the course of HIV infection, but is rare in patients with hemophilia.[394] Diagnosis may be difficult because fever, anemia,[395] thrombocytopenia,[396,397] nephropathy, neurologic dysfunction, and elevated LDH levels secondary to lymphoma, drug reactions or pulmonary infection with *Pneumocystis carinii* occur commonly in this population.[391] The pathogenesis of HIV-associated thrombotic microangiopathy is not well understood. It has been suggested that the function of the microvascular endothelium is disrupted by opportunistic organisms or infection with HIV, drugs such as fluconazole[398] or valacyclovir,[187] and alterations in plasma cytokines.[391] ADAMTS13 deficiency in the presence or absence of inhibitory antibodies has been reported[399,400] and may be associated with high D-dimer levels.[401] HIV-associated thrombotic microangiopathy responds to plasma exchange, and responses to antiretroviral therapy have been reported.[78,391] The role of splenectomy is less well studied.[78] The long-term prognosis is dependent on the severity of the underlying syndrome.[7,402] Prior to the introduction of effective antiretroviral therapy, many patients had advanced AIDS on presentation and died within 1 to 2 years of their underlying disease, but survival has improved in patients treated with aggressive plasma therapy, antiretrovirals, and other supportive measures.[7,78,391]

Pregnancy-Associated Thrombotic Microangiopathy

The differential diagnosis of MAHA associated with gestation is complex.[20,403–405] Thrombotic microangiopathy may be difficult if not impossible to distinguish from other causes of MAHA unique to pregnancy, such as preeclampsia, the syndrome of hemolysis-elevated liver function tests and thrombocytopenia (HELLP) and acute fatty liver associated with DIC.[403,406] The severity of the renal and neurologic abnormalities and the time during gestation at which the signs and symptoms of thrombotic microangiopathy first appear may provide clues needed to prevent critical delays in therapy.[20,403,404]

Approximately 10% of cases of idiopathic TTP occur in association with pregnancy.[75,305,407] In one series, 40 of 45 cases of TTP were diagnosed antepartum. Among those diagnosed during pregnancy, the mean gestational age at the onset of symptoms was 23.5 weeks in one series,[408] although overall TTP is more common in the third trimester or immediately postpartum.[305,406] In the absence of appropriate therapy, maternal and fetal mortality approach 90%. There is no evidence that uterine evacuation leads to resolution.[403,404,409,410] ADAMST13 levels fall progressively during pregnancy but severe deficiency (<5%) is seen only in women with TTP.[305] The prognosis has improved dramatically since the advent of plasma exchange, and continuing pregnancy does not impair response.[407,408] Many patients carry to term successfully, although the overall risk of fetal loss remains significant.[411]

Patients with chronic, relapsing TTP are likely to recur during subsequent pregnancies.[304,407] Anecdotal evidence suggests that prophylactic treatment with antiplatelet agents or corticosteroids may reduce the frequency and severity of relapse.[407] Other patients have been managed with periodic transfusion of plasma or plasma fractions, but more intensive treatment may be needed during pregancy.[304]

Sporadic HUS also occurs in association with pregnancy and has previously been termed malignant nephrosclerosis, irreversible postpartum renal failure, or postpartum intravascular coagulation.[403] The disorder primarily affects primiparas who present with MAHA,

thrombocytopenia, renal insufficiency and hypertension beginning a minimum of 48 hours after an otherwise normal pregnancy. Neurologic symptoms are less frequent and severe.[404] In one series, the mean time to onset of symptoms was 26.6 days after delivery,[408] a finding that helps to distinguish HUS from other causes of pregnancy-associated MAHA and thrombocytopenia such as preeclampsia and HELLP. Occasional patients with familial thrombotic microangiopathy display clinical manifestations for the first time during pregnancy, and occasional cases associated with VTEC infection have occurred intrapartum.[20,412,413] The prognosis of pregnancy-associated HUS remains relatively poor. The mortality rate formerly approached 50% and an additional 10% to 15% were left with chronic renal insufficiency.[414] Responses to plasma exchange or infusion have been reported, though their frequency is uncertain. Uterine evacuation does not lead to remission, and fetal outcome depends on successful treatment of the mother.[404]

FUTURE DIRECTIONS

The syndromes of thrombotic microangiopathy are uncommon, though the associated morbidity and mortality are significant. Despite dramatic progress in understanding the genetic and molecular basis of these disorders, important aspects of their pathogenesis, for example the factors that incite these disorders in specific individuals, remain poorly understood. Nevertheless, a disorder universally fatal 30 years ago has a far better prognosis today, and we are beginning to understand the reasons why therapy previously considered empiric is efficacious. As our understanding of the genetics, biochemistry, and immunology of these disorders evolves, it is likely that improved approaches to treatment will follow as well. We look forward to better definition of the role of ADAMTS13 protease and antibody levels in diagnosing, guiding therapy for, and predicting relapse of TTP, as well as to a better understanding of the risk of pregnancy in women with a history of thrombotic microangiopathy. The application of new and specific immunosuppressive approaches may also lead to improved outcomes and prevention of relapse.

CHAPTER 140

THROMBOCYTOPENIA DUE TO PLATELET DESTRUCTION AND HYPERSPLENISM

Theodore E. Warkentin

Thrombocytopenia is defined as a platelet count below the lower limit of the normal range (approximately 150×10^9/L). Sometimes, an expanded definition of thrombocytopenia is appropriate. For example, an abrupt drop in the platelet count can signify the onset of a platelet-destructive process such as heparin-induced thrombocytopenia (HIT)[1] or bacteremia, even if the platelet count remains above 150×10^9/L.

In the clinical evaluation of the thrombocytopenic patient, three questions must be asked. First, could the patient have pseudothrombocytopenia? Second, what is the most likely explanation for the thrombocytopenia? And third, what are the likely risks posed by the causative disorder and the severity of the thrombocytopenia? For example, very severe thrombocytopenia caused by drug-dependent antibodies or platelet-reactive autoantibodies often is associated with bleeding. By contrast, thrombocytopenia caused by heparin-dependent antibodies or attributable to disseminated intravascular coagulation (DIC) secondary to adenocarcinoma is strongly associated with thrombosis. Often, the underlying cause of the thrombocytopenia (eg, bacteremia, cancer, cirrhosis), rather than the thrombocytopenia itself, poses the greater risk.

Thrombocytopenia can be caused by any of four general mechanisms: (a) platelet underproduction, (b) increased platelet destruction, (c) platelet sequestration, and (d) hemodilution. Platelet underproduction usually occurs with underproduction of other blood cell lines and usually is characterized by pancytopenia. Thrombocytopenia caused by increased platelet destruction develops when the rate of platelet destruction surpasses the ability of the bone marrow to produce platelets. Platelet destruction may be caused by immune or nonimmune mechanisms (Table 140–1). Thrombocytopenia due to platelet sequestration is caused by redistribution of platelets from the circulation into an enlarged splenic vascular bed. Hemodilution is characterized by a decrease in the number of platelets, as well as red and white cells, caused by the administration of colloids, crystalloids, or platelet-poor blood products. In pregnant women, the differential diagnosis must be expanded to include causes unique to these patients (Table 140–2).

APPROACH TO THE THROMBOCYTOPENIC PATIENT

History and Physical Examination

Certain information should be ascertained, including (a) the location and severity of bleeding (if any); (b) the temporal profile of the hemostatic defect (acute, chronic, or relapsing); (c) presence of symptoms of a secondary illness, such as a neoplasm, infection, or an autoimmune disorder such as systemic lupus erythematosus (SLE); (d) a history of recent medication use, alcohol ingestion, or transfusion; (e) presence of risk factors for certain infections, particularly human immunodeficiency virus (HIV) infection and viral hepatitis; and (f) family history of thrombocytopenia (see Chapter 121).

During the physical examination, evidence of hemostatic impairment should be sought, as well as secondary causes for thrombocytopenia. The signs of platelet bleeding include petechiae and purpura (see Chapter 121). Petechiae typically occur in the dependent regions of the body or on traumatized areas. Spontaneous mucous membrane bleeding (wet purpura), epistaxis, and gastrointestinal bleeding indicate more serious hemostatic defects. Although petechiae are common in patients whose platelet count is less than 10 to 20×10^9/L, most patients whose platelet count is greater than 50×10^9/L do not exhibit any signs of hemostatic impairment. The physical examination may identify an explanation for the thrombocytopenia. For example, enlarged lymph nodes can indicate a viral infection, such as infectious mononucleosis or HIV infection, or a neoplastic lymphoproliferative disorder. An enlarged spleen suggests hypersplenism.

Laboratory Evaluation

The laboratory tests used for the evaluation of a patient with thrombocytopenia are summarized in Table 140–3 (also see Chapter 122). The blood film is examined to exclude pseudothrombocytopenia, which is characterized by in vitro platelet clumping. This phenomenon, which occurs in approximately 1/1000 blood samples examined, is most often caused by naturally occurring, platelet glycoprotein complex GPIIb/IIIa (integrin $\alpha_{IIb}\beta_3$)-reactive autoantibodies that produce aggregation of platelets in the presence of the calcium-chelating anticoagulant ethylenediamine tetra-acetic acid (EDTA).[2,3] The platelet aggregates are not counted by the electronic particle counter, so the automated platelet count appears falsely low. The correct platelet count usually can be determined by collecting the blood into sodium citrate or heparin anticoagulants or performing a count on nonanticoagulated finger prick samples; maintaining the blood sample at 37°C also will reduce platelet clumping in many instances.[3] EDTA-dependent pseudothrombocytopenia has no pathologic significance, other than potentially placing a patient in jeopardy for inappropriate treatment for thrombocytopenia that does not exist. A much less common (1/10,000 blood samples) antibody-mediated pseudothrombocytopenic disorder is platelet satellitism, in which rosette-like clusters of platelets are seen around neutrophils.[4] This entity is produced by immunoglobulin G (IgG) antibodies that recognize EDTA-induced cryptic epitopes on both platelet GPIIb/IIIa and neutrophil FcγIII receptors.

The bone marrow examination can be helpful in assessing platelet production, particularly if megakaryocytes are reduced in number or abnormal in appearance. Examination of the bone marrow can be diagnostic in a few disorders (eg, leukemia, metastatic tumor, Gaucher disease, megaloblastic anemia).

Elevated platelet-associated IgG (PAIgG) is observed in patients with either immune or nonimmune thrombocytopenia; therefore, these assays are not useful diagnostically. There is evidence that glycoprotein-specific platelet antibody assays, such as the monoclonal antibody immobilization of platelet antigens (MAIPA) assay or antigen capture enzyme (ACE) immunoassay, are relatively specific for detection of autoimmune thrombocytopenic disorders.[5] Chapter 138 discusses these disorders in more detail.

In patients in whom the mechanism of chronic thrombocytopenia is unclear, an indium 111 (^{111}In)-labeled autologous platelet survival study can be helpful. Three patterns can be seen: (a) a normal platelet survival and recovery (underproduction); (b) a marked reduction in the platelet life span (increased destruction); and (c) a reduced recovery but a normal or near-normal life span (sequestration). ^{111}In-labeled platelets also can be used to image accessory splenic tissue in patients with idiopathic thrombocytopenic purpura (ITP) in whom

Table 140–1 Mechanisms of Platelet Destruction

Type of Thrombocytopenia	Specific Example(s)
Immune-Mediated	
Autoantibody-mediated platelet destruction by reticuloendothelial system (RES)	Primary and secondary idiopathic (immune) thrombocytopenic purpura*
Alloantibody-mediated platelet destruction by RES	Neonatal alloimmune thrombocytopenia*; posttransfusion purpura*; passive alloimmune thrombocytopenia; alloimmune platelet transfusion refractoriness*
Drug-dependent, antibody-mediated platelet destruction by RES	Drug-induced immune thrombocytopenic purpura (eg, quinine) (see Table 140–6)
Platelet activation by binding of immunoglobulin G (IgG) Fc of drug-dependent IgG to platelet Fcγlla receptors	Heparin-induced thrombocytopenia
Non–Immune-Mediated	
Platelet activation by thrombin or proinflammatory cytokines	Disseminated intravascular coagulation (DIC)*; septicemia/systemic inflammatory response syndromes
Platelet destruction via ingestion by macrophages (hemophagocytosis)	Infections, certain malignant lymphoproliferative disorders
Platelet destruction through platelet interactions with altered von Willebrand factor (vWF)†	Thrombotic thrombocytopenic purpura*; hemolytic uremic syndrome*
Platelet losses on artificial surfaces	Cardiopulmonary bypass surgery*; use of intravascular catheters
Decreased platelet survival associated with cardiovascular diseases	Congenital and acquired heart disease; cardiomyopathy; pulmonary embolism

*See other relevant chapters for a discussion of thrombocytopenia in these disorders.
†Although platelet destruction is not directly caused by antibodies, immune mechanisms can explain altered vWF (eg, autoimmune clearance of vWF-cleaving metalloprotease).

Table 140–2 Differential Diagnosis of Thrombocytopenia in Pregnancy

Incidental thrombocytopenia of pregnancy (gestational thrombocytopenia)
Preeclampsia/eclampsia*
Disseminated intravascular coagulation (DIC) secondary to:
Abruptio placentae
Endometritis
Amniotic fluid embolism
Retained fetus
Preeclampsia/eclampsia*
Peripartum/postpartum thrombotic microangiopathy
Thrombotic thrombocytopenic purpura
Hemolytic uremic syndrome

*Preeclampsia/eclampsia usually is not associated with overt DIC.

splenectomy fails to effect a cure or in whom postsplenectomy relapse occurs.

Therapy

The bleeding risk for thrombocytopenic patients can be reduced by avoiding drugs that impair hemostasis (eg, alcohol, antiplatelet agents, anticoagulants) and invasive procedures (intramuscular injections). If drug-induced thrombocytopenia is suspected, as many medications as possible should be stopped. Life-threatening bleeding episodes should be treated with platelet transfusions, regardless of the mechanism of the thrombocytopenia.

The underlying cause and anticipated natural history of the thrombocytopenic disorder influence the decision whether to transfuse platelets for prophylaxis against bleeding. As a general rule, patients with chronic thrombocytopenic disorders characterized by increased platelet destruction (eg, chronic ITP) or chronic underproduction (eg, aplastic anemia, myelodysplasia) can tolerate long periods of severe thrombocytopenia without major bleeding. In addition, a prophylactic transfusion can trigger alloimmunization against human leukocyte antigen (HLA) or platelet antigens, thereby jeopardizing future therapeutic platelet transfusions. Therefore, prophylactic platelet transfusions are seldom indicated for these patients. When such patients have a transient but major hemostatic risk such as trauma or certain surgeries, however, the platelet count should be maintained above 50×10^9/L. Invasive procedures such as thoracentesis, paracentesis, and liver biopsy usually are not associated with excess bleeding if the platelet count is greater than 50×10^9/L.[6]

Prophylactic platelet transfusions should not be given to patients with HIT, thrombotic thrombocytopenic purpura, or hemolytic uremic syndrome, because they could exacerbate platelet-mediated thrombotic complications.

ANATOMY AND PHYSIOLOGY

The Spleen: Anatomy and Function

The spleen is a small, well-perfused organ receiving about 5% of the cardiac output.[7] Its anatomy is uniquely suited for its function; the progressive branching of the splenic artery into the trabecular and then central arteries helps separate the plasma from the cellular elements (see Chapter 163). The central arteries arise perpendicularly from the trabecular arteries and skim off the plasma layer from the cells. Soluble antigens in the plasma are delivered to the white pulp, where phagocytic cells process the antigens and initiate antibody production.

The cell-rich hemoconcentrated fraction of the blood is delivered to the red pulp. A small percentage of this blood flows directly to the splenic veins (the closed system), but most moves into the splenic cords (the open system). Here the cellular elements percolate through a meshwork of reticulum fibers, reticuloendothelial cells, and supporting cells, to reach the splenic sinuses. The cells enter the sinuses by passing through narrow fenestrations in the basement membrane of the endothelial cells lining the sinuses. The blood exits through the splenic vein into the portal system. Because the veins in the portal system lack valves, any increase in portal pressure is transmitted to the splenic microcirculation.

The spleen has a number of important roles. It is the largest lymphoid organ in the body and plays a pivotal role in host defense by

Table 140–3 Laboratory Tests Used to Investigate a Patient With Thrombocytopenia

Test	Rationale
Common Tests	
Complete blood count (CBC)	Isolated thrombocytopenia usually is caused by platelet destruction, whereas involvement of all cell lines suggests underproduction or sequestration
Examination of the blood film	Pseudothrombocytopenia (platelet clumps) Toxic changes and granulocyte "left shift" suggest septicemia Atypical lymphocytes suggest viral infection Red cell fragments suggest TTP or HUS Parasites (eg, in malaria) White cell inclusions suggest hereditary macrothrombocytopenia
Blood cultures	Bacteremia, fungemia
Antinuclear antibody test	Systemic lupus erythematosus
Direct antiglobulin test	Exclude immune hemolysis accompanying ITP (Evans syndrome)
Coagulation assays	
Activated partial thromboplastin time (APTT), prothrombin time (INR), thrombin time, fibrinogen, D-dimer assay	Disseminated intravascular coagulation (DIC)
Lupus anticoagulant assay (nonspecific inhibitor), anticardiolipin and anti-β_2-glycoprotein I assays	Antiphospholipid antibody syndrome
Serum protein electrophoresis; IgG, IgM, IgA levels	ITP associated with lymphoproliferative disorder (monoclonal); hypersplenism associated with chronic hepatitis (polyclonal)
HIV serologic studies	HIV-associated thrombocytopenia
Bone marrow aspiration, biopsy	Assess megakaryocyte numbers and morphology; exclude primary marrow disorder
Specialized Tests	
Glycoprotein-specific platelet antibody assays (eg, MAIPA)	Relatively specific assay for primary and secondary ITP
Drug-dependent increase in platelet-associated IgG	Specific assay for drug-induced immune thrombocytopenia
Drug-dependent platelet activation (eg, platelet serotonin release assay) and/or Platelet factor 4/heparin (or polyanion) ELISA	Heparin-induced thrombocytopenia
Radionuclide platelet lifespan study with imaging (eg, ^{111}In platelet survival study)	Define the mechanism of thrombocytopenia; identify an "accessory" spleen postsplenectomy

ELISA, enzyme-linked immunosorbent assay; HIV, human immunodeficiency virus; HUS, hemolytic uremic syndrome; IgG, immunoglobulin G; INR, international normalized ratio; ITP, idiopathic (immune) thrombocytopenic purpura; MAIPA, monoclonal antibody immobilization of platelet antigens; TTP, thrombotic thrombocytopenic purpura.

clearing microorganisms and antibody-coated cells. The spleen also is important for antibody synthesis, especially against soluble antigens. The filtering function of the spleen includes (a) culling (removal of damaged or senescent cells and bacteria), (b) pitting (removal of red cell inclusions and parasites), and (c) remodeling (reticulocyte sequestration and maturation). The spleen also acts as a (d) large reservoir for platelets (accommodating about one-third of the platelet mass in normal individuals).[7] By contrast, the human spleen contains less than 2% of the total red blood cell mass, although in some animals (dogs and cats), the spleen is a much more important red cell reservoir.

Physiologic Platelet Sequestration

Radiolabeled platelet studies have shown that approximately 30% of the total platelet mass exists as a freely exchangeable pool in the spleen.[7] Because the normal platelet life span is 9 to 10 days, a platelet spends approximately a third of its life, or 3 days, within the spleen. In patients with hypersplenism, as many as 90% of platelets can be found in the spleen.

After the labeled platelets are injected, accumulation is apparent in both the liver and the spleen.[8] An initial, irreversible phase of hepatic uptake occurs. This equilibrates during the first 5 minutes and may reflect hepatic clearance of platelets damaged in the labeling procedure. Simultaneously, there is a slow rise in activity over the spleen that peaks in about 20 minutes. Splenic platelet uptake is thus dependent on input (spleen blood flow) and output (clearance).

The splenic platelet pool size can be decreased and the platelet count increased with intravenous infusions of epinephrine in normal persons and in patients with splenomegaly.[7] By contrast, isoprenaline increases the pool size.[9] Splenic blood flow increases with increasing spleen size, although perfusion (flow per unit of tissue volume) falls.[10] Blood flow can be increased in some inflammatory disorders (eg, SLE) without an increase in spleen size. A marked increase or decrease in splenic perfusion alters the proportion of platelets within the spleen.

The most important determinant of the splenic platelet pool is the spleen size.[10] The measurement of spleen size can thus be helpful in predicting the degree of thrombocytopenia expected from excess platelet pooling in the spleen. For example, if the splenic platelet pool is 90% (ie, 10% outside the spleen), the platelet count will be reduced by a factor of 7 (because normally 70% of platelets lie outside the spleen). Consequently, and as a general rule, even if the spleen is massively enlarged, very severe thrombocytopenia ($<20 \times 10^9$/L) is virtually never seen. On the other hand, mild thrombocytopenia may be explained by mild splenomegaly that may not be detectible on physical examination but demonstrable by imaging studies.

PATHOLOGIC PLATELET SEQUESTRATION: HYPERSPLENISM

Definition

Hypersplenism is a syndrome characterized by splenomegaly and any or all of the following cytopenias: anemia, leukopenia, or thrombocytopenia. Implicit in the definition is that the cytopenias will correct following splenectomy. Although splenomegaly is almost

always present in hypersplenism, many patients with splenomegaly do not have hypersplenism. The hypersplenism usually is the result of an identifiable pathologic process, but rarely, the cause of the splenomegaly remains elusive, and the hypersplenism is termed *primary*.

Pathogenesis

A list of the disorders producing splenomegaly and hypersplenism is presented in Table 140–4. An increase in the size of the spleen can be caused by several mechanisms. An increase in the workload of the spleen can be due to immunologic stress (infection, inflammation, or an autoimmune disorder) or to increased red cell removal (red cell membrane disorders, hemoglobinopathies). Portal hypertension also will increase the size of the spleen, producing congestive splenomegaly. Benign and malignant infiltrative disorders also can increase splenic size (infiltrative splenomegaly) and cause hypersplenism. Some of these disorders produce thrombocytopenia by more than just hypersplenism (eg, marrow replacement by tumor, immune-mediated platelet clearance). Thus, the demonstration of an enlarged spleen does not necessarily mean that the cytopenias are caused solely by hypersplenism.

The thrombocytopenia of hypersplenism is caused primarily by increased splenic platelet pooling.[7,10] A massively enlarged spleen can hold greater than 90% of the total platelet mass. In the absence of altered platelet production, the total body platelet mass usually is normal and the platelet life span is near normal.[7] Usually, the splenic transit time remains normal (approximately 10 minutes), but the absolute number of platelets retained within the enlarged spleen is increased. All of these platelets remain part of the exchangeable pool. In hypersplenism, the thrombocytopenia is moderately severe (platelet counts of 50×10^9/L to 150×10^9/L). Severe thrombocytopenia (less than 20×10^9/L) suggests another diagnosis. Therefore, it is unusual for patients with hypersplenism to have evidence of hemostatic impairment attributable to thrombocytopenia, or to need specific interventions to raise the platelet count. Plasma volume expansion occurs in hypersplenism, but hemodilution plays a relatively minor role in the thrombocytopenia. In some patients, impaired hepatic production of thrombopoietin may contribute to severe thrombocytopenia that cannot be explained solely by hypersplenism in advanced liver disease.[11]

The neutropenia of hypersplenism is caused by an increase in the marginated granulocyte pool, a portion of which is located in the spleen. The neutropenia of hypersplenism usually is asymptomatic.

Diagnosis

Thrombocytopenia is likely to be caused by hypersplenism when (a) splenomegaly is present, (b) the thrombocytopenia is mild to moderate in severity, (c) moderately reduced neutrophil and low-normal hemoglobin levels are found, and (d) no or minimal evidence for impaired hematopoiesis is observed on bone marrow examination. Ultrasonography, computed tomography (CT), and radionuclide imaging are of comparable sensitivity in documenting splenomegaly,[12] and an imaging study should be performed when suspected splenomegaly is not evident on physical examination. The mean platelet volume (MPV) often is slightly decreased in hypersplenism, but this finding is not sufficiently specific to be diagnostically useful. An ^{111}In-labeled platelet survival study can be diagnostic of hypersplenism, demonstrating reduced platelet recovery and a normal platelet life span. Determining the cause of the splenomegaly usually is the most important issue.

Therapy

Several maneuvers can improve or correct the cytopenias attributable to hypersplenism, including total or partial[13] splenectomy, partial splenic embolization,[14] and, in patients with congestive splenomegaly, surgical or transjugular intrahepatic portosystemic shunting.[15] Cytopenias secondary to hypersplenism, and thrombocytopenia in particular, are almost never sufficiently severe to justify treatment, however. Consequently, the decision to perform one of these interventions usually depends on other considerations. For example, splenectomy should be considered for relief of pain or early satiety

Table 140–4 Differential Diagnosis of Splenomegaly and Hypersplenism

Infections
Acute
Viral (viral hepatitis, infectious mononucleosis, cytomegalovirus infection)
Bacterial (septicemia, salmonellosis, brucellosis, splenic abscess)
Parasite (toxoplasmosis)
Subacute and chronic
Subacute bacterial endocarditis
Tuberculosis
Malaria
Kala-azar
Fungal disease
Inflammation
Felty's syndrome
Systemic lupus erythematosus
Serum sickness
Rheumatic fever
Sarcoidosis
Congestive Splenomegaly
Intrahepatic
Cirrhosis
Extrahepatic
Portal vein obstruction
Splenic vein obstruction
Hepatic vein occlusion (Budd-Chiari syndrome)
Chronic passive congestion
Heart failure
Hematologic Disorders
Red cell disorders: hemolytic anemias, thalassemia, sickle cell disorders
Neoplasia
Malignant
Myeloproliferative disorders
Myeloid metaplasia
Polycythemia rubra vera
Essential thrombocythemia
Chronic leukemia
Chronic myeloid leukemia

Amyloidosis
Cysts

associated with massive splenomegaly (eg, in myelo- or lymphoproliferative disorders), or for splenomegaly of unknown origin (for investigation of possible splenic lymphoma[16]).

Short-term complications from splenectomy include infections, bleeding, and thromboembolism. The major long-term risk associated with splenectomy is overwhelming septicemia; this risk can be reduced by vaccination. All patients should be vaccinated against pneumococci, meningococci, and *Haemophilus*, preferably at least 2 weeks before splenectomy.[17] Splenectomy for congestive hypersplenism in the setting of portal hypertension carries high morbidity and mortality rates[18]; consequently, splenectomy is performed only after careful consideration. Splenectomy also is associated with high morbidity (50%) and mortality (10%–15%) rates in myeloid metaplasia and does not alter the natural history of this disorder. Thus, splenectomy usually is performed for palliation of intractable symptoms.

Splenectomy in Gaucher disease usually corrects the cytopenias, relieves abdominal discomfort, and in children improves growth. Partial rather than total splenectomy has been used in an attempt to avoid shifting the deposition of glucocerebroside from spleen to bones. Often, however, recurrence of splenomegaly and hypersplenism results after partial splenectomy. Enzyme replacement therapy can reduce the morbidity from hypersplenism (see Chapter 53).

DRUG-INDUCED THROMBOCYTOPENIC SYNDROMES

Many drugs can cause thrombocytopenia. Some drugs (eg, anticancer chemotherapeutic agents, valproic acid[19]) cause dose-dependent thrombocytopenia, generally through myelosuppressive mechanisms. An important disorder encountered by hematologists is unexpected thrombocytopenia caused by immunologic (idiosyncratic) mechanisms. The frequency of these reactions varies considerably among drugs, and ranges from very rare (less than 1/10,000), for commonly used drugs such as acetaminophen, aspirin, quinine/quinidine, and trimethoprim-sulfamethoxazole,[20] to common (1%–5%), for other drugs such as gold[21] and unfractionated heparin.[1,22–25]

Immunologic drug-induced thrombocytopenia can occur by different mechanisms (Fig. 140–1).[26] For example, thrombocytopenia can result when the Fab terminus of the pathogenic IgG binds to a complex composed of drug (or drug metabolite) and a platelet mem-

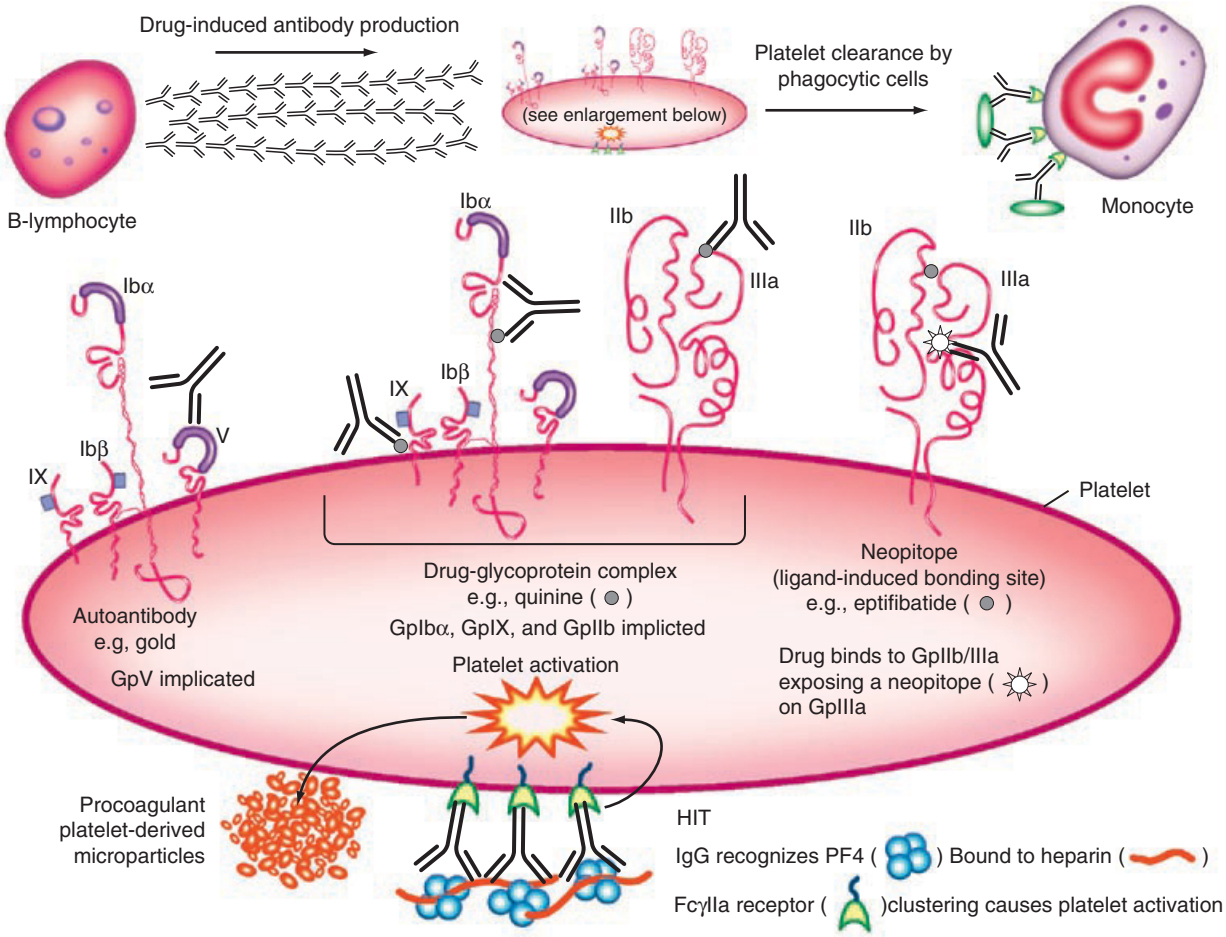

Figure 140–1 Mechanisms of drug-induced immune thrombocytopenia. Four immune thrombocytopenic syndromes are illustrated. On the bottom of the schematic platelet, heparin-induced thrombocytopenia (HIT) is illustrated, indicating that IgG antibodies bind to complexes of platelet factor 4 (PF4) and heparin, with the Fc regions of the antibodies binding to the platelet FcγIIa receptors, resulting in platelet activation (including generation of procoagulant, platelet-derived microparticles). On the top of the schematic platelet, three mechanisms are illustrated that lead to increased platelet clearance by phagocytic cells. From left to right, these are: autoantibody-induced immune thrombocytopenia (eg, gold-induced antiglycoprotein V [GPV] antibodies); drug-dependent antibodies reactive against drug (or drug metabolite)/platelet glycoprotein complex(es) (eg, quinine-induced thrombocytopenia, in which drug-dependent antibodies against GPIbα, GPIX, and GPIIb have been implicated, resulting in an antibody/drug/glycoprotein ternary complex); and antibodies against neoepitope(s) formed in the presence of a drug (eg, eptifibatide-induced immune thrombocytopenia caused by formation of ligand-induced binding site elsewhere on the GPIIb/IIIa complex following eptifibatide binding). Note that preexisting (naturally occurring) antibodies can explain abrupt-onset thrombocytopenia in a patient receiving eptifibatide for the first time.

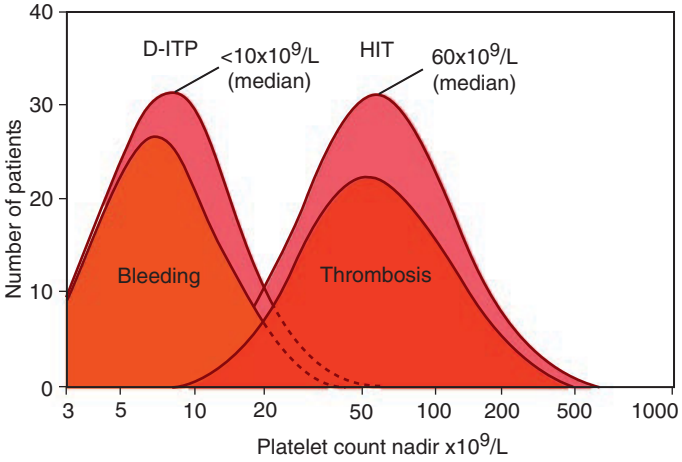

Figure 140–2 Severity of thrombocytopenia in drug-induced immune thrombocytopenia: a comparison of HIT versus other drug-induced immune thrombocytopenic disorders (D-ITP). Whereas D-ITP is strongly associated with petechiae and purpura, HIT is strongly associated with thrombosis. Note: the heights of the D-ITP and HIT curves are not drawn to scale, as HIT is more common than all D-ITP disorders combined. From: Warkentin TE: Drug-induced immune-mediated thrombocytopenia-from purpura to thrombosis. N Engl J Med 356:891, 2007.

brane component (typically, platelet GPIIb/IIIa or GPIb/IX/V). The Fc portions of the pathogenic IgG molecules do not bind to platelets but rather interact with the Fc receptors on phagocytic cells of the reticuloendothelial system, which ingest the platelets, leading to accelerated platelet clearance. Severe thrombocytopenia (platelet counts usually less than 20×10^9/L) typically is observed (Fig. 140–2).[26] This mechanism is exemplified by quinine- and quinidine-induced thrombocytopenia. Sometimes, the Fab terminus binds to a neoepitope on platelet GPIIb/IIIa induced by the drug, but with the drug itself not comprising part of the neoepitope. This mechanism is exemplified by the GPIIb/IIIa receptor antagonist, eptifibatide. Rarely, some drugs may cause otherwise typical platelet glycoprotein-reactive autoantibodies to form (as with gold-induced thrombocytopenia or acute ITP following administration of certain vaccines).

Another distinct form of drug-induced thrombocytopenia is exemplified by HIT. In this disorder, the Fab portion of the pathogenic IgG binds to platelet factor 4 (PF4), an α-granule protein that is immunogenic when complexed to heparin or other sulfated polysaccharides. The Fc portions of the IgG molecules bind to platelet FcγIIa receptors, initiating intense platelet activation. Either because HIT is a platelet activation syndrome or because of the relatively low numbers or special orientation (to platelet Fc receptors) of the HIT antibodies, the thrombocytopenia is typically mild or moderate, rather than severe (Fig. 140–2).

Finally, drug-induced antibodies can explain thrombocytopenia by unusual mechanisms. For example, the antiplatelet agents ticlopidine and clopidogrel are rare causes of thrombotic thrombocytopenic purpura, possibly because drug-dependent antibodies form against the von Willebrand factor (vWF)-cleaving metalloprotease ADAMTS13. Quinine is another cause of microangiopathic hemolysis, although in this situation the terms *hemolytic uremic syndrome* and *DIC* are often used, reflecting the prominent renal failure and/or coagulation abnormalities observed in some affected patients.

Heparin-Induced Thrombocytopenia

Heparin is the most important cause of immune-mediated drug-induced thrombocytopenia for several reasons. First, heparin is a widely used anticoagulant (see Chapter 137). Second, HIT is relatively common, occurring in approximately 1% to 5% of postoperative patients, and 0.5% to 1% of medical patients who receive unfractionated heparin derived from porcine intestine for 7 to 14 days.[1,22–25] The risk of HIT is somewhat higher in women (odds ratio, 1.5–2.0).[25] Finally, HIT paradoxically can cause life- or limb-threatening venous or arterial thrombosis.[22,27,28]

Pathogenesis

Heparin binds reversibly and saturably to platelets and can weakly activate platelets in vitro. In general, the direct platelet-activating effects of heparin, as well as its immunogenicity, are proportional to its size and degree of sulfation; consequently, low-molecular-weight heparin (LMWH) is less likely to cause HIT than is unfractionated heparin.[22–25]

HIT is caused by heparin-dependent IgG that activates platelets via their FcγIIa receptors.[29] The HIT antigens reside on large multimolecular complexes formed between (cationic) PF4—a member of the C-X-C subfamily of chemokines—and (anionic) heparin.[30–32] Although heparin-treated patients can form IgM and IgA heparin-dependent antibodies, these are unlikely to cause HIT.[33] A unique laboratory characteristic of HIT is that high heparin concentrations (10–100 U/mL) inhibit platelet activation by the pathogenic IgG[34]; this laboratory feature is exploited in diagnostic testing for HIT (see the later section "Diagnosis").

In vivo thrombin generation contributes to the pathogenesis of some of the unusual sequelae of HIT,[28] which can include venous thrombosis,[22] warfarin-associated venous limb gangrene,[35–37] and DIC.[38–40] Thrombin generation in HIT results from the generation of procoagulant microparticles from platelets activated by HIT antibodies,[41] as well as from expression of tissue factor by endothelial cells or monocytes activated by HIT antibodies (Fig. 140–3).[28,31,42]

Thrombocytopenia develops in only a minority of patients who generate HIT antibodies.[1,22–24,33] Differing risk for HIT may reflect variability among different patients for their platelets to be activated by HIT IgG,[43] as well as differing levels and immunoglobulin class composition of HIT antibodies.[33] Poorly defined clinical factors also influence risk of HIT, which occurs more often in postsurgery patients than in medical or obstetric patients.[25] Additionally, the clinical situation influences the type of HIT-associated thrombosis: venous thromboembolism typically develops in orthopedic patients with HIT, whereas thrombosis develops equally often in arteries and in veins in cardiovascular patients with HIT.[24]

Clinical Features

Most patients with HIT have moderate thrombocytopenia: The median platelet count nadir is approximately 50×10^9 to 60×10^9/L[24,44]; for 90% of patients, the platelet count nadir is greater than 20×10^9/L (Fig. 140–2). In the rare patient whose platelet count falls to less than 10×10^9/L, DIC, red cell fragmentation, and circulating normoblasts are more likely to be present.[39,40] Thrombosis in HIT can complicate a relative platelet count fall (eg, by greater than 50%) even when the platelet count nadir never falls below 150×10^9/L).[1,23,38]

The platelet count fall usually begins 5 to 10 days after the initiation of heparin therapy.[22,45] Sometimes, thrombocytopenia begins several days *after* a brief exposure to heparin (delayed-onset HIT).[27,38–40] On exceptionally rare occasions, a transient prothrombotic disorder that resembles HIT clinically and serologically occurs without apparent preceding heparin exposure ("spontaneous HIT").[46] HIT is highly prothrombotic: In at least 50% of patients, a thrombosis develops in association with HIT.[1,22–26,45] Both venous (deep vein thrombosis, pulmonary embolism) and arterial (especially aortic and iliofemoral arterial thrombosis, cerebrovascular accidents, myocardial infarctions) thrombi occur. Other complications include painful dermal erythema or necrosis at the sites of subcutaneous heparin injection[47] and acute inflammatory[38] or transient memory disturbances[38] following heparin bolus injections to sensitized persons.

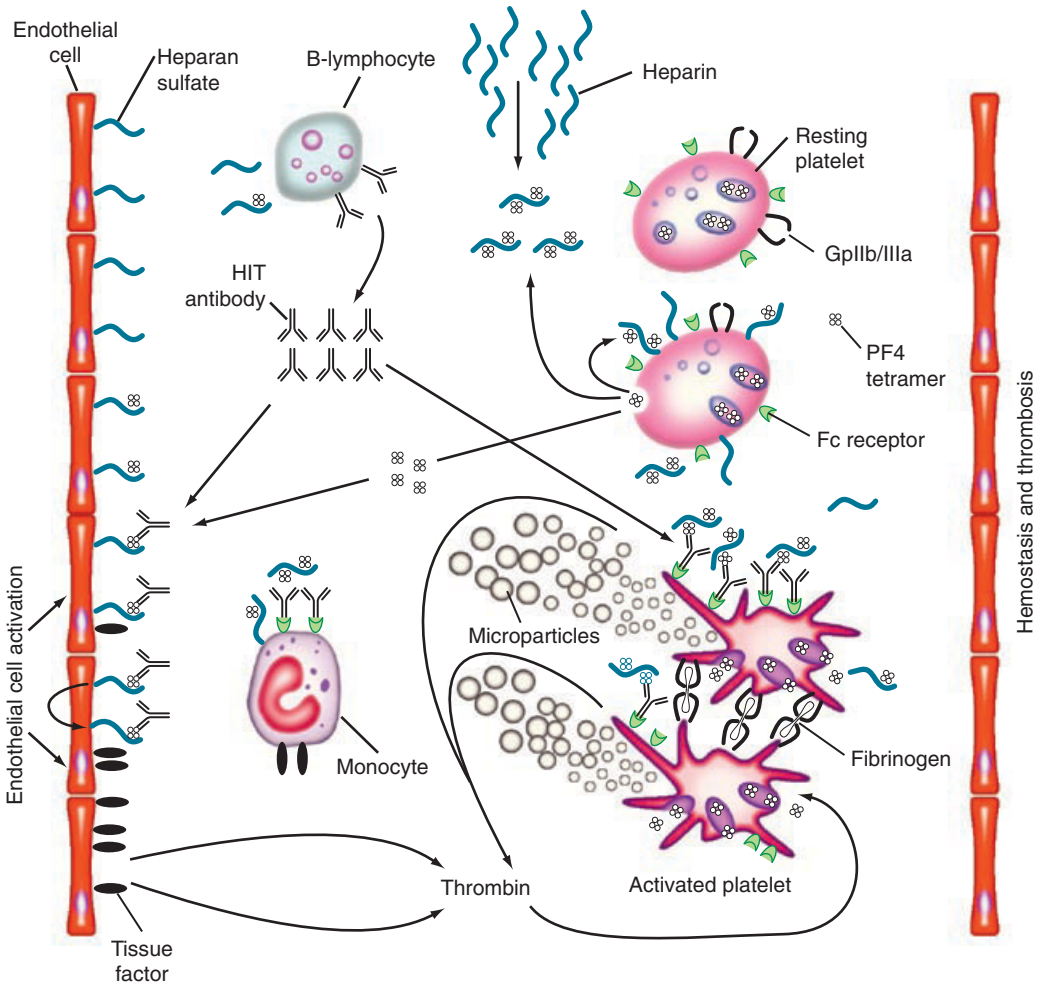

Figure 140–3 Pathogenesis of heparin-induced thrombocytopenia (HIT). Heparin produces mild platelet activation, resulting in release of platelet factor 4 (PF4) from platelet α-granules and the formation of immunogenic PF4-heparin complexes. B lymphocytes generate IgG immunoglobulins that recognize the PF4-heparin complexes; the Fc "tails" of the IgG bind to platelet FcγIIa receptors, resulting in Fc receptor clustering and consequent "strong" platelet activation. Platelet-derived microparticles are generated that accelerate thrombin generation. The HIT antibodies also recognize PF4 bound to endothelial heparan sulfate, leading to immunoinjury that causes endothelial activation. Recent evidence suggests that HIT antibodies also activate monocytes. The greatly increased thrombin generation observed in HIT helps to explain its association with venous and arterial thrombosis, as well as some of its unusual clinical features (eg, warfarin-induced venous limb gangrene, decompensated disseminated intravascular coagulation [DIC]), and also provides a rationale for treatments that control thrombin (eg, with direct thrombin inhibitors). (Reprinted with permission from Greinacher A, Warkentin TE: Treatment of heparin-induced thrombocytopenia: An overview. In Warkentin TE, Greinacher A [eds.]: Heparin-Induced Thrombocytopenia, 4th ed. New York, Informa Healthcare USA, 2007, p 287.)

Unexplained hypotension or abdominal pain in a patient with HIT suggests bilateral adrenal hemorrhagic infarction, which can lead to acute adrenal failure; this hemorrhagic necrosis results from adrenal vein thrombosis.[48]

Diagnosis

Assays for HIT antibodies can be classified as platelet "activation" and PF4-polyanion "antigen" assays.[49,50] Activation assays that utilize washed platelets (eg, platelet carbon 14 (^{14}C) labeled-serotonin release assay) are quite sensitive and specific for detecting clinically significant HIT antibodies.[1,22,23,33,44,50] Important quality control maneuvers include the selection of platelet donors whose platelets respond well to Fc receptor stimulation, as well as the inclusion of negative and positive HIT sera of variable reactivity to ascertain that the test platelets can identify weaker HIT sera.[43] A characteristic activation profile is produced by HIT serum: increased platelet activation at low heparin concentrations (0.05–0.3 U/mL), but background platelet activation at high heparin concentrations (10–100 U/mL).[43,50]

Two enzyme-linked immunosorbent assays (ELISAs) are commercially available for detecting antibodies that recognize PF4 bound either to heparin or to the polyanion, polyvinyl sulfonate.[49,50] These assays are very sensitive for detecting HIT antibodies but are more likely than washed platelet activation assays to detect clinically insignificant anti-PF4/heparin antibodies.[33] Thus, results of laboratory tests must be interpreted in the clinical context—that is, HIT is a clinicopathologic syndrome.[49,50] Activation and antigen assays are not 100% concordant, and there are advantages for reference laboratories to be able to perform both types of assay.[33] In general, serum or plasma from patients with clinical HIT have strongly positive assay results, whereas clinically insignificant antibodies give weaker results.[33,49,50]

Management

All heparin should be discontinued in patients strongly suspected to have HIT, including heparin "flushes" of intravascular catheters (with

Table 140–5 Treatment Schedules for Lepirudin, Bivalirudin, and Argatroban

Anticoagulant	Dosing Protocol for HIT-Associated Thrombosis*	Anticoagulant Monitoring†	Metabolism	Half-Life (minute)	Comment
Lepirudin	±Bolus: 0.4 mg/kg; initial infusion rate: 0.05–0.10 mg/kg/hour‡[52,56]	1.5–2.5 × baseline aPTT	Renal	80	Approved dosing regimen is too high; risk of anaphylaxis, especially on reexposure; minor prolongation of INR (compare to "Argatroban")
Bivalirudin	No bolus; initial infusion rate: 0.15–0.20 mg/kg/hour	1.5–2.5 × baseline aPTT	Enzymatic (80%); renal (20%)	25	Small but favorable experience for treating HIT; minor prolongation of INR (compare to "Argatroban")
Argatroban	No bolus: initial infusion rate: 2 μg/kg/minute	1.5–3.0 × baseline aPTT	Hepatobiliary	40–50	Initial dose 0.5 μg/kg/minute in hepatic insufficiency**; moderate or marked prolongation of INR, which complicates warfarin anticoagulation

*The initial lepirudin infusion rate range is substantially less than that indicated in the package insert (0.15 mg/kg/hour), as there is emerging evidence that the approved dosing regimen is too high. Some experts routinely avoid the bolus except for life- or limb-threatening thrombosis.
†Generally, the patient's baseline aPTT should be used for calculating target range, when appropriate; otherwise, the mean laboratory normal range can be used.
‡Major dose reduction in renal insufficiency is required.
**Reduced initial dosing (eg, 0.5–1.0 μg/kg/min) is also appropriate in patients in intensive care units, with cardiac failure, or postcardiac surgery.
aPTT, activated partial thromboplastin time; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio.

substitution of saline flushes). Of note, there appears to be a high risk (approximately 25%–50%) for subsequent thrombosis in patients with serologically confirmed HIT in whom heparin is simply discontinued.[27,44,51] It is increasingly accepted that further anticoagulation is indicated in most patients strongly suspected as having "isolated" HIT[28,52]—that is, HIT recognized because of thrombocytopenia rather than because of HIT-associated thrombosis.[24] The recognition of thrombin generation in the pathogenesis of HIT[28,35] has provided a rationale for use of anticoagulant agents that inhibit thrombin or its generation. Currently, three such anticoagulants—recombinant hirudin (lepirudin), bivalirudin, and argatroban—are available in the United States for treatment of HIT (Table 140–5). (Danaparoid is an anticoagulant "heparinoid" with predominant antifactor Xa activity that is effective for treating HIT[52–54]; however, danaparoid was discontinued in the United States in April 2002, but it remains available in Canada, the European Union, Australia, New Zealand, and Japan.)

The recombinant hirudin derivative lepirudin (Refludan) is a 65-amino-acid polypeptide that inactivates thrombin by forming a tight, noncovalent 1:1 complex with it. Lepirudin is approved for the treatment of HIT-associated thrombosis in the European Union, the United States, and elsewhere.[55] Hirudin is renally excreted, and the drug must be avoided (or the dosage substantially reduced) in patients with renal failure. With normal renal function, the half-life is about 80 minutes. Anticoagulant monitoring is performed using the activated partial thromboplastin time (target aPTT, 1.5 to 2.5 times the baseline aPTT). In the treatment of HIT-associated thrombosis, lepirudin reduced a composite end point (encompassing new thrombosis, limb amputation, and all-cause mortality) from 47.8% (in historical controls) to 21.3%.[55] The end point of new thrombosis was reduced from 27.2% to 10.1%.[55] Major bleeding complications were seen in about 20% of patients (compared with 7.1% in controls), which has resulted in recommendations to administer initial doses lower than that recommended in the package insert, even in patients with normal renal function.[52,56] In patients with isolated HIT (an "off-label" indication), lepirudin given in "prophylactic" doses (0.1 mg/kg/hour given intravenously without an initial bolus, and adjusted to an aPTT of 1.5 to 2.0 times baseline) resulted in new thrombosis in 2.7% of patients and in 9.0% of patients with the combined end point.[57] Similarly low rates of thrombosis have also been observed in postmarketing studies of patients given lepirudin for isolated HIT. Recently, fatal anaphylactic reactions following administration of an intravenous bolus have been reported, with a frequency as high as 1/400 patients following reexposure.[58] The risk of anaphylaxis is another reason to avoid bolus dosing in most clinical situations.[52]

Bivalirudin (Angiomax) is a 20-amino-acid thrombin inhibitor modeled after hirudin that is composed of two peptide fragments that recognize the thrombin active site and its fibrinogen-binding sites, linked by a tetraglycine spacer. Its half-life is only about one-third that of lepirudin (25 vs 80 minutes), and only minor dose adjustments are needed in renal insufficiency because bivalirudin undergoes enzymatic metabolism. It is approved for anticoagulation during percutaneous coronary interventions (PCIs), including for patients in whom heparin is contraindicated because of HIT.[59] Its short half-life and predominant enzymatic (nonorgan) elimination are reasons why it is a major option for intraoperative anticoagulation for cardiac surgery, when heparin is contraindicated because of acute or recent HIT.[52,60] Experience using bivalirudin "off-label" to treat HIT outside the setting of PCI is limited.[59,60] Anaphylaxis has not been reported.

Argatroban (marketed without a trademark in the United States; Novastan, Argatra, and Arganova outside the United States) is a small-molecule (527-Da) direct thrombin inhibitor that undergoes predominant hepatobiliary excretion and is therefore suitable for use without dose adjustment in patients with renal failure (the dose is reduced by three-quarters in patients with hepatic insufficiency).[61–63] Argatroban is approved in the United States for both treatment and prevention of thrombosis in HIT. It is given in the same dosage for both indications (usual starting infusion rate of 2 μg/kg/minute without initial bolus). Argatroban (in substantially higher doses) is also approved for anticoagulation during PCI in patients with previous or acute HIT. Its half-life is 40 to 50 minutes. Argatroban prolongs the INR more than lepirudin and bivalirudin, and a higher-than-usual target INR during warfarin cotherapy (which depends on the thromboplastin reagent used to measure the INR) can be expected (see Caveats in next section).[63] Argatroban reduced the frequency of a composite end point (new thrombosis, limb amputation, and all-cause mortality) from 56.5% (in historical controls) to 43.8% and 41.5% in two studies of patients with HIT complicated by thrombosis; new thrombosis event rates were reduced from 34.8% to 19.4% and 13.1%, respectively.[61,62] In patients with isolated HIT, argatroban reduced the rate of new thrombosis from 15.0% to 6.9%, and the combined event rate of new thrombosis, limb amputation, and all-cause mortality from 38.8% to 25.6%.[61]

Caveats in Treatment of Heparin-Induced Thrombocytopenia

Warfarin and other vitamin K antagonists (coumarins) should not be used during the acute thrombocytopenic phase of HIT.[26,28,35–37,52] A

particularly high-risk situation is HIT associated with deep vein thrombosis, especially if there is overt (decompensated) DIC. This is because deep vein thrombosis in a patient with HIT treated with warfarin can progress to venous limb gangrene.[35–37] The laboratory marker of this unusual syndrome is a high INR (generally, greater than 4.0), which corresponds to the combination of a marked reduction of protein C together with persisting thrombin generation (as shown by elevated thrombin–antithrombin complex levels) during warfarin therapy.[35] However, although warfarin (in theory) should be safe in a patient whose thrombin generation is controlled (eg, using a thrombin inhibitor), it is important nevertheless to delay warfarin until substantial resolution of thrombocytopenia has occurred (to more than 150×10^9/L).[52] This is because warfarin-induced prolongation of the aPTT can result in underdosing of the direct thrombin inhibitor,[37] and because stopping the direct thrombin inhibitor before resolution of the HIT during warfarin overlap can lead to limb loss due to fulminant venous limb gangrene.[36,37]

Using sensitive assays for HIT antibodies, LMWH reacts similarly to standard, unfractionated heparin in vitro. Furthermore, because LMWH can lead to worsening of clinical HIT, these agents should not be used to treat HIT.[52] Fondaparinux (Arixtra) is a novel anticoagulant with exclusive antifactor Xa activity based on its strong resemblance to the antithrombin-binding "pentasaccharide" sequence within heparin (see Chapter 137). Fondaparinux use has been associated with formation of anti-PF4/heparin antibodies at a frequency similar to that of LMWH; however, unlike the situation with LMWH, the antibodies do not interact with PF4/fondaparinux.[64] Fondaparinux may prove to be an effective anticoagulant in patients with acute HIT, although to date, experience in patients with serologically confirmed HIT is minimal, and important questions regarding appropriate dosing for HIT are unresolved.[28,52]

Although primary treatment for HIT should include an anticoagulant that inhibits thrombin or reduces thrombin generation, certain treatment adjuncts can be used in certain situations. These include surgical thromboembolectomy, high-dose intravenous immunoglobulin (VIG), antiplatelet drugs such as aspirin, and plasmapheresis.

These several caveats, along with recommendations for management of patients with suspected HIT, are summarized in the box on Diagnosis and Treatment of Heparin-Induced Thrombocytopenia.

Prevention

Platelet monitoring in patients receiving heparin should reflect the overall risk of HIT (ie, the preparation, the dose, and the clinical situation).[49,52] At least alternate-day platelet count monitoring should be considered in patients at relatively high risk for developing HIT (eg, postoperative orthopedic and cardiovascular patients receiving prophylactic-dose unfractionated heparin). Monitoring at least two or three times a week should be considered for patients at moderate risk for developing HIT (eg, medical patients receiving unfractionated heparin, postoperative patients receiving unfractionated heparin "flushes" or LMWH). The frequency of HIT is low with LMWH,[22–25] particularly in medical patients or during pregnancy, and routine platelet count monitoring may not be required in such settings.[49,52] In addition, HIT only rarely begins 14 or more days after initiation of a course of heparin, so routine monitoring beyond this period may not be required.

Anticoagulation and Previous Heparin-Induced Thrombocytopenia

HIT antibodies are transient and usually are undetectable several weeks or a few months after an episode of HIT.[45] Thus, if HIT antibodies are not detectable, it is appropriate to use heparin for a brief indication in those situations in which an alternative anticoagulant has drawbacks (eg, heart surgery).[45,52,65] Heparin should be avoided preoperatively (eg, argatroban[66] or bivalirudin[59] can be used for heart catheterization). Patients requiring urgent heart surgery during acute or recent HIT (with antibodies still detectable) have been successfully anticoagulated with alternate anticoagulant approaches (eg, bivalirudin, lepirudin[67] or heparin plus an antiplatelet agent such as epoprostenol[68] or tirofiban[65]), but each of these approaches has certain disadvantages. For example, lepirudin in high doses for cardiac surgery requires monitoring with the ecarin clotting time (not widely available), and patients can develop severe bleeding if renal failure occurs; epoprostenol causes hypotension, and there is limited experience in cardiac surgery using this approach. Bivalirudin shows the greatest promise for use in cardiac surgery, but special surgical and anesthesiologic maneuvers are required (as bivalirudin undergoes proteolysis, thus posing risk of thrombosis within stagnant blood).[52]

A diagnostic and therapeutic approach to HIT, beginning with the "4 T's,"[69] is shown in the accompanying box.

DRUG-INDUCED IMMUNE THROMBOCYTOPENIA

A large number of drugs can cause a syndrome that mimics acute ITP (Table 140–6).[20,21,26,70–103] Typically, severe thrombocytopenia (platelet count usually less than 20×10^9/L) (Fig. 140–2), together with petechiae and purpura, develops usually within weeks, but occasionally much longer after initiation of therapy with the responsible drug. Drug-induced immune thrombocytopenia is much less common than HIT. For example, a relatively "common" cause of this syndrome is trimethoprim-sulfamethoxazole (*co*-trimoxazole), even though it occurs in only approximately 1/25,000 patients who receive this drug combination.[20] Important exceptions to these generalizations occur with immune thrombocytopenia that results from GPIIb/IIIa receptor antagonists; these reactions are relatively common (affecting about 0.5%–1% of patients) and usually occur within hours of first use, as a result of preexisting, naturally occurring antibodies.[82–95] Another exception is carbimazole-induced thrombocytopenia, in which mild thrombocytopenia is explained by the presence of the platelet glycoprotein target (platelet endothelial cell adhesion molecule-1 [PECAM-1]) in relatively small quantities on the platelet surface.[99] Besides the atypical immune-mediated syndromes of HIT and GPIIb/IIIa antagonist thrombocytopenia, the most common drugs in absolute terms that are implicated as causing severe immune thrombocytopenia are quinine (outpatients) and vancomycin (inpatients).[79]

Pathogenesis

Drug-dependent binding of the Fab component of IgG to platelet glycoproteins leads to platelet destruction. This occurs because the IgG-sensitized platelets are recognized by the Fc receptors of phagocytic cells. For quinine- and quinidine-induced immune thrombocytopenia, both the GPIIb/IIIa and GPIb/IX/V complexes have been implicated as targets for the drug-dependent IgG (see Fig. 140–1). By contrast, for sulfa antibiotic- and naproxen-induced immune thrombocytopenia, the GPIIb/IIIa complex is predominantly involved.[76,104] Sometimes, drug metabolites rather than the parent drug form the antigen.[80] A trimolecular complex is formed among IgG Fab, the drug (or metabolite), and the platelet glycoprotein. In contrast with HIT, platelet Fc receptors are not involved. Drug-dependent IgG binding is remarkably heterogeneous with respect to binding affinity, number of binding sites per platelet, and the range of drug concentrations required. A recent study of quinine-induced immune thrombocytopenia identified two different types of antibodies: quinine-dependent antibodies that bind to platelets in the presence of drug, and quinine-specific antibodies that reacted with quinine-conjugated albumin. The pathophysiologic implications of this latter group of antibodies remains unclear.

Diagnosis and Treatment of Heparin-induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) should be clinically suspected when thrombocytopenia occurs during (or soon after) heparin therapy that has a temporal profile consistent with immune sensitization to heparin. Four relevant questions-the "4 T's"-should be asked[69]:

***T*hrombocytopenia:** Does the patient have thrombocytopenia? A greater than 50% fall in the platelet count can indicate HIT even if the platelet count has not fallen to below 150×10^9/L). (*Note*: Very severe thrombocytopenia, such as with platelet count below 10×10^9/L, is only very rarely caused by HIT.[26])

***T*iming:** Is the timing of the platelet count fall consistent with immune sensitization? In HIT, platelets usually fall 5 to 10 days after starting a course of heparin (first day of heparin is day zero); a more rapid fall in the platelet count can occur if the patient is already sensitized from an exposure to heparin within the past 100 days.

***T*hrombosis:** Has thrombosis or other sequelae of HIT occurred? (*Note*: Besides venous and arterial thrombosis, patients with HIT can develop skin lesions at heparin injection sites, or systemic inflammatory or cardiorespiratory reactions that begin 5 to 30 minutes after an intravenous heparin bolus).

O*t*her: Are other explanations for thrombocytopenia present? HIT is relatively less likely when compelling clinical evidence exists for another cause for the thrombocytopenia, such as positive blood cultures.

Steps in Management of Clinically Suspected Heparin-Induced Thrombocytopenia

1. Confirm that thrombocytopenia is present (repeat CBC), test for DIC, and test for HIT antibodies.
2. Assess clinically and radiologically for thrombosis (eg, duplex ultrasound for lower-limb deep vein thrombosis).
3. Stop all heparin (including heparin "flushes" and, possibly, use of heparin-coated intravascular catheters [catheters in situ for several days may not have significant residual heparin).
4. Initiate alternative anticoagulation, generally in therapeutic doses (options: lepirudin, argatroban, bivalirudin,* danaparoid,*† fondaparinux [?]‡), if HIT is strongly suspected.
5. Although initial treatment decisions are made on clinical grounds, results of testing for HIT antibodies can influence subsequent treatment, including the decision to resume heparin if HIT has been ruled out using one or more sensitive assays for HIT antibodies.

Caveats

- Do not give low-molecular-weight heparin to treat HIT.
- Do not give warfarin or other coumarin anticoagulants until the platelet count has substantially recovered (to greater than 150×10^9/L), and administer only in low initial doses (warfarin, 5 mg or less) and with a minimum 5-day overlap with a parenteral anticoagulant.
- Do give vitamin K (e.g. 5–10 mg IV over 30–60 min) if HIT is diagnosed after warfarin has already been given, so as to reduce risk of coumarin necrosis and to avoid underdosing of direct thrombin inhibitor because of aPTT prolongation by warfarin.
- Do not give prophylactic platelet transfusions (unless the patient is bleeding).

*Not approved for treatment of HIT in the United States (except, in the case of bivalirudin, for anticoagulation during PCI).

†Withdrawn from US market, but is available in numerous other countries.

‡Theoretically, fondaparinux should be effective for HIT, but only anecdotal use has been reported, and appropriate dosing for acute HIT is unresolved.

Clinical Features

Patients with drug-induced immune thrombocytopenia typically present with petechiae, purpura, and severe thrombocytopenia (platelet count often less than 20×10^9/L). Sometimes systemic symptoms such as fever and chills occur in patients with abrupt-onset thrombocytopenia. Usually, the thrombocytopenia becomes clinically apparent 1 to 2 weeks after initiation of the drug,[79] but the thrombocytopenia can begin even after a patient has been taking a drug for several years. Usually the platelet count begins to rise within a few days of discontinuing the implicated drug, but occasionally several weeks are required for recovery, possibly because of generation of drug-independent IgG (platelet autoantibodies).[105]

Rarely, distinct drug-dependent IgG molecules destroy red and/or white cells in addition to platelets. For example, both platelet- and leukocyte-reactive quinidine-dependent IgG molecules have been detected in a patient with quinidine-induced bicytopenia.[106] Sometimes, the immune process is directed against a pluripotent hematopoietic stem cell, resulting in pancytopenia accompanied by marrow aplasia or hypoplasia (eg, gold-, carbamazepine-, or quinidine-induced pancytopenia). A bone marrow biopsy should be performed in patients with suspected drug-induced bicytopenia or pancytopenia, because a hypoplastic marrow can indicate the serious complication of drug-induced aplastic anemia.

Diagnosis

A high index of clinical suspicion often is required to make the diagnosis. Quinine is widely available—as an ingredient in tonic water, for example, or as an additive to street drugs. Demonstration of drug-dependent binding of IgG to platelets in vitro is important in diagnosis. Labeled immunoglobulin-specific probes (eg, phase II assays) or glycoprotein capture techniques (phase III assays) can be used (see Table 140–6).

There are certain caveats in diagnostic testing. First, metabolites rather than parent drug must sometimes be used to detect the IgG.[80] Second, wash buffer in these assays may require the inclusion of the target drug (or metabolite). Third, even despite these maneuvers, the sensitivity of in vitro assays is relatively low, and the diagnosis of drug-induced immune thrombocytopenia often must be made on clinical grounds alone. Sometimes, the diagnosis is confirmed by inadvertent or deliberate reexposure to the suspected drug. However, deliberate drug rechallenge often is not performed because of its risk.

Management

As many drugs as possible should be discontinued in patients with suspected drug-induced immune thrombocytopenia. If further drug treatment is necessary, an alternate, immunologically non–cross-reactive substitute should be used. Spontaneous improvement in the platelet count usually begins within a few days of discontinuing the offending drug, although in some cases, complete recovery may take 2 weeks or longer. Platelet transfusions should be given to patients with life-threatening bleeding. High-dose IVIG, 1 g/kg given over 6 to 8 hours for 2 consecutive days, could be helpful in some situations. Corticosteroids appear to be relatively ineffective for treatment of drug-induced immune thrombocytopenia.[107]

GOLD-INDUCED THROMBOCYTOPENIA

Gold-induced immune thrombocytopenia occurs in as many as 1% to 3% of treated patients.[21] A genetic predisposition is suggested by the association with HLA-DR3, which is found in approximately 85% of affected patients.[21] The thrombocytopenia typically occurs during the first 20 weeks of therapy, before 1000 mg of gold has been given. Rarely, the thrombocytopenia begins much later, sometimes

even several months after discontinuation of the gold. Although the onset of thrombocytopenia typically is abrupt, regular platelet count monitoring is important, because an early diagnosis can be made in some patients. The thrombocytopenia often persists for several months despite discontinuation of the gold, probably because of gold-induced autoimmune thrombocytopenia (drug-independent autoantibodies against GPV have been implicated) (see Fig. 140–1).[75] Although most patients will eventually respond to corticosteroids, immediate albeit generally transient correction of severe thrombocytopenia usually can be achieved with high-dose IVIG. Some patients with persisting thrombocytopenia benefit from splenectomy or use of gold-chelating agents (dimercaprol, *N*-acetylcysteine).

DRUG-INDUCED AUTOIMMUNE THROMBOCYTOPENIA

Certain drugs besides gold have been reported to initiate autoimmune thrombocytopenia (eg, levodopa,[102] procainamide[108]). Because the pathogenic antibodies are by definition drug independent, however, it is difficult to establish causation. The mumps–measles–rubella vaccine can cause a severe but generally self-limited thrombocytopenia that is clinically and serologically indistinguishable from childhood acute ITP.[109]

DRUG-INDUCED IMMUNE THROMBOCYTOPENIA OF RAPID ONSET

Rapid onset of thrombocytopenia (within hours) can occur if a patient with preexisting drug-dependent antibodies is (re)exposed to the drug. This situation is relatively common in HIT (about 25% of patients identified),[45] because repeated treatment with heparin is common, and heparin use itself can result in the complication (HIT-associated thrombosis) that might lead to further use of heparin. However, because HIT antibodies are transient, rapid-onset HIT occurs in patients with recent heparin exposures, usually within the past 100 days.[45] By contrast, repeated episodes of quinine-induced thrombocytopenia of abrupt onset can be many months or even years apart, because these antibodies persist for much longer in the circulation. Thrombocytopenia of rapid onset is commonly seen with GPIIb/IIIa receptor antagonists (see next section).

THROMBOCYTOPENIA DUE TO GPIIb/IIIa RECEPTOR ANTAGONISTS

Several thrombocytopenic syndromes have been reported with use of GPIIb/IIIa receptor antagonists (abciximab, eptifibatide, tirofi-

ban) administered briefly by the intravenous route during PCIs such as angioplasty or stenting: (a) rapid-onset thrombocytopenia, within a few hours of drug administration (in 0.4%–2% of patients)[82,83,89,94]; (b) rapid-onset pseudothrombocytopenia (in approximately 1%–2%)[84]; and (c) delayed-onset thrombocytopenia, beginning 5 to 7 days after drug administration (rare).[85,86] In patients who have received continuous dosing with an oral GPIIb/IIIa antagonist (one of the investigational agents roxifiban, orbofiban, and xemilofiban), thrombocytopenia has developed beginning either within hours or a few days of initial dosing, or during the second or third week of therapy.[93–95] The frequency of rapid-onset thrombocytopenia is higher among patients who receive a second course, especially if it follows the initial exposure by only a few weeks.[87] Thrombocytopenia typically is severe (median platelet count nadir, about 5×10^9/L to 10×10^9/L), but clinical effects vary dramatically, ranging from absence of petechiae or other signs of bleeding (in 50% of patients) to fatal hemorrhage (in less than 5%).[90,93] Some patients develop anaphylactoid reactions accompanying the abrupt platelet count declines.[82] Some investigators have proposed that the antibodies may cause thrombosis in some patients.[91,92]

These syndromes are caused by at least two mechanisms. First, antibodies of IgG (and possibly IgM[87]) class can bind to neoepitopes on the GPIIb/IIIa complex generated by these drugs (or their metabolites)—that is, ligand-induced binding sites (see Fig. 140–1).[90,93,95] Up to 5% of humans and nonhuman primates have naturally occurring IgG antibodies that will bind to GPIIb/IIIa receptors in the presence of drug,[93,110] which could explain why rapid-onset thrombocytopenia occurs so often with these agents. A second mechanism is applicable to abciximab (ReoPro), a chimeric Fab fragment comprised of murine GPIIb/IIIa-reactive sequences and human framework sequences). Interestingly, although a high frequency of normal persons (74%) have antibodies that recognize platelets coated with abciximab, these "normal" antibodies were shown to differ from those detected in patients in whom thrombocytopenia developed after a second exposure to abciximab[87]: whereas the pathogenic antibodies recognized murine sequences within abciximab, the "normal" (nonpathogenic) antibodies were specific for the carboxyl terminus (C terminus) (papain cleavage site) of Fab fragments prepared from normal human IgG.[87] Drug-dependent antibodies also can be generated beginning about a week following a brief intravenous exposure. The antibodies differ among patients with respect to the precise neoepitopes recognized and display variable degrees of cross-reactivity among the different GPIIb/IIIa receptor antagonists ("fibans")[90]; this explains why a repeat treatment course with another GPIIb/IIIa receptor antagonist may not necessarily produce a repeat thrombocytopenic episode.[88]

Some naturally occurring antibodies bind to GPIIb/IIIa only in the presence of low calcium concentrations, thus explaining pseudothrombocytopenia—falsely low platelet count estimates due to ex vivo aggregation of platelets collected into anticoagulants, especially EDTA.[84] The rare syndrome of delayed-onset thrombocytopenia following brief intravenous exposure might result from high-titer GPIIb/IIIa-reactive antibodies that bind even in the absence of the drug.

Platelet transfusions are indicated in bleeding patients, although their efficacy has not been established. Platelet transfusions are most likely to be effective in the treatment of abciximab-induced thrombocytopenia, because its highly avid binding to GPIIb/IIIa means that little free plasma abciximab can bind to the transfused platelets (cf. the reversible GPIIb/IIIa receptor antagonists eptifibatide and tirofiban). Platelet transfusions are not indicated in pseudothrombocytopenia, which underscores the importance of reviewing the blood film when apparent thrombocytopenia is recognized after treatment with one of these agents.

Various in vitro assays utilizing flow cytometry[87,90,110] or ELISA[87,90,95] have been developed recently to detect these antibodies. Because some pathogenic antibodies are naturally occurring, it is theoretically possible to identify patients at high risk for rapid-onset thrombocytopenia in elective situations (see box on Approach to Patients With Thrombocytopenia Following Percutaneous Coronary Interventions).

Approach to Patients with Thrombocytopenia Following Percutaneous Coronary Interventions

Four diagnoses should be considered in patients who develop thrombocytopenia within minutes or a few hours following percutaneous coronary interventions (PCIs) utilizing one or more of the following pharmacologic agents: (a) heparin, (b) platelet glycoprotein GPIIb/IIIa inhibitor (eg, abciximab, eptifibatide, tirofiban), or (c) iodinated contrast agent.

- **GPIIb/IIIa inhibitor-induced pseudothrombocytopenia.** The patient has no symptoms or signs of bleeding, and platelet aggregates are seen in the blood film. The platelet count is falsely reported as low by the automated particle counter, which fails to count aggregated platelets. No treatment is required.
- **GPIIb/IIIa inhibitor-induced thrombocytopenia.** The platelet count falls abruptly, often to profoundly reduced levels (typical nadir, 5 to 20×10^9/L). Hemostatic impairment is variable, ranging from no petechiae to fatal hemorrhages; occasionally, patients develop anaphylactoid reactions. Treatment involves stopping all platelet antagonists and anticoagulants and giving platelets if the patient has signs of bleeding. Prophylactic platelet transfusions also can be considered if the platelet count is very low (less than 10×10^9/L). Testing for drug-dependent antibodies can be accomplished using flow cytometry or enzyme-linked immunosorbent assay (ELISA).
- **Rapid-onset heparin-induced thrombocytopenia.** In patients who have preexisting HIT antibodies because of recent heparin exposure (generally, within the past 100 days), rapid-onset HIT can occur when heparin is given during PCI. This is much less common than GPIIb/IIIa inhibitor-induced thrombocytopenia or pseudothrombocytopenia, so presumptive treatment of HIT with a nonheparin anticoagulant is rarely indicated in this situation.
- **Radiocontrast-induced immune thrombocytopenic purpura.** Very rarely, patients who have previously received iodinated contrast can develop abrupt-onset, severe thrombocytopenia following exposure to contrast during PCI. Platelet transfusions (with or without high-dose intravenous immunoglobulin [IVIG]) are appropriate for a bleeding patient.

MISCELLANEOUS DRUG-INDUCED THROMBOCYTOPENIC SYNDROMES

Drug-Induced Thrombotic Microangiopathy

Several drugs can trigger a syndrome of thrombocytopenia, fragmentation hemolysis, and renal failure known as drug-induced hemolytic uremic syndrome (see Chapter 139). This syndrome has been established for quinine, in which multiple quinine-dependent antibodies reactive against platelets, red cells, leukocytes, and endothelial cells have been reported.[111] Treatment is with plasmapheresis, as for more typical thrombotic thrombocytopenic purpura (TTP). Typically, affected patients recover, although some require short-term hemodialysis. Although a similar syndrome may be caused by mitomycin, cyclosporine, and penicillamine, it should be noted that many patients who receive these drugs have underlying illness (gastric adenocarcinoma, bone marrow transplantation,[112] and collagen vascular disease, respectively) that are themselves associated with hemolytic uremic syndrome These patients generally are much less responsive to plasma

exchange than others with idiopathic TTP. TTP rarely can be caused by drugs[113] such as ticlopidine,[114] clopidogrel,[115] and simvastatin. Autoantibodies against vWF-cleaving metalloproteinase have been identified in ticlopidine-induced TTP.[114]

Drug-Induced Disseminated Intravascular Coagulation

On rare occasions, quinine causes severe thrombocytopenia accompanied by marked coagulation abnormalities indicative of DIC.[116,117] This syndrome overlaps that of quinine-induced thrombotic microangiopathy, and the explanation for why some patients have more prominent coagulopathy is unknown. Although all patients with HIT have biochemical evidence of increased thrombin generation, only about 10% to 20% evince overt DIC.

Nonidiosyncratic Drug-Induced Thrombocytopenia

Most antineoplastic drugs produce a dose-dependent pancytopenia caused by injury to hematopoietic cells, including megakaryocytes and their progenitor cells. Typically, the platelet count nadir occurs at a predictable period following treatment and then quickly recovers. Unexpectedly severe or prolonged thrombocytopenia in patients receiving chemotherapy should suggest alternate explanations for the thrombocytopenia (eg, idiosyncratic thrombocytopenia caused by another drug).

Mild to moderate thrombocytopenia develops in approximately 20% of patients who take valproic acid (an antiepileptic agent); bleeding symptoms are uncommon.[19] The mechanism of thrombocytopenia in this setting is unknown, but the condition appears to be nonidiosyncratic, because the risk of thrombocytopenia correlates strongly with serum concentrations of valproic acid metabolite.[19] Amrinone is another agent that can cause generally mild, dose-dependent thrombocytopenia.[118]

Rapid Nonimmune Drug-Induced Thrombocytopenia

Some drugs produce rapid but generally mild and transient drops in the platelet count. These drugs include heparin,[28] protamine, bleomycin, hematin, ristocetin (no longer clinically used), desmopressin (particularly in patients with type 2B von Willebrand disease), and porcine factor VIII. The mechanism(s) for thrombocytopenia in these syndromes are obscure. Sometimes, however, acute thrombocytopenia is IgG-mediated: for example, we have observed that some rapid-onset thrombocytopenic reactions to heparin—particularly when accompanied by systemic inflammatory symptoms and signs—are attributable to IgG-mediated HIT in patients who were recently sensitized to heparin.[38,45]

Drug Hypersensitivity Reactions

Mild to moderate thrombocytopenia is sometimes observed in patients with systemic drug hypersensitivity reactions.[119,120] Comorbid clinical features can include generalized rashes, fever, cholestasis, and leukopenia. Allopurinol, isoniazid, sulfasalazine, and phenothiazine drugs, among others, have been implicated in these reactions.

Thrombocytopenia Secondary to Biologic Response Modifiers

Use of purified or recombinant biologic response modifiers such as interferon,[121,122] interleukin-2,[123] and certain colony-stimulating factors has resulted in severe, reversible thrombocytopenia in some patients. Antilymphocyte globulins also can produce severe thrombocytopenia.[124]

OTHER CAUSES OF DESTRUCTIVE THROMBOCYTOPENIA

Incidental Thrombocytopenia of Pregnancy

Maternal thrombocytopenia occurs in 4% to 8% of pregnancies.[125–128] Most affected women are healthy and have no history of thrombocytopenia, and their thrombocytopenia is incidentally detected by routine blood testing. The cause of the mild reduction in platelet count (usually 75×10^9/L to 150×10^9/L) is unknown. This condition is benign, without an increased risk for maternal bleeding or neonatal thrombocytopenia. Accordingly, no special maneuvers are indicated in these women, and the route of delivery should be determined by obstetric indications (see Chapter 138).

Preeclampsia/Eclampsia

Preeclampsia is characterized by the onset of hypertension and proteinuria during pregnancy, especially in a primigravida near term. Preeclampsia complicates approximately 5% of pregnancies, and the frequency is higher in black women. Thrombocytopenia occurs in about 20% of preeclamptic patients, and in almost half of patients with eclampsia.[126,128] In addition, some patients have evidence for a platelet function defect.[129] A subset of patients with preeclampsia have microangiopathic *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets, widely known as the HELLP syndrome.[130] This condition usually indicates severe preeclampsia and may be associated with a higher risk of maternal and fetal complications.[130,131] Repeated clinical and laboratory assessment of these patients is important, because this syndrome can mimic other life-threatening complications of pregnancy, such as overt DIC, TTP, septicemia, and acute fatty liver of pregnancy.

Increased platelet destruction is the mechanism for the thrombocytopenia in preeclampsia. However, activation of the coagulation system is relatively modest,[132] suggesting that thrombin generation may not be a major factor to explain the thrombocytopenia. Endothelial dysfunction (impaired nitric oxide synthesis) is another potential explanation for increased platelet turnover in preeclampsia.[133]

Pharmacologic control of hypertension and rapid delivery are the treatments for preeclampsia and will usually result in resolution of the thrombocytopenia within a few days. Because of the associated platelet function defects, some physicians recommend demonstrating a normal bleeding time in moderately thrombocytopenic patients before epidural anesthesia is performed in this group of patients. Some physicians, however, consider epidural anesthesia to be relatively safe, even in patients with moderate thrombocytopenia.[134] In those patients in whom delivery is not an option (ie, premature fetus), treatment with bed rest and aggressive antihypertensive therapy has been reported to result in an improved platelet count. However, the clinical course is markedly variable, and some patients develop life-threatening organ failure. Plasmapheresis has been used in some patients, especially if there is evidence of thrombotic microangiopathy and organ dysfunction.[135] Plasma exchange would seem appropriate in such a patient whose clinical picture has features that overlap with those of TTP.

Infection

Infection is a common cause of thrombocytopenia, occurring in approximately 50% to 75% of patients with bacteremia or fungemia, and in almost all patients with septic shock or DIC.[136] Even when caused by bacteremia, the thrombocytopenia generally is mild to moderate in severity and usually is not accompanied by significant coagulation abnormalities or bleeding. The likelihood of laboratory evidence for DIC increases as the platelet count falls to less than 50×10^9/L, however. The mechanisms for thrombocytopenia in septicemia in the absence of DIC are uncertain but could include chemokine-induced macrophage ingestion of platelets (hemophagocytosis[137]) and direct activation of platelets by endogenous mediators of inflam-

Table 140–7 Mechanisms for Thrombocytopenia Complicating Infections

Mechanism for Thrombocytopenia	Selected Example(s)*
Increased Platelet Destruction	
Disseminated intravascular coagulation	Meningococcemia
Hemophagocytosis	Septicemia, Epstein–Barr virus infection
Platelet-reactive autoantibodies (acute)	Varicella, subacute bacterial endocarditis (rare)
Platelet-reactive autoantibodies (chronic)	HIV infection
Hemolytic uremic syndrome	Verocytotoxin-producing *Escherichia coli*, *Shigella*, HIV infection
Antibodies against platelet-adsorbed microbial antigens	Malaria
Hypersplenism	
Acute	Disseminated *Mycobacterium avium* infection in HIV infection
Chronic	Viral chronic active hepatitis, malaria
Decreased Platelet Production	
Replacement of marrow by granulomas	Ehrlichiosis, tuberculosis
Infection of megakaryocytes	HIV infection
Transient virus-induced aplasia	Parvovirus B19 infection (erythroblastopenia predominates)
Multiple Mechanisms	
Platelet destruction plus hypersplenism	Recurrent malaria
Increased platelet destruction, decreased platelet production, hypersplenism	Chronic HIV infection

*References can be found in Hoffman R, Benz EJ Jr, Shattil SJ, et al (eds.): Hematology: Basic Principles and Practice, 3rd ed. New York, Churchill Livingstone, 2000.

mation (eg, platelet-activating factor)[138] or certain microbial products.[139,140] In rare situations, platelet-reactive autoantibodies are implicated.[141] Various explanations for thrombocytopenia in different types of infection are listed in Table 140–7.

Unexplained thrombocytopenia in a hospitalized patient warrants studies to exclude infection, such as blood cultures. Prompt recognition and treatment of the infection constitute the most important therapy, as platelet count recovery tends to parallel the resolution of the infection. Prophylactic platelet transfusions are generally not required unless the platelet count falls to less than 10×10^9/L, or unless comorbid clinical features increase the likelihood of serious bleeding (eg, concomitant coagulopathy, an invasive procedure, uremic platelet dysfunction). The use of heparin for patients with septic shock and DIC is controversial (Chapter 132). However, heparin may benefit a subset of patients with clinical evidence of DIC and microvascular thrombosis (eg, acral tissue ischemia or necrosis) and is recommended for use in these patients. The possibility of acquired protein C deficiency complicating acute DIC also should be considered in septic patients with purpura fulminans, such as that secondary to meningococcemia, because treatment with vitamin K, plasma, and possibly recombinant activated protein C[142] could be beneficial.

Thrombocytopenia in patients infected with HIV poses a special diagnostic problem, because there are many potential explanations for the thrombocytopenia, which often coexist (see Chapter 158).[143,144] These include immune platelet destruction, impaired platelet production secondary to HIV infection of megakaryocytes, drug-induced myelosuppression (commonly implicated drugs include zidovudine, ganciclovir, and trimethoprim-sulfamethoxazole), HIV-associated thrombotic microangiopathy, hypersplenism, and marrow infiltration by tumor or opportunistic infections. Platelet kinetic studies have shown a complex interaction of decreased platelet production, increased platelet destruction, and splenic platelet sequestration.[145] Immune mechanisms for platelet destruction include antibodies that cross-react with GPIIb/IIIa complexes ("molecular mimicry")[146,147] and immune complexes containing IgM antiidiotype antibodies (which could explain the paradox of high levels of platelet-associated IgG and IgM with low serum levels of platelet-reactive antibodies).[148] Anti-HIV chemotherapy (eg, zidovudine, HAART) often raises the platelet count in patients with HIV-associated thrombocytopenia. Most patients with HIV-associated thrombocytopenia respond to conventional treatments for ITP, including corticosteroids, splenectomy, IVIG, and, particularly, anti-D.[143,149,150]

Systemic Lupus Erythematosus

Immune-mediated thrombocytopenia, which occurs in as many as 25% of patients with SLE,[151] is associated a twofold increased risk of organ-damage events in this patient population.[152] Many different types of platelet-IgG interactions are described (eg, antiglycoprotein,[153,154] anti-antiglycolipid,[155] β_2-glycoprotein I-containing immune complexes[156]). In addition, antithrombopoietin, anti-c-Mpl (thrombopoietin receptor), and anti-CD40 ligand autoantibodies have been reported.[154,157–159] Multiple causes for thrombocytopenia-increased platelet destruction, hypersplenism, even impaired platelet production related to antibody-induced megakaryocytic hypoplasia[157,158]—are reported. The predominant explanation for thrombocytopenia in SLE remains unknown.

Several thrombocytopenic syndromes are seen in patients with SLE. For many patients, the thrombocytopenia is chronic, resembling ITP, and is the predominant clinical manifestation of the lupus.[151] Often, these patients have a prolonged bleeding time despite mild thrombocytopenia.[160] Some thrombocytopenic patients with SLE have antiphospholipid antibodies and are at increased risk for thrombotic rather than bleeding complications (see Chapter 131). Acute, severe thrombocytopenia can be a prominent feature in patients with a severe multisystem exacerbation of lupus.[151] Rarely, patients with SLE develop an illness that closely resembles TTP or hemolytic uremic syndrome; these patients should be treated with plasma exchange.[161,162] Thrombocytopenia as a feature of SLE-associated, viral-induced macrophage activation syndrome has been reported.[163,164]

Treatment of the thrombocytopenia of SLE is similar to that of ITP (see Chapter 138). Corticosteroids constitute the first line of therapy, but many patients do not respond or require high doses. Additionally, patients with SLE may be at relatively higher risk for avascular necrosis of the femoral head. High-dose IVIG may be useful in a bleeding patient to transiently increase the platelet count.[165] Before resorting to splenectomy, one could try danazol (an attenuated androgen), in doses of 200 to 800 mg/day.[166,167] Higher doses can cause hepatitis. Typically, several weeks are required before a benefit is seen. Splenectomy probably is as effective in achieving platelet

count remission in SLE as in ITP.[167,168] Patients with refractory thrombocytopenia sometimes benefit from more aggressive therapies, such as with azathioprine, intermittent-pulse cyclophosphamide, plasmapheresis synchronized with pulse cyclophosphamide,[169] cyclosporine,[170,171] or, possibly, rituximab (anti-CD20 chimeric monoclonal antibody).[172]

Antiphospholipid Syndrome

The antiphospholipid syndrome (Chapter 131) is characterized by occurrence of one or more clinical events (venous or arterial thrombosis, recurrent miscarriages, thrombocytopenia) associated with IgG, IgM, or IgA antibodies that recognize a complex of one or more protein cofactors (eg, β_2-glycoprotein I, annexin V, prothrombin, protein C, protein S) bound to negatively charged phospholipid.[173–175] Many patients (30%–50%) with this syndrome have thrombocytopenia,[176–178] which is typically mild and intermittent; approximately 15% have autoimmune hemolysis. The antiphospholipid syndrome should be considered in patients who develop idiopathic lower-limb or abdominal vein (mesenteric, renal, adrenal) thrombosis, cerebral venous (dural sinus) thrombosis, cardiac valvulitis, nonatheromatous arterial thrombosis (especially thrombotic stroke in a patient younger than 50 years of age), dermal microvascular thrombosis (acrocyanosis, digital ulceration or gangrene, livedo reticularis), or acute multiorgan failure associated with DIC and/or widespread thrombosis of the microvasculature ("catastrophic antiphospholipid syndrome").[173–180]

The mechanism of the prothrombotic tendency in patients with antiphospholipid syndrome remains elusive, but interference with endothelial cell function, impaired fibrinolysis,[181,182] antibody-mediated platelet activation, formation of endothelial microparticles,[183] interference with thrombin,[184] and factor Xa[185] degradation by antithrombin, disturbance in the protein C anticoagulant pathway[186] or anticoagulant activity of β_2-glycoprotein I all have been described.[187] Disruption of the antithrombotic annexin V antithrombotic "shield" by antiphospholipid antibodies has been proposed to explain pregnancy losses through placental vascular thrombosis.[188] There is evidence that thrombocytopenia in patients with antiphospholipid syndrome is associated with platelet glycoprotein-reactive autoantibodies.[189]

Antiphospholipid antibodies are detected by either of two methods: (a) solid-phase ELISA with purified phospholipids (usually cardiolipin) as target antigens or (b) a "functional" assay for so-called lupus anticoagulant activity, shown by demonstrating inhibition of certain phospholipid-dependent coagulation assays, such as the aPTT or the Russell viper venom time.[173] Although antiphospholipid antibodies frequently are detected in patients with SLE, they also can be found in patients with other autoimmune disorders, malignancy, or infections, or as a complication of certain drugs (eg, procainamide). Often no associated condition is identified ("primary" antiphospholipid syndrome). Antiphospholipid antibodies of low titer are sometimes found in normal persons, particularly the elderly, or during normal pregnancy. Autoantibody "cluster" studies show that anticardiolipin, lupus anticoagulant, and anti–double-stranded DNA antibodies occur together more often than with other SLE-associated autoantibodies (eg, anti-Sm, anti-Ro, anti-RNP).[190]

There are intriguing parallels between the antiphospholipid syndrome and HIT[191]: in both disorders, the antibodies are directed at a protein target (β_2-glycoprotein I and PF4, respectively) bound to a negatively charged species (anionic phospholipid and heparin, respectively). For both, high-titer IgG antibodies that result in a positive "functional" test result (lupus anticoagulant activity and HIT-IgG-induced platelet activation, respectively) are most likely to be associated with clinical disease.[192] Both disorders are characterized by the paradox of thrombocytopenia associated with increased risk for venous and arterial thrombosis.

To help physicians diagnose the antiphospholipid syndrome, clinical and laboratory criteria have been developed,[193,194] with recent revisions.[195,196] The laboratory criteria include the presence of anticardiolipin, anti-β_2-glycoprotein I, or lupus anticoagulant antibodies (moderate- to high-titer IgG or IgM) on two or more occasions at least 12 weeks apart. The major clinical criteria are thrombosis and complications of pregnancy. Thrombosis can involve large arteries or veins, or small vessels within any organ. The complications of pregnancy include one or more unexplained deaths of normal fetus(es) after week 10 of gestation or premature births (before 34 weeks), or greater than three spontaneous abortions before week 10 of gestation.

Specific treatment for the thrombocytopenia usually is not required. For many patients, long-term anticoagulant or antiplatelet therapy, or both, are needed to prevent recurrent thromboses. For those patients with recurring pregnancy losses and antiphospholipid antibodies, randomized trials have documented the benefit of low-dose aspirin combined with either low-dose unfractionated heparin[197] or LMWH.[198,199]

Malignancy

Thrombocytopenia complicating malignant disorders most frequently results from antineoplastic treatment or marrow replacement by tumor. However, certain thrombocytopenic syndromes have been associated with malignancy, including autoimmune thrombocytopenia, DIC, and thrombotic microangiopathy.

Immune thrombocytopenia attributable to platelet glycoprotein-reactive autoantibodies can complicate neoplastic lymphoproliferative diseases such as Hodgkin disease, non-Hodgkin lymphoma, chronic lymphocytic leukemia, and multiple myeloma.[200,201] Sometimes the thrombocytopenia responds to treatment of the neoplasm, although in some patients (particularly those with Hodgkin disease), the thrombocytopenia is indistinguishable from ITP and is not related to the activity of the lymphoma.

DIC occurs in certain malignancies, particularly adenocarcinomas of the pancreas, stomach, lung, colon, breast, and prostate.[202–204] Some patients present with venous or, less commonly, arterial thrombosis as the first clinical manifestation of their malignancy. In these patients, the presence of thrombocytopenia is an important clue that should prompt investigations for DIC, such as measurement of fibrinogen or fibrin D-dimer levels. In our experience, the platelet count typically rises to normal or even elevated levels during heparin therapy, as heparin ameliorates the DIC process; however, recurrent thrombocytopenia and thrombosis can recur within hours of discontinuing the heparin therapy.[204,205] Cancer patients with DIC and deep vein thrombosis also are at increased risk for warfarin-associated venous limb gangrene.[204,205] The role of various tumor-associated procoagulant substances—such as "cancer procoagulant' (a 68-kd cysteine proteinase that activates factor X independently of tissue factor/factor VIIa[206]) and cancer-associated tissue factor (which is expressed on tumor cells,[207] as well as circulating microparticles,[208–210]) —suggest pathophysiologic parallels with microthrombosis in HIT, as both cancer-associated DIC and acute HIT are risk factors for phlegmasia cerulean dolens and venous limb gangrene during anticoagulation with warfarin. Thus, cancer patients with DIC should receive heparin (especially, LMWH) rather than warfarin anticoagulation (see box on Diagnostic Considerations in the Patient with Limb Ischemia and Thrombocytopenia). DIC with hemorrhagic manifestations is characteristically seen in some patients with prostate adenocarcinoma, and in many patients with acute promyelocytic leukemia. It is crucial to recognize promyelocytic leukemia, because treatment with all-*trans*-retinoic acid produces differentiation of the malignant cells, thereby rapidly reducing the life-threatening bleeding risks attributable to hyperfibrinolysis in this disorder.[211]

A destructive thrombocytopenic disorder that resembles hemolytic uremic syndrome or TTP has been described in patients with advanced cancer.[212] In some patients, mitomycin treatment may have contributed to the microangiopathy. DIC usually is not present. Some patients respond transiently to plasmapheresis, but for many, response to any therapy is poor.

Diagnostic Considerations in the Patient with Limb Ischemia and Thrombocytopenia

Concurrence of limb ischemia/necrosis and thrombocytopenia suggests one of several hematologic emergencies:

- **Heparin-induced thrombocytopenia (HIT).** Occlusion of large lower-limb arteries by platelet-rich "white clots" is characteristic of heparin-induced thrombocytopenia. The major clue is an otherwise unexplained platelet count fall that begins 5 or more days after initiation of heparin. Urgent thromboembolectomy may be limb sparing. Sensitive assays for HIT antibodies give strong positive results. See also subsequent entry for warfarin.
- **Adenocarcinoma-associated disseminated intravascular coagulation.** Severe venous or arterial thrombosis can develop in patients with metastatic adenocarcinoma who have disseminated intravascular coagulation (DIC), especially within hours after stopping heparin. A clinical clue is an otherwise unexplained rise in platelet count that occurred during initial heparin therapy. See also entry for warfarin.
- **Warfarin-induced phlegmasia cerulea dolens/venous limb gangrene.** Coumarin anticoagulants such as warfarin can lead to venous ischemia (phlegmasia cerulea dolens) or venous limb gangrene in patients with DIC caused by HIT or adenocarcinoma. Limb loss can occur even though the limb pulses are palpable.
- **Sepsis-associated microvascular thrombosis.** Acquired natural anticoagulant failure (eg, antithrombin or protein C depletion) can complicate DIC associated with sepsis, leading to acral limb ischemia or necrosis.
- **Septic embolism.** Rarely, infective endocarditis or aneurysmal thrombosis leads to the constellation of thrombocytopenia with infection and acute limb ischemia.
- **Antiphospholipid syndrome.** Autoimmune thrombocytopenia and hypercoagulability can interact to produce acute limb ischemia and thrombocytopenia in a patient with antiphospholipid syndrome.

Macrophage Activation (Hemophagocytic) Syndrome

The macrophage activation (or hemophagocytic) syndrome comprises a heterogeneous group of disorders characterized by variable cytopenias and morphologic evidence of macrophage phagocytosis of red cells, granulocytes, and platelets; hyperferritinemia, hypercytokinemia, and sepsis-like features are characteristic, with potential for evolution to fatal multiple organ failure.[213,214] Some adult patients have an aggressive disease characterized by high fever, weight loss, prominent hepatosplenomegaly, severe pancytopenia, elevated liver enzymes, and often a terminal infection. Both T- and B-cell lymphomas can explain such a dramatic syndrome.[215,216] However, similar patients with fulminant illness have been described following otherwise unremarkable bacterial or viral infections (particularly those due to the Epstein–Barr virus[217]). In children also, the high mortality rate associated with hemophagocytic lymphohistiocytosis warrants aggressive treatment, including antineoplastic chemotherapy and bone marrow transplantation.[218] Nonneoplastic but nonetheless severe hemophagocytosis can be seen in patients with certain infections (eg, babesiosis,[219] ehrlichiosis,[220] HIV infection[221,222]), as well as in patients with rheumatologic disorders (SLE,[163,164,223] Still disease,[224] ankylosing spondylitis[225]). Laboratory indicators of macrophage activation syndrome include markedly elevated ferritin, soluble CD163 and CD25 levels, and morphologic evidence of hemophagocytosis.[213,214] Treatment should be directed at the underlying illness. Early administration of high-dose gammaglobulin appears to benefit some patients with nonneoplastic macrophage activation syndrome.[226]

Solid Organ and Bone Marrow Transplantation

Thrombocytopenia commonly occurs during episodes of solid organ allograft rejection.[227] It is possible that platelet activation and deposition in the transplanted organ vasculature contribute to the rejection process. Antirejection therapies also can cause thrombocytopenia through increased platelet destruction (antilymphocyte globulin[228]) or marrow suppression (azathioprine[228]). Posttransplantation hemolytic uremic syndrome develops in approximately 5% of renal transplant recipients[229,230] and in even fewer recipients of liver or heart transplants.[230] Although cyclosporine sometimes is implicated in hemolytic uremic syndrome, it usually can be safely resumed following recovery.[231]

Early, severe thrombocytopenia caused by marrow-ablative therapy invariably accompanies bone marrow transplantation (BMT). Platelet count recovery to greater than 50×10^9/L is more rapid (16 vs 35 days) in patients receiving autologous mobilized peripheral blood progenitor cells than in those undergoing autologous BMT.[231] Severe persistent thrombocytopenia despite recovery of red and white cells is relatively common following marrow or peripheral blood transplantation[232]; autoimmune thrombocytopenia has been implicated in some patients.[233] Late-onset thrombocytopenia following BMT that responds to corticosteroids, IVIG, and splenectomy also has been attributed to autoimmune thrombocytopenia. Rarely, transplantation-associated alloimmune thrombocytopenia can be caused by donor–recipient incompatibility involving platelet-specific alloantigens such as Pl^{A1} or Br^a.[234]

A syndrome of thrombocytopenia, red cell fragmentation, and renal impairment can occur in as many as 10% of patients undergoing BMT, usually beginning 3 to 12 months following transplantation (BMT-associated thrombotic microangiopathy).[112,235,236] The pathogenesis remains obscure; reduced ADAMTS13 levels have not been implicated.[237,238] The hematologic abnormalities can be mild and remit spontaneously, although patients often have residual azotemia and hypertension. More severely affected patients usually do not benefit from plasmapheresis.[239] The syndrome has a poor overall prognosis, and many patients will die irrespective of any intervention.

Cardiopulmonary Bypass Surgery

Excess bleeding is an important problem in patients who undergo heart surgery utilizing cardiopulmonary bypass.[240] Many of these patients receive blood transfusions, and approximately 5% require reoperation for postoperative bleeding.

Thrombocytopenia and transient platelet dysfunction (Chapter 142) are observed in virtually every patient. Typically, the platelet count falls by 35% to 65%, primarily as a result of hemodilution, but also because of bleeding and losses within the extracorporeal perfusion device. The bleeding time rises markedly during heart surgery (to greater than 30 minutes) but usually improves to less than 15 minutes shortly after surgery, and to normal several hours later. By contrast, the thrombocytopenia persists for 3 to 4 days, followed by recovery of the platelet count to values exceeding the preoperative baseline.

The pathogenesis and clinical significance of the hemostatic defect in these patients remain uncertain, but the explanation probably is multifactorial. Studies have described transient, *intrinsic* defects in platelet function.[241] These defects include decreased in vitro platelet aggregation, decreased platelet surface membrane proteins,[242] selective depletion of platelet α-granules,[241] and evidence of in vivo platelet activation[243] and platelet vesiculation.[243] The platelet dysfunction in heart surgery also is attributable to an *extrinsic* platelet defect resulting from thrombin inhibition by the high doses of heparin.[244] Furthermore, an important role for hyperfibrinolysis in the pathogenesis of bleeding is shown by elevated D-dimer levels in bleeding patients,[245] as well as the efficacy of antifibrinolytic agents[246] in the prevention and treatment of heart surgery-associated bleeding. Other factors in some patients include residual heparin effect following

bypass (including heparin rebound[247]) and preoperative use of aspirin. Treatment of platelet dysfunction after cardiopulmonary bypass is discussed in Chapter 142.

THROMBOCYTOPENIA ASSOCIATED WITH CARDIOVASCULAR DISEASE

Congenital Cyanotic Heart Disease

Thrombocytopenia caused by a decrease in platelet life span occurs in some patients with severe cyanotic congenital heart disease and is approximately related to the severity of the polycythemia. Bleeding occurs in a few patients and can be related to platelet function defects, coagulopathy, or hyperfibrinolysis. Reducing the hematocrit by phlebotomy sometimes helps to correct the hemostatic defects.

Valvular Heart Disease

Increased platelet turnover is common in valvular heart disease, and some patients have mild thrombocytopenia. The pathogenesis of the platelet consumption is not well understood, but the defect could be related to increased platelet–vWF interactions at high shear.[248,249] Indeed, high-molecular-weight multimers of vWF are reduced in some of these patients, which explains why bleeding from gastrointestinal angiodysplasia in patients with aortic stenosis typically resolves following aortic valve replacement.[250,251] Thrombocytopenia secondary to consumptive coagulopathy can be seen in intracardiac thrombosis associated with valvular heart disease.[140,252]

Pulmonary Vascular Disorders

Disorders characterized by pulmonary hypertension can be accompanied by thrombocytopenia, the pathogenesis of which is poorly defined. Thrombocytopenia can occur in association with pulmonary embolism,[205,253,254] possibly as a result of DIC. When evaluating such a patient, the clinician should inquire about current or recent heparin exposure, because HIT and pulmonary embolism are strongly associated.[22,44]

CHAPTER 141

HEREDITARY DISORDERS OF PLATELET FUNCTION

Joel S. Bennett

A prolonged bleeding time in a patient with a normal platelet count suggests the presence of von Willebrand disease or a disorder of platelet function. von Willebrand disease is discussed in Chapter 129, and acquired disorders of platelet function are discussed in Chapter 142. Hereditary disorders of platelet function disorders are considered in this chapter. For discussion purposes, these disorders can be classified into disorders of platelet adhesion, aggregation, secretion, or procoagulant activity according to the predominant aspect of platelet function affected.

DISORDERS OF PLATELET ADHESION

Bernard-Soulier Syndrome (Glycoprotein Ib/IX/V Deficiency)

Described in 1948 by Bernard and Soulier, the Bernard-Soulier syndrome is a rare platelet function disorder characterized by a prolonged bleeding time, large platelets, and thrombocytopenia.[1] Patients with the Bernard-Soulier syndrome bleed because their platelets cannot adhere to von Willebrand factor (VWF), a consequence of deficiency or dysfunction of the platelet glycoprotein (GP) Ib/IX/V (GPIb-IX-V) complex.[2–4]

Biology and Molecular Aspects of the Disorder

Following disruption of the vascular endothelium, circulating platelets adhere to exposed subendothelial connective tissue. In addition to connective tissue components such as collagen, fibronectin, and laminin, at the high shear rates present in arterioles and the microcirculation, platelet adhesion requires the presence of VWF.[5,6] VWF is an elongated multimeric glycoprotein, each monomer of which contains two sequence motifs that interact with platelets (see Chapter 128).[7] One motif located in the A1 domain of VWF enables subendothelial VWF to interact transiently with the GPIb-IX-V complex on unactivated platelets, thereby causing platelets to translocate (or roll) along the exposed subendothelial surface. The second motif, located in the C1 domain, mediates the stable interaction of VWF with the integrin αIIbβ3 (GPIIb-IIIa) on activated platelets.[8] Although VWF is also a component of plasma, soluble VWF does not bind spontaneously to GPIb-IX-V.[9] What prevents the spontaneous binding of soluble VWF to platelets is uncertain. However, exposing soluble VWF to the antibiotic ristocetin or the snake venom protein botrocetin in vitro enables it to bind to GPIb-IX-V.[10,11] Whether there are physiologic correlates for ristocetin and botrocetin is unclear. One possibility is that the A1 domain of subendothelial VWF, but not soluble VWF, is in a conformation that allows it to bind to GPIb-IX-V.[12] A second possibility is that shear stress changes the conformation of the A1 domain, GPIb-IX-V, or both, allowing spontaneous VWF binding to GPIb-IX-V.[13]

GPIb-IX-V, the protein complex affected in Bernard-Soulier platelets, is a noncovalent heterotrimer consisting of the heavily glycosylated 165,000 mol wt protein GPIb,[14] the 20,000 mol wt protein GPIX[15] and the 82,000 mol wt protein GPV.[16] There are approximately 25,000 copies of GPIb and GPIX on the platelet surface but only half as many copies of GPV, suggesting that individual GPIb-IX-V complexes contain two copies of GPIb, two copies of GPIX, and one copy of GPV. Whether GPIb-IX-V is also expressed by endothelial cells remains an area of controversy.[17–19] GPIb itself is a disulfide-linked heterodimer containing a 143,000 mol wt α subunit (GPIbα) and a 22,000 mol wt β subunit (GPIbβ).[20] GPIbα can be cleaved by trypsin or a calcium-dependent platelet protease into a soluble 135,000 mol wt heavily glycosylated amino (N)–terminal fragment named glycocalicin and a membrane-embedded 25,000 mol wt carboxyl (C)–terminal remnant that remains disulfide-linked to GPIbβ and associated with GPIX.[21] The N-terminal portion of glycocalicin contains binding sites for VWF and thrombin. Its C-terminal portion consists of a variable number of tandem 13 residue mucin-like repeats to which multiple O-linked, sialic acid–rich hexasaccharides are appended.[22,23] GPIbα extends into the platelet cytoplasm where residues 567 to 571 in its cytoplasmic tail bind to the C-terminus of filamin A (actin-binding protein),[24,25] thereby linking it to the platelet cytoskeleton[26] and where residues 580 to 590 and 605 to 610 bind to the adaptor protein 14–3-3 linking it to platelet signaling pathways.[27–29] The cytoplasmic portions of GPIbβ and GPIX are acylated with palmitic acid through thioester linkages at free cysteine residues.[30] This modification may stabilize the interaction of these subunits with the membrane lipid bilayer or with other membrane proteins. In addition, the cytoplasmic portion of GPIbβ can be phosphorylated at Ser166 by cyclic AMP-dependent protein kinase A,[31] a reaction that inhibits collagen-induced platelet actin polymerization.[32] The role of GPV in GPIb-IX-V function is unclear. Although GPV can be cleaved by thrombin,[33] this is not required for VWF binding to GPIbα. GPV cleavage also does not activate platelets,[34] and it is controversial whether it has a role in regulating the ability of thrombin to activate platelets.[35–38]

The N-terminal portion of GPIbα, as well as GPIbβ, GPIX, and GPV, contain leucine rich repeats (LRRs) with the consensus sequence L-L--N-L--LPPGLL-G---L-.[16,39] LRR were first detected in the plasma protein leucine rich α_2 glycoprotein and have been detected in an increasing number of proteins.[39] GPIbα contains eight LRR (seven were predicted from sequence information),[9] whereas GPIbβ and GPIX contain one each and GPV contains fifteen. The amino acids flanking the LRR are also conserved.[39] A crystal structure for the VWF A1 domain bound to residues 1 to 290 of GPIbα revealed that LRR 1 and five to eight of GPIbα bound tightly to the A1 domain, largely as a result of long-range electrostatic attraction.[9] Moreover, conformational changes in a flexible loop located near the carboxyl terminus of the GPIbα fragment, termed the β-*switch*[9] or *R-loop*,[40] and the site of several gain-of-function mutations responsible for platelet-type von Willebrand disease,[9] may be needed for VWF binding to GPIbα. The function of the LRR in GPIbβ, GPIX, and GPV is unknown; but they do not function as *leucine-zippers* and are not located in regions known to be involved in intermolecular associations.

Studies of GPIb-IX-V biosynthesis using Chinese hamster ovary cells indicate that although small amounts of GPIbα can be detected on the surface of cells expressing GPIbα and GPIbβ, GPIbα expression is much more efficient when the cells coexpress GPIbα, GPIbβ, and GPIX.[41] Moreover, GPIbβ is the subunit that links GPIbα to GPIX.[42] Thus, mutations that result in the deficient expression of any one of the components of GPIb-IX-V can produce the Bernard-

Soulier syndrome. Conversely, GPV is not required for GPIb-IX-V expression, and the basis for its absence from Bernard-Soulier platelets is unknown.[43]

Etiology and Pathogenesis

The effects of GPIb-IX-V deficiency are not limited to the inability of affected platelets to adhere to VWF. Most Bernard-Soulier platelets are large when observed on peripheral blood smears.[16] However, there is contradictory evidence about the size of these platelets in the circulation. It has been reported that circulating Bernard-Soulier platelets are of normal size,[44] but have increased membrane, perhaps located in the surface-connected open-canalicular system and extruded when platelets spread during the preparation of a blood smear.[45] Others have found that circulating Bernard-Soulier platelets have an increased volume,[46] a more spherical shape,[46] and a more deformable membrane than normal platelets.[47] The molecular basis for the large size of Bernard-Soulier platelets is unknown. However, amelioration of macrothrombocytopenia in a murine Bernard-Soulier model via expression of an IL4-GPIbα fusion protein suggests that the absence of the GPIbα cytoplasmic domain contributes to this abnormality.[48] Although the serum prothrombin time has been reported to be shortened in the Bernard-Soulier syndrome[49] and collagen-induced platelet procoagulant activity and Factor XI binding to be absent,[50] prothrombin consumption, measured by a two-stage assay, is normal[51]; and the expression of platelet factor 3[51] and prothrombinase activity by Bernard-Soulier platelets is increased.[52] An unexplained decrease in thrombin-, trypsin-, and thromboxane-stimulated phospholipase C activity has also been reported.[53] GPIb-IX is a target for some drug-dependent antiplatelet antibodies induced by quinidine and quinine[54]; and as would be expected, these antibodies fail to bind to Bernard-Soulier platelets.[55]

Genetic Aspects

The Bernard-Soulier syndrome is an autosomal recessive disorder.[16] In most instances, GPIb-IX-V is not present on the surface of Bernard-Soulier platelets; but in a few cases, 7% to 47% residual GPIb or GPIb-IX has been detected.[56] When it has been possible to study heterozygotes, many, but not all, have had platelets that are larger than normal and a GPIb content intermediate between normals and affected individuals.[57,58] Consistent with the rarity of the syndrome, consanguinity has often been present in affected families.

The gene for each component of the GPIb-IX-V complex has been localized and characterized. The *GPIbα* gene is located on chromosome 17p12-ter, the *GPIbβ* gene on chromosome 22q11.2, the *GPIX* gene on chromosome 3q21, and the *GPV* gene on chromosome 3q29.[16] Each gene has a compact *intron-depleted* structure, such that the genes for GPIbα, GPIbβ, and GPV contain two exons and the gene for GPV contains three.[59] The open reading frame and 3′ untranslated region of each is encoded by a single exon except for the *GPIbβ* gene where its single intron is inserted into the codon for the fourth residue of its signal peptide.[60] The genes are also similar in that their 5′ flanking regions contain potential binding sites for GATA, Ets, and Sp-1 transcription factors like other genes expressed by megakaryocytes.[61–63] In addition, polymorphic variation in the region surrounding the translation initiation site of GPIbα seems to be a determinant of the level of GPIb-IX-V expression.[64]

At least 47 different mutations responsible for the Bernard-Soulier syndrome have been identified: 18 involving the gene for GPIbα, 18 involving the gene for GPIbβ, and 11 involving the gene for GPIX. Most mutations have been missense mutations or nucleotide deletions and insertions resulting in frameshifts and premature stop codons. However, several unique mutations have been identified: deletion of the entire GPIbβ locus on chromosome 22q11.2, occasionally in the setting of the velocardiofacial syndrome;[65] a C to G transversion in the GATA binding site of the GPIbβ promoter resulting in decreased GPIbβ gene transcription[66]; and an Ala140Thr substitution in the transmembrane domain of GPIX.[67] The latter is noteworthy because it suggests that transmembrane domain interactions are involved in efficient GPIb-IX-V expression and is consistent with the impaired GPIb-IX expression observed when the transmembrane domain of GPIbβ was mutated in vitro.[68] It is also noteworthy that eleven mutations have been reported multiple times, suggesting that there may be *hot spots* for mutation in the *GPIbα, GPIbβ*, and *GPIX* genes.

Clinical Presentation

The Bernard-Soulier syndrome presents in infancy or childhood with bleeding characteristic of defective platelet function: ecchymoses, epistaxis, and gingival bleeding.[16] Later manifestations include menorrhagia and postpartum, gastrointestinal, and posttraumatic hemorrhage. Hemarthroses and expanding hematomas are unusual. Although the severity of hemorrhage among affected individuals is variable, bleeding can require frequent transfusion and suppression of menses. In a review of 59 cases, there were 10 deaths.[69] In some patients the severity of hemorrhage inexplicably declined over the course of the disease.[69]

Laboratory Findings

The bleeding time in patients with the Bernard-Soulier syndrome is markedly prolonged to greater than 20 minutes.[16] Platelet counts may vary within kindreds and in a given patient. Most patients are thrombocytopenic to some degree and patients with platelet counts less than 20,000/μl have been reported.[70] Platelets seen on stained peripheral blood smears are large with 30% to 80% having a mean diameter greater than 3.5 μm.[57] Occasional platelets are as large as 20 to 30 μm in diameter. Erythrocytes and white blood cells are normal and distinctive abnormalities have not been observed in marrow megakaryocytes by light microscopy,[71] but abnormalities in the demarcation membrane system have been observed by electron microscopy.[72] The laboratory tests that distinguish Bernard-Soulier from normal platelets are the failure of Bernard-Soulier platelets to agglutinate in the presence of ristocetin and decreased or absent agglutination after exposure to botrocetin.[16] In contrast to von Willebrand disease, these abnormalities cannot be corrected by the addition of normal plasma. Absent ristocetin-induced agglutination and normal platelet aggregation can be reproduced in the whole blood aggregometer, obviating the difficulty of preparing platelet-rich plasma containing a sufficient number of Bernard-Soulier platelets for conventional aggregometry.[73] Aggregation of Bernard-Soulier platelets induced by agonists such as adenosine diphosphate (ADP), collagen, and epinephrine is normal (Fig. 141–1).[16] However, the rate of thrombin-stimulated aggregation has been reported to be reduced.[74] Although a defect in prothrombin consumption, manifested by a short serum prothrombin time, has been reported, expression of platelet factor 3 activity by Bernard-Soulier platelets is normal or increased.[51]

Differential Diagnosis

There are several conditions associated with large platelets and thrombocytopenia (macrothrombocytopenia, Table 141–1) that can be readily differentiated from the Bernard-Soulier syndrome because Bernard-Soulier platelets fail to agglutinate in the presence of ristocetin.[75]

Macrothrombocytopenia is characteristic of patients with mutations in the *MYH9* gene located on chromosome 22q12.3-q13.2 that encodes the nonmuscle myosin heavy chain IIA (NMMHC-IIA).[76,77] Although classically segregated into four separate autosomal dominant inherited syndromes (the May-Hegglin anomaly and the Sebastian, Fechtner, and Epstein syndromes) based on the presence or absence of Döhle body-like leukocyte inclusions, hereditary nephritis, cataracts, and sensorineural deafness, detailed evaluation of families

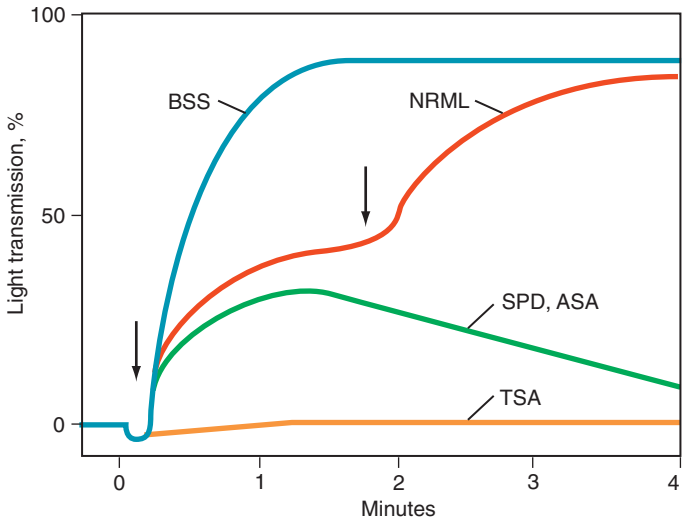

Figure 141–1 Platelet aggregation in response to adenosine diphosphate (ADP). Following the addition of ADP to a stirred aliquot of platelet-rich plasma in an aggregometer, there is a brief decrease in light transmission, indicated by the solid arrow, because of platelet shape change. When normal (**NRML**) or Bernard-Soulier platelets (**BSS**) are examined, shape change is followed by either a single continuous wave of aggregation at high ADP concentrations or two waves of aggregation at lower ADP concentrations. The hatched arrow at the inflection point between the first and second waves of aggregation is the point at which platelet secretion occurs. δ-Storage pool deficient platelets (**SPD**) generally undergo only a first wave of aggregation and the aggregates may dissociate. Aspirin-treated platelets (**ASA**) only undergo first wave aggregation when stimulated by ADP. Thrombasthenic platelets (**TSA**) undergo shape change, but do not aggregate regardless of the platelet agonist.

Platelet-type von Willebrand disease

in whom *MYH9* mutations have been identified has revealed a heterogeneous distribution of symptoms within individual families and has not revealed genotype-phenotype correlations.[78] For example, cataracts, hearing loss, and abnormal renal function has be detected in family members affected by the May-Hegglin anomaly, but this syndrome was initially defined by the absence of these symptoms. Thus, it seems appropriate to consider these syndromes as a single entity whose variability results from the variable expression of *MHY9* mutations and whose common feature is macrothrombocytopenia. In general, the function of platelets affected by *MHY9* mutations is normal[79–81]; if hemorrhage occurs, it is usually caused by thrombocytopenia.[82] However, in some patients said to have the Fechtner and Epstein syndromes, abnormal platelet aggregation and secretion have been described.[83,84]

The pathogenesis of *MHY9*-related disorders is currently unclear. Most cells express multiple myosin II isoforms; but platelets only express NMMHC-IIA, perhaps accounting for the commonality of macrothrombocytopenia. Cytoskeletal proteins are involved in the biogenesis of platelets from megakaryocyte proplatelets, but exactly how they participate in the release of platelets from proplatelets is still poorly understood.[85,86] Nonetheless, altered cytoskeletal organization has been observed in platelets from patients with *MYH9* mutations,[87] implying that perturbed cytoskeletal dynamics is responsible for the macrothrombocytopenia. Whether perturbed cytoskeletal dynamics results from deficient myosin ATPase activity,[88] haploinsufficiency caused by protein instability,[89,90] or a dominant-negative effect on NMMHC-IIA assembly seems to vary according to the particular MHY9 mutation.[91] The Döhle body-like inclusions in the leukocytes of patients with the May-Hegglin anomaly and the Sebastian and Fechtner syndromes observed on stained blood smears are composed of aggregates of NMMHC-IIA and ribosomes.[92] However, it is important to note that even in the absence of visible Döhle body-like inclusions, NMMHC-IIA aggregates may be detected in leukocytes by immunostaining.[78,93] Thus, *MHY9*-related disorders must always be considered in the differential diagnosis of macrothrombocytopenia.

Large platelets and thrombocytopenia also occur in the Gray Platelet syndrome, a disorder resulting from platelet α granules deficiency.[94] In contrast to Bernard-Soulier platelets, these platelets are pale gray on Wright-stained blood smears and agglutinate normally in the presence of ristocetin.[95] In the autosomal dominant Montreal platelet syndrome, giant platelets, thrombocytopenia, and a prolonged bleeding time are associated with spontaneous platelet aggregation at pH 7.4 and normal agonist-induced platelet aggregation.[96] So-called Mediterranean macrothrombocytopenia refers to putative differences in platelet count and platelet size among Europeans of Northern and Mediterranean origin;[97] in Italy, this may be caused by heterozygosity for the Bernard-Soulier syndrome.[98] Conversely, Mediterranean stomatocytosis/macrothrombocytenia, the rare combination of stomatocytic hemolysis and macrothrombocytopenia, has been reported to result from excess plant sterols in the blood and to be caused by mutations in the *ABCG5* and *ABCG8* genes linked to phytosterolemia.[99] Sex-linked macrothrombocytopenia has been described in patients with specific mutations of the GATA-1 transcription factor[100–102] and macrothrombocytopenia with dystrophic megakaryocytes and neutrophils lacking sialyl Lewis S antigen has been described in an infant who died at age 37 months because of hemorrhage.[103] In the Paris-Trousseau syndrome,[104] a component of the Jacobsen syndrome,[105] deletion of the long arm of chromosome 11 at q23.3 results in mild thrombocytopenia, subpopulations of large platelets and platelets containing giant α granules, and the expansion of immature megakaryocyte progenitors.[106] The syndrome is thought to be caused by loss of *FLI1*, a gene located on the deleted portion of chromosome 11, whose product is a transcription factor that acts synergistically with GATA-1 to mediate the transcription of megakaryocytic-specific genes.[107,108] In the context of the Jacobsen syndrome, the Paris-Trousseau syndrome is accompanied by facial dysmorphism; ophthalmic, digital, and cardiac abnormalities; and variable psychomotor retardation.[105] There are also anecdotal reports of thrombocytopenia and giant platelets, often associated with a mild bleeding diathesis, but lacking the features of either Bernard-Soulier syndrome or the *MHY9* disorders.[109,110] In two of these reports, macrothrombocytopenia was associated with the presence of large platelet granules whose origin was uncertain.[111,112]

Acquired Bernard-Soulier-like disorders can be differentiated from the congenital Bernard-Soulier syndrome by history. Antibodies to GPIb occur in some patients with idiopathic thrombocytopenic purpura,[113] but it has not been possible to determine if the antibodies

Table 141–2 Treatment of Inherited Disorders of Platelet Function

themselves are responsible for bleeding because of concomitant thrombocytopenia. Two patients with myelodysplasia and an acquired Bernard-Soulier–like syndrome have been reported.[114,115] A patient has also been reported with a lymphoproliferative disorder and clinical bleeding; the patient had a prolonged bleeding time, normal platelet count and platelet morphology, and a circulating IgG antibody that inhibited ristocetin-induced platelet agglutination but was directed against an unidentified 210,000 mol wt platelet protein.[116] In *Platelet-Type von Willebrand disease*, mutations within the VWF binding domain of GPIbα induce spontaneous VWF binding to GPIbα and the clinical picture of Type IIB von Willebrand disease.[9,117,118]

Therapy

Treatment of hemorrhage in patients with the Bernard-Soulier syndrome usually requires platelet transfusion (Table 141–2). Hormonal control of menses has been effective in managing menorrhagia.[119] Splenectomy has been attempted to increase the platelet count[120] but has resulted in only transient increases and has not ameliorated the platelet function defect. Corticosteroids are not beneficial in this disorder. Desmopressin acetate (DDAVP) has been reported to shorten the bleeding time in some, but not all, affected individuals in whom it has been administered,[121–124] but its efficacy in patients with hemorrhage is unclear. Conversely, a number of anecdotal reports suggest that recombinant VIIa may be effective in the treatment of hemorrhage in Bernard-Soulier syndrome patients, but the degree of effectiveness has varied[125–129] Lastly, two sisters with the Bernard-Soulier syndrome and histories of significant bleeding were successfully treated by hematopoietic stem-cell transplantation.[130]

Platelet Collagen Receptors

Collagen plays an essential role in platelet function as a substrate for platelet adhesion, a binding site for VWF in the extracellular matrix, and an agonist for platelet aggregation and secretion. Although several platelet membrane proteins interact with collagen (including GPIIb,[131] GPIV,[132] a 65,000 mol wt protein that binds to type 1 collagen,[133] a 47,000 mol wt protein[134] and a 68,000/72,000 mol wt doublet[135] that bind to type III collagen, and a protein with a mol wt of 85,000 to 90,000[136]) only GPVI[137] and the integrin α2β1[138,139] are physiologic platelet receptors for collagen.

GPVI

GPVI, a 62,000 mol wt member of the immunoglobulin gene superfamily,[140,141] is associated with the γ chain of the Fc receptor in the plasma membrane of human platelets.[142] Exposure of normal platelets, but not GPVI-deficient platelets, to collagen or collagen-like peptides results in the tyrosine phosphorylation of the Fc receptor γ chain and the proteins SLP-76, Syk, Lyn, LAT, and phospholipase Cγ2, followed by platelet aggregation.[143,144] Murine platelets lacking either the Fc receptor γ chain or Syk are unable to respond to collagen[145] and the interaction of GPVI-deficient human platelets with either immobilized and soluble collagen is markedly impaired.

There are eight reports of patients whose platelet specifically lacked GPVI,[146] three of which concern patients with congenital GPVI deficiencies.[147–149] These patients had mild bleeding diatheses[147–149] and platelets that failed to aggregate following stimulation with collagen despite the presence of normal amounts of α2β1. However, the platelets of two retained some ability to adhere to collagen-coated surfaces.[148,149] A fourth patient has been reported with a more severe bleeding disorder that included epistaxis requiring transfusion, severe bleeding after trauma, and significant postpartum hemorrhage.[150] The platelets of this patient expressed GPVI and the FcR γ chain, but aggregated poorly in response to collagen, convulxin, and collagen-related peptide (CRP), as well as to heparin-induced thrombocytopenia antibodies, implying a defect in collagen-induced signaling downstream of the FcR γ chain. GPVI deficiency as been reported in conjunction with the gray platelet syndrome.[151] Four patients have been described, whose plasma contained autoantibodies against GPVI that inhibited collagen-induced platelet function,[152–155] as well as two patients, one with myelodysplasia and a second with chronic lymphocytic leukemia, whose platelets did not respond to collagen or convulxin but contained GPVI by flow cytometry.[156]

α2β1

α2β1 (GPIa-IIa, VLA-2) is a widely expressed integrin that binds with high affinity to type I collagen, as well as to collagen types II to V and to laminins 1 and 5, depending on the cellular context.[157] Besides platelets, α2β1 is present on endothelial cells, fibroblasts, epithelial cells, Schwann cells, and activated T cells.[158] α2β1 is one of nine integrins whose α subunit contains a 200 residue I-domain that is largely, if not exclusively, responsible for ligand binding.[159] The relative contributions of α2β1 and GPVI to collagen-initiated platelet function remains unclear. Current data suggest a model in which platelet tethering initiated by platelet GPIb-IX-V binding to collagen-bound VWF enables GPVI to bind to collagen and generate *outside-in* signals. In turn, these signals increase the affinity of α2β1 for collagen, resulting in platelet adhesion to collagen that is sufficiently firm to resist the shear stress of flowing blood.[139,160,161]

In support of a role for α2β1 in mediating physiologic platelet responses, several patients have been reported with platelets lacking α2β1 and failing to interact normally with collagen. Two patients were investigated because of the presence of a bleeding diathesis.

Platelets from the first contained approximately 15% to 25% of the normal amount of α2, failed to aggregate in response to collagen, and failed to adhere to collagen under both static and flow conditions.[162,163] Platelets from the second lacked α2 as well as the α granule protein thrombospondin, failed to aggregate in response to low concentrations of collagen, and adhered to, but did not spread on, collagen-coated surfaces.[164] Two families were also investigated because of autosomal dominant thrombocytopenia and mild cutaneous bleeding.[165] Platelets of affected family members expressed 38% to 63% of the normal amount of α2β1 and adhered poorly to collagen-coated surfaces, whereas collagen-induced platelet aggregation was either normal or only slightly perturbed.

There are also inherited differences in the density of α2β1 on the platelet surface that result from polymorphisms in the coding and promoter regions of the α2 gene.[166–168] In vitro studies suggest a positive correlation between α2β1 expression and platelet adhesion to type I and type III collagen.[169] In addition some, but not all, epidemiologic studies have suggested that increased α2β1 expression is a risk factor for myocardial infarction and stroke in younger individuals and for diabetic retinopathy in patients with type II diabetes mellitus.[170–176]

DISORDERS OF PLATELET AGGREGATION

Glanzmann Thrombasthenia (Glycoprotein IIb-IIIa Deficiency)

Originally described by Glanzmann in 1918,[177] thrombasthenia is a rare bleeding disorder characterized by a prolonged bleeding time, a normal platelet count, and absent macroscopic platelet aggregation.[178] Platelets from affected individuals are unable to aggregate because of a deficiency or dysfunction of the platelet membrane GPIIb-IIIa complex.[179]

Biology and Molecular Aspects of the Disorder

The formation of a hemostatically effective platelet plug requires platelet aggregation.[180] In contrast to platelet adhesion, platelet aggregation is an active metabolic process, requiring platelet stimulation by agonists such as thrombin, collagen, and ADP and exposure of a binding site for fibrinogen or VWF on the GPIIb-IIIa complex.[181–183] Fibrinogen or VWF bound to GPIIb-IIIa crosslinks adjacent platelets into an occlusive plug. The GPIIb-IIIa complex, also known as αIIbβ3, is a member of the integrin family of adhesion receptors[184] and like other members of this family, resides on the cell surface in an equilibrium between inactive (low affinity) and active (high affinity) conformations.[185] Platelet stimulation shifts GPIIb-IIIa to its active conformation, enabling it to bind ligands and mediate platelet aggregation.[185] Platelet stimulation also enables the interaction of the GPIIb-IIIa cytoplasmic tails with submembranous actin filaments via intermediary cytoskeletal proteins such as talin and α-actinin, thereby providing a mechanism for transmitting the force of cytoskeletal contraction to the fibrin clot resulting in clot retraction.[186,187]

GPIIb-IIIa is a calcium-dependent heterodimer and dissociates into GPIIb and GPIIIa monomers in the presence of calcium chelators.[188] By electron microscopy, the heterodimer appears as a 12 × 8 nm globular head with two 18 nm stalks extending from one side.[189] When incorporated into phospholipid vesicles, the globular head extends approximately 20 nm above the vesicle surface with the tips of the tails inserted into the phospholipid.[190]

GPIIb has an unreduced mol wt of 136,000 and dissociates into a 125,000 mol wt heavy chain (GPIIbα) and 23,000 mol wt light chain (GPIIbβ) following disulfide bond reduction.[188] GPIIbα binding to GPIIIa is responsible for heterodimer formation,[191] whereas GPIIbβ anchors GPIIb in the platelet membrane.[192] GPIIb is synthesized as single chain precursor (pro-GPIIb) in the rough endoplasmic reticulum (ER)[192] where it associates with GPIIIa. The resulting heterodimer is then transported to the Golgi complex where pro-GPIIb is cleaved into heavy and light chains.[193] In contrast to GPIIb, GPIIIa is a single chain protein containing 56 cysteine residues and 28 disulfide bonds;[194] its apparent mol wt of 90,000 on unreduced sodium dodecyl phosplate (SDS) gels increases to 110,000 following disulfide bond reduction.[188] The disulfide bonds in GPIIIa are concentrated in three regions of the extracellular portion of the molecule: a cysteine-rich, protease-resistant amino terminus (residues 1–62), a protease-sensitive central region (residues 101–422), and a disulfide-rich, protease-resistant core (residues 423–622).[195] In addition, there is a long-range disulfide bond between cysteine residues 5 and 435 that results in a large protease-sensitive loop.[196]

In the absence of heterodimer formation, GPIIb and GPIIIa monomers are retained in the ER and are eventually degraded.[197] The factors responsible for the retention of uncomplexed monomers are unknown. However, it is clear from studies of various thrombasthenic mutants that the formation of GPIIb-IIIa heterodimers alone is not sufficient to guarantee egress of GPIIb-IIIa from the ER.[197,198]

Platelets also express a second GPIIIa (β3)-containing integrin, the vitronectin receptor (αvβ3), whose αv subunit is highly homologous to GPIIb.[199] There are 50- to 500-fold fewer copies of αvβ3 than GPIIb-IIIa on platelets.[200,201] Moreover, GPIIb-IIIa expression is restricted to cells of the megakaryocytic lineage,[202] whereas αvβ3 is expressed by a variety of cells including endothelial cells, smooth muscle cells, and osteoclasts.[203] The extracellular portions of αvβ3 and GPIIb-IIIa have been crystallized and their structures solved.[204,205] The structures reveal that the amino terminus of αv and GPIIb fold into a β-propeller, as had been predicted.[206] The β-propeller is followed by *thigh* and two *calf* domains with a flexible *genu* between the thigh and first calf domains. The GPIIIa head consists of a βA domain whose fold resembles that of integrin α subunit *I-domains* and contains a metal ion binding or MIDAS motif. The interface between the β-propeller and the βA domain is the site at which αv and GPIIb interact with the β3 and resembles the interface between the Gα and Gβ subunits of G proteins. The remainder of the extracellular portion of GPIIIa consists of plexin semaphorin integrin (PSI) domain, four tandem epideimal growth factor (EGF) repeats, and a relatively unique carboxyl-terminal βTD domain. In the crystal structure of αvβ3, the molecule is severely bent because of the flexibility of the αv and GPIIIa stalks. Thus, it has been proposed that when αvβ3 (and by analogy GPIIb-IIIa) is activated, the molecule straightens to resemble the molecules visualized by electron microscopy.[189,204,207]

Etiology and Pathogenesis

There are approximately 80,000 copies of GPIIb-IIIa on the surface of unstimulated platelets.[208] Glanzmann thrombasthenia results when platelets lack sufficient numbers of functional GPIIb-IIIa complexes to support platelet aggregation.[179] However, the platelets of obligate thrombasthenic heterozygotes aggregate normally, indicating that 50% of the normal amount of GPIIb-IIIa is at least sufficient to support platelet aggregation.[209]

GPIIb-IIIa deficiency is responsible for additional abnormalities of platelet function. Thrombasthenic platelets do not spread normally on the subendothelial matrix, an aspect of platelet adhesion that is mediated by GPIIb-IIIa binding to fibronectin and VWF.[210] The amount of fibrinogen in the α granules of thrombasthenic platelets is decreased to absent.[178] Because human megakaryocytes do not synthesize fibrinogen,[211] α granule fibrinogen is derived from plasma by a GPIIb-IIIa-mediated endocytic process.[212–215] Thus, the absence of functional GPIIb-IIIa on thrombasthenic platelets accounts for their deficit in α granule fibrinogen. Several biochemical reactions in platelets that require the presence of GPIIb-IIIa are impaired in thrombasthenic platelets. For example, the tyrosine phosphorylation of multiple platelet proteins, including proteins with molecular weights of 140,000 and 50,000 to 68,000, depends on ligand binding to GPIIb-IIIa; and the tyrosine phosphorylation

of proteins such as pp125^{FAK} as well as proteins with molecular weights of 95,000 to 97,000 requires platelet aggregation.[216] Calpain, a calcium-dependent thiol protease, is activated when stirred normal platelets are stimulated by thrombin, but not when thrombasthenic platelets are treated in a similar manner.[217] The redistribution of several proteins, including spectrin, talin, vinculin, pp60(src), and p62(yes), to a detergent-insoluble platelet cytoskeleton follows thrombin-stimulated platelet aggregation; but it does not occur when thrombasthenic platelets are treated in this way.[218] The kinetics of calcium exchange in unstimulated thrombasthenic platelets is inexplicably decreased[219] because it is unclear what role, if any, GPIIb-IIIa plays in calcium transport.[220,221] Clot retraction in blood containing thrombasthenic platelets is either absent or reduced,[178] a finding consistent with the ability of GPIIb-IIIa to link the fibrin clot to the platelet cytoskeleton.[186]

Aspects of platelet function that do not depend on GPIIb-IIIa are normal in thrombasthenia. Thrombasthenic platelets interact normally with collagen fibrils[222] and undergo secretion when stimulated by "strong agonists" such as thrombin.[223] Incubation of thrombasthenic platelets with ristocetin induces VWF binding to GPIb-IX-V[10] and thrombasthenic platelets adhere to VWF in the subendothelium.[210] Thrombasthenic platelets also express normal amounts of procoagulant activity following lysis.[52] However, agonist-stimulated prothrombinase activity varies and is influenced by the nature of platelet agonist.[52,224]

Table 141–3 Mutations That Impair GPIIb-IIIa Function

Mutation	Affected Subunit	Reference
Tyr143His	GPIIb	242
Arg-Thr insertion into the Cys146-Cys167 loop	GPIIb	257
Arg995Gln	GPIIb	258
Cys560Arg	GPIIIa	255

Cys560Arg	GPIIIa	255
Cys579Ser	GPIIIa	254
Arg724Stop	GPIIIa	256

Genetic Aspects

The genes for GPIIb and GPIIIa are located on the long arm of chromosome 17 at q21→23[225] with the GPIIb gene a minimum distance of 365 kb downstream from the GPIIIa gene.[226] The GPIIb gene (*ITGA2B*) spans approximately 18 kb, is located in a region that contains at least 7 complete and 3 incomplete Alu repeats, and consists of 30 exons ranging in size from 46 bp to 220 bp.[227] Like the genes for other proteins expressed in megakaryocytes, its 5′ flanking region lacks TATA or CAAT boxes. Instead it contains a linear array of regulatory elements that includes two motifs recognized by the GATA-1 transcription factor and its cofactor FOG;[228,229] sequences flanking each GATA-1 binding site that are recognized by Fli-1 and perhaps other members of the Ets family of transcription factors;[230–233] and an Sp1-binding silencer element located between the GATA-1 sites.[234] In addition, regions located 2.5 to 7.1 kb upstream and 2.2 to 7.4 kb downstream from the GPIIb gene are necessary for consistent high level gene expression.[235] The gene for GPIIIa (*ITGB3*) spans 63 kb and contains 15 exons.[236,237] Like the GPIIb gene, the 5′ flanking region of the GPIIIa gene lacks TATA or CAAT boxes.[238] Specific regulatory motifs that control GPIIIa gene expression in megakaryocytes have not been identified. Although the organization of exons in many genes reflects the distribution of functional domains in the protein they encode, this does not appear to be true for either the GPIIb or the GPIIIa gene.

Glanzmann thrombasthenia is an autosomal recessive disorder with clusters of disease in populations where consanguinity is common and has been subclassified into three types based on the amount of GPIIb-IIIa present per platelet and the presence or absence of α granule fibrinogen and clot retraction.[178] In type I, platelets contain less than 5% of the normal amount of GPIIb-IIIa and clot retraction and α granule fibrinogen are absent. In type II, platelets contain 10% to 20% of the normal amount of GPIIb-IIIa, clot retraction is decreased, and α granule fibrinogen is present. In *variant* thrombasthenia, the platelet content of GPIIb-IIIa equals 50% of normal, indicating that the GPIIb-IIIa abnormality is qualitative, rather than quantitative.

Expression of GPIIb-IIIa on the platelet surface requires the formation of correctly folded GPIIb-IIIa heterodimers in the ER of megakaryocytes.[239] Thus, a mutation in the gene for either GPIIb or GPIIIa can impair GPIIb-IIIa expression and produce thrombasthenia, observations confirmed in murine models of GPIIb-IIIa deficiency.[240,241] At least 126 unique mutations responsible for thrombasthenia have been identified in the genes for GPIIb and GPIIIa, 68 in *ITGA2B*, and 58 in *ITGB3*. Many mutations are listed in a Glanzmann thrombasthenia database that can be queried at http://sinaicentral.mssm.edu/intranet/research/glanzmann/menu. The mutations are a mix of missense mutations (52%), nonsense mutations (14%), nucleotide deletions and insertions (28%), and alternative splicing (6%). Most mutations result in Type I and Type II thrombasthenia, but several have resulted in *variant thrombasthenia* where the GPIIb-IIIa abnormality is qualitative rather than quantitative (Table 141–3). Five such mutations (Tyr143His in GPIIb[242] and Asp119Tyr,[243] Val193Met,[244] Arg214Trp,[245,246] and Arg214Gln[247] in GPIIIa) are located in regions of GPIIb-IIIa that have been implicated in ligand binding and may perturb GPIIb-IIIa function by preventing its interaction with fibrinogen or VWF.[248,249] A sixth mutation, a Ser752Pro substitution in the cytoplasmic tail of GPIIIa, inexplicably prevents GPIIb-IIIa activation by cellular agonists.[250–252] A seventh mutation in GPIIIa, Ser123Pro, did not impair GPIIb-IIIa expression or agonist-induced ligand binding but was associated with absent ADP- and collagen-induced platelet aggregation.[253] In addition, three mutations involving cysteine residues located at the third and fourth EGF domains of GPIIIa (Cys560Phe,[254] Cys560Arg,[255] and Cys579Ser[254]) resulted in type II thrombasthenia and also induced constitutive ligand binding activity in the residual GPIIb-IIIa.

Four nonvariant mutations in GPIIb and GPIIIa are also noteworthy. In the first, the codon for Arg724 in GPIIIa is converted to a stop codon, resulting the synthesis of a truncated molecule lacking 39 carboxyl-terminal amino acids and the assembly of GPIIb-IIIa heterodimers that are unable to transduce inside-out and outside-in signals.[256] In the second, the insertion of two amino acids (arginine and threonine) into the Cys146-Cys167 loop of GPIIb results in an inactive thrombasthenic variant,[257] attesting to the importance of this region of GPIIb in ligand binding. In the third, an Arg995Gln mutation in the conserved GFFKR motif of the GPIIb cytoplasmic tail resulted in *poor*, but not absent, platelet aggregation,[258] in contrast to the constitutive GPIIb-IIIa activation predicted from disruption of a activation-constraining cytoplasmic clamp.[259] In the fourth, a Cys560Arg mutation in GPIIIa locked GPIIb-IIIa in a high-affinity conformation but produced a thrombasthenic-phenotype, perhaps because the low number of constitutively active GPIIb-IIIa complexes expressed on the platelet surface were insufficient to support platelet aggregation.[255]

Clinical Presentation

The clinical manifestations of thrombasthenia in a large cohort of patients have been described in detail.[178] Thrombasthenia typically presents with mucocutaneous bleeding during the neonatal period or infancy, occasionally with bleeding following circumcision. Spontaneous petechiae are uncommon and bleeding generally results from conditions that would cause bleeding in an otherwise normal individual. Next to purpura, epistaxis is the most frequent type of bleeding, especially during childhood. Gingival bleeding, often related to poor dental hygiene, and menorrhagia are frequent. Bleeding at menarche may be severe and require transfusion. Similarly, parturition represents a severe hemorrhagic risk. Other hemorrhagic manifestations include gastrointestinal bleeding and hematuria, but hemarthroses and deep hematomas are unusual. Serious bleeding may follow trauma or surgery in patients not transfused with normal platelets. However, the severity of hemorrhage in thrombasthenia is unpredictable, even within single kindreds, and does not correlate with the extent of GPIIb-IIIa deficiency. Thus, one sibling may experience life-threatening bleeding requiring frequent transfusion, whereas another suffers only mild bruising and epistaxis. The apparent decline in the clinical severity of thrombasthenia with age is likely caused by a decrease in the incidence of conditions such as epistaxis with aging.

Laboratory Findings

Platelet counts and platelet morphology on peripheral blood smears are normal. The bleeding time of affected individuals is markedly prolonged.[222] A diagnosis of thrombasthenia is usually suspected after platelet aggregometry reveals absent agonist-stimulated platelet aggregation (see Fig. 141–1). Platelet secretion induced by strong agonists such as thrombin is normal, but secretion in response to weak agonists such ADP and epinephrine does not occur. Coagulation tests, such as the prothrombin time and the partial thromboplastin time, are normal in thrombasthenia, whereas clot retraction in the presence of thrombasthenic platelets is absent or reduced.

Differential Diagnosis

A history of lifelong bleeding, a prolonged bleeding time, and absent platelet aggregation are diagnostic of thrombasthenia and differentiate it from other disorders of platelet adhesion and secretion. Instances of acquired thrombasthenia have been reported and can be differentiated from congenital thrombasthenia by history. Although autoantibodies against GPIIb-IIIa have been detected frequently in patients with idiopathic thrombocytopenic purpura,[260,261] autoantibodies that induce a thrombasthenic-like state are unusual.[262–265] A patient with multiple myeloma has been reported whose $IgG_1\kappa$ paraprotein was directed against GPIIIa and inhibited GPIIb-IIIa function.[266] Congenital afibrinogenemia may be associated with a prolonged bleeding time and decreased in vitro platelet aggregation caused by the absence of sufficient fibrinogen to support normal platelet aggregation.[267]

Patients have also been reported who presented with a thrombasthenia-like phenotype, but whose GPIIb-IIIa abnormality is unclear. In one patient with variant thrombasthenia, GPIIb-IIIa was present but dissociated abnormally in the presence of low concentrations of EDTA.[268] The platelets of a second patient with a mild thrombasthenia-like illness aggregated poorly in response to ADP and other agonists and had a deficit in the surface pool, but not the internal pool, of GPIIb-IIIa.[269] Similarly, the platelets of a third reported patient contained a normal amount of GPIIb-IIIa but here unable to aggregate in response to the usual platelet agonists.[270] In the LAD-III/LAD-1/variant syndrome, patients manifest mucocutaneous bleeding and absent platelet aggregation, despite normal or nearly normal GPIIb/IIIa expression.[271–273] Concurrently, they suffer from recurrent and severe bacterial infections caused by defective leukocyte integrin function, implying that the syndrome results from a general defect in integrin activation. In some affected kindreds, defective expression of the Rap-1 activator CalDAG-GEFI has been detected in platelets and leukocytes.[273,274] Moreover, disruption of the gene for CalDAG-GEFI in mice reproduces many of the features of the syndrome.[275] Thus, because Rap-1 has been implicated in the activation of both platelet and leukocyte integrins, it is likely that at least in some patients, CalDAG-GEFI deficiency is the abnormality responsible for the syndrome.

Therapy

The mainstay of treatment of bleeding in thrombasthenia is transfusion of normal platelets (see Table 141–2). Because bleeding is a life-long problem, use of HLA-matched platelets should be considered to lessen the chance of refractoriness to transfusion due to platelet alloimmunization. In rare instances thrombasthenic patients develop antibodies against normal GPIIb and GPIIIa following transfusion, potentially limiting the effectiveness of transfused platelets.[276,277] Protein A Sepharose immunoadsorption has been reported to restore the efficacy of transfused platelets in this situation.[278] Oral contraceptives have been useful in controlling menorrhagia. Regular dental care is essential in minimizing gingival bleeding. Fibrinolytic inhibitors such as epsilon aminocaproic acid or tranexamic acid, in addition to platelet transfusions, may help control bleeding after dental extractions. Corticosteroids are not efficacious in managing bleeding in thrombasthenic patients.[222] Although DDAVP has been reported to shorten the bleeding time in a patient with thrombasthenia and to have a beneficial effect during minor dental surgery,[121] this is the only report of an effect of DDAVP in thrombasthenia.[279] Recombinant factor VIIa has been found to be efficacious for the treatment of bleeding episodes and for obtaining surgical hemostasis in thrombasthenic patients, particularly in patients who have developed alloantibodies from prior platelet transfusions.[280–282] Lastly, the thrombasthenia of five affected individuals has been corrected by bone marrow transplantation.[283–286]

DISORDERS OF PLATELET SECRETION

Platelets contain four types of granules: dense granules containing ADP, adenosine triphosphate (ATP), calcium, serotonin, and pyrophosphate; α granules containing a variety of proteins, some derived from the plasma, others synthesized by the megakaryocyte; lysosomes containing acid hydrolases; and microperoxisomes containing a peroxidase activity. Following platelet activation, the contents of these granules are extruded in an exocytic process known as *platelet secretion*.[287] Inherited disorders of platelet secretion result from a deficiency of one or more of the types of platelet granules or from abnormalities in the platelet secretory mechanism. Secretion disorders are a frequent cause of mild to moderate bleeding manifested by easy bruising, menorrhagia, and excessive postoperative and postpartum blood loss. In one group of 145 patients presenting with such symptoms, 18% were found to have a deficiency of platelet granules, 19% to have an abnormality in the platelet secretory mechanism, and 36% to have von Willebrand disease.[288] No explanation for the bleeding diathesis could be found in 27% of the patients. Patients with platelet secretion disorders usually have a prolonged bleeding time, absence of the second wave of platelet aggregation when platelets are stimulated by ADP and epinephrine, and decreased aggregation when platelets are stimulated by collagen. These disorders must be differentiated from the acquired abnormalities of platelet secretion induced by drugs such as aspirin or systemic diseases such as uremia and multiple myeloma (see Chapter 142) and from the various types of von Willebrand disease (see Chapter 129).

DISORDERS OF SECRETION CAUSED BY ABNORMALITIES OF PLATELET α GRANULES

The Gray Platelet Syndrome (α Granule Deficiency)

The gray platelet syndrome, described by Raccuglia in 1971,[94] is a rare disorder that results from the specific absence of morphologically recognizable α granules in the platelets of affected individuals.

Biology and Molecular Aspects of the Disorder

Normal platelets contain approximately 50 spherical or elongated structures termed α *granules* that contain a variety of proteins, some of which are specific or relatively specific for platelets and others that are also found in plasma.[289] The former include platelet factor 4 (PF4) , β-thromboglobulin (βTG), platelet-derived growth factor, and thrombospondin and the latter include fibrinogen, VWF, albumin, coagulation factor V, IgG, fibronectin, and a number of protease inhibitors.[290] The platelet-specific proteins and several of the plasma proteins such as VWF[291] are synthesized by megakaryocytes, whereas others reach the α granules via endocytosis of circulating protein.[292] The α granule membrane contains many of the same proteins present in the platelet plasma membrane (GPIIb-IIIa[293] and GPIb-IX-V)[294] and others specific for α granules (P-selectin[295,296] and osteonectin).[297] Each can be translocated to the platelet surface following platelet activation.

Etiology and Pathogenesis

Electron micrographs of megakaryocytes and platelets from patients with the gray platelet syndrome reveal absence of normal α granules[298] and the presence of vacuoles and small α granule precursors containing material that stains for VWF and fibrinogen.[299] The other types of platelet granules are present in normal numbers. The outer membranes of the vacuoles and small α granule precursors contain P-selectin and GPIIb-IIIa which can be translocated to the platelet surface after thrombin stimulation.[293,300] These observations indicate that α granules are present in gray platelets and suggest that the abnormality responsible for the gray platelet syndrome is an inability to target proteins to these structures.[301] The inability to package and retain PF4, βTG, and platelet-derived growth factor in α granules would account for the elevated plasma concentrations of PF4 and βTG and the bone marrow fibrosis observed in patients with the syndrome.[302] The abnormality responsible for the gray platelet syndromes appears to be restricted to megakaryocytes because electron micrographs of endothelial cells from affected patients reveal typical Weibel-Palade bodies suggesting that these cells are capable of packing VWF normally.[303] A report of three children with the gray platelet syndrome whose neutrophils also had a gray appearance caused by a decrease in secondary granules suggests that the abnormality responsible for the gray platelet syndrome could also affect other blood cell lines.[304] However, in another report of five affected individuals, neutrophil granularity was normal,[305] suggesting that either the gray platelet syndrome is heterogenous or that the three reported children suffer from a unique familial hypogranular neutrophil and platelet disorder. With regard to the former possibility, two macrothrombocytopenic disorders resembling the gray platelet syndrome have been described. In the White platelet syndrome, autosomal dominant macrothrombocytopenia was associated with mild to moderate bleeding, defective platelet aggregation, incomplete α granule formation, and 30% or more gray-appearing platelets on blood smears.[306] In the Medich giant platelet disorder, macrothrombocytopenia was associated with a marked decrease in platelet α granules. In contrast to classic gray platelets, empty vacuoles without granule contents were not present in the platelet cytoplasm but were replaced by membranous inclusions resembling cigars or scrolls.[307]

Clinical Presentation and Laboratory Findings

Patients with the gray platelet syndrome present with a lifelong history of mild to moderate mucocutaneous bleeding,[308] but one patient developed subgaleal and epidural hematomas following head trauma.[309] Patients also exhibit variably prolonged bleeding times, moderate thrombocytopenia, reticulin fibrosis of the bone marrow, and large platelets whose gray appearance on a Wright-stained blood smear gives the name to the disorder.[94,95] Platelet counts vary from 25,000 to 150,000/μl, but generally range between 60,000 and 100,000/μl. Studies of platelet aggregation have produced variable results. Aggregation induced by ADP, epinephrine, arachidonic acid, and the calcium ionophore A23187 has generally been normal or nearly normal,[310] but collagen-induced aggregation has been reported to be decreased to absent in some, but not all, cases, perhaps due to an associated deficiency of GPVI.[95,151,309] Responses to thrombin have also been variable, with reports of decreased aggregation and secretion in response to low thrombin concentrations,[95,310–312] impaired increments in intracellular calcium[313] and decreased generation of inositol-1,4,5-triphosphate.[314] Gray platelets agglutinate normally when exposed to ristocetin and the content of their dense granules is normal.[315] As expected, the PF4, βTG, fibrinogen, VWF, factor V, fibronectin, and thrombospondin content of gray platelet α granules is markedly decreased. Surprisingly, gray platelets contain substantial quantities of albumin and IgG,[316] proteins normally present in α granules. The PF4 and βTG concentrations in the plasma of affected individuals are normal or elevated.[95,310]

Genetic Aspects

Genetic analysis of families with the gray platelet syndrome support the possibility that platelet α granule deficiency may be a heterogenous disorder. Falik-Zaccai and colleagues reported 59 cases of the gray platelet syndrome.[308] Although the presence of the disorder in males and females in the same family suggested that it is an autosomal disease, its mode of inheritance remains uncertain. For example, a family has been reported in which the gray platelet syndrome was inherited in an X-linked fashion and associated with an Arg216Gln mutation in the *GATA1* gene.[317] A disorder resembling the gray platelet syndrome is present in the Wistar Furth strain of rat and is inherited as an autosomal recessive.[318] Hematopoietic zinc finger (*HZF*) null mice also have features resembling the gray platelet syndrome, but sequence analysis of the *HZF* gene and studies of *HZF* protein expression in five gray platelet syndrome patients from three different families did not identify abnormalities in this gene.[319]

Therapy

Treatment of severe bleeding episodes may require the transfusion of normal platelets (see Table 141–2). DDAVP was found to shorten the bleeding time in one patient and was used as successful prophylaxis for a dental extraction.[320]

The Quebec Platelet Disorder (Factor V Quebec)

Two unrelated families with an autosomal dominant bleeding disorder of moderate severity have been identified in Quebec.[321–323] Their disorder is characterized by mild thrombocytopenia, defective epinephrine-induced platelet aggregation, a decrease in the amount of multiple α granule proteins, and bleeding unresponsive to platelet transfusion, but controlled by fibrinolytic inhibitors. The disorder in the index family was initially attributed to a decrease in platelet factor V, hence the name Factor V Quebec.[324] In contrast to the gray platelet syndrome, the α granules in platelets of the Quebec platelet disorder appear to be morphologically normal.[322] However, the amount of α granule proteins, including factor V, multimerin, fibrinogen, VWF, fibronectin, osteonectin, and thrombospondin, is decreased

and many are substantially degraded.[322] Further, analysis of α granule proteolytic activity revealed that the ectopic expression of urokinase-type plasminogen activator in α granules is responsible for the biochemical and clinical features of the disorder.[325,326] The basis for the ectopic expression of urokinase-type plasminogen activator is unknown.[327] A patient with a longstanding bleeding disorder has also been reported with platelets containing a reduced amount of α granule factor V but no evidence of ectopic α granule proteolytic activity, indicating that some other process was responsible for the reduction in α granule factor V.[328]

DISORDERS OF SECRETION DUE TO DEFICIENCY OF PLATELET DENSE GRANULES

Dense Granule Deficiency (δ-Storage Pool Disease)

Biology and Molecular Aspects of the Disorder

Normal platelets contain three to six 200 to 300 nm dense or δ granules that serve as intracellular storage sites for ADP, ATP, calcium, pyrophosphate, and serotonin.[329] Because of their high calcium content, δ granules can be visualized in electron micrographs of unfixed, unstained platelet whole mounts.[329] They can also be visualized by electron microscopy of thin sections of fixed platelets after staining with uranyl ions (uranaffin reaction) and by fluorescence microscopy after staining platelets with mepacrine (quinacrine).[329] The δ granule membrane contains a 40,000 mol wt protein named granulophysin (CD63) that is translocated to the platelet surface following platelet activation[330] and corresponds to the melanoma-associated antigen ME491, the lysosomal membrane protein-1 (LIMP-1), and the lysosomal membrane-associated protein-3 (LIMP-3).[331] The δ granule membrane also contains P-selectin, GPIb, and GPIIb-IIIa.[332] δ Granules undergo exocytosis coincident with the second wave of platelet aggregation (see Fig. 141–1).[333] ADP secreted from δ granules is thought to be involved in propagation of the primary platelet response;[334,335] the function of the other δ granule contents is presently unknown.

Platelet δ granules are related to a group of lysosome-related granules including melanosomes, neutrophil azurophilic granules, the lytic granules of cytotoxic T lymphocytes and natural killer cells, basophilic granules in basophils and mast cells, and class II major histocompatibility complex compartments in antigen-presenting cells.[331,336] The biogenesis of δ granules in megakaryocytes is poorly understood. However, δ-storage pool deficiency occurs in tyrosinase-positive albinism in humans[331]; pigment dilution syndromes in mice and rats[331]; and as part of a Chediak-Higashi–like syndrome in cattle, cats, mink, foxes and killer whales,[337] implying that that the biogenesis of dense granules, melanosomes, and lysosomes is related. How dense granules accumulate ATP and ADP is also unknown. One candidate for mediating ATP and ADP accumulation is MRP4 (multidrug resistance protein 4, ABCC4), a nucleotide transport pump, because it colocalizes with dense granules by immunofluorescence microscopy and its distribution is altered in dense granule-deficient platelets.[338] A second candidate is the gene *Slc35d3*, a nucleotide sugar transporter, that was identified in a strain of hypopigmented ashen mice (a model of the human Griscelli syndrome[339]) that independently developed platelet dense granule deficiency.[340]

Normal platelets contain two pools of adenine nucleotides that exchange slowly, if at all.[341] One pool is a metabolic nongranule pool in which the ratio of ATP : ADP content is 8 : 1 to 10 : 1. The second pool is present in the δ granules and contains 65% of the platelet adenine nucleotides with an ATP : ADP ratio of 2 : 3. Thus, in normal platelets, the whole platelet ATP : ADP ratio is less than 2.5. Conversely, serotonin is not synthesized by megakaryocytes, but it is taken up from the plasma and stored in the δ granules where it is protected from platelet monoamine oxidase.[342]

Etiology and Pathogenesis

δ-Storage pool disease is a heterogeneous group of disorders with δ granule deficiency as the common feature. The disorder can be subdivided into deficiency states associated with albinism and those in otherwise normal individuals.[343] δ-Storage pool disease has been reported in some patients with the Wiskott-Aldrich syndrome/X-linked thrombocytopenia,[344,345] the syndrome of thrombocytopenia with absent radii,[346] Ehlers-Danlos syndrome,[347] and osteogenesis imperfecta.[348] When δ-storage pool disease is associated with albinism, as in the Hermansky-Pudlak syndrome (HPS) (oculocutaneous tyrosinase-positive albinism, platelet dense granule deficiency, ceroid-like inclusions in cells of the reticuloendothelial system, progressive pulmonary fibrosis, and granulomatous colitis)[331] and the Chediak-Higashi syndrome (CHS) (partial oculocutaneous albinism, frequent pyogenic infections, and giant lysosomal granules in cells of hematologic and non-hematologic origin),[337] there is a quantitative deficiency of δ granules. In the platelets of nonalbinos, however, the number of uranaffin- and mepacrine-positive granules is normal to only slightly decreased, suggesting an inability to package the δ granule contents.[349,350] The platelet content of granulophysin also parallels the apparent number of δ granules in storage pool–deficient patients, being low in patients with the HPS and CHS, but normal in nonalbinos.[351] In some nonalbino patients, the δ granule abnormality is also associated with a variable deficiency of α granules (αδ-storage pool disease).[352,353] Although the content of lysosomal acid hydrolases in platelets from patients with δ-storage pool disease is normal, thrombin-induced acid hydrolase secretion may be impaired in severely affected individuals, an abnormality that can be corrected by the addition of ADP in vitro.[335] The ability of δ-storage pool–deficient platelets to form thrombi on the subendothelium has been studied ex vivo under various conditions of shear.[210] Thrombus dimensions are reduced in proportion to the magnitude of the dense granule deficit and are reduced even further when αδ-storage pool disease platelets are examined, suggesting that δ and α granule contents either potentiate thrombus growth on the subendothelium or help to stabilize thrombi in the presence of high shear stress.

Clinical and Laboratory Findings

Patients with δ-storage pool disease have a mild to moderate bleeding diathesis characteristic of patients with platelet secretion defects. Platelet counts and morphology are usually normal and bleeding times are usually prolonged.[288] Further, the volume of blood emerging from bleeding time wounds is increased over normal, particularly at early time points,[354] suggesting that δ granule contents may be involved in the contraction that follows vascular transection. The quantity of thromboxane B_2, a metabolite of thromboxane A_2, in the collected blood is also decreased, especially in patients with αδ-storage pool disease, a finding consistent the impaired agonist-induced prostaglandin and thromboxane synthesis often detected in these platelets.[355] Aggregometer tracings of δ-storage pool–deficient platelets stimulated by weak agonists such as ADP and epinephrine usually lack a second wave of aggregation (see Fig. 141–1).[356] Responses to low concentrations of collagen are also diminished to absent, but responses to high collagen concentrations may be normal or nearly normal.[357] Although this pattern of aggregation is typical for δ-storage pool disease, patients have been reported with normal aggregation studies.[288] The steady-state serotonin content of δ-storage pool–deficient platelets is decreased even though the rate of uptake of serotonin is normal,[341] because without storage sites, the serotonin either leaks out of the platelet or is metabolized by platelet monoamine oxidase. In δ-storage pool deficiency, the dense granule pool of ADP no longer contributes to the whole platelet content of ADP and the ATP : ADP ratio of δ-storage pool–deficient platelets is 3.0 or greater. This alteration in ATP : ADP ratio is extremely helpful in the diagnosis of δ-storage pool deficiency, especially when the typical aggregation abnormalities are absent.[288] Flow cytometry of mepa-

Table 141–4 Hermansky-Pudlak Syndrome Subtypes[360,361]

Human Subtype	Mouse Mutation	Affected Gene	Protein Complex	Reference
HPS-1	Pale ear	*HSP1*	BLOC-3	360–362, 367, 368
HPS-2	Pearl	*AP3B1*	AP-3	372, 374, 375
HPS-3	Cocoa	*HPS3*	BLOC-2	377, 378
HPS-4	Light ear	*HPS4*	BLOC-3	371
HPS-5	Ruby eye-2	*HPS5*	BLOC-2	379, 380
HPS-6	Ruby eye	*HPS6*	BLOC-2	380, 381

HPS-8	Reduced Pigmentation	*BLOC1S3*	BLOC-1	386

crine-labeled platelets may be a rapid method to detect δ-storage pool–deficient platelets,[358,359] but its sensitivity compared to measurement of the ATP : ADP ratio has not been tested.

Genetic Aspects

HPS and CHS are inherited as autosomal recessive disorders.[331,337] There are eight known human HPS genes and fifteen genetically distinct strains of mice have phenotypes similar to human HPS.[360,361] Moreover, eight of the mutant mouse genes are orthologs of the human HPS genes (Table 141–4). HPS-1, the HPS prototype, although rare in the general population, occurs with a frequency of 1 in 1800 in northwest Puerto Rico.[362,363] It is also one of the most common causes of oculocutaneous albinism in Japanese.[364] Besides δ-storage pool disease and tyrosinase-positive albinism, patients with HPS-1 suffer from decreased visual acuity, nystagmus, granulomatous colitis, and usually fatal pulmonary fibrosis.[365,366] HPS-1 results from mutations in a gene located on human chromosome 10q23.1–23.3 that encodes an 80,000 mol wt protein and corresponds to the gene responsible for the mouse mutant *pale ear*.[362,367,368] HPS-1 in Puerto Rico results from a 16-bp duplication in exon 15 of *HPS-1*[369] and at least 22 additional mutations have been identified in non-Puerto Ricans.[361] The HPS-1 protein is one component of a cytosolic and membrane-bound complex (BLOC-3, biogenesis of lysosome-related organelles complex 3) that also contains the 77,000 mol wt protein that is mutated in HPS-4.[360] Thus, the HPS-1 and HPS-4 proteins participate in the same step in vesicle development, and the phenotypes of patients with HPS-1 and HPS-4 are similar.[370] The gene mutated in HPS-4 corresponds to the gene involved in the mouse mutant *light ear*.[371] HPS-2 results from mutations in *ADTB3A*, the gene encoding the β3A subunit of the adaptor complex AP-3; mutations in this gene are also responsible for the mouse mutant *pearl*.[372] The AP-3 complex contains four subunits (δ, β3A, μ3A, and σ3), interacts with clathrin, and is thought to recruit cargo proteins to newly formed vesicles.[373] Patients with HPS-2 have phenotypes ranging from mild to severe and are distinguished from other HPS mutants by the presence of neutropenia and recurrent childhood infections.[372,374,375] HPS-3, a relatively mild form of HPS,[376] is the human homologue of the mouse mutant *cocoa*.[377] HPS-3 results from mutation of a gene located on human chromosome 3q24 encoding a 113,700 mol wt protein of unknown function.[378] HPS-5 results from mutation of a gene located on chromosome 11p14 and has been identified in five patients who manifested hypopigmentation and platelet storage pool disease without colitis or pulmonary fibrosis.[379] HPS-6, detected in a single patient from Belgium[380] and 20 individuals from an extended Israeli Bedouin family,[381] produces a phenotype similar to HPS-5 and results from mutation of the HPS6 gene located on chromosome 10q24.1-q25.1.[381] HPS-5 and HPS-6 correspond to the mouse mutants *ruby-eye 2* and *ruby-eye*, respectively.[380] Like HPS 1 and 4, the similarity of the phenotypes of HPS3, HPS5, and HPS6 suggest the responsible genes act within the same pathway. In support of this suggestion, biochemical studies indicate that HPS3, HPS5, and HPS6 interact to form a multisubunit complex called BLOC-2.[382] HPS-7, identified in a Portuguese woman with mild HPS, results from a mutation in the gene for dysbindin, mutation of which is also responsible for the mouse mutant *sandy*.[383] Dysbindin is a component of the BLOC-1 complex that also contains the proteins pallidin, muted, and cappuccino, each of which is associated with a variant of murine HPS.[384,385] HPS-8 was identified in a large consanguineous Pakistani family that presented with incomplete oculocutaneous albinism and platelet storage pool disease and was found to be caused by a frameshift mutation in the gene *BLOC1S3*, another component of the BLOC-1 complex.[386] Although the function of BLOC-1, BLOC-2, BLOC-3, and AP-3 in the biogenesis of platelet δ granules is not known, BLOC-1 and AP-3 have been shown to physically associate and to facilitate the trafficking of melanosomal membrane protein tyrosinase-related protein 1.[387] Similarly, BLOC-1 has been found to associate with BLOC-2 where it participates in a cargo transport pathway from early endosomes to melanosomes.[387,388]

CHS results from mutations in the gene *CHS1* (*LYST*) located on human chromosome 1q42–q43.[389,390] *CHS1* is the ortholog of the murine *bg* gene, mutation of which is responsible for the beige mouse.[390] *CHS1* encodes a 430,000 mol wt cytosolic protein whose role in normal lysosome development is unknown.[337] There appears to be a genotype–phenotype correlation between various *CHS1* mutations and the clinical course of CHS.[391–393] Thus, mutations that prevent the synthesis of the full-length CHS1 protein are associated with a severe childhood form of CHS that usually progresses to a fatal accelerated lymphoproliferative phase, often following infection with Epstein-Barr virus. Missense mutations, however, have been associated with a milder clinical course with less frequent infections and survival into adolescence and adulthood, but are associated with progressive neurologic deficits.

Therapy

Bleeding in patients with δ-storage pool disease can be controlled by the transfusion of normal platelets (see Table 141–2). However, this is seldom necessary because the potential risks of platelet transfusion far outweigh the benefits when bleeding is not life-threatening. Moreover, other methods to readily improve hemostasis without the risks of transfusion are available. Bleeding has been controlled by the administration of cryoprecipitate[394] or DDAVP.[395] The latter avoids the transfusion of blood products and should be regarded as the initial therapy of choice. DDAVP is a vasopressin analogue whose pressor effects (V_1 vasopressin receptors) are substantially less than its antidiuretic effects (V_2 vasopressin receptors). Infusion of the drug releases large multimers of VWF and tissue plasminogen activator from tissue stores.[279] The released VWF accounts for the beneficial

effect of the drug on the bleeding time in some forms of von Willebrand disease. The precise mechanism of its ability to shorten the bleeding time in patients with platelet function disorders is uncertain. Nonetheless, in several series of patients with platelet disorders, shortening of the bleeding time in response to DDAVP occurred in 43% to 100% of patients.[395–397] This variability in response rate indicates that if DDAVP is to be used for surgical prophylaxis, a bleeding time must be obtained after the DDAVP infusion to insure that the patient has responded.

In a single unconfirmed study, prednisone at doses of 20 to 50 mg for 3 to 4 days was used to improve hemostasis in patients with inherited platelet disorders.[398] Shortening of the bleeding time was seen within 3 days and persisted for up to 3 to 7 days after the prednisone was stopped. However, prednisone was ineffective in shortening the bleeding time in patients with thrombasthenia[222] or in normal individuals given aspirin.[399] There are also reports suggesting that recombinant VIIa can be effective in managing bleeding in patients with storage pool disease.[126,400]

HPS, in particular the HPS-1 and HPS-4, is associated with progressive pulmonary fibrosis that is generally fatal by the fourth to sixth decades of life.[401] The pathogenesis of the fibrosis is uncertain, but it may result from the disruption of type II pneumocytes by ceroid, resulting in inflammation, cytokine production, and fibroblast proliferation.[401] The drug pirfenidone, an antifibrotic agent, has been reported to slow the progression of pulmonary fibrosis in patients with HPS.[402] One patient with HPS and pulmonary fibrosis was treated successfully by bilateral lung transplantation.[403]

Bone marrow transplantation has been effective in reversing the immunologic and hemostatic manifestations of CHS,[404] but surviving patients later develop neurologic deficits.[337]

DISORDERS OF SECRETION DUE TO AN ABNORMAL SECRETORY MECHANISM

In this uncommon group of disorders, platelet function resembles that of individuals who have been given platelet inhibitory drugs such as aspirin (see Fig. 141–1). Thus, there is marked impairment of aggregation and secretion in response to weak platelet agonists such as ADP, epinephrine, and low concentrations of collagen, whereas responses to stronger agonists such as higher concentrations of collagen may be normal or near normal. Bleeding times of patients with this type of secretion defect are usually prolonged. However, when the bleeding time is normal or only slightly prolonged, it may become markedly prolonged 2 hours after the ingestion of three aspirin tablets.[405]

Etiology and Pathogenesis

Stimulated platelets secrete the contents of their cytoplasmic granules by a process that involves granule convergence at the center of the platelet, fusion of the granule membranes with the membranes of the surface-connected open canalicular system, and extrusion of the granule contents into the platelet's external milieu.[287] This process requires coupling agonist receptors on the platelet surface to the effector systems responsible for platelet secretion and is discussed in detail in Chapter 116.

The disorders of platelet secretion discussed in this section represent a heterogeneous collection of abnormalities in stimulus-response coupling. In many instances, the evidence linking the reported biochemical abnormalities to defective platelet secretion is not definitive. Patients have been reported with platelets displaying abnormalities in arachidonic acid metabolism including impaired coupling of the thromboxane A_2 (TxA_2) receptor and phospholipase C,[406] as well as deficiencies of cyclooxygenase[407–412] and thromboxane synthetase.[413,414] Diminished platelet responsiveness to endogenous and exogenous TxA_2 has been attributed to abnormalities of platelet TxA_2 receptors.[415–417] An Arg 60 Leu mutation in the first cytoplasmic loop of the TxA_2 receptor, detected in five Japanese patients, impairs TxA_2-stimulated inositol-1,4,5-triphosphate formation, calcium mobilization, and phosphatidic acid formation without affecting TxA_2-binding.[418] Impaired platelet responsiveness to the calcium ionophores A23187[416,419,420] and ionomycin[421] has been reported, as has impaired GPIIb-IIIa activation and pleckstrin phosphorylation following platelet stimulation by multiple agonists caused by a mutation in the transcription factor CBFA2 that results in decreased expression of protein kinase C-θ.[422,423] A patient whose platelets responded poorly to ADP, epinephrine, collagen, thrombin, the TxA2 analogue U46619, and platelet-activating factor was found to have decreased platelet membrane GTPase activity caused by decreased expression of the gene for Gαq,[424,425] a phenotype that reproduces that of the Gαq-deficient mouse.[426] Another patient with a mild inherited bleeding disorder associated with abnormal platelet aggregation and secretion, reduced generation of inositol 1,4,5 trisphosphate, and reduced intracellular calcium mobilization was found to have a platelet-specific defect in phospholipase C-β2.[427,428] Several patients have been reported with platelets responding poorly to ADP because of defects in the Gαi-coupled ADP receptor $P2Y_{12}$.[429–435] A patient with a lifelong bleeding diathesis and platelets that responded poorly or not all to weak agonists was found to have reduced expression of the Gα subunit $G\alpha_{i1}$.[436] In addition, there are reports of patients whose platelets respond poorly to epinephrine[437–439] and to platelet-activating factor.[439,440] In one group of eleven patients with impaired platelet responses to low concentrations of collagen, eight were noted to have abnormal responses to other weak agonists, such as ADP, epinephrine, TxA_2, and the prostaglandin endoperoxide analogue U44169, but normal responses to strong agonists such as thrombin and high concentrations of collagen.[441] This suggests a defect in coupling weak agonist stimulation to secretion, rather than a defect in the secretory machinery itself. In the remaining patients, responses to strong agonists were abnormal and the platelets were unable to synthesize TxA_2.

Genetic Aspects

Most reports have been of individual patients so that determination of the mode of inheritance has not been possible. When families were studied, the mode of inheritance appeared to be autosomal dominant in some cases[409,411,414,415,437] and autosomal recessive in others.[442]

Therapy

The approach to therapy in patients with these disorders is identical to that described above for patients with disorders of platelet secretion due to deficiency of platelet dense granules (see Table 141–2).

DISORDERS OF PLATELET PROCOAGULANT ACTIVITY

The plasma membrane of activated platelets provides a surface for the assembly of the *tenase* and *prothrombinase* complexes that activate coagulation factor X and prothrombin, respectively (see Chapter 118). This procoagulant activity was previously termed *platelet factor 3*. Although there remains uncertainty whether specific membrane structures serve as receptors for this activity, it is clearly associated with a calcium-induced exposure of anionic phospholipids on the platelet surface.[443] The phospholipid composition of the platelet plasma membrane, like that of other cells, is asymmetric with phosphatidylcholine and sphingomyelin localized predominantly in the outer membrane leaflet and phosphatidylserine and phosphatidylethanolamine concentrated in the inner leaflet. This asymmetry is established by at least two enzymatic activities: *flippase*, an ATP-dependent aminophospholipid translocase[444,445] that directs the inward transporter of lipids and *floppase*, an ATP-requiring transporter encoded by the gene *ABCC1*, that directs the transport of choline- and amino-phospholipids to the outer leaflet.[443] Following

an agonist-stimulated rise in intraplatelet $Ca,^{2+}$ membrane asymmetry is lost with exposure of anionic phospholipids on the platelet surface,[446] as well as on platelet membrane vesicles or microparticles,[447] events that may or may not be related.[448] A similar response to increased intracellular calcium has been detected in erythrocytes[449] and lymphocytes.[450] The rapid Ca^{2+}-induced movement of phospholipids between membrane leaflets may be mediated by a membrane-associated phospholipid *scramblase*, the precise identity of which remains unresolved.[451] One such candidate scramblase may be a proline-rich 37,000 mol wt type II membrane protein that is a member of a four-gene family[452] expressed by erythrocytes and platelets as well as a variety of hematologic and nonhematologic tissues and cell lines.[453] Although the redistribution of membrane phospholipids that accompanies apoptosis also requires scramblase activity, the development of platelet procoagulant activity and apoptotic membrane changes appear to operate through different pathways.[454]

Isolated deficiency of platelet procoagulant activity is exceedingly rare. In addition to the one well-studied patient after whom the disorder was named (Scott syndrome),[455] three additional patients have been reported.[224,456] A recessive disorder identical to the Scott syndrome has also been reported in a pedigree of German shepherd dogs.[457] The initial patient presented with a history of a spontaneous retroperitoneal hematoma and bleeding after surgery and dental proceduces.[455] Although prothrombin and partial thromboplastin times, bleeding times, and platelet function studies were normal, serum prothrombin times were short and the patient's platelets were unable to express normal procoagulant activity. Although the patient's platelets secreted normal quantities of factor Va activity, they expressed only 20% to 25% of the normal number of factor Xa binding sites.[458] In addition, factor X activation by factor IXa and factor VIIIa was impaired, suggesting a concomitant deficiency of factor IXa and/or factor VIIIa binding sites.[459] When stimulated with the combination of thrombin and collagen, there was decreased exposure of anionic phospholipids on the platelet surface and decreased membrane vesiculation.[460–462] Similarly, there was decreased membrane vesiculation and procoagulant activity when the patient's erythrocytes were treated with the ionophore A23187.[449] Although membrane-associated phospholipid scramblase activity in the patient's platelets, erythrocytes, and lymphocytes was impaired, Ca^{2+} induced function of the isolated scramblase incorporated into proteoliposomes was indistinguishable from normal[451] and normal amounts of scramblase mRNA and protein were present in Scott syndrome lymphocytes.[463] This suggests that a reaction affecting scramblase function may be responsible for the syndrome. In support of this suggestion, decreased store-operated (capacitative) Ca^{2+} entry has been detected in a French patient.[464,465] Conversely, store-operated Ca^{2+} entry was unaffected in two unrelated patients,[466] whereas partial restoration of platelet procoagulant activity by valinomycin suggested a defect in the Gardos channel, a Ca^{2+} dependent K^+ channel.[467]

CHAPTER 142

ACQUIRED DISORDERS OF PLATELET FUNCTION

José A. López and Evelyn Lockhart

The acquired disorders of platelet function are among the most common of hematological abnormalities, a reflection of the sensitivities of platelets to external and internal perturbations. The clinical challenge in evaluating acquired disorders of platelet function is to determine whether observed derangements in platelet function pose a threat to the patient. Although platelet function can be altered to predispose to either hemostatic or thrombotic disorders, this chapter deals primarily, but not exclusively, with platelet disorders that may compromise hemostasis. We attempt also to guide the clinician in trying to determine the clinical importance of these disorders, but the marked variations in bleeding risks associated with any particular disorder of platelet function make this a difficult task. Bleeding in patients with acquired platelet dysfunction is likely to occur less frequently and predictably than in those affected by severe inherited platelet disorders such as Bernard-Soulier or Glanzmann thrombasthenia (see Chapter 141) and may manifest itself only in the setting of trauma or surgery or in the presence of additional hemostatic defects.

The laboratory evaluation of these patients may illuminate these disorders (see Chapter 122) but offer little concrete guidance in management. Acquired platelet defects (Table 142-1) often exhibit abnormal laboratory test results, such as a prolonged closure time on a platelet function analyzer or abnormal aggregation. Historically, the bleeding time has been used to evaluate bleeding risk in patients with jaundice or uremia; but it measures hemostasis only in one vascular bed (the skin) and bears inherent interoperator variability. These platelet assays are useful as a research tool; however, defects as quantified by laboratory tests, including the bleeding time, do not correlate precisely with risk for bleeding, and thus are not predictive of bleeding in these patients. Additionally, some acquired platelet disorders manifest with thrombosis, a risk that currently has no effective screening test. Lastly, tests that depend on assessing the functions of platelets ex vivo do not assess the contributions of labile substances from the endothelium (see Chapter 117) and occasionally (as in platelet aggregometry) lack the component of flow, a key factor with in vivo platelet function.

INTRINSIC DISORDERS OF PLATELET FUNCTION

Chronic Myeloproliferative Disorders

Clinical Features and Epidemiology

The myeloproliferative disorders (MPDs) include polycythemia rubra vera (PV), essential thrombocythemia (ET), and myelofibrosis with myeloid metaplasia. All three disorders are characterized by bone marrow hypercellularity, atypical megakaryocytic hyperplasia, and megakaryocyte clustering. Each chronic MPD is clonal, with the molecular lesion involving a hematopoietic stem cell. Thus, even when the phenotype is dominated by excessive proliferation of erythrocytes, such as in PV, the platelets are also products of the abnormal clone. Recent work from several laboratories has defined an important causative mutation in the disorder as producing a single, relatively conserved amino acid change (V617F) in the signaling protein JAK2.[1–5] This gain-of-function mutation is not present in the germ line but is acquired in hematopoietic stem cells, increasing the sensitivity of hematopoietic precursors to stimulation by erythropoietin and thrombopoietin, accounting for the increased red cell and platelets counts observed in the MPDs. It is estimated that this mutation can be found in 95% of patients afflicted with polycythemia vera and in 50% to 60% of those with essential thrombocythemia or idiopathic myelofibrosis (see Chapters 68, 70, 71).[6]

The MPDs all can display various degrees of leukocytosis or thrombocytosis; PV is often characterized by a marked elevation in the hematocrit. Particularly in PV and ET, thrombosis or bleeding account for a high percentage of the associated morbidity of the disorders, with thrombosis being the most frequent consequence. Thrombosis in PV and ET varies in location, with reports of arterial, venous, and microcirculatory locations; generally, arterial thrombosis is the most common.[7] Microcirculatory disturbances such as erythromelalgia, a syndrome of erythema and burning pain, are more frequently seen with ET, and result from platelet-rich arteriolar microthrombi that can lead to ischemia and gangrene. Bleeding in both PV and ET is primarily mucocutaneous. Some bleeding episodes can be in part attributed to thrombosis, such as variceal bleeding resulting from thrombosis-induced portal hypertension.[8] However, bleeding tendencies in these patients can be worsened by the use of aspirin as medical intervention for their thrombotic risks.

Polycythemia rubra vera in particular has been well studied in a large, prospective clinical study with respect to the risks of this disorder for hemorrhage and thrombosis. In the recently completed European Collaboration on Low-dose Aspirin in Polycythemia study, 633 (38.4%) of the 1638 patients enrolled had a history of thrombotic events. Of these cases, approximately three-quarters were arterial and one-quarter were venous. Of the former, ischemic stroke and transient ischemic attacks accounted for most events. The mean followup duration was 2.7 ± 1.3 years (range, 0–5.3 years). During this time, 122 patients (7.4%) experienced nonfatal thrombosis, of which 87 cases were arterial and 50 were venous. Of the 164 patients who died during the study, thrombosis accounted for 41% of the deaths and bleeding for only 7%. In this study, the biggest predictors of thrombotic risk were age older than 60 years and prior history of thrombosis. Risk was also increased in patients with diabetes mellitus or congestive heart failure and in smokers.

The rates of thrombotic and hemorrhagic complications in essential thrombocythemia have been studied in 21 retrospective cohort trials, reviewed by Barbui and colleagues.[9] At the time of diagnosis, the rates of thrombosis ranged from 9% to 84% in these trials, whereas rates of hemorrhage ranged from 3.9% to 63%. As in patients with PV, age older than 60 and a history of prior thrombosis predict the risk for recurrent thrombosis.[10]

The Pathogenesis of Bleeding and Thrombosis

Several intrinsic platelet function defects have been associated with the MPDs, but their clinical importance is uncertain. These may result, at least in part, from an increased sensitivity of the platelets to activation, a potential consequence of the JAK2 gain-of-function mutation. For example, a recent study demonstrated an increased risk for thrombosis in patients with chronic MPD when the mutant kinase could be detected in platelets alone or in platelets and

Table 142–1 Acquired Disorders of Platelet Function

Hypothermia
Miscellaneous disorders

granulocytes.[11] Likewise, a study of patients with essential thrombocythemia demonstrated that the presence of the JAK2 mutation in platelets correlated with increased platelet expression of tissue factor and P-selectin, decreased expression of CD41and CD42b, and increased quantities of platelet-neutrophil aggregates, all indicators of a hyperreactive platelet phenotype.[12] However, the precise relationship of the JAK2 mutation to platelet function and thrombotic risk remain to determined.

The bleeding time is prolonged in few patients, and significant bleeding complications can occur in patients with normal bleeding times. Elevation of the platelet count per se correlates poorly with the risk for hemorrhage or thrombosis in some studies, but spontaneous bleeding is rare in patients with platelet counts of less than 1,000,000/μL. Very high platelet counts, more than 1.5×10^6 platelets/μL, have been associated with an acquired form of von Willebrand disease, in which the largest multimers of von Willebrand factor (vWF) are deficient, presumably because many are adsorbed by the binding sites on the elevated numbers of platelets.[13–16]

One situation clearly associated with an increased risk for excessive bleeding, particularly with surgery, is the increased whole blood viscosity and high hematocrit in patients with uncontrolled polycythemia vera.[17] Leukocytosis has also recently been identified as a risk factor for thrombosis in PV, as it is in ET.[18,19]

The platelets of patients with MPDs can show various morphologic abnormalities, including size and shape variability as well as decreased numbers of secretory granules. Platelet survival may be decreased in ET. The most common platelet abnormality is decreased aggregation and secretion in response to agonists, particularly epinephrine, adenosine diphosphate (ADP), and collagen. These abnormalities are not merely caused by the high platelet count, because patients with reactive thrombocytosis have functionally normal platelets.[20] In what may appear to be a paradox, some patients demonstrate spontaneous in vitro platelet aggregation in platelet-rich plasma. The significance of this is unknown because it is also occasionally seen in normal individuals. Decreased platelet aggregation or secretion and decreased procoagulant activity may be caused by the following: (a) decreased agonist-induced release of arachidonic acid from membrane phospholipids; (b) decreased conversion of arachidonic acid to prostaglandin endoperoxides or lipoxygenase products; (c) decreased platelet responsiveness to thromboxane A_2 (TXA_2); (d) decreased dense-granule or α granule contents; or (e) decreased α_2-adrenergic receptors. Specific platelet membrane abnormalities have also been reported, including deficiencies of glycoproteins Ib and IX, causing an acquired form of the Bernard-Soulier syndrome[21]; a deficiency of receptors for prostaglandin D_2[22]; a deficiency in the number of c-*MPL* receptors[23]; and an increased number of Fc receptors.[24] Because MPDs are clonal in origin, the platelet abnormalities may develop from a clone of abnormal megakaryocytes.[25] Alternatively, such findings may result from platelet hyperreactivity and previous activation.[12]

It is important to emphasize several features about the platelet function defects reported in MPDs. First, no defect has consistently predicted a risk for bleeding or thrombosis. Second, no defect is unique to, and therefore predictive of, a particular MPD. Third, their relative frequency has varied widely in different reported series. Therefore, the clinical importance of the described abnormalities of platelet function in MPDs is unknown. It is unlikely that any of these abnormalities of platelet function has a major clinical role in myeloproliferative diseases, given that the major complication associated with these disorders is thrombosis rather than bleeding and the observation that bleeding is most commonly seen with platelet counts greater than 1.5×10^6/μL.[13–15] Nevertheless, the recent elucidation of the gain-of-function JAK2 mutation as an important molecular cause of the MPDs suggests that platelet hyperfunction contributes to the increased risk of thrombosis associated with these disorders.

Management

Two large studies have established age and history of a prior thrombosis as important risk factors for thrombosis in PV.[26,27] In 1986 the Polycythemia Vera Study Group published guidelines recommending that all patients with PV be phlebotomized to keep the hematocrit less than 45%. Those at low risk for thrombosis (age younger than 60 years and no history of prior thrombosis) generally required no further therapy. In patients at higher risk, cytoreduction was recommended. Current recommendations for therapy still largely follow these guidelines, but new treatments are available for cytoreduction.[28] Hydroxyurea, with or without aspirin, has been shown effective in reducing the risk of thrombosis in patients with essential thrombocythemia.[29] Younger patients can be treated with α-interferon, because they tolerate this therapy better than older patients. Even in those receiving cytoreductive therapy, thrombosis remains a serious complication, a fact that served as the rationale for the European Collaboration on Low-dose Aspirin in Polycythemia study. Aspirin therapy in PV had not been in routine use, except for the treatment of digital ischemia,[30] because of its perceived association with hemorrhagic complications, a perception based on the early cessation of an aspirin trial by the Polycythemia Vera Study Group.[31] The European Collaboration on Low-dose Aspirin in Polycythemia study was a multicenter study conducted in Europe that examined both the natural history of PV and the antithrombotic effect of low-dose (100 mg/d) aspirin. Aspirin lowered the incidence of nonfatal myocardial infarction and stroke by approximately 60% and reduced both overall mortality and cardiovascular mortality by 46% and 59%, respectively. Patients with PV should therefore be treated with low-dose aspirin unless there is a clear contraindication to its use.[32]

In patients with low-risk essential thrombocythemia and moderate platelet counts, platelet-lowering therapy is unnecessary, given the low risk for thrombosis and bleeding.[5] Reduction of the platelet count with hydroxyurea should be considered in patients with other risk factors for cardiovascular disease and in patients otherwise at high risk: those with a prior history of thrombosis, age older than 60 years, and with platelet counts of greater than 1.5×10^6/mL. A recent study compared hydroxyurea plus aspirin with anagrelide plus aspirin for the prevention of the thrombotic complications of essential thrombocythemia.[33] Anagrelide is a drug originally developed as a platelet inhibitor, but it was found to lower platelet counts by inhibiting the proliferation and differentiation of megakaryocytes.[34–36] Anagrelide is much more expensive than hydroxyurea. Both regimens achieved good long-term control of platelet counts, but patients in the anagrelide group were much more likely to suffer both thrombotic

and hemorrhagic complications, and to progress to myelofibrosis. Inexplicably, those in the anagrelide group experienced more venous thrombosis. There was no significant difference in death rate between the two groups. This study reinforces the recommendation of hydroxyurea with aspirin as first-line therapy for high-risk patients, on the basis of efficacy, safety, and cost.

LEUKEMIAS AND MYELODYSPLASTIC SYNDROMES

Bleeding in patients with the leukemias and myelodysplastic syndrome is almost always caused by thrombocytopenia, but abnormalities of platelet function have been described. In acute myelogenous leukemia and its variants, platelets may be larger than normal, abnormally shaped, and have a marked variation in the number of granules. Abnormal platelet structure and function have been described, especially associated with acute megakaryoblastic leukemia (FAB M7),[37,38] with one study describing three patients with decreased aggregation to collagen, ADP, epinephrine, and the thromboxane analogue U46619, along with a decreased platelet serotonin content.[37] Platelet abnormalities can also be seen in the myelodysplastic syndromes, with defective aggregation and glass bead retention described, associated most commonly with hypolobulated megakaryocytes and the $5q^-$ syndrome.[39] Abnormal platelet function has also been described in association with B-cell malignancies: with hairy cell leukemia, which can persist after splenectomy,[40] and with chronic lymphocytic leukemia,[41] in which the patient's platelets showed dramatically reduced responses to glycoprotein VI agonists collagen and convulxin.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is another clonal disorder that involves all blood cells. The hematopoietic stems cells and their progeny are defective in the synthesis of the glycosylphosphatidylinositol attachments required for some membrane proteins, leading to a defect in all glycosylphosphatidylinositol-linked proteins on blood cells,[42] including platelets.[43] Thromboembolism is a leading cause of mortality in PNH, affecting at least half of these patients and preferentially targeting the hepatic veins.[44] Several mechanisms have been proposed to explain this association, but it is unclear that the platelets have an important role.[45] The platelet function abnormalities described in PNH range from hypersensitivity to agonists to dysfunction. One study showed platelets to be hypersensitive to epinephrine, ADP, and collagen, as judged by their abilities to aggregate and to release ^{14}C serotonin.[46] The release of total nucleotides was also markedly increased over normal with all aggregating agents. By contrast, another study examining platelets from PNH patients showed them to be profoundly hyporeactive, as measured by defective clot formation, adhesion, and aggregation.[47] However, this was interpreted as being a consequence of chronic overstimulation of the platelets while in the circulation.

Platelet activation and increased platelet microparticle formation have also been demonstrated in patients with paroxysmal nocturnal hemoglobinuria.[48,49] Nevertheless, a strong correlation exists between thromboembolic disease and the number of circulating abnormal neutrophil clones.[50] It is likely that the level of abnormal granulocyte clones reflect the number of abnormal platelet clones.[51] Warfarin prophylaxis in patients with high numbers of abnormal clones significantly reduces the thrombotic risk and carries minimal bleeding risk in nonthrombocytopenic patients. A recent open-label study of eculizumab, a humanized monoclonal antibody against human complement C5 that prevents assembly on the cell surface of the membrane-attack complex, demonstrated a greater than 10-fold reduction in thromboembolic events in treated patients as compared with untreated patients.[52] Eculizumab effectively reduced thrombotic episodes, even in those taking antithrombotic medications, and reduced the rates of both arterial and venous thromboses. These encouraging results may signal a new era of therapy for PNH patients, because eculizumab has also been shown to decrease transfusion requirements, reduce fatigue, and improve general well being.[53]

Table 142–2 Drug-Induced Platelet Dysfunction

Mechanism: Known
Inhibition of GPIIb/IIIa-fibrinogen Interaction
Abciximab, eptifibatide, oral $\alpha_{IIb}\beta_3$ inhibitors, fibrinolytic agents
Inhibition of ADP Receptors
Ticlopidine, clopidogrel
Stimulation of Adenyl Cyclase
Epoprostenol, iloprost, beraprost
Stimulation of Guanyl Cyclase
Nitrites, nitroprusside
Inhibition of Phosphodiesterase
Methyl xanthines (theophylline), dipyridamole, sildenafil and related drugs
Inhibition of Thromboxane Pathway
Aspirin, nonsteroidal antiinflammatory drugs, moxalactam, losartan
Inhibition of Calcium Flux
Verapamil, calcium channel blockers (nifedipine, diltiazem)
Inhibition of Serotonin Uptake
Tricyclic antidepressants, fluoxetine
Mechanism: Unknown
Antibiotics
β-Lactam antibiotics, penicillins, nitrofurantoin
Plasma Expanders
Dextran, hydroxyl ethyl starch
Anesthetics
Dibucaine, procaine, cocaine, halothane
Phenothiazines
Chlorpromazine, promethazine, trifluoperazine
Oncologic Drugs
Mithramycin, daunorubicin, BCNU
Immunosuppressive Drugs
FK 506, cyclosporin, mycophenolic acid
Radiographic Contrast Agents
Renographin-76, Renovist II, Conray 60
Antihistamines
Diphenhydramine, chlorpheniramine
Miscellaneous
Clofibrate, hydroxychloroquine

ADP, adenosine diphosphate; BCNU, bis-chloroethyl-nitrosourea.

EXTRINSIC PLATELET DISORDERS

Drugs That Affect Platelet Function

Numerous drugs affect platelet function (Table 142-2). For several, inhibition of platelet function is their intended effect (Fig. 142-1); for most, platelet dysfunction is an unintended and undesired side effect. Antiplatelet agents are discussed more fully in Chapter 137. For all these drugs, their effects on platelet function are defined by an abnormality of platelet aggregation or of the bleeding time, but

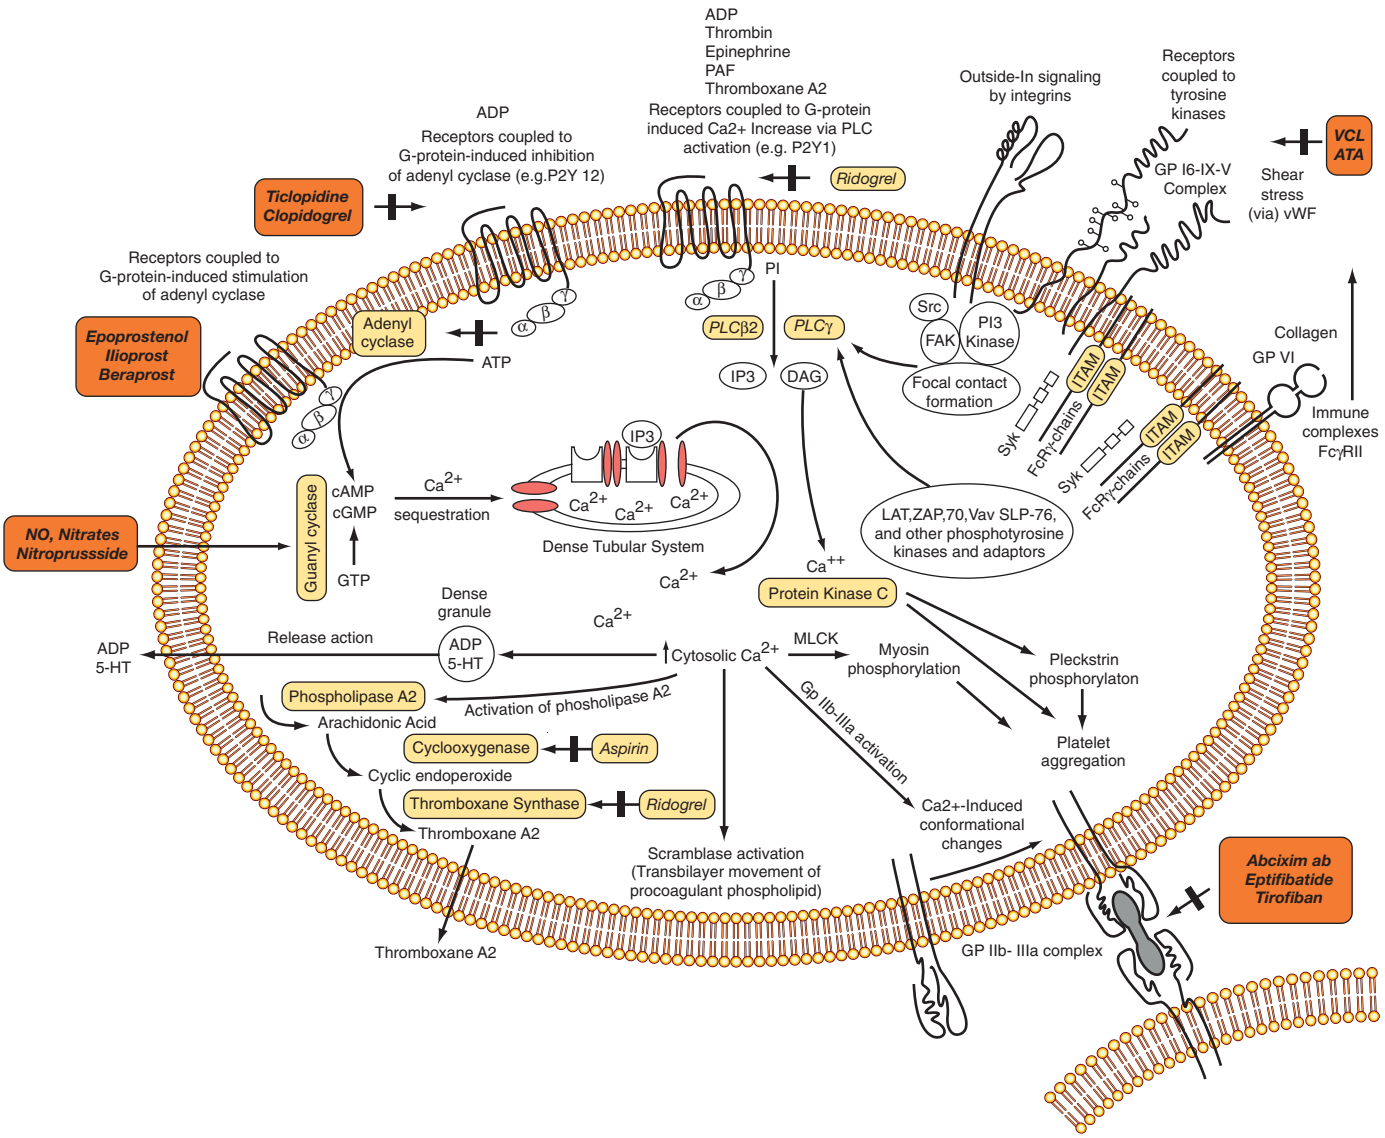

Figure 142–1 Mechanism of inhibition of platelet function by various drugs. Some of the drugs shown, such as Ridogrel, VCL, and ATA, are not now used clinically. ADP, adenosine diphosphate; ATA, aurin tricarboxylic acid; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanyl monophosphate; DAG, diacylglycerol; GP, glycoprotein; GTP, guanyl triphosphate; 5-HT, serotonin (5-hydroxytryptamine); IP3, inositol triphosphate; ITAM, immunoreceptor tyrosine-based activation motif; MLCK, myosin light chain kinase; NO, nitric oxide; PAF, platelet activating factor; PI, phosphatidylinositol; PLA2, phospholipase A2; TXA_2, thromboxane A_2; VCL, rA1 domain of von Willebrand factor; vWF, von Willebrand factor.

their contribution to a risk of excessive bleeding is definitively established only for aspirin, clopidogrel, ticlopidine, and the inhibitors of $\alpha_{IIb}\beta_3$ function.

Aspirin

Aspirin has been in routine use worldwide for more than 100 years and is still by far the most common agent associated with platelet dysfunction.[54] The primary mechanism by which aspirin impairs hemostasis is through irreversible acetylation of the enzyme cyclooxygenase (COX)-1, an early enzyme in the synthetic pathway that leads to the formation of the potent platelet agonist, TXA_2. Because platelets have no nuclei and therefore retain only a limited capacity to synthesize new proteins, a single small dose of aspirin (40–100 mg) or as little as 10 mg taken daily for one week can completely inhibit TXA_2 production and therefore impair the function of a cohort of platelets for their circulating life span. Aspirin also acetylates the isoform of cyclooxygenase present in endothelial cells, COX-2; COX-2 acetylation blocks synthesis of prostacyclin, a strong inhibitor of platelet function.[55] However, COX-2 is markedly less sensitive than COX-1 inhibition by aspirin,[54] and endothelial cells, unlike platelets, are able to synthesize new enzymes quite rapidly.[56]

Platelets exposed to aspirin either in vivo or in vitro predictably demonstrate impaired aggregation to epinephrine, ADP, arachidonic acid, and low concentrations of collagen and thrombin,[57] a result of defective TXA_2 production. These agonists have therefore been defined as *weak* agonists, requiring that TXA_2 diffuse out of the platelet, bind its platelet membrane receptors, and reinforce aggregation by promoting α and dense granule secretion. Aspirin-treated platelets stimulated with these agonists demonstrate only a primary, reversible wave of aggregation without granule secretion. Stronger agonists (high concentrations of thrombin and collagen) do not require TXA_2 synthesis to cause platelet secretion and irreversible aggregation, which probably accounts for the observation that hemostasis in healthy aspirin-treated subjects is usually normal.

Aspirin also prolongs the bleeding time but less consistently than it induces the platelet aggregation abnormality. Early studies demonstrated that the mean template bleeding time of a group of normal subjects was significantly increased 2 hours after ingestion of two to

three aspirin tablets (650–975 mg).[58,59] Prolongation of the bleeding time can be demonstrated as long as 4 days after a single dose of aspirin[60] when new, normally functioning platelets replace a sufficient fraction of the aspirin-inhibited cohort. Despite its effect on the mean bleeding times, aspirin prolongs the bleeding time above the normal range in only about one half of normal subjects.[58,59] Smaller single doses of aspirin (150–160 mg) that consistently cause abnormal platelet aggregation do not prolong the bleeding time; daily ingestion of 30 mg of aspirin (but not 10mg) usually does.[61]

The bleeding time is reputed to be the most direct test of platelet function because it is performed directly on the patient and because it correlates with the platelet count in select patients.[62] However, the bleeding time did not predict bleeding in one study of patients taking aspirin for rheumatic disease who were undergoing gastric endoscopic biopsy[63] or in uremic patients undergoing renal biopsy.[64] These data emphasize that the bleeding time cannot be automatically accepted as an accurate representation of systemic hemostasis.[65]

Aspirin most dramatically prolongs the bleeding times in patients with other hemostatic defects. For example, one study of patients with severe hemophilia, who often already have slightly prolonged bleeding times,[66] showed that 5 of 11 patients treated with two to three aspirin tablets experienced sustained hemorrhage from the bleeding time incisions,[67] requiring transfusion with plasma or factor VIII. Patients with mild hemophilia appeared to be at less risk from aspirin ingestion; in none of 16 patients was the bleeding time prolonged longer than values in the normal control group.[67] Small doses of aspirin also cause a greater than normal prolongation of the bleeding time in patients with chronic renal failure and have been associated with reports of major bleeding.[68] The combination of ethanol and aspirin has a synergistic effect on increasing the bleeding times in normal subjects.[69]

Clinical Importance of the Aspirin-Induced Defect in Platelet Function

In contrast to the antithrombotic effect of aspirin, which appears unrelated to the dose above small threshold doses, gastrointestinal mucosal toxicity is dose related.[70] The mechanism of mucosal injury appears to be separate from the effect on hemostasis, involving ionic trapping of aspirin within gut mucosal cells[71] and diminished synthesis of protective gut prostaglandins.[72,73] The inhibitory effect of even a single dose of aspirin on gastric prostaglandin synthesis is prolonged, with one study showing that gastric COX activity was still suppressed by 57% 72 hours after a single 325-mg dose of aspirin.[74]

Bleeding can originate from both discrete ulcers and diffuse mucosal damage and is more common from the upper gastrointestinal tract. The risk of bleeding is increased even with doses of aspirin as low as 10 to 30 mg/day;[75] the protective effect of resistant coatings is unproved.[76] Recently, a nitric oxide-donating form of aspirin (NCX-4016) has been shown to enhance the cardioprotective effect of aspirin while sparing the gastrointestinal tract.[77]

The gastrointestinal risk of aspirin is enhanced in the elderly (older than 65) and in those with concomitant medical conditions such as cardiovascular disease, as well as in those taking certain other medications, such as other nonsteroidal antiinflammatory agents.[76] Aspirin seems to also delay the healing of gastric ulcers, possibly because it interferes with the release of growth factors such as endostatin and vascular endothelial growth factor from platelets.[78]

The clinical importance of the antithrombotic effect of aspirin was clearly demonstrated in a study of 22,071 physicians who received either 325 mg of aspirin every other day or placebo over the course of 5 years.[79] Those receiving aspirin had a 44% decreased incidence of myocardial infarction. Aspirin treatment was also associated with a small but significant increase in mucocutaneous bleeding as evidenced by easy bruising, hematemesis, melena, epistaxis, as well as an increased incidence of blood transfusion. Because even lower doses have been shown to be effective in preventing thrombosis, it is likely that the risk of bleeding can be reduced further while maintaining an antithrombotic effect.

The likelihood that aspirin will cause bleeding is increased in the presence of other hemostatic defects. The risk of bleeding is increased if aspirin is given simultaneously with warfarin in high-intensity anticoagulation regimens (international normalized ratio 3.0–4.5), but the occurrence of major hemorrhagic events may not be increased.[80] Similarly, aspirin may unmask mild hereditary disorders of platelet function.[81] For example, patients with mild von Willebrand disease often have a normal bleeding time that becomes markedly increased with aspirin therapy.[81] Conversely, aspirin given during treatment of acute coronary syndromes in combination with fibrinolytic and other antithrombotic agents does not appear to increase the incidence of major bleeding episodes,[82,83] with the exception of its combination with clopidogrel, which is associated with a slight increase in bleeding complications over treatment with aspirin alone.[84]

Several studies have addressed the risk of postoperative hemorrhage in patients taking aspirin. The results, as may be expected with a very mild hemostatic defect, are inconsistent. Some studies report increased blood loss in patients taking aspirin who undergo cardiac surgery, but others do not.[85] Increased chest tube blood loss in aspirin-treated patients was not associated with worse clinical outcomes, such as a need for reoperation or greater numbers of units of blood transfused.[68,86]

In studies of patients undergoing elective total hip replacement by a single surgeon, aspirin treatment (1.2–3.6 g/day) was begun the day before surgery and continued for 7 days.[87] The blood loss was 20% greater in the treated group in one study, but this was considered clinically unimportant and required no additional care.[87] A study of 200 patients undergoing general or gynecologic surgery also suggested that there was greater surgical blood loss in patients who had taken aspirin.[88] The surgeon and the anesthesiologist observed "greater than expected bleeding" in 12 of 55 patients who had taken aspirin and had abnormal results on platelet aggregation studies, compared with 7 of 97 patients who had not taken aspirin and had normal aggregation studies. The other 48 patients in this study either claimed they had not taken aspirin but were found to have abnormal platelet aggregation—a frequent occurrence in many studies caused by habitual and forgotten aspirin use (33 patients)—or had taken aspirin but their platelet aggregations were normal (15 patients). Of these 48 patients 8 were believed to have excessive bleeding at surgery. Although the results were interpreted as demonstrating increased surgical bleeding following aspirin treatment, it is important to note that "greater than expected bleeding" also occurred in the control patients. This observation is inevitable in all subjective evaluations of bleeding, either surgical or medical. The observer always expects and hopes for a normal hemostatic response, but the range of "normal" bleeding is great, and patients with more bleeding are often viewed with concern.

Recent evidence suggests that aspirin may in fact be beneficial in the perioperative period. There is a well-recognized syndrome of platelet dysfunction following cardiopulmonary bypass (see also section on cardiopulmonary bypass), and until recently aspirin administration has been believed to be contraindicated.[89] However, a recent observational study noted that patients receiving aspirin within 4 hours of cardiopulmonary bypass had markedly improved outcomes, with improvements in virtually every parameter of bypass-related morbidity, including, unexpectedly, the incidence of bleeding.[90] The benefit of aspirin in this study has been attributed to modulation of the proinflammatory properties of platelets[89] but may also involve benefits unrelated to aspirin's effect on platelets. Aspirin was also noted to positively influence the outcome of microsurgery, a benefit ascribed to decreased thrombosis at the sites of microsurgical anastomoses and to decreased TXA_2-mediated vasoconstriction downstream of these sites.[91]

Thus, aspirin appears to have a small effect on increasing surgical bleeding, which can be significant. The risk is not increased, however, with minimally invasive trauma such as spinal or epidural anesthesia.[92,93] In other cases aspirin therapy may actually positively influence the outcome of surgery.[90,91] These data on aspirin represent well the

clinical paradigm for acquired disorders of platelet function: they are common; the defect is usually mild; normal individuals vary in their sensitivities to aspirin; platelet aggregation and the bleeding time are subject to technical vagaries; the risk for increased bleeding in the individual subject who is otherwise healthy is minimal and unpredictable; but a definite risk for increased bleeding with aspirin can be demonstrated when large groups of healthy subjects are analyzed or when individuals are studied who have concomitant pathologic (eg, hemophilia) or physiologic (eg, childbirth) conditions that predispose them to hemorrhage.

Other Nonsteroidal Antiinflammatory Drugs

In addition to aspirin, many other drugs used for their antiinflammatory and analgesic properties can cause platelet dysfunction.[85] As with aspirin, their mechanism of action appears to be the inhibition of the activity of COX-1; but in contrast to aspirin, these agents only temporarily affect COX-1 function, inhibiting the enzyme only as long as the active drug circulates. Among these agents, therefore, only drugs such as piroxicam, which has a plasma half-life of more than 2 days,[94] affect platelets for more than a few hours. As with aspirin, the most sensitive indication of impaired platelet function is the inhibition of in vitro platelet aggregation and secretion. These agents prolong the bleeding time minimally and transiently or not at all, consistent with the bleeding time being a less sensitive measure of the aspirin-induced defect.[85] The platelet function analyzer–100 more reliably detects the defect manifested as a prolonged clotting time with the collagen/epinephrine cartridge.[95]

Reports of bleeding correlate with the effects of these agents on platelet function, suggesting that they increase the risk for excessive bleeding less than aspirin. As with aspirin, they may increase the bleeding times in patients with severe hemophilia; but in two studies, therapeutic doses of ibuprofen had no effect on the bleeding time in 19 of 20 patients with hemophilia.[96] Therefore, the clinical approach to patients taking any drug that can inhibit COX-1 should be similar, but the reversibility of the effect of nonaspirin antiinflammatory drugs provides an added margin of safety when these agents are used. The additional risk for bleeding with surgery should be negligible, but a prudent course would be to discontinue these drugs the day before a procedure. Analgesics such as acetaminophen and sodium or choline salicylate do not inhibit platelet function and have no adverse effects on hemostasis.[96]

Recently, a class of drugs with greater selectivity for COX-2 than for COX-1 has entered clinical use, the coxibs. These drugs were developed for the treatment of patients with chronic pain or chronic inflammatory disorders to diminish the risk of gastrointestinal bleeding and ulceration.[97] Although these drugs have little affect on platelet function because they do not inhibit COX-1, nevertheless they have as a group been associated with an increased risk of cardiovascular events, including thrombosis.[98] Although COX-2 is involved in promoting inflammatory states, which are associated with thrombosis, a major consequence of its inhibition is to diminish endothelial synthesis of prostacyclin I_2, a major component of the platelet inhibitory functions of healthy endothelium.[98]

Adenosine Diphosphate Receptor Antagonists

The thienopyridines ticlopidine, clopidogrel, and prasugrel inhibit ADP-mediated platelet activation and aggregation.[99] ADP-induced platelet activation involves a rise in free cytoplasmic Ca^{2+} because of influx from the extracellular fluid and mobilization from internal stores, and a drop in intracellular cyclic adenosine monophosphate (cAMP) coupled to inhibition of adenylyl cyclase. ADP receptors can be divided into two groups: the G-protein-coupled receptors, termed *P2Y,* and the inotropic receptors, *P2X.* Platelets contain two P2Y receptors, $P2Y_1$ and $P2Y_{12}$, complexed to the heterotrimeric G proteins, G_q and G_{i2}, respectively. ADP binding to $P2Y_1$ is necessary for platelet aggregation but is not sufficient. Rather, $P2Y_1$ is responsible for ADP-induced platelet shape change, and its engagement by ADP triggers a transient aggregatory response. $P2Y_{12}$, coupled to inhibition of adenylyl cyclase, mediates the amplification of the aggregation response and increases thrombus stability.[100]

The thienopyridine derivatives covalently modify the $P2Y_{12}$ receptor, preventing receptor-coupled inhibition of adenylyl cyclase activity. These drugs have no effects on arachidonic acid metabolism and hence act synergistically with aspirin to inhibit platelet function. The thienopyridines are all prodrugs of similar structures that produce active metabolites that bind irreversibly to $P2Y_{12}$, inhibiting ADP-mediated aggregation for up to 10 days after withdrawal of the drug, paralleling the platelet life span.[101] Because most platelet agonists require ADP for their full activity, the thienopyridines inhibit platelet activation by all agonists except strong agonists at high concentrations.[102] They have a further hypothetical advantage over aspirin in that they inhibit shear-induced platelet aggregation.[103]

The thienopyridines are administered orally, with fewer gastrointestinal side effects if taken with meals. All thienopyridines must be metabolized in the liver to their active forms. At lower doses, the full pharmacologic effect requires 3 to 5 days for ticlopidine and 4 to 7 days for clopidogrel. A doubling of the bleeding time can be observed after 3 to 7 days of treatment. When a rapid therapeutic effect is desired, therapy can be initiated with a loading dose, 500 mg for ticlopidine, and 300 to 600 mg for clopidogrel. At these doses, clopidogrel significantly impairs platelet function within 90 minutes of administration.[104,105]

Ticlopidine was the first thienopyridine for which clinical benefit was demonstrated in patients presenting with a wide range of cardiovascular diseases, including stroke, myocardial infarction, and the thrombotic complications of peripheral arterial disease.[106] Ticlopidine use, however, is limited by its slow onset of action and frequent side effects, which force discontinuation of the drug in 20% of patients. The most common side effects are diarrhea, nausea, and skin rash, but neutropenia and thrombotic thrombocytopenic purpura are the most severe, with estimated incidences of about 3.3% and 0.02%, respectively.[106]

Clopidogrel has an excellent side-effect profile, is well tolerated even at high doses (600 mg/day), and has largely replaced ticlopidine in the United States. More importantly, the incidence of thrombotic thrombocytopenic purpura is 100-fold less than with ticlopidine and is comparable to that of the general population, with about one case per 4 million patients treated.[107] No cases of clopidogrel-associated severe neutropenia have been reported, and the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events trial showed that there is no need for routine complete blood counts in patients taking clopidogrel.[108]

Prasugrel, an investigational drug, appears to be converted to its active form much more efficiently than does clopidogrel.[109]

Overall, the rates of bleeding complications of the thienopyridines are similar to those seen with aspirin, with the combination of aspirin and clopidogrel being associated with higher postoperative bleeding after coronary artery bypass grafting than with either drug alone.[110]

Platelet $\alpha_{IIb}\beta_3$ Antagonists

In the past decade, a new class of agents targeted at the major platelet integrin, $\alpha_{IIb}\beta_3$, has emerged for use in the treatment of acute coronary syndromes[111]; these agents are intended to produce a transient effect akin to the defect in Glanzmann thrombasthenia, but there are important differences between the drug effect and the disease.

Three intravenous $\alpha_{IIb}\beta_3$ antagonists are currently in use, having been evaluated in tens of thousands of patients presenting with various forms of cardiovascular disease. Although these agents share many similarities in their pharmacodynamics and therapeutic effects, they also have a number of clinically important pharmacokinetic differences.

Abciximab

The first $\alpha_{IIb}\beta_3$ inhibitor approved for clinical use, abciximab (ReoPro), is a human-murine chimeric Fab fragment of a monoclonal antibody that targets the β_3 subunit of $\alpha_{IIb}\beta_3$ and therefore also reacts with another integrin that shares the β_3 subunit, $\alpha_V\beta_3$. Although $\alpha_{IIb}\beta_3$ expression is restricted to megakaryocytes and platelets, $\alpha_V\beta_3$ is expressed on platelets, at low levels, and in cells of the vascular wall, including endothelial cells and fibroblasts.[112] The clinical relevance of this cross-reactivity is unclear.

Intravenous administration of a standard 0.25 mg/kg bolus of abciximab blocks approximately 80% of surface $\alpha_{IIb}\beta_3$ and inhibits platelet aggregation to a similar extent, although the extent of inhibition is variable.[111] This level of blockade increases the bleeding time only mildly.[54] The bleeding time is only markedly prolonged when receptor blockade exceeds 90%. Following the bolus dose, abciximab is infused at 0.125 g/kg/min for 12 hours. Several trials have established this as a clinically effective regimen.[111]

Free plasma levels of abciximab drop rapidly after its administration, with an initial half-life of approximately 30 minutes and most of the drug remaining bound to platelets. This explains why patients with thrombocytosis may require larger weight-adjusted doses of abciximab to attain a therapeutic antiplatelet effect.[113] Conversely, platelet inhibition is more profound in patients with lower platelet counts treated with the usual dose of abciximab.

Abciximab is not excreted in the urine and is probably metabolized by the reticuloendothelial system at the time platelets (with bound abciximab) are cleared from the circulation. Although a daily platelet turnover rate of 10% would predict that no abciximab would be detected in blood after 10 days of its administration, platelet-bound abciximab has been observed up to 3 weeks following its initial administration, suggesting platelet-to-platelet redistribution of the drug or release of new platelets from megakaryocytes that had previously bound the drug. Several in vitro and in vivo studies confirm abciximab's ability to exchange from one platelet to another.[114]

Because of the low plasma levels of unbound abciximab, the drug's inhibitory effect can be rapidly reversed by platelet transfusion; and hemostasis should be normal when the concentration of infused platelets exceeds 50,000/μL, as it is in normal individuals. However, because of abciximab's ability to redistribute to the newly transfused platelets, the platelet-bound abciximab may produce a gradual inhibitory effect on the infused platelets[114]; and in severe or refractory bleeding it may be necessary to infuse a very large dose of platelets, sufficient to leave 50% of $\alpha_{IIb}\beta_3$ receptors free, a number shown to be sufficient for normal hemostasis in studies of Glanzmann thrombasthenia heterozygotes. Without platelet transfusions, platelet aggregation generally returns to baseline levels within 12 to 24 hours after discontinuing abciximab.

Eptifibatide

Eptifibatide (Integrilin) is a cyclic heptapeptide based on the KGD (Lys-Gly-Asp) sequence found in barbourin, a platelet-inhibitory disintegrin from the venom of the Southeastern Pigmy rattlesnake, *Sistrurus miliarius barbouri.*[115] Barbourin differs from other integrin-binding proteins with the Arg-Gly-Asp (RGD) canonical sequence in that the arginine is conservatively substituted by lysine, a change that renders the protein a specific inhibitor of $\alpha_{IIb}\beta_3$.[115] Eptifibatide incorporates the KGD sequence within a cyclic seven-member peptide of high potency.

Eptifibatide differs pharmacokinetically from abciximab in several important ways.[111] For example, unlike abciximab, intravenous eptifibatide infusion produces high levels of unbound drug. Platelet transfusions therefore are not a good method for acutely reversing eptifibatide's antiplatelet effect, because the newly transfused platelets are rapidly inhibited. However, its short plasma half-life of approximately 2.5 hours allows for rapid clearance of eptifibatide and the reversal of its antiplatelet effect when administration is discontinued. Platelet aggregation has been shown to return to normal in approximately 4 hours, with the bleeding time normalizing within 1 hour.[111]

Tirofiban

Tirofiban (Aggrastat) is a peptidomimetic agent based on the RGD sequence, with a pharmacokinetic profile similar to that of eptifibatide.[111] Tirofiban antagonizes $\alpha_{IIb}\beta_3$ and does not cross-react with $\alpha_V\beta_3$.[116,117] As with eptifibatide, the maximum antiplatelet effect is seen at concentrations that leave a high concentration of unbound drug in the plasma.[111] Therefore, platelet transfusions are not commonly effective in reversing tirofiban's antiplatelet effect. However, its half-life is even shorter than that of eptifibatide (approximately 2 hours), and its anti-platelet effect is reversed rapidly after discontinuation of infusion.

The data thus far indicate that the main therapeutic benefit of $\alpha_{IIb}\beta_3$ antagonists is obtained in patients undergoing percutaneous coronary intervention (PCI), regardless of whether it is elective or for the treatment of an acute coronary syndrome.[118] As a class, the $\alpha_{IIb}\beta_3$ antagonists have been demonstrated to be beneficial in patients undergoing PCI, with an overall relative risk reduction in the composite of death, myocardial infarction, or urgent target vessel revascularization of 30% to 50% at 30 days ($P < 0.01$).[119,120] Whether the three drugs in current use are significantly different in their clinical efficacy in patients undergoing PCI is a matter of controversy. However, the data thus far indicate that the three drugs are probably similar in the long-term (<6 months after PCI) in the reduction of death, myocardial infarction, and the need for urgent target-vessel revascularization.[121]

Limitations and Adverse Effects of the $\alpha_{IIb}\beta_3$ Antagonists

Bleeding

Millions of patients have been treated with intravenous $\alpha_{IIb}\beta_3$ antagonists in various clinical scenarios, and the data are compelling that these drugs have a very good safety profile.[118] Importantly, none is associated with an increased risk of intracranial hemorrhage.[122]

Thrombocytopenia

Up to 1% of patients receiving abciximab may develop profound thrombocytopenia (platelet count <20,000/μL).[123] A decrease in the platelet count is appreciable within the first hours after administration. It is therefore essential that a platelet count be obtained 2 to 4 hours after initiating treatment. Most patients with severe thrombocytopenia respond well to platelet transfusions and their platelet counts usually recover within 5 days but may take more than one week to do so. Because patients receiving abciximab frequently also receive heparin, heparin-induced thrombocytopenia must be excluded. Ethylenediaminetetraacetic acid–dependent pseudothrombocytopenia should also be considered and ruled out by examination of a blood smear for the presence of platelet aggregates.

Many patients require readministration of abciximab, raising the possibility that antibodies against the drug will complicate therapy. The safety of readministration was studied systematically in the ReoPro Readministration Registry.[123] The study found that abciximab readministration has a high clinical success rate and is not associated with hypersensitivity reactions, excessive bleeding, or death, and the incidence of thrombocytopenia is no greater than that seen in patients receiving abciximab for the first time. However, thrombocytopenia tended to be profound, relatively refractory to platelet infusion, and more often delayed. It is therefore recommended that clinicians obtain a second platelet count 24 hours after the readministration of abciximab and that they maintain a high

index of suspicion for the delayed development of abciximab-induced thrombocytopenia.

Antibiotics

Antibiotics can also affect platelet function.[85] Those most commonly affecting platelet function are the penicillins and cephalosporins, which share a β-lactam ring structure. Some of these produce predictable dose- and duration-related effects on the bleeding time.[124–126] Because the effect on bleeding time is seen only in patients who are receiving large parenteral doses of antibiotics, this is a potential problem only for hospitalized patients. In a study of 74 hospitalized patients with a consistently prolonged bleeding time, the likely cause was penicillin in 39 patients (30 patients were receiving penicillin G, more than 15,000,000 U/day, and 9 were receiving ampicillin, 6 to 8 g/day) and aspirin or related drugs in 7 patients.[126]

The structural properties that cause some, but not all, penicillins and cephalosporins to affect platelet function are unknown. The side chain structure alters the antibacterial and pharmacologic properties of the penicillins and cephalosporins and may also determine their effects on platelet function. It is postulated that the antibiotic associates with the platelet plasma membrane by a lipophilic mechanism, perturbing multiple receptor-agonist interactions and/or stimulus-response coupling.[127] The characteristic laboratory observation is the occurrence of a prolonged bleeding time and abnormal platelet aggregation after several days of high-dose parenteral therapy.[125,126] These abnormalities usually do not subside until several days after the antibiotic is discontinued.

The frequency of clinically important bleeding in patients taking β-lactam antibiotics is low and is not predicted by a prolonged bleeding time, and the causal relation to antibiotic treatment is unproved.[128] For each report implicating an antibiotic as a cause of hemorrhage, many more patients receive the same antibiotics in large doses without bleeding complications.[128]

In conclusion, antibiotic-induced platelet dysfunction appears to have little clinical importance, and the potential effect on platelet function should not be considered in the decision to use any antibiotic in any clinical situation. An exception to this conclusion may be moxalactam. The frequency of clinically important hemorrhagic complications with moxalactam appears to be greater than with other antibiotics.[128] This drug has been demonstrated to produce a dose-dependent inhibition of ADP- and collagen-induced platelet aggregation, and to result in defective TXA_2 generation,[129] which suggests that it acts on the thromboxane synthesis pathway, much as aspirin does. Furthermore, unlike most other β-lactam antibiotics, moxalactam contains a methylthiotetrazole-leaving group that has been implicated in the inhibition of synthesis of vitamin K-dependent coagulation factors.[130] Therefore, moxalactam-induced bleeding may be caused by the combination of deficiencies in vitamin K-dependent coagulation factors and impaired platelet function.

Nitrofurantoin, an antibiotic structurally unrelated to the β-lactam antibiotics, may mildly prolong the bleeding time and impair platelet aggregation at blood concentrations higher than 20 μM.[131] Nitrofurantoin is not known to cause clinical bleeding.

Other Drugs

Drugs That Increase Platelet Cyclic Nucleotide Concentration

Elevation of the platelet concentration of cAMP by any mechanism inhibits platelet function and is a major mechanism of action of the thienopyridines, discussed earlier in adenosine diphosphate receptor antagonists section. Prostacyclin and its analogues increase cAMP synthesis by the stimulation of adenylyl cyclase, and they have been studied as antithrombotic substitutes for heparin in cardiopulmonary bypass surgery and hemodialysis.[132] Prostacyclin is one of the most potent endogenous inhibitors of platelet functions but has not been shown to be more effective than aspirin in clinical trials, and its clinical use is limited by its vasodilatory side effects. Prostacyclin-like agents that have been used include epoprostenol (the synthetic salt of prostacyclin), treprostinil, inhalational prostacyclin (iloprost), and an orally active stable analogue (beraprost). In spite of the potent inhibition of platelet aggregation by prostacyclin in vitro, the effects on the bleeding time are minimal and inconsistent.

Cilostazol is a cyclic nucleotide phosphodiesterase inhibitor with both platelet inhibitory and vasodilatory effects; its current clinical use for peripheral vascular disease in the United States was preceded by its use in Japan and other Asian countries. In addition to its selective inhibition of phosphodiesterase (one of the major cAMP hydrolyzing enzymes in platelets), cilostazol also inhibits adenine nucleotide uptake, a property not seen in other phosphodiesterase inhibitors that further enhances its antiplatelet activity.[133]

Dipyridamole has several biologic effects, including phosphodiesterase inhibition, targeting the PDE5 isoform that degrades cyclic guanosine monophosphate (cGMP).[134] It also enhances the release, and prevents the breakdown, of prostaglandin prostacyclin I_2.[135] Primarily used for prevention of stroke, its usefulness was demonstrated by a meta-analysis of recent randomized trials showing that the combination of dipyridamole, particularly the modified release form, and aspirin was more efficacious than aspirin alone in secondary prevention of vascular events after transient ischemic attacks or stroke.[136] Dipyridamole has been associated with a significantly increased risk of gastrointestinal bleeding when used either as a single agent or in combination with aspirin.[137]

Recently, inhibitors of PDE5 have become popular in the treatment of erectile dysfunction.[138] PDE5 is expressed in platelets and its inhibition results in increases in the level of platelet cGMP, an effect similar to the effect of the well-known inhibitor of platelet function, nitric oxide. One study examined the activation response of platelets drawn from patients taking sildenafil (Viagra) when stimulated with either ADP or low-dose thrombin. The results showed significantly reduced activation to ADP in sildenafil-treated platelets, suggesting that the drug impairs selected pathways of platelet function in vivo. Several reports of sildenafil-associated bleeding have appeared, including epistaxis,[139,140] hemorrhoidal bleeding,[141] spontaneous intracranial hemorrhage,[142] and acute variceal bleeding.[143]

Anticoagulants

Although heparin is best known for its anticoagulant effect and its adverse effect in causing thrombocytopenia and paradoxical thrombosis (see Chapter 137), it has the potential to affect platelet function. Heparin can bind to the platelet surface,[144] cause platelet aggregation and secretion,[145] and impair vWF-dependent platelet function.[146] Heparin can also increase the bleeding time.[147] Whether these phenomena are related to the bleeding complications of heparin use is unknown. The prolonged bleeding time is probably caused by heparin's inhibition of thrombin generation, analogous to the slight but significant increase in bleeding times in patients with hemophilia.[66]

Paradoxically, heparin has also been shown to be capable of inducing the association of vWF with the GPIb complex.[148] Whether this is restricted to certain individuals or occurs only at certain heparin doses is unclear, but it raises the possibility that this mechanism may contribute to heparin-induced thrombosis.

Fibrinolytic Agents

Bleeding during therapy with plasminogen activators is predominantly caused by the effects of hypofibrinogenemia and increased fibrin(ogen) degradation products on fibrin clot formation, usually combined with a structural lesion in the blood vessel wall (see Chapter 137). In addition, pharmacologic doses of streptokinase, urokinase, and tissue plasminogen activator may impair platelet function through

several potential mechanisms, all related to excessive production of plasmin.[149] First, very high levels of fibrin(ogen) degradation products coupled with very low levels of fibrinogen may impair platelet aggregation. Second, the binding of plasminogen to the platelet surface may facilitate its conversion to the proteolytic enzyme, plasmin, by plasminogen activator.[150] On the platelet surface, plasmin can degrade GPIb (thereby impairing the interaction of the platelet with vWF[151]) and fibrinogen (thereby dispersing platelet aggregates).[152] Third, plasmin can inhibit platelet aggregation by blocking the release of arachidonic acid from platelet membranes, limiting thromboxane production.[153] The clinical importance of these observations is unknown.

In addition to depressing platelet function, plasmin has been shown to directly activate platelets,[154–157] an effect that has been postulated to account for reocclusion after tissue plasminogen activator treatment for myocardial infarction.[158] The mechanism involves cleavage of protease-activated receptors, in particular PAR4.[159]

Plasma Expanders

Dextrans are partially hydrolyzed branched polysaccharides of glucose. Of the two preparations in clinical use, one has an average molecular size of 70,000 to 75,000 (often termed *dextran 70*) and one has an average molecular size of 40,000 (termed *dextran 40* or *low-molecular-weight dextran*). Both preparations are effective plasma expanders and can affect platelet function, but there are data suggesting that the high-molecular-weight molecules have a greater effect on hemostasis.[160] Dextran infusion also impairs platelet aggregation and platelet procoagulant activity and can cause a modest reduction in plasma vWF concentration. However, dextran has no effect on platelet function when added directly to platelet-rich plasma in vitro.[161] Because of these effects on platelet function, dextran has been used as an antithrombotic agent, and its efficacy in preventing fatal postoperative pulmonary emboli appears to be equivalent to that of subcutaneous heparin.[162] This therapeutic effect is achieved without any increased risk for bleeding, as demonstrated in a large double-blind trial comparing dextran with placebo during general surgery.[163]

Hydroxyethyl starch, known as *hetastarch,* is a synthetic glucose polymer with an average molecular weight of 450,000 (range, 10,000–1,000,000) that is also used for plasma expansion. Hetastarch use has been associated (albeit inconsistently) with abnormal platelet function, and this appears to be more evident with use of the higher molecular weight forms.[164] Like dextran, it can prolong the bleeding time, particularly if administered in doses of greater than 20 mL/kg of a 6% solution, and predispose to bleeding if administered simultaneously with heparin or is used in a patient with a preexisting hemostatic defect.[165]

Cardiovascular Drugs

Administration of nitroglycerin, isosorbide dinitrate, or nitroprusside can decrease platelet aggregation and secretion in vitro; but the effects in vivo are minimal and inconsistently observed.[85] The mechanism of platelet inhibition appears to involve the production of nitric oxide from the drug, with concomitant increases in platelet cAMP and, more markedly, cGMP.[166] α-Adrenergic receptor blockers such as propranolol, metoprolol, nebivolol, and pindolol have also been shown to inhibit platelet aggregation, apparently through mechanisms independent of α-adrenoreceptor blockade.[167,168] Several of these agents have been shown to blunt platelet aggregatory responses to ADP and collagen[169] and decrease platelet TXA_2 production in response to agonists.[167] Blunting of serotonin uptake by platelets and inhibition of the response to serotonin have also been demonstrated.[170] Numerous reports also exist on antiplatelet effects of the calcium channel blockers nifedipine, verapamil, and diltiazem. These studies have demonstrated inhibition of platelet aggregation in vitro when high concentrations (micromolar) of the drug were used with washed platelets.[152] This effect is seen primarily with epinephrine as the agonist, and it does not appear to be related to inhibition of calcium ion flux. The proposed mechanisms of action include inhibition of epinephrine binding to α_2-adrenergic receptors, inhibition of the platelet response to TXA_2, and inhibition of serotonin-induced aggregation. In therapeutic doses, the calcium channel blockers do not prolong the bleeding time. Quinidine, an antiarrhythmic drug, can act as an antagonist of platelet α_2-adrenergic receptors at high concentrations. In a single report, a patient taking 800 mg of quinidine and 650 mg of aspirin daily developed melena and generalized petechiae with a normal platelet count and a bleeding time of longer than 35 minutes.[171] Subsequent studies on two normal volunteers showed that quinidine caused a mild increase in the bleeding time that was apparently potentiated by aspirin.

Psychotropic Agents

Platelets from patients taking tricyclic antidepressant drugs (imipramine, amitriptyline, nortriptyline) or phenothiazines (chlorpromazine, promethazine, trifluoperazine) may have impaired in vitro aggregation and secretion responses to ADP, epinephrine, and collagen; but this effect is not associated with an increased risk for bleeding.[85] Numerous reports have also appeared on the antiplatelet effects of the widely used selective serotonin reuptake inhibitors (paroxetine, sertraline, fluoxetine), which may block the only means of platelet serotonin uptake for storage;[172,173] the effect of the drug in decreasing platelet serotonin levels has been documented.[174,175] Prolonged bleeding time,[176] excessive bruising,[177] and defective platelet aggregation have all been noted in patients taking fluoxetine.[178] Additionally, patients taking serotonin reuptake inhibitors exhibit a higher incidence of gastrointestinal bleeding, with concomitant nonsteroidal antiinflammatory drug use increasing the bleeding risk beyond the sum of the individual effects of the two drugs.[179] Further evidence of the antiplatelet effects of serotonin reuptake inhibitors, especially those that bind the serotonin transporter with high affinity, is the reduction in risk for myocardial infarction seen in patients taking these drugs when compared to patients taking other antidepressants or no drugs at all.

Cocaine

Cocaine accounts for more drug-related visits to emergency departments in the United States than any other drug except alcohol. Its use is associated with a large increase in the incidence of myocardial infarction in individuals who are otherwise at low risk, and it has been hypothesized that platelet aggregation contributes substantially to this risk.[180] In vitro, however, cocaine has been shown to inhibit platelet aggregation to several agonists and to be capable of dissociating preformed aggregates.[181]

Oncologic Drugs

Administration of mithramycin has been associated with decreased platelet aggregation, increased bleeding time, and mucocutaneous bleeding.[182] Daunorubicin and bis-chloroethyl-nitrosourea can each inhibit platelet aggregation and secretion when added to platelet-rich plasma, but there has been no suggestion of clinically important bleeding caused by defective platelet function in patients receiving the drug.[85]

Statins

The statins, inhibitors of the key enzyme in cholesterol synthesis, 3-hydroxy-3-methylglutaryl coenzyme A reductase, are widely used in the therapy of hypercholesterolemia.[183] These agents, which include lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, and cerivastatin, decrease the risks for cardiovascular death and complica-

tions through a variety of mechanisms, including reductions in the rate of thrombosis. Among these effects are decreases in platelet reactivity, brought about by the beneficial effects on vascular thrombogenicity, with increased production of endothelial nitric oxide and prostacyclin, and by directly decreasing platelet reactivity.[184] Membrane cholesterol content, which is lowered by the statins, has been correlated with platelet reactivity,[185,186] with recent evidence demonstrating that the content of cholesterol in these membranes correlates with localization of important membrane adhesive and agonist receptors within membrane microdomains known as rafts.[187] Statins, in addition to lowering plasma and membrane cholesterol levels, also reduce the activity of stimulatory signaling pathways that employ such signaling molecules as the small GTP-binding proteins Ras, Rho, and Rac, which require posttranslational prenylation to be targeted to cell membranes. Statins inhibit protein prenylation.[188] No bleeding complications have been associated with statin use, but a substudy of the Platelet Receptor in Ischemic Syndrome Management (PRISM) trial showed that their sudden withdrawal in the setting of acute coronary events (known coronary artery disease and chest pain within the previous 24 hours) was associated with an increased cardiac risk compared with that seen in patients who continued to receive statins (relative risk, 2.93) or who had never received statins.[189] This increase in cardiac events was partially attributed to increased platelet reactivity, mediated through direct and indirect mechanisms.

Miscellaneous Drugs

Clofibrate, another lipid-lowering drug, diminishes platelet responsiveness to ADP, collagen, and epinephrine when given to patients with type II hyperbetalipoproteinemia and can diminish the responsiveness of normal platelets to ADP and epinephrine in vitro.[85] Ketanserin, which has been studied for its potential to prevent atherosclerotic complications, decreases platelet aggregation in response to serotonin. Antihistamines and some radiographic contrast agents can also impair platelet aggregation. The mechanism of action of these agents is unknown.[85] The commonly used antihypertensive drug losartan, an angiotensin II receptor antagonist, interacts with the TXA_2 receptor and inhibits thromboxane-dependent platelet adhesion and aggregation.[190]

Foods and Food Additives

Certain foods and food additives can have important effects on platelet function, particularly when consumed in large quantities. In a classic study published in 1979, Dyerberg and Bang[191] reported that Greenland Eskimos on traditional diets had markedly prolonged bleeding times compared with gender- and age-matched Danish control subjects (mean 8.1 min versus 4.8 min), and they correlated this finding with an impaired secondary wave of platelet aggregation to ADP and collagen and high plasma levels of ω-3 fatty acids. The proposed mechanisms by which ω-3 fatty acids (eicosapentaenoic acid, C20:5ω-3; and docosahexaenoic acid, C22:6ω-3) interfere with platelet function is through their competition with arachidonic acid for the 2-acyl position of membrane phospholipids, or access to COX-1.[192,193] The action of platelet cyclooxygenase on the ω-3 fatty acids not only reduces TXA_2 synthesis to platelet agonist stimulation through competition with the substrate arachidonic acid, it also leads to the production of inhibitory eicosanoids. The latter mechanism was substantiated in the original study of Eskimos by the demonstration that administration of aspirin decreased the bleeding time in all subjects tested but not to *normal* levels.[191] Additionally, ω-3 fatty acids may increase the production of antiaggregatory prostaglandins from cells of the vascular wall.[191]

Ethanol, one of the most commonly and excessively ingested substances in the world, acts synergistically with aspirin to prolong the bleeding time.[69] In addition, ethanol acts cooperatively with agents that block binding of fibrinogen to GPIIb/IIIa in reducing platelet aggregation to several agonists; this effect is not solely caused by effects on TXA2 generation.[194] One study found that ethanol was capable of inhibiting collagen-induced platelet aggregation, secretion, arachidonate mobilization, and TXA_2 formation but did not inhibit platelet adhesion to deendothelialized rabbit aortae.[195]

Other food components or additives may affect platelet function and have been suspected of increasing the risk for minor bleeding. Easy bruising noted after eating Chinese food has been attributed to an effect on platelets by a substance in black tree fungus.[196] A component of onion extract can inhibit platelet arachidonic acid metabolism.[197] Ajoene, a component of garlic, is an inhibitor of fibrinogen binding to platelets and platelet aggregation.[198] Extracts from frequently consumed spices—cumin, turmeric, and clove—can decrease platelet thromboxane production and inhibit platelet aggregation.[199]

It can be concluded that platelets are sensitive to an enormous variety of therapeutic and dietary compounds.[85] However, an increased risk for clinically important bleeding has been demonstrated only for aspirin and agents specifically designed to inhibit platelet function. Reports of increased bleeding with all other agents must be viewed with caution. Despite this qualification, it would be prudent for the clinician to have a thorough understanding of the antiplatelet effects of drugs prescribed and to always consider the potential impacts of drug- or diet-induced platelet dysfunction, particularly in patients with coexisting hemostatic defects (see later in Patients on Anti-platelet Drugs Awaiting Surgery).

CHRONIC RENAL FAILURE

Clinical Features

The recognition of severe hemorrhage as a distinct complication of renal failure is generally attributed to Reisman's description in 1907 of two patients with Bright disease who had severe and generalized bleeding.[200] Reisman proposed that the cause was "a toxin analogous to the hemorrhagins of snake venom." However, the bleeding in Reisman's patients could have been attributed to any of a number of other associated conditions.[200] Others observed a "tendency to hemorrhage" in patients with chronic glomerulonephritis in the predialysis era, and the descriptions of epistaxis and menometrorrhagia[201] suggest a primary platelet abnormality. However, in the era before dialysis, death in patients with chronic renal failure occurred primarily from hyperkalemia and pulmonary edema.[202] After dialysis treatment became established, the major causes of death became infection and the underlying cause of the renal failure. Hemorrhage caused 6 of 100 deaths in one series, but additional factors could have contributed in each case.[202] The current prognosis for patients with end-stage renal disease is excellent, with a significant proportion surviving past 10 years and some reported to survive up to three decades on hemodialysis.[203] Bleeding problems were not mentioned in this discussion, and bleeding was not considered in reviews published in the past 25 years on the clinical course and management of patients with chronic renal failure. However, bleeding and thrombosis in patients with chronic uremia continue to be discussed.[204]

A more objective indication of the rarity of a significant bleeding diathesis in patients with renal failure is the extensive experience with percutaneous renal biopsy. In a study of 1000 consecutive percutaneous renal biopsies performed at the Mayo Clinic, 69 patients had hematuria, which cleared in 50 patients within 2 days.[64] Hypertension was a more significant factor than the bleeding time in predicting the occurrence of complications.[64] Another study of 183 consecutively performed renal biopsies reported three episodes of hemorrhage that required surgical intervention; all were the results of needle lacerations of the kidney or spleen.[205] In an analysis of 5120 renal biopsies performed at 15 institutions, there were no deaths, and the severe bleeding complications appeared to be related to anomalous vessels, heparin anticoagulation, or the presence of amyloid in the

kidney.[206] The reports with other invasive procedures in patients with chronic renal disease are few, but they suggest that bleeding complications are rare after abdominal surgery, liver and bone marrow biopsies, and tooth extractions.[207]

By contrast, gastrointestinal tract hemorrhage is a common complication and frequent cause of death in patients with acute renal failure, and patients with chronic renal failure account for a significant proportion of patients undergoing endoscopy for upper gastrointestinal bleeding.[208] Experimental data suggest that chronic uremia renders the gastric mucosa susceptible to acid injury.[209] More than 90% of patients with renal failure and gastrointestinal bleeding have an anatomic diagnosis at endoscopy: Angiodysplasia is most common, with *peptic* lesions (gastric or duodenal ulcer, erosive esophagitis, gastritis, or duodenitis) also common.[208] Rectal ulcers can also cause sudden, massive lower gastrointestinal hemorrhage.

These observations suggest that serious, spontaneous hemorrhage is uncommon in patients with chronic renal failure. Nevertheless, platelet dysfunction is believed to constitute the primary hemostatic abnormality in uremia.[210] Descriptions of bleeding in uremia have often focused on the laboratory phenomena of abnormal platelet aggregation or a prolonged bleeding time, rather than actual hemorrhagic episodes in patients.[204] As with the drug-induced disorders of platelet function discussed earlier in drugs that affect platelet function section, abnormal platelet function in uremia is far more common than clinically important bleeding. Furthermore, laboratory evaluation of platelet function may not be a good predictor of the risk of hemorrhage.

Tests of Hemostasis and Platelet Function in Uremia

Platelet aggregation studies are frequently abnormal in uremic patients, but the occurrence abnormalities do not appear to correlate with the severity of the renal failure or the occurrence of bleeding.[211] The bleeding time may also be prolonged in uremia and does not necessarily correlate with the severity of the renal failure.[211] Furthermore, controversy exists as to whether the bleeding time is a useful predictor of risk for clinically important bleeding.[65,212] One study found no difference in bleeding complications whether or not a bleeding time was performed before renal biopsy.[213]

Anemia, which does correlate with the severity of renal failure, is an independent cause of a prolonged bleeding time.[214–217] The relation of the hematocrit to the bleeding time was first discerned by Duke, in 1910, who found that the bleeding time in thrombocytopenic patients was corrected by transfusion of fresh whole blood, but when thrombocytopenia recurred, the bleeding time was not as prolonged in the presence of a higher hematocrit. Furthermore, it has been noted that bleeding times can be prolonged with severe anemia caused by vitamin B_{12} or iron deficiency and can be corrected when the anemia is corrected with red blood cell transfusions.[214] Therefore, severely anemic patients with chronic renal failure would be expected to have prolonged bleeding times. The relation of the bleeding time to hematocrit in these patients has been confirmed by correction of the bleeding time with the transfusion of washed red blood cells and by treatment with erythropoietin.[216,218] There was a suggestion in these reports that bleeding symptoms also improved with the correction of the anemia. It is believed that anemia is associated with an increased bleeding time because of the demonstrated tendency of red blood cells to displace the less dense platelets to the periphery of the cylindrical blood vessel, where the platelets are able to surveil the vascular wall for defects.[219]

In contrast to the studies of platelet function performed to understand the possible increased risk for bleeding in patients with chronic renal failure, coagulation and fibrinolytic activities have been investigated to understand the increased risk for thrombotic complications, a major cause of mortality.[204] Although the data are inconsistent, markers of ongoing coagulation are often seen in patients with uremia, suggesting the presence of a prothrombotic state.[204,220]

Pathogenesis of Abnormal Platelet Function in Uremia

Even though the anemia of renal failure appears to be the major cause of the prolonged bleeding time, there is also evidence of abnormal platelet function. Platelet aggregation abnormalities persist when the hematocrit is normalized by red blood cell transfusion[215,216] or erythropoietin treatment.[221] The defects appear to result from intrinsic defects of the platelets and from substances in the plasma capable of inhibiting the function of normal platelets. Deficiencies in the number of GPIb complexes in uremic platelets have been reported, the number inversely correlating with the creatinine level.[222] Consistent with this finding, another study demonstrated that defective ristocetin-induced platelet aggregation of uremic platelet-rich plasma was not corrected by resuspending the platelets in normal platelet-poor plasma. Likewise, uremic platelets suspended in normal plasma were defective in their adhesion to deendothelialized rabbit vessels at a high shear rate, a test of the competency of the interaction between GPIb and vWF.[223] Conversely, the same study demonstrated that plasma factors also influence platelet function by showing that normal platelets suspended in uremic plasma acquire an adhesion defect that is possibly related to an abnormality of the interaction of vWF with the subendothelium. This led to the suggestion that vWF may be abnormal in uremia. Two studies have demonstrated normal to elevated vWF antigen and activity (measured as ristocetin cofactor activity) in uremic patients, but with decreased levels of the largest and most hemostatically active multimers,[224,225] reflected in one study as a decreased ratio of activity to antigen level compared with normal subjects.[224] Taken together, the various studies consistently indicate that the first step of platelet adhesion at sites of vessel wall injury is defective, a defect that could reach clinical significance if coupled with other defects of platelet function.

The platelets of uremic patients frequently exhibit reduced fibrinogen binding, aggregation, and secretion in response to a wide variety of agonists. This abnormality may be retained by the platelets after their separation from uremic plasma, and in some experiments uremic plasma has induced these defects in normal platelets. Uremic platelets may also exhibit a reduction in several of the biochemical responses necessary for aggregation and secretion, including the rise in cytoplasmic free calcium levels, release of arachidonic acid from membrane phospholipids, conversion of arachidonic acid to TXA_2, and dense-granule and α-granule secretion. Abnormal cytoskeletal assembly and deficient tyrosine phosphorylation have also been noted in uremic platelets, abnormalities only partially corrected by dialysis.[226]

The accumulation of dialyzable platelet-inhibitory substances in the plasma of uremic patients has long been recognized. The ability of uremic plasma to inhibit platelet function was demonstrated by Horowitz and colleagues,[227] who showed reduced ADP-induced platelet aggregation and a prolonged Stypven clotting time, a measure of platelet procoagulant activity. This activity, previously called *platelet factor 3,* is vital to the support of blood coagulation on the platelet surface and requires externalization of the anionic phospholipid phosphatidylserine. One uremic substance described by Horowitz and coworkers with platelet inhibitory properties is guanidinosuccinic acid,[228] which accumulates in uremic plasma as an alternative byproduct of L-arginine metabolism,[212] a consequence of the inhibitory effect of high urea levels on enzymes of the urea cycle. Like L-arginine, guanidinosuccinic acid is a precursor of nitric oxide, production of which is increased in endothelial cells and platelets in uremic patients and experimental animals.[212] Consistent with an important role for nitric oxide in uremia, infusion of the nitric oxide synthesis inhibitor monomethyl L-arginine reduced the bleeding time in uremic rats.[229] Suppression of nitric oxide production appears to correlate with the benefit of conjugated estrogens in improving the bleeding time in uremia.[230] Increased expression of vascular prostacyclin has also been described in uremic rats, a factor that would further depress in vivo platelet function.[231]

Dialysis itself may be associated with alterations in platelet function. For example, hemodialysis may cause transient increases in the bleeding time and reduced responsiveness to platelet agonists in

vitro,[232] and chronic hemodialysis and peritoneal dialysis are associated with an increase in *reticulated* platelets, suggesting accelerated platelet turnover.[233] Of the two forms of dialysis, hemodialysis appears to have the greatest effect on platelet function, with one study noting abnormal cytoskeletal assembly and defective tyrosine phosphorylation to thrombin stimulation in the platelets of patients on hemodialysis, parameters that returned almost to normal with the institution of ambulatory peritoneal dialysis.[226] The cause of the defect associated with hemodialysis is likely to be the chronic low-level platelet activation associated with the procedure. In particular, polymerization and depolymerization of actin, release of granules and exposure of granule proteins on the platelet surface, and shedding of membrane proteins are all effects likely to render the platelets relatively refractory to subsequent activation.

As would be expected, platelets from uremic patients may be unusually sensitive to medicines that decrease platelet function. Aspirin has been reported to be more effective in prolonging the bleeding time in uremic patients than in control subjects, and this effect may occur by mechanisms other than the irreversible inhibition of COX-1 function. Similarly, β-lactam antibiotics that prolong the bleeding time may have a greater effect in uremic patients and may increase the occurrence of bleeding, particularly if renal clearance of the antibiotic is reduced.[85,217]

Mild thrombocytopenia has been reported in cases of chronic renal failure, in which setting it is probably caused by a combination of diminished marrow production and diminished platelet survival.[217] However, a platelet count of less than 100,000/μL should alert the physician to the possibility of thrombocytopenia caused by a systemic disease, such as multiple myeloma, systemic vasculitis, the hemolytic-uremic syndrome, preeclampsia, renal allograft rejection, or an adverse reaction to a drug such as heparin.

Erythropoietin deficiency can also contribute to the hemostatic defect of uremia. Consistent with this, defective tyrosine phosphorylation in uremic endothelial cells is restored when erythropoietin is added (see Uremic Bleeding section).[234]

CARDIOPULMONARY BYPASS

Clinical and Laboratory Features

Although cardiopulmonary bypass is accompanied by decreased plasma levels of coagulation factors and increased fibrinolytic activity, abnormal platelet function is a prominent observation in these patients. A fall in the platelet count and platelet dysfunction are seen in most patients undergoing bypass surgery with either a bubble or a membrane oxygenator.[235] A prolonged bleeding time (longer than expected for the degree of thrombocytopenia), decreased platelet aggregation, decreased platelet agglutination in response to ristocetin, and a decreased concentration of α-granule or dense granule contents are typically found in patients following bypass surgery.[235] Despite these abnormalities, excessive bleeding is uncommon, occurring in only approximately 5% of patients. Bleeding, usually manifesting as excessive chest tube blood loss (defined as >100 mL/h), has multiple causes: surgical complications, excessive protamine dose, and possibly also platelet function abnormalities.[236–240]

Recently, several surgeries have taken advantage of deep hypothermia circulatory arrest, especially those involving the thoracic aorta and congenital heart abnormalities. Neurological dysfunction is associated with this procedure and is believed to be at least partially caused by platelet microaggregates formed in response to the low temperature.

Pathogenesis of the Platelet Disorder

As with hemodialysis, the platelet defect caused by cardiopulmonary bypass is most likely caused by the effects of platelet activation and fragmentation within the extracorporeal circulation. The severity of the platelet abnormalities thus correlates with the duration of the bypass procedure.[241,242] Following uncomplicated surgery, platelet function returns to normal in 1 hour[241]; however, a much longer time may be required in some patients,[243] and the platelet count typically does not return to normal for several days.[240] Thrombocytopenia is caused by hemodilution, accumulation of platelets within the bypass circuit, and, to a lesser extent, sequestration of damaged platelets in the liver. Platelet dysfunction following bypass may be caused by reversible adhesion and aggregation of platelets to fibrinogen adsorbed from plasma onto the bypass circuit material; mechanical trauma and shear stress; cardiotomy suction; trace concentrations of circulating thrombin and ADP; complement activation; hypothermia; blood conservation devices; bypass priming solutions; and, with bubble oxygenators, exposure of platelets to the blood–air interface.[85] Cardiopulmonary bypass also consistently causes the appearance of platelet fragments, or membrane *microparticles,* evidence that the platelet surface membrane is subjected to severe mechanical stress and activation during the procedure.[242] These data indicate that a considerable amount of platelet aggregation occurs during cardiopulmonary bypass, simultaneously producing deleterious effects from substances released from the platelets and the new adhesive molecules exposed on their surfaces, and rendering the platelets relatively refractory to subsequent activation stimuli.

Another surgical cause of platelet dysfunction relates to the use of deep hypothermic circulatory arrest in some surgeries. This procedure involves cooling the vital organs to temperatures between 15°C and 22°C (59°F and 71.6°F) for the purpose of neuroprotection during complex surgeries of the aortic arch or intracerebral aneurysms.[244] During the period of deepest hypothermia, the circulation is stopped, making for bloodless surgical fields. Complications of deep hypothermic circulatory arrest include coagulopathy and neurological sequelae, with evidence that the latter problem may involve hypothermic activation of platelets and formation of microaggregates.[245]

Management

A study on the use of aspirin in patients undergoing coronary artery bypass grafting indicates that earlier practices of avoiding platelet inhibitors may in fact lead to increased morbidity of all types, ranging from death to ischemic complications involving the heart, the gut, and the kidneys.[90] Patients who received aspirin within 48 hours of their surgery reduced their risk of dying by one-third and their risk of nonischemic complications involving the heart, kidneys, and gastrointestinal tract by approximately two fifths. In the same study, it was noted that the patients who received either platelets or antifibrinolytic therapy as prophylaxis against postoperative bleeding were at increased risk for adverse complications and death. Thus, except in the setting of acute hemorrhage with evidence of platelet dysfunction, platelet transfusion should be avoided. Likewise, it is perhaps best to treat patients with aspirin soon after bypass surgery to decrease the incidence of deleterious effects. In addition to the known benefit of aspirin in preventing graft occlusion in patients undergoing coronary artery bypass grafting, the evidence would appear to warrant early institution of aspirin therapy in patients who have undergone cardiopulmonary bypass for other reasons and in whom aspirin therapy is not otherwise contraindicated.

When postoperative blood loss is greater than anticipated, it can be treated with DDAVP after cessation of bypass, but most clinical trials have not demonstrated a beneficial effect of this agent.[246,247] In these studies, a benefit of DDAVP seemed more apparent in patients undergoing more complex cardiac surgical procedures. Potential risks of DDAVP include hyponatremia, hypotension, and thrombosis.[246]

Attempts have been made to prevent platelet activation during bypass surgery in humans and experimental animals by infusion of prostaglandin E_1 or prostacyclin. By increasing the platelet concentration of cAMP and reducing platelet responsiveness, these agents partially prevent the occurrences of thrombocytopenia and platelet function abnormalities.[248] However, the hypotensive properties of

these agents limit their usefulness. Antifibrinolytics (tranexamic acid, ε-aminocaproic acid, aprotinin) have been shown to be effective in reducing the loss of blood following cardiopulmonary bypass.[249] Aprotinin has been studied for its potential to protect platelets from activation by thrombin, plasmin, and other proteases generated during cardiopulmonary bypass. At high doses, aprotinin appears better than either ε-aminocaproic acid or desmopressin at reducing postoperative blood loss and is at least as good as tranexamic acid.[250] However, aprotinin has recently been reported to be associated with increases in late mortality and renal toxicity after cardiopulmonary bypass. Because the methodologies of these studies have clear limitations, continued use has been approved after review by the Food and Drug Administration, albeit limited to coronary artery bypass grafting and with cautions for greater postoperative vigilance.

In the management of the neurological sequelae of deep hypothermic circulatory arrest, evidence exists that treatment with the $\alpha_{IIb}\beta_3$ inhibitors eptifibatide or tirofiban may improve outcomes by preventing microvascular occlusion.[245]

ANTI-PLATELET ANTIBODIES

Immunoglobulins bind platelets nonspecifically and specifically and have the potential in both instances of interfering with platelet functions. In several pathologic conditions, including idiopathic thrombocytopenic purpura (ITP), systemic lupus erythematosus (SLE), and platelet alloimmunization, the antibodies lead to accelerated platelet destruction and thrombocytopenia. Generally, the surviving platelets, known as *stress platelets* display enhanced function.[251] Indeed, bleeding times in ITP may be shorter than expected for the degree of thrombocytopenia. Sometimes, however, the hemorrhagic tendency is greater than expected from the drop in platelet count or persists when the platelet count has recovered, signaling that the bound antibody may be perturbing platelet function. Immune thrombocytopenia is common; significantly impaired hemostasis caused primarily by antibody-mediated platelet dysfunction is not. In one study, 3 of 49 patients with ITP, whose platelet counts had recovered after therapy with either corticosteroids or splenectomy, continued to display elevated bleeding times and persistence of mucocutaneous hemorrhage.[252]

Clinical and Laboratory Features

In some patients with ITP or SLE, platelet dysfunction may be suspected because mucocutaneous bleeding symptoms occur at a platelet count that is usually sufficient for normal hemostasis (>50,000/μL), and the bleeding time may be longer than expected for the degree of thrombocytopenia. Patients with antiplatelet antibodies may exhibit defective platelet function in vitro, even if they do not have prolonged bleeding times or clinical symptoms of excessive bleeding—a situation similar to that described for the effects of aspirin ingestion and renal disease. For example, in two studies, 13 of 19 patients with ITP demonstrated impaired platelet aggregation to ADP, epinephrine, or collagen.[253,254] In two other studies, 22 of 35 patients with SLE were found to have decreased platelet aggregation in response to these agonists.[255,256] These platelet function abnormalities appeared to be antibody-mediated, because IgG purified from the plasma or eluted from the platelets of some of the patients inhibited the aggregation of normal platelets.

Platelet antibodies may impair several aspects of platelet function. The most frequently observed abnormality is absence of platelet aggregation in response to low concentrations of collagen, and absence of the second wave of irreversible aggregation in response to ADP or epinephrine. This pattern is identical to the abnormalities caused by aspirin, described earlier. In ITP and SLE, the abnormal aggregation may be related to the decreased platelet content of dense- and α-granule contents or to an activation defect manifested by diminished conversion of arachidonic acid to TXA_2.

Pathogenesis

Impairment of platelet function by autoantibodies or alloantibodies usually involves interference with the functions of the target antigens. For example, alloantibodies (eg, anti-PI^{A1}) and autoantibodies have been described that interfere with the functions of $\alpha_{IIb}\beta_3$, sometimes causing a syndrome similar to Glanzmann thrombasthenia.[257–261] These antibody-associated thrombopathies can be severe. Interference with $\alpha_{IIb}\beta_3$ function perhaps is to be expected, given that $\alpha_{IIb}\beta_3$ is the most common protein antigen on the platelet surface and the most common target of autoantibodies.[262] Impairment of GPIb functions has also been described, in one case producing a syndrome of severe refractory thrombocytopenia and a functional defect closely resembling that seen in Bernard-Soulier syndrome.[263] An interesting aspect of antibodies against GPIb is the potential that they may be associated with more severe thrombocytopenia than when other antigens are targeted[264]; this finding is consistent with the observation that anti-GPIb antisera inhibited megakaryopoiesis in vitro[265] and with the finding that monoclonal GPIb antibodies inhibited in vitro proplatelet formation.[266] Autoantibodies have also been described that interfere with platelet collagen-binding function, targeting GPIa (integrin α_2),[267,268] GPIV,[268] and GPVI.[269,270] The latter glycoprotein was in fact identified as an important receptor for collagen based on the functional impairment in collagen response caused by patient antisera.[269,271]

Other antibodies have been described that can activate platelets. Of particular interest is the report of a patient who presented with immune thrombocytopenia and an antibody against CD9 (a member of the tetraspanin protein family) whose antibody could activate normal platelets.[272] After remission with recovery of the platelet count, the patient relapsed, this time with an antibody against the platelet Fc receptor, FcγRIIA. The latter antibody blocked the ability of the first antibody to activate platelets, confirming that activation involved stimulation of the Fc receptor. Platelets that have been activated and induced to secrete, but have not been incorporated into aggregates, are expected to be refractory to platelet agonists and deficient in secretory granule contents, essentially leading to an acquired storage pool deficiency, which has also been described in association with autoantibodies.[273]

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (see Chapter 132) is sometimes associated with acquired storage pool disease, believed to result from repeated stimulation leading to what are graphically termed *exhausted platelets.*[274] It has also been suggested that the elevated fibrin(ogen) degradation products and low fibrinogen levels that occur in patients with disseminated intravascular coagulation may inhibit platelet function. Although purified fibrin(ogen) degradation products can impair platelet aggregation in vitro, the concentrations required to do this are unlikely to be found in vivo.[275] Another feature of disseminated intravascular coagulation, hypofibrinogenemia, is unlikely to contribute to a defect in platelet aggregation, except in extreme cases, as fibrinogen concentration in plasma exceeds by at least 10-fold the quantity needed to saturate fibrinogen receptors on platelets.[276]

DYSPROTEINEMIAS

Clinical Features

Although thrombotic complications are not uncommonly seen in dysproteinemias (and attributed to hyperviscosity), bleeding complications have likewise been attributed to excessive paraproteins acting through several pathophysiologic mechanisms. Platelet dysfunction is observed in approximately one-third of patients with IgA myeloma or Waldenström macroglobulinemia, in 15% of patients with IgG

myeloma, and occasionally in patients with benign monoclonal gammopathy.[277] Additional hemostatic problems in these patients can be caused by the hyperviscosity syndrome,[278] a heparin-like coagulation inhibitor,[279] or complications of amyloidosis (eg, acquired factor X deficiency[280] or fibrinolysis[281]). Patients may have markedly abnormal results on laboratory tests (eg, the thrombin time) with no evidence of clinical bleeding.[277]

Pathogenesis

Abnormalities of platelet function correlate with the concentration of the plasma paraprotein. Myeloma proteins can inhibit all platelet functions—aggregation, secretion, procoagulant activity, and clot retraction—and normal platelets can acquire these defects when incubated with the purified monoclonal immunoglobulin.[282] In some cases, specific interactions of the monoclonal protein have been described. One IgA myeloma protein inhibited the ability of a suspension of aortic connective tissue to aggregate normal platelets.[283] The bleeding time and bleeding symptoms of the patient from whom this paraprotein was isolated were corrected when the IgA myeloma protein was removed by plasmapheresis. One patient suffered a fatal hemorrhage from an IgG1κ paraprotein that bound GPIIIa (β_3 integrin) and inhibited platelet aggregation.[284] A number of reports have described acquired von Willebrand disease in patients with myeloma, benign monoclonal gammopathy, or chronic lymphocytic leukemia.[285] In some patients, the plasma concentration of vWF was decreased, in others the larger multimers were deficient. The myeloma protein may interact with vWF and accelerate its clearance from plasma or interfere with its binding to platelet GPIb.

Management

Because bleeding appears to be correlated to high plasma paraprotein concentrations,[286] plasmapheresis should be performed expeditiously to reduce the paraprotein; effectiveness of this therapy can be evaluated by amelioration of bleeding symptoms. Chemotherapy for the underlying plasma cell neoplasm should be begun to effect a longer-lasting reduction of the paraprotein. DDAVP infusion, with or without plasmapheresis, may be transiently effective in patients with acquired von Willebrand disease.[285]

COMMENTS ON THE MANAGEMENT OF SELECTED BLEEDING DISORDERS

Liver Disease

The bleeding diathesis observed with fulminant or end-stage liver disease is multifactorial, with contributing causes such as thrombocytopenia, anemia, deficiencies in liver-synthesized coagulation factors, and excessive fibrinolysis well-described.[287,288] Chronic liver disease and hepatic cirrhosis of various causes have been reported to prolong the bleeding time and cause other platelet function abnormalities that may be related to a decrease in GPIb.[289] Although some studies have shown an association between prolonged bleeding time and gastrointestinal hemorrhage in cirrhotic patients,[290] other studies showed that the bleeding time and platelet aggregation abnormalities correlated best with the degree of thrombocytopenia,[291] suggesting that no specific platelet function defect exists in liver disease. However, this latter study did not evaluate patients by the severity of liver disease. One study found an aspirin-like defect in patients with severe liver disease, with defective aggregation and TXB_2 production.[292] Interestingly, one study of cirrhotic patients with hepatocellular carcinoma showed that platelets sampled from the portal circulation showed significantly decreased and delayed collagen aggregation as compared to samples from the systemic circulation.[293] In addition to portal hypertension and esophageal varices, this finding may point to localized vascular bed factors (including increased prostacyclin I_2) which may contribute specifically to variceal bleeding.

Patients on Antiplatelet Drugs Awaiting Surgery

Hematologists are often consulted to assess the risk of bleeding and to advise on the management of patients taking antiplatelet drugs and those who are scheduled for surgery and other invasive procedures. The decision to discontinue antiplatelet therapy is arbitrary, and there are no empirical guidelines. It is a common practice to discontinue antiplatelet therapy even for minor surgery. However, serious adverse events have been reported in association with preoperative interruption of antithrombotic treatments. Therefore, the risk of intraoperative or postoperative bleeding should be carefully weighed against the dangers of precipitating a thrombotic event.

The risk of bleeding in patients taking aspirin is minimal. Nevertheless, when a relatively healthy patient who is taking aspirin is scheduled for an invasive procedure, aspirin should ideally be discontinued for at least 5 days. This period of time is sufficient for replacement of approximately one-half of the aspirin-exposed platelets with new platelets that were not exposed to aspirin, resulting in a sufficient number (eg, approximately 100,000/μL) to affect hemostasis during any surgical procedure. However, because aspirin use is so common and because the drug is present in hundreds of pharmaceutical products, it may not be feasible to discontinue aspirin and wait 5 days for a procedure in some patients. Significant excessive bleeding caused by aspirin is rare, and any serious bleeding that does occur during an operative procedure is likely caused by a surgically correctible lesion. If severe hemorrhage caused by deficient platelet function is suspected, a platelet transfusion would be promptly effective, but this will only rarely be indicated. Aspirin use does not appear to be a reason to delay necessary surgery except in patients in whom the nature of the surgical procedure requires the absolute minimum risk for excessive bleeding (eg, some plastic-surgical, neurosurgical, or ophthalmologic procedures). The use of prophylactic platelet transfusions in this clinical setting is discouraged.

The thienopyridines, ticlopidine and clopidogrel, when used as a single agent, have a safety profile for bleeding similar to that of aspirin, but the data are less extensive. These two drugs undergo biotransformation in vivo to active metabolites that covalently modify the ADP receptor $P2Y_{12}$. The full antiplatelet effect of ticlopidine in vivo requires 3 to 5 days of oral administration, whereas an antiplatelet effect of clopidogrel is apparent within 2 hours of administration. Because, like aspirin, platelet inhibition with these agents is irreversible, it would be prudent to wait 5 days off the drug before surgery.

Because the thienopyridines have been found to be synergistic with aspirin in their effects on platelet function, their use in combination with aspirin has become standard therapy after stent placement and for the treatment of acute coronary syndromes. The bleeding risk is increased in patients receiving both medications. In the case of a patient presenting for emergency surgery, prophylactic platelet transfusion should still be avoided, and platelet transfusion should be considered only in the setting of severe or refractory hemorrhage.

Uremic Bleeding

Prolonged bleeding times and abnormal platelet aggregation are common in uremic patients, but they do not always predict an increased risk for hemorrhage or constitute an indication for transfusion or therapeutic intervention. If a patient with abnormal platelet function and a long bleeding time requires an invasive procedure, such as a kidney or lung biopsy or a laparotomy, and there is no history to suggest an increased risk for bleeding, it may be less risky to carry out the procedure without specific treatment to correct the

platelet defect than to delay and attempt to normalize a laboratory value.

When therapy is indicated, the best strategy to improve hemostasis is to perform dialysis. Dialysis improves platelet function and normalizes the prolonged bleeding time in uremia and diminishes the risk for bleeding. For example, intensive dialysis decreases the occurrence of acute gastrointestinal bleeding, a major cause of morbidity and mortality in patients with acute renal failure. Peritoneal dialysis and hemodialysis are equally effective, but evidence of in vivo platelet activation is only seen in patients treated with hemodialysis.

If bleeding does complicate a procedure, the cause is most likely structural and should be managed as it would be in patients without renal failure. Similarly, patients with chronic renal failure who present with hemorrhage should by evaluated as are other bleeding patients; uremia should not be assumed to be the cause of bleeding.

Several treatment modalities, apart from intensive dialysis, may improve the bleeding time, and anecdotal observations suggest that they may also improve hemostasis. However, these modalities have not been uniformly effective, and prospective studies have not been performed. Therefore, therapy for bleeding in a patient with chronic renal failure should take into consideration the severity of bleeding, the anticipated severity of the hemostatic risk from surgery or trauma, and the risks of the therapy.

Infusion of DDAVP (L-deamino-8-D-arginine vasopressin, desmopressin) has been used in the management of bleeding in uremia and avoids the risk associated with the infusion of blood products. An intravenous or subcutaneous dose of 0.3 mg/kg administered over 15 to 30 minutes shortens the bleeding time in 50% to 75% of uremic patients. This correction occurs within 30 to 60 minutes and lasts for up to 4 hours, correlating with increases in the overall plasma concentration of vWF and in the fraction of vWF made up of higher-molecular-weight multimers. DDAVP has been reported to be effective in preventing surgical bleeding in uremic patients, but controlled trials of its efficacy are lacking. Another unresolved issue is whether uremic patients as a whole experience excessive surgical bleeding. DDAVP has less pressor effect than natural vasopressin, and side effects are uncommon but may include facial flushing, mild tachycardia, water retention, hyponatremia severe enough to cause seizures, arterial thrombosis, and memory loss. DDAVP stimulates the release of vWF from endothelial cells, which may account for its therapeutic effect, but other mechanisms may be involved, including a direct priming effect on the platelets.

Increasing the hematocrit, either by red blood cell transfusion or by treatment with recombinant human erythropoietin, is associated with a correction of the bleeding time and possibly reduced tendency to bleed. The mechanism by which anemia prolongs the bleeding time in uremia is unknown but may relate to the absence of the normal effect of axial streaming of erythrocytes in the center of the bloodstream that forces the platelets toward the edge of the blood vessel and thereby facilitates their ability to detect disruptions of the endothelium.[219] It has also been proposed that erythrocytes facilitate activation of platelets by releasing ADP, a contribution diminished by anemia.[294] The benefits of increasing the hematocrit by transfusion must be weighed against the risk of infection associated with transfusion of blood products.

Conjugated estrogens have also been reported to shorten prolonged bleeding times in uremic patients and to correct the bleeding diathesis.[295] Even a single 50-mg dose of oral conjugated estrogen (Premarin) may be effective. In support of this, conjugated estrogens have been shown to shorten the prolonged bleeding time in uremic rats.[296] The correction of the bleeding time in this model was abolished by the nitric oxide precursor L-arginine, and administration of estrogens to uremic rats decreases the expression of nitric oxide synthase. These findings suggest that the estrogen effect on hemostasis in uremia might be mediated by changes in the nitric oxide synthetic pathway.

Some studies have reported that cryoprecipitate infusions shorten the bleeding time in patients with uremia, but others have not; it is unlikely that the benefit justifies the risk.

CHAPTER 143

HUMAN BLOOD GROUP ANTIGENS AND ANTIBODIES

Marion E. Reid and Connie M. Westhoff

INTRODUCTION

An important clinical concern in transfusion medicine occurs when a patient requiring transfusion is found to have unexpected blood group antibodies. Although these antibodies can be characterized in terms of specificity, immunoglobulin class, and in vitro characteristics, no fool-proof method exists to predict the clinical significance. The potential for adverse effects of transfusion should be assessed by correlating the serological information with clinical experiences reported in the literature and with the patient's medical history. For example, a patient who has not been exposed to red blood cells (RBCs) by transfusion or pregnancy is unlikely to have a clinically significant alloantibody.

ERYTHROCYTE BLOOD GROUP ANTIGENS

Erythrocyte blood group antigens are polymorphic, inherited, carbohydrate, or protein structures located on the surface of the RBC membrane. There are 29 different blood group systems, with more than 250 associated blood group antigens (Table 143–1). The protein antigens are primarily located on integral transmembrane proteins, but a few are on glycosylphosphatidylinositol (GPI)-linked proteins. Some antigens are carbohydrates attached to proteins or lipids, some require a combination of a specific portion of protein and carbohydrate, and a few antigens are carried on proteins that are adsorbed from the plasma. Many proteins carrying blood group antigens reside in the erythrocyte membrane as complexes with other proteins,[1] and many components carrying blood group antigens have been assigned cluster of differentiation numbers.

Recognition of a blood group antigen begins with discovery of an antibody. When an individual whose RBCs lack an antigen is exposed to RBCs that possess the antigen, he or she may mount an immune response and produce antibodies that react with the antigen. Depending on the characteristics of the antibody and the number and topology of antigens in the RBC membrane, the interaction between antibody and antigen may result in sensitization, agglutination, or hemolysis when complement is activated. In blood group testing, most assays are designed to result in agglutination and clumping of the RBCs is the detectable endpoint.[2] The ability to detect and identify blood group antigens and antibodies has contributed significantly to current safe supportive blood transfusion practice, to the appropriate management of pregnancies at-risk for hemolytic disease of the newborn (HDN), and to management of organ transplantation.

Terminology

Some blood group systems bear the family surname in which the antibody was first discovered (Kell, Kidd, Duffy, etc.), with abbreviations to indicate alleles (K/k, Jk^a/Jk^b, and Fy^a/Fy^b etc.). Others were given letter designations (A, B, D, M, N, etc.). A committee for terminology of RBC surface antigens, organized by the International Society for Blood Transfusion, works to standardize terminology of new blood group antigens.[3]

MOLECULAR BASIS OF BLOOD GROUP ANTIGENS AND PHENOTYPES

Most genes encoding blood group antigens have been cloned and sequenced,[4] and the molecular basis of most blood group antigens has been determined.[5,6] Details concerning the alleles associated with blood group antigens and phenotypes can be obtained from the following Web site: www.ncbi.nlm.nih.gov/projects/mhc/xslcgi.fcgi?cmd=bgmut/home. Knowledge of the gene has allowed determination or predictions regarding the structure and function of the components carrying blood group antigens as well as an appreciation of diseases associated with loss of expression of some blood groups, such as null phenotypes (Table 143–2). Knowledge of the gene has made it possible to perform DNA analyses to type multiply transfused patients, determine gene dosage (zygosity), and perform noninvasive fetal typing not possible by classical hemagglutination. Table 143–3 lists examples of DNA-based assays useful in the transfusion medicine.

Blood Group Antibodies

The common causes of immunization against blood group antigens are transfusion, pregnancy and occasionally transplantation or practices such as sharing needles. In addition, microbes encountered by way of the digestive tract and other mucosal surfaces regularly (eg, anti-A, -B, -P, $-P^k$) or sometimes (eg, anti-M, -P1, $-Le^a$, $-Le^b$) result in production of so-called naturally occurring antibodies. These antibody specificities are the most common antibodies present in children and nontransfused male patients.

Antibodies recognizing antigens in the ABO blood group system are by far the most clinically significant. Others occur in the following approximate order, from the most to the least commonly encountered in transfusion practice: anti-D, anti-K, anti-E, anti-c, anti-Fy^a, anti-C, anti-Jk^a, anti-S, and anti-Jk^b. Other clinically significant antibodies occur with an incidence of less than 1% of immunized patients.[7,8]

Antibodies considered clinically insignificant unless the antibody reacts in tests performed strictly at 37°C (98.6°F) include those to A1, P1, M, N, Lu^a, Le^a, Le^b, and Sd^a antigens. A few antibodies that react at 37°C (98.6°F) by the indirect antiglobuin test (IAT) but are usually clinically insignificant include those of the Knops and Ch/Rg systems. Table 143–4 summarizes the immunoglobulin class and clinical significance associated with some alloantibodies. A brief clinical and technical description of most blood group antibodies can be found in reviews.[9–11]

Compatibility testing (patient's serum against donor's RBCs) still uses techniques that were described more than 100 years ago for direct agglutination, and more than 50 years ago for indirect agglutination. The hemagglutination technique is simple; is inexpensive; does not require sophisticated equipment; and, when done correctly, is sensitive and specific in terms of clinical relevance.

Blood group IgM antibodies to carbohydrate antigens (eg, in ABO, P1, Le, H and P systems) often agglutinate antigen-positive RBCs suspended in a saline medium (direct agglutination). Most

Table 143–1 Blood Group Systems

ISBT System Name (Number)	Gene Name HGNC (ISBT)	Chromosome Location	Predicted Topology (Number of amino acids AA)	Component Name (CD number)	Associated Blood Group Antigens (Null phenotype)
ABO (001)	*ABO*	9q34.2	Glycosyltransferases Type II (354 AA)	Carbohydrate	A, B, A, B, A1
MNS (002)	*GYPA (MN)* *GYPB (Ss)*	4q31.21	Type I (131 AA) (72 AA)	GPA (CD235a) GPB (CD235b)	M, N, S, s, U, Vw + 40 more (En(a–); U–; M^kM^k)
P (003)	*P1*	22q11.2-qter	Galactosyltransferase	Carbohydrate	P1
Rh (004)	*RHD* *RHCE*	1p36.11	Multipass: 12 spans (417 AA)	RhD (CD240D) RhCE (CD240CE)	D, C, E, c, e, G, V, Rh17 + 42 more (Rh_{null})
Lutheran (005)	*LU*	19q13.32	Type I IgSF (597 AA) (557 AA)	Lutheran glycoprotein B-CAM (CD239)	Lu^a, Lu^b, Lu3, Lu4, Au^a, Au^b + 13 more (Recessive Lu[a–b–])
Kell (006)	*KEL*	7q34	Type II (732 AA)	Kell glycoprotein (CD258)	K, k, Kp^a, Kp^b, Ku, Js^a, Js^b + 21 more (K_0 or K_{null})
Lewis (007)	*FUT3(LE)*	19p13.3	Fucosyltransferase Type II (361 AA)	Carbohydrate Adsorbed from plasma	Le^a, Le^b, Le^{ab}, Le^{bh}, ALe^b, BLe^b (Le[a–b–])
Duffy (008)	*DARC (FY)*	1q23.2	Multipass: 7 spans (338 AA)	Fy glycoprotein (CD234)	Fy^a, Fy^b, Fy3, Fy4, Fy5, Fy6 (Fy[a–b–])
Kidd (009)	*SLC14A1(JK)*	18q12.3	Multipass: 10 spans (389 AA)	Kidd glycoprotein	Jk^a, Jk^b, Jk3 (Jk[a–b–])
Diego (010)	*SLC4A1 (DI)*	17q21.31	Multipass: 14 spans (911 AA)	Band 3, AE1 (CD233)	Di^a, Di^b, Wr^a, Wr^b, Wd^a, Rb^a + 15 more
Yt (011)	*ACHE (YT)*	7q22	GPI-linked (557 AA)	Acetyl-cholinesterase	Yt^a, Yt^b
Xg (012)	*MIC2 (XG1)*	Xp22.33	Type I (180 AA) (163 AA)	Xg^a glycoprotein CD99	Xg^a
Scianna (013)	*ERMAP(SC)*	1p34.2	Type I (475 AA)	*ERMAP*	Sc1, Sc2, Sc3, Rd + 3 more (Sc: –1,–2,–3)
Dombrock (014)	*ART4 (DO)*	12p12.3	GPI-linked (314 AA)	Do glycoprotein; ART 4 (CD297)	Do^a, Do^b, Gy^a, Hy, Jo^a (Gy[a–])
Colton (015)	AQP1 (CO)	7p14	Multipass: 6 spans (269 AA)	*Aquaporin*	Co^a, Co^b, Co3 (Co[a–b–])
Landsteiner-Wiener (016)	ICAM4 (LW)	19p13.2	Type I IgSF (241 AA)	LW glycoprotein (ICAM-4) (CD242)	LW^a, LW^{ab}, LW^b (LW[a–b–])
Chido/ Rodgers (017)	*C4A, C4B (CH/RG)*	6p21.32	Adsorbed from plasma	C4A; C4B	CH1, CH2, Rg1 + 6 more
Hh (018)	*FUT1(H)*	19q13.33	Fucosyltransferase Type II (365 AA)	Carbohydrate (CD173)	H (Bombay or Oh)
Kx (019)	*XK (XK)*	Xp21.1	Multipass: 10 spans (444 AA)	XK glycoprotein	Kx (McLeod)
Gerbich (020)	*GYPC (GE)*	2q14.3	Type I (128 AA) (107 AA)	GPC (CD236) GPD	Ge2, Ge3, Ge4 + 5 more (Leach phenotype)
Cromer (021)	*CD55 (CROM)*	1q32.2	GPI-linked (347 AA)	DAF (CD55)	Cr^a, Tc^a, Tc^b, Tc^c, Dr^a, Es^a, IFC + 8 more
Knops (022)	*CR1(KN)*	1q32.2	Type I (1998 AA)	CR1 (CD35)	Kn^a, Kn^b, McC^a, Sl^a, Yk^a + 4 more
Indian (023)	*CD44 (IN)*	11p13	Type I (341 AA)	Hermes antigen (CD44)	In^a, In^b + 2 more
Ok (024)	*BSG (OK)*	19p13.3	Type I IgSF (248 AA)	Neurothelin, basigin (CD147)	Ok^a
RAPH (025)	*MER2*	11p15.5	Not known	Not defined	MER2 (Raph–)
JMH (026)	*SEMA-L (JMH)*	15q24.1	GPI-linked (656 AA)	H-Sema-L, Semaphorin 7A (CD108)	JMH + 4 more
I (027)	*IGNT*	6p24.2	*N*-Acetylglucosaminyltransferase type II (400 AA)	Carbohydrate	I (I– or i adult)
Globoside(028)	*3GALT3* or *βGalNAcT1*	3q26.1	*N*-acetylgalactosaminyltransferase type II (331 AA)	Carbohydrate (Gb_4, globoside)	P (P–)
GIL (029)	*AQP3(GIL)*	9p13.3	Multipass: 6 spans (292 AA)	AQP3	GIL (GIL–)

IgSF, immunoglobulin super family; ISGN, International Society for Gene Nomenclature; type I, Protein with a single pass through the RBC lipid bilayer with its amino terminus to the outside of the cell; type II = Protein with a single pass through the RBC lipid bilayer with its amino terminus to the inside of the cell.

Table 143–2 Blood Groups, Function and Disease Association

Function	System Name	Present in Other Tissue	Null Phenotype	Disease Association
Structure				
Interacts with protein 4.1 and p55	Gerbich	Fetal liver, renal endothelium	Leach	Hereditary elliptocytosis, hemolytic anemia; decreased protein 4.1 and p55 *Plasmodium falciparum*[96]
Structure and Transport				
Anion transport	Diego	Granulocytes, kidney: intercalated cells of distal and collecting tubules	1 case: transfusion dependent	Southeast Asian ovalocytosis, hereditary spherocytosis, renal tubular acidosis
Transport; possible neurotransmitter	Kx	Fetal liver, adult skeletal muscle, brain, pancreas, heart	McLeod	Acanthocytosis, muscular dystrophy, hemolytic anemia; McLeod syndrome sometimes associated with CGD
Possible structural function	Rh	No	Rh_{null}	Hemolytic anemia; hereditary stomatocytosis–Rh_{null} syndrome; reduced expression and mosaicism; hematological malignancies
Ammonia Transport	RhAG	Homologs in kidney, brain, gut, gallbladder, liver, etc.		
Urea transport	Kidd	Vasa recta endothelium Renal medulla	Jk(a–b–)	Impaired urea transport, urine concentrating defect
Water transport	Colton	Kidney, liver, gall bladder, eye, capillary endothelium	Co(a–b–)	Urine concentrating defect
Glycerol/water/urea transport	GIL		GIL-negative	
Receptor and adhesion molecules				
Chemokine/*Plasmodium vivax* receptor	Duffy	Endothelial and epithelial cells, Purkinje cells, colon, lung, spleen, thyroid, thymus, kidney	Fy(a–b–): Resistance to *P. vivax*	Receptor for *P. vivax*
Binds hyaluronic acid, mediates adhesion of leukocytes	Indian	Wide tissue distribution	1 case: congenital dyserythropoietic anemia	
Binds laminin	Lutheran	Fetal liver, placenta, arterial walls, BM epithelium	Lu(a–b–) recessive type	Increased expression possibly involved in vasoocclusion in sickle cell disease[83]
Ligand for integrins	Landsteiner-Wiener		LW_{null} also Rh_{null}	Depressed in pregnancy and in some malignant diseases
Possible adhesion	Ok	All cells tested		
Adhesion molecules	Xg	Fibroblasts, fetal liver, spleen, thymus, adrenal, adult BM		
Adhesion molecule. Function in RBCs not known	JMH			Absent from PNH III RBCs
Possible adhesion	Scianna		Sc:–1,–2,–3	See reference 79
Enzymes				
Cleaves big endothelin 3 to ET-3 (a potent vasoconstrictor)	Kell	Bone marrow, fetal liver, testes, brain, lymphoid tissue, heart	K_{null} (K_0)	
Enzymatic (AChE)	Yt	Granulocytes, innervated tissue, including brain and muscle		Absent from PNH III RBCs
Enzymatic (ART4)	Dombrock		Gy(a–)	Absent from PNH III RBCs
Complement				
Part of the complement cascade	Chido/Rodgers	Plasma	C4: deficient RBCs predispose for SLE	Certain phenotypes increased susceptibility to autoimmune conditions and infections
Complement regulation; binds C3b; disassembles C3/C5 convertase	Cromer	Vascular endothelium, Epithelia GI, GU, CNS. Soluble form in plasma and urine	*Inab*	Absent from PNH III RBCs; Dr^a is the receptor for uropathogenic *Escherichia coli*
Complement regulation; binds C3B and C4b; mediates phagocytosis	Knops	Blood cells, glomerular podocytes, follicular dendritic cells	No case reported	Antigens depressed in certain autoimmune and malignant conditions

Table 143–2 Blood Groups, Function and Disease Association—cont'd

Function	System Name	Present in Other Tissue	Null Phenotype	Disease Association
Other				
	ABO	Epithelial cells, secretions, ectoderm, and endoderm	Group O	Altered expression in some hematological disorders: leukemia
	H	Broad distribution soluble: all fluids except CSF in secretors	Bombay (O_h)	Decreased in some tumour cells; increased in hematopoietic stress
	Lewis	Blood cells, GI, skeletal muscle, kidney, adrenal	Le(a–b–)	Increased expression in fucosidosis
Glycosylation	I	Broad tissue distribution	i	Cataracts in Asians
	GLOB	Blood cells; soluble form in cyst fluid	P^k and p	Receptor *E. coli* and Parvovirus B19
Carrier of negative charge on sialic acid; complement regulation; receptor for microbes	MNS		M^k M^k lack GPA and GPB En(a–) lack GPA S–s–U: lack GPB	Decreased *P. falciparum* invasion; may be receptor for *E. coli*

CGD, chronic granulomatous disease; CNS, central nervous system; GI, gastrointestinal; GL, glycolipid; GP, glycoprotein; GU, genitourinary; IgSF = immunoglobulin super family; PNH, paroxysmal nocturnal hemoglobinuria; RBC, red blood cell; BM = bone marrow.

Table 143–3 Uses of DNA-Based Assays in the Clinical Laboratory

Type patients who have been recently transfused
Identify a fetus at risk for hemolytic disease of the newborn
Type RBCs coated with immunoglobulin
Type patients with AIHA to select antigen-negative RBCs for absorption of autoantibodies when searching for underlying alloantibodies
Type donors, including mass screening for antigen-negative donors, when appropriate antisera are not readily available
Type donors for antibody screening cells and identification panels
Determine which phenotypically antigen-negative patients can receive antigen-positive RBCs without being immunized
Type patients who have an antigen that is expressed weakly on RBCs
Identify partial D
Resolve blood group A, B, and Rh discrepancies
Determine *RHD* zygosity

AIHA, autoimmune hemolytic anemia; RBC, red blood cell.

other antigens (eg, in Rh, Kell, Duffy, and Kidd systems) are proteins and are detected by the antiglobulin test, which detects IgG antibodies and/or complement on the RBCs. The *indirect* antiglobulin test (IAT) is used to detect RBCs sensitized in vitro, such as antibody detection and identification, antigen typing, and crossmatching. The *direct* antiglobulin test (DAT) is used to detect RBCs sensitized in vivo such as alloantibodies in transfusion reactions or HDN, and autoantibodies in warm autoimmune hemolytic anemia or cold hemagglutinin disease.

Compatibility Procedures and Location of Antigen-Negative Blood

In most countries, a blood sample from a prospective recipient is tested for ABO, D, and detection of unexpected (ie, other than anti-A and anti-B) blood group antibodies. Blood typing problems should be resolved and when antibodies are detected they should be identified. Once a patient is actively immunized to an RBC antigen and produces a clinically significant alloantibody, the patient is considered immunized for life and should be transfused with antigen-negative RBCs, even if the antibody is no longer detectable. Patients with passively acquired antibody (eg, neonates, recipients of plasma and platelet products, Rh immune globulin, intravenous immune globulin) must be transfused with antigen-negative RBCs only while the passive antibody is present. Knowing the specificity of an antibody helps establish whether it is likely to be clinically significant and determine the approach necessary to provide an adequate supply of compatible blood. Selection of blood for transfusion to patients with blood group alloantibodies is the joint responsibility of staff at the hospital and donor blood center. The transfusion service staff are a vital conduit for communication between the patient's physician and/or consultant hematologist and the donor center staff to determine the predicted immediate and on-going transfusion needs of the patient and to ensure that antigen-negative blood is available for the patient as appropriate. To some extent selection of antigen-negative blood depends on the urgency of the transfusion.

Transfusion management of patients who require chronic transfusion therapy, in particular patients with sickle cell anemia, has been the subject of much debate.[12,13] Some programs attempt to prevent alloimmunization by prophylactic transfusion of blood that is antigen-matched for D, C, E, and K or for many additional antigens (Table 143–5). There is no consensus at present as to the best approach, but the goal is to provide blood that will survive maximally.

It is important not to delay surgery or transfusion unnecessarily by attempting to obtain antigen-negative RBCs for patients with antibodies that are not clinically significant. Also, in hemolytic anemia caused by warm-reactive autoantibodies, compatibility may be difficult to demonstrate. In this scenario, the important issue is to be sure that there are no clinically significant alloantibodies underlying the warm reactive autoantibodies (see box on "Laboratory Methods for Detecting Blood Group Antigens and Antibodies").

Disease Association

The absence of some blood group antigens and their carrier molecules can result in disease. For example, an absence of the Rh proteins causes stomatocytosis and compensated hemolytic anemia (Rh_{null} syn-

Table 143–4 Characteristics of Some Blood Group Alloantibodies (the Antibodies Are Listed in Approximate Order of Clinical Significance)

			Clinical	
Antibody specificity	**IgM (Direct)**	**IgG (Indirect)**	***Transfusion Reaction***	***HDN***

Xg^a	Rare	Most	None	None

HDN, hemolytic disease of the newborn.
*Most examples of these antibodies are both IgM and IgG.
**Seldom hemolysis of fetal cells but high incidence of recurrent spontaneous abortions.

Table 143–5 Approaches to Supplying RBC Products to Sickle Cell or Other Transfusion-Dependent Patients

Provide antigen-negative blood after the patient has made the corresponding alloantibody
Provide phenotype-matched blood after the patient makes the first antibody
Provide blood matched for D, C, E, and K antigens
Provide blood matched for D, C, E, c, e, K, Fy^a, Fy^b, Jk^a, and Jk^b antigens
Provide completely phenotyped RBC products including antigens such as U, Js^b, and hr^B

RBC, red blood cell.

drome), whereas an absence of Xk protein causes the McLeod syndrome. RBCs and white blood cells from patients with leukocyte adhesion deficiency II (also known as congenital disorder of glycosylation type II) lack antigens that depend on fucose. Thus, the RBCs have the Bombay, Le(a–b–) phenotype and the white blood cells lack sialy-Le^x, which explains the high white blood cell count and infections in these patients.[14,15] Hemagglutination is a simple test that can be used to diagnose these three syndromes.

In patients with paroxysmal nocturnal hemoglobinuria, a proportion of the RBCs will lack antigens carried on GPI-linked proteins. Other associations between blood group antigens and diseases are summarized in Table 143–2. Diseases associated with antibodies to blood group antigens include hemolytic disease of the newborn, warm autoimmune hemolytic anemia, cold hemagglutinin disease, and paroxysmal cold hemoglobinuria. Hemagglutination is a valuable aid in diagnosis of these conditions.

Blood Group Systems

Presented here is a brief description of the most clinically relevant blood group systems in approximate order of clinical significance. Information about these and other blood group systems is given in Table 143–1, Table 143–2, and Table 143–4. For further information and prevalence of blood group antigens in different populations, the interested reader is referred to specialized texts such as *Human*

Laboratory Methods for Detecting Blood Group Antigens and Antibodies

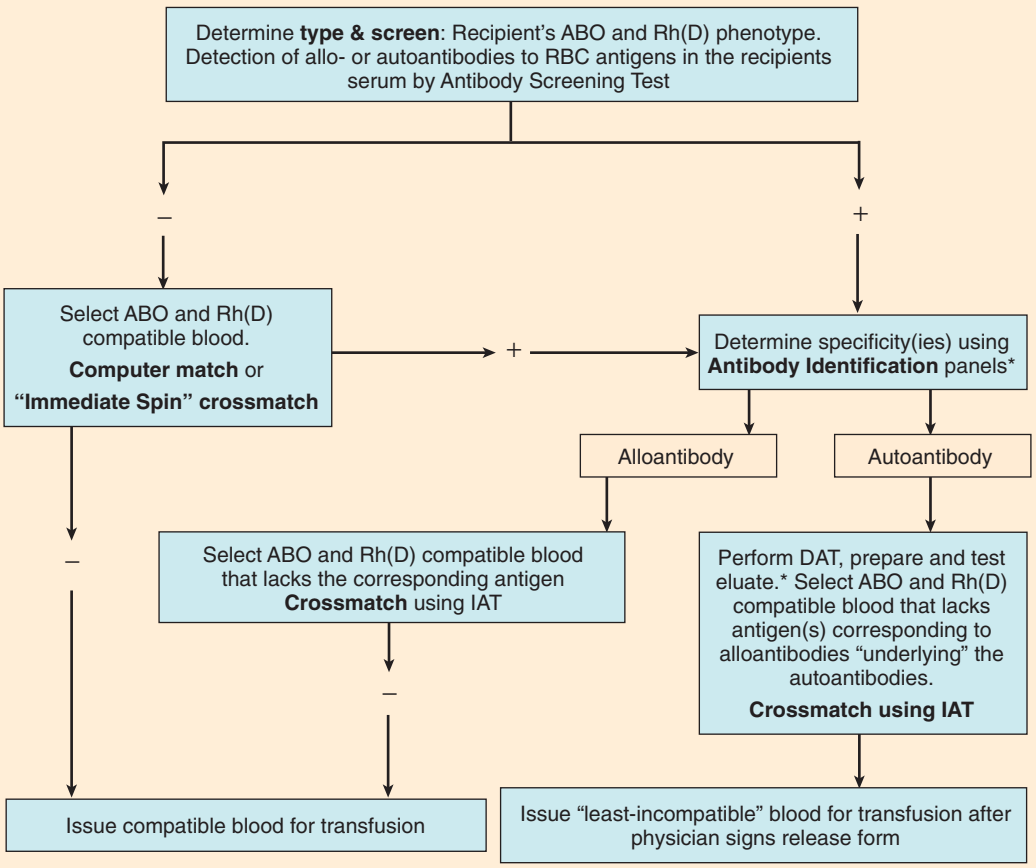
Manual or gel-column methods based on agglutination of red blood cells (RBCs) are still the most common serologic assays performed in transfusion medicine laboratories. Automated assays based on agglutination, and automated solid-phase adherence assays are primarily used in large centers.

The serologic behavior of RBC antibodies primarily reflects the immunoglobulin isotype, but is also influenced by the target antigen copy number. Most antibodies to carbohydrate antigens such as those in the ABO, Lewis, and P blood group systems are naturally occurring and are of the IgM isotype. These multivalent antibodies optimally bind and directly agglutinate to RBCs at temperatures less than 37°C (98.6°F). In contrast, antibodies occurring following immunization to protein antigens such as those in the Rh, Kell, Kidd, and Duffy blood group systems are of the IgG isotype. These bivalent antibodies optimally bind to, but do not directly agglutinate, RBCs at 37°C (98.6°F). The addition of an antiglobulin reagent (ie, rabbit antihuman IgG; Coombs serum) is required to induce RBC agglutination.

Blood Group Typing

ABO

Commercially available human polyclonal and mouse monoclonal anti-A and anti-B are used to determine the ABO type of patient and donor, and these reagents directly agglutinate RBCs at room temperature. To confirm a patient's ABO type, the serum is tested for the presence of the corresponding agglutinins by testing with commercially available group A and group B RBCs. In both cases, hemagglutination is macroscopically visible, and an antiglobulin reagent is not required.



Rh

Patient and donor RBCs are routinely tested for the presence of the D antigen in the Rh system. Reagents containing monoclonal anti-D that directly agglutinate D-positive RBCs (designated Rh positive) suspended in saline at room temperature are commonly used for patient testing. Testing for expression of a weak D antigen on RBCs is required for donor units.

Identification of Serum Alloantibodies or Autoantibodies

Most alloantibodies in patient sera are of the IgG isotype and do not directly agglutinate antigen-positive RBCs. Thus, the most common assay used to detect these antibodies is the indirect antiglobulin test (IAT), formerly known as the indirect Coombs test. In this assay (*antibody screening*), patient serum is incubated at 37°C (98.6°F) with commercially available reagent RBCs of known antigen type. After incubation unbound antibodies are removed from the RBCs by washing with saline; and an antiglobulin reagent containing either rabbit antihuman IgG, or a mixture of rabbit antihuman IgG and murine monoclonal antihuman complement, is added. If the RBCs are agglutinated, this indicates the presence of an alloantibody, an autoantibody, or both. The distinction between alloantibody and autoantibody and the determination of the specificity of the alloantibody are determined by testing the serum against a panel of different

Pretransfusion Compatibility Testing

*When mixtures of antibodies or an antibody to a high prevalence antigen is present, the sample should be referred to a Reference Laboratory.

Laboratory Methods for Detecting Blood Group Antigens and Antibodies—cont'd

reagent RBCs (usually 10) varying in antigen phenotype (*antibody identification*). Agglutination of all panel cells suggests the presence of an antibody to a high prevalence antigen or of an autoantibody; differential reactivity suggests the presence of an alloantibody or antibodies to a specific RBC antigen.

The IAT is also used to crossmatch donor blood for transfusion. Patient serum is tested against RBCs from a donor with a compatible ABO and D (not necessarily identical) antigen type. A positive reaction indicates the probable presence of an alloantibody in the recipient directed against a donor RBC antigen. The specificity of this alloantibody can be determined by testing panel cells as discussed above.

Detection of RBC Coated in Vivo With Immunoglobulin and Complement (DAT)

The direct antiglobulin test (DAT), formerly known as the direct Coombs' test, detects the presence of antibody or complement (or both) on the surface of RBCs. This technique is used in the analysis of delayed hemolytic transfusion reactions, testing for hemolytic disease of the newborn, and the evaluation of patients with suspected autoimmune hemolytic anemia. Patient RBCs obtained in ethylenediaminetetraacetic acid (EDTA) are washed with saline and then incubated with a commercially available antiglobulin reagent containing either anti-human IgG or a mixture of anti-human IgG and anti-human complement. The test is positive if agglutination is seen after the addition of the antiglobulin reagent. Antiglobulin reagents containing anti-IgM or anti-IgA are available in specialized centers to detect coating of RBCs *in vivo* by antibodies of these isotypes.

Blood Groups, The Blood Group Antigen FactsBook, and AABB *Technical Manual.*[2,5,6]

Carbohydrate Blood Groups

ABO and Hh

The ABO blood group system is by far the most clinically significant, because of the presence of naturally occurring IgM antibodies (and sometimes IgG). The original observation by Landsteiner that certain human erythrocyte suspensions were agglutinated other human sera, led to the recognition of ABO polymorphism. This initial observation is still the cornerstone of modern transfusion practice more than a century later.

Antigens and Their Synthesis

ABH antigens occur on glycoproteins and glycolipids and are synthesized in a stepwise fashion by glycosyltransferases that sequentially add specific monosaccharides in specific linkages to a growing oligosaccharide precursor chain (reviewed in Clausen and Hakomori[16]). The terminal sugar determines antigen specificity (Fig. 143–1). The precursor substrate for A and B antigens is the H antigen, the terminal sugar of which is fucose added by fucosyltransferases encoded by the *FUT1* gene. The A and B transferase enzymes differ only by the nature of the monosaccharide added to the chain. *N*-acetyl-D-galactosamine is added by A-transferase, and D-galactose by B-transferase. In clinical practice, four ABO phenotypes (A, B, O, and AB) are discriminated. In addition, two common variations of group A, A_1, and A_2, can be distinguished. The differences between A_1 and A_2 phenotypes are both quantitative and qualitative. The A_1 transferase is more efficient in converting H to A antigen (approximately 5 times more A sites per RBC on A_1 RBCs than on A_2 RBCs) and in addition has the capacity to make the A_1 antigen the repetitive A epitope.[17] Quantitatively normal ABH expression also requires the branching of carbohydrate chains, which is performed by the blood group I enzyme, a 6-β-*N*-acetylglucosaminyltransferase.

Some H antigen precursor remains on A and B RBCs in this order: $A_2 > B > A_2B > A_1 > A_1B$. In addition to expression on cells of ectodermal and mesodermal origin (eg, RBC), some individuals also express ABH antigens in cells of endodermal origin (eg, secretions and plasma). This is caused by the activity of another fucosyltransferase (Secretor or Se transferase), encoded by *FUT2*, which has similar properties but different tissue expression compared to *FUT1* (H transferase). Approximately 20% of the population are nonsecretors and lack FUT2 activity.[18]

Inherited and Acquired ABH Variants

In addition to the main ABO blood types, there are many other inherited phenotypes, which have a weaker expression of the specified antigen, eg, A_3, A_x, A_{el}, B_3, B(A), and cisAB.[6,19] This can cause problems in determining the ABO blood group; but for patients needing immediate transfusion, the selection of O red cells and AB plasma products are an option. In blood donors, if weak expression of A or B antigens is not detected, the major risk is if the red cells are transfused to a patient whose antibodies may cause accelerated destruction of the transfused cells.

Rare *Bombay* phenotype RBCs (first reported in Bombay, India) lack H antigen, and consequently, A and B antigens. Other variants with weak H expression on RBCs, with or without H in secretions, also occur (para-Bombay) and have been reviewed by Oriol.[18]

Acquired B antigen results from the action of bacterial deacetylase, an enzyme that can remove an acetyl group from the A-terminal sugar, *N*-acetylgalactosamine. Galactosamine is similar to galactose, the B-specific terminal residue, and anti-B reagents can crossreact with the deacetylated structure.[20] Acquired B can occur in individuals suffering from gram-negative infections of gastrointestinal origin or carcinoma. The clinical significance is that AB blood may be transfused, sometimes with fatal outcome.[21] Other polyagglutinable states exist (eg, T, Tn, Tk) that are detected by naturally occurring antibodies found in the serum of most people, which can be identified by a panel of lectins.

A or B antigen expression can weaken in patients with acute leukemia or stress hematopoiesis. Chromosomal deletions or lesions that involve the *ABO* locus can result in the loss of transferase expression in the leukemic cell population. A decrease in A or B antigen expression, when found without a hematological disorder, can be prognostic of a pre-leukemic state.

Genes

The *ABO* gene was cloned in 1990 following purification of A transferase.[22,23] There are only four amino acid differences between A and B transferases in the catalytic domain, two of which (Leu266Met and Gly268Ala) are primarily responsible for the substrate specificity.[24] The group O phenotype results from mutations in A or B alleles that cause a loss of glycosyltransferase activity. The most common group O (O_1) results from a single nucleotide deletion near the 5′ end of

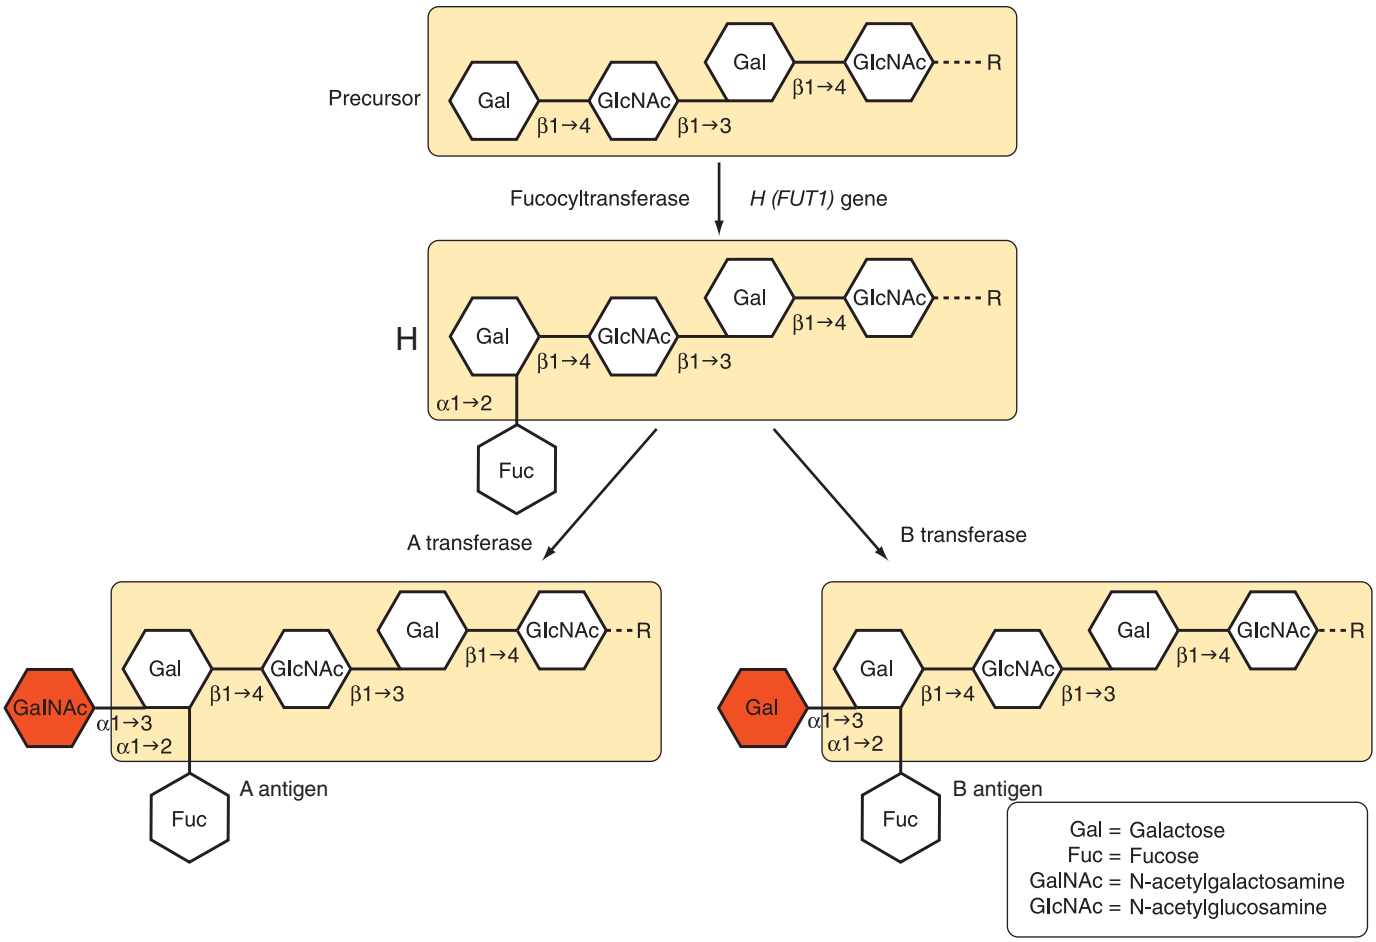


Figure 143–1 Biochemical structures of ABH antigens. Schematic representation of the terminal portions of the carbohydrate structures carrying the H, A, and B antigens on red blood cells.

the gene that causes a frameshift and early termination with no active enzyme production.[25] The *ABO* gene has seven exons and A or B subgroups (with few exceptions) result from a variety of mutations in exon 7 that cause alterations in the catalytic domain of the glycosyltransferase.[26] The rare B(A) and *cis*-AB phenotypes express both A and B from a single allele caused by variant glycosyltransferases that have a combination of A- and B-specific residues. Numerous common and rare *ABO* alleles have been reported and current information is available on the blood group antigen gene mutation database Web site (www.ncbi.nlm.nih.gov/projects/mhc/xslcgi.fcgi?cmd=bgmut/home). In addition to single-point mutations, recombination and gene conversion events between common alleles can result in hybrids with unexpected transferase activity. This makes genomic typing of ABO difficult.[27]

The fucosyltransferase enzymes required for H synthesis are encoded by two closely linked genes on chromosome 19, *FUT1* (or *H*) and *FUT2 (*or *Se* for *secretor)* with differential substrate and expression in tissues.[18] Homozygosity for defective *FUT2* alleles is responsible for the nonsecretor phenotype in which A, B, and/or H antigen are not present in secretions. Individuals homozygous for null alleles at both the *FUT1* and *FUT2* loci have the Bombay phenotype.[28,29]

Transplantation

As tissue antigens, ABH are important in solid organ transplantation. Recipient antibodies react with antigens on the transplanted organ and complement activation at the surface of endothelial cells can result in rapid destruction and hyperacute rejection.[30] However, successful transplantation across ABO barriers is possible, particularly with blood group A_2 to O, and with current immunosuppressive and pretreatment regiments including removal of ABO antibodies.[31] Allogeneic bone marrow transplantations are routinely performed irrespective of ABO compatibility, but occasionally initial hemolysis or pure red cell anemia can result because of persisting anti-A or anti-B titers in the recipient.

ABO Antibodies

Anti-A and anti-B are found in the sera of individuals who lack the corresponding antigens. They are produced in response to environmental stimulants, such as bacteria, and have therefore been termed *naturally occurring* antibodies.[32] These antibodies are produced after birth, reaching a peak at 5 to 10 years of age, and declining with increasing age. The antibodies are mostly IgM and can activate complement, which, in conjunction with the high density of ABO antigen sites on RBCs, are responsible for the severe, life-threatening transfusion reactions that may result following ABO-incompatible transfusions. In contrast, HDN caused by ABO antibodies is usually mild because, (a) placental transfer is limited to the fraction of IgG anti-A and anti-B found in maternal serum, (b) ABH antigens are not fully developed on fetal RBCs because of lack of fully branched carbohydrate chains, and (c) tissue ABH antigens provide additional targets for the antibodies. ABO HDN is most often seen in non–group O infants of non-white group O mothers.

Platelets have intrinsic A, B, and H antigens, and thus ABO incompatibility can compromise the outcome in platelet transfusions.[33] However, platelets from donors with an A_2 phenotype lack both A and H antigens. Approximately 20% of group A platelets would be from A_2 donors and would be appropriate for *universal* use.

Platelets from A_2 donors may also be a superior product for patients undergoing A/O major mismatch allogeneic progenitor cell transplantation.[34]

Potent anti-H (along with anti-A and anti-B) found in O_h (Bombay) or para-Bombay nonsecretors will destroy transfused RBCs of any ABO group, so these individuals must be transfused only with blood of the Bombay phenotype. In contrast, anti-H in non-Bombay individuals including those with low expression of H antigen, notably A_1B and A_1, is usually IgM, reacts only at lower temperatures and is, therefore, clinically insignificant.[6]

Other Carbohydrate Blood Group Systems

In addition to the ABO and H blood group systems, several other antigens of carbohydrate nature are known. As for all glycoconjugate structures, sequential enzymatic action is required to build the antigenic epitopes and the genetic background of all these involves different glycosyltransferase loci.

The *null* p, P_2^k and P_1^k phenotypes are of clinical interest because of potent naturally occurring antibodies that are present in plasma of individuals whose RBCs lack the glycolipid-based antigens P1/P/P^k, P1/P or P, respectively. In analogy with the ABO blood group system, antibodies of IgM and IgG class (anti-PP1P^k, anti-P1P, or anti-P) are made against the missing antigens. Although the incidence of the null phenotypes is only 5 to 10 per million, they have attracted considerable interest because of their relationship to disease and as receptors for pathogens.

Women with p and P^k phenotypes suffer a high incidence of spontaneous abortion, a phenomenon most likely caused by attack of the placenta by anti-P. Anti-P and anti-P^k cause hemolytic transfusion reactions if antigen-positive blood is transfused. Transient auto–anti-P, produced following a viral infection, causes paroxysmal cold hemoglobinuria and lysis of P-positive RBC. P antigen (also known as globoside) is the cellular receptor for parvo-B19 virus that causes *Erythema infectiosum* (fifth disease) in children, sometimes complicated by severe aplastic anemia caused by lysis of early erythroid precursors. P-fimbriated *Escherichia coli* express both P- and P^k-binding molecules at the tips of their pili, a finding with implications for uropathogenicity. Individuals lacking P, or P^k and P, appear naturally resistant to these bacterial and viral infections. In contrast to anti-P and anti-P^k, it should be noted that anti-P1 is a cold-reactive agglutinin that seldom has clinical importance.[35]

Lewis antigens are fucosylated glycolipids synthesized by nonerythroid cells, circulate in plasma, and are passively adsorbed onto RBC.[36] Antibodies to Lewis can be made by people homozygous for nonfunctional 4-α-fucosyltransferases encoded by the FUT3 gene. The Le^a and Le^b antigens are not antithetical and in clinical practice only Le(a–b–) people make anti-Le^a or anti-Le^b. These antibodies are of IgM class and seldom cause any clinical problems.[6]

The i and I antigens are nonterminal epitopes on linear and branched carbohydrate structures, respectively, carrying ABH antigens in their terminal ends. During the first years of life, linear chains are modified into branched chains, resulting in the appearance of I antigens.[37] The i phenotype is rare among adults but is the normal state on RBCs from fetuses and infants. The gene encoding the I-branching β-1,6-*N*-acetylglucosaminyltransferase (IGnT) has three alternative forms of exon 1 with common exons 2 and 3. Mutations in exon 2 or exon 3 silence IGnT and give rise to the form of the i phenotype that is associated with cataracts in Asians.[38,39] Mutations in exon 1C (IGnTC or IGnT3) silence the gene in erythrocytes, but not in other tissues, and lead to the i phenotype without cataracts.[40]

Alloanti-I made by a person with the rare i adult phenotype can be clinically significant and cause destruction of transfused I+ RBCs. The sera of all people contain auto-anti-I that is clinically benign and reactive only at or below room temperature. In contrast, cold hemagglutinin disease is characterized by a high titer of complement-fixing monoclonal anti-I, which cause in vivo hemolysis and hemolytic anemia. The titer and thermal range of anti-I is often increased following infection with *Mycoplasma pneumoniae*. If transfusion cannot be avoided, donor RBCs should be transfused through a blood warmer.[41]

Table 143–6 The Incidence of the Principal Rh Haplotypes

Fisher-Race Haplotype	Modified Weiner Haplotype	Incidence (%)		
		White	*African Black*	*Asian*
Rh-positive

Protein Blood Groups

Rh and LW Blood Group Systems

The Rh system is second only to the ABO system in importance in transfusion medicine. This is because Rh antigens, especially D, are highly immunogenic. Thus, in most countries, blood for transfusion is tested and labeled with the D antigen type (Rh-positive or Rh-negative); and D–recipients are transfused with D–RBC products.

Three systems for naming Rh antigens have been used. Two are shown in Table 143–6, which indicates the incidence of the common Rh haplotypes present in different ethnic groups. The Fisher-Race nomenclature was based on the premise that there were three closely linked genes (D, C/c, and E/e), whereas the Wiener nomenclature (Rh-Hr) was based on his belief that a single gene encoded one *agglutinogen* that carried the factors D, C/c, and E/e. Although neither theory was correct (there are two genes; *RHD* and *RHCE,* correctly proposed by Tippett[42]), for written communication the Fisher-Race designation (CDE) is often preferred, and for spoken communication a modified version of Wiener's nomenclature is preferred. Use of uppercase *R* indicates that D antigen is present and use of a lowercase *r* (or *little r*) indicates that it is absent. The C or c and E or e antigens carried with D are represented by subscripts: 1 for Ce (R_1), 2 for cE (R_2), 0 for ce (R_0), and Z for CE (R_z). The presence of these antigens without D are represented by superscript: *prime* for Ce (r′), *double-prime* for cE (r″), and *y* for CE (r^y). This terminology allows one to convey the common Rh antigens present (the phenotype) with a single term.

The third system uses numerical designations to more accurately represent the serologic data, to be free of genetic interpretation, and to be computer friendly. This numerical nomenclature, with a few exceptions (Rh17, Rh32, Rh33), is not widely used in the clinical laboratory.

Genes, Proteins, Antigens, and Phenotypes

The Rh proteins are designated RhD (encoded by *RHD*), which carries the D antigen, and RhCE (encoded by *RHCE*), which carries the CE antigens (either ce, cE, Ce, or CE). RhD differs from the various forms of RhCE by 32 to 35 amino acids (Fig. 143–2), and both are covalently linked to fatty acids (palmitate) in the lipid bilayer of the RBC. RhD and RhCE form a complex in the RBC membrane

with the RhAG (Rh-associated glycoprotein). Other proteins present in the Rh-complex are CD47 (an integrin-associated protein), LW, glycophorin B, and possibly band 3 (the anion exchanger).[43]

The D-negative (Rh-negative) phenotype is prevalent in whites (15%–17%), less common in African descent (3%–5%), and rare in Asians (<0.1%). The absence of D in Europeans is primarily caused by a deletion of the *RHD* gene. Rare D-negative whites and Asians carry a *RHD* gene that is silenced because of a variety of molecular events. D-negative African blacks have *RHD* genes that either contain a 37-bp duplication that results in a premature stop codon, a hybrid *RHD-CE-D*, or *RHD* deletion.[6] This is important when designing PCR-based methods to predict the D status.

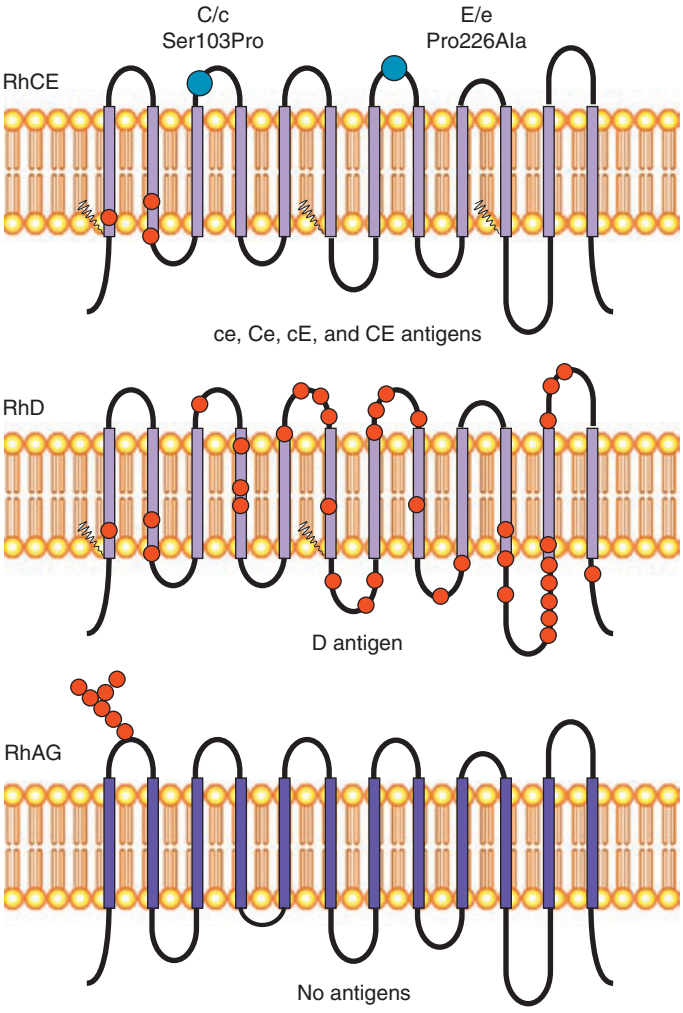

Figure 143–2 Model of Rh proteins RhCE, RhD, and RhAG. The Rh proteins are predicted to have a similar membrane topology. The amino acid differences between RhD and RhCE are shown as **open circles**. Positions 103 and 226, which are critical for C/c and E/e expression, respectively, are indicated as **black circles**.

RBCs with weak D (formerly known as D^u) require the IAT for detection and are caused by amino acid changes predicted to be in the intracellular or transmembrane regions of RhD (Fig. 143–3).[44] Most individuals with a weak D phenotype can safely receive D-positive blood and do not make anti-D.[45]

Partial D antigens (D categories or D mosaics) result from a single point mutation in *RHD* resulting in amino acid changes, which are predicted to be extracellular (see Fig. 143–3), or by replacement of *RHD* nucleotides or exons by the equivalent of part of *RHCE*. RBCs with a partial D antigen may have a strong or weak expression of the D antigen. Because patients with partial D antigens can make anti-D to the D epitopes they lack, they ideally should receive D-negative blood. In practice most type as D-positive and are recognized only after they make anti-D. Future implementation of *RHD* genotyping will help distinguish partial D.[46]

Several phenotypes, including D - -, Dc- and DC^w-, have an enhanced expression of D antigen and no or variant CE antigens. They are caused by replacement of portions of *RHCE* by *RHD*. The RhD sequences in RhCE along with a normal RhD explain the enhanced D and account for the lack, or reduced expression, of CE antigens. Immunized people with these CE depleted phenotypes make anti-Rh17.

C and c antigens differ by four amino acids, but only residue Ser103Pro is predicted to be extracellular. E and e differ by one amino acid, Pro226Ala (see Fig. 143–2). The RhD and various combinations of RhCE proteins (ce, Ce, cE, and CE) depicted in Figure 143–2 are typical for most white transfusion recipients. However, Rh proteins in other ethnic groups often have additional polymorphisms, and this fact often complicates transfusion in patients with sickle cell disease. For example, the RBCs of more than 30% of blacks are VS+ because of a Leu245Val and Gly336Cys substitution in Rhce, and expression of these antigens is associated with variant expression of e. Many other amino acid changes in Rhce, as well as in RhD, are associated with production of Rh antibodies in patients with sickle cell disease.[5,46–48]

The Rh_{null} phenotype is rare and occurs on two genetic backgrounds; the *regulator* type caused by mutations in *RHAG*, which encodes Rh-associated glycoprotein, and the *amorph* type caused by mutations in *RHCE* on a deleted *RHD* background. Rh_{null} RBCs are stomatocytic, fragile, and the patients have anemia, suggesting that the Rh proteins have an important structural role in the erythrocyte membrane.[49]

Antibodies

Most Rh antibodies are IgG and do not activate complement. As a result, primarily extravascular hemolysis, rather than intravascular hemolysis, occurs in transfusion reactions involving Rh antibodies. Rh antibodies are almost always caused by red cell immunization from pregnancy or transfusion, and usually persist for many years.

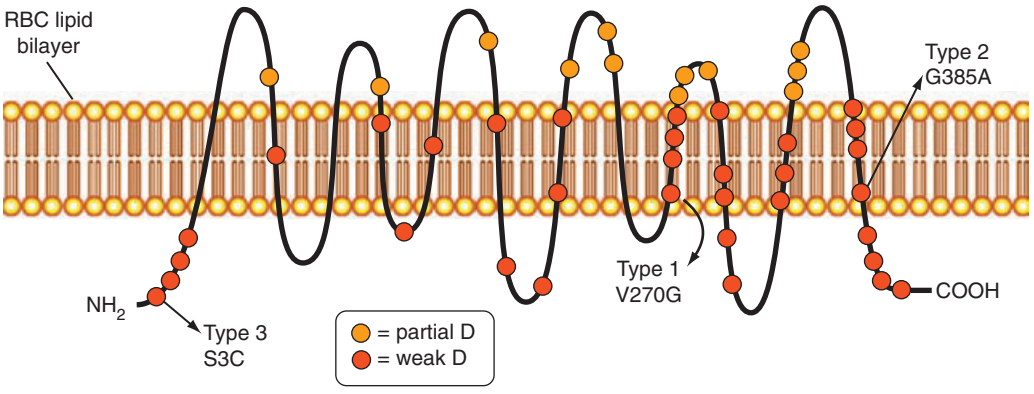

Figure 143–3 Model of weak D and partial D. The predicted location of the amino acid mutations responsible for weak D phenotypes is shown as **black circles**. Type 1, 2, and 3 (shown at the three **arrows**) are found in approximately 90% of weak D phenotypes. The location of amino acid residues responsible for partial D phenotypes is shown as **open circles**.

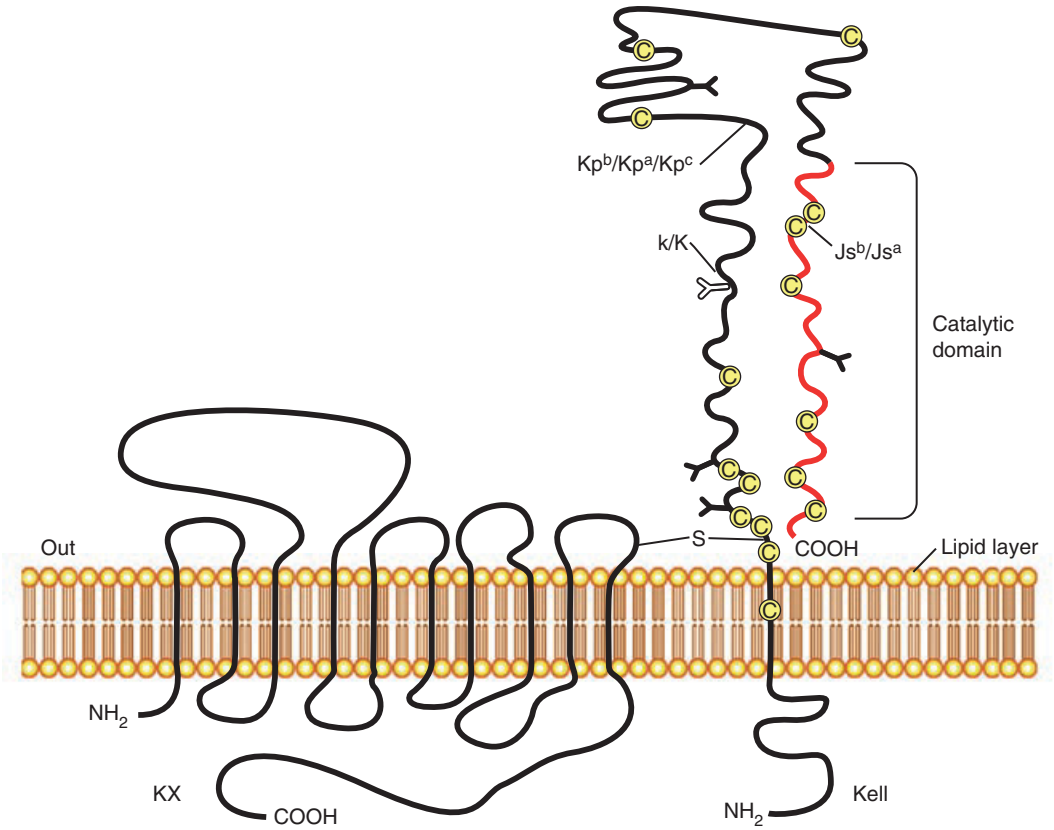

Figure 143–4 Model of Kell and Kx proteins. Kell is a single-pass protein, but Kx is predicted to span the red blood cell membrane 10 times. In the RBC, Kell and Kx are linked by a disulfide bond, shown as **S**, and the locations of the more common Kell antigens are indicated. The N-glycosylation sites are shown as **Y**. The **hollow Y** represents the N-glycosylation site that is not present on the K (K1) protein.

Anti-D can cause severe transfusion reactions and HDN, but the incidence of anti-D has decreased with the prophylactic use of Rh immune globulin. Most Rh antibodies should be considered as having the potential to be clinical significant for HDN and transfusion reactions. If serum antibody levels fall below detectable levels, subsequent exposure to the antigen characteristically produces a rapid secondary immune response.

Autoantibodies to high-prevalence Rh antigens often occur in the sera of patients with warm autoimmune hemolytic anemia as well as in some cases of drug-induced autoimmune hemolytic anemia.[50]

LW Blood Group System

Rh and LW are independent blood group systems but have a phenotypic relationship: In adults, D-positive RBCs have a stronger expression of LW antigen than D-negative RBCs, and anti-LW can be confused with anti-D. Transient loss of LW antigens from RBCs has been described in pregnancy and patients with diseases, particularly Hodgkin disease, lymphoma, leukemia, sarcoma, and other forms of malignancy. Loss of LW antigens is usually associated with the production of antibodies that appear to be alloanti-LW.[51]

Kell and Kx Systems

The Kell protein is highly folded through multiple intrachain disulfide bonds and in the RBC membrane Kell is covalently linked to XK protein (Fig. 143–4). Twenty-seven of the Kell antigens result from a single amino acid substitution in the Kell protein.[52] The K antigen is remarkably immunogenic for only differing from wild-type (k) by one amino acid, and it appears that loss of an N-glycan exposes the peptide, thereby rendering it immunogenic.

Weak expression of Kell antigens can be inherited, or acquired and transient. Inherited weak expression occurs with the K_{mod} phenotype, the McLeod phenotype, when Kp^a is in *cis*, or with the Leach and Gerbich types of Ge-negative phenotypes.[53] Transient depression of Kell system antigens occurs in autoimmune hemolytic anemia, with microbial infections, and in two cases of idiopathic thrombocytopenia purpura.[6] The lack of Kell antigens (the K_0 or K_{null} phenotype) is caused by several different gene defects.[54]

HDN caused by anti-K can result in severe neonatal anemia. Maternal antibody titers and amniotic bilirubin levels are not good predictors of the severity of the disease. Kell antigens are expressed early during erythropoiesis and anti-K has been shown to suppress erythropoiesis in vitro.[55,56] This may explain the low level of bilirubin observed, in the face of neonatal anemia. Other unusual consequences of Kell antibodies include risk of fetal thrombocytopenia and neutropenia.[57,58]

McLeod Syndrome

This rare syndrome is associated with the loss of expression of Kx protein caused by mutations and deletions in the *XK* gene.[59,60] The syndrome, manifest only in males, may be underdiagnosed. The characteristics, which often develop only after the fourth decade of life, are summarized in Table 143–7. Few patients with chronic granulomatous disease also have the McLeod phenotype because of X-chromosome deletions encompassing both genes. Carrier females have two populations of RBCs (one of the McLeod phenotype and one of normal phenotype).

Duffy Blood Group System

The Duffy (FY) glycoprotein (Fig. 143–5) is a promiscuous chemokine receptor found on RBCs and on endothelial cells in the kidney and brain that binds a family of chemotactic and proinflammatory peptides from the CXC (IL-8, MGSA) and the CC (RANTES, MCP-1, MIP-1) classes. The physiological role of FY is unclear, but on RBCs the receptor may allow RBCs to act as scavengers for excess

Table 143–7 Comparison of Characteristics of McLeod Phenotype With Normal and K_0 RBCs

Characteristics	Normal Kell phenotype	K_0 (K_{null}) RBCs	McLeod RBCs
Pathology	None	None	Muscular and neurological defects (with and without CGD)
Creatine kinase level	Normal	Normal	Elevated
Morphology	Discocytes	Discocytes	Acanthocytes
Gene defect	Not applicable	Mutations in *KEL*	Deletions and mutations in *XK*
Kell system antigens	++++	0	Weak
Kx antigen	+	++	0

CGD, chronic granulomatous disease; RBC, red blood cell.
For more information on the McLeod syndrome, see Web site: www.nefo.med.uni-muenchen.de/~adanek/McLeod.html/.

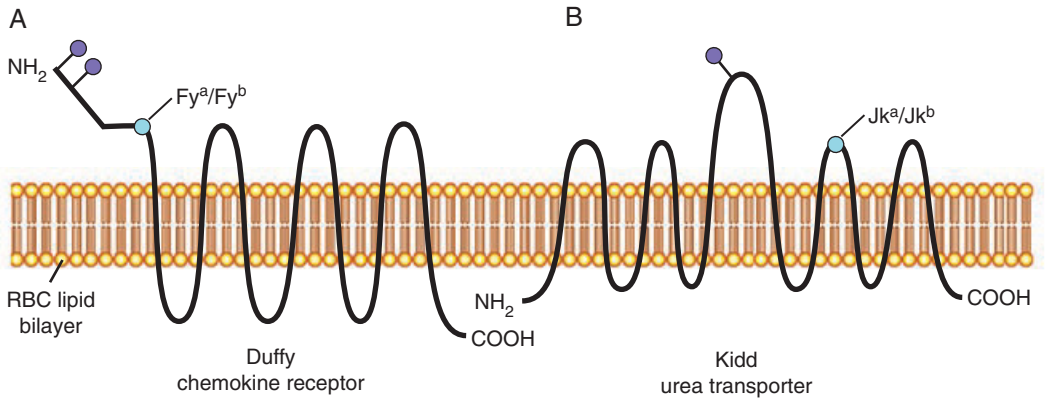

Figure 143–5 Model of Duffy (FY) and Kidd (JK) proteins. **A.** The Duffy glycoprotein is homologous to chemokine receptors and is predicted to have a seven-transmembrane domain structure. The location of the Fy^a/Fy^b polymorphism is shown as an **open circle**, and the glycosylation sites as a **ball and stick**. **B.** Predicted 10-transmembrane domain structure of the Kidd/urea transporter. The location of the polymorphism responsible for the Kidd antigens is shown as an **open circle** and the site for the N-glycan (**ball and stick**) are indicated.

chemokines. FY is also a receptor to which *Plasmodium vivax* merozoites can bind to invade RBC and cause malaria.[61]

Antigens. The Fy^a and Fy^b antigens differ by a single amino acid (Gly42Asp) located on the N-terminal extracellular domain of the FY glycoprotein and is responsible for the common Fy(a+b–), Fy(a–b+), and Fy(a+b+) phenotypes. The null Fy(a–b–) phenotype is rare in most ethnic groups but is common in people of African and Arabian origins. The null phenotype most often results from a mutation in the promoter region of *FYB* that disrupts a binding site for the erythroid transcription factor GATA-1 and results in loss of FY on RBCs.[62] Because the erythroid promoter controls expression only in erythroid cells, FY expression in other tissues is unaffected. All African blacks with a mutated GATA box to date have been shown to carry *FYB* and therefore Fy^b is expressed on nonerythroid tissues. This explains why Fy(a–b–) individuals make anti-Fy^a but not anti-Fy^b. Fy(a–b–) caused by a mutated GATA box on an *FYA* allele has been found in Papua New Guinea, another malaria-endemic region.[63]

Antibodies. FY antigens are much less immunogenic than K; and most antibodies are IgG, subclass IgG1, and arise from stimulation by transfusion. Anti-Fy^b is much less common than anti-Fy^a and the antibodies can cause delayed hemolytic transfusion reactions (DHTR) and rarely HDN. Anti-Fy3 is made by extremely rare Fy(a–b–) individuals who lack FY protein on all cells.

Kidd Blood Group System

The JK blood group molecule (see Fig. 143–5) was implicated in urea transport when RBCs lacking all JK antigens were shown to resist lysis in 2 M urea.[64] The gene encoding a human urea transporter, *HUT11*, was cloned and the protein was shown to express antigens in the Kidd system.[65,66] The JK/HUT11 protein in RBCs and kidney medulla is a constitutive urea transporter. Failure to express Kidd does not result in an overt clinical syndrome; the only observed manifestation is a reduced capacity to concentrate urine.[67]

Antigens. The Jk^a and Jk^b antigens differ by a single amino acid (Asp280Asn)[68] and are responsible for the common Jk(a+b–), Jk(a–b+) and Jk(a+b+) phenotypes. The Jk(a–b–) or Jk_{null} phenotype is rare but occurs with greater incidence in Polynesians, Asians, and Finns. The silent alleles in Polynesians/Asians have splice-site or missense mutations that abolish expression of Jk^b, and large deletions and premature stop codons in *JKA* alleles have been found in rare white Jk_{null} pedigrees.[6]

Antibodies. Neither anti-Jk^a nor anti-Jk^b is common, but JK antibodies are responsible for at least one-third of cases of delayed DHTRs.[41] The antibodies often drop to undetectable levels, or react only with cells that are homozygous for the antigen, and escape detection in the sensitized patient's serum prior to transfusion. JK antibodies only rarely cause HDN; and if they do, typically, it is not severe. Anti-Jk3, sometimes referred to as anti-Jk^{ab}, is produced by Jk(a–b–) individuals and reacts with Jk(a+) and Jk(b+) RBCs and rare donor components must be located for transfusion.

MNS System

M and N antigens are carried on alternative forms of glycophorin A (GPA), whereas S and s antigens are carried on alternative forms of glycophorin B (GPB). M/N and S/s are homologous proteins encoded by adjacent genes, and therefore, show linkage disequilibrium in inheritance of the antigens. The MNS system is highly polymorphic

and most of the 46 antigens are the result of amino acid substitutions or rearrangements between *GYPA* and *GYPB*.[69] Persons who are S-s-, usually blacks, may lack the high incidence antigen, U, caused by a deletion of *GYPB* or express U weakly due to an altered form of *GYPB*.[69,70]

Antibodies. Anti-S, -s, and -U are usually IgG and can be clinically significant antibodies. Anti-M and anti-N are usually naturally occurring, reactive at room temperature or below, and often clinically insignificant. Anti-En^a is an umbrella term for immune antibodies that react with determinants on GPA.

Other Protein Antigens. Antibodies to antigens in these systems are less common than those described earlier in this chapter. Information regarding their general clinical significance is summarized it Table 143–4.

The Lutheran System

Lutheran (LU), along with *Secretor,* provided the first example of autosomal linkage in humans, the first example of autosomal crossing over, and the first indication that crossing over in humans is more common in females than in males.[71,72] The Lutheran system consists of four antithetical pairs of antigens and 10 independent high-prevalence antigens.

Antibodies. Antibodies in this system are rarely encountered because the antigens are not highly immunogenic. They are usually IgG and give characteristic agglutinates surrounded by unagglutinated RBCs. They can cause mild transfusion reactions but do not typically cause HDN. Anti-LU3 is found in the serum of immunized people of the rare recessive LU(a–b–) phenotype, and the antibody is usually IgG and may cause a delayed transfusion reaction or HDN. Blood with the LU(a–b–) phenotype should be used for transfusion of patients with these antibodies.

Diego System

The Diego blood group antigens are on Band 3, the red cell anion exchanger (AE1), and the N-glycan on AE1 carries most red cell A, B, H, I, and i blood group activity. The Di^b antigen has a prevalence of greater than 99.9%. The Di^a antigen is rare in most populations, with the exception of South American Indians where Di^a occurs in 54%, and approximately 12% of Native Americans are Di(a+).[73]

Antibodies. Diego antibodies are usually IgG and do not bind complement. These antibodies have caused transfusion reactions (usually delayed) and HDN.

Yt Blood Group System

The Yt system was named in 1956 when and antibody was found in the serum of patient whose last name was Cartwright. Yt^a occurs with a prevalence of more than 99% in random blood samples; and Yt^b is found with a prevalence of approximately 8%, with the exception of Israelis where it has a prevalence of 20% or higher.[74]

Antibodies. Yt antibodies usually are IgG and do not bind complement. These antibodies have caused delayed transfusion reactions, but not HDN.

Xg Blood Group System

Xg glycoprotein has 48% identity with CD99 glycoprotein, which has been implicated in cell-to-cell adhesion events, activates a caspase-independent apoptosis pathway in T cells, and is expressed on human RBCs as well as all other human tissue tested.[75,76,77] The gene encoding Xg^a is not subject to X-inactivation caused by the expression of a duplicate gene, *MIC2*, located telomeric and in the pseudoautosomal region of the X chromosome. The difference between Xg(a+) and Xg(a–) is the level of Xg^a antigen on the RBC. The prevalence of Xg^a differs in males (65.6%) and females (88.7%), and there is a phenotypic association between the expression of Xg^a and CD99.[5]

Antibodies. Anti-Xg^a is usually IgG and may bind complement. Some anti-Xg^a are apparently naturally occurring. These antibodies have not caused transfusion reactions or HDN.[5]

Scianna Blood Group System

The Scianna antigens are expressed by the red cell adhesion protein, erythrocyte membrane-associated protein.[78,79] Sc1 is a high-prevalence antigen (prevalence ≈99.9%), and Sc2 is a low-prevalence antigen (1%).

Antibodies. Scianna antibodies are usually IgG and some bind complement. These antibodies have not caused transfusion reactions; and although they have caused cord RBCs to be positive in the DAT, they have not caused HDN. Several examples of autoanti-Sc1 have been reported, some reactive in tests using patient serum but not plasma. Autoanti-Sc3-like antibodies have been described in one patient with lymphoma and in one patient with Hodgkin disease whose RBCs had suppressed Sc antigens.[80]

Dombrock Blood Group System

Dombrock antigens are carried on a GPI-linked glycoprotein that is a member of the mono-ADP-ribosyltransferase family (ART4), but Do has no demonstrable enzyme activity on the RBC. The Dombrock blood group system consists of two antithetical antigens, Do^a and Do^b, and three antigens of high prevalence; Gregory (Gy^a), Holley (Hy), and Joseph, (Jo^a). The Gy(a–) phenotype is the null of the system.

Antibodies. Do^a and Do^b antigens are poor immunogens, and anti-Do^a and anti-Do^b are rarely found as single specificities. Antibodies in the Do system are usually IgG and do not bind complement. These antibodies have caused delayed transfusion reactions and a positive DAT, but no clinical HDN.[9]

Colton Blood Group System

The Colton antigens are carried on aquaporin-1 (AQP-1), the first water channel protein characterized in mammals, and is also found in the kidney.[81] The function of AQP-1 in RBCs may be to rehydrate rapidly after shrinking in the hypertonic environment of the renal medulla.[82] Co^a has a prevalence of 99.9%, its antithetical antigen Co^b has a prevalence of 10%, and Co3 is present on all RBCs except those of the very rare Co(a–b–) null phenotype. Apparently healthy propositi with the Co(a–b–) phenotype and AQP-1 deficiency have RBCs with an 80% reduction in the ability to transport water.[83] The residual water transport in these RBCs may be through another member of the water channel protein family, AQP-3, which transports water, glycerol, and urea, and carries the blood group antigen GIL.[84]

Antibodies. Antibodies in the Colton system are usually IgG and some bind complement. The antibodies have caused delayed transfusion reactions and HDN.[9]

Gerbich Blood Group System

The Gerbich system antigens are carried on glycophorin C (GPC) and glycophorin D. There are three high-prevalence antigens (Ge2, Ge3, and Ge4) and five low-prevalence antigens. The two glycoproteins are products of the *GYPC* gene. The gene consists of four exons and the smaller glycophorin D is generated by the use of an alternative translation initiation site. There are three different molecular bases for the Gerbich null phenotype.[85]

Antibodies. The antibodies may be immune or naturally occurring. Most are IgG and some of these bind complement; some antibodies may be IgM. Although some antibodies have caused delayed transfusion reactions, others have been benign. Clinical HDN has not been reported, but the antibodies have been eluted from cord RBCs that tested positive on DAT. Clinically significant auto–anti-Ge have been reported. Because Ge-negative donors are rare, it is important to test siblings of Ge-negative patients for compatibility, and to urge such patients to donate blood for long-term storage.[9] Antibodies to low-prevalence antigens in the Ge blood group system are rare, and RBCs from almost all random donors are compatible; there is no difficulty in finding blood for transfusion of patients with these antibodies.

Cromer Blood Group System

The Cromer antigens are carried on decay accelerating factor (DAF, CD55), a complement control protein attached to the RBC membrane through GPI-linkage. Cromer is a system of two sets of antithetical antigens, $Tc^a/Tc^b/Tc^c$ and WES^a/WES^b, eleven high-prevalence antigens, and three low-prevalence antigens. The Cr(a–) phenotype is the least rare of the negative phenotypes, and with the exception of one Spanish-American woman, all people with Cr(a–) RBCs are black. Most of the other phenotypes are exceedingly rare.

Antibodies. Antibodies in the Cromer system are usually IgG and do not bind complement. The antibodies have caused mild delayed transfusion reactions but not HDN. When a patient's antibody is directed at a high-prevalence antigen, it is important to test siblings in the quest for compatible blood and to urge the patient to donate blood for long-term storage when clinical status permits.

Knops Blood Group System

The Knops blood group antigens are carried on complement receptor 1 (CR1). Kn^a, Sl^a, and McC^a, antigens are fairly common and have a similar prevalence (>90%) in different populations; however, Sl^a is present on RBCs of 98% of whites, but on only 60% of blacks. Typing for Knops system antigens can be challenging because of the low level of expression on the RBCs, as some disease processes cause CR1 deficiency can lead to false-negative results. RBC CR1 is important in the processing of immune complexes, binding them for transport to the liver and spleen for removal from the circulation. The CR1 copy number per RBC (and thus antigen strength) is reduced in Systemic lupus erythematous (SLE), cold hemagglutinin disease, paroxysmal nocturnal hemoglobinurin (PNH), hemolytic anemia, insulin-dependent diabetes mellitus, AIDS, some malignant tumors, and any condition associated with increased clearance of immune complexes. CR1, and the Sl^a antigen in particular, may act as a receptor for the malarial parasite *Plasmodium falciparum*, and thus, the Sl(a–) phenotype may provide selective advantage.[86]

Antibodies. Antibodies in the Knops system are usually IgG and they do not bind complement. The antibodies do not cause transfusion reactions or HDN, and once identified, they can be ignored for clinical purposes. Identification may be complicated by the fluctuation of antigen expression on RBCs. Anti-Kn^a is the most common antibody in whites, and anti-Sl^a is the most common in African Americans.[19]

Indian Blood Group System

The antigens of the Indian system are carried on CD44.[87] CD44 has a diverse range of biologic functions involving cell–cell and cell–matrix interactions in cells other than RBCs.[87] It is an adhesion molecule in lymphocytes, monocytes, and some tumor cells. CD44 binds to hyaluronate and other components of the extracellular matrix and is also involved in immune stimulation as well as signaling between cells.[88] In^b is a common antigen, and In^a is rare in white persons but has a prevalence of 4% in Indians, 10% in Iranians, and nearly 12% in Arabs.

Antibodies. Antibodies in the Indian system are usually IgG and do not bind complement. Some antibodies may directly agglutinate RBCs, but the reactivity is greatly enhanced by the IAT. These antibodies have caused decreased RBC survival and a positive DAT in the neonate but not HDN. A severe, delayed, hemolytic transfusion reaction caused by anti-In^b has been reported.[89]

Ok Blood Group System

The Ok antigen is carried on CD147, whose function on RBCs is unknown. CD147 on tumor cells is thought to bind an unknown ligand on fibroblasts, which stimulates their production of collagenase and other extracellular matrix metalloproteinases, thus enhancing tumor cell invasion and metastasis.[90] In studies with CD147 knockout mice, RBCs were apparently not compromised. CD147 may be involved in the function of the blood-brain barrier[91] and lymphocyte inactivation.[92] The eight known Ok(a–) probands are Japanese.

Antibodies. The original example of anti-Ok^a is IgG and does not bind complement. This antibody caused reduced red cell survival but not HDN. Only one other example of human anti-Ok^a is known.

RAPH Blood Group System

The MER2 antigen in the RAPH blood group system was originally defined by monoclonal antibodies (1D12, 2F7). It is carried on CD151 (tetraspanin). All three people (two probands) with anti-MER2 had renal failure requiring dialysis, skin lesions, neurosensory deafness, and nail dystrophy.[93,94] Of English blood donors 92% are MER2-positive, and 8% are MER2-negative. The antigen strength varies among different RBC samples.

Antibodies. The three examples of human anti-MER2 (anti-RAPH) are IgG and two of the three antibodies bind complement. These antibodies have not caused HDN or transfusion reactions; indeed, two siblings with the antibody have received numerous crossmatch-incompatible RBC transfusions without problems. The three antibody producers were Indian Jews.[93]

Antigens Adsorbed From Plasma

Chido/Rodgers Blood Group System

Although the Ch and Rg antigens are readily detected on RBCs, they are located on the fourth component of complement (C4), which becomes bound to RBCs from the plasma. In complement activation through the classical pathway, C4 becomes bound to the RBC membrane and undergoes further cleavage; ultimately, a tryptic fragment, C4d, remains on the RBC. This C4d glycoprotein carries the Ch/Rg blood group antigens. The antigens are stable in stored serum or plasma, and the phenotypes of this system are most accurately defined in plasma by hemagglutination inhibition tests.

Antibodies. Antibodies in the Ch/Rg system are usually IgG and do not activate complement and are considered benign and nebulous. There can be considerable variation in the reaction strength obtained with different RBC samples. Although these antibodies do not generally cause transfusion reactions, they have caused anaphylactic reactions.[95] The antibodies have not caused HDN.

FINAL COMMENTS

Over the last decade, as information was gained about the genes encoding the membrane components carrying blood group antigens, it has been possible to determine the function of many of the components, understand the basis of disease associations, and develop DNA-based assays with clinical usefulness. Despite the rapid growth

of knowledge about blood groups, the simple hemagglutination test remains the principle assay for blood grouping and compatibility testing; it also is valuable in aiding in diagnosis. For example, it is used as part of the investigation of hemolytic disease of the newborn, warm autoimmune hemolytic anemia, cold hemagglutinin disease, paroxysmal hemoglobinuria, and paroxysmal nocturnal hemoglobinuria, and it can be used to directly diagnose rare conditions such as the Rh syndrome (by testing and showing that they lack D, C, E, c and e antigens), the McLeod Syndrome (by testing RBCs with anti-Kx and showing they lack Kx antigen), and leukocyte deficiency syndrome II (LADII) (by testing RBCs and showing they lack A, B, H, Le^a and Le^b antigens). DNA-based genotyping assays are an invaluable adjunct to classic hemagglutination but are unlikely to completely replace this simple, effective technique.

CHAPTER 144

HUMAN PLATELET ANTIGENS

Thomas J. Kunicki and Diane J. Nugent

PLATELET MEMBRANE GLYCOPROTEINS

Among the variety of glycoproteins (GPs) on the human platelet surface, there are several that contribute to the immunogenic makeup of the platelet (Table 144–1). Foremost among these are the integrins, which serve important roles in platelet function as receptors for protein components of the extracellular matrix, such as collagen, and/or bind to plasma glycoproteins, such as fibrinogen or von Willebrand factor (VWF). Other immunogenic glycoprotein receptors are unique to the megakaryocyte/platelet lineage, such as the GP Ib-IX-V complex.

INTEGRINS

The integrins are membrane GP heterodimers, each consisting of noncovalently associated α and β subunits.[1] The specificity of an integrin is dictated in large part by the identity of its α subunit, even though ligand binding per se may occur with a significant portion of the β subunit. The number of possible αβ combinations is apparently limited, however, and selective pairing in humans between several α and β subunits has led to the discovery of more than 24 different integrins. These ubiquitous receptors mediate a wide range of cell adhesion events that are important to every fundamental area of human biology, including embryonal development, immunocompetence, wound healing, and hemostasis. Two platelet membrane receptors that figure prominently in the antigenic profile of platelets, the cohesion receptor $\alpha_{IIb}\beta_3$ and the collagen receptor $\alpha_2\beta_1$, belong to the integrin receptor family.

THE PLATELET COHESION RECEPTOR, INTEGRIN $\alpha_{IIb}\beta_3$

The numerically predominant platelet integrin $\alpha_{IIb}\beta_3$ (initially designated GP IIb-IIIa) mediates the common cohesive pathway that results from platelet activation in vivo, that is, platelet aggregation supported by the binding of adhesive proteins, such as fibrinogen and VWF. The α subunit of this integrin, α_{IIb}, is synthesized exclusively by megakaryocytes. Consequently, $\alpha_{IIb}\beta_3$ is a unique marker for platelets or cell lines with a megakaryocytic phenotype. Glanzmann thrombasthenia (GT) is an inherited disorder of platelet function characterized by an inability of platelets to bind fibrinogen and undergo agonist-induced aggregation.[2] The molecular defect in this disease involves either a quantitative or a qualitative abnormality of $\alpha_{IIb}\beta_3$.

THE PLATELET COLLAGEN RECEPTOR, INTEGRIN $\alpha_2\beta_1$

Another integrin that contributes significantly to platelet function is the collagen receptor $\alpha_2\beta_1$ (GPIa-IIa). A high affinity interaction of platelet $\alpha_2\beta_1$ with collagen anchors the platelet more firmly to the matrix, permitting the formation of an activated, procoagulant platelet monolayer.[3] Platelet adhesion in flowing blood mediated by $\alpha_2\beta_1$ is supported by several collagen types, including types I, III, IV, and VI, and the rate of platelet monolayer formation is directly proportional to the platelet $\alpha_2\beta_1$ density.[4] Signal transduction is mediated by both $\alpha_2\beta_1$ and the platelet-specific collagen receptor, GPVI, facilitating and likely accelerating platelet activation and leading to aggregate formation.[5,6] Unlike α_{IIb}, the α_2 subunit is a single chain molecule and, like several other integrin α subunits, contains an additional 129 amino acid segment known as the *I-domain*.[1] Inherited platelet deficiencies of the α_2 subunit have been described, and patients with these deficiencies exhibit chronic mucocutaneous bleeding and prolonged bleeding times.[7,8] The expression of $\alpha_2\beta_1$ on platelets differs markedly between normal subjects and depends on the inheritance of at least three haplotypes of the α_2 gene.[4]

Regulation of $\alpha_2\beta_1$ expression could certainly modulate the antigenicity of this membrane receptor. It is also possible that similar factors influence expression of other platelet integrins, including $\alpha_{IIb}\beta_3$, but the extent to which that occurs remains to be determined. Two other integrins, the fibronectin receptor $\alpha_5\beta_1$,[9] and the laminin receptor $\alpha_6\beta_1$,[10] are expressed by platelets, but neither has yet been shown to contribute significantly to platelet immunogenicity.

THE RECEPTOR COMPLEX GLYCOPROTEIN Ib-IX-V

The pattern of membrane GPs existing as functional complexes is repeated in the case of the nonintegrin adhesion receptor complex Ib-IX-V. The functional complex is actually a heptamer composed of one molecule of GPV associated with two molecules of each of three other gene products, GPIbα, GPbβ, and GPX .[11] With blood flow conditions ranging from low to high shear, the initial *transient* arrest of platelets on collagen requires VWF acting as a bridge between collagen and the GPIb complex.[12] The VWF binding site on the complex is located within the amino-terminal domain of GPIbα.[13] The Bernard-Soulier syndrome (BSS) is an inherited disorder of platelet function characterized by defective platelet adhesion to subendothelium and a quantitative or qualitative defect in the Ib-IX-V complex caused by mutations in genes encoding the GPIbα or the GPIX components.[2]

PLATELET GLYCOLIPIDS

Glycolipids play an important role in the structural and functional characteristics of the platelet membrane, as is true of all cell types. Less is known about platelet glycolipid structure and immunogenicity, compared to our knowledge of the platelet GPs. Several immunogenic glycolipid components of the membrane have been identified (Table 144–2).[14] The predominant glycolipid on human platelets is lactosyl ceramide, representing 64% of the neutral glycolipids. Other neutral glycolipids include trihexosyl ceramide, glycosyl ceramide, and globoside. The principal fatty acids associated with these neutral glycolipids are behenic acid (22:0), arachidic acid (20:0), and lignoceric acid (24:0). Ganglioside I (identified as hematoside or GM3) represents 92% of the acidic glycolipids, ganglioside II represents 5% of the platelet acidic glycolipid composition.

Table 144–1 Functional Properties of Selected Membrane Glycoprotein Complexes

GP	Alternate Names	Receptor Function	Protein Ligands
Ib-IX-V	GPIb complex	Adhesion	VWF
$\alpha_{IIb}\beta_3$	GPIIb-IIIa, CD41/CD61	Adhesion Cohesion	Fibrinogen Fibrinogen Fibronectin Vitronectin VWF
$\alpha_2\beta_1$	GPIa-IIa, VLA-2, CD49b/CD29	Adhesion	Collagen
$\alpha_5\beta_1$	GPIc-IIa, VLA-5, CD49e/CD29	Adhesion	Fibronectin
$\alpha_6\beta_1$	GPIc′-IIa, VLA-6, CD49f/CD29	Adhesion	Laminin

CD, cell differentiation (antigen); GP, glycoprotein; VLA, very late activation (antigen); VWF, von Willebrand factor.

ALLOANTIGENS

The proliferation of serologically defined alloantigens on platelet GPs has led to the development of a consensus nomenclature, in which each of the alloantigens is prefixed as *human platelet antigen* (HPA-).[15] These designations as well as the alternate (original) names are given in Table 144–3. The HPA- nomenclature does not take into consideration linkage between many of these polymorphisms. Particularly in the case of integrin β_3, they are distributed among a limited number of major haplotypes. Two clinically significant syndromes are the direct result of sensitization to platelet-specific alloantigens: neonatal alloimmune thrombocytopenia and posttransfusion purpura.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA AND POSTTRANSFUSION PURPURA

Neonatal Alloimmune Thrombocytopenia Purpura

Neonatal alloimmune thrombocytopenia purpura (NATP) is caused by maternal sensitization to paternal alloantigens on fetal platelets (Table 144–4). A correct diagnosis of NATP must first eliminate other causes of thrombocytopenia that may occur during pregnancy. When severe, NATP may result in intracerebral hemorrhage leading to hydrocephalus and fetal death. Fetal hydrocephalus, unexplained fetal thrombocytopenia with or without anemia, or recurrent miscarriages should be considered as indicators of possible NATP.[16] Multiparous women with a history of at least one incident of NATP should be monitored carefully for subsequent episodes. Postnatal management involves transfusion of compatible platelets, and washed maternal platelets are often used. Antenatal management is controversial but can include a combination of maternal intravenous gamma globulin administration, intrauterine platelet transfusions, and corticosteroid therapy, with simultaneous close monitoring of fetal platelet counts throughout the pregnancy.[16]

The biologic diagnosis is normally made by genotyping of maternal and paternal platelet alloantigens and a serologic search for antibodies in maternal plasma or serum that react with paternal platelets.

It is intriguing that only a fraction of those mothers negative for the platelet antigen in question deliver infants affected with NATP. For example, in Western populations, responsiveness to HPA-1a is most commonly the cause of NATP, yet the frequency of homozygous HPA-1b mothers in the general white population is 2%, and estimates of the incidence of NATP are no greater than 0.05%. A key to understanding this discrepancy lies in the finding that responsiveness to HPA-1a shows an human leukocyte antigen (HLA) restriction.[17] Individuals who are homozygous for Pro_{33} (homozygous HPA-1b) and responsive to the predominant HPA-1a antigen are almost exclusively HLA DRB3*0101[17] or DQB1*02.[18] In the case of DRB3*0101, the calculated risk factor is 141, a risk level equivalent to that of the hallmark of HLA-restriction in autoimmune disease, ankylosing spondylitis and HLA B27.[19] In contrast, responsiveness of homozygous HPA-1a individuals to the HPA-1b allele is not linked to HLA.[19,20] T cells are the likely candidates for providing HLA-restriction in this case, and Maslanka and colleagues[19] provided evidence that in one case of NATP, T cells that share CDR3 (CD) R3 motifs are stimulated by peptides that contain the same Leu_{33} polymorphism that is recognized by anti-HPA-1a alloantibodies.

In five cases of alloimmunization against the less frequent antigen, HPA-6b, there was a clear association between responsiveness and the major histocompatibility complex haplotype DRB1*1501, DQA1*0102, DQB1*0602.[21] This alloimmunization likely involves different HLA class II molecules than those involved in immunization against HPA-1a.

Responsiveness to HPA-1a is not the sole cause of NATP. In a large study of 348 cases of clinically suspected NATP,[22] 78% of serologically confirmed cases were caused by anti-HPA-1a and 19% anti-HPA-5b. All other specificities accounted for no more than 5% of cases. In reports from other laboratories, the association of NATP with other alloantigens, such as HPA-3a, HPA-3b, HPA-1b, or HPA-2b, has been noted but is rare.[23] Obviously, differences in allelic gene frequencies between different racial or ethnic populations have an important affect on the frequency of responsiveness to a particular alloantigen. Table 144–5 summarizes some known variation in allelic gene frequencies between different world populations.[24–31] Thus, in the Japanese population, anti-HPA-1a has never been shown to be involved in NATP, and antibodies specific for HPA-4b play a dominant clinical role.[32] This is probably because the gene frequency for the HPA-1b allele among the Japanese (0.02) is much lower than that found in Western populations (0.15). Conversely, the gene frequency of the HPA-4b allele in Japan (0.0083) is higher than that observed in Western populations (<0.001).

Posttransfusion Purpura

Posttransfusion purpura (PTP) is a rare transfusion reaction that follows 7 to 10 days after an immunogenic blood (platelet) transfusion (see Table 144–4). It most often affects previously nontransfused, multiparous women. As with NATP, there is an increased risk to develop PTP among HLA-DR3–positive individuals, and HPA-1a is the antigen most often implicated (in European white populations).[33,34] High-titered antibodies against HPA-1a are usually detected in the patient's serum. Several cases of PTP associated with antibodies specific for HPA-5a have been reported,[35,36] and antibodies specific for HPA-15a have also been documented.[37] The paradox of PTP is that, although the recipient's platelets do not express the immunogen (typically, HPA-1a), the offending antibodies bind to

and can be eluted from the recipient's platelets. An interesting theory is that, in cases of PTP, a transient loss of tolerance for the immunogen (most often integrin $\alpha_{IIb}\beta_3$) results in autoantibody production.[38] This theory is supported by the finding that recombinant antibodies derived from PTP patients during the acute stage resemble autoantibodies, with a low degree of somatic mutation,[38] and PTP does not reoccur if incompatible platelets are readministered.[39] In this scenario, the allospecific antibodies detected after the acute phase of PTP may not completely explain the pathophysiology of the disorder.

MOLECULAR GENETICS OF PLATELET ALLOANTIGENS

By convention, the designation HPA has been assigned to alloantigen systems in which the precise polymorphism that accounts for the serologic difference between alleles has been identified. Of the sixteen HPA systems defined to date (see Table 144–3), nine are expressed by the integrin β_3 subunit (HPA-1, HPA-4, HPA-6, HPA-7, HPA-8, HPA-10, HPA-11, HPA-14, and HPA-16); two are localized on the integrin α_{IIb} subunit (HPA-3 and HPA-9); two are found on the integrin α_2 subunit (HPA-5 and HPA-13); one is expressed by the GP Ibα (HPA-2); one, by GPIbβ (HPA-12); and the last is located on CD109 (HPA-15).

Table 144–4 Alloimmune Thrombocytopenias

Neonatal Alloimmune Thrombocytopenia
Incidence is 1 per 3000 in a retrospective study and 1 per 2200 births in one prospective study.
Maternal antibodies are produced against paternal antigens on fetal platelets.
Similar to erythroblastosis fetalis, except that 50% of cases occur during first pregnancy.
Most frequently implicated antigens are HPA-1a and HPA-5_α (United States/Europe).
In the case of responsiveness to HPA-1a, there is a high-risk association with HLA DRB3*0101 or DQB1*02.
In the case of responsiveness to HPA-6b, there is an increased association with HLA DRB1*1501, DQA1*0102, or DQB1*0602.
Posttransfusion Purpura
Nearly all reported patients have been women previously sensitized by pregnancy or transfusion (<5% were men).
Thrombocytopenia usually occurs 1 week after transfusion.
Homozygous HPA-1b individuals account for most (>60%) cases.
High-risk association with HLA DRB3*0101 or DQB1*02.
Enigmatically, the recipient's antigen-negative platelets are destroyed by autologous antibody.

HLA, human leukocyte antigen; HPA, human platelet antigen.

HPA-1

The HPA-1 alloantigen system is defined by the Leu^{33}/Pro^{33} polymorphism that is enclosed within a small 13 amino acid loop formed by the pairing of Cys^{26} with Cys^{38}.[40] This region of the molecule is held proximal to the distal cysteine-rich region in the middle of β_3 by a long-range disulfide bond linking Cys^5 and Cys^{435}.[41] The importance of three-dimensional structure imposed by the Cys^{26}-Cys^{38} disulfide bond constraint to expression of the HPA-1 determinants is evidenced by the fact that linear peptides corresponding to the β_3(26–38) sequence are not antigenic[42] and the antigens are not lost following denaturation of β_3 in ionic detergents. However, they are immediately destroyed on subsequent disulfide bond reduction. The complex structure of the β_3 molecule and the sensitivity of the determinants to this structure is the likely explanation for observed heterogeneity in binding properties of anti-HPA-1a alloantibodies.[43] Although all alloantibodies would bind to the denatured molecule or to recombinant amino-terminal segments of the molecule expressed in *Escherichia coli*,[44] a subset of antibodies appear to require presentation of the antigenic loop within a more native environment, such as the nondenatured molecule.[43] Anti–HPA-1a antibodies inhibit clot retraction and platelet aggregation, in the latter case presumably because they block the binding of fibrinogen.[45]

An R93Q mutation in β_3 can also attenuate antibody binding to the HPA-1a epitope,[46] either through conformational changes in the amino terminal region of the β_3 molecule or through an attenuation of the immune processing of that epitope.

Other cells that express β_3, as the beta subunit of the vitronectin receptor, including endothelial cells, fibroblasts, and smooth muscle cells, also express HPA-1 epitopes. This could contribute to the complexity of the clinical symptoms in alloimmune-mediated thrombocytopenia. At this time, little, if anything, is known about the involvement of tissues other than platelets in these conditions.

HPA-2

Two previously described polymorphisms of the Ib-IX-V complex, termed *Ko* and *Sib*, are now known to be reflections of two linked polymorphisms, one of which defines the diallelic system, HPA-2.[47]

Table 144–5 Gene Frequencies of the Major Alloantigenic Alleles in Various World Populations

HPA-	Western	Japanese	Amerindian	Black	Korea	African-American	Finnish	Thai
1a	0.85	0.998	>0.993	0.885	0.995		0.86	>0.998
1b	0.15	0.002	<0.007	0.115	0.005		0.14	<0.002
2a	0.93		0.058	0.852		0.82	0.91	0.917
2b	0.07		0.042	0.148		0.18	0.09	0.083
3a	0.61						0.59	0.37
3b	0.39						0.41	0.63
4a	>0.99	0.989						0.991
4b	<0.01	0.011						0.009
5a	0.89					0.79	0.95	0.973
5b	0.11					0.21	0.05	0.027

In the GP Ibα sequence, a Thr/Met polymorphism at residue 145, is associated with HPA-2a and HPA-2b epitopes, respectively.

HPA-3

The HPA-3 system is associated with an Ile^{843}/Ser^{843} polymorphism of α_{IIb}.[48]

HPA-4

Another diallelic human alloantigen system known as *Pen* (or *Yuk*) is found on β_3 and is associated with an Arg^{185}/Gln^{186} polymorphism.[49] Given the proximity of the Pen polymorphism to the RGD binding domain (residues 109–171) of β_3, it is not surprising that anti–HPA-4a antibodies completely inhibit aggregation of HPA-4a homozygous platelets.[45]

Other cells that express β_3 as the β subunit of the vitronectin receptor, including endothelial cells, fibroblasts, and smooth muscle cells, also express HPA-1 and HPA-4 epitopes.[50] This could contribute to the complexity of the clinical symptoms in patients with alloimmune-mediated thrombocytopenia. At this time, little, if anything, is known about the involvement of tissues other than platelets in these conditions.

HPA-5

The HPA-5 system is located on the integrin subunit α_2.[51] The detection of this system was facilitated by the development of a highly sensitive murine monoclonal antibody-based monoclonal antibody immobilization of platelet antigen assay.[52] Like the preceding alloantigenic systems, the HPA-5 system is diallelic. Roughly 1000 to 2000 copies of α_2 are present on the surface of normal platelets, and each α_2 molecule expresses a single HPA-5 epitope.[53] The integrin α_2 is distributed on a wide variety of cells, but nothing is currently known about the antigenicity of the HPA-5 determinants on receptors expressed by cell types other than platelets.

The density of the $\alpha_2\beta_1$ integrin is known to correlate with the α_2 SNP C807T. However, in a study of 79 HPA-5(a/a) mothers giving birth to HPA-5(a/b) offspring, Panzer and colleagues[54] determined that there was no increased risk of maternal-fetal HPA-5 incompatibility among mothers whose genotype is 807T.

HPA-6

This system, originally defined by the alloantigens Ca^a or Tu^a, is created by the β_3 Arg^{489}/Gln^{489} polymorphism resulting from a G/A substitution at base 1564.[55]

HPA-7 and HPA-8

The alloantigen Mo^a has been localized to β_3.[56,57] The alloantigen Sr^a is classified as a private alloantigen, because it appears to be inherited within a single family or family group but not expressed by the general population. The unique feature of the HPA-8 polymorphism is that it is associated with an Arg^{636}/Cys^{636} substitution and thereby results in an additional unpaired cysteine residue.[56] Since its initial characterization, it has been accepted that all cysteine residues in β_3 are involved in disulfide bridges. Despite the addition of this new sulfhydryl group, the Arg^{636}-containing β_3 subunit still associates with α_{IIb} and contributes to an expressed $\alpha_{IIb}\beta_3$ complex without apparent impairment of function.

The alloantigen system HPA-7 results from a C to G substitution at bp 1267 of β_3 resulting in replacement of Pro^{407} by Ala^{407}.[57] Mo^a is a low-frequency alloantigen and has been detected in only 1 of 450 random donors outside of the initial family of the propositus.

HPA-9

The HPA-9 system, originally named for the alloantigen Max^a, is the second system to be localized to the integrin α_{IIb} subunit. It is defined by the Val^{837}, Met^{837} polymorphism.[58]

HPA-10

This system, initially named *La*, is defined by the β_3 Arg^{62}/Gln^{62} polymorphism.[59]

HPA-11

The private antigen Gro^a is defined by integrin β_3 residue His^{633} (A_{1996}).[60] The corresponding Gro^b allele is defined by the substitution Arg^{633} (G_{1996}).

HPA-12

On GPIbβ, the Glu^{15}/Gly^{15} (A_{141}/G_{141}) dimorphism creates the ly^a and ly^b alleles, respectively.[61] Ly^a (HPA-12a) has been found in 1 of 300 unrelated German donors.

HPA-13

The Sit(a) alloantigen, identified in a single severe case of NATP and present in 1 in 400 German subjects, is defined by integrin α_2 mutation C2531T.[62] This mutation results in a Thr^{799} Ø Met^{799} substitution and results in a modest decrease in platelet response to collagen in vitro.

HPA-14

One case of NATP has been attributed to antibodies specific for Oe^a, and none of 600 unrelated blood donors was found to carry this antigen. Deletion of the β3 residue Lysine[611] is the cause of the expression of Oe^a,[63] and this isoform is in linkage disequilibrium with HPA-1b.

HPA-15

The HPA-15 alloantigenic polymorphism, Gov, is uniquely expressed by a different protein receptor. Kelton and colleagues[64] initially described the Gov system that is now known to be carried by the 175 kd glycosyl phosphatidylinositol-anchored GP CD109. Alloantibodies defining each of two alleles (Gov^a/Gov^b) were detected in two patients who had received multiple platelet transfusions[64] and, more recently, three patients who had developed NATP.[65] An A2108C single nucleotide polymorphism of the CD109 gene, resulting in a Tyr^{703} Ø Ser^{703} substitution, defines the Gov alloantigen system.[66]

ADDITIONAL ALLOANTIGENS

One additional private antigen, Va^a, is associated with the integrin $\alpha_{IIb}\beta_3$, but it has not been determined which subunit bears the determinants.[67] Lastly, the alloantigen Pe^a is expressed by GPIba.[68]

ISOANTIGENS

Isoantibodies are produced against an epitope that is expressed by all normal individuals and is not polymorphic. In the area of human platelet immunology, a classic example of isoimmunization can and

does occur when a patient with an inherited deficiency of a membrane GP has been subjected to multiple platelet transfusions to correct a bleeding diathesis. Such inherited disorders are GT and BSS, wherein the individual either lacks or expresses an altered form of $\alpha_{IIb}\beta_3$ in the case of GT or Ib-IX-V in the case of BSS. Isoantibodies developed by transfused patients do not distinguish any of the allelic forms of the GPs (eg, HPA-3 or HPA-1 alloantigens on $\alpha_{IIb}\beta_3$) but react with the platelets of all normal persons tested. Because the propositus does not express the platelet GP that carries the epitope in question, these antibodies do not bind to their own platelets.

ISOANTIBODIES IN GLANZMANN THROMBASTHENIA

Several cases have been documented in which GT patients have produced antibodies specific for α_{IIb}, β_3, or the $\alpha_{IIb}\beta_3$ complex. Recently, we defined an idiotype (OG) that is associated at high frequency with isoantibodies specific for integrin subunit β_3 generated by GT patients.[69,70] Patient OG suffered from persistent, often serious bleeding episodes as a result of both his GT phenotype and the fact that he had generated a very high-titered IgG isoantibody inhibitor of platelet cohesion.[70] The study of the OG idiotype presented an excellent opportunity to compare and contrast disease-related $\alpha_{IIb}\beta_3$ inhibitors of human origin with other natural or synthetic inhibitors of this integrin receptor. Rabbit polyclonal anti-OG idiotype binds to IgG specific for $\alpha_{IIb}\beta_3$ obtained from eleven nonrelated GT patients, including an unrelated patient ES, studied extensively by Coller and colleagues,[71] who had developed isoantibodies of very similar specificity. Conversely, anti-OG does not recognize $\alpha_{IIb}\beta_3$-specific antibodies produced by other unrelated GT patients, who had developed isoantibodies with specificities distinct from that of the OG isoantibody. Moreover, anti-OG does not recognize $\alpha_{IIb}\beta_3$-specific antibodies developed by any patients with idiopathic thrombocytopenic purpura (ITP) or six representative patients with alloimmune thrombocytopenias; and anti-OG never binds to IgG from any of several nonimmunized control individuals.

Anti-OG binds to selected protein ligands of $\alpha_{IIb}\beta_3$, namely, fibrinogen, vitronectin, and VWF, but not to other known protein ligands, such as fibronectin or type I collagen. The epitope or epitopes recognized by anti-OG on these three adhesive proteins are either very similar or identical, because each protein can inhibit the binding of anti-OG to any of the others. The epitope on fibrinogen recognized by anti-OG resides in the β_3 chain and is likely contained within the first 42 amino acids from the amino-terminus.[72] Because OG IgG inhibits fibrinogen binding to $\alpha_{IIb}\beta_3$, the specificity of the OG idiotype defines a novel binding motif for the integrin $\alpha_{IIb}\beta_3$ that is shared by fibrinogen, vitronectin, and VWF but distinct from previously described RGD-containing sites on the fibrinogen α_{IIb} chain or the fibrinogen β_3 chain carboxyl-terminal decapeptide site. Moskowitz and colleagues[72] have employed specific proteolytic forms of fibrinogen to confirm that the epitope recognized by anti-OG is located within Bβ(1–42). This represents an excellent example of molecular mimicry in which an antigen-selected IgG inhibitor of $\alpha_{IIb}\beta_3$ function shares a novel recognition sequence common to three physiologic protein ligands of that receptor.

ISOANTIBODIES IN BERNARD-SOULIER SYNDROME

Because BSS is less frequently encountered than GT, it follows that isoantibodies produced in conjunction with this syndrome are also less frequently encountered. In the only clear-cut case of such an isoantibody,[73] the isolated IgG impaired both normal platelet adhesion to subendothelial elements and in vitro aggregation in response to ristocetin and bovine factor VIII.

CD36

The frequency of platelet CD36 (GPIV) deficiency, which occurs most often in Asians and blacks, is approximately 4%; and a subset of these individuals is at risk for immunization against CD36.[74] In five cases of neonatal thrombocytopenia, isoantibodies reactive with CD36 were identified in the mothers of the affected infants. Two black mothers were homozygous for a T1264G substitution in the CD36 gene, and a European white mother was homozygous for a novel deletion of exons 1 through 3. These findings and the results of prior reports indicate that isoimmunization against CD36 can cause neonatal isoimmune thrombocytopenia, refractoriness to platelet transfusions, and PTP.[74]

AUTOANTIGENS

Autoimmune (or idiopathic) thrombocytopenia purpura (AITP or ITP) is the most frequently encountered form of immune thrombocytopenia.[75] This disorder can be classified as acute or chronic on the basis of the duration of the thrombocytopenia, the chronic form persisting longer than 6 to 12 months (see Chapter 131). The acute, self-limiting form occurs predominantly in children, often after a viral illness or immunization, and affects boys and girls with equal frequency. The chronic form is mainly an adult illness and affects twice as many women as men. Life-threatening bleeding occurs in up to 1% percent of patients with ITP. The reason that some patients sustain severe hemorrhagic complications and others do not remains unexplained; but because of differences seen in the clinical expression of chronic and acute ITP, it has been theorized that the mechanisms of disease for each form are probably different.

It had been hoped that the antigenic targets in acute and chronic forms of ITP might be different so that antigen identity might one day be used as an early indicator of clinical outcome. Subsequent studies have shed more light on this issue and have demonstrated that autoantibody specificity in chronic versus acute ITP is quite similar, particularly in children.[76,77] Nonetheless, a distinction between antigen specificity and an acute versus chronic course in cases of ITP may yet be found in the early stages of the autoimmune response. Clearly, prospective studies aimed at answering this question are still warranted.

Although most autoantibodies apparently induce thrombocytopenia, few induce platelet dysfunction without an increase in platelet clearance (see Chapter 131).[78,79] The proportion of the two types of autoantibody, that which leads to platelet clearance and that which blocks platelet function, may be an important factor controlling the unpredictable clinical severity of ITP.

GLYCOPROTEINS AS AUTOANTIGENS

Integrin $\alpha_{IIb}\beta_3$

The integrin $\alpha_{IIb}\beta_3$ was the first platelet membrane component to be identified as a dominant antigen in patients with chronic ITP,[80] and subsequent studies from several laboratories have confirmed the important contribution of this receptor to the autoantigenic makeup of the human platelet.[75]

Integrin Subunit β_3

Attempts to further localize autoepitopes on either integrin subunit have been more successful with regard to β_3. Early on, Kekomaki and colleagues[81] defined a prominent autoantigenic region as the 33 kd chymotryptic fragment of β_3 located within the cysteine-rich region of β_3, which was bound by both plasma autoantibodies and autoantibody eluted from patients' platelets. Fujisawa and colleagues[82] subsequently determined that plasma autoantibodies in 5 of 13 patients with chronic ITP was bound to peptides representing β_3 residues 721 to 744 or 742 to 762, namely, the carboxy-terminal region of β_3 that is presumed to be located in the cytoplasm of the platelet. Their role in the pathogenesis of immune thrombocytopenia is clouded by the fact that this portion of the β_3 molecule is located within the cytoplasm, not on the surface, of the resting platelet.

However, internal autoantigens are the hallmark of many immune-mediated diseases, such as polymyositis and systemic lupus erythematosus.[83] As with these diseases, one can postulate that the autoantigen is primarily internal, but at some point is expressed on the surface of the platelet surface, perhaps with activation or senescence, at which time the autoantibody can bind and remove the cell from circulation.

The report by Fujisawa[84] is one of many suggesting that autoantibodies to $\alpha_{IIb}\beta_3$ can bind to cryptic epitopes or neoantigens that are expressed with platelet activation or senescence. Platelets normally accumulate IgG on the membrane surface as they age or become activated over 7 to 10 days, and then they are cleared by reticuloendothelial cells in the spleen.[85] Using Fab′2 fraction of IgG it has been shown that normal individuals have autoantibodies in their sera that specifically bind to senescent antigens on red blood cells and platelets to mediate clearance of spent or dysfunctional cells.[86,87] The role of these naturally occurring autoantibodies in pathologic immune destruction of cells is unclear. Animal studies suggest that the initial binding of the pathogenic antiplatelet autoantibody may trigger the expression of senescent or cryptic antigens on the platelet membrane, resulting in a second wave of immunoglobulin binding and clearance by naturally occurring autoantibodies.[88]

More recently, additional autoantigenic epitopes have been identified on the β_3 subunit. Nardi and colleagues[89] identified the peptide $\beta_3{}^{49-66}$ as a site that is bound by most affinity-purified antibodies isolated from serum immune complexes of immunologic thrombocytopenic patents infected with human immunodeficiency virus type 1. This is not a peptide that is bound by serum IgG antibodies from control subjects or patients with the classic form of ITP.

Identification of autoimmune epitopes has been aided by the development of the phage-display peptide library. Bowditch and colleagues[90] used a filamentous phage library that displays random linear hexapeptides to identify peptide sequences recognized by AITP autoantibodies. Plasma antibody eluates from patients were used to select for phage-displaying autoantibody-reactive peptides. They identified anti-$\alpha_{IIb}\beta_3$ antibody-specific phage encoding the hexapeptide sequences Arg-Glu-Lys-Ala-Lys-Trp (REKAKW), Pro-Val-Val-Trp-Lys-Asn (PVVWKN), and Arg-Glu-Leu-Leu-Lys-Met (RELLKM). Each phage showed saturable dose-dependent binding to immobilized autoantibody, and binding could be blocked with purified $\alpha_{IIb}\beta_3$. The binding of plasma autoantibody to the phage encoding REKAKW could be blocked with a synthetic peptide derived from the β_3 cytoplasmic tail; however, the PVVWKN was not. Using sequential overlapping peptides from the β_3 cytoplasmic region, an epitope was localized to the sequence Arg-Ala-Arg-Ala-Lys-Trp (β_3 734–739).

Integrin Subunit α_{IIb}

Autoantibodies reactive with α_{IIb} were identified in two patients with chronic ITP[91,92]; and in one patient, the antibody was subsequently shown to react with a chymotryptic, 65 kd, COOH-terminal fragment of the α_{IIb} heavy chain.[92] Ethylenediaminetetraacetic acid (EDTA)–dependent autoantibodies represent a special category that are absorbed by autologous platelets when whole blood is drawn in EDTA. In one such case of EDTA-dependent *pseudothrombocytopenia*, an IgM antibody was shown to bind to α_{IIb} by immunoblot assay and crossed immunoelectrophoresis.[93]

Further work by Gevorkian and associates[94] used phage display to map an autoepitope on α_{IIb}. A filamentous phage library was employed that displays random peptides, 11 amino acids in length flanked on each side by a cysteine, to identify peptide sequences recognized by an antiplatelet autoantibody known to block fibrinogen binding to $\alpha_{IIb}\beta_3$. Phage from individual colonies, after the fourth round of purification, were tested for binding to the autoantibody. A phage expressing the sequence CTGRVPLGFEDLC exhibited saturable dose-dependent binding to immobilized autoantibody. This binding could be blocked with purified $\alpha_{IIb}\beta_3$ and α_{IIb} but not by β_3. The peptide amino acid sequence has partial identity with amino acids 4 through 10 and with amino acids 31 through 35 on α_{IIb}. This work suggests that the autoantibody binds to a combinatorial epitope within the first 35 amino acids of α_{IIb}.

Autoantigenic epitopes may be conformational and dependent on the tertiary configuration of the molecule. Given the fluid nature of the platelet membrane and the remarkable metamorphosis that occurs with activation and adhesion, it is not surprising that conformational antigenic sites would come and go. In fact, Shadle and associates[95] describe a neoantigen on α_{IIb}, which is only revealed following the normal binding of fibrinogen to its receptor, the $\alpha_{IIb}\beta_3$ complex. Serum autoantibodies have been described that demonstrate increased binding to platelets in the presence of calcium chelators, such as EDTA, heparin, or other drugs.[93] Some autoantibody binding may be directed to neoantigens and thus is enhanced after changes in membrane GPs induced by agents such as EDTA or heparin.

Human Monoclonal Autoantibodies

How large is the autoepitope repertoire on a given GP antigen? The answer to this important question affects on the feasibility of developing therapeutic and diagnostic measures based on epitope specificity. Since the autoantibodies that react with a given epitope are likely to share idiotypes, one can approach this question from two angles, analyzing the epitope repertoire, the idiotype repertoire, or both. Two studies have addressed the extent of the autoantigen repertoire on $\alpha_{IIb}\beta_3$ by analyzing the competitive binding between human autoantibodies and murine monoclonal antibodies.[96,97] However, the limited number of studies that have used this approach have generated conflicting results, and there remain insufficient data to judge the size of the autoepitope repertoire on $\alpha_{IIb}\beta_3$. Additional analyses aimed at epitope localization will be necessary, and perhaps novel approaches will expedite this task. One such novel approach is the development of human monoclonal autoantibodies specific for $\alpha_{IIb}\beta_3$ and other platelet GPs.

Human monoclonal antibodies are an alternative tool in the search for GP epitopes that are autoimmunogenic in humans. The first human monoclonal antibody against a platelet GP was developed by Nugent and associates,[83] derived from an ITP individual producing an antibody against β_3. This human monoclonal antibody detects a neoantigen associated with β_3 that is expressed only on stored or thrombin-activated platelets. A number of human monoclonal autoantibodies specific for the heavy chain of GPIb were generated from the lymphocytes of an ITP patient with serum autoantibody specific for Ib.[98] The heavy chain variable region genes of four of these antibodies have been sequenced and found to be markedly homologous to human immunoglobulin, germ-line, heavy-chain variable region genes.[98] Another human monoclonal autoantibody was produced that is specific for the heavy chain of α_{IIb}.[84] The epitope recognized by this antibody (2E7) has been identified as a contiguous amino acid sequence with residues 231 to 238 with an immunodominant tryptophan residue at position 235.[99] This was the first time that the precise epitope on α_{IIb} or β_3 recognized by a human antibody had been identified.

The $\alpha_{IIb}\beta_3$ molecule is a member of the greater family of adhesion molecules or integrins, and α_{IIb} has significant homology with other integrin α chains. A comparison of the 220 to 238 sequence of α_{IIb} and seven other integrin α subunits revealed significant homology between α_{IIb} and other α integrin chains, yet 2E7 did not bind to the other cell types that express these related integrin family members, such as endothelial cells, lymphocytes, monocytes, or neutrophils. In the highly homologous region spanning residues 234 through 238, α_{IIb} differs from the other α chains only in position 235 (TrpØLeu). Ironically, this tryptophan plays a critical role in determining the immunogenic epitope recognized by 2E7.

From the foregoing analysis, it is clear that further studies are required to determine the extent to which the production of human autoantibodies to platelet GPs is clonally restricted. Given a selected number of idiotypes (Ids) related to autoimmunity to $\alpha_{IIb}\beta_3$, one could potentially use the antiidiotype (anti-Id) to modulate immunization to $\alpha_{IIb}\beta_3$. Along these lines, it has been reported that intra-

venous immunoglobulin, which is routinely used to reverse acute thrombocytopenia in patients with ITP, may contain anti-Id directed to idiotypes of autoantibody but not alloantibodies that recognize $\alpha_{IIb}\beta_3$.[100] Nugent and colleagues[101] have defined a DM idiotype that is characteristic of human autoantibodies that are specific for the Ib heavy chain. Their study clearly suggests that the repertoire of idiotypes expressed by human autoantibodies specific for membrane GPs, such as those of the human platelet, will be narrowly defined and thus amenable to study.

The production of human monoclonal autoantibodies or recombinant Fab fragments from patients with immune thrombocytopenia provides researchers with specific antibody probes to map target antigens. Human monoclonal antibodies have an advantage over serum antibodies in that they are monoclonal and circumvent problems associated with using a polyclonal serum where many different, low-titer autoantibodies can be found with reactivity against a variety of epitopes.

GPIb Complex

Autoantibodies to components of the GPIb complex are also frequently encountered in adult chronic ITP. He and associates[102] have made progress in the localization of selected autoantigenic epitopes on the GP Ib molecule. Epitopes were most frequently found on a recombinant fragment of Ibα corresponding to residues 240 through 485 and next most often on a fragment representing residues 1 through 247. In the case of those antibodies reactive with the former sequence, further epitope mapping identified the dominant determinant as the nine amino acid sequence TKEQTTFPP (residues 333–341).[102] In some cases in which autoantibody to Ib-IX was detected, the clinical presentation proved to be particularly severe and refractory to therapy.[101] One case of *pseudo–Bernard-Soulier syndrome* (dysfunction of the Ib-IX-V receptor complex) was reported to be caused by an autoantibody to Ib.[103] Finally, in the subset of childhood ITP cases associated with varicella-zoster infection, the GP V component of this receptor was found to be the dominant target of serum autoantibodies that do not cross-react with viral antigens.[104] At the same time, in another group of children with this disease, it was found that serum antibodies specific for viral antigens can cross-react with normal platelet antigens and may thus contribute to platelet clearance.[105]

Unlike the $\alpha_{IIb}\beta_3$ complex, autoantibodies directed against GPIb are almost universally associated with pathologic immune destruction of platelets. Thus far, no one has described naturally occurring antibodies reacting with GPIb in either resting or activated platelets. Although only 15% to 30% of AITP patients have autoantibodies that bind to GPIb, there is no background binding of antibodies in normal plasma, so the characterization of this antigen is much more straightforward. Furthermore, using antiidiotypic reagents, it appears that the repertoire of idiotypes expressed by anti-GPIb antibodies from patients with AITP is very narrowly defined.[101] In this study, affinity purified antiplatelet GPIb antibody from patient DM who produced a very high titer anti-GPIb autoantibody was used to immunize rabbits and mice for the production of rabbit polyclonal and murine monoclonal anti-DM idiotypic antibodies. These reagents were highly specific for the DM idiotype and could be used to screen a large number of serum samples from normal individuals and patients with AITP. Furthermore, the rabbit polyclonal and certain of the murine monoclonal antibodies block binding of the immunizing antibody, DM, to platelets or purified GPIb. Approximately 95% of AITP serum samples from patients who are positive for the DM idiotype contained anti-GPIb autoantibody ($P < 0.00001$).

The GPIbα heavy chain is a large molecule and contains Leucine-rich repeats and a region in the middle of the GP that is heavily glycosylated. The NH2-terminal region of GPIb is responsible for binding to von Willebrand antigen, mediating platelet adhesion. Theoretically, there could be a variety of antigenic sites on this molecule; but in the studies examining frequency of DM idiotype positive, anti-GPIb autoantibodies, only 12% to 15% of the anti-GPIb plasmas was negative for DM idiotypic antibodies. Half of these were from patients who had developed drug-dependent antibodies, which bound to the GPIb-IX complex, particularly those associated with the ingestion of quinine or quinidine. These results suggest that the DM idiotype is tightly associated with autoantibodies against GPIb in patients with AITP; and, although DM is not the only autoepitope on GPIb, it is certainly present as one of the anti-GPIb antibodies in the serum of most patients with autoantibodies to this complex.

The DM autoantigen has been mapped to the heavy chain of the GPIb complex. Following trypsin treatment of affinity purified GPIb complex, the DM autoantibody specifically recognizes a site on the 40 to 45 kd fragment of the GPIbα molecule, the same region where von Willebrand protein binds to mediate platelet adhesion. Ongoing research to identify the sequence of the DM autoepitope will provide a critical piece of information which is currently lacking in AITP, namely what role do these GP sequences play in antigen selection of certain pathologic autoantibody idiotypes.

GPV

In the mid-1980s, when screening for antigen specific autoantibodies became available, many researchers hoped that the patterns of target antigen reactivity might be predictive of the clinical course of AITP, that is, acute versus chronic. In fact, an initial report looking at eight children with acute AITP using immunoblot technique failed to demonstrate anti-β_3 antibody even though this was the dominant antigenic target recognized by autoantibodies from patients with chronic AITP.[106] This was followed by a report from the same laboratory[107] demonstrating serum antibody reactivity to GPV in four pediatric patients with thrombocytopenia associated with varicella (chickenpox) infection. GPV is a thrombin-sensitive, 85 kd GP of unknown function on the platelet surface. There was no evidence of immune complexes in these patients or varicella antigens adsorbed to the surface of their platelets. Because all of the children with varicella-related AITP and acute childhood form of AITP achieved resolution of thrombocytopenia within 6 months, there was some hope that GPV reactivity would be a marker for mild disease and these patients could escape aggressive immunosuppressive therapy.

Integrin $\alpha_2\beta_1$

Platelet integrin $\alpha_2\beta_1$ is an important collagen receptor on the platelet membrane. Although present in a much lower concentration than $\alpha_{IIb}\beta_3$ or the GPIb complex, this receptor has also been shown to be a target autoantigen in 10% to 20% of chronic AITP patients.[108] Moreover, serum IgG autoantibodies specific for integrin subunit α_2 were identified in a unique case of autoimmune platelet dysfunction after myasthenia gravis.[108] This autoantibody inhibited aggregation of normal platelets induced by collagen or wheat germ agglutinin. This was the first case wherein autoantibodies to α_2 were associated with a chronic hemorrhagic disorder.

Efforts to map the specific epitope on this receptor have been unsuccessful even though several groups have suggested that the binding of these antibodies, because they impair function, might be near the binding site of collagen. Deckmyn and associates describe a plasma autoantibody directed against a protein comigrating with α_2 and recognized by the patient's antibody when affinity-purified $\alpha_2\beta_1$ was used as antigen.[108] The $\alpha_2\beta_1$ complex was immunoprecipitated from a platelet lysate by the patient's plasma, and purified platelet specific IgGs from this patient inhibited aggregation of normal platelets induced by collagen or by wheat germ agglutinin. Dromigny and associates[109] described a 48-year-old woman in whom they found increased bleeding times, impaired collagen-induced platelet aggregation, and the presence of autoantibodies directed against $\alpha_2\beta_1$ and the GPIb complex.

Glycolipids as Antigens

Several reports have implicated cardiolipin, lactosylceramide, and other glycosphingolipids as autoantigenic targets (see Table 144–2).[110,111] van Vliet and associates[111] analyzed the binding of serum IgG/IgM antibodies from 30 ITP patients to platelet glycosphingolipids separated by high-performance thin-layer chromatography. Acidic glycosphingolipids, namely sulfatides and gangliosides, were identified as the major targets of serum autoantibodies. In 13 of the 30 serum samples, 5 with anticardiolipin antibodies, antibodies bound to sulfatides, whereas four serum samples showed antibody binding to gangliosides. Koerner and associates[110] employed a more efficient phase partition separation of acidic glycosphingolipids from neutral glycosphingolipids and were able to demonstrate that serum antibodies specific for neutral glycosphingolipids were more characteristic of ITP. Two classes of glycosphingolipids autoantigens were defined: those associated with general autoimmunity and detected in the sera of patients with either systemic lupus erythematosus or ITP and those peculiar to platelet-specific autoimmunity and detected only in the sera of ITP patients. Two glycosphingolipid forms belong to the platelet-specific group, but they are present at minute levels, and further characterization awaits large-scale purification. One-half (6 of 12) of patients with ITP had serum IgG or IgM antibodies that bound these platelet-specific glycosphingolipids. Sera from none of 10 patients with nonimmune thrombocytopenia, none of 10 patients with SLE and only 1 of 18 normal subjects gave positive reactions with the platelet-specific glycosphingolipid group. The general glycosphingolipid antigen group includes globotriaosyl ceramide, globotetraosyl ceramide, and a third unidentified neutral glycosphingolipid. Antigens in the general group were bound by IgG or IgM antibodies in the sera of 10 of 10 patients with systemic lupus erythematosus, 8 of 12 patients with ITP, and none of 10 patients with nonimmune thrombocytopenia or 18 control subjects. These findings provide compelling support for a role of neutral glycosphingolipids as antigenic targets in selected cases of ITP.

ANIMAL MODELS OF IDIOPATHIC THROMBOCYTOPENIA PURPURA

Many investigators have searched in animals for clinical correlates of human ITP. These attempts have been largely unsuccessful, but an exception may have recently evolved from concerted studies in dogs. As pointed out in a recent series of reports by Lewis and Meyers,[112] there is now substantial evidence that ITP in dogs and ITP in humans are clinically analogous syndromes. In 32 cases of canine ITP, increased platelet-bound IgG was detected in most animals ($n = 30$), and Ig eluted from the platelets of 11 of 19 affected dogs bound to homologous normal canine platelets.[112] Furthermore, Ig specific for integrin subunits α_{IIb} and/or β_3 was detected in the sera of 4 of 17 dogs tested. The authors have concluded that, in cases of canine ITP, Ig bound to the surface of platelets is directed against host antigens and that the target antigen is frequently $\alpha_{IIb}\beta_3$. Given the similarities between these findings and the cumulative experience with human ITP, the canine model may prove to be a valuable tool to further understand the pathogenesis of the autoimmune response to platelet antigens.

T-CELL ABNORMALITIES IN IDIOPATHIC THROMBOCYTOPENIA PURPURA

As with other autoimmune diseases, elevated numbers of T-cell receptor γ/δ-positive T lymphocytes have been noted in patients with both acute and chronic ITP, as initially described by Ware and Howard.[113] Analysis of the nucleotide sequences used by these T-cell receptor γ/δ T cells demonstrated a diverse set of *VDJC* gene rearrangements, characteristic of a superantigen response. Further evidence for T-cell reactivity in ITP came from the observations that isolated T-cell clones showed in vitro proliferation against allogeneic platelets, the numbers of Vβ8+ T cells were elevated, and platelet stimulation resulted in measurable interleukin (IL)-2 secretion.[113] These results provided the first evidence that patients with ITP have platelet-reactive T lymphocytes identifiable at the clonal level.

T-cell proliferative responses to platelet membrane GPs were examined in 21 patients with chronic ITP or systemic lupus erythematosus, with or without thrombocytopenia, and 10 healthy donors.[114] T cells from all subjects failed to respond to detergent-soluble, native GPs, but tryptic peptides of integrin $\alpha_{IIb}\beta_3$ stimulated T cells from nearly all subjects, including the normal individuals. Similar T-cell proliferation in healthy individuals in response to $\alpha_{IIb}\beta_3$ had been described previously by Filion and associates.[115] These findings implied that some autoreactive T cells, directed against membrane antigens present on platelets, were not necessarily eliminated by intrathymic deletion but are present in a suppressed state in normal individuals. In the ITP patients, the T-cell response was restricted by HLA-DR, the responding T cells had a $CD4^+$ phenotype, and the proliferation was accelerated relative to normal subjects, suggesting in vivo T-cell activation.[115] None of the peripheral blood mononuclear cell culture supernatants from healthy donors contained a significant amount of IgG anti-$\alpha_{IIb}\beta_3$ antibody, but all showed trypsin-digested $\alpha_{IIb}\beta_3$-induced T-cell proliferation. These findings led to the conclusion that $CD4^+$ HLA-DR-restricted T cells reactive with $\alpha_{IIb}\beta_3$ epitopes are involved in production of antiplatelet autoantibody and are implicated in the pathogenesis of chronic ITP.

CYTOKINES

Considerable effort has been focused on the measurement of cytokines in ITP in an effort to further characterize the influence of T-helper subsets in the autoimmune origin of this disease. Unfortunately, most studies draw conclusions based on a single cytokine profile determination. Because cytokine signaling is dynamic and may fluctuate rapidly, it is difficult to draw valid conclusions from a single assay. In addition, the presence of soluble cytokine receptors may confound the results if these are not measured directly in parallel with cytokines. To distinguish a normal versus pathologic immune response in patients with acute and chronic ITP, multiple samples must be obtained over time, with attention paid to both the cytokine and its soluble receptor. The studies described subsequently have incorporated multiple samples and controls in the overall analysis. Nonetheless, there remains a degree of disparity between the results obtained in children versus adults.

In pediatric ITP patients, a Th1 type of cytokine response is the norm, characterized by very low levels of IL-4 and IL-6 but elevated levels of IL-2, interferon-γ, and tumor necrosis factor-α.[116] In adults with chronic ITP, malignancy associated with ITP, or the autoimmune lymphoproliferation syndrome associated with defects in the Fas apoptosis pathway, there are elevated levels of IL-10, IL-11, IL-6, and IL-13.[117–120] One expects successful therapy to be associated with favorable changes in cytokine profiles. Although many treatment regimens have been efficacious in ITP, in only a few instances has there been documentation of cytokine profile changes following therapeutic intervention with the most common drugs, intravenous immunoglobulin, and anti-D immunoglobulin.[121,122]

Zimmerman and associates[121] reported that intravenous immunoglobulin and dexamethasone induced an alteration of T-lymphocyte subsets and suppression of T-lymphocyte proliferation in vitro. Although equally effective in the treatment of ITP in children, they found that anti-D caused significantly less inhibition than intravenous immunoglobulin or dexamethasone in children with chronic ITP, and anti-D did not affect T-lymphocyte subsets.

Bussel and colleagues[122] compared the changes in IL-6, IL-10, MCP-1, and tumor necrosis factor-α cytokine levels after treatment with intravenous immunoglobulin and anti-D in thrombocytopenic adults. There was an increase in all but tumor necrosis factor-α

within 2 hours after administration of anti-D. After intravenous immunoglobulin administration, there was a significant increase in IL-10 levels within 4 hours (but not 2 hours) after therapy. It was concluded that the early increase in these macrophage-synthesized cytokines after anti-D administration reflects the substantial interaction of antibody-coated erythrocytes with macrophages.[121]

DRUG-INDUCED IMMUNE THROMBOCYTOPENIA (QUININE/QUINIDINE) PURPURA

Although drug-induced immune thrombocytopenia purpura (DITP) may be a complication of therapy employing a variety of drugs, it is most frequently seen in the United States with the administration of quinine and quinidine.[123] It has been proposed that the following criteria be met before an individual can be considered to have DITP: (a) the patient is not thrombocytopenic prior to administration of the drug; (b) thrombocytopenia follows drug ingestion and begins to reverse shortly after cessation of drug; (c) thrombocytopenia does not reoccur after cessation of drug treatment; and (d) all other causes of thrombocytopenia are ruled out.[124]

Cumulative evidence now favors a mechanism whereby the drug induces the expression of a neoantigen on the platelet surface[125] that is recognized by circulating antibodies only in the presence of the drug. The observation that platelets from BSS patients (lacking Ib-IX-V) failed to lyse in the presence of drug-dependent antibody, specific drug, and complement, was the first indication that a specific platelet antigen is recognized by such antibodies.[126] This finding led other laboratories to confirm that purified Ib-IX would compete for drug plus antibody and was therefore likely to contain the antigenic epitope in question. Evidence of direct binding of such antibodies to Ib-IX was first provided by Chong and associates,[127] and Berndt and associates[128] established that the complex of both Ib and IX are likely required for maximum antigen expression.

Chong and associates[129] showed that one quinine-dependent antibody binds to an epitope on the amino-terminal portion of Ibα, and five other quinine-dependent antibodies recognize a complex-specific epitope proximal to the membrane associated region of Ib-IX. Each of six quinidine-dependent antibodies contained two specificities, one for the same Ib-IX complex epitope described earlier and the other for IX alone. Additional observations were that antibodies reactive with Ib-IX are more predominant (12 of 12 patients) than those that bind $\alpha_{IIb}\beta_3$ (3 of 12 patients) and antibodies specific for Ib-IX-V are present in titers 8- to 32-fold higher than the corresponding antibodies that bind to $\alpha_{IIb}\beta_3$ in the same patient samples. In each case, those antibodies that bound to Ib-IX-V were distinct from those that recognized $\alpha_{IIb}\beta_3$. The specificity of quinine- and quinidine-dependent antibodies for a conformation-sensitive epitope or epitopes on the GPIX component of the complex was confirmed by Lopez and associates[130] using monoclonal antibody inhibition assays. Rifampicin-dependent antibodies bind to a similar or identical epitope on GPIX as that recognized by quinine-dependent antibodies.[131]

Regions of $\alpha_{IIb}\beta_3$ that bind to quinine- or quinidine-dependent antibodies have also been further localized by Visentin and associates.[132] Of 13 patient serum samples containing such antibodies, 10 were reactive with both Ib-IX and $\alpha_{IIb}\beta_3$, 2 reacted with Ib-IX alone, and 1 reacted with $\alpha_{IIb}\beta_3$ alone. Again, in those serum samples in which both specificities were identified, the anti-Ib-IX-V antibodies were distinct from those that bound to $\alpha_{IIb}\beta_3$. Seven serum samples containing anti-$\alpha_{IIb}\beta_3$ antibodies were further characterized: Three bound only to the $\alpha_{IIb}\beta_3$ complex, one bound to α_{IIb} alone, and three bound to β_3 alone. On β_3, a 17 amino acid sequence in the *hybrid* and PSI homology domains of β_3 is a dominant epitope.[125] In the case of sulfonamide-induced immune thrombocytopenia,[133] the causative antibodies are almost exclusively specific for calcium-dependent (complex-specific) epitopes on the integrin $\alpha_{IIb}\beta_3$.

In addition, serum samples from 20 patients with quinine-induced thrombocytopenia and 5 patients with DITP after intake of carbimazole were found to have drug-dependent antibodies specific for platelet endothelial cell adhesion molecule 1.[134] Thus, integrin $\alpha_{IIb}\beta_3$ and the GPIb-IX-V complex are not the only antigenic targets in DITP.

One additional intriguing aspect of certain cases of DITP is worthy of mention, because it may have an important bearing on our understanding of the autoimmune response to platelets in general. Based on anecdotal evidence, it has been suspected that some cases of chronic ITP[135] are initiated in clinical situations that, from all appearances, could be classified as DITP. The only difference is that selected autoantibodies persist long after exposure to the insulting drug. Direct evidence to support of this contention was obtained by Nieminen and Kekomaki.[136] In that report, it was found that the DITP patients with Ib-IX specific antibodies, despite an intense and acute thrombocytopenia, recovered promptly after drug removal. Conversely, DITP patients with more prolonged thrombocytopenia and persistently elevated platelet Ig more than 1 month after drug removal had antibodies that reacted with additional target antigens, including integrin $\alpha_{IIb}\beta_3$. To better understand the pathogenesis of both DITP and classic ITP, in the future it may become important to distinguish the acute but readily reversible clinical situation that we accept as DITP from the more complex disease situation that may be initiated by drug exposure but evolve into a more classic form of ITP.

HEPARIN-ASSOCIATED IMMUNE THROMBOCYTOPENIA

Heparin-associated immune thrombocytopenia (HIT) is a life-threatening condition that results in thrombocytopenia and can be associated with thrombosis. Unlike quinine- or quinidine-dependent antibodies, the actual binding of heparin-dependent antibodies (HDA) to the platelet surface appears to be of very low affinity and was difficult to demonstrate in earlier studies, until the report of Lynch and Howe.[137] It was also determined that HDAs differ from other forms of drug-dependent antibodies in that they can often be *activating*, causing not only thrombocytopenia but also heparin-dependent platelet aggregation, thromboxane synthesis, and granule release that can be quantitated by preloading platelets with [^{14}C]serotonin. The consequences of HIT therefore are multiplied by often serious thrombotic complications. Approximately 30% of these patients die, with an additional 20% developing vascular occlusions that result in gangrene and subsequent amputation.[138]

Although the precise mechanism of HDA binding to platelets eluded investigators for many years, it was generally accepted that the activating properties of HDA must be mediated by Fc-dependent binding to platelets. In this regard, Kelton and associates[139] showed that the platelet-release reaction induced by HDA could be blocked by pretreating platelets with human or goat IgG Fc fragments; Adelman and associates[140] showed that the Fab regions of HDA alone are insufficient to cause platelet activation; Chong and associates[141] showed that purified rabbit IgG and its Fc, but not Fab, fragments markedly inhibited platelet aggregation induced by HDA. Several groups also observed that the monoclonal anti-Fc receptor antibody, IV.3, could block platelet activation by HDA.[139,142]

Subsequent findings from several study groups have led to the consensus that the dominant pathologic factor in HIT is circulating antibody specific for a complex of heparin (H) and platelet factor 4 (PF4). It is now accepted that H-PF4 complexes, which are detected in 85% of patients with HIT,[143] can bind to the membrane of platelets[144–146] or endothelial cells,[144] leading directly to thrombocytopenia in the former case. In those cases in which the HDAs are IgG, the Fc portion can cross-link to the platelet FcγRIIA receptor, inducing platelet activation, release, aggregation, and thrombosis[144,147,148] However, HIT can also be associated with antibodies of IgM and IgA isotypes,[149] in which case the Fc(μ)R of lymphocytes or the Fc(α)R of monocytes and neutrophils, as well as complement activation, may play a role in the pathology of this disorder.

Recent evidence derived from the analysis of affinity-purified anti-PF4-heparin IgG (HIT IgG) from the plasma of two patients with

HIT indicates that HIT IgG is the component of HIT plasma that directly induced platelet aggregation.[150] It is the Fab region of HIT IgG that binds to PF4-heparin on the surface of activated platelets. Only then does the Fc portion of HIT IgG further activate the same or adjacent platelets through engagement of the Fc receptor. Platelet activation results in PF4 release, which enhances further antibody binding and more release. This process can be further complicated by the generation of procoagulant platelet-derived microparticles.[151]

Alternative protein targets may be involved in selected cases of HIT. For example, in 9 of 15 patients with HIT that lacked detectable antibodies to H-PF4 complexes, Amiral and associates[152] found evidence of autoantibodies specific for the chemokines neutrophil-activating peptide 2 and IL-8. PF4 is approximately 60% homologous to neutrophil-activating peptide 2 and 40% homologous to IL-8, leading to the proposal that HIT involving these proteins could proceed along a mechanism similar to that invoked for PF4.

CHAPTER 145

HUMAN LEUKOCYTE ANTIGEN AND HUMAN NEUTROPHIL ANTIGEN SYSTEMS

Ena Wang, Sharon Adams, David F. Stroncek, and Francesco M. Marincola

This chapter reviews human leukocyte antigen (HLA) and human neutrophil antigen (HNA) systems. A general background of the structure, function, and nomenclature of both systems and their relevance in clinical hematology is presented. Analysis of HLA gene products is applied in clinical settings (a) to select compatible donor-recipient pairs for transplantation, (b) to select HLA-compatible single donor platelet products for thrombocytopenic patients refractory to standard transfusion of random pooled platelets, (c) to screen for genetic factors that may contribute to the prevalence of diseases, and (d) for forensic purposes in which the identity of individuals may contribute to solving legal disputes or criminal investigations. In addition, we discuss new applications that have broadened the relevance of HLA in the area of immune pathology. Human leukocyte antigen phenotypes determine the suitability of patients for epitope-specific immunization. Tetrameric HLA/epitope complexes (tHLA) allow enumeration of antigen-specific T-cell responses. Furthermore, molecular identification of T-cell epitopes associated with distinct diseases and characterization of the communication between immune effector cells through HLA/HLA ligand interactions extend the relevance of HLA to biologic fields. These biologic fields encompass natural killer (NK) and cytotoxic T-cell function, antigen recognition in the context of infection, autoimmunity, graft-versus-neoplasia (GVN) effect, and autologous cancer rejection. Finally, the recognition that polymorphism extends to other protein families relevant to immune pathology including cytokines, their receptors, and killer cell inhibitory receptors has broadened the significance of immunogenetics beyond HLA. Thus, this chapter emphasizes the importance of viewing human pathology through the kaleidoscopic complexity of human polymorphism.

GENETICS, STRUCTURE, AND FUNCTION OF HLA MOLECULES

Human leukocyte antigen embrace a family of genes clustered in the short arm of chromosome 6 as the human version of the major histocompatibility complex (MHC), initially identified in mice as responsible for graft rejection between genetically unrelated strains (transplantation antigens).[1] Credit for the description of the human MHC goes to three individuals. In 1952, Jean Dausset observed that serum of individuals who had received several transfusions contained hemoagglutinins specific for donor's leukocytes. In 1958, Rose Payne noted that the only requirement for the development of hemoagglutinins against leukocytes was a history of previous transfusion or pregnancy and concluded that these antibodies were directed against antigens on the surface of circulating leukocytes. This conclusion was concomitantly and independently confirmed by Jon van Rood, who observed that multiple pregnancies immunize mothers against leukocytes leaked from the fetus into the mother's circulation. Based on these discoveries, the term *human leukocyte antigen* was subsequently adopted.[2] It should be clarified, however, that this historical name is misleading. Neither is HLA molecule expression limited to leukocytes nor do they display, in natural conditions, antigenic behavior. In fact, several are expressed by most somatic cells; and, rather than being antigens, they chaperon protein bioproducts to the cell surface for recognition by T cells. There is, however, some substance to the name, because HLA, by virtue of being densely packed on the cell surface, are exposed to recognition in a foreign environment such as allotransplantation or xenoinfusion performed to induce anti-HLA antibodies as diagnostic reagents.

ORGANIZATION OF THE HLA GENES

Human leukocyte antigen genes comprise a string of coding sequences that regulate the expression of molecules with similar but not identical function. Residing in a region that spans approximately 4000 kb of the short arm of chromosome 6 (Figure 145–1),[3] HLA contains several genes and pseudogenes characterized by sequence homology and functional similarity. Of them, 47 are officially recognized by the World Health Organization nomenclature committee[4] and include classic HLA class I and class II genes associated with antigen processing such as *PSMB8* and *PSMB9* (proteasomal units) or *TAP1* and *TAP2* associated with peptide transport. Both HLA and HLA-associated genes can be physically grouped into three subregions according to chromosomal location. In centromeric to telomeric direction, the first is HLA class II region comprising the α and β chains of HLA-DR, -DQ, -DP, -DM, and -DO as well as *TAP* and *PSMB.* Sandwiched between the class II and class I region, class III region encodes for functionally unrelated genes such as complement components, heat shock proteins, and tumor necrosis factor. The reason for their genetic link to the HLA complex is unknown, but their immunologic function seems more than coincidental. The class I region is most telomeric and includes HLA-A, -B and -Cw loci, the nonclassic HLA-E, -F, and -G loci and several pseudogenes.

General terminology separates HLA genes into classic and nonclassic. Classic HLA genes have been well characterized and are clearly associated with presentation of antigen to immune cells. They are further subdivided into class I (HLA-A, -B, -C) and class II (HLA-DR, -DQ, and -DP). In general, HLA class I and II genes have very similar structure and function.[5,6] They contain six to eight exons coding for functionally distinct domains (Figure 145–2). The first exon encodes a leader sequence; the following exons (exons 2–4) are highly polymorphic and encode extracellular domains responsible for peptide binding and T-cell antigen receptor (TCR) engagement. Because they are exposed on the cell surface, these domains are also responsible for alloreactivity. The last exons encode a conserved transmembrane and small intracellular domains whose function is unclear.

Only the heavy chain of HLA class I is encoded in the MHC region. Genes encoding HLA-A, -B, and -C contain three exons coding for α_1, α_2, and α_3 extracytoplasmic domains, one transmembrane, and three cytoplasmic domains (Figure 145–3). The associated class I light chain, β_2-microglobulin, is encoded on chromosome 15.[7] By contrast, the HLA class II molecule is composed of a heterodimer of an α and a β chain encoded in the MHC region. Although the genetics are different, the protein product is structurally similar to HLA class I, with two helices resulting in the antigen presenting part of the molecule (Figure 145–4).

All DR molecules use DRA for α chains but can use alleles coded by DRB1, DRB3, DRB4, or DRB5 for β chains. DP, DQ, DM, and DO molecules are the product of *DPA1* and *DPB1, DQA1* and *DQB1, DMA* and *DMB,* and *DOA* and *DOB* genes, respectively.

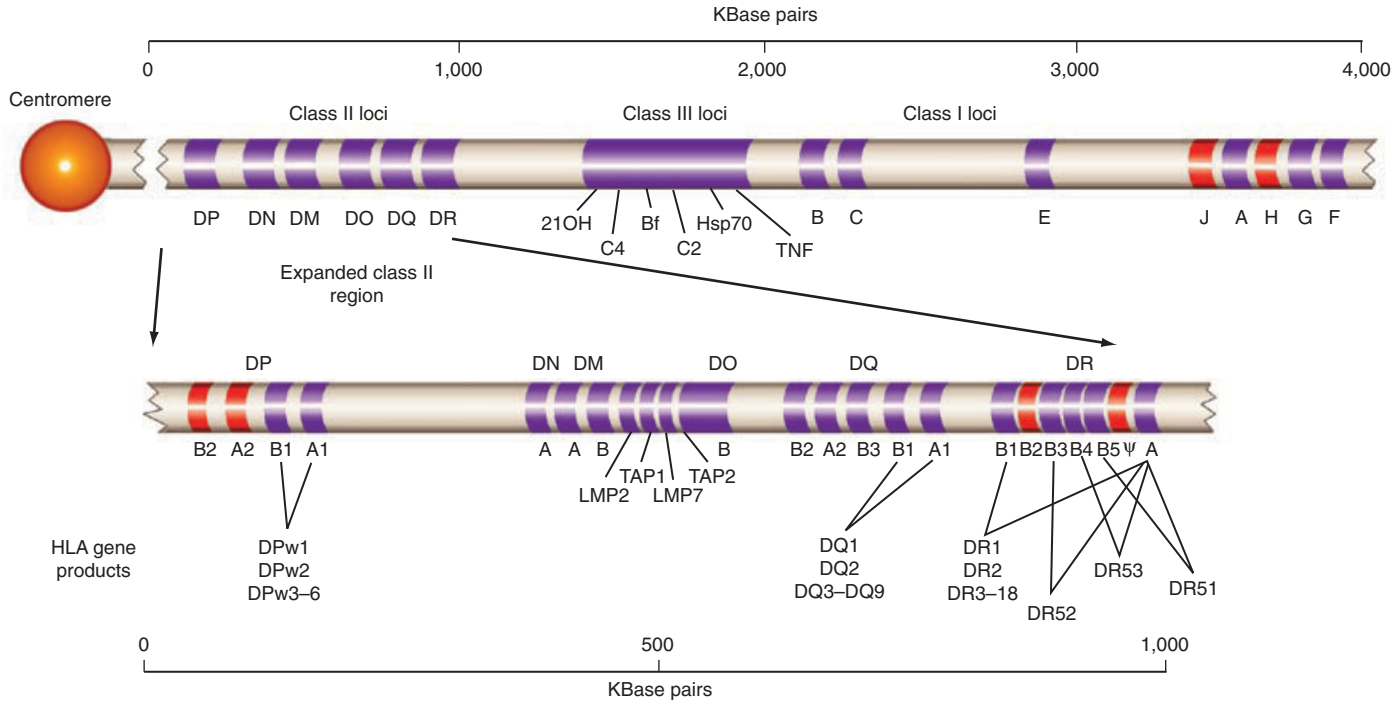

Figure 145–1 Physical map of the HLA genetic complex, illustrating the clusters of genes according to the class of encoded gene products. The symbol ψ represents four DRB pseudogenes, designated 7, 8, and 9. Other pseudogenes are shown in gray. HLA, human leukocyte antigen.

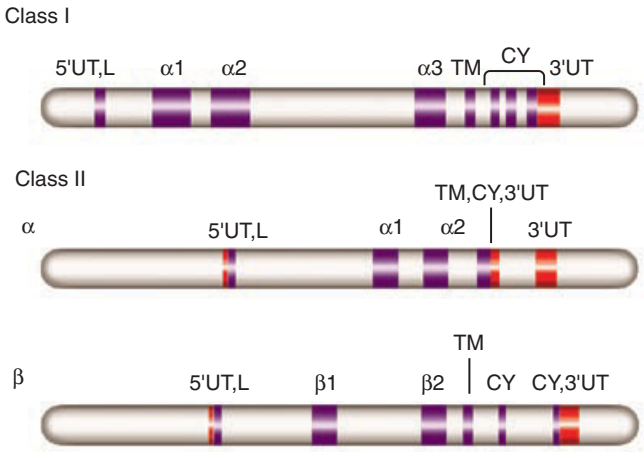

Figure 145–2 Organization of class I and II MHC genes. 5′ UT and 3′ UT, untranslated regions in the 5′ and 3′ ends of the gene; α, β, exons encoding extracellular domains; CY, exon encoding cytoplasmic tail; L, leader sequence; TM, transmembrane exon. (From Germain RN, Malissen B: Analysis of the expression and function of class-II major histocompatibility complex-encoded molecules by DNA-mediated gene transfer. Annu Rev Immunol 4:281, 1986.)

Human leukocyte antigen DRB1 locus is expressed in all HLA haplotypes (the set of HLA alleles derived from the same parental chromosome and therefore genetically linked). However, only one other HLA DR locus is present in each individual chromosome. Thus, each haplotype can have either DRB5 (DR1 haplotype); DRB3, -B4, or -B5 loci (DR2 haplotype); DRB4 locus (DR4 and DR7 haplotype); or none (DR8 and DR10 haplotype).[3]

INHERITANCE AND LINKAGE DISEQUILIBRIUM

Because of their proximity within a short chromosomal distance, HLA genes are inherited en bloc from each parent unless a recombi-

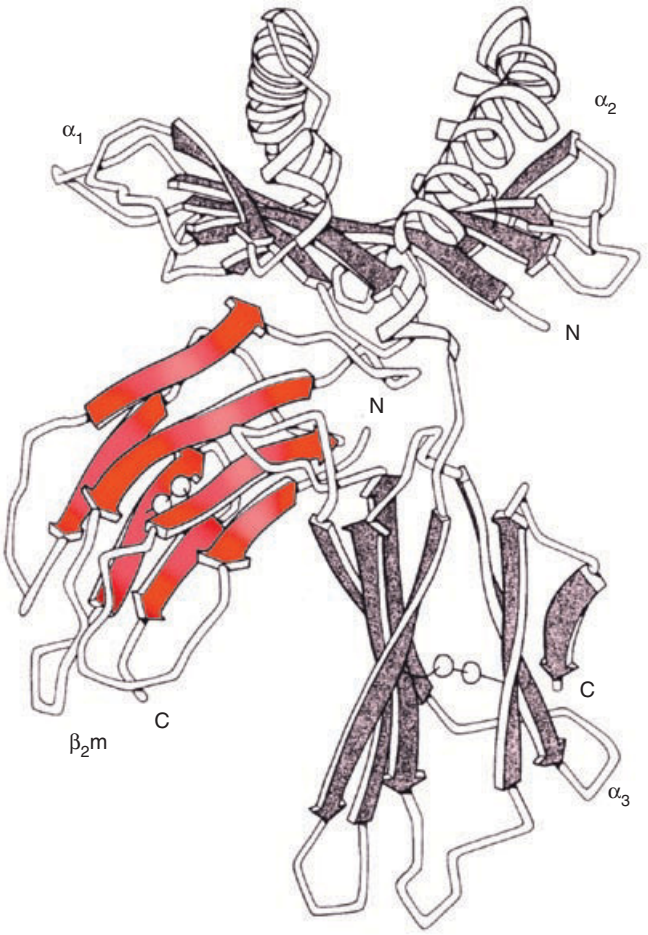

Figure 145–3 Three-dimensional configuration of HLA-A2, modeled from x-ray crystallographic studies. HLA, human leukocyte antigen. (From Bjorkman PJ, Saper MA, Samraoui B, et al: Structure of the human class I histocompatibility antigen, HLA-A2. Nature 329:506, 1987.)

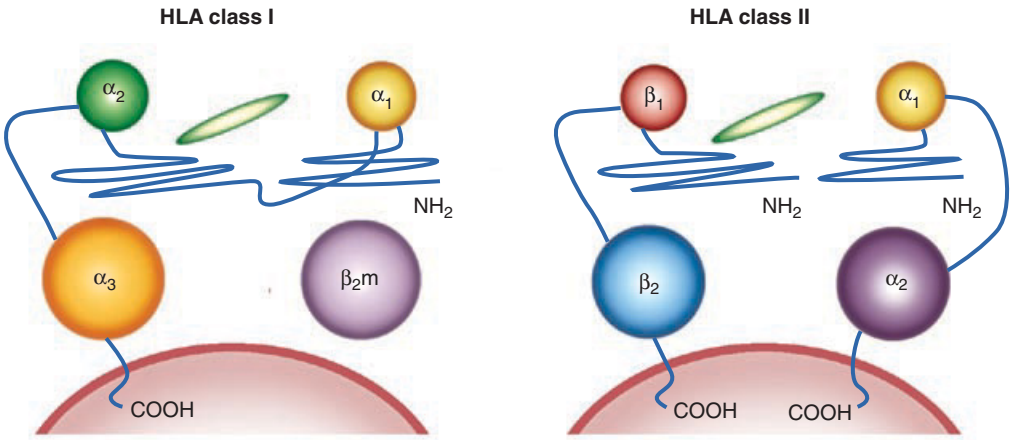

Figure 145–4 Schematic diagram of HLA class I and class II molecules pointing to their structural similarity. In both HLA classes, two immunoglobulin-type domains reside close to the cell membrane (α_3 and β_2 m for class I and α_2 and β_2 for class II). The other two domains project toward the extracellular milieu with α-helices (α_1 and α_2 for class I and α_1 and β_1 for class II) and a platform of parallel β-sheets that form a peptide binding groove. HLA, human leukocyte antigen.

nant event occurs. Thus, each HLA haplotype behaves as a unit and is transmitted through generations according to mendelian principles. Because there are four possible genotypes (two from each parent), the probability of genotypic identity between two siblings is 25%. Most HLA phenotypically identical siblings are also HLA genotypically identical, because the genetic pool of derivation is restricted to the parents. In 2% of cases, recombinant HLA haplotypes (a set of genes derived partially from two chromosomes through recombination) deviate from this rule.

The occurrence of HLA haplotypes within a population with a frequency higher than expected from the prevalence of individual alleles is called *linkage disequilibrium.* In large populations gene frequencies achieve equilibrium within a few generations unless selective pressure influences individuals' survival and mating capacity (Hardy-Weinberg principle). In equilibrium, gene prevalence is maintained based solely on its frequency. Thus, assuming that there were 18, 36, and 8 alleles for the HLA-A, -B, and -C loci, respectively (number of alleles known when this example was described[2]), theoretically $18 \times 36 \times 8 = 5184$ HLA class I allelic combinations or haplotypes would be possible. Adding HLA class II genes to the calculation yields an astronomical number, making unlikely the identification of two HLA-matched individuals. However, individual alleles occur with different frequency, and an allele that occurs with high frequency is predominant in a given population, such as HLA-A2 in whites and A24 or A11 in Asians.[8] Because predominant alleles come with the related haplotype, most theoretical permutations never occur, and the chances of identifying matched individuals are much higher than theoretically possible.

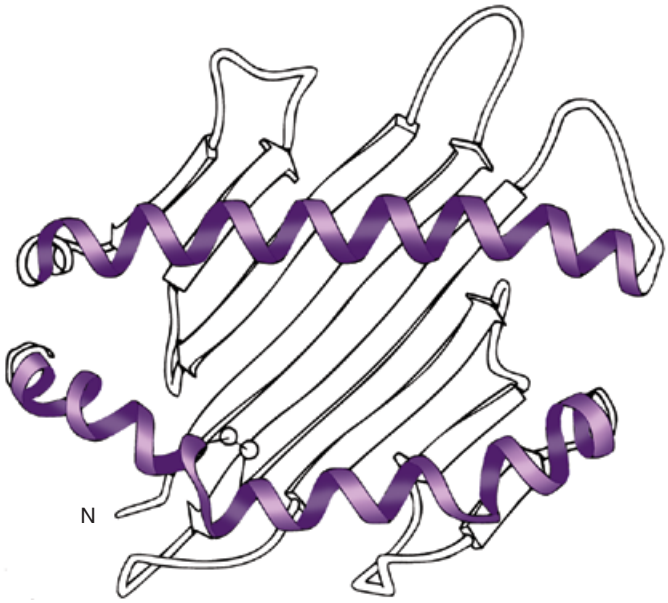

Figure 145–5 Scheme of the peptide groove of an HLA class I molecule, formed by the α_1 and α_2 domains at the side and the β-sheets at the bottom. The view is looking down on the vertically oriented molecule: the T-cell receptor point of view. HLA, human leukocyte antigen. (From Bjorkman PJ, Saper MA, Samraoui B, et al: Structure of the human class I histocompatibility antigen, HLA-A2. Nature 329:506, 1987.)

STRUCTURE OF THE HLA CLASS I AND II

The structure of HLA molecules and their relationship with their natural ligand, the TCR, has been well characterized by crystallography.[9–11] Human leukocyte antigen molecules are heterodimer glycoproteins belonging to the immunoglobulin super family with common features (see Figure 145–4). This includes two α-helical domains protruding toward the extracellular milieu. Between them lies a flat surface formed by β-sheet structures that contributes to the formation of a groove accommodating peptides generated from intracellular (HLA class I) or extracellular proteins (HLA-class II) (Figure 145–5). The helixes/peptide complex is exposed for TCR recognition. Because HLA polymorphism is clustered within the α-helixes and β-sheets domains, peptides display variable affinity for distinct HLA alleles.[12,13] It has been proposed that a given peptide can bind to closely related alleles, and HLA superfamilies with similar binding characteristics have been described.[14–16] However, peptide binding to related but distinct HLA alleles is associated with conformational dissimilarity caused by differential interaction with variant residues in the binding groove.[17] The TCR interaction with HLA required for productive engagement spans a surface including the peptide and portions of the α and β helix.[11,18–20] This double requirement of interaction between TCR and HLA/peptide complex represents the structural basis for HLA restriction. Degenerate and promiscuous TCR recognition of peptides presented by distinct HLA alleles within the same superfamily has also been described.[21] Although this concept holds in general, several exceptions can be expected because single amino acid variants in the HLA molecule may disallow binding of a peptide[22] or may not be permissive to TCR engagement.[23,24]

The binding affinity of a given peptide for a HLA allele can be predicted through algorithms that compile available information to identify amino acid residues that fit distinct pockets of the HLA groove.[12,25] Several algorithms implement this information with

experimental testing based on the refolding capability of HLA heavy chains exposed to known peptide sequences in the presence of β_2-microglobulin and/or their dissociation rates (see Web site www.bimas.dcrt.nih.gov or www.uni-tuebingen.de/uni/kxi). This is based on the principle that the affinity of a peptide for a given HLA promotes that stability of the noncovalent assembly of heavy chain with β_2-microglobulin.[12,26] Finally, peptide binding can be shown by direct elutriation from purified HLA heavy chains.[13,27]

Beyond the *interactive* component of the HLA molecule with TCR, other domains act as coreceptors for the TCR. CD8+ cytotoxic T cells bind to the α_3 domain of HLA class I through CD8, whereas CD4+ T cells interact with HLA class II-specific domains. Although the coreceptor/TCR interaction is not an absolute requirement in most cases, it determines HLA class I or II restriction of individual T cells.[28]

Specific to HLA class I is the assembly with β_2-microglobulin on stabilization in the presence of high-affinity peptides derived from the cleavage of intracellular proteins (endogenous pathway of antigen presentation).[29] Most peptides derive from degradation of self-protein in the cytosol by proteasomes (PSMB) and other proteases.[30] Soluble peptides (9–10 amino acids long) are then chaperoned into the endosomal compartment by transporter molecules associated with antigen processing (TAP1 and TAP2). Within this compartment, they bind to heavy chains according to each individual's HLA phenotype. The binding and stability of the HLA/peptide complex depends on the affinity of each peptide for a particular allele. If the stability is sufficient, the peptide-loaded HLA migrates to the cell surface. Intracellular pathogens produce proteins that are also degraded by proteasomes into peptides that compete with self-peptides for binding to HLA class I molecules. Thus, the function of the endogenous pathway of antigen presentation is to provide information to the extracellular compartment of intracellular events. In physiologic conditions, only self-peptides are presented, and therefore, minimal interactions occur with circulating T cells. During infection, pathogen-derived peptides signal cellular infection to T cells, whereas antibodies that cannot cross the cell membrane remain insensitive to intracellular pathogens. Several pathogens, such as cytomegalovirus, can interfere with this process as well as with reduction of HLA/peptide density on the cell surface and, consequently, diminished T-cell recognition.[31,32] This escape mechanism can be counteracted by the host through increased susceptibility of virally infected cells to NK cell-mediated cytolysis.[33] Reciprocally, viruses can evade NK cells and escape recognition by modulating HLA expression.[34–36]

Human leukocyte antigen class II molecules bind to longer peptides derived from the metabolism of molecules endocytosed from the extracellular compartment (exogenous pathway of antigen presentation).[29] This is a specialized process used by *professional* antigen-presenting cells such as macrophages and dendritic cells. Human leukocyte antigen class II molecules are assembled within the endosomal compartment where they are composed of a heterotrimer. This includes the α and β chains plus a short invariant chain that stabilizes the molecule by occupying its groove while chaperoning its migration to the endosomal compartment where exogenous antigen is processed. Upon uptake, the exogenous antigen undergoes limited proteolysis in the membrane-bound acidic endosomal compartment (MHC class II peptide-loading compartment, MIIC). Upon entering the MIIC, the pre-HLA class II complex is degraded and antigenic peptides are loaded with the help of the nonclassic HLA-DM molecule.[37]

EXPRESSION OF HLA MOLECULES

There are genetic and structural differences between the two classes of HLA alleles. The most striking difference is functional, because HLA class I molecules are expressed by most nucleated cells with the exception of germinal cells, whereas HLA class II molecules are expressed mainly by specialized antigen presenting cells.[38,39] Human leukocyte antigen class I molecules are also expressed by platelets.[40] They are responsible for refractoriness after multiple transfusions[41–44] and sufficiently, though minimally, by reticulocytes to be targets of alloantibodies during hemolytic transfusion reactions.[45] Human leukocyte antigen class II proteins are expressed constitutively by cells associated with the initiation of the immune response such as monocytes, macrophages, and B cells[46] or by immune cells activated by cytokines during inflammation. Thus, HLA class I molecules instruct the host about the condition of individual cells as potential targets for CD8+ cytotoxic T cells responsible for clearing the organisms of altered cells. Human leukocyte antigen class II molecules initiate immune responses by taking up pathogen components and presenting them to $CD4^+$ helper T cells, which can in turn initiate humoral and facilitate cellular immune responses.

Expression of HLA alleles is sensitive to environmental conditions and can be modulated by cytokines among which interferons play a major role.[47] This is particularly important for HLA-B and -C normally expressed at a lower density than HLA-A but which are more sensitive to cytokine induction.[48,49] In addition, HLA class II molecules can be expressed by most cells following cytokine stimulation.[50,51] Thus, the ability of cells to present antigen in association with HLA is strongly influenced by the surrounding environment. This might explain why chronic inflammation induced by alloreactions during graft-versus-host disease (GVHD) may facilitate the presentation of tumor-specific antigens by tumor cells with consequent development of GVN effect. In addition, it might explain how systemic administration of proinflammatory cytokines such as interleukin-2 may stimulate immune responses by increasing the antigen-presenting ability of cells within the tumor microenvironment.[52]

HLA POLYMORPHISM AND ITS CLINICAL SIGNIFICANCE

A striking characteristic of the HLA system is its extreme polymorphism.[53] By chance, most individuals are heterozygote and, therefore, carry two different alleles for each HLA gene that, being codominant, are equally expressed on the cell surface. Because everybody carries three HLA class I (-A, -B, and -C) and three HLA class II (-DR, -DQ, and -DP) genes, most individuals (with the exception of homozygotes) express six different HLA class I and six different HLA class II molecules on the surface of their cells. This has important functional implications, because HLA polymorphism is clustered in domains of the HLA molecule associated the peptide-binding and interaction with the TCR. Thus, most individuals have a broad repertoire of molecules capable of presenting different pathogen components to immune cells. Therefore, it is believed that HLA polymorphism improves the chances of a given species of surviving infection.[54] This paradigm is difficult to demonstrate in human pathologic conditions in which the natural history of infectious diseases rarely correlates with HLA phenotype. An exception is the strong association between HLA-B*5701 and lack of progression to acquired immunodeficiency syndrome of individuals infected with HIV.[55] Associations have been observed between HLA phenotype and predisposition for nasopharyngeal carcinoma.[56,57] This is of particular interest because nasopharyngeal carcinoma is a virally induced cancer against which T cells can mediate immune surveillance. Human leukocyte antigen associations have also been described with less consistency for other virally driven tumors, such as cervical carcinoma,[58] or immunogenic tumors, such as melanoma.[59,60]

The difficulty in demonstrating conclusive associations between infectious disease and HLA in humans could be caused by the successful implementation of antigen presentation through a broad repertoire of HLA genes, which could compensate for each other in limitations in antigen presentation. Chickens carry a single MHC locus and their susceptibility to infection appears to be clearly related to MHC. For instance, Kaufman has shown that chickens carrying a particular Bf (the only MHC class I gene in chickens) allele are fully protected from Rouse virus–induced sarcomas, because this allele (B-f12) can bind several antigenic peptides from its proteins. On the contrary chickens homozygous for B-f4 are killed by the same infection, since this allele cannot bind peptides from sarcoma virus proteins.[54]

HLA polymorphism is the basis of alloimmunization, because most individuals are likely to have different HLA molecules on the surface of their cells. Hundreds of HLA alleles have been identified through high-resolution typing, making the chances of two individuals having identical HLA phenotypes extremely low. Thus, partial mismatches are commonly accepted in transplantation cases, which are at the root of hyperacute, acute, and chronic rejections. Hyperacute rejection is caused by preformed antibodies against donor HLA alleles in patients presensitized by multiple transfusions.[61] Acute and chronic rejection result from a combination of humoral and cellular immune reactivity toward HLA alleles of the donor.[62,63] In addition to allosensitization, HLA alleles can mediate GVHD, whereby hematopoietic cells derived from the grafted tissue recognize and reject the host tissues. They do this by identifying polymorphisms of intracellular proteins of the host (minor histocompatibility antigens) presented in association with donor/recipient matched HLA alleles.

NONCLASSIC MHC AND MHC CLASS I CHAIN-RELATED MOLECULES

Besides the three ubiquitously expressed highly polymorphic *classic* HLA class I molecules, humans encode three relatively conserved *nonclassic,* selectively expressed (HLA-E, -F, and -G) MHC class I genes (also known as MHC-Ib). These evolved at different rates in primates reflecting differential involvement in the modulation of immune responses.[4,64,65] In addition, these molecules are characterized by unique patterns of transcription, protein structure, and immunologic function.[66]

The MHC class I–related chain genes (*MICA* and *MICB*) are located within the MHC region and are characterized by high polymorphism (more than 50 alleles so far identified).[67] The molecules encoded by these genes do not appear to bind peptides or associate with β_2 microglobulin. Their polymorphic variants are not concentrated around the peptide binding groove, yet they seem to have functional significance, because most mutations are nonsynonymous, suggesting selective pressure as a driving force. Their tissue distribution is restricted to epithelial and endothelial cells and fibroblasts. It appears that *MIC* genes modulate the function of NK and CD8+ T cells by binding the NKG2D stimulating receptor.[68] Also, *MIC* has been implicated in transplant rejection because alloantibodies against them are often found in transplant recipients that may exert complement mediated cytotoxicity against endothelial cells from the graft.

Other *unusual* MHC-like molecules are present in the genome and have disparate functions, including presentation of lipid antigens (CD1), transport of immunoglobulins (Fc receptor), and regulation of iron metabolism (hemochromatosis gene product).[69] Contrary to classic MHC class I genes that are constitutively expressed, nonclassic MHC and *MIC* gene expression is dependent on stimulation by proinflammatory cytokines.[70] In addition, two nonclassic MHC class II proteins (HLA-DM and HLA-DO) have been described that function as mediators of peptide exchange by stabilizing empty MHC class II molecules.[37] Finally, it is possible that several nonclassic MHC molecules whose function is to present peptides to lymphocytes may be present throughout the genome. Because of their limited polymorphism, however, these genes may have evolved to serve specialized presentation functions.[71]

Characterized by low polymorphism, the regulation of HLA-G expression follows a nonclassic behavior. *Aberrant* cytokine-responsive regulatory sequences[72–74] may be responsible for its predominant expression by trophoblasts that do not express other HLA proteins.[75] It may also account for its low levels in a variety of human tissues.[76] Lack of responsiveness to common immunostimulatory pathways (NFκB, interferon-γ, or CIITA) is most pronounced in HLA-G cells and is shared by other nonclassic MHC such as HLA-E.[77] Also, HLA-G is expressed in a variety of cancers.[72] It is hard to know what the relevance of HLA-G expression is, because it can occur in various membrane-bound or soluble isoforms with distinct functional characteristics.[72] Functional isoforms that include the α-1 and α-2 domains bind and present peptides from cytoplasmic proteins.[78] Because of the minimal polymorphism, however, the repertoire of peptides presented is likely to be limited, suggesting that peptide binding is necessary to stabilize the molecule rather than being involved in antigen presentation.

Functionally, HLA-G is thought to modulate the function of NK cells through interactions with their inhibitory receptors.[79] In addition, the HLA-G leader sequence contains a peptide that can bind and stabilize the expression of HLA-E, which, in turn, inhibits NK cells.[80] Because the HLA-G-derived leader peptide has the strongest affinity for HLA-E (among all HLA class I molecules), it is likely that HLA-G is a powerful direct and indirect inhibitor of NK cells, reducing the risk of cardiac rejection[81] or inducing immune escape of cancer cells.[72] Although much has been published about the immunoregulatory role of HLA-G, its true function remains mysterious, principally because of discordant findings reported by various groups.[73] With the goal of achieving consensus, a workshop was recently organized to standardize methods of analysis of HLA-G.[66]

HLA-E is minimally polymorphic,[4] binds hydrophobic peptides from other HLA class I leader sequences, and interacts with CD94/NKG2 lectin-like receptors present predominately on NK and partially on CD8+ T cells.[82–85] The peptide binding is highly specific and stabilizes the HLA-E protein, allowing its migration to the cell surface. Thus, surface density of HLA-E is an indirect reflection of the number of HLA class I alleles expressed by a cell.[86] The interaction of HLA-E with CD94/NKG2 protects HLA-E expressing cells from killing. Cells damaged by viral infection or neoplastic degeneration may lose HLA class I expression. As a backup mechanism of protection, reduced HLA class I expression results in decreased expression of HLA-E, leading to vulnerability to NK cells.[87] Some viruses express mimic peptides that bind and stabilize HLA-E so that, although classic MHC molecules are downregulated, HLA-E expression is maintained, allowing the pathogen to simultaneously escape CD8+ T and NK cell killing.[88]

The function of HLA-F remains enigmatic. Its transcriptional regulation is closest to classic HLA molecules in that it can be induced by NFκB, interferon regulatory factor-1, and class II trans-activator.[89] However, contrary to classic HLA molecules, HLA-F is predominantly empty, mostly intracellular, with a restricted pattern of expression.[90] Its tissue distribution appears to be limited to B cells, and therefore it is mostly found in lymphatic organs.[90] Structural studies suggest that HLA-F is a peptide-binding molecule and may reach the cell surface under favorable conditions when a suitable peptide is present.[91] Once on the cell surface, HLA-F may interact with the effector cell receptors IL-T2 and IL-T4, as suggested by HLA-F tetrameric complexes binding studies.[91] Thus, it is possible that in specific yet unknown conditions, HLA-F may modulate the function of immune effector cells similarly to HLA-E and HLA-G.

NON-HLA POLYMORPHISM AND ITS CLINICAL SIGNIFICANCE

Although this chapter is dedicated to HLA, it would be incomplete without mentioning the increasingly recognized polymorphisms of other immune modulators. The significance of non-HLA polymorphism is evidenced by the development of GVHD in the presence of HLA identical matching among relatives. As recently summarized,[92] three general areas of polymorphism are being investigated: NK cell receptor genes, minor histocompatibility antigens, and cytokines. Over the last decade, much progress has been made in identifying the mechanisms of action of NK cells. A major breakthrough was made in the discovery of HLA class I–specific inhibitory receptors as well as on the role that they play in the regulation of NK function with consequent effects on the eradication of hematologic malignancies, prevention of graft rejection, or induction of GVHD.[93] NK cells recognize HLA molecules via killer immunoglobulin-like inhibitory receptors (KIR). The regulation of NK cell function by KIR receptors is further discussed in Chapter 13. KIRs are glycoproteins encoded

Table 145–1 HLA Class-I Alleles Recognized by Different KIRs

KIR	HLA Class I Allele	Amino Acid Sequence Motif
P58.1 (KIR2DL1)	HLA-Cw2, Cw4, Cw5, Cw6	*Asn 77, Lys 80*
P58.2 (KIR2DL2/3)	HLA-Cw1, Cw3, Cw7, Cw8	*Ser 77, Asn 80*
P70 (KIR3DL1)	HLA-Bw4 public specificity	*Aa 77–83*
P140 (KIR3DL2)	HLA-A3, A11	
(KIR2DL4)	HLA-G	

HLA, human leukocyte antigen; KIR, killer immunoglobulin-like receptor.

by at least 17 different genes located on chromosome 19q13.4.[94] All human KIR genes derive from a gene encoding three immunoglobulin (Ig)-like domains (D0, D1, and D2) and a long cytoplasmic tail. However, the KIRs genes are diverse and may encode either two or three Ig-like domains and either a long or short cytoplasmic tail (Table 145–1). The long cytoplasmic tails contain one or two immunoreceptor tyrosine-based inhibition motifs.[95] Although KIR molecules with long cytoplasmic tails inhibit NK cytotoxicity, those with short tails do not. The names given to KIR genes are based on the molecule that they encode. The first digit corresponds to the number of Ig-like domains in the molecule and a *D* denotes *domain.* The D is followed by either an *L* for *long* cytoplasmic tail or *S* for *short* cytoplasmic tail or *p* for a *pseudogene.* The last digit indicates the number of the KIR gene.[96]

Expression of KIR in individual NK cells is complex because NK cells may express several members of the KIR family. The number of KIR genes in each haplotype varies among individuals. The most common haplotype is known as group A, which is made up of 6 genes (2DL1, 2DL2 or 2DL3, 3DL1, 3DL2, 2DS4, and 2DL4). Various KIR genes can recognize different HLA-A, -B and -C molecules. Human leukocyte antigen-C antigens can be divided into two groups based on polymorphisms at amino acid positions 77 and 80 of their class I heavy chains. One group has asparagine (asn) at position 77 and lysine (lys) at 80 and the other has serine (ser) at 77 and asn at 80. Some KIRs recognize HLA-C antigens with asn 77 and lys 80, whereas other KIRs recognize HLA-C antigens with ser 77 and lys 80. The polymorphism at position 80 is most important. Another group of KIR reacts with HLA-B antigens that carry specific combinations of amino acids at positions 77 and 83 of the heavy chain that form HLA-Bw4. Because a single KIR can interact with multiple HLA class I alleles, KIR recognition of HLA class I molecules is degenerate. Another NK inhibitory receptor (CD94-NKG2A) recognizes the nonclassical HLA-E molecule. In addition, each of the KIR genes are extensively polymorphic.

Because the genes for KIR, HLA, and CD94-NKG2A are located in separate chromosomes, they segregate independently and, consequently, individuals can carry genes for KIR for which there is no correspondent HLA ligand.[97] Because HLA-E is expressed in all individuals, NK cells that bear the CD94-NKG2A receptor are not alloreactive. Because the specificity of KIR for their ligands is broad and each individual carries several KIRs, it is likely that in most cases all NK cells of a given person express at least one KIR that is specific for a self-HLA class I allele. Thus, in autologous settings, NK cells kill only aberrant cells that have lost HLA class I expression. By contrast, NK cells can kill allogeneic cells that do not express HLA class I alleles recognized by their KIR. Thus, by knowing the KIR repertoire of a given transplant recipient and the HLA type of the donor, it would theoretically be possible to predict the likelihood of an NK-mediated alloreaction. Importantly, it appears that *alloreactive* NK cells undergo proliferation on exposure to the stimulatory cells and, therefore, can preferentially expand in the presence of allogeneic tissue. NK cells also express activating receptors that are responsible for their lytic activity. Although the identity of the ligands for these receptors has not been identified, it is possible that they are expressed primarily by activated or proliferating cells. It is therefore possible that during the inflammatory process induced in allogeneic conditions, normal cells can become activated by cytokines and express ligands, which are responsible for NK activation in the absence of HLA class I molecules reactive with the inhibitory receptors.[93] The relevance of KIR in transplantation has been well studied in the context of haploidentical hematopoietic transplantation. In this case, several combinations are possible: NK cells from the graft express KIRs that do not interact with the donor's HLA (graft-versus-host alloreactivity). It seems that the presence of graft-versus-host reactive NK cells associated with incompatibilities between donor and recipient (especially HLA-Cw families) has favorable effects in the outcome of acute myeloid leukemia.[98] Alternatively, a good match may be present between graft NK and host HLA as well as between host NK and graft HLA. In such a case, no alloreactivity occurs. Finally, the graft's HLA type may be unsuitable for the host's NK repertoire and the host's reactivity may lead to graft rejection. Alloreactive grafted NK cells seem to prevent GVHD while inducing GVN.[93]

Like HLA, KIR genes are polymorphic, and their variability is clustered in positions likely to affect the overall structure of the molecule. The relevance of KIR gene polymorphism in the outcome of bone marrow transplantation (BMT) is unclear. It appears that the risk of GVHD is highest in the context of unrelated BMT when the recipient KIR genotype is *included* in the donor KIR genotype.[99] These results show that compatibility between KIR genotypes themselves may influence the outcome of BMT.

The minor histocompatibility antigens (mHags) are represented by polymorphic molecules whose peptides containing variant sequences are presented by HLA alleles. They have been shown to be targets of cytotoxic T cells, which can lyse leukemia cells.[100,98] In addition, some mHags are selectively expressed by neoplastic cells.[101] At present, little is known about the identity of mHag epitopes in the context of various HLA types and their significance in the development of GVHD and GVN.

Cytokines are another large family of molecules associated with antigen recognition, graft rejection, and GVHD. Their polymorphism is becoming an important area of investigation in the context of transplantation, autoimmunity, and cancer.[102] Polymorphic sites reside in regulatory regions so that genetic variants are associated with high or low production of a given cytokine rather than differences in its function. A Web site compiles information about cytokine polymorphism (www.bris.ac.uk/Depts/PathAndMicro/services/GAI/cytokine4.htm). Although no consensus has been achieved yet, several studies have shown associations between various cytokine genotypes and propensity toward disease and transplant outcome. These studies have been summarized elsewhere.[92,103] A strong association was recently noted between a low interleukin-10 producer genotype and a tendency to develop melanoma and prostate cancer.[104,105]

HLA NOMENCLATURE

The history of the HLA system nomenclature was summarized by Sir Walter Bodmer who, together with Ruggiero Ceppellini, was primarily involved in its development.[106] It began as HL-A, for *human leukocyte locus A.* With the recognition that HLA molecules are encoded by more than one locus, the A came to stand for *antigen* and a locus designation was added after HLA (ie, HLA-A, -B, -C, -D, etc.).[2] From then on, the World Health Organization has updated the nomenclature regularly, the last being in December 2004 after the 14th International Histocompatibility Workshop (Table 145–2).[4] At present two systems are used. An immunologically defined nomenclature is based on the identification of HLA antigens on the surface of leukocytes. Therefore, HLA phenotypes described by immunologic methods are conventionally called *HLA antigens.*[107] The second system is based on the molecular identification of nucleotide sequences in genomic DNA, and results are conventionally referred to as HLA-alleles. Because molecular typing has higher resolution, it has gained increasing popularity.

IMMUNOLOGICALLY DEFINED HLA NOMENCLATURE

Immunologically defined nomenclature follows this rule: HLA separated by a hyphen from a capital letter identifying the locus encoding distinct HLA class I (-A, -B, -C) or class II (-DR, -DQ, -DP) antigens. The letter is followed by a number that identifies a serologic family of alleles sharing epitopes recognized by alloantibodies or alloreactive cytotoxic T cells. With improved understanding of the molecular genetics of the HLA region, various appendages have been removed from the HLA nomenclature. For instance, the letter *w* was used to indicate a provisional assignment, and this has been discontinued, but it is occasionally added to HLA-C antigen nomenclature to distinguish it from complement genes; DP and DW also maintained this letter to reinforce the dependency of their immune identification predominantly through cellular techniques. Finally, HLA-Bw4 and -Bw6 retain the *w* to emphasize that the public epitopes are shared by several HLA-B and some HLA-antigens. More recently, a bridge between immunologic and molecular nomenclature has been proposed whereby HLA antigens that encompass a single gene product can be assigned a two-digit numeric extension corresponding to the molecular nomenclature for that allele.[108]

SEQUENCE-DEFINED ALLELIC NOMENCLATURE

The Tenth International Histocompatibility Workshop recommended in 1987 a sequence-based nomenclature[108] to describe alleles not distinguishable by immunologic methods. Since then, the number of HLA alleles has rapidly increased. A total of 422 new alleles were named since the previous report in 2003, and as of December 2004,[4] 349 designations were given to HLA-A, 627 to -B, and 182 to -Cw alleles (1180 named HLA class I alleles). Assignments for HLA class II included 394 HLA-DRB1, 61 -DQB1, and 116 -DPB1 alleles. Other designations are summarized in Table 145–2. Human leukocyte antigen designates molecules belonging to the human MHC followed by the locus (-A, -B, etc). Alleles are then identified after an asterisk (*). A four-digit number is used in which the first two digits refer to the original serologic family (eg, HLA-A2 serologically would be HLA-A*02). The last two digits designate alleles sequentially identified within that family. Often numbers are missing because an original assignment was revoked (eg, this is why there is no HLA-A*2401). When silent mutations are identified (variation in nucleotide sequence that does not translate into changes in amino acid sequence), the name of the allele remains identical, but another two digits are added to designate a variant that has no functional significance. New sequences are submitted to EMBL (www.ebi.ac.uk/Submissions/index.html), GeneBank (www.ncbi.nlm.nih.gov/Genbank/index.html), or DDBJ (http://www.ddbj.nig.ac.jp/sub-e.html).

Requirements for new allele naming were described by Marsh and associates.[4] The World Health Organization committee also made recommendations about naming alleles with aberrant expression such as HLA-G isoforms and KIR. Some alleles are identifiable at the genomic level but are not translated into protein (pseudo genes). These are indicated by the addition of an N (for null) following the numerical designation of the allele. Mutations inducing a reduction of expression are marked by *L* (*low expression*). An *S* denotes alleles expressed as soluble *secreted* molecules, such as HLA-B*4402010S characterized by an intronic variant that disallows the expression of the trans-membrane domain of the HLA molecule and is, therefore, only in soluble form. Differential splicing of HLA-G leads to production of membrane-bound and soluble forms, which are respectively denoted by a lower-case *m* or *s* before HLA. Limited cytoplasmic expression is denoted by C and aberrant expression by A. Finally, KIR polymorphism will be classified by a new system that is in preparation.[4,97,109] A nomenclature system for cytokine polymorphism has not yet been developed.[110]

HLA TYPING IN CLINICAL HEMATOLOGY AND DETERMINATION OF COMPATIBILITY HLA TYPING

Originally, HLA typing was done primarily in support of transplantation or transfusion needs with the purpose of identifying histocompatibility through the best match between donor and recipient. Allosensitization of recipients previously exposed to heterologous cell products is tested by identifying alloreactive antibodies in serum and cross-match procedures are performed to grade compatibility of candidate donor-recipient pairs. In addition, HLA testing has been applied to identify links between a given disease and the genetic make-up of its carriers.[111] Strong associations are exemplified by birdshot uveitis (a disease occurring exclusively in HLA-A29 individuals),[112] type I diabetes and other autoimmune diseases,[113–115] or long-term survival of HIV infected individuals.[55] These studies evaluated the role that genetic background may have contributed over environmental factors.[111,116] Human leukocyte antigen associations are thought to be caused by the differential ability of distinct alleles to present immunogenic epitopes[112,113] or by the close linkage to the HLA class III region where potent immunomodulators such as tumor necrosis factor α are located.[117] It has also been suggested that HLA associations may be predictors of immune responsiveness of cancer to immune therapy.[60] However, such associations have remained quite difficult to reproduce.[118] Human leukocyte antigen typing is requested for enrollment of patients into and interpretation of immunization protocols,[24] because specific HLA/epitope combinations require high-resolution typing.[22,119]

Serologic testing takes advantage of fetomaternal sensitization. In mammals, the progeny carries a full haplotype of paternal origin, and pregnant women may develop antibodies against the paternal haplotype. Maternal serum samples are collected at term and characterized by testing their ability to kill HLA-bearing repository cell lines of known phenotype in the presence of complement (complement-dependent cytotoxicity [CDC]).[120] Then CDC is used for HLA typing by exposing circulating cells expressing HLA class I (most cells) and class II (predominantly B cells) antigens from the individual (to be typed to previously characterized sera or monoclonal antibodies).[121] Conversely, already typed repository cell lines are used in CDC to identify alloantibodies in sera of sensitized individuals. The fraction of cell lines killed by the sera roughly grades the intensity of allosensitization or panel reactive antibody (PRA) reactivity. Some antibodies activate complement and kill with poor efficiency, known as the *cytotoxicity negative absorption positive (CYNAP) phenomenon.*[122] As judged by cytotoxicity testing, CYNAP may underestimate allosensitization. By modifying CDC with the addition of antihuman antibodies suitable for complement activation, CYNAP can be circumvented (augmented CDC). In this case, however, relatively innocuous antibodies can cause overestimation of clinically relevant allosensitization.[123] Other methods identify alloantibodies, including immobilization of HLA molecules on solid surface to capture soluble antibodies[124–126] and flow cytometry using a spectrum of microbeads loaded with known HLA alleles.[127,128] An interlaboratory comparison of serum screening for HLA antibody determination suggested that enzyme-linked immunosorbent assay and flow cytometry yield higher PRA activity values compared with CDC or augmented CDC.[125] However, the study suggested a lack of consistency among participant laboratories, leaving unsolved the question of which method most accurately defines clinically relevant allosensitization and a panel of various methods may be most informative.[72]

Complement-dependent cytotoxicity is declining in interest in the United States because most laboratories are switching to easier-to-handle and higher resolution molecular methods. However, immunologic methods remain valuable to characterize functional aspects of HLA because molecular methods cannot define whether an HLA allele is expressed nor, at least until recently,[129] grade allosensitization. Thus, it is likely that immunologic methods will continue to complement molecular methods in the future.[129]

The usefulness of conventional serologic typing has been limited by the availability of allele-specific sera. Most importantly, as anti-

Table 145–2 Name of Genes in the HLA Region Considered by the WHO Nomenclature Committee[4]

Name	Previous Equivalents	Molecular Characteristics	# of Alleles (July 2004)
HLA-A	–	Class I α-chain	349
HLA-B	–	Class I α-chain	627
HLA-B	–	Class I α-chain	182

HLA, human leukocyte antigen; WHO, World Health Organization.

bodies identify structural differences on the surface of HLA molecules, variants caused by nucleotide polymorphism in nonexposed areas such as the peptide binding groove of the HLA heavy chain are not detectable. However, these differences are of functional significance because they determine the specificity and affinity of peptide binding[130,131] and T-cell recognition of self and allogeneic target cells.[23,132] DNA-based typing directly determines the sequence,[133] and its resolution is limited only by the number of allele-specific probes used to identify an ever growing number of alleles (see Web site www.anthonynolan.com/HIG/index.htm). Various polymerase chain reaction (PCR)-based methods have been described among which sequence-specific primer[133,134] and sequence-specific oligonucleotide probe[135,136]–based methods are the most universally used. The rich nature of HLA has led to proportionally increasing complexity of the assays used to cover all possible alleles. As a consequence, accurate HLA typing for donor and recipient matching in transplantation has become increasingly complex and burdensome. In addition, because of the important role that HLA molecules play in antigen presentation and the stringency of the relationship between epitope and associated HLA allele, high-resolution typing is increasingly requested for appropriate enrollment of patients into immunization protocols aimed at the enhancement of T-cell responses.[137] Therefore, high-resolution HLA typing is increasingly in demand in clinical and experimental settings.

Although oligonucleotide-based methods could theoretically discriminate any known polymorphic site, they have two major limitations. First, they require a specific PCR reaction for each allele investigated. Because each individual has only two alleles for each locus, a disproportionately large number of PCR reactions must be performed to cover all possible polymorphisms to identify the two borne by the individual tested. Because both methods are based on specific interactions with known oligonucleotide sequences unique to a particular allele, they cannot identify unknown polymorphisms unless the variation occurs within the region spanned by one of the oligos used in the assay. Because of these limitations, interest is growing for definitive typing methods that yield conclusive information about the identity of the alleles typed. The most comprehensive method is sequence-based typing. Unfortunately, its use has been limited by cost of equipment and reagents and by the high level of expertise and time required for the interpretation of each typing. More recently, high-throughput, robotic, sequence-based typing has been developed that allows sequencing of hundreds of genomic fragments each day.[138–140] However, even sequence-based typing has some technical limitations. Some combinations of HLA class I and class II alleles result in ambiguous allele combinations that require additional testing for resolution.[141] Finally, new methods based on high-density array technology are being developed that may allow extensive typing of known and unknown polymorphisms on microchips.[142,143]

High-resolution methods yield high-resolution information of an individual's HLA type. However, the wealth of information is counterbalanced by increased difficulty in identifying suitable HLA alleles during donor-recipient pairing or accrual into immunization protocols restricted to specific HLA-epitope combinations. Thus, at present, clinicians are faced with the daunting task of applying high-resolution typing results of unclear relevance to clinical settings.[144]

TESTING FOR ALLOSENSITIZATION AND DETERMINATION OF COMPATIBLE RECIPIENT/DONOR PAIRS

Any cell containing product transfused or transplanted between different individuals should be compatible in an ideal situation. Yet, in most cases, histocompatibility is not prospectively sought. Thus, patients with multiple exposures to blood products often become reactive to various antigens, including HLA. Transplant candidates often develop prior alloreactivity following transfusion of platelet concentrates contaminated with leukocytes, even though the incidence of allosensitization is much less because of leukodepletion of blood products. Alloreactivity must be documented before transplantation, because alloreactive patients can still undergo transplantation, provided that the donor has no mismatched HLA antigens reacting with the patient's antibodies. Patients who have received repeated platelet transfusions may become allosensitized and, consequently, refractory to further transfusions unless HLA-compatible platelets are used. Obviously, the best compatibility consists of identical matching. It is often impossible to identify a perfectly matched unrelated donor, particularly in the case of rare HLA types, Thus, other strategies are adopted to identify the best possible match or *compatible mismatch.* Selection of unrelated donor-recipient pairs is carried out through typing with serologic, cellular, and molecular methods.[145] The chances of identifying compatible donors based on full or partial HLA matching have become increasingly low with the increasing resolution of the typing methods.[144] To broaden compatibility, matching criteria of donor-recipient pairs are based on shared public epitopes assigned to cross-reacting groups (CREGs)[146] or shared amino acid polymorphisms defined through sequence information (Table 145–3).[147] The preexistence of alloantibodies restricts the identification of compatible donors even further. Highly sensitized recipients with PRA activity exceeding 85% of tested specificities (generally between 30 and 60) represent a particularly challenging group.[148] An alternative approach to the exclusion of alloreactive determinants is the inclusion of *acceptable* antigen mismatches expressed in a panel of cells that give negative reactions with the recipient sera,[149] which extends the repertoire of possible donors. All these are fundamental tools for the identification of nonrelated, not fully matched donor-recipient pairs. Unfortunately, even these compromises often fail to identify a suitable match.

Duquesnoy[148] recently described a molecularly based algorithm to identify histocompatible pairs called HLAMatchmaker. This method focuses on the structural basis of HLA class I polymorphism so that compatible HLA mismatches can be identified without extensive serum screening. This algorithm is based on the principle that short amino acid sequences (triplets) characterizing polymorphic sites of the HLA molecules are critical components of allosensitizing epitopes. Such amino acids reside in the α helices and β loops of the heavy chain. Because each HLA molecule expresses a characteristic string of these determinants, it is possible to characterize each molecule according to the linear sequence of amino acid triplets present on its surface. Based on the reasonable assumption that none of the triplets present in the HLA repertoire of the recipient is self-immunogenic, it is possible through a process of *electronic recombination* to identify donors with HLA alleles different from the recipient's but containing exclusively shared triplets. These HLA alleles will be compatible, because they do not contain any epitope absent in the recipient.

In theory, a large number of triplets could occur if polymorphisms were randomly distributed. However, most HLA molecules span conserved domains and only a total of 142 different polymorphic triplets designate serologically defined HLA-A, -B, and -C antigens.[148] Triplet polymorphism can occur in 30 locations on HLA-A, 27 in HLA-B, and 19 in HLA-C chains. Because the HLAMatchmaker algorithm includes interlocus comparison, it is possible to accumulate the information into a single database. Among the 142 polymorphic triplets, 29 are polymorphic for one class I locus but monomorphic for another class I locus. Such polymorphic triplets cannot be immunogenic because they are always present on the patient's own HLA antigens, whereas the remaining 113 triplets have immunogenic potential. With this algorithm, it is possible to significantly broaden the number of *molecularly matched* HLA alleles and significantly increase the chances of identifying a compatible donor, particularly in those cases in which the recipient has a rare HLA phenotype. In addition, HLAMatchmaker considers triplets that are present in the panel cells that give negative reactions with the recipient's serum. These negative panel cells can be expected to share antigens with the patient's, but other HLA antigens may be present and contain mismatched triplets apparently not immunogenic for that patient. Such triplets are therefore acceptable and can be added to the algorithm for the identification of possible donors. Thus, HLAMatchmaker

Table 145–3 Population Frequencies of Major Cross Reactive or Determinants Present on HLA-A and -B Gene Products

Major Cross-Reactive Group	Public Epitope	Associated Private Epitopes	Approximate Epitope Frequency (%)*
1C	1p	A1, 3, 9 (23, 24), 11, 29, 30, 31, 36, 80	79

HLA, human leukocyte antigen.
*North American white populations of European origin.

assesses HLA compatibility at a molecular level by determining whether or not a triplet in a given position of a mismatched HLA antigen is also found in the same position in any of the recipient's own HLA-A, HLA-B, and HLA-C molecules. A shared triplet in the same position on a mismatched HLA antigen cannot elicit a specific antibody response in that patient. This hypothesis needs future testing, because this strategy might represent a revolutionary tool for the identification of potential donors. Preliminary verification of the algorithm in a series of high PRA renal patients suggested that this is a proper strategy at least in highly sensitized renal transplantation candidates waiting for unrelated donors.[150] HLAMatchmaker is also effective at selecting an optimal HLA-typed platelet component for alloimmunized thrombocytopenic patients.[151]

A new version of HLAMatchmaker considers so-called eplets and is based on the structural definitions of functional epitopes on well-characterized protein antigens that have been complexed with antibody.[152] Eplets represent amino acid residue configurations within a 3 to 3.5 Angstrom radius of each polymorphic residue on the HLA molecular surface. Many eplets correspond to triplets but eplets represents a more complete repertoire of structurally defined epitopes.

THE HLA MOLECULES AS ANTIGENS AND HLA ALLOIMMUNIZATION

By no means are HLA molecules antigenic in physiologic condition (with the exception of maternofetal alloimmunizaton). However, because of their high density on the surface of cells, they can become highly immunogenic in the nonphysiologic event in which cells from different individuals are exposed to another person's immune system. The mechanism or mechanisms leading to allosensitization are believed to follow two pathways. The first pathway mimics the one followed during most immune reactions in which antigen is up taken by antigen-presenting cells and presented to autologous lymphocytes (indirect pathway). In this case the donor's HLA molecules are processed into peptides through the exogenous pathway of antigen presentation and presented to autologous T cells as linear peptides.[153,154] This pathway is believed to be responsible for the development of alloantibodies as well as T-helper cell responses, but its role in the development of cytotoxic T cell responses remains unclear. Because this pathway depends on the presentation of donor HLA molecules by recipient HLA alleles, it may explain why the humoral response to HLA class I allodeterminants correlates with the HLA phenotype of the responder.[155] The indirect pathway of HLA allorecognition has been associated with allograft rejection.[156] Because the function of HLA molecules is to present antigenic determinants to T cells, it could be easily envisioned how minor changes in their structure could be misinterpreted as antigenic epitopes. Intact HLA molecules residing on the surface of donor cells are a perfect target for T-cell–mediated allorecognition (direct pathway) either through the direct cytotoxic effect of T cells against target cells or by the activation of helper T cells, through HLA class II engagement, which leads to stimulation of antibody-mediated immune responses.[157]

Humoral responses mediated most frequently by IgM are predominant in the sensitization to infrequent allogeneic exposure, because they require smaller amounts of antigenic material. T-cell responses become more manifest in the context of transplantation in which the persistence of the allogeneic stimulus allows the expansion and sustenance of alloreactive cytotoxic T cells. Antibodies and TCR have different requirements for their engagement, which means epitopes recognized by T cells and antibodies are different. Antibodies require interaction with a small structure, including a limited number of amino acids; thus, any sequence combination on the surface of an HLA allele not present in the individual exposed to the alloreaction may represent an epitope. T cells have much lower binding affinity for their ligand and require a complete interaction with the peptide as well as the α and β helices of the HLA class I heavy chain.[11] Although several B-cell epitopes recognized by antibodies can be identified in a given HLA molecule, generally the whole HLA molecule is necessary for T-cell–dependent allorecognition. Definition and topographic mapping of epitopes defined by serologic or cellular methods has revealed distinct regions of hypervariability in the α-1 and α-2 domains of the class I heavy chains and in the α-1 and β-1 domains of class II molecules.[158] Two types of antibody-defined epitopes can be identified according to their frequency among HLA alleles. Private epitopes are almost but not totally unique for a single serologically defined HLA antigen and are used for typing. These epitopes are generally shared by all molecular alleles present in that given family, and fine differences among alleles within a general

family cannot be distinguished by antibodies. Public epitopes are more widely distributed and cluster distinct serologic families into groups. These epitopes bear an immunodominant character. Immune sera that identify public epitopes have been considered predictive of major CREGs with the idea that alloreactivity among patients belonging to the same CREG may be less likely (Table 145–3). The predictive value of CREGs in transplant outcome or platelet transfusion results, however, remains to be demonstrated.

Not all subjects who have been exposed to alloantigens develop alloantibodies, and in fact exposure to low doses of donor-specific HLA antigens through donor transfusion may have a beneficial effect on graft survival.[159] Obviously, the degree of compatibility in the context of allosensitization may vary according to the degree of mismatch between donor and recipient. In addition, alloantibodies are one aspect of alloreaction that does not take into account cellular responses. These have been more difficult to document, although they are likely to play an important role in the context of acute transplant rejection. Several hypotheses have been discussed about the reason or reasons for the capriciousness of allosensitization, including the presence of regulatory immune responses or cytokine-mediated immunosuppression. Currently, the mechanism modulating the quality and quantity of alloimmunity remains elusive; and different aspects of this algorithm are discussed ad hoc in this chapter, with particular attention to molecularly defined algorithms for the prediction of histocompatibility.[129,148,160,161]

Clearly, HLA matching is beneficial in patients undergoing renal transplantation. An analysis of more than 150,000 recipients receiving transplants in different centers participating in the Collaborative Transplant Study showed that a complete mismatch (6 HLA-A+B+DR) had a 17% lower survival expectation than no mismatch ($P < 0.0001$).[162] Matching was particularly beneficial in patients with highly reactive preformed alloantibodies. The same study suggested that high-resolution matching based on molecular typing improved graft survival. Similar results were observed in cases of cardiac transplantation in which HLA matching yielded significantly better results ($P < 0.0001$). This is particularly important because donor hearts are currently not allocated according to HLA match in most centers. In cases of liver transplantation, HLA matching was not beneficial.[163]

Donor-specific hyporesponsiveness has been particularly well documented in the context of renal allotransplantation and may limit the need for immunosuppression. A recent randomized study suggested that pretransplant donor transfusions improved the survival of cadaver kidney grafts in patients receiving modern immunosuppressive regimens, but the mechanism remains unclear.[164,165] Although most centers currently do not implement deliberate blood transfusions, the usefulness of this approach needs to be investigated further.

Approximately 5% to 10% of platelet transfusions are given to patients who have been previously exposed to HLA class I expressing heterologous cells and are reactive to HLA antigens. Such patients are refractory to random-donor platelets and must be given HLA-matched or *semi-matched* plateletpheresis components.[41–44] However, a provision of HLA-matched platelets does not always improve platelet recovery and survival. Possibly, the ineffective platelet transfusion is in part caused by unrecognized HLA mismatches between the donor and recipient resulting from the low-resolution methods used for typing, and higher resolution methods have been advocated. It is currently controversial whether or not molecularly based HLA typing confers an advantage over serologic typing, and this principle was recently questioned in the context of hematopoietic cell transplantation.[166,167]

HLA AS A FUNCTIONAL MEDIATOR OF GRAFT-VERSUS-HOST DISEASE AND/OR GRAFT-VERSUS-NEOPLASIA EFFECT

Allogeneic or syngeneic bone marrow transplantation is used predominately for the treatment of hematologic malignancies[168–170] and other hematologic disorders such as aplastic anemia,[171] thalassemia,[172] or myelodysplastic syndrome.[173] This strategy can induce long-term disease-free survival in chronic myelogenous leukemia patients.[168,169] The objective of bone marrow transplantation in cases of malignancy is to cure the patient by eradication of the neoplastic cells with myeloablative chemotherapy followed by restoration of hematopoiesis through the transplantation of normal hematopoietic stem cells derived from HLA-compatible normal donors. This strategy is characterized by the insurgence of an immune reaction toward the host's normal cells (GVHD),[174–176] which is often associated and preferentially targets neoplastic cells (GVN effect).[177–184] Both the GVHD and the GVN effect occur in the presence of a full HLA match; thus, the HLA molecules are not targets of allosensitization themselves but present polymorphic molecules expressed by the recipient's cells recognized by the grafted immune cells.

GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease represents the alloimmune reaction of donor lymphocytes against normal cells of the recipient. Graft-versus-host disease occurs predominantly in association with hematopoietic progenitor cell transplantation (HPCT) compared to other types of transplants because the hematopoietic transplant is enriched of immune cells. Myeloablative therapy is generally administered before transplantation and, as a consequence, in most cases prevents graft rejection. Graft-versus-host disease is a major complication of HPCT, and a fine balance between GVHD and graft rejection is maintained by modulating the level of posttransplantation immunosuppression.[184] In addition, other major disturbances associated with HPCT such as overwhelming infection, leukemia or tumor relapse, and other regimen-related morbidities are strongly influenced by the treatment of GVHD. With the advent of nonmyeloablative HPCT for the treatment of nonhematologic diseases such as solid tumors, GVHD has reached a predominant role because of its close association with GVN effect.

T-cell depletion has been advocated for the prevention of GVHD by decreasing the probability of cellular and humoral alloresponses.[185,186] This strategy decreases the occurrence of GVHD but is associated with an increased risk of graft rejection and tumor or leukemia relapse.[184] In fact, Weiden and colleagues[187] observed that survivors of severe acute GVHD had a significantly lower incidence of tumor relapse compared with patients who did not experience GVHD. This association appeared mandatory and it was believed that the beneficial GVN reaction was inseparable from GVHD.

The risk of GVHD increases with genetic distancing between donor and recipient. Thus, recipients of transplants from HLA-identical twins have a lesser chance of developing GVHD than recipients of transplants from HLA-unrelated donors and from donors with only a partial HLA match.[188,189] Interestingly, however, although the genetic closeness between donor and recipient appears to decrease the risk of GVHD, it also decreases the therapeutic benefit, with increased chances of tumor relapse.

GRAFT-VERSUS-NEOPLASIA EFFECT

It was originally observed that a beneficial collateral effect of GVHD was the rejection of neoplastic cells by the donor immune system in the context of hematologic malignancies (graft-versus-leukemia effect).[177] It was rapidly recognized that the graft-versus-leukemia effect could play a powerful therapeutic role in the treatment of refractory malignant disorders, including some solid tumors (graft-versus-tumor effect).[181] Because the biology and clinical principles underlining the two effects are likely similar, for simplicity, in this chapter we coin a unifying term: *graft-versus-neoplasia effect.* Indeed, there is a perception that the GVN reaction is the most potent form of tumor immunotherapy currently in clinical use. Its mechanism of action is still poorly understood. T cells definitely play a fundamental role in the initiation and maintenance of the alloreaction toward neoplastic cells.[190] A sevenfold increase in the chance of relapse was

noted in patients with chronic myelogenous leukemia who received a T-cell–depleted BMT as compared with a subset of patients who had received a T-cell–repleted BMT but did not develop GVHD.[185,186] This result suggested that GVHD is a biologic entity different from GVN effect. In addition, on leukemia relapse, administration of donor lymphocyte infusion could re-induce clinical remission.[191] Finally, leukemia-specific CD8+ T cells have been identified in circulating lymphocytes at the time of leukemia regression.[192] NK cells play an additional role in mediating this phenomenon, and clinical data suggest that mismatch of NK receptor and ligands during allogeneic BMT can be used to enhance the GVN effect.[93,193] Appreciation of the GVN effect has led to the development of nonmyeloablative stem cell transplants designed to immunosuppress the host to a level sufficient to permit engraftment of the donor immune cells to generate GVN without inducing the serious complications associated with myeloablation.[184] The GVN effect has gained popularity in the last decade to the point that allogeneic-based immunotherapeutic approaches have been advocated for several nonhematologic malignancies.[184] The rationale is largely based on the assumption that the immune cell repertoire capable of recognizing cancer cells in the allogeneic context is broader than in the autologous system. Donor T cells can target not only tumor-specific antigens but also allelic variants of these antigens; mHag; and, in the case of HLA-mismatched transplants, HLA antigens disparate from the donor expressed by the tumor cells.[194–196] Although there are several theories about how GVN effect occurs, it remains unclear why allo-T cells have a better chance of targeting tumor cells in an allogeneic context as compared with the natural insurgence of antitumor immunity described for several solid tumors.

HLA AND T-CELL–DIRECTED IMMUNIZATION

The last decade has witnessed remarkable progress in the identification and mapping of T-cell epitopes for various infectious diseases and cancer. In particular, progress was made in mapping HLA associated epitopes for HIV, cytomegalovirus, and Epstein-Barr virus.[197–200] In addition, the molecular identification of tumor-associated antigens has yielded a large number of epitopes that could be used to immunize against neoplasia.[201] A comprehensive discussion of these topics is beyond the scope of this chapter, but we address a few points framing the relevance of HLA in the context of T-cell–directed immunization.

The identification of T-cell epitopes led to two major areas of clinical investigation. The first is active-specific immunization to prevent or treat ongoing infections or cancer. The second is the harvest and in vitro expansion of immunization-induced T cells for adoptive transfer. In general, active immunization has proved successful in inducing epitope-specific T cells easily detectable among circulating lymphocytes.[119,202–204] However, often the immunization-induced enhancement of T-cell function is not associated with clinical improvement. Although the reason for the clinical ineffectiveness of immunization-induced T cells is unclear, it has been postulated that they may be quantitatively[203] or qualitatively[205] inadequate for eradicating disease. Therefore, a second strategy is being pursued whereby the number of antigen-specific T cells is amplified in vitro for autologous or donor-derived adoptive transfer. This second strategy has met some promising success in the context of ganciclovir-resistant cytomegalovirus infection,[206] Epstein-Barr virus–induced posttransplantation lymphoproliferative disorders,[207] and metastatic melanoma.[208]

Whether delivered as a primary form of therapy or to prime in vivo T cells for further ex vivo expansion, epitope-specific vaccination encounters the major limitation of a stringent requirement for HLA allelic association. Although superfamilies of HLA alleles may share epitopes,[14,15] in practical terms, clinically relevant HLA/epitope associations are restricted to few peptide/allele combinations for a given protein.[22] Patients considered for enrollment in immunization protocols are best served by high-resolution HLA typing to exclude subtypes with unproven immunogenic potential for a given epitope. To bypass the stringent HLA requirements demanded by epitope-specific vaccination, whole-antigen delivery is suggested. This is based on the assumption that the epitope repertoire of a protein can be adjusted to distinct HLA phenotypes by a cellular process of *self-selection* naturally coupling peptides to HLA according to binding affinity. Although theoretically indisputable, in practice the truth of this assumption depends on the efficiency with which individual molecules are processed and presented in association with distinct HLA alleles. Even in these settings, high-resolution typing is desirable because it allows accurate interpretation of immunization results by allowing a comparison between the detailed genetic makeup of the individual receiving the vaccine and his or her antigen-specific immune response. It is likely that in the future HLA laboratories will receive increasing demands for high-resolution, definitive typing for appropriate patient enrollment and for subsequent interpretation of immune responses.

MONITORING IMMUNE RESPONSES WITH TETRAMERIC HLA-PEPTIDE COMPLEXES

A growing understanding of the molecular immunology of T-cell interactions with HLA/epitope complexes in the context of infectious disease, virally induced malignancies, and spontaneous tumors as well as interest in their treatment with T-cell–directed vaccines has generated more attention on issue of using accurate methods to quantify ex vivo the extent of antigen-specific immune responses.[209] The most commonly used assays available for the enumeration of antigen-specific T cells include tHLA; intracellular fluorescence-activated cell sorter staining for cytokine expression on cognate stimulation; detection of cytokine release by enzyme-linked immunospot assay; and quantitative real-time PCR, recently reviewed by Keilholz and associates.[210] Tetrameric HLA/peptide complexes are complexes of four HLA molecules combined with a specific peptide and bound to a fluorochrome (Figure 145–6). These complexes bind to complementary TCR and identify antigen-specific T cells,[211] measuring cellular responses against specific epitopes with sensitivity as low as 1 in 5000 CD8+ T cells. To synthesize tHLA molecules, soluble HLA heavy chain containing a biotinylation site and recombinant β_2-microglobulin are synthesized and purified. They are then refolded in the presence of the specific epitope and the monomer is isolated by gel filtration and is biotinylated. Fluorescent streptavidin is added to induce tetramerization. An aliquot of tetramers is added to the peripheral blood mononuclear cells together with other antibodies for a more detailed characterization of antigen-specific T cells.[205] Analysis is performed using a flow cytometer. Because of the specificity of vaccines, the patient's HLA type and specific peptide must be identified and synthesized to provide the adequate tetramer. Pentameric HLA/peptide complexes have recently become available and in some laboratories have replaced the use of tHLA.

Analysis of tHLA offers many potential advantages over other T-cells assays. This method is quantitative and enables an estimation of the avidity between TCR and peptide-loaded HLA class I molecules. Tetrameric HLA/peptide complexes staining does not kill the labeled cells, allowing sorting of subpopulations by flow cytometry for additional analysis or expansion for adoptive transfer. With tHLA specific T cells can be analyzed from blood samples without the prerequisite of in vitro culture and all specific cytotoxic T lymphocytes are detected, regardless of their functional status.[203,205,212]

HLA Summary

The relevance of HLA in clinical pathology has broadened from its role as a predictor of allosensitization to a mediator of GVHD and GVN. The understanding of action mechanisms in various nonclassic HLA genes as well as KIR has opened a new field. The study examining the function of the innate immune response in the context of transplantation and other immunopathologies is a result of this.

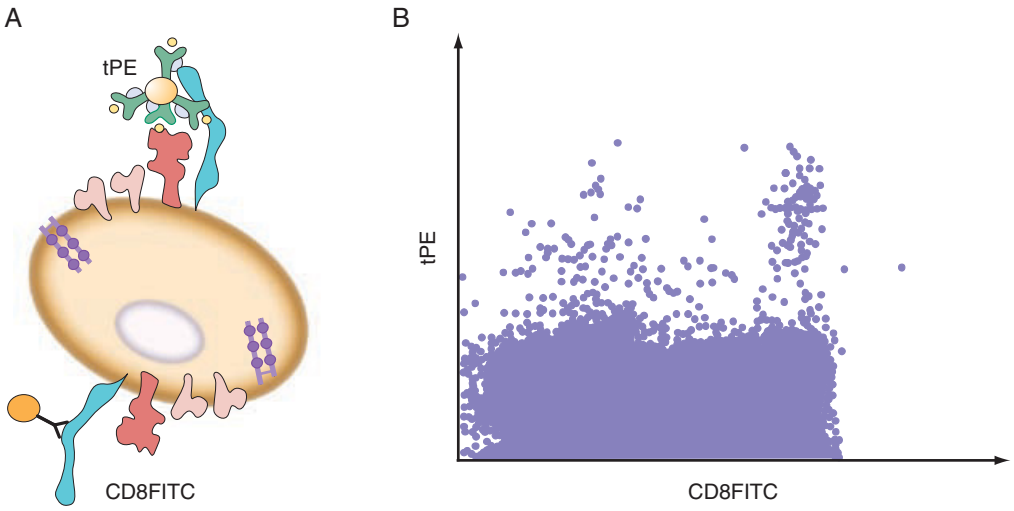

Figure 145–6 Schematic representation of the mechanism of binding of tetrameric peptide/human leukocyte antigen complexes (tHLA) to antigen-specific T cells. **A**, Binding of tHLA to T-cell receptor (TCR). The tHLA consists of four HLA/peptide complexes identical to the ones recognized by the T cell on the surface of live cells. Each HLA molecule is modified to contain one biotin molecule that serves as a bridge for binding to tetravalent streptavidin molecules fluorescently labeled. **B**, Actual FAC analysis result of CD8+, tHLA-positive T cells. (Modified from Monsurro V, Nargosen D: Immunotracking of specific cancer vaccine CD8+ lymphocytes. ASHI Q 26:100, 2003.)

Together with HLA, immunogenetics is rapidly growing, driven by the realization that polymorphism is the hallmark of human immunopathology as its spans mHag, KIR, cytokines, and their receptors. Each of these is interwoven in an intricate array of interdependent functions that cannot be discounted. Modern methods should be able to adopt high-throughput systems for the parallel assessment of all these variables when addressing the genetic makeup of an individual in correlation with the natural or therapeutic history of his or her disease. The comparison of donor and recipient protein profiling and cytokine polymorphism may offer insights into the rejection mechanism when matched-donor grafts are used. Finally, the increased use of T-cell–directed immunization is driving renewed interest in high-resolution typing of HLA molecules to allow a more accurate interpretation of clinical and immunologic results.

HUMAN NEUTROPHIL ANTIGENS AND THEIR CLINICAL SIGNIFICANCE

Lalezari and colleagues described the first granulocyte antigens. These antigens were designated *N* for neutrophil. Each antigen system was described alphabetically and each allele was described numerically in order of discovery. They identified NA1 in 1966 and its allele, NA2, in 1972.[213,214] In 1971, Lalezari and coworkers described another granulocyte antigen, NB1.[215] Reports of several other granulocyte antigens followed.

A new nomenclature was established in 1998 by the International Society of Blood Transfusion Working Party (Table 145–4).[216] In this nomenclature, antigen systems are referred to as *human neutrophil antigens,* or HNA. The antigen systems—that is, the polymorphic forms of the immunogenic proteins—are indicated by integers, and specific antigens within each system are designated alphabetically by date of publication. Alleles of the coding genes are named according to the Guidelines for Human Gene Nomenclature. Neutrophil antigens NA1 and NA2 became HNA-1a and HNA-1b in the new nomenclature and NB1 became HNA-2a.

Neutrophil antigens were first characterized using clinically important allo- and autoantibodies. Most often, neutrophil-specific alloantibodies are directed toward antigens in the HNA-1 or HNA-2 systems. The availability of many different alloantibodies and monoclonal antibodies to HNA-1 and HNA-2 antigens has allowed the characterization of these antigen systems. In addition, three other antigens systems have been partially characterized, HNA-3, HNA-4, and HNA-5. The serology, biochemistry, molecular biology, and clinical significance of these antigens are reviewed here.

Table 145–4 ISBT Nomenclature

Antigen System	Antigens	Location	Former Name	Alleles
HNA-1	HNA-1a	FcγRIIIb	NA1	FCGR3B*1
	HNA-1b	FcγRIIIb	NA2	*FCGR3B*2*
	HNA-1c	FcγRIIIb	SH	*FCGR3B*3*
HNA-2	HNA-2a	CD177 (NB1 gp)	NB1	*CD177*1*
HNA-3	HNA-3a	70–95 kD gp	5b	Not defined
HNA-4	HNA-4a	CD11b (CR3)	Mart[a]	CD11B*1
HNA-5	HNA-5a	CD11a (LFA-1)	Onda	*CD11A*1*

CR3, C3bi receptor; gp, glycoprotein; HNA, human neutrophil antigen; ISBT, International Society of Blood Transfusion; LFA-1, leukocyte function antigen-1.

THE HNA-1 ANTIGEN SYSTEM

Expression of HNA-1 Antigens

Human neutrophil antigens -1 antigens are expressed only on neutrophils. HNA-1 antigens are located on the low-affinity Fc-γ receptor IIIb (FcγRIIIb), CD16.[217–220] FcγRIIIb, HNA-1a, HNA-1b, and HNA-1c antigens are expressed on all segmented neutrophils, approximately one-half of neutrophilic metamyelocytes, and approximately 10% of neutrophilic myelocytes.[221] Neutrophil expression of FcγRIIIb and HNA-1 antigens are diminished by the treatment of neutrophils with stimulants such as complement component C5a and chemotaxin F-met-leu-phe or granulocyte colony-stimulating factor (G-CSF). Soluble FcγRIIIb is present in plasma and it has the same HNA-1 polymorphisms found on neutrophils. FcγRIIIb released from granulocytes is the source of the soluble FcγRIIIb and HNA-1 antigens.[222]

Table 145–5 Nucleotide Differences Among the Genes Encoding the HNA-1a, HNA-1b, and HNA-1c Antigens of FcγRIIIb Base Pair Position

HNA, human neutrophil antigen.
*N-Glycosylation site.
†Stop codon.
Note: Differences among genes are in bold.

Biochemistry

FcγRIIIb is a glycoprotein with 233 amino acids and is glycosylphosphatidylinositol (GPI) anchored.[217–220] Its molecular weight is 50 to 80 kD, and the glycoprotein has *N*-linked carbohydrate side chains. Human neutrophil antigen–1a form of FcγRIIIb is 50 to 65 kD, the HNA-1b form of FcγRIIIb is 65 to 80 kD, and the heterozygous form is 50 to 80 kD. Differences in *N*-glycosylation account for the differences in molecular mass.

Molecular Biology

FcγRIIIb and the HNA-1 antigens are encoded by the *FCGR3B* gene located on chromosome 1q23–24 within a cluster of two families of FcγR genes, *FCGR2* and *FCGR3.* The *FCGR3* family is made up of *FCGR3A* and *FCGR3B. FCGR3B* is highly homologous to *FCGR3A,* which encodes FcγRIIIa. Only four nucleotides differ between *FCGR3B* and *FCGR3A* (Table 145–5). The most important difference between the two genes is a C to T change at 733 in *FCGR3B* that creates a stop codon. As a result, *FCGR3A* has 21 more amino acids than *FCGR3B* and *FCGR3A* is a transmembrane rather than GPI-anchored glycoprotein. FcγRIIIa is not recognized by antibodies specific to HNA-1 antigens, but the similarities between *FCGR3A* and *FCGR3B* complicate genotyping of HNA-1 alleles.

HNA-1a, -1b, and -1c Polymorphisms

The neutrophil-specific HNA-1 antigen system is made up of the three alleles, HNA-1a, -1b, and -1c.[223] The antigens are also known as NA1, NA2, and SH (see Table 145–4). The gene frequencies of the three alleles vary widely among different racial groups. Among whites, the frequency of the gene encoding HNA-1a, *FCGR3B*1,* is between 0.30 and 0.37 and the frequency of the gene encoding HNA-1b, *FCGR3B*2,* is from 0.63 to 0.70.[224–228] In Japanese and Chinese populations, the *FCGR3B*1* gene frequency is from 0.60 to 0.66 and the *FCGR3B*2* gene frequency is from 0.30 to 0.33.[224,226–228,217,219–221] The gene frequency of the gene encoding HNA-1c, *FCGR3B*3,* also varies among racial groups. *FCGR3B*3* is expressed by neutrophils in 4% to 5% of whites and 25% to 38% of African Americans.[229]

The *FCGR3B*1* gene differs from the *FCGR3B*2* gene by only five nucleotides in the coding region, at positions 141, 147, 227, 277, and 349 (see Table 145–5).[217–220] Four of the nucleotide changes result in changes in amino acid sequence between the HNA-1a and HNA-1b forms of the glycoprotein. The fifth polymorphism at 147 is silent. The glycosylation pattern of the protein differs between the two antigens because of two nucleotide changes at bases 227 and 277. HNA-1b form has six *N*-linked glycosylation sites and HNA-1a form has four glycosylation sites.

The gene encoding the HNA-1c form of FcγRIIIb, *FCGR3B*3,* is identical to *FCGR3B*2* except for a C to A substitution at nucleotide 266 resulting in an alanine to aspartate change at amino acid 78 of FcγRIIIb (see Table 145–5).[223] In many cases, *FCGR3B*3* exists on the same chromosome with a second or duplicate *FCGR3B* gene.[230,223] One group has found that in Danish people, *FCGR3B*3* always exists as a duplicate gene in association with *FCGR3B*1.*[231] However, in other populations duplicate *FCGR3B*3* genes were associated with both *FCGR3B*1* and *FCGR3B*2.*

Several other sequence variations in *FCGR3B* have been described.[226] These chimeric alleles have single-base substitutions involving one of the five single nucleotide polymorphisms that distinguish *FCGR3B*1* and *FCGR3B*2. FCGR3B* alleles that more closely resembled *FCGR3B*2* were found more often in African Americans than in whites or Japanese.[226]

FCγRIIIB Deficiency

Blood cells from patients with paroxysmal nocturnal hemoglobinuria lack the GPI-linked glycoproteins and their granulocytes express reduced amounts of FcγRIIIb and the HNA-1 antigens.[220] Genetic deficiencies of granulocyte FcγRIIIb and HNA-1 antigens have also been reported. With inherited deficiency of FcγRIIIb, the *FCGR3B* gene is deleted along with an adjacent gene, *FCGR2C.*[232,225] Among white subjects the incidence of individuals homozygous for *FCGR3B* deletion is about 0.1%.[233,234] However, among Africans and African Americans the incidence is much higher; in one study, 3 of 126 Africans were found to be *FCGR3B* deficient[229] and in another 1 of 53 were found to be *FCGR3B* deficient.[226]

Function of HNA-1 Antigens

The low-affinity Fc-γ receptors link humoral immunity to cellular immune function; specifically, FcγRs on effector cells recognize cytotoxic IgG molecules and immune complexes containing IgG molecules. Polymorphisms in FcγRIIIb affect neutrophil function. Neutrophils that are homozygous for HNA-1b have a lower affinity for IgG3 than granulocytes homozygous for HNA-1a.[235] Neutrophils from people who are homozygous for HNA-1b phagocytize erythrocytes sensitized with IgG1 and IgG3 anti-Rh monoclonal antibodies and bacteria opsonized with IgG1 at a lower level than granulocytes homozygous for HNA-1a.[236,237]

Clinical Relevance of FCγRIIIB Deficiency

Despite the important role of FcγRIIIb in neutrophil function, deletion of the entire *FcγRIIIB* gene does not cause major clinical problems, and most people with FcγRIIIb deficiency are healthy. However, too few patients have been studied to identify a slight increase in susceptibility to infection or autoimmune disease due to FcγRIIIb deficiency. In a study of 21 people with FcγRIIIb deficiency, 2 were found to have autoimmune thyroiditis and 4 had multiple episodes

of bacterial infections.[232] Other smaller studies and case reports have found that despite their FcγRIIIb deficiency, all individuals, except for the one person with systemic lupus erythematosus, were healthy, had no circulating immune complexes, and showed no increased susceptibility to infections.

FCGR3B Polymorphisms and Disease Associations

Several studies suggest that *FCGR3B* polymorphisms affect the incidence and outcomes of some autoimmune and inflammatory diseases, but the results seem contradictory. Children with chronic immune thrombocytopenia purpura are more likely to be *FCGR3B*1* homozygous than control subjects,[238] but Spanish patients with systemic lupus erythematosus are more likely to be *FCGR3B*2* homozygous.[239] Myasthenia gravis is more severe in *FCGR3B*1* homozygous patients,[240] but multiple sclerosis is more benign in *FCGR3B*1* homozygous patients.[241] Patients with chronic granulomatous disease who are *FCGR3B*1* homozygous are less likely to develop major gastrointestinal or genitourinary tract infectious complications than heterozygous and *FCGR3B*2* homozygous chronic granulomatous patients.[242] Because *FCGR3B* is clustered with FCGR3A and FCGR3B on chromosome 1q22, it is possible that some of these findings may be caused in part by linkage disequilibrium among Fc receptors.

THE HNA-2 ANTIGEN SYSTEM

Human neutrophil antigen–2 system has one well-described allele, HNA-2a. It was previously known as NB1.[215] Monoclonal antibodies specific to HNA-2a have been clustered as CD177.

Expression of HNA-2a

HNA-2a is neutrophil-specific antigen. It is expressed only on neutrophils, neutrophilic metamyelocytes, and myelocytes.[221,243] HNA-2a is unique in that it is expressed on subpopulations of neutrophils. The mean size of the HNA-2a-positive subpopulation of neutrophils is 45% to 65%.[244–246] The expression of HNA-2a is greater on neutrophils from women than men.[246,247] The size of the HNA-2a positive subpopulation of neutrophils from women is approximately 60%, compared with approximately 50% for men. The expression of HNA-2a falls with age in women but remains constant in men.[246] Neutrophil expression of HNA-2a is greater in pregnant women than in healthy female blood donors.[247] The surface expression of HNA-2a is slightly upregulated by treatment with the chemotactic peptide F-met-leu-phe.[244] The administration of G-CSF to healthy subjects for several days increases the proportion of neutrophils expressing HNA-2a to near 90%.[248]

NB1 Glycoprotein Biochemistry

The glycoprotein carrying HNA-2a, NB1 glycoprotein, is located on neutrophil plasma membranes and secondary granules[244,249] and is linked to the plasma membrane via a GPI anchor.[244] Although some GPI-anchored proteins are shed by F-met-leu-phe treated neutrophils, NB1 glycoprotein is not, nor is soluble NB1 glycoprotein present in plasma.[244] The molecular weight of NB1 glycoprotein is 58 to 64 kD and it contains *N*-linked carbohydrate side chains.[244,249]

Molecular Biology

The gene encoding NB1 glycoprotein, *CD177,* is located on chromosome 19q13.31 and its coding region consists of 1311 bp that code for a protein of 416 and a signal peptide of 21 amino acids.[250,251] The predicted protein has two cysteine-rich domains, three potential *N*-linked glycosylation sites, and a potential ω-site for attachment of the GPI anchor.[250] This gene belongs to the *Ly-6* snake toxin superfamily. Other genes in this family include urokinase type plasminogen activator receptor (uPAR) (CD87) and decay accelerating factor (CD59).

Two different groups sequenced *CD177* independently. One group sequenced it as the gene encoding HNA-2a and called the gene *NB1,*[250] and the other group sequenced it as a gene overexpressed in granulocytes from people with polycythemia rubra vera and called the gene *PRV-1.*[252] The *NB1* and *PRV-1* alleles differ at only 4 bp.[250] Bettinotti and colleagues[253] used Human Genomic Project databases to characterize the structure of the *PRV-1* and *NB1* genes. They described the intron and exon structure of *NB1,* but they found only one gene homologous to both *PRV-1* and *NB1,* suggesting that they are alleles of the same gene that they called *CD177.* In addition, they found a pseudogene homologous to exons 4 through 9 of *CD177.*[253]

Polymorphisms

HNA-2a is expressed on neutrophils by approximately 97% of whites, 95% of blacks, and 89% to 99% of Japanese.[246,254,255] HNA-2a has been reported to have an allele, NB2; but the product of this gene cannot be reliably identified with alloantisera, and no monoclonal antibody specific for NB2 has been identified.[256]

Human neutrophil antigen–2a negative neutrophil phenotype is caused by a *CD177* transcription defect.[257] HNA-2a genes from two women with HNA-2a-negative neutrophils who produced HNA-2a-specific alloantibodies have been studied, and *CD177* cDNA sequences were present in both women.[257] However, all neutrophil CD177mRNA contained accessory sequences that were considered to be introns. Human neutrophil antigen 2a–negative phenotype was the result of different off-frame insertions at the RNA level, resulting in NB1 gp deficiency in neutrophils.[257]

Role of NB1 Glycoprotein in Neutrophil Function

The role of *CD177* in neutrophil function is unknown. In some studies HNA-2a may have a role in the adhesion of neutrophils to endothelial cells.[258] Upregulation of HNA-2a after F-met-leu-phe stimulation, HNA-2a internalization on antibody cross-linking, and activation of the respiratory burst after binding of HNA-2a antibodies to HNA-2a-bearing neutrophils suggest a possible role as receptor molecule.[259]

Clinical Relevance of HNA-2 Antigens

The rare women who produce HNA-2a–specific alloantibodies and who lack NB1 glycoprotein are healthy. The expression of HNA-2a is reduced on neutrophils from people with paroxysmal nocturnal hemoglobinuria and chronic myelogenous leukemia.[243] It is unknown whether the lack of expression of HNA-2a on neutrophils from patients with paroxysmal nocturnal hemoglobinuria or chronic myelogenous leukemia has any clinical significance. *CD177* mRNA is overexpressed by neutrophils from patients with polycythemia rubra vera and essential thrombocytosis.[252,260] Some groups are using quantitative real-time PCR to measure neutrophil *CD177* mRNA levels to assist with the diagnosis of polycythemia rubra vera and essential thrombocytosis. Patients with essential thrombocytosis and increased CD177 mRNA levels have been reported to have increased risk of thrombocytosis and bleeding.[261] Patients with polycythemia rubra vera and essential thrombocytosis have been found to have gain of function mutations in the gene encoding Janus kinase-2 (JAK2)[262–266] and the increased expression of CD177 mRNA in neutrophils from these patients may be secondary to the JAK2 mutation.

HNA-3 ANTIGEN SYSTEM

Human neutrophil antigen–3 antigen system has one antigen, HNA-3a, that was previously known as 5b. HNA-3a is expressed by neutrophils, lymphocytes, platelets, endothelial cells, kidney, spleen, and placental cells. HNA-3a has a gene frequency of 0.66 and is located on a 70 to 95 kD neutrophil glycoprotein.[267] The gene encoding HNA-3a has not yet been cloned, and the nature and function of the 70 to 95 kD gp is unknown. Although the biologic role for this system has not been established, several cases of transfusion-related acute lung injury (TRALI) have been associated with transfusion of plasma containing anti-5b.[268,269]

HNA-4 AND HNA-5 ANTIGEN SYSTEMS

Human neutrophil antigen–4 and HNA-5 antigens are located in the β_2 integrins. Each antigen system contains only a single antigen, HNA-4a and HNA-5a, respectively. Human neutrophil antigen–4a antigen was previously known as Mart(a). HNA-4a was defined by an antibody in the sera of three nontransfused multiparous blood donors. The antigen was shown to have autosomal dominant inheritance and has a phenotype frequency of 99.1% in white subjects. HNA-4a has been located on the αM chain (CD11b) of the C3bi receptor (CR3) and is caused by a single nucleotide substitution of G to A at position 302.[270] The substitution would be predicted to result in an Arg to His polymorphism at amino acid 61. The significance of the antibody is unknown and none of the infants of the three multiparous women with anti-HNA-4a showed evidence of neonatal alloimmune neutropenia.

A second polymorphism of the β_2 integrins, HNA-5a, was first described as Ond(a). A chronically transfused man with aplastic anemia became alloimmunized to HNA-5a. HNA-5a was found to be expressed on the αL integrin unit, leukocyte function antigen-1 (LFA-1) (CD11a), and is caused by a G to C single nucleotide substitution at position 2446. This change predicts an amino acid change of Arg to Thr at amino acid 766.[270]

CLINICAL SIGNIFICANCE OF ANTIBODIES TO NEUTROPHIL ANTIGENS

Alloimmune Neonatal Neutropenia

During pregnancy, mothers can become alloimmunized to neutrophil antigens. Maternal IgG directed to neutrophils can cross the placenta and destroy the neonate's neutrophils. Maternal alloimmunization to neutrophil antigens can occur in utero and affect the first child. Most neonates experience isolated neutropenia, but the cytopenias are self-limiting and resolve as the antibody is cleared. The alloimmunized mothers produce and carry the antibodies; but the antibodies do not react with the mother's blood cells or tissues, and they have normal neutrophil counts. Antibodies to neutrophil-specific antigens HNA-1a, HNA-1b, and HNA-2a most commonly cause neonatal alloimmune neutropenia (Table 145–6).[267,271] Antibodies to HNA-1c and HNA-3a rarely cause alloimmune neonatal neutropenia. Mothers with FcγRIIIb deficiency have produced FcγRIIIb-specific antibodies that caused neonatal neutropenia.[234,267,271]

Newborns with alloimmune neutropenia are usually asymptomatic. Most often, the neutropenia is detected in the first week of life when the neonate becomes febrile or develops an infection and a neutrophil count is done. Typically, the counts are 0.100 to 0.200 $\times 10^9$/L. Some neonates have normal neutrophil counts the first day of life, but they become neutropenic on their second day.[271] White blood cell count, platelet count, and hemoglobin are usually normal; but eosinophilia or monocytosis may be present. If a bone marrow biopsy is performed, it often shows normal numbers of erythroid progenitors and megakaryocytes with hyperplasia of myeloid progenitors.

Table 145–6 Specificities of Antibodies in Alloimmune Neonatal Neutropenia

Antigen	$N = 18$[271,251]	$N = 48$[267,253]
HNA-1a	28%	10%
HNA-1b	22%	8%
FcγRIIIb	0%	8%
HNA-2a	11%	2%
HNA-3a	0%	2%
Unknown	0%	15%
HLA class I[271,251]	11%	54%
Negative	28%	38%

HLA, human leukocyte antigen; HNA, human neutrophil antigen.

The clinical course is quite variable. An occasional infant is asymptomatic, but almost all affected children have an infection. The most common infections are umbilicus infections, skin infections, abscesses, and respiratory tract infections. Less commonly, infants experience otitis media, urinary tract infections, and gastroenteritis. Serious infections such as sepsis, pneumonia, and meningitis can occur. The duration of the neutropenia may be as short as a few days or as long as 28 weeks.[271] The mean duration of neutropenia is about 11 weeks.[271]

For an asymptomatic child, no immediate treatment may be required. Prompt and aggressive antibiotic treatment of children with fevers or other signs of infections is indicated. Intravenous immunoglobulin has a limited role in the treatment of neonatal alloimmune neutropenia. Approximately half the patients treated have a transient increase in count lasting only a few days. The use of G-CSF to treat alloimmune neutropenia has also had mixed results. The administration of G-CSF elevates the neutrophil count in some but not all neonates.[271]

AUTOIMMUNE NEUTROPENIA OF CHILDHOOD

Autoimmune neutropenia has been well described in children.[272–275] Typically, the onset of the autoimmune neutropenia of children begins at 8 months of age, but children between 1 and 36 months of age can be affected. Most studies found that neutrophil counts recover spontaneously by the age of 5 years, with a median of 13 to 20 months of neutropenia.[272–275]

In most cases, children presented with severe neutropenia, having neutrophil counts less than 0.5 $\times 10^9$/L. Monocytosis has been reported to occur in up to 38% of patients. Bone marrow biopsies in affected patients usually show normal to hypercellular marrow with a decreased number of mature granulocytes. Febrile episodes and infections, including bacterial skin infections, otitis media, respiratory tract infections, and urinary tract infections, are common. Life-threatening complications are rare.

Antibodies to neutrophils can be detected in up to 98% of affected patients. If an antibody specificity is identified, the antibodies are almost always specific to epitopes located on FcγRIIIb. The antibodies are directed to HNA-1a in 10% to 46% of patients, to HNA-1b in 2% to 3% of patients, and rarely to FcγRIIIb epitopes expressed by granulocytes from all donors.[273,274]

Autoimmune neutropenia has been treated with corticosteroids, intravenous immunoglobulin, and G-CSF. Approximately half the patients responded to intravenous immunoglobulin, but neutrophil counts remained elevated for only 1 week.[273] Almost all the patients responded to G-CSF and 75% to corticosteroids, and neutrophil counts remained elevated as long as the drugs were given.

TRANSFUSION REACTIONS

Antibodies to neutrophil and HLA antigens can cause febrile nonhemolytic transfusion reactions and TRALI. Prior to the widespread transfusion of leukocyte-reduced blood components, approximately 0.5% of transfusions were associated with febrile nonhemolytic transfusion reactions, and leukocyte antibodies are a common cause of these reactions. These febrile reactions are caused by the interaction of leukocyte antibodies in the transfusion recipient with leukocytes contained in the transfused blood components. These reactions can be prevented by the use of components that have been filtered to remove leukocytes.

A more serious type of transfusion reaction associated with leukocyte antibodies is the acute noncardiac pulmonary edema, or TRALI. This entity is characterized by acute respiratory distress that usually occurs within 4 hours after a transfusion. These reactions are characterized by dyspnea, hypoxia, and bilateral pulmonary infiltrates on chest radiograph without cardiomegaly or pulmonary vascular congestion. The mortality rate associated with TRALI is approximately 5%.[276] Of patients with TRALI, 80% have rapid resolution of pulmonary infiltrates and return of arterial blood gas values to normal within 96 hours after the initial respiratory insult. However, pulmonary infiltrates have persisted for at least 7 days after the transfusion reaction in 17% of TRALI patients.

Transfusion-related acute lung injury has been associated with both neutrophil and HLA antibodies. Antibodies reported in these reactions include HNA-1a, HNA-1b, HNA-2a, HNA-3a, and HLA class I and II antibodies. Most these cases involve the passive transfusion of the offending antibody in donor plasma, as contrasted with the reactivity of the recipient's antibody with donor leukocytes to cause febrile nonhemolytic reactions. Retrospective studies involving antibodies to HNA-3a have implicated blood components from single donors with anti-HNA-3a in several TRALI cases.[269]

GRANULOCYTE TRANSFUSIONS

Granulocyte transfusion recipients sometimes produce antibodies specific to HNA-1a, HNA-1b, and HNA-2a. The transfusion of granulocytes to patients with these antibodies can result in febrile transfusion reactions and pulmonary transfusion reactions.[277] Hematopoietic progenitor cell transplant recipients who produce HNA-2a antibodies as a result of granulocyte transfusions have experienced marrow graft failure.[278]

NEUTROPHIL ANTIGENS SUMMARY

Two neutrophil antigen systems, HNA-1 and HNA-2, have been well described, and three others, HNA-3, HNA-4, and HNA-5, have been described in part. HNA-1 antigens are located on FcγRIIIb, and antibodies to these antigens are frequently implicated in autoimmune and alloimmune neutropenia. HNA-2a is located on NB1 glycoprotein, and antibodies to HNA-2a are found in patients with alloimmune and autoimmune neutropenia. The gene expressing this protein is overexpressed by neutrophils in patients with polycythemia rubra vera. Antibodies to HNA-3a are rare; but relative to other neutrophil antibodies, may be more frequently associated with cases of TRALI. The significance, if any, of HNA-4a and HNA-5a antibodies is uncertain.

CHAPTER 146

PRINCIPLES OF RED BLOOD CELL TRANSFUSION

Melissa M. Cushing and Paul M. Ness

The clinical practice of transfusion medicine has evolved substantially in the past century. Several critical advances have spurred progress since the discovery of the ABO system just over 100 years ago. The description of Rh and the introduction of a safe and effective anticoagulant-preservative solution (suggested by Loutit and Mollison[1]) allowed for the preservation of blood products. Another important landmark was the development of the antiglobulin test by Coombs,[2] which permitted the detection of antibodies in recipient plasma that did not produce direct agglutination in the test tube but might be capable of causing in vivo red blood cell destruction.

It was not until the mid-1960s, however, with the introduction of plastic blood packs by Walter and Murphy,[3] that the era of component therapy began. This innovation, combined with the ability to store blood for extended periods, revolutionized transfusion practice. Today, approximately 15 million units of blood are transfused each year in the United States.

RED BLOOD CELL PRESERVATION AND STORAGE

The first key to the storage of blood for later transfusion is a stable, minimally toxic anticoagulant with preservative properties. During the early 1900s, it was recognized that citrate met these criteria.[4] Although slightly more toxic than heparin, if given rapidly and in large amounts, citrate has preservative action that heparin lacks. Citrate has the added advantage of not causing systemic anticoagulation in the recipient.

The other factor essential for long-term storage is a mechanism to maintain cell viability and function. Fresh transfused red blood cells have a good survival rate in the recipient's circulation, with a destruction rate approximately equal to that of the recipient's own cells: 1% per day.[5] The arbitrary standard used for stored red blood cells requires 75% to remain in the circulation for 24 hours.

Adenosine Triphosphate Levels

Adenosine triphosphate (ATP) levels appear to be a major determinant of red blood cell viability.[6] The drop in cellular ATP levels during storage has been correlated with increased cell rigidity and with loss of membrane lipid, leading to decreased red blood cell life span.[7] For this reason, most efforts to extend red blood cell storage have focused on ways to maintain intracellular ATP levels. First, dextrose was introduced into the citrate solution (citrate-phosphate-dextrose [CPD]: 21 days), to which adenine was added (CPDA-1: 35 days). Three additive solutions containing additional dextrose and adenine (Nutricel, or AS-3) or dextrose and adenine plus mannitol (Adsol, or AS-1) and (Optisol, or AS-5) allow extension of the maximum storage time to 42 days (Table 146–1).

2,3-Diphosphoglycerate Levels

Stored red blood cells must also maintain their capacity to deliver oxygen. It was not until 1967 that the central role of 2,3-diphosphoglycerate (2,3-DPG) in releasing oxygen from oxyhemoglobin was recognized.[8,9] Attention was then focused on ways to maintain high levels of 2,3-DPG in stored blood cells. The first anticoagulant introduced on a large scale, acid citrate-dextrose, was ineffective because of its low initial pH; however, the subsequently developed CPD, with its higher initial pH and slower fall in pH, was superior. CPDA-1 and additive solutions have not further improved 2,3-DPG maintenance. Although 2,3-DPG depletion of stored red blood cells is known to decrease oxygen delivery, the clinical significance of this finding is unclear. 2,3-DPG levels in stored blood cells are rapidly regenerated in vivo, rising to greater than 50% of normal within several hours and to normal within 24 hours.[10] Although a patient with normal cardiac status should be able to compensate by increasing cardiac output to maintain normal oxygen delivery until 2,3-DPG levels are regenerated, an improvement in 2,3-DPG preservation in stored red blood cells is still desirable.

By-Products of Red Blood Cell Storage With Potentially Adverse Effects

Infusion of large volumes of blood with citrate anticoagulant over a short period may cause plasma citrate levels to reach the toxic range. The primary concern is the cardiovascular effects of hypocalcemia caused by chelation of calcium by citrate. The risk of citrate toxicity is exacerbated by liver dysfunction or liver immaturity. Despite these theoretical considerations, there is little documented evidence of clinical citrate toxicity, and the problem can usually be prevented by slower infusion. If large amounts of blood have to be infused over a very short period, administration of calcium gluconate can be considered, but whether the benefits justify the risk is controversial.[11]

Another issue with prolonged storage is the excess potassium in the red blood cell supernatant that could potentially cause cardiac arrhythmias. At a storage temperature of 4°C, the red blood cell sodium-potassium pump is essentially nonfunctional, and intra- and extracellular levels gradually equilibrate. In addition, hemolysis results in increased potassium in the supernatant. However, because the total volume of plasma in red blood cell concentrates is low (approximately 70 mL), the total potassium burden is only approximately 5.5 mEq at product expiration. Practically speaking, the potassium load is rarely a clinical problem except in the setting of preexisting hyperkalemia and renal failure. In this situation, fresher units of red blood cells or washed red blood cells can be used.

Microaggregates consisting of platelets, leukocytes, and fibrin form during blood storage. Although studies have shown that pulmonary dysfunction after massive transfusion may be significantly diminished by the use of a microaggregate filter of pore size 20 to 40 μm,[12] other studies have not confirmed microaggregates as the cause of hypoxia.[13] Because microaggregate filters have been found to slow the infusion rate, their use is not uniformly recommended in cases of trauma. The growing use of prestorage, leukoreduced blood has reduced the importance of this issue. Since their introduction in the 1960s, plastic blood bags used for storing red blood cells have been made from polyvinylchloride containing the lipophilic plasticizer di(2-ethyl)phthalate (DEHP), which confers pliability. The safety of DEHP has been questioned for years owing to its tendency to leach from the bag and to be present at levels of 50 to 70 mg/L in stored red blood cells.[14] Numerous studies in animal models have

addressed the toxicity of the substance and are summarized in a comprehensive review.[15,16] The situation is complicated by a significant stabilizing effect of DEHP on the red blood cell membrane, with red blood cells stored in various containers that lack DEHP having unacceptable recovery at the end of the storage period. This decreased recovery has been shown to be due to increased hemolysis and increased osmotic fragility.[17]

Storage Length of Red Blood Cells

During storage, RBCs undergo a series of biochemical and biomechanical changes that reduce their survival and function. In addition, accumulation of biological by-products during RBC storage may be harmful to recipients of blood transfusions. Increasing numbers of studies have raised concern that prolonged RBC storage adversely affects clinical outcomes.[18] One recent study reported an association between red cell storage length and adverse outcome in cardiac surgery patients.[19] Multivariate analysis in another recent study, also looking at cardiac surgery patients, showed no effect of storage time on survival or ICU stay.[20] A large, prospective, randomized clinical trial would be helpful in determining the true clinical significance of the effect of red cell storage duration on patient outcomes.

RED BLOOD CELL COMPONENTS

Modern transfusion medicine practice is aimed at providing the specific component of the blood required, rather than whole blood: red cells for oxygen-carrying capacity, plasma for coagulation proteins, and platelets for microvascular bleeding. The component therapy approach allows for optimal use of a limited community resource (Table 146–2). Today, the clinician wishing to increase the patient's oxygen-carrying capacity is more likely to be using a red blood cell concentrate than whole blood, although there may still be situations in which whole blood, if available, is appropriate. For particular clinical applications, several modifications can be made to red blood cell products to render them leukocyte or plasma depleted. Red blood cells can also be frozen for long-term storage.

Table 146–1 Biochemical Changes in Stored Red Blood Cells

Variable	CPDA-1 *Fresh*	CPDA-1 *35 Days*	Adsol *35 Days*
In vivo survival (at 24 hours) (%)	100	<71.0	<88.0
pH	<7.5	<6.7	<6.7
ATP (% initial)	100	<45.0	<76.0
2,3-DPG (% initial)	100	<10.0	<10.0
Plasma K^+ (mEq/L)	5.1	<78.5	<49.0

Data from Zuck TF, Bensinger TA, Peck CC, et al: The in vivo survival of red cells stored in modified CPD with adenine: Report of a multi-institutional cooperative effort. Transfusion 17:34, 1977; and Moore GL, Peck CC, Sohmer RR, Zuck TF: Some properties of blood stored in anticoagulant CPDA-1 solution: A brief summary. Transfusion 21:135, 1981.

Whole Blood

A unit of whole blood is collected in CPDA-1 anticoagulant, giving it a shelf-life of 35 days and a volume of approximately 510 mL (450 mL of blood plus 63 mL of CPDA-1). Within 24 hours of collection, the platelets,[21] as well as the granulocytes, are dysfunctional, and several plasma coagulation factors have fallen to suboptimal levels.[22]

Whole blood has the advantage of correcting simultaneous deficits in oxygen-carrying capacity and blood volume. Therefore, whole blood is indicated in the management of trauma or in surgical cases involving extensive blood loss. In this setting, whole blood has two distinct advantages: (a) it provides colloid osmotic pressure and some coagulation factors not supplied by crystalloid solutions and (b) it does not expose the recipient to red blood cells and plasma from different donors.

The goal of using whole blood for all cases of concomitant red blood cell and volume deficit is difficult to achieve in practice. Most indications for whole blood transfusion are now well managed exclusively with blood component therapy, but the use of fresh whole blood has persisted in military settings.[23] In the civilian setting, the simultaneous need for volume and oxygen-carrying capacity can usually be met by combining red cells with crystalloid or colloid solutions. In some cases of trauma and cardiovascular surgery, platelet transfusion may be indicated to combat microvascular bleeding from dilutional thrombocytopenia or bypass-associated platelet dysfunction. The transfusion of platelets usually supplies the equivalent of several units of relatively fresh plasma so that there is often no reason for further donor exposure by the administration of frozen plasma.

Red Blood Cell Concentrates

Red blood cell concentrates are obtained from whole blood after removal of most of the plasma for the production of frozen plasma or platelets, or both. At most blood centers, the red blood cells are then mixed with 100 mL of an additive nutrient solution that extends the storage period to 42 days and results in flow properties similar to those of whole blood.[24]

Table 146–2 Red Blood Cell Components: Characteristics and Indications

Component	Characteristics	Indications
Whole blood	High volume; good flow	Combined red cell/volume deficit (massive hemorrhage; exchange transfusion)
Red blood cells	Lower volume Higher hematocrit	Red cell deficit
Leukocyte-reduced red blood cells	Good flow in AS-1	Prevention of febrile reactions Reduction of alloimmunization Reduction of immunomodulatory effects
Washed red blood cells	Plasma depletion Must use within 24 hours	Prevention of severe allergic reactions Prevention of anaphylaxis in IgA deficiency
Frozen red blood cells	Long-term storage Plasma and leukocyte depletion Must use within 24 hours of thawing	Rare donor unit storage Autologous storage for postponed surgery

Red blood cell concentrates are the product of choice for the correction of an isolated defect in oxygen-carrying capacity, as in cases of chronic anemia. In addition, red blood cells rather than whole blood are used for the emergent transfusion of patients of unknown ABO type. Concentrated type O red blood cells are transfused after the plasma containing isohemagglutinins is removed to prevent potential hemolysis of the recipient's red blood cells.

Leukocyte-Reduced Red Blood Cells

Leukocyte-reduced red blood cells (LRRCs) can be prepared by a variety of methods, resulting in differing degrees of white blood cell removal. Early techniques of preparation involved centrifugation or washing with saline, whereby the buffy coat was repeatedly removed. Currently, the most widely used method of leukoreduction is filtration, which can be performed either in the laboratory or at the bedside. The various filters on the market result in greater than 99% leukocyte reduction while depleting less than 10% of the red blood cells.[25] Blood bags with in-line filters, which allow prestorage leukoreduction, are now more commonly used and have been shown to decrease febrile nonhemolytic transfusion reactions compared to bedside leukoreduction filters.[26]

The major indication for the use of LRRCs has been the prevention of the nonhemolytic febrile transfusion reaction, the most common adverse effect of transfusion, particularly in multiply transfused patients or multiparous females. Traditionally, these reactions are believed to be mediated by antibodies directed against leukocyte antigens,[27] but whether lymphocyte HLA antigens or granulocyte-specific antigens are the major targets has remained a subject of controversy. Depletion of leukocytes to less than 5×10^8 has been shown to prevent, or at least ameliorate, such reactions in most patients.[28] Increasing evidence has accumulated suggesting that cytokines play a role in causing these reactions.[29] Because cytokines may be released from leukocytes during storage, prestorage leukoreduction procedures have become the preferred mode of leukoreduction.

A second important indication for LRRCs is the prevention of alloimmunization to HLA antigens that can adversely affect post-transfusion platelet increments, such as in cancer patients undergoing chemotherapy. This approach will be effective only if platelets for transfusion can also be white blood cell depleted. According to current AABB standards, the total leukocyte number must be less than 5×10^6 when intended for this purpose. With the introduction of third-generation leukoreduction filters for both red blood cells and platelets, this goal is achievable. A multicenter study known as TRAP showed that the use of leukoreduction filters for platelet products significantly decreased the rate of alloimmunization but did not totally eliminate the problem.[30] Leukoreduction has also been studied for its ability to prevent transfusion-mediated immunosuppression, which is of particular concern in the postoperative period. Data collected to date suggest that this practice may be of value.[31] Indeed, even simple removal of the buffy coat from red blood cells (which is a routine procedure during component preparation in Europe) may provide a sufficient degree of leukoreduction.[32] Because component preparation in the United States does not include a buffy coat removal step and because soluble white blood cell fragments may be capable of mediating immunomodulation, a prestorage leukoreduction method would be required to abrogate this adverse effect in transfusion recipients in the United States. However, despite numerous studies looking for cancer recurrence or increases in infections, the data remain contradictory.[33]

Washed Red Blood Cells

Red blood cells are washed, using isotonic saline solutions, by either automated or manual techniques. Automated techniques are more efficient, but there is always some degree of red blood cell loss with each wash cycle. When the washing is performed in an open system, the resulting product must be transfused within 24 hours because of concerns over potential bacterial contamination.

The primary aim of washing is to remove plasma proteins, although some leukocytes and platelets are removed simultaneously. The major indication for washed red blood cells is the prevention of severe allergic transfusion reactions, thought to be mediated by recipient antibodies (most likely IgE) to donor plasma proteins. Washing is recommended when reactions are recurrent and severe, even in the face of antihistamine administration. In IgA-deficient patients who have preformed antibody to IgA, IgA-containing plasma can actually cause anaphylaxis.[34] Multiple cell washes may be required to remove the contaminating plasma protein.[35]

Another setting in which washed cells have been advocated is paroxysmal nocturnal hemoglobinuria. However, one study has suggested that these patients do not require washed cells and this indication for washed cells has become less popular in recent times.[36]

Irradiated Red Blood Cells

Red blood cells are irradiated with a minimum dose of 25 Gy. Red cells expire 28 days after irradiation or the original expiration date, whichever is sooner. A method is used to ensure that irradiation has occurred with each batch. The primary aim of irradiating is to prevent the frequently fatal risk of transfusion-associated graft-versus-host disease (TA-GVHD). Graft-versus-host disease can occur after the transfusion of immunologically competent donor lymphocytes, usually to an immuno-incompetent recipient. Irradiation is performed to inactivate immunocompetent lymphocytes. Some indications for irradiated products include neonates, patients with hematologic malignancies, stem cell transplant recipients, and patients with congenital immune deficiencies. There is still much debate among experts regarding which additional patient populations may be at risk for TA-GVHD. It has been suggested that a policy of universal blood component irradiation could prevent TA-GVHD in patients with currently unsuspected risks, including advanced age.[37]

Frozen Red Blood Cells

Red blood cells can be frozen (with glycerol used as a cryoprotective agent) and stored in liquid nitrogen or mechanical freezers. The required concentration of glycerol depends on the rate and the temperature of freezing.[38,39] The freezing process destroys other blood constituents, except for a small percentage of immunocompetent lymphocytes. Red blood cells are prepared for transfusion by thawing and washing away the glycerol using a series of progressively less hypertonic saline solutions, allowing glycerol to diffuse gradually from the cells to prevent hemolysis. The cells are resuspended in isotonic saline solution containing glucose. The extensive washing removes approximately 99.9% of the plasma as well as cellular debris.

Red blood cells can be stored in the frozen state for at least 10 years with good viability. After thawing and washing, storage is typically limited to 24 hours because of the open system. Frozen cells have been shown to maintain prefreezing ATP and 2,3-DPG levels. To maintain these factors at high levels, the standard is to freeze within 6 days of collection. When it is necessary to freeze older units, rejuvenation with a solution containing pyruvate, glucose, phosphate, and adenine has provided excellent results.[40] The major indication for frozen red blood cells is the stockpiling of rare donor units for patients who have developed alloantibodies. Some patients with rare phenotypes can make autologous donations that can be frozen for later use. Cells from autologous donors can be frozen if more units are required than can be collected in the 42-day liquid storage period or if surgery is postponed. Because of the high cost and cumbersome nature of freeze–thaw procedures, other uses of frozen red blood cells are somewhat difficult to justify.

APPROPRIATE TRANSFUSION PRACTICE IN VARIOUS CLINICAL SETTINGS

The response to red blood cell transfusion varies from patient to patient. In the absence of increased red blood cell destruction or sequestration, 1 unit of red blood cells can be expected to increase the hemoglobin level by 1 g/dL or the hematocrit level by approximately 3%. This rise is usually not measurable until approximately 24 hours after transfusion, when the plasma volume has had time to return to normal. On the basis of a half-life of approximately 57.7 days for donor red blood cells, Mollison and associates[5] calculated that an average-sized adult requires 24 mL of red blood cells per day to maintain a given hematocrit level, assuming no red blood cell production. Patients with red cell aplasia require approximately 2 units of red blood cells every 2 weeks.

Several factors can adversely affect the survival of transfused red blood cells. Hemolysis, caused by either immune red blood cell damage or mechanical trauma, shortens the survival of transfused cells, much as it shortens the survival of the patient's own cells. Hypersplenism can lead to initial sequestration as well as increased destruction of red blood cells. Continued blood loss is another obvious cause of suboptimal response to transfusion. It should also be emphasized that transfusion suppresses erythropoiesis, so that the net result of transfusion may be less than expected if transfusions are administered on a chronic basis.

Chronic Anemia

As a rule, signs and symptoms attributable to anemia are unlikely to develop at a hemoglobin level of greater than 7 or 8 g/dL. When the anemia is of gradual onset, the body's compensatory mechanisms for maintaining oxygen delivery to the tissues come into play. Both cardiac output and intracellular 2,3-DPG increase, and thus, oxygen unloads at a lower oxygen saturation of hemoglobin. When chronic anemia is due to red blood cell destruction, the healthy bone marrow responds by increasing production up to sixfold.

Red blood cell transfusion is always symptomatic and supportive rather than definitive therapy for anemia. Transfusion should be used only when there is no definitive treatment for the underlying cause, or when the severity of the anemia and the clinical manifestations in the patient make it impossible to wait for the effects of the treatment to be realized.

Generalizations about whether or when to transfuse red blood cells, and how many, are difficult to make and are usually inappropriate. The clinical impact of anemia varies, depending on its pathogenesis, rate of onset, the presence or absence of accompanying hypovolemia, and, most importantly, the individual patient. The hemoglobin level at which a given individual manifests the signs and symptoms of anemia relates, in part, to underlying health status, cardiorespiratory reserve, and activity level.

Perioperative Period

Many generalizations have been made about the appropriate transfusion management of acute blood loss, often with little hard data to support the arguments. One rule of thumb is that blood loss of 10% or less of total blood volume requires no replacement therapy at all; loss of up to 20% can be replaced exclusively with crystalloid solutions; and loss of greater than 25% generally requires red blood cell transfusion to restore oxygen-carrying capacity, along with crystalloid and sometimes colloid solutions to restore intravascular volume to maintain perfusion. For years, the figure of 10 g/dL of hemoglobin had been used as the gold standard for the red blood cell transfusion trigger during the perioperative period, but 7 g/dL is now more commonly used.[41,42]

In the aftermath of transfusion-transmitted human immunodeficiency virus, however, this approach is no longer justified. Each case must be evaluated individually on the basis of clinical signs and symptoms, rather than on the basis of laboratory values. If the cardiovascular system is healthy and the degree of hypoperfusion is not significant, good tissue oxygenation can be maintained at much lower hemoglobin levels. A National Institutes of Health consensus conference suggested that many surgical patients do not need transfusion unless the hemoglobin level falls to less than 7 g/dL.[41] Reexamination of these issues has laid to rest the long-held belief that these lower hemoglobin levels interfere with wound healing or automatically make general anesthesia a risk.

Given that red blood cell transfusion should be tailored to individual needs, the question arises as to whether there is any readily available, objective measurement that can be used to determine how low the hemoglobin level can safely be allowed to fall before red blood cell transfusion is initiated. Several studies of acute normovolemic anemia in rats,[43] dogs,[44] and baboons[45,46] have focused on the whole-body oxygen extraction ratio as an indicator of when to transfuse. These studies make the seemingly valid assumption that the heart is the major organ at risk. With progressive hemodilution, healthy animals with normal coronary arteries were able to maintain normal levels of oxygen consumption through a moderate increase in cardiac output, an increase in coronary blood flow, and a linear increase in the extraction ratio up to 50%. As the hematocrit level fell to less than 10%, however, oxygen consumption began to fall off and the animals were no longer able to increase the extraction ratio enough to compensate for the low oxygen blood tension. An extraction ratio of 50% was found to represent the critical point at which the myocardium converted from aerobic to anaerobic metabolism, reflected in net lactate production. At this point, metabolic acidosis set in, resulting in hemodynamic instability. In a subsequent study, investigators compared the response to acute normovolemic anemia in healthy dogs to the response in dogs with critical coronary stenosis and found that both groups converted to anaerobic metabolism and went into congestive heart failure at an extraction ratio greater than 50%, but that an extraction ratio greater than 50% occurred at a hematocrit level of 17.0% in the dogs with critical stenosis, compared with a hematocrit level of 8.6% in the healthy group.[47] On the basis of these studies, it seems reasonable to extrapolate to humans and to suggest that the extraction ratio, if it were readily obtainable from standard hemodynamic monitoring devices, could be used to help assess transfusion need and that an extraction ratio of 50% might be a useful red blood cell transfusion trigger, because it appears to be a valid indicator of marginal myocardial oxygen reserve in both healthy persons and individuals with coronary artery disease. A limited number of studies have addressed the usefulness of the extraction ratio as a transfusion trigger in humans. One study monitored the oxygen extraction ratio in patients undergoing CABG and found that an extraction ratio of 45% or more could act as a safe transfusion trigger and allow a reduction in allogeneic blood transfusion.[48]

Clinical studies within the last 10 years make this issue even more confusing. Physicians have used a hemoglobin value of 10 g/dL for many years as a convenient transfusion trigger. A recent randomized controlled trial compared a liberal transfusion strategy with hemoglobin maintained at 10 to 12 with a restrictive hemoglobin value of 7 to 8 for critically ill patients. The study showed that patients with the lower hemoglobin values did better than the patients who underwent transfusion with the liberal indication.[49] On the other hand, a retrospective analysis of a large cohort of elderly patients with acute myocardial infarction showed that patients with a hematocrit level less than 33% who subsequently underwent transfusion had a lower mortality rate when measured at 30 days.[50]

The possibility of immunomodulation by allogeneic transfusions in humans was first suggested more than 30 years ago when improved renal allograft survival was reported in pretransplant transfusion recipients.[51] A potential link between allogeneic transfusion and an increased rate of cancer recurrence and postoperative infection was first raised in the 1980s, and numerous retrospective and prospective observational studies supporting these contentions have been reported in the literature since that time. These studies, as well as reports from investigations with opposing data, have been analyzed in numerous

reviews on the topic.[52–55] Studies in experimental animals have also yielded contradictory results. Research using animal models and human subjects on the specific immunomodulatory effects of transfusion has consistently pointed to depression of cell-mediated immunity, although the specific defects seen have varied.[56,57] The mediators of these immunomodulatory effects appear to be leukocytes present in cellular blood components, including whole blood and red blood cells.[53] Several well-designed, prospective, randomized controlled trials have been conducted comparing transfusion with leukoreduced blood components or autologous blood to transfusion with unmodified allogeneic blood components. On the basis of previous reports and the apparent pathogenesis of the immunomodulation, it was predicted that the recipients of leukoreduced blood or autologous blood would have a significantly lower risk of immunomodulation. However, the results of these studies have also varied, and controversy continues.[58]

In the debate concerning leukoreduction, some experts believe that the medical benefit has been demonstrated for many recipients and suggest that the technology be applied universally because the only downside is cost.[58] In the absence of data suggesting universal benefit,[59] however, others argue that the technology should be applied selectively to patients who will clearly benefit. Although it is generally agreed that leukoreduced red blood cells will lower the risk of febrile, nonhemolytic transfusion reactions, lower the risk of cell-associated viral infections, such as cytomegalovirus, and reduce the risk of alloimmunization, it is not clear whether patients without specific indications will benefit. A large randomized study showed no benefits to patients without specific indications in a short-term analysis.[60] The long-term benefits of universal leukoreduction and the ability of a universal program to avoid transfusion errors are promoted by some experts.[61] Several randomized controlled clinical studies of leukoreduced red blood cells in cardiac surgery have demonstrated decreased mortality in recipients of leukoreduced blood components; perhaps these studies will become the tipping point to universal leukoreduction in the United States.[62–64]

Red Blood Cell Transfusion in Neonates

In neonates, as is often the case with adult patients, it is convenient to consider periodic, small-volume transfusion separately from massive transfusion situations. The trigger for transfusion and the optimal type of component are very different in the two settings. The potential adverse effects may be quite distinct, particularly in infants.

Low-volume red blood cell transfusion is rarely indicated in full-term infants unless acute blood loss has occurred at birth or an intrauterine situation has led to prenatal anemia. In contrast, premature infants are frequent recipients of these transfusions. In the intensive care setting, the premature infant is subjected to frequent blood sampling, and iatrogenic anemia may necessitate transfusion. Anemia of prematurity is also a well-recognized entity, with premature infants having a slightly lower Hb value at birth. In addition, the postnatal decline in Hb occurs earlier and is more pronounced in premature infants.[65] The mechanism for anemia of prematurity appears to involve a relatively lower output of erythropoietin in response to a given degree of anemia.[66] This phenomenon is attributed in part to the fact that the liver, rather than the kidney, is the major site of erythropoietin production in these infants.[67] Although some practitioners have considered this degree of anemia to be physiologic, the benign nature of this condition remains controversial.

Another debate among neonatologists concerns the triggers for red blood cell transfusion, as in what clinical signs and symptoms are valid reflections of poor tissue oxygenation. Congestive heart failure and severe pulmonary disease are generally accepted indications for transfusion, but recurrent apnea, tachypnea, tachycardia, and failure to thrive are also used as transfusion triggers.[65,68] In recent times, the rate of transfusion and the donor exposure rate of premature infants have consistently declined. These changes, however, reflect improvements in patient care (eg, microtesting methods resulting in less iatrogenic blood loss; the use of surfactant resulting in decreases in respiratory distress) and the use of a single unit to supply one infant over a longer period rather than being attributable to changes in the transfusion trigger. The prolonged use of single units has become possible with the advent of the sterile docking technology, which preserves the full shelf-life of the unit of red blood cells, as well as with the accumulating solid evidence that fresh blood is not necessary for low-volume transfusions in neonates, because supernatant potassium and decreased pH are not of concern in this setting.[62,65] Two recent studies have provided additional information about the relative risks and benefits of using restrictive rather than more liberal criteria for very low birth weight infants. One study showed that a liberal transfusion practice resulted in more infants receiving transfusion but conferred little evidence of benefit.[69] The other study showed a lower risk of apnea and major brain injury for the liberal transfusion arm of the study.[70] Therefore, the safest transfusion trigger in the preterm infant still remains unclear and further studies are indicated. Finally, several trials of erythropoietin therapy in premature infants have been undertaken.[71] The administration of relatively high-dose erythropoietin has been shown to raise hemoglobin levels and reticulocyte counts in healthy premature infants, but the effect in sicker neonates is unclear. Although transfusion exposure was decreased, the significance of this observation is diminished, given the promise of new strategies for limiting transfusions and donor exposure. Therefore, the high cost of erythropoietin treatment and the increased risk of retinopathy associated with erythropoietin treatment may not be justified in this patient population.[72,73]

In the case of massive transfusion, the situation differs, with marked increases in transfusion in recent years in full-term as well as premature infants. Despite the decline in Rh hemolytic disease of the newborn, this disease remains a prominent indication for exchange transfusion. The two triggers for exchange are (a) rapidly rising levels of unconjugated bilirubin that may lead to kernicterus and permanent central nervous system damage and (b) congestive heart failure secondary to severe anemia. Exchange transfusion is especially beneficial in cases of hemolytic disease of the newborn because it clears the bilirubin and the offending antibody from the circulation and removes antibody-coated red blood cells before lysis, while providing a source of red blood cells lacking the offending antigen. A two-blood-volume exchange is commonly performed by using a fresh unit of blood concentrated to a final hematocrit level of approximately 50%. In cases of hyperbilirubinemia resulting from other causes (eg, that associated with liver immaturity in premature infants), phototherapy is the treatment of choice because its effects are usually more sustained, and exchange transfusion is used only for cases of marked elevations.[74] Extracorporeal membrane oxygenation and open-heart surgery are two other situations in which the neonate may be exposed to large volumes of allogeneic red blood cells. The extracorporeal membrane oxygenation circuit requires a prime with red blood cells, as do many of the types of extracorporeal circuits used for cardiopulmonary bypass.[74]

Although accumulating evidence supports the safety of using red blood cell units of any age and with any preservative solution for low-volume transfusions in neonates, the same transfusion policies may not apply to massive transfusion. Newborn physiology is unique in several ways that may have implications for massive transfusion therapy. The newborn does not handle metabolites in a mature fashion. Renal immaturity may lead to problems in clearing potassium or acid from stored red blood cells, and the immature liver may not catabolize citrate efficiently. These problems are accentuated and protracted in the premature infant. To address the concern about potassium load, fresh (<5 days old) or washed red blood cells are often used, although the necessity of this practice is actively debated.[75,76] Fresh blood may also be preferred because of its higher 2,3-DPG levels and better red blood cell integrity. The citrate problem is probably best handled by using slow infusion rates, because the use of bicarbonate or calcium replacement to counteract the acid load or calcium-chelating effects of citrate is controversial. Finally, the use of red blood cells stored in the newer preservative solutions (CPDA-1, Adsol, Nutricel, Opitsol) is avoided by some

authorities because of the risk of renal damage and renal stones due to adenine metabolites. In addition, the potential toxicity of the various additives is of concern, as is a significant depletion of plasma proteins associated with transfusion of units with additive solutions.[77,78] If CPD red blood cells are not available, the additive solution can be removed and the cells washed. Red blood cells preserved in additive solutions also have a lower hematocrit, which must be taken into account in making calculations for exchange transfusion.[74]

The humoral and cellular immune systems of the neonate are also immature; again, the problem is accentuated in the premature infant with two implications for transfusion therapy. There is a small but real risk of transfusion-induced graft-versus-host disease in premature infants receiving red blood cell transfusions[79] and in the fetus undergoing intrauterine transfusion.[80] Irradiation of red blood cells should be performed in both settings. Another risk of transfusion in low birth weight (<1500 g) premature infants is the development of clinical cytomegalovirus (CMV) infection in infants of cytomegalovirus-seronegative mothers.[81] CMV safe blood, either CMV seronegative or leukoreduced, should be provided to these infants.[82]

ALTERNATIVES TO ALLOGENEIC RED CELL TRANSFUSIONS

There are many alternatives to standard allogeneic red cell transfusions for a patient requiring elective surgery (Table 146–3). Alternatives include banking autologous units before the surgery, acute normovolemic hemodilution, pharmacologic therapies (ie, erythropoietin or fibrinolysis inhibitors), perioperative salvage, virally inactivated donor red cells, or blood substitutes. All options have their own unique benefits and drawbacks. In cases where an emergency transfusion is needed, the first three options would not be available, as they all require significant planning. Only virally inactivated components and red cell substitutes (both of which are still works in progress) would be available for unanticipated transfusion needs.

Autologous Blood Transfusion

Advantages of Autologous Blood Transfusion

The substitution of autologous blood components for those collected from other (allogeneic) donors eliminates transfusion-transmitted diseases such as hepatitis and acquired immunodeficiency syndrome. Immunologic complications related to the transfusion of foreign cells, including hemolysis and febrile reactions to white blood cells, are also prevented. Other advantages, though possible, are less clearly established. For example, erythropoiesis may be sufficiently stimulated in the repeatedly bled autologous donor to hasten recovery from postoperative anemia.[83] Intraoperatively salvaged red blood cells are spared the acquired membrane defects ("storage lesion") and 2,3-diphosphoglycerate deficiency of refrigerated allogeneic cells.[84] Some investigators believe that allogeneic blood transfusions may contribute to immunosuppression in the recipient[85] and therefore to an increased risk of cancer dissemination[86] whereas autologous blood should not. However, a randomized trial of autologous versus allogeneic blood transfusion in patients with colon cancer was unable to detect any differences in prognosis, thereby disputing the contribution to immunosuppression by allogeneic blood.[87]

An important drawback to these techniques is their increased expense, in contrast to the simpler allogeneic transfusions they replace.[88] In addition, the availability of autologous components may result in their use in situations where transfusion might not have otherwise been considered.[89] Patients with suboptimal compensatory erythropoiesis and donation-induced anemia at the time of surgery are also more likely to be given transfusions.

Some patients and their families ask for directed blood donations, hoping to select blood donors that are known to them and presumably have less risk. This practice has not been shown to have any medical benefit, may cause reduced or delayed blood availability, and should not be considered a worthwhile transfusion alternative.

Preoperative Autologous Blood Collection

The typical volunteer allogeneic blood donor is allowed to give 1 unit of blood no more than once every 8 weeks, to prevent iron deficiency. However, provided that bone marrow erythropoiesis can be stimulated and satisfactory iron supplies maintained, blood can be collected as frequently as once a week from an autologous donor.[90] Although the shelf-life of refrigerated red blood cells is limited to 42 days, frozen storage for up to 10 years is possible at less than −65°C, using glycerol as a cryopreservative.

From a cardiovascular standpoint, phlebotomy is well tolerated by a variety of seemingly high-risk donors, including the elderly,[91] children,[92] pregnant women,[93] and patients with coronary artery disease.[94] By contrast, anemia frequently develops during the donation interval and limits the number of autologous units that can be collected. In addition to marginal iron stores, erythropoietin levels often do not increase during the donation interval, probably because the hematocrit level of most donors is not allowed to fall to less than 30%.[95] This situation may be improved by the administration to autologous donors of the recombinant growth hormone erythropoietin.[96] Common indications for autologous blood donation are listed in Table 146–4. The use of preoperatively donated autologous blood

Table 146–4 Common Indications for Autologous Blood Techniques

Surgical/Obstetric Procedures	Preoperative Donations	Perioperative Salvage
Intraabdominal vascular procedures	Yes	Yes*
Open heart surgery	Yes	Yes*
Total hip replacement	Yes	Yes†
Total knee replacement	Yes	Yes‡
Scoliosis repairs	Yes*	Yes
Radical prostatectomy	Yes	Yes§
Placenta previa	Yes	No*
Multiple gestations	Yes	No*

*The safety of blood containing amniotic fluid has not been conclusively established.

†The need for postoperative salvage has not been conclusively established.

‡Intraoperative salvage is unnecessary when a tourniquet technique is used; postoperative salvage may be of value when procedure is performed without cement.

§The risk of cancer spread after transfusion of intraoperatively salvaged blood has not been established.

Table 146–5 Autologous Blood Salvage Systems*

Characteristics of Collected Blood							
System	*Hardware*	*Software*	*Hematocrit*	*Free Hemoglobin*	*Platelet Count*	*Coagulation Factors*	*Fibrin Degradation Products*
Collection without washing	Rigid plastic container	Plastic bag	Low (25%)	Very high (200 mg%)	Low (100,000/mm^3)	Low (35%–75%)	High (300 mg%)
Collection followed by washing	Integral or separate blood cell processor	Disposable plastic bowl and tubing	High (60%)	Low (<50 mg%)	Very low (10,000/mm^3)	Absent (0%)	Absent (0%)

*Typical results of laboratory tests are shown. Transfusion of large volumes of salvaged blood results in similar alterations in these tests in the recipient. Data from Noon GP: Intraoperative autotransfusion. Surgery 84:719, 1978; and Silva R, Moore EE, Bar-Or D, et al: The risk : benefit ratio of autotransfusion-comparison to banked blood in a canine model. J Trauma 24:557, 1984.

has also been reported for a variety of other surgical procedures, including radical prostatectomy; hysterectomies and other gynecologic procedures; colorectal, biliary, and gastric surgery; and neurosurgery.[97]

Autologous blood has been safely collected from women during pregnancy for use during childbirth. Nevertheless, the transfusion rate at delivery is quite low (<2.5% in many institutions)[98] and most autologous donations are unused. Long-term (frozen) storage of autologous red blood cells in the absence of a planned transfusion episode is largely ineffective and expensive.

Intraoperative Blood Salvage

Interest in salvaging blood shed at surgery has been stimulated by the introduction of automated instruments for autologous blood salvage over the past 30 years. Systems for blood collection without processing are usually modifications of disposable suction devices (Table 146–5). Blood is collected under low vacuum pressure into a plastic bag seated within a hard outer canister. An anticoagulant such as citrate can be added. As soon as the bag is full, or within 4 hours of the start of collection (to prevent bacterial overgrowth), the contents of the bag are reinfused into the patient by gravity without any washing or further processing, except passage through a standard blood filter.

Alternatively, the contents in the bag can be washed to remove free hemoglobin, surgical irrigant solutions, and other debris. Although this step is theoretically attractive and increasingly popular, its necessity before reinfusion of shed blood has not been established.[99] Instruments that include both a reservoir for collecting salvaged blood and a centrifugal washer have been developed. Large aliquots (>500 mL) can be fully washed in as little as 3 minutes. As a result of this speed, autologous blood salvage has become practical in situations in which blood loss may be extremely rapid, such as trauma or liver transplantation.

The hematocrit level of unwashed blood is typically low because of dilution from irrigating surgical fluids and some degree of mechanical hemolysis. Free hemoglobin levels are sometimes greater than 1000 mg% in unwashed blood, and hemoglobinemia and hemoglobinuria may occur after the transfusion, although renal sequelae are surprisingly low.[99] Despite this evidence of red blood cell injury, the survival rate of ^{51}Cr-labeled salvaged cells is normal in most patients studied.[100]

Transfusion of salvaged blood has resulted in coagulation abnormalities, including hypofibrinogenemia, prolonged prothrombin time and partial thromboplastin time, elevated fibrin degradation products, and thrombocytopenia.[101] These coagulation abnormalities most likely reflect the characteristics of the salvaged blood itself, which, after exposure to serosal surfaces, becomes deficient in coagulation factors and platelets and, in the case of unwashed blood, has high levels of fibrin degradation products (see Table 146–4).[102]

Fat, fibrin, bone fragments, and microaggregates often contaminate salvaged autologous blood. However, infusion of unwashed blood has not been proved harmful in either animals or humans, possibly because routine blood filters remove most particulate material.[103] Other contaminants, such as heparin, topical antibiotics, hemostatic agents, and biologic substances such as tissue enzymes, can be at least partially removed by washing.[104,105] Complete removal of bacteria is also not possible, even when the salvaged blood is washed with antibiotics. Thus, collection of blood from a contaminated site (eg, with intestinal contents) is usually considered to be contraindicated. Tumor cells have also been found in blood salvaged during cancer operations and many practitioners consider cancer another contraindication.[105]

Approximately one-half the blood lost during surgery can be salvaged. The rest is usually irretrievably absorbed in drapes and sponges or damaged during collection. The use of salvaged autologous blood has been associated with a 50% reduction in allogeneic blood use in orthopedic procedures such as spinal surgery[106] and hip replacement[107] and is also effective in vascular surgical procedures such as aortic reconstruction.[108] Autologous salvage has been a useful adjunct in the treatment of some Jehovah's Witnesses, whose literal acceptance of the Bible includes abstention from routine allogeneic blood transfusions.[109]

Both the canister systems and red blood cell processors used to collect intraoperative autologous blood can also be employed to collect postoperative blood drainage, such as that from the mediastinum after open heart surgery,[110] from the knee or hip after orthopedic procedures,[111] or from the peritoneal cavity after hepatic injury.[112] Because blood salvaged from a serosal cavity has little residual fibrinogen and platelets, clotting is not a problem, and the addition of anticoagulants is usually unnecessary.[113] Shed mediastinal blood after open-heart surgery contains high levels of cardiac muscle enzymes, especially creatine kinase, as well as lactate dehydrogenase from hemolyzed red blood cells.[114,115] Therefore, reinfusion of shed blood results in elevated levels of both enzymes, which can confound the diagnosis of myocardial infarction in the postoperative period.[116,117] Reinfusion of shed mediastinal blood has been shown to reduce the need for allogeneic transfusions.[118]

Hemodilution

The collection of autologous blood during surgery for later reinfusion at the end of the procedure was first suggested in open-heart operations, in which it was hoped that a supply of platelets undamaged by exposure to the membrane oxygenator might reduce the incidence of coagulopathies.[119] Hemodilution itself reduces red blood cell loss: a patient with a hematocrit level of 45% and 2 L blood loss during surgery loses roughly 900 mL of red blood cells, but one with a hematocrit level of 20% from hemodilution loses only 400 mL of red blood cells. Hemodilution is probably less expensive to accomplish than preoperative autologous blood donation and may be the only option available when surgery is performed in other than elective settings.[120] Proponents claim that the induced anemia may even be beneficial to the patient, in that oxygen delivery at a hematocrit level

of 30% is enhanced by an increased cardiac output resulting from the decreased blood viscosity.[121]

Reductions in allogeneic blood needs have been reported after marked intraoperative hemodilution (after the hematocrit is lowered by 50%).[122] More modest hemodilution (eg, removal of 2 U of blood at the beginning of surgery) is also beneficial, according to some investigators.[123,124] but not others.[125,126] Furthermore, one group has provided evidence that hemodilution may jeopardize patients at risk of ischemic myocardial injury. More research is needed to establish the safety and ideal protocols for this form of blood conservation. The availability of blood substitutes may facilitate augmented hemodilution for some patients who are expected to have large volumes of blood loss or who refuse blood transfusions.

BLOOD SUBSTITUTES

The search for blood substitutes began when our early scientific ancestors tested alternatives to human blood, including animal blood, milk, and wine. Modern research into the use of animal blood includes the work by Amberson et al, who reported the successful use of a bovine hemosylate for exchange transfusions in cats and dogs.[127] Further work revealed that human and bovine hemosylates caused renal dysfunction in human recipients. The suspected cause of this nephrotoxicity was the stromal lipid component of the RBC membrane.[128,129] The logical next step in the search for the ideal substitute was the development of stroma-free hemoglobin (hemoglobin tetramer). Unfortunately, in 1978 Savitsky et al demonstrated renal dysfunction, hypertension, and abdominal pain using stroma-free hemoglobin (Hb) in healthy volunteers.[130] It was hypothesized that these adverse events were due to the instability of the hemoglobin tetramer. Since then, efforts have been made to produce stabilized products with desirable oxygen off-loading characteristics and extended intravascular retention times.

Today, the US blood supply is safe and has sufficient capacity to meet most patient needs. There is room for considerable improvement, however, in supply levels and risk reduction. The gap between a shrinking donor pool (owing to willingness and/or ability) and increasing transfusion requirements of an aging population continues to narrow. The threat of new and emerging infections results in the vulnerability of human-derived oxygen carriers. Recent battles against West Nile virus and variant Creutzfeldt–Jakob disease underscore the risk of a tainted blood supply and depletion of transfusion resources. Theoretically, the ideal red cell substitute would solve both of these issues (Table 146–6). There have been many attempts to develop red cell substitutes in the past, but no product has been able to fulfill all of the above criteria or meet the Food and Drug Administration's requirements of purity, potency, and safety.

Table 146–6 The Ideal Red Cell Substitute

Delivers oxygen (and maybe enhances delivery)
Does not transmit disease
Does not have immunosuppressive effects
Available in abundant supply
Universally compatible (no need to type and crossmatch)
Prolonged shelf-life and stable at a range of temperatures
Similar in vivo half-life to the red blood cell
Available at a reasonable cost
Easy to administer
Able to access all areas of the human body (including ischemic tissue)
Effective on room air or ambient conditions

TYPES OF RED CELL SUBSTITUTES

It is important to differentiate between "blood substitutes" and red cell substitutes. Red cell substitutes are oxygen carriers and do not replace all components and functions of blood, for example, coagulation factors and white blood cells. There are three categories of oxygen carriers that show promise as red blood cell substitutes: perfluorocarbons, hemoglobin-based oxygen carriers (HBOC), and engineered red blood cells.

Perfluorocarbons

Perfluorocarbons (PFC) are chemically and biologically inert artificial fluorinated organic fluids that are immiscible in water and have a high solubility for oxygen. The amount of dissolved oxygen in PFC is directly related to the ambient oxygen tension—unlike Hb; gas molecules are not chemically bound to PFC, but are absorbed and released by simple diffusion.[131] Oxygent (Alliance Corp, San Diego, CA) is a second-generation concentrated PFC emulsion based on perflubron (perfluorooctyl bromide; $C_8F_{17}Br$) with a shelf-life of up to 2 years. It requires oxygen inhalation by the patient, as the oxygen delivery capacity is less than 30% of normal blood. A large European multicenter phase III study has shown that Oxygent in conjunction with acute normovolemic hemodilution (ANH) reduced the need for RBC transfusion in 492 patients undergoing major noncardiac surgery.[132] However, a phase III trial studying Oxygent in patients undergoing cardiopulmonary bypass was terminated in the United States because of a possible increase in stroke rates in the Oxygent treatment arm. Although some PFC are still being investigated, there are no major trials ongoing in the United States. Perftoran, a perfluorocarbon approved for clinical use in Russia and Mexico, has been shown to be safe in a study of cardiac surgery patients who received Perftoran along with acute normovolemic hemodilution. The patients who received Perftoran had higher arterial oxygen levels and received less allogeneic transfusions than the patients who just underwent hemodilution.[133]

Hemoglobin-Based Oxygen Carriers

The stroma of the red cell causes many of the problems in allogeneic human red cell transfusions. The red cell membrane ultimately fails and limits the shelf-life. The red cell membrane also contains the antigens that limit compatibility. Unfortunately, initial efforts to develop HBOC that focused on unmodified Hb failed—unmodified tetramers naturally dissociate into dimers outside of the RBC. This unmodified tetrameric Hb is associated with renal toxicities, gastrointestinal effects, and vasoconstriction.

The HBOC currently in clinical development are stroma-free and engineered to produce desirable oxygen dissociation characteristics as well as an adequate in vivo half-life with minimal toxicities. Stroma-free Hb has a very high oxygen affinity compared with native Hb in an RBC because of a lack of 2,3-diphosphoglycerate (DPG). Furthermore, the Hb tetramer is such a small molecule that the kidney rapidly removes it.

Four different methods have been suggested to avoid toxicities: stabilization, polymerization, conjugation, and Hb vesicles. Hb can be stabilized using an alpha-chain cross-linker (Diaspirin Cross-Linked Hb); this approach was pursued by Baxter Healthcare (Deerfield, IL). The second approach, polymerization, involves intermolecular cross-linking of tetramers to increase intravascular retention time. Polymerization with agents such as glutaraldehyde not only increases the molecular size of the molecule but also increases Hb concentration and decreases oncotic pressure. This approach is being pursued by Northfield Laboratories (Evanston, IL). Conjugation involves the binding of a larger molecule, such as polyethylene glycol or dextran, potentially allowing the Hb-conjugate to remain in the vasculature longer due to its increased size. Conjugation is being

attempted by Sangart (San Diego, CA). A drawback of conjugation is an increased viscosity compared to normal blood.[134] The final approach, Hb vesicles, uses liposome-encapsulated Hb to mimic the actual red blood cell. The Hb molecule is inserted into a lipid membrane derived from natural lecithins or synthetic phospholipids. These products have an effective oxygen delivery system, high Hb concentration and should be stable during storage with a plasma half-life of 4 to 20 hours without risk of renal toxicity; however, they have a tendency toward methemoglobin formation. Although Hb vesicles appear to be an attractive option, there are no clinical trials with these products at the current time.

HBOC can be prepared from different Hb sources. Human Hb probably would not alleviate supply concerns, because the amount of outdated human blood is likely to be inadequate to make large supplies of HBOC. Bovine Hb has been used as a source of Hb because of its naturally low oxygen affinity and its ability to be directly polymerized (to avoid renal excretion) without prior manipulation. Bovine Hb has a molecular structure similar to human Hb but has enhanced oxygen unloading in ischemic tissue. Unlike human Hb, which is regulated by 2,3-DPG, the affinity of bovine Hb is partially regulated by serum chloride ions.[135] Although this product removes the constraint of using human donated red blood cells, there are uncertainties about using bovine Hb because of its potential to transmit disease (eg, bovine spongiform encephalopathy) and its potential immunogenicity. Biopure Corp (Cambridge, MA) has pursued the commercial development of a bovine HBOC.

Researchers have explored two options for recombinant sources of Hb. There is a hybrid Hb product which is a synthetic heme bound to recombinant human serum albumin. This product has a similar p50 to human red blood cell Hb and has an intravascular circulation time of greater than 36 hours in rats.[136] The second alternative, which was pursued by Somatogen, is completely recombinant Hb molecules. These products are either developed in microorganisms (*Escherichia coli*, yeast) or in transgenic plants or animals. A first-generation product developed in *E coli* was discontinued because of vasoconstrictive effects in animals. Harvesting of the human Hb and purification techniques still require major improvement, and scaling up research methods to make an adequate supply of clinical material will be a significant hurdle. At the current time, recombinant Hb is still within preclinical development.

HBOC are a work in progress, but several shortcomings have emerged across the class. Although molecular size has increased to the point where it is not immediately removed by the kidney, the molecules are still seen as foreign in the recipient and quickly cleared by the reticuloendothelial system. The plasma half-life is generally 24 hours or less, thus unlikely to have a role in patients with chronic anemia. In addition, free Hb is a scavenger of nitric oxide (NO); because NO plays a key role in vasomotor control, specifically vasodilation, its removal by Hb results in a vasoconstrictive effect leading to hypertension (systemic and pulmonary).

Three HBOC products remain in advanced clinical development (Fig. 146–1): Hemopure (Biopure Corp, Cambridge, MA), Hemospan (Sangart, San Diego, CA), and Polyheme (Northfield Laboratories, Evanston, IL). All three products have recently faced significant challenges in proving their safety and efficacy in late phase clinical trials.[137]

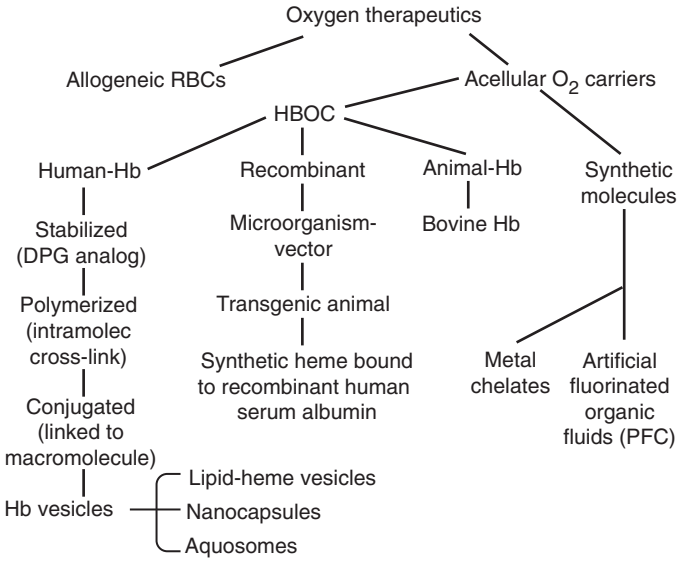

Figure 146–1 Three HBOC products remain in advanced clinical development: Hemopure (Biopure Corporation, Cambridge, MA), Hemospan (Sangart, San Diego, CA), and Polyheme (Northfield Laboratories, Evanston, IL).

Engineered Red Blood Cells

Owing to the difficulty of finding compatible red blood cells in patients who become alloimmunized as a result of frequent transfusions, there have been efforts to create universal donor red blood cells. Two approaches have been proposed to attain this goal. Covalent binding of polyethylene glycol masks red cell antigens. Alternatively, red cell antigens can be enzymatically removed by exoglycosidase treatment, which has only been partially successful thus far. The strategy of an engineered red blood cell, though still in its infancy, does not address concerns such as limited supply, storage limitations, and disease transmission.

Potential Clinical Applications

Red blood cell substitutes have many potential applications. One of the most compelling would be use for resuscitation during military and civilian traumas. In developing a specific plan to avoid the consequences of blood unavailability after national disasters involving large-scale injuries, blood substitutes could play a key role as an immediate treatment option. In addition to these acute emergency situations, there is a wide range of less urgent applications where oxygen carriers might provide a viable solution to difficult situations, including augmenting perioperative hemodilution, transfusion of patients who refuse human blood components because of religious beliefs, transfusion of patients with rare blood types or antibodies to high incidence antigens, organ preservation for transplant surgery, and transfusion in patients with autoimmune hemolytic anemia in whom it is difficult to detect underlying antibodies.

One of the most promising roles for red cell substitutes is to avoid transfusion of donor red cells, especially when compatible red blood cells are not available. Other roles include use as a volume expander or resuscitative fluid, as well as clinical situations where tissue oxygenation is needed but the tissues do not have access to red blood cells. An example of this attractive potential indication for the use of red blood cell substitutes is to target tissue ischemia, with specific focus on vital organs. Another application that has been studied in both preclinical and clinical studies is the use of red cell substitutes to increase tumor Po_2 levels to enhance sensitivity to radiation and chemotherapy.[138,139] Finally, preclinical studies using red cell substitutes to preserve tissues and prolong the storage time of an organ prior to transplantation have been conducted.[140]

Patients with hemoglobinopathies comprise a unique population that might receive added benefits from red cell substitutes versus donor red cells. These patients tend to be chronically transfused and also seem to be at a higher risk for becoming alloimmunized per unit transfused compared to the general population.[141] The universal compatibility of red cell substitutes would be ideal to protect these patients from further alloimmunization and the risks of delayed hemolytic transfusion reactions. In addition, the availability of blood for sickle cell patients requiring phenotyped RBCs would be improved. Red cell substitutes could be useful as urgent therapy for acute chest syndrome or other emergency vasoocclusive events until compatible blood is found.

There have been a number of other successful reports of red cell substitutes used in Jehovah's Witnesses. For religious reasons, many Jehovah's Witnesses have refused blood transfusions, even in cases of life-threatening blood loss. Fractions derived from blood are not prohibited by the religion; the decision is left to the individual as a "matter of conscience." Many Witnesses accept and even seek out blood substitutes. Severe anemia in a Jehovah's Witness makes a blood substitute a very attractive therapeutic option as a bridge to provide oxygen transport until the patient's own endogenous production can compensate for the anemia.

Patients with autoimmune hemolytic anemia are another population that may benefit from a safe and effective red blood cell substitute. It is often difficult to find compatible blood for patients with this disease because the autoantibody can make it difficult to detect coexisting alloantibodies.[142] Red cell substitutes are universally compatible and thus could become an important bridge for patients until compatible blood could be found.[143]

Toxicities

The safety of red cell substitutes remains a serious concern. Although cross-linking and polymerizing Hb subunits have reduced the incidence of nephrotoxicity, problems with vasoconstriction and pressor effects have not been completely eliminated. Vasoconstrictive responses, including increased systemic and pulmonary arterial pressures, are thought to result from the binding of nitric oxide to Hb. Hb interaction and scavenging of nitric oxide is also thought to play a role in some gastrointestinal effects of the products, such as dysphagia.[144]

The complications of red cell substitutes in septic patients are not known. Cell-free Hb substances may support bacterial virulence by offering a ready supply of iron, thus sustaining bacterial replication and inhibiting neutrophil function.[145] Although animal data has been suggestive of a potential clinical problem, clinical trials to date have not established this risk.

The immunogenicity of HBOC is still being studied. Because the modified human hemoglobins have been chemically changed it may be possible for them to trigger an immune response in humans. Bovine Hb has an even greater chance of causing immunogenicity in humans, because of its substantial differences from the protein structure of human Hb. To date, no serious immune or allergic responses have been reported, but most patients have only had single-incident exposures to these products, usually over short periods of time. Animal studies by manufacturers have not demonstrated a problem.

The Future of Red Cell Substitutes

Proving the benefit of red cell substitutes in clinical trials has not been easy for a number of reasons. First, in order to reduce use of donor red blood cells, we must prove that the risks presented by HBOC or PFC are not greater than those of blood transfusions. This fact has not yet been established. Second, without specific transfusion triggers or guidelines, it is difficult to establish whether a transfusion has actually been avoided. Finally, the goal of reducing transfusion-related expenses may not be achievable because HBOC are likely to initially be very expensive.

Red cell substitutes have a promising value proposition for transfusion services—increase the availability of blood components and remove donor and contamination safety risks. Existing products suffer from critical shortcomings (in vivo half-life) that make them more suitable for short-term gaps (eg, acute blood loss, ischemia, bridge until compatible red cells become available) than long-term solutions. Substitutes not based on human blood introduce potentially more complex safety hurdles, such as immunogenicity and fear of prion contamination in bovine-derived products.

CHAPTER 147

PRINCIPLES OF PLATELET TRANSFUSION THERAPY

Aleksandar Babic and Richard M. Kaufman

PLATELET COLLECTION AND MANUFACTURING

Platelet products are either prepared from whole blood donations (platelet concentrates), or are collected by apheresis (single donor platelets, SDPs). In the United States, whole blood-derived platelet concentrates are made using the platelet-rich plasma (PRP) method. First, a whole blood unit is separated by gentle centrifugation (slow spin) into red cells and PRP. The PRP is then centrifuged a second time (hard spin) to isolate one platelet concentrate plus one unit of plasma. Each platelet concentrate contains approximately 5.5×10^{10} platelets suspended in a plasma volume of approximately 50 mL. In Europe and Canada, the alternate buffy coat method is used to produce platelet concentrates. Platelets are stored at room temperature under continuous gentle agitation for up to 5 days. (Seven-day platelet storage is permissible under certain conditions, discussed in Infections Risks.) To prepare an adult dose of platelets for transfusion, four to six platelet concentrates are pooled together.

Apheresis platelet units are collected from a single platelet donor by continuous flow centrifugation using an automated device. A high volume of whole blood is processed through the machine, and the platelets are retained in a sterile collection bag. By AABB standards, an apheresis platelet unit should contain a minimum of 3×10^6 platelets,[1] a dose that is approximately equivalent to six pooled platelet concentrates. Current devices actually allow many different combinations of blood products to be collected during a single apheresis donation, such as a unit of platelets plus a unit of RBCs. Apheresis platelet units generally contain less than 1×10^6 white blood cells per unit; thus they meet the current AABB definition for leukoreduced blood products ($<5 \times 10^6$ WBCs/unit).[1] Although apheresis platelets cost more to produce than whole blood derived platelet concentrates, they have become increasingly popular. In the United States in 2004, approximately 1.4 million therapeutic doses of platelets were provided as apheresis platelets, and only 256,000 doses were administered as whole blood-derived platelet concentrates.[2,3]

Apheresis platelets provide some (limited) advantages over whole blood-derived platelet concentrates. Radiolabeling studies indicate that apheresis platelets circulate longer in vivo than pooled concentrates,[4] most likely reflecting gentler handling and less platelet activation during collection. Recipients of apheresis platelets are exposed to fewer donors per transfusion (one donor versus six as with a pool of platelet concentrates), so in principle apheresis platelets should pose a lower risk of viral transmission than whole blood-derived platelets. However, given that the per unit transfusion-transmission risks for HIV and Hepatitis C Virus have been cut to approximately 1 in 2,000,000,[5] the actual safety advantage of apheresis platelets over whole blood-derived platelets is small. Data from surveillance culture studies do suggest that apheresis platelets may be less likely than platelet concentrates to become contaminated with bacteria.[6] At one time, it was predicted that apheresis platelets would be less likely than pooled concentrates to provoke platelet alloimmunization, by virtue of exposing recipients to fewer unique donor HLA antigens. This hypothesis was not confirmed empirically, however.[7,8] Although they express surface HLA class I antigens, platelets appear to be rather poor immunogens. HLA alloimmunization to platelets primarily appears to be triggered by contaminating white blood cells within a platelet unit. Thus, alloimmunization is not platelet dose-dependent, and simply providing leukoreduced platelet units prevents most cases of immune-mediated platelet refractoriness.[8]

PROPHYLACTIC PLATELET TRANSFUSION

Today, the vast majority of platelet units are transfused prophylactically, to prevent bleeding in nonbleeding patients rather than to treat active bleeding.[9] Prior to 1960, platelet transfusions were not widely available, and death from hemorrhage was common among patients with leukemia who received chemotherapy. In 1962, Gaydos and colleagues published a seminal study demonstrating a relationship between platelet count and likelihood of bleeding.[10] After this study was published, prophylactic platelet transfusion rapidly became standard practice. Of note, no specific platelet transfusion trigger was suggested by the authors based on their data. Regardless, a platelet count of 20,000/μL was widely adopted as the standard prophylactic platelet transfusion trigger.

Later studies suggested that a lower transfusion trigger would be as effective as a trigger of 20,000/μL. Slichter and Harker, for instance, performed red cell radiolabeling studies in thrombocytopenic patients who were not receiving platelet transfusions. They demonstrated that only patients with platelet counts below 5000/μL had significantly elevated fecal red cell loss.[11] Years later, several clinical studies directly challenged the 20,000/μL trigger. Platelet transfusion triggers of 10,000/μL versus 20,000/μL were compared directly in three randomized prospective studies of patients with acute leukemia.[12–14] All of these studies, as well as large nonrandomized prospective trials,[15,16] demonstrated no increased risk of bleeding when a trigger of 10,000/μL is used. Notably, all of these trials included provisions for transfusing thrombocytopenic patients at platelet counts above 10,000/μL if associated risk factors for bleeding (eg, fever) were present. Although few studies have directly examined prophylactic platelet transfusion in the specific setting of hematopoietic stem cell transplantation (HSCT), the 10,000/μL trigger has been widely applied to the HSCT patient population, and it appears to be safe.[17,18] Clinical factors are usually more important determinants of bleeding risk than the platelet count alone. Approximately two-thirds of bleeding events post-HSCT occur in patients with platelet counts above 20,000/μL.[19,20]

Prophylactic Platelets for Invasive Bedside Procedures

At present, there are no large randomized trials evaluating the need for platelet prophylaxis prior to invasive bedside procedures such as lumbar puncture. However, there exist retrospective data providing reassurance that moderate thrombocytopenia does not pose a serious risk for performing such procedures. Howard et al[21] reviewed the records of 956 consecutive pediatric patients with newly diagnosed acute lymphoblastic leukemia who underwent lumbar puncture. No serious hemorrhagic complications were observed following 5223 lumbar punctures, including 170 procedures that were done when the platelet count was 11,000 to 20,000/μL. The authors concluded that prophylactic platelet transfusion was unnecessary in patients with platelet counts above 10,000/μL. Lumbar punctures were performed in only 29 patients with platelet counts of 10,000/μL or less,

making it difficult to assess the risk of bleeding in patients with very low platelet counts. A similar, albeit much smaller retrospective study examined the same issue in adult patients with acute leukemia.[22] No hemorrhagic complications were observed following 195 lumbar punctures, including 35 that were done with a platelet count of 20,000 to 30,000/μL. Finally, for other common bedside procedures such as central venous catheter placement, platelet counts of 20,000 to 30,000/μL are generally considered to be adequate, although again data from prospective studies are unavailable.

Prophylactic Platelets for Major Surgical Procedures

There are currently no data from randomized trials addressing the question of what constitutes an adequate platelet count prior to surgery. Retrospective studies, though, suggest that patients with platelet counts of 50,000/μL or higher are not at excess bleeding risk during surgery. Bishop and colleagues[23] reported a series of 95 patients with acute leukemia who underwent 130 surgical procedures with platelet counts of less than 50,000/μL. Intraoperative blood loss exceeded 500 mL in only 7% of cases. No relationship was seen between the preoperative platelet count and surgical blood loss. These data suggest that prophylactic platelet transfusions need not be administered prior to surgery when the preoperative platelet count is at least 50,000/μL. This rule-of-thumb is thought to apply to most types of surgery (cardiac, orthopedic, etc.). For a few types of surgeries though, requiring a higher platelet count (70,000–100,000/μL) is traditional, although no published data currently exist either to support or refute this approach. These settings include neurosurgery, retinal surgeries, and other procedures where the risk is not that the patient may exsanguinate, but rather that even a minor bleed might cause clinically significant damage in a vulnerable vital structure such as the brain.

Prophylactic Platelet Dosing

Lowering the standard prophylactic platelet transfusion trigger from 20,000/μL to 10,000/μL is believed to have helped conserve the limited supply of platelets in the United States. A complementary approach to lowering the transfusion trigger is altering the dose of prophylactic platelets administered. There are currently thought to be two distinct clearance mechanisms for platelets. Most platelets undergo senescence after circulating in the peripheral blood for 8 to 10 days. But there is also evidence for a second clearance route, in which there is a fixed daily loss of platelets that occurs independent of platelet age. Platelets exiting the circulation via this second route are postulated to function in maintaining vascular integrity.[24] This small fixed daily platelet requirement has been estimated to be 7.1×10^9 platelets/L/day. In principal, a low dose of platelets could be used to meet this daily requirement. Mathematical modeling has suggested that using a low dose (eg, pools of three whole blood-derived platelets versus the current six) would save approximately 22% of prophylactic platelets over time.[25] On the other hand, higher prophylactic platelet doses would be predicted to reduce the total number of transfusion events.[26,27] Randomized trials are now underway that are designed to empirically determine the optimal dosing strategy for prophylactic platelets.[28–30]

THERAPEUTIC PLATELET TRANSFUSION

A small number of studies published in the 1970s and early 1980s suggested the idea of using a purely therapeutic platelet transfusion strategy—transfusing platelets only to treat active bleeding, rather than administering prophylactic platelets in thrombocytopenic patients.[31–33] This concept was revived recently by Wandt and colleagues,[16] who reported a series of 140 hematopoietic stem cell transplants in which no prophylactic platelets were given to clinically stable patients, regardless of platelet count, unless the patient had WHO grade II or higher bleeding. Patients deemed to be clinically unstable (defined as fever >38.5°C, infection or known coagulation factor disorder) were given prophylactic platelet transfusions for platelets less than 10,000/μL. No WHO grade III or IV bleeding was observed. Grade II bleeding was seen in 26 transplants (19%). No clinically relevant bleeding was seen in the remaining 114/140 patients (81%). The first 60 patients in this study were compared to 60 historical controls who were transfused with prophylactic platelets for a platelet count of less than 10,000/μL. The total number of platelets transfused was only 111 in the therapeutic group compared to 237 in the historical control group. Thus the therapeutic strategy was quite effective in this study.

ADVERSE EFFECTS OF PLATELET TRANSFUSION

Infectious Risks

Platelets are associated with the same range of infectious pathogens as any other blood component, but septic transfusion reactions, caused by bacterially contaminated units, comprise a unique risk of platelet transfusion. Over time, improvements in donor screening virtually eliminated the risk of transfusion transmission of hepatitis B virus, hepatitis C virus, and HIV. The risk of septic transfusion reactions remained fairly constant over this same time period, so eventually platelet bacterial contamination became, by default, the most frequent infectious risk of transfusion. Unlike other blood components, which are stored either refrigerated or frozen, platelets are stored at room temperature. The reason is that if platelets are refrigerated prior to transfusion, they are cleared rapidly from the recipient's circulation.[34] Although room temperature storage allows transfused platelets to circulate in vivo, it has the downside of promoting bacterial growth. Because of this risk, platelet storage is ordinarily limited to only 5 days, making platelet inventory management extremely challenging.

In the 1990s, numerous studies demonstrated that contaminating bacteria, usually representing skin flora from the donor, could be cultured out of approximately 1/3,000 platelet units.[35] Clinically apparent septic transfusion reactions were thought to occur following approximately 1/25,000 platelet transfusions, although there is considerable uncertainty around this point estimate.[35] In 2002, an open letter calling for immediate action to reduce the risk of platelet bacterial contamination[36] led to the proposal of AABB standard 5.1.5.1. The standard states:

> *5.1.5.1 The blood bank or transfusion service shall have methods to limit and detect bacterial contamination in all platelet components. Standard 5.6.2 applies [skin disinfection].*[37]

How this standard is being met varies by facility. Many blood collection centers have begun routinely culturing platelet units using an automated culture system. The BacT/ALERT system (BioMerieux), used by many centers, works by continuously monitoring for bacterial production of CO_2 within culture bottles. Platelet units are sampled on the day after collection. The samples are cultured for a period of time, typically 24 hours, and if the cultures fail to produce abnormal levels of CO_2, the product is released into inventory. Overall, culture-based bacterial screening appears to have decreased, but not eliminated, the risk of septic reactions. Reducing the risk even further may ultimately require alternative approaches, such as pathogen reduction.[38–41] Nonculture methods such as pH and glucose testing (using a dipstick or automated analyzer) and Gram staining are employed by some facilities; however, the sensitivity and specificity of these nonculture methods is demonstrably inferior to culture-based methods.[42,43] Rapid, point-of-issue tests that could be used to verify the sterility of a platelet unit just before release are under development. It is hoped that that some of the costs associated with testing for platelet bacterial contamination will be offset by the benefits of being able to extend platelet storage beyond the 5-day limit.

The FDA has approved the use of 7-day-old platelets in the context of a large surveillance study (PASSPORT)[44,45]; the quality of even older platelet units is being evaluated.

A number of alternate approaches to the problem of bacterial contamination have been proposed. These include freezing platelets using a cryopreservative such as DMSO or trehalose[46,47] and refrigerating platelets after glycosylation.[48–50] Pathogen inactivation systems, utilizing photosensitive dyes/UV light, can provide up to 6 logs of killing of spiked virus or bacteria within a unit of platelets or red cells.[51–56] One such system has been licensed for use in Europe. At this time, however, no pathogen inactivation system is licensed for use in the United States.

Allergic and Febrile Nonhemolytic Transfusion Reactions

The typical RBC unit contains approximately 20 mL of plasma. Platelet units contain far more plasma, approximately 200 mL on average. There are multiple potential adverse effects associated with this large plasma content. First, allergic transfusion reactions are frequently associated with platelet transfusion. Allergic reactions to platelet transfusions occur when the recipient has a preexisting allergy to a plasma protein component. Allergic reactions can range from mild, uncomplicated urticarial reactions to full-blown anaphylaxis. Febrile nonhemolytic reactions, defined as a rise in temperature of more than 1°C, may also be seen following platelet transfusion. In a provocative study, Heddle and colleagues demonstrated that it is in fact the plasma component of platelet units, rather than the cellular component, that causes most such reactions.[57] Cytokines that accumulate during product storage have been implicated.

ABO and Hemolytic Reactions to Platelets

Whenever possible, platelet units are assigned so as to match the donor plasma with recipient red cell type. For example, a type A patient would ordinarily receive type A or AB platelets, which do not contain anti-A antibody. When platelet inventories are constrained, however, it is a frequent practice to provide ABO-incompatible platelets: for example, type A patient can receive type O platelets, containing anti-A. The passive transfusion of donor anti-A or anti-B to a patient rarely results in a clinically apparent reaction. Occasionally, however, hemolysis may be observed. Most often, this occurs with units from type O donors, who occasionally have high titer anti-A, anti-B and/or anti-A,B antibody. In a typical type O adult, the titer of circulating anti-A is on the order of 1:128-1-256. Some donors, for unclear reasons, have anti-A titers of 1:10,000 or higher. Recipients of products from donors with high-titer anti-A (and less frequently, anti-B) rarely do have clinically apparent hemolysis, and a small number of fatalities have been reported.[58] This is considered to be a low-risk event, but may be on the rise in the United States because of the increased number of single-donor apheresis platelet units used.[59] One strategy to deal with this issue is to measure the anti-A/B titer on all platelet donors; components exceeding a threshold titer are assigned to type-specific recipients. An alternate strategy is to gently reduce the load of plasma in a platelet unit prior to transfusing the unit to a non–ABO-identical recipient.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI), an acute respiratory distress reaction associated with the transfusion of any plasma-containing blood component, deserves mention. Although TRALI can be seen with any blood component, it most commonly follows transfusion of plasma or platelet units. RBCs are a much less common cause of TRALI. It is hypothesized that higher volumes of plasma provide higher loads of TRALI-precipitating anti-HLA or anti-neutrophil antibody, making plasma and platelets higher-risk components for TRALI. Irrespective of the type of blood component causing TRALI, the diagnosis of TRALI remains one of exclusion, and treatment is supportive.

Rh(D) Sensitization

The Rh(D) antigen is the most immunogenic red cell protein antigen. More than 80% of individuals who are Rh(D) negative will form an anti-D antibody following a single Rh(D)-positive RBC transfusion.[44] Anti-D antibodies are associated with both hemolytic transfusion reactions as well as hemolytic disease of the fetus and newborn. For this reason, it is standard practice to provide Rh(D)-negative individuals exclusively with Rh(D)-negative RBC units. Platelet units contain a small number of contaminating RBCs. In the case of platelet concentrates, approximately 0.3 to 0.5 mL RBCs may be present. Current apheresis platelets contain far fewer RBCs—approximately 0.0002 to 0.0007 mL per unit.[60] Ordinarily, Rh(D)-negative platelet units are given to Rh(D)-negative recipients. However, inventory constraints frequently force blood banks to provide Rh(D)-positive platelet products to Rh(D)-negative recipients. Transfusion of such units is associated with a low but nonzero risk of sensitization and formation of anti-D. Anti-D antibody formation can be prevented by administering Rh immune globulin, as is done to prevent fetomaternal Rh sensitization in Rh(D)-negative mothers of Rh(D)-positive children. The risk of sensitization is especially low among Rh(D)-negative immunocompromised patients transfused with Rh(D)-positive platelets, for example, HSCT patients.[61] In this setting, the value of RhIg prophylaxis appears to be marginal.

PLATELET REFRACTORINESS

Causes of Refractoriness to Platelet Transfusion

Platelet refractoriness is defined as an inappropriately low platelet increment following repeated platelet transfusions. It can be caused by nonimmune and/or immune factors (Table 147–1). The most commonly reported nonimmune causes of platelet refractoriness include fever, sepsis, bleeding, splenomegaly, and disseminated intravascular coagulation.[62] In a subset of cases, platelet refractoriness is immune-mediated. Platelets express HLA class I antigens, ABO antigens,[63] and several platelet-specific antigens. Any of these molecules may potentially serve as an immune stimulus in a transfusion recipient. Antibodies directed against HLA molecules are responsible for most cases of immune-mediated platelet refractoriness, whereas antibodies to the human platelet antigens (anti-HPA antibodies) are less frequently implicated.[8]

Diagnosis of Platelet Refractoriness

Because less than half of all platelet-refractory patients have demonstrable anti-HLA or antiplatelet antibodies,[64,65] evaluation of both an immediate response to platelet transfusion and an 18- to 24-hour posttransfusion platelet survival is needed to help establish the cause of platelet refractoriness. Platelet counts obtained from 10 minutes to 1 hour after transfusion that repeatedly fail to demonstrate a corrected count increment (CCI) of more than 5000/μL usually indicate immune-mediated platelet refractoriness.[66] If the 10-minute to 1-hour posttransfusion platelet count shows a reasonable increment but the platelet count falls back to baseline by 18 to 24 hours, a nonimmune mechanism of refractoriness may be presumed (Table 147–1). In cases of suspected immune-mediated refractoriness, HLA antibody screening (panel reactive antibody or PRA) provides valuable supporting evidence that allosensitization has occurred.[67,68] A patient with a PRA greater than 70% may be considered to be "severely immunized,"[69] and a good candidate for HLA-matched platelets (below).

Table 147–1 Causes of Refractoriness to Platelet Transfusion

Nonimmune
Fever
Sepsis
Drug-associated
Active bleeding
Splenomegaly
Disseminated intravascular coagulation
Venoocclusive disease
Immune
Anti-HLA antibodies
Anti-HPA antibodies
ABO mismatch
Drug-dependent antibodies

Detection of Anti-HLA Antibodies

Several assays are available to detect presence of anti-HLA class I antibodies in serum of alloimmunized patients. One of the most commonly used tests is the National Institutes of Health lymphocytotoxicity assay (LCTA).[70] The results of LCTA correlate well with the response to platelet transfusion.[18,71] However, this assay will not detect anti-HLA antibodies that do not activate complement.[72] The anti-HLA antibodies can also be detected using HLA-specific solid-phase enzyme-linked immunosorbent assay,[73] glycoprotein-specific monoclonal antibody-specific immobilization of platelet antigens,[72] or flow cytometric detection of antibody binding to beads coated with purified HLA antigens.[74] This flow cytometry-based methodology has significantly improved sensitivity over LCTA[75] and, similarly to solid-phase assays, it can detect both complement-fixing and non–complement-fixing antibodies.[74] All our patients with suspected platelet refractoriness due to alloimmunization are evaluated for presence of anti-HLA antibodies using flow cytometry-based assays.

Detection of Antiplatelet Antibodies

Most commonly used methods for detection of anti-HPA antibodies are solid-phase assays utilizing purified platelet antigens for detection of antibody specificity. However, extensive testing for anti-HPA antibodies is not widely accepted as a critical step in the workup of platelet refractory patients, mostly because of conflicting data on significance of these antibodies in platelet refractoriness.[8,76,77]

Prevention of Alloimmunization

Although they express HLA class I antigens, platelets themselves are fairly weak immunogens. It has been shown that contaminating leukocytes in platelet products are primarily responsible for stimulating HLA antibody formation in platelet transfusion recipients.[8,78–80] Thus, removing white cells from blood products (leukoreduction) is an essential means of preventing alloimmunization and subsequent platelet refractoriness. The definitive study showing this was the Trial to Reduce Alloimmunization to Platelets (TRAP study),[8] which compared alloimmunization rates in 530 newly diagnosed AML patients randomized to receive either unmodified, pooled platelet concentrates (control); filtered, pooled platelet concentrates (F-PC); filtered single-donor apheresis platelets (F-AP); or UV-B-irradiated pooled platelet concentrates (UVB-PC). Anti-HLA antibodies were detected in 45% of controls, compared with 17% to 21% of patients receiving modified platelets. 13% of control group patients became platelet-refractory, versus only 3% in the F-PC group, 4% in the F-AP group, and 5% in the UVB-PC group.

Table 147–2 Management of the Platelet-Refractory Patient

Obtain 10-minute to 1-hour posttransfusion platelet count on two occasions.
If there is an appropriate increment in platelet count after a single platelet transfusion, continue to transfuse random platelets and treat nonimmune factors associated with decreased platelet survival such as sepsis, DIC; discontinue offending drugs, etc.
If the 10-minute to 1-hour posttransfusion platelet counts demonstrate no platelet increment (or only a marginal increment) obtain patient's HLA type and also screen the patient for presence of anti-HLA antibodies (Panel Reactive Antibody test, PRA).
While awaiting HLA antigen typing and antibody screening results, consider transfusion of "fresh" (<3 days old) ABO-matched platelets.
If PRA shows less than 20% reactivity, continue with "fresh" ABO matched random platelets.
If PRA shows more than 20% reactivity, obtain anti-HLA antibody specificity. Use recipient's HLA typing information to locate grade A or B matched platelet units for transfusion. Avoid transfusion of platelets containing antigens against which the recipient has antibodies. Consider recruiting recipient's family for platelet donation.
Transfusion of crossmatch-compatible platelets is an option if there is a poor response to grade A or B matched platelets and/or if recipient has antibodies to platelet-specific antigens.
All HLA-matched or crossmatched platelet units must be irradiated prior to transfusion to prevent transfusion-associated graft-versus-host disease.

Table 147–3 Traditional Platelet Selection Guidelines for Refractoriness Due To Alloimmunization

ABO antigens are expressed on platelets. Consider transfusion of ABO-matched platelets while awaiting recipient's HLA type and antibody specificity.
Platelet matching for recipient's HLA-A and HLA-B antigens is important.
Platelet matching for recipient's HLA-C antigens is not essential.
Determine the antigen specificity of recipient's antiplatelet antibodies and try to transfuse antigen-negative platelets.
Some HLA antigens may be weakly expressed on platelets. Consider giving platelets mismatched for those antigens (eg, HLA-B12 and its splits B44,B45)
If HLA-matched platelets are unavailable, consider transfusion of platelets mismatched for HLA antigens that are serologically cross-reactive with recipient's HLA antigens.
If platelets mismatched for serologically cross-reactive antigens are not effective, matching for HLA associated antigen systems such as Bw4/Bw6 may be helpful.[94]

Management of the Platelet-Refractory Patient

When platelet refractoriness has been demonstrated, several strategies may facilitate achieving therapeutic platelet increments in vivo (Table 147–2). A trial of ABO-matched, fresh (1–2 days old) platelets may be helpful.[81,82] In cases of immune-mediated refractoriness, a trial of HLA-matched platelets,[67,83–85] antigen-negative platelets,[86] or crossmatched platelets[87–89] should be considered. The basic principles for selection of HLA-matched platelets are outlined in Table 147–3. In

Table 147–4 Grades of HLA-Matched Platelets

Match Grade	Description
A	4-antigen match (Donor and recipient match at both HLA-A and -B loci)
B1U	1 antigen unknown or blank (eg, Donor is: A2, –; B5, 27)
B1X	1 cross-reactive group*
B2UX	1 antigen blank and 1 cross-reactive*
C	1 mismatched antigen present
D	2 or more mismatched antigens present
R	Random

*The clusters of HLA antigens that share antigenic epitopes can be classified into cross-reactive antigen groups (CREG). Antibodies recognizing one HLA molecule within the group cross-react with other members of the same group.

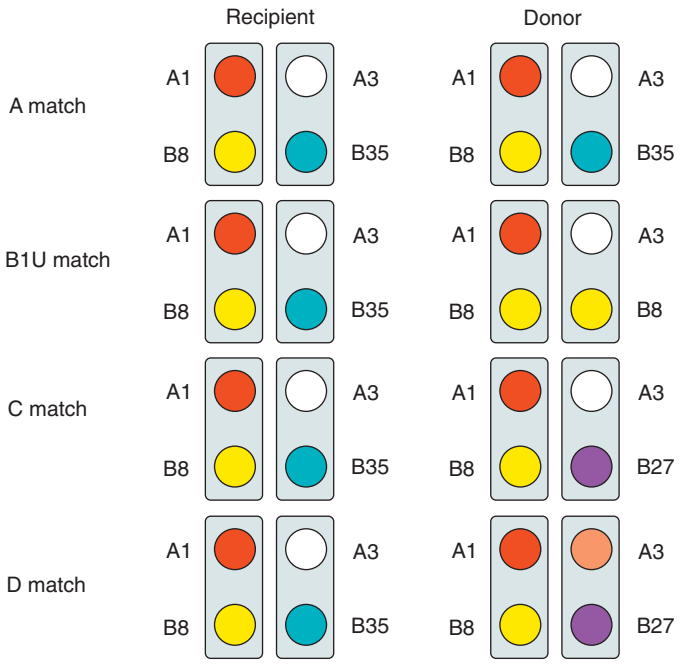

Figure 147–1 Examples of donor/recipient pairs on the basis of HLA match.

most cases, alloimmune refractory patients will show some degree of response to HLA-matched platelets.[90] Because of the high degree of polymorphism of the HLA loci, it is often not possible to find perfect HLA-A and -B locus matches, leading to the use of platelets mismatched at one or more loci (Table 147–4). In general, transfusion of grade A or BU matched platelets can result in an increase in platelet count that is superior to platelet increment obtained using either crossmatched platelets or platelets with different degrees of HLA mismatching (BX, C, or D).[83] Examples of different categories of matches are provided in Fig. 147–1. An additional step that may help in finding compatible platelets is flow cytometric detection of anti-HLA antibody specificity using single HLA antigen-coated beads.[91] This information can be used to find donors that may be HLA mismatched with the recipient but whose platelets lack the antigens to which the patient has specific antibodies.[86] Furthermore, family members may be considered as platelet donors in addition to the available pool of HLA-matched volunteer donors. As an alternative to HLA antigen matching, patients may benefit from receiving donor platelets that are crossmatch compatible with the patient's serum.[92] The major benefit of crossmatching is a potentially larger pool of donors that would have been excluded by strict HLA antigen matching. Also, platelet crossmatching may be helpful in cases of refractoriness due to antibodies directed against platelet-specific antigens.

The most challenging cases are those rare instances involving immune-refractory patients who are actively bleeding, and HLA-matched platelets or crossmatched platelets are either ineffective or unavailable. In such cases, patients are typically transfused with repeated doses of random HLA-incompatible platelets during hemorrhagic episodes. The efficacy of this practice is unclear. Data from an animal model system suggest that limited benefits might be obtained in alloimmune-refractory patients transfused with a large number of pooled random donor platelets because of a transient decrease in the alloantibody titer.[93]

CHAPTER 148

PRINCIPLES OF NEUTROPHIL (GRANULOCYTE) TRANSFUSIONS

Ronald G. Strauss

Current cytapheresis technology permits collection of large numbers of several types of blood leukocytes from healthy donors or patients—who often are stimulated with recombinant cytokines—to be used for transfusion and transplantation or for further processing (eg, ex vivo expansion and genetic manipulation) and storage. Neutrophils (PMNs) are granulocytic leukocytes that are collected and issued as a standard blood component (granulocytes, pheresis). This chapter analyzes the use of granulocyte (ie, neutrophil) transfusions (GTX) as an adjunct to antimicrobial drugs in the treatment and prevention of progressive infections in patients with neutropenia or PMN dysfunction.

Life-threatening infections with bacteria, yeast, and fungus continue to be a consequence of severe neutropenia ($<0.5 \times 10^9$/L blood PMNs) and disorders of PMN dysfunction. The most frequent situation seen today is neutropenic fever and infection with yeast or fungus after intense chemotherapy for hematologic malignancies or in conjunction with hematopoietic progenitor cell transplantation. Neutropenic infections cause considerable morbidity, occasionally are fatal, and add considerable cost to the management of these patients.

Previous attempts to prevent infections in severely neutropenic patients by transfusing PMN concentrates (ie, prophylactic GTX) achieved only questionable success. Although rates of certain infections were significantly reduced by prophylactic GTX, many adverse effects, such as pulmonary infiltrates and cytomegalovirus infections, were reported, and GTX were expensive. Similarly, use of therapeutic GTX to resolve existing infections has not gained lasting acceptance, despite many reports documenting significant benefit.[1] This lack of enthusiasm for GTX can be explained by the continuing development of new and very effective antimicrobial drugs to prevent and treat infections and by the availability of recombinant hematopoietic growth factors and peripheral blood hematopoietic progenitor cell (PBHPC) transfusions—both of which hasten patient recovery from myelotoxic therapy and shorten the period of risk for neutropenic infections. The lack of familiarity of some oncology and transplant physicians with the markedly improved modern PMN concentrates available for transfusion today may limit use of GTX.

Historically, PMN concentrates were collected for transfusion from unstimulated donors or those stimulated only with corticosteroids and contained woefully inadequate numbers of PMNs.[1] Currently, very large numbers of PMNs can be collected from normal donors using granulocyte-colony stimulating factor (G-CSF) plus corticosteroid marrow stimulation followed by large-volume leukapheresis, during which several liters of donor blood are processed.[2] In this chapter, the historic and modern experiences with GTX is reviewed and the current technology of PMN collection is discussed.

THERAPEUTIC GRANULOCYTE TRANSFUSIONS IN NEUTROPENIC PATIENTS' HISTORICAL EXPERIENCE

In the third edition of this book, 34 papers were reviewed that reported the therapeutic use of GTX—collected before the advent of G-CSF donor stimulation—in severely neutropenic patients ($<5 \times 10^9$/L blood PMNs). Data were tabulated (Table 148–1) according to the index infection that prompted GTX therapy. Patients were counted only once (eg, patients with septicemia were listed only in the septicemia group, even if they had another infection, such as pneumonia). As an exception, all patients with invasive fungal infections were counted together because it was impossible to accurately separate sepsis, pneumonia, sinusitis, and so forth into distinct categories. All patients given GTX for a designated type of infection were enumerated in the "Treated" column. The treated patients, those for whom the actual course and mortality of the index infection could be clearly documented, were enumerated again in the "Evaluable" column. GTX therapy was considered successful if so stated by the author. Combining data from multiple reports of varying experimental design is of limited value for drawing conclusions, and it was done simply to document the breadth of historic reported experience.

To obtain more definitive information regarding efficacy of historic GTX (ie, collected without G-CSF), the seven controlled studies were analyzed in more detail.[3–9] In these seven studies, the response of infected neutropenic patients to treatment with GTX plus antibiotics (study group) was compared with that of comparable patients given antibiotics alone and evaluated concurrently (control group). The design, size, and results of these seven studies are presented in Tables 148–2 and 148–3. Three of the seven studies reported a significant overall benefit for GTX.[6–8] In two additional studies,[3,5] overall success was not demonstrated for GTX, but certain subgroups of patients were found to benefit significantly. Some measure of success for GTX was evident in five of the seven controlled studies. However, this success was counterbalanced by four studies that were negative in some respect—two totally[4,9] and two partially negative.[3,5]

An explanation of these inconsistent results is evident on critical analysis of the adequacy of GTX support (see Table 148–3). Patients in the three successful trials received relatively high doses of PMNs (generally $\geq 1.7 \times 10^{10}$/day).[6–8] Donors were selected to be erythrocyte and leukocyte compatible. By contrast, the four controlled studies yielding negative results can legitimately be criticized. Two of the four studies with negative conclusions used PMNs collected by filtration leukapheresis for some patients.[3,5] It is now known that such PMNs are defective, and they are no longer transfused. In the negative studies using PMNs collected by centrifugation leukapheresis,[4,5,9] the dose was extremely low (0.41 to 0.56×10^{10} per concentrate). As another factor, investigators in two of the four negative studies[3,9] made no provision for the possibility of leukocyte alloimmunization, as donors were selected solely on the basis of erythrocyte compatibility. Finally, control subjects responded reasonably well to antibiotics alone in three of the four negative studies,[3,5,9] suggesting that some patients fared so well with conventional treatment that they had no apparent need for additional therapeutic modalities.

These impressions from the seven controlled GTX trials have been analyzed by formal meta-analysis,[10] and conclusions were that the dose of PMNs transfused and the survival rate of the nontransfused control subjects were primarily responsible for the differing success rates of the historical studies. In clinical settings in which the survival rate of nontransfused control subjects was low, study subjects benefitted from receiving adequate doses of GTX—prompting the authors to suggest that severely neutropenic patients with life-threatening infections be considered for GTX given in adequate doses.[10]

MODERN EXPERIENCE

Fungal and yeast infections occur frequently in patients with severe neutropenia or PMN dysfunction, and these infections pose a major challenge to the efficacy of modern therapeutic GTX. Recipients of hematopoietic progenitor cell transplants—particularly marrow transplant patients—often become severely neutropenic, exhibit PMN dysfunction, and manifest defective cellular and humoral immunity for months after transplantation. Altered immunity is particularly profound when marrow is T-lymphocyte depleted to diminish graft-versus-host disease. Hence, all types of infection pose a threat, with fungal and yeast infections being major problems.[11,12] In a series of 1186 marrow transplant patients, 10% developed a noncandidal fungal infection, with only 17% of infected patients surviving.[11] When the marrow graft is depleted of T lymphocytes, the rate of infection is increased two- to sevenfold above that occurring with standard bone marrow transplantation.[12]

Table 148–1 Infectious Problems in Neutropenic Patients Treated With Historic Granulocyte Transfusions in 34 Studies

Type of Infection	Treated	Evaluable	Success Rate (%)
Bacterial septicemia	298	206	127/206 (62)
Sepsis organism unspecified	132	39	18/39 (46)

Data are insufficient to determine the proper role of GTX in treating fungal infections. Historic case reports,[13–15] experimental studies in animals,[16,17] and experience in treating patients with chronic granulomatous disease[18] have supported the efficacy of GTX in fungal infections. In contrast, a large clinical study reported that GTX, collected in the pre G-CSF era, were of no benefit in treating fungal and yeast infections in 87 bone marrow transplant patients, 50 of whom received GTX.[19] Unfortunately, this study was a retrospective review with several shortcomings and must be interpreted cautiously.

At this time, no randomized clinical trials of therapeutic GTX collected after G-CSF donor stimulation have been reported to establish the efficacy or potential toxicity of modern GTX. However, 10 case reports and uncontrolled studies will be reviewed.[13,20–28] Clark and colleagues[13] and Catalano and coworkers[21] each reported single patients (Table 148–4) with aplastic anemia undergoing progenitor cell transplantation with fungus infections that responded favorably to strikingly different doses of PMNs. Similarly, Ozsahin and associates[22] and Bielorai and colleagues[23] each reported single patients (see Table 148–4) with chronic granulomatous disease and fungal infections that responded favorably to GTX during the transplantation period. Bielorai and coworkers[24] reported a single patient (see Table 148–4) with acute leukemia and sepsis with progressive, antibiotic-resistant bacteria whose infection cleared slowly with GTX. It is impossible, in these single reports of very complicated patients, to firmly ascribe the good outcome to the GTX.

Hester and colleagues[20] transfused 15 patients with hematologic malignancies and infections (Table 148–5). PMNs were collected from donors stimulated only with G-CSF and selected without regard for leukocyte compatibility. Although GTX were successful in most patients, it was not possible to distinguish responses of fungus versus yeast infections. Lee and associates[28] transfused 25 patients with hematologic malignancies (see Table 148–5), many of whom were infected with multiple organisms. PMNs were colleted from donors stimulated with G-CSF alone (66% of donors), G-CSF plus dexamethasone (25% of donors), or dexamethasone alone (8% of donors). Of patients with sepsis, 50% (2 of 4) responded favorably, and 38% (8 of 21) of patients with progressive localized infections responded favorably.

Grigg and associates[25] transfused 11 patients (see Table 148–5). Eight patients had hematologic malignancies and progressive infections—five of the eight undergoing progenitor cell transplantation and three receiving chemotherapy. Three additional patients who were undergoing progenitor cell transplantation had stable fungus infections. PMNs were collected from donors stimulated only with G-CSF and selected without regard for leukocyte compatibility. Success was excellent for bacterial and stable fungus infections,

Lee et al[28]	5.1–10.6	G-CSF 5 μg/kg -and/or- Dexamethasone 3 mg/m^2	Pentastarch 6–10 L processed	40% (10 of 25) Success with multiple-organism infections

G-CSF, granulocyte-colony stimulating factor; GTX, granulocyte transfusions.
*Assumptions made as PMN dose expressed ×10^{10} unclear in these reports. PMN dose calculated using values for range of leukocytes collected, percentage of collected cells being myeloid and volume of units collected (Grigg et al). Dose calculated that would be given to a 70-kg recipient for Peters et al.

but was quite poor for progressive fungus infections with organ dysfunction—a troubling pattern reported by others.[27]

Peters and colleagues[26] transfused 30 patients (see Table 148–5) with hematologic disorders—18 undergoing progenitor cell transplantation. PMNs were collected from donors stimulated with G-CSF or prednisolone and selected without regard for leukocyte compatibility. The exact PMN dose transfused is uncertain because values from 0.9 × 10^{10} to 14.4 × 10^{10} can be calculated from data reported, and it was impossible to distinguish the success of GTX from G-CSF versus prednisolone-stimulated donors. However, the outcome of bacterial infections appeared to be superior to that of fungus infections.

Price and coworkers[27] transfused 19 patients (see Table 148–5) with hematologic malignancies, 16 of whom had received progenitor cell transplants and 3 who were pretransplantation recipients. PMNs were collected from donors stimulated with G-CSF and dexamethasone. Although donors were selected without regard for leukocyte compatibility, recipients were documented not to exhibit evidence of leukocyte alloimmunization at study entry. Bacterial infections responded well and yeast infections responded modestly. Despite very high PMN doses, success for invasive fungus infections was dismal.

No firm conclusions can be drawn from these somewhat anecdotal reports of modern therapeutic GTX for several reasons: (a) no concurrent control subjects were included (ie, randomly assigned to receive no GTX or GTX from donors stimulated only with corticosteroids); (b) the number of patients reported was quite small; and (c) PMN collection methods were variable, with a broad range of PMN doses transfused. On the basis of these preliminary findings, bacterial infections appeared to respond well to modern GTX, relatively mild fungus and yeast infections responded modestly well, whereas serious fungus infections with tissue damage resisted even the large doses of PMNs transfused with modern GTX.[25–27] The precise role of modern therapeutic GTX, collected from donors stimulated with G-CSF plus corticosteroids, in the management of infected, neutropenic, oncology/transplant patients awaits definition by randomized clinical trials.

EXPERIENCE IN INFANTS AND CHILDREN

Most patients with congenital disorders of PMN dysfunction have adequate numbers of blood PMNs, but they are susceptible to serious infections because their PMNs fail to kill pathogenic microorgan-

isms. Patients with severe forms of PMN dysfunction are relatively rare, and no randomized clinical trials have been reported to establish the efficacy of therapeutic GTX in their management. Firm recommendations about the use of GTX to treat patients cannot be made. However, several patients with chronic granulomatous disease, complicated by progressive life-threatening fungal infections, have been reported to benefit.[29–37] Because of the possibility of alloimmunization to leukocyte and red blood cell antigens plus the risk of transfusion-transmitted infections, therapeutic GTX are recommended only for progressive infections that cannot be controlled with antimicrobial drugs. Because of lifetime problems with infections, prophylactic GTX are impractical.

Neonates (infants within the first month of life) are another group of patients who may suffer life-threatening bacterial infections caused, at least in part, by PMN dysfunction and neutropenia. Neutropenia must be viewed differently in neonates than in older patients, as in the latter, GTX are considered usually when the blood PMN count falls to less than 0.5×10^9/L. By contrast, because normal neonates exhibit a physiologic neutrophilia, absolute blood PMN counts as high as 3.0×10^9/L (ie, relative neutropenia) might prompt consideration of GTX in neonates.[38] The mechanism of neutropenia cannot always be identified, but in some infants, a marked decrease in the marrow PMN storage pool can be demonstrated. For example, these forms (metamyelocytes and segmented PMNs) account for 26% to 65% of all nucleated cells in normal marrow, but in some neonates with sepsis, this value will be less than 10% of nucleated marrow cells.

Six controlled trials[39–44] have assessed the role of GTX in treating neonatal infections. Although four of the six[39–42] found a significant benefit for GTX, the controlled studies, when assessed by meta-analysis, were insufficiently homogeneous to permit clear recommendations regarding the efficacy of GTX.[10] The dose of PMNs transfused was identified as the primary reason for disagreements between studies. When leukapheresis PMN concentrates were transfused, GTX were beneficial. When buffy coats were transfused, GTX were not beneficial.[10] The role of therapeutic GTX for neonatal infections is unclear at present and, because they are transfused only rarely at this time, they will not be discussed further. However, the possible roles of immunoglobulin and cytokine therapies for neonatal sepsis will be discussed later.

PROPHYLACTIC GRANULOCYTE TRANSFUSIONS IN NEUTROPENIC PATIENTS

Based on historic reports, prophylactic GTX were of marginal value. In 12 reports,[45–56] benefits were few, whereas risks and expenses were substantial. However, some measure of success was found in 7[45–51] of 12 studies; the remaining 5 studies failed to show a benefit for prophylactic GTX.[52–56] In none of these five negative studies were large numbers of PMNs obtained from matched donors and transfused daily. In a situation analogous to that for the negative therapeutic GTX trials, the failure of prophylactic GTX might be explained, at least in part, by inadequate transfusions.

The role of modern prophylactic GTX (ie, from G-CSF stimulated donors) has not been established by definitive clinical trials. However, two factors suggest possible success (a) because of the rapid recovery from myeloablation, hastened by peripheral blood hematopoietic progenitor (PBHPC) transfusions and treatment of patients with recombinant growth factors, the period of severe neutropenia may be as short as 1 week; and (b) this relatively brief period of severe neutropenia might literally be eliminated by transfusing large doses of PMNs collected from donors stimulated with G-CSF plus corticosteroids. A few studies have begun to explore this possibility (Table 148–6).

Bensinger and colleagues[57] transfused seven allogeneic marrow recipients with PMNs collected from their HLA-identical or syngeneic marrow donors after G-CSF stimulation. Because donors experienced leukapheresis on consecutive days, collection techniques were quite variable in terms of quantities of hydroxyethyl starch infused and liters of donor blood processed, and the number of PMNs collected varied from 0.3 to 14.4×10.[10] Recipients received an average of 7.6 GTX while awaiting marrow recovery, and recipients were given 5 μg/kg G-CSF daily to maintain a mean blood PMN count of 0.95×10^9/L measured 24 hours posttransfusion. The goals of this study were to evaluate the feasibility and safety of collecting and transfusing PMNs from G-CSF stimulated donors; patient outcomes were not reported.

Adkins and associates[58] transfused 10 allogeneic marrow recipients with PMNs collected from their HLA-matched sibling marrow donors (see Table 148–6). Leukapheresis was performed on days 1,

Author's Approach to Therapeutic GTX

Indicated for severe bacterial, yeast, or fungal infection in a neutropenic patient ($<0.5 \times 10^9$ neutrophils (PMN)/μL blood) when the infection progresses despite optimal antimicrobial therapy.

Collect PMNs (4 to 8×10^{10}) from allogeneic blood donors, as follows:

1. Stimulate neutrophilia by giving the donor 300 to 480 μg of G-CSF subcutaneously 12 hours before beginning leukapheresis, with or without 8 mg dexamethasone orally 12 hours before beginning leukapheresis.
2. Process 10 L of donor blood using a continuous-flow blood separator with citrated hydroxyethyl starch solution infused throughout the collection.

Transfuse one granulocyte concentrate (4 to 8×10^{10} PMNs) daily until bone marrow recovery (blood PMNs $> 1.0 \times 10^9$/L without GTX) or clinical resolution of infection.

Table 148–6 Modern Prophylactic Granulocyte Transfusion Studies Using PMNs Collected From Granulocyte-Colony Stimulating Factor–Stimulated Donors in Hematopoietic Progenitor Cell Transplant Recipients

Investigator	PMNs $\times 10^{10}$ Per Each GTX	Stimulation	Leukapheresis	Outcomes
Bensinger et al[57]	4.2	G-CSF 3.5–6 μg/kg	Variable	Not reported
Adkins et al[58]	4.1 (day 1) 5.1 (day 3) 6.1 (day 5)	G-CSF 5 μg/kg × 5 days posttransplant	Hetastarch 7 L processed Days 1, 3, and 5	60% (6 of 10) afebrile 40% (4 of 10) febrile 3 culture positive
Adkins et al[59]	5.6 (day 2) 7.0 (day 4) 8.5 (day 6) 9.9 (day 8)	G-CSF 10 μg/kg	Hetastarch 7 L processed Days 2, 4, 6, and 8	Reduction of fever and antibiotics if no leukocyte antibodies

G-CSF, granulocyte-colony stimulating factor; GTX, granulocyte transfusions.

3, and 5 posttransplant, and GTX were infused. Recipients were given 7.5 μg/kg G-CSF every 12 hours until blood PMNs were greater than or equal to 1.5×10^9/L. Recipient blood PMNs were maintained at greater than 1.5×10^9/L throughout the 5 days of posttransplant GTX. By comparison, a historic group of control recipients treated with G-CSF, but no GTX, exhibited mean blood PMN counts less than 0.5×10^9/L posttransplant. Prophylactic GTX seemed promising in this setting and, perhaps, would have been even more effective (ie, higher recipient blood PMN counts and fewer infections) if given daily. In another study, Adkins and coworkers[59] transfused 23 autologous PBHPC recipients with PMNs collected from first-degree relative donors (see Table 148–6). Leukapheresis was performed on posttransplant days 2, 4, 6, and 8, and GTX were infused. Recipients were given 5 μg/kg G-CSF daily until the blood PMN count was greater than or equal to 1.5×10^9/L. Recipients were studied for the effects of lymphocytotoxic antibodies (ie, leukocyte alloimmunization) on GTX effectiveness. The 15 recipients who did not exhibit lymphocytotoxic antibodies during the 10-day study period experienced a mean of 4.1 febrile days and required 7.3 days of antibiotics. Values for the eight recipients with lymphocytotoxic antibodies were less desirable—6.3 febrile days and 10.5 days of antibiotics. Rates of documented infections were not reported.

No firm conclusions can be drawn from these reports of modern prophylactic GTX because no nontransfused control subjects were included; few patients were studied; and most patients were given GTX every other day, rather than daily—possibly providing a less than optimal dose of PMNs. Modern prophylactic GTX appear promising, but their efficacy, potential adverse effects, and economic analysis await definition by randomized clinical trials.

ALTERNATIVE OR ADDITIVE MEASURES TO GRANULOCYTE TRANSFUSIONS

Patients with severe neutropenia, particularly those undergoing chemotherapy or hematopoietic progenitor cell transplantation, exhibit a variety of abnormalities in multiple body defense mechanisms, not all of which can be corrected by GTX. Consequently, infections that occur in these patients do not always respond to GTX, and a number of additional therapies have been evaluated. Two that appear to hold promise are the use of recombinant myeloid growth factors (ie, cytokines) and intravenous immunoglobulin (IVIG).

Recombinant myeloid growth factors such as G-CSF and granulocyte–macrophage colony-stimulating factor (GM-CSF) are glycoprotein cytokines that enhance the production, differentiation, and function of myeloid cells.[60] As recently reviewed,[61] studies of cytokine production in neonates have yielded conflicting results, with investigators reporting values that are higher than, equal to, or lower than adult values. Generally, the dysregulation of expression and production of hematopoietic cytokines in neonates contributes to quantitative and qualitative myeloid abnormalities that lead to decreased availability and function of blood PMNs.[61] Several trials of G-CSF and GM-CSF, used to prevent and to treat neonatal sepsis, have been reported.[61] Although most studies have shown some benefit, such as improved production and function of PMNs, reduction in the incidence of infections and/or mortality has not been convincingly shown.[61]

In older children and adult patients, G-CSF and GM-CSF have been used to accelerate marrow recovery after chemotherapy and to successfully diminish the rate of acquired infections and the need for prolonged hospitalization.[60] In contrast to success in preventing neutropenic infections, the role of G-CSF and GM-CSF in treating already established infections is not as firmly documented. Regardless of solid evidence, these growth factors frequently are given to patients with neutropenia and severe infections, and it seems reasonable to consider adding therapeutic GTX when severe bacterial, yeast, or fungal infections are progressing in neutropenic patients, despite the use of appropriate antibiotics plus recombinant cytokines.

Collection and Transfusion of Neutrophil Concentrates

To ensure adequate numbers and quality of PMNs for transfusion, PMNs must be collected from stimulated donors by automated leukapheresis using an erythrocyte sedimenting agent, such as hydroxyethyl starch.[2] A major limitation of GTX efficacy has been the inability to transfuse adequate numbers of perfectly functioning PMNs. Under the stress of a severe bacterial infection, the marrow of an otherwise healthy adult will produce between 10^{11} and 10^{12} PMNs in 24 hours. Granulocyte concentrates collected from healthy donors who are not stimulated with corticosteroids or G-CSF will contain between 0.2 and 0.8×10^{10} PMNs—approximately 1% of a healthy marrow's output. Hence, donor stimulation is mandatory to achieve even a hope of a reasonable PMN dose per GTX.

Donor stimulation with properly timed corticosteroids (≥24 hours before leukapheresis) will increase the yield to approximately 2×10^{10} PMNs.[67] Stimulation with G-CSF, alone or in combination with corticosteroids, will produce higher but variable PMN yields; yields with prophylactic GTX were of marginal value Yields of 4 to 8×10^{10} PMNs are achieved regularly, and posttransfusion blood PMN counts frequently increase to 1 to 3×10^9/L, with PMNs detected in the recipient's bloodstream for several hours after GTX. Currently, PMN donors are optimally stimulated using 300 to 480 μg G-CSF given subcutaneously, plus 8 mg dexamethasone taken orally approximately 12 hours before beginning leukapheresis.[68] A recent report suggested that adrenal corticosteroids might cause posterior subcapsular cataracts in PMN donors.[69] Although this report must be confirmed by study of larger numbers of PMN donors, it seems logical to include this cautionary information in donor consent forms or to stimulate PMN donors using only G-CSF until the issue is resolved.

Each institution must assess local needs. If, despite optimal antimicrobial and other supportive therapy, neutropenic patients suffer significant morbidity or mortality from infections, GTX should be considered. Once therapeutic transfusions have been prescribed, they must be given effectively (≥2×10^{10} PMNs per dose with corticosteroid stimulation, ≥4×10^{10} PMNs per dose with G-CSF, and never <1×10^{10} PMNs per dose). Transfusions are continued until the infection has resolved or until blood PMNs have risen above 1.0×10^9/L. It seems logical that patients with evidence of alloimmunization (platelet refractoriness, leukocyte antibodies, repeated febrile transfusion reactions, or posttransfusion pulmonary infiltrates) should receive GTX collected from donors selected to be leukocyte compatible by HLA matching and/or leukocyte crossmatching. However, it has not been clearly shown that attempts to improve leukocyte antigen compatibility do, in fact, increase the success of GTX in alloimmunized patients—particularly when modern GTX from G-CSF-stimulated donors are transfused. Granulocyte concentrates should be transfused as soon as possible after collection because PMN functions begin to deteriorate rapidly. Some delay between collection and transfusion is inevitable, and granulocyte concentrates are usually stored briefly at 22°C, with little or no agitation. It is highly desirable to transfuse granulocyte concentrates within 6 hours of collection; they should not be given if more than 24 hours old.

The use of IVIG, to prevent or to treat neonatal sepsis, has appeal because this therapy may correct abnormalities of humoral immunity and neutrophil function. In studies of experimental infections, IVIG proved beneficial by increasing opsonic activity and by improving PMN kinetics.[62,63] Although the precise role of IVIG in the management of human infants is controversial, this therapy has been given (with mixed results) to prevent and to treat infections. Most prophylactic studies evaluating IVIG to prevent infections have documented few positive effects, but a few have reported true benefit.[64,65] In

contrast, several therapeutic studies reported benefit from adding IVIG to antibiotics during the treatment of neonatal infections.[66] However, the data remain insufficient to justify the routine use of IVIG as standard therapy to prevent and/or treat infections in preterm infants.

CHAPTER 149

TRANSFUSION OF PLASMA DERIVATIVES: FRESH-FROZEN PLASMA, CRYOPRECIPITATE, ALBUMIN, AND IMMUNOGLOBULINS

Cassandra D. Josephson and Christopher D. Hillyer

Plasma and its derivatives are valuable resources, but cost, risk of infectious disease transmission, although rare, and other adverse effects mandate their appropriate use. Plasma can be separated from packed red blood cells (pRBC) through centrifugation of whole blood at the time of collection or can be collected by apheresis as a single product or as a byproduct of platelet or red blood cell apheresis. Plasma can be processed into derivatives through cold ethanol fractionation (method of Cohn).[1] In this chapter, the features and uses of fresh-frozen plasma (FFP), F24 plasma (F24), cryoprecipitate, albumin, and intravenous (IVIG) and intramuscular immunoglobulin are discussed. The use of plasma-derived clotting factor concentrates as therapy for specific congenital clotting factor deficiencies is discussed in Chapter 150.

FROZEN PLASMA

Plasma is the acellular, fluid compartment of blood and it consists of 90% water, 7% protein and colloids, and 2% to 3% nutrients, crystalloids, hormones, and vitamins. The protein fraction contains the soluble clotting factors: fibrinogen, factor XIII, von Willebrand Factor (vWF), factor VIII primarily bound to its carrier protein vWF, and the vitamin K-dependent coagulation factors II, VII, IX, and X. Clotting proteins are the constituents for which transfusion of plasma is most often required.

Plasma frozen at −18°C or colder within 6 hours of donation can be labeled as FFP. This product may be stored up to 1 year before use, at which time it is thawed over 20 to 30 minutes. The activities of the labile coagulation factors (V and VIII) decrease after thawing, but remain adequate for at least 24 hours. A second type of frozen plasma, the most commonly used in the United States, is F24 plasma. To be labeled as F24 plasma, it must be frozen at −18°C or colder within 24 hours of collection. FFP and F24 are considered to be equivalent products for most patient populations. The difference between the historic data on FFP compared to F24 is a reduction in the following factors: fibrinogen 12%, FV 15%, FVIII 23%, and FXI 7%.[2] However, because factor VIII is an acute phase reactant, its levels are quickly replenished in recipients without hemophilia A. Therefore, FFP and F24 use may be interchangeable for patients without factor VIII deficiency.[3] A third type of frozen plasma is termed *cryosupernatant* or *cryoreduced-plasma* (CRP). The Food and Drug Administration (FDA) has recently licensed this component as "Plasma, Cryoprecipitate Reduced"—notice that it is devoid of its cryoprecipitate fraction, formed when FFP is thawed at 4°C.[19] The cryosupernatant component is then refrozen at −18°C or colder. A fourth frozen product, solvent detergent-treated plasma, is no longer commercially available because of the manufacturer's loss of licensure in April 2002. Plasma that is not immediately frozen as FFP or F24 becomes "liquid plasma" (stored at 1 to 6°C) or "source plasma" (stored at −18°C or colder). These products are used for the preparation of plasma derivatives: albumin, clotting factor concentrates, and immunoglobulin preparations.

INDICATIONS

The indications for the use of FFP and F24, the clinical conditions for which FFP and F24 administration is not indicated, and investigational uses are listed in Table 149–1. Audits of transfusion practices have consistently demonstrated that frozen plasma use is inappropriately high.[4,5] Specifically, FFP and F24 should not be used (a) to reconstitute "whole blood" by coadministration with red blood cells (RBCs); (b) as a simple volume expander; or (c) as a source of nutrients. Appropriate uses are described in detail in the following sections.

Liver Disease and Transplantations

Patients with severe liver disease may have low levels of the vitamin K-dependent clotting factors (II, VII, IX, and X) (see Chapter 124). These patients develop a prolonged prothrombin time (PT) and partial thromboplastin time (PTT). In addition, the thrombin time (TT) may be prolonged, fibrin split products may be elevated, and in later stages the fibrinogen level may decrease. Hemorrhage, most often secondary to an anatomic lesion, may be complicated by the coagulopathy resulting from these abnormalities.

Infusions of FFP and F24 are indicated during bleeding if the coagulation test results are abnormal. In the absence of anatomic lesions, bleeding does not usually occur until the PT is greater than 16 to 18 seconds or the PTT is greater than 55 to 60 seconds. Frozen plasma products are not recommended prophylactically before a surgical challenge or liver biopsy unless these values are exceeded.[6] In fact, the PT and PTT are poor predictors of surgical bleeding, and mild abnormalities in these coagulation tests may be impossible to correct—even with infusion of large quantities of plasma.[7,8] Orthotopic liver transplantation complicated by preexisting severe liver disease, lack of clotting factor synthesis during the anhepatic stage, massive pRBC transfusion, and disseminated intravascular coagulation (DIC) may require large volumes of FFP.[9] Transfusion should be guided by clinical assessment of bleeding, coagulation test results, and thromboelastographic changes.[10,11]

Massive Transfusion

The administration of FFP and F24 to patients receiving large quantities of pRBC (>1 blood volume in 24 hours in an adult) is often recommended because of a dilutional coagulopathy arising from blood replacement with pRBC and crystalloid solutions, both of which lack coagulation factors. Dilutional thrombocytopenia, another potential result of massive transfusion, may complicate the coagulopathy in these patients.[12]

In general, FFP and F24 transfusions are of little value in nonbleeding patients who have received less than 6 to 10 units of pRBC. In some patients, however, shock associated with DIC and dilutional

Table 149–1 Administration of Fresh-Frozen Plasma and F24 Plasma

Indicated
Multiple acquired coagulation factor deficiency[9–19]
Liver disease
Massive transfusion
Disseminated intravascular coagulation
Rapid reversal of warfarin effect
Plasma infusion or exchange for thrombotic thrombocytic purpura, hemolytic uremic syndrome, syndrome of hemolysis, elevated liver enzymes, and low platelets or Refsum's disease[20–23]
Congenital coagulation defects (see Chapter 126)[a]
C1-esterase inhibitor deficiency[a]—acute episodes and prophylaxis of angioedema
Investigational
Meningococcal sepsis[104]
Acute renal failure in the context of multiorgan failure[105]
Not Indicated
Immunodeficiency
Burns
Wound healing
Reconstitution of packed red blood cells
Volume expansion
Source of nutrients

[a]Fresh-frozen plasma is used in the absence of specific factor concentrate.

coagulopathy may occur, necessitating use of frozen plasma products.[11] Although several studies have demonstrated the ineffectiveness of routine FFP infusions in patients receiving more than 10 units of pRBC within 24 hours, many physicians still choose to transfuse FFP in the face of continued bleeding. Ketchem et al has shown that early use of plasma and platelets in trauma patients undergoing massive transfusion appears to decrease the incidence of coagulopathy in those patients.[13] However, it is far more effective to use FFP to replace depleted clotting factors reflected by abnormal laboratory tests than to use predetermined formulations (eg, 1 unit of FFP for every 5 units of pRBC transfused).[14]

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation may be secondary to sepsis, liver disease, hypotension, surgery-associated hypoperfusion, trauma, obstetric complications, leukemia (usually promyelocytic), or underlying malignancy (see Chapter 131). Successful treatment of the underlying cause is paramount. Patients with DIC and bleeding should be given frozen plasma products in amounts sufficient to correct or ameliorate the hemorrhagic diathesis. However, in patients with severe liver disease, bleeding, and DIC, FFP infusions often fail to normalize the PT and PTT.[15]

Rapid Reversal of Warfarin Effect

Warfarin inhibits the hepatic synthesis of vitamin K-dependent clotting factors (II, VII, IX, and X) by blocking the recovery of the form of vitamin K that is active in the carboxylation of these proteins (see Chapter 129). Warfarin therapy induces functional deficiencies of these factors, which correct within 48 hours after the discontinuation of warfarin if diet and vitamin K absorption are normal. Vitamin K administration corrects the coagulopathy in 12 to 18 hours.[16] In patients anticoagulated with warfarin who have active bleeding, require emergency surgery, or have serious trauma, the deficient clotting factors can be immediately provided by prothrombin complex concentrates (PCC), or frozen plasma product transfusion. PCC should be chosen as first-line therapy, especially if volume overload is a concern. FFP is recommended as standard of care if PCCs are unavailable.[17,18] To replenish the vitamin K-dependent coagulation factors such that adequate hemostasis (normalized PT) is established, a large volume of frozen plasma may be required. Markris et al has demonstrated that FFP contains insufficient amounts of vitamin K-dependent factors to reverse the effects of warfarin completely.[18] In patients without bleeding but with significantly prolonged PTs, the potential danger of significant hemorrhage is often overemphasized and must be weighed against the risks of plasma infusion when PCCs are not available.[19] In addition, some case reports appear to support the "off label" use of recombinant FVIIa for warfarin reversal in the context of head trauma; controlled trials have not been executed as yet.[156]

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

In patients with thrombotic thrombocytopenic purpura (TTP), FFP/F24 as simple transfusion or in plasma exchange is the treatment of choice because plasma contains the needed vWF-cleaving protease. Plasmapheresis is preferred in most patients, including those at risk for fluid overload, such as those with renal or cardiac impairment (see Chapter 138). Plasmapheresis is most effective in those patients who have an autoantibody, acquired TTP. This is due to the removal of a patient's plasma containing the inhibitor coupled with the addition of donor plasma containing the functional vWF-cleaving protease.[20,21] The FDA has approved the use of CRP for refractory TTP, defined as those who are unresponsive to standard therapy with FFP. Some authorities advocate the use of CRP as a first-line therapy for TTP, an off-label use of the component. However, in 2001 The North American TTP Group published a multicenter prospective randomized trial comparing exchange transfusion with FFP to CRP for the initial treatment of TTP. They demonstrated that survival was the same in both study groups and established equal efficacy between FFP and CRP for the initial therapy in TTP.[22,23]

Standard therapy involves daily plasmapheresis with FFP/F24 or CRP replacing 1.0 to 1.5 plasma volumes. Treatment should be initiated immediately or at least within 24 hours of diagnosis.[24] The total number of treatments is based on the patients' clinical response, but the average number of exchanges to achieve remission are approximately.[25]

DOSAGE

One unit of FFP or F24 derived from a unit of whole blood contains 200 to 280 mL. When plasma is collected by apheresis, as much as 800 mL can be obtained from one individual (jumbo plasma units). On average, there is 0.7 to 1 unit/mL of activity of each coagulation factor per milliliter of FFP and 1 to 2 mg/mL of fibrinogen. The appropriate dose of FFP may be estimated from the plasma volume, the desired increment of factor activity, and the expected half-life of the factor being replaced. Alternatively, the plasma dosage may be estimated as 8 to 10 mL/kg, and ideally should be ordered as the number of milliliters to be infused.[26] In critically ill patients higher doses of FFP should be considered, 30 mL/kg.[27] The frequency of administration depends on the clinical response to the infusion and the normalization of laboratory parameters.

COMPATIBILITY AND SIDE EFFECTS

Frozen plasma is screened for unexpected RBC antibodies at the time of collection and should be ABO-type compatible for transfusion. Tests for serologic compatibility, major and/or minor crossmatching, are not performed before administration. Alloimmunization to RBC antigens may occur with FFP transfusion, but this is rare.[28]

A Case of Transfusion-Related Acute Lung Injury

A 30-year-old woman with precursor B-cell ALL in DIC presents with respiratory distress, severe hypoxemia, hypotension, and fever 2 hours after receiving 2 units of FFP. The patient's hypotension does not respond well to intravenous fluids. On physical exam she has rales and decreased breath sounds. No murmur is auscultated and no jugular venous distention is observed. Her chest x-ray reveals bilateral pulmonary infiltrates.

Transfusion-related acute lung injury (TRALI) is a clinical diagnosis. The exact pathophysiology of TRALI has not been clearly established. Clinicians should be keenly aware of the transfusion reaction and especially how it relates to plasma product administration. Reporting these types of cases to the medical director of the blood bank at the institution is imperative to help with the understanding of this type of transfusion reaction and prevention of the reaction in the patient or other patients in the future. Please see the transfusion reaction chapter for more details about TRALI.

Table 149–2 Administration of Cryoprecipitate

Indicated
Fibrinogen deficiency
Massive transfusion[35]
Reversal of thrombolytic therapy[154,155]
Congenital afibrinogenemia
Dysfibrinogenemia[34]
Factor XIII deficiency[a]
Fibrin glue[41–44]
Renal stone removal[106]
Possibly Indicated
Some patients with hemophilia A or von Willebrand disease[39]
Uremic bleeding
Investigational
Wound healing (as a source of fibronectin)[107]
Premature rupture of membranes[45]
Not Indicated
Sepsis (postoperative)

[a]Cryoprecipitate is used in the absence of specific factor concentrate. This product is not FDA-approved in the United States.

Fever, chills, and allergic reactions may occur and are treated symptomatically. Occasionally, severe allergic reactions with symptoms of bronchoconstriction or noncardiogenic pulmonary edema are seen. Some of these cases are thought to be due to HLA antibodies present in donor plasma that react with recipient leukocytes. The phenomenon has been termed transfusion-related acute lung injury (TRALI). TRALI is now reportedly the leading cause of mortality related to transfusion, and may be underdiagnosed because it can occur in the context of extremely ill patients.[29,30]

Anaphylactic reactions may occur after infusion of plasma (containing IgA) into patients with complete IgA deficiency and antibodies to IgA.[31] For such patients, it is possible to obtain IgA-deficient plasma from donors in the national registry.

Transmission of infectious disease by frozen plasma products has been significantly reduced, but the risk is not yet completely eliminated. Frozen plasma is not thought to transmit the cell-associated cytomegalovirus.[32]

CRYOPRECIPITATE

Cryoprecipitate is prepared from 1 unit of FFP thawed at 4°C. The precipitate is then refrozen in 10 to 15 mL of plasma and stored at −18°C or colder for 1 year. Cryoprecipitate contains 80 to 100 units of factor VIII, 100 to 250 mg of fibrinogen, and 50 to 60 mg of fibronectin. Initially the plasma also contains 40% to 70% of vWF. Anti-A and anti-B antibodies may also be present, but in small amounts.

For clinical purposes, cryoprecipitate should be considered the blood product most rich in factor VIII, vWF, XIII, fibrinogen, and fibronectin—the plasma proteins with the highest molecular weights. Cryoprecipitate is used predominately to treat bleeding associated with fibrinogen and factor XIII deficiency states.[33] It is rarely used to treat vWF and factor VIII deficiencies. Congenital deficiencies of these factors and their treatments are discussed in Chapters 122, 124, 126, 117, 128, 32, and 150.

Indications

The indicated, investigational, and nonindicated clinical conditions for administration of cryoprecipitate are listed in Table 149–2. Specific indications and inappropriate uses are discussed subsequently.

Fibrinogen Deficiency

Fibrinogen deficiency is the primary indication for cryoprecipitate transfusion. The deficiency may present in the form of congenital afibrinogenemia (rare) or dysfibrinogenemia, severe liver disease, DIC, or during massive transfusion.[34–38] These patients often have concomitant decreases in clotting factor levels and require the coadministration of frozen plasma products. It is important to obtain fibrinogen measurements because levels less than 100 mg/dL cause prolongation of the PT and PTT, despite adequate clotting factor replacement. Very low levels of fibrinogen occur during liver transplantation, where transfusion support with cryoprecipitate is vital.[9,19]

Von Willebrand Disease

Von Willebrand factor (vWf), required for platelet binding to damaged vascular endothelium, is low, absent, or dysfunctional in von Willebrand disease (vWD). DDAVP (desmopressin acetate [1-deamino, 8-D-arginine], vasopressin) remains the treatment of choice in type I vWD. However, in DDAVP nonresponders who have type I vWD or in those individuals not eligible for DDAVP with types II and III vWD, therapy with plasma-derived vWF-containing concentrates is the treatment of choice. As a last resort, if vWF-containing concentrates are unavailable and severe bleeding is occurring, cryoprecipitate may be administered. However, recent advances in clotting factor concentrates and viral inactivation methods may make the use of "wet" cryoprecipitate to treat vWD obsolete.[39,40]

Fibrin Glue and Sealants

Fibrin glue results from the mixture of a fibrinogen source (from FFP, platelet-rich plasma, or heterologous [90%] or, more recently, autologous cryoprecipitate) with bovine thrombin. The enhanced local hemostasis achieved by fibrin glue is through the action of thrombin on fibrinogen. As adjunct therapy, this product has been used successfully in cardiac surgery to control multiple small blood leaks as a result of adhesions, and to reduce blood loss and the factor concentrate requirement in patients with von Willebrand disease undergoing various surgical procedures.[41] Autologous and heterologous fibrin clot preparations have been used in meniscal tear repair,[42] in establishing

patency of anastomosis in vasovasostomy,[43] in the treatment of postoperative neonatal chylothorax, and midtrimester premature rupture of membranes.[44,45] The infectious risks (eg, human immunodeficiency virus [HIV] and hepatitis) associated with the use of heterologous fibrin glue are eliminated by replacement with the autologous source. Production of fibrin glue is a non-FDA-approved preparation, but it has been widely used in Europe for more than 20 years. There are recently FDA-approved alternatives to fibrin glue termed *fibrin sealants*. They may have some advantages—such as standardization of production—over locally made fibrin glue, but are much more expensive.[46] Other complications related to bovine thrombin (anaphylaxis, formation of antibodies to factor V) or related to the activation of coagulation have been reported with fibrin glue and fibrin sealants.[47]

Uremic Bleeding

Abnormal bleeding is a common complication of uremia and is primarily due to platelet dysfunction and defective interaction with endothelium. Use of cryoprecipitate as a source of vWF has been speculated to correct the platelet dysfunction. However, cryoprecipitate has been shown not to affect platelet aggregation in vitro, but does shorten the bleeding time. In 1980, a single study published in the *New England Journal of Medicine* led to the widespread, but temporary, use of cryoprecipitate for the treatment of uremic bleeding.[48] Since that time, variable response reports have been published.[49] Therefore, cryoprecipitate may be beneficial in the management of uremic bleeding.

Dosage

The dosage of cryoprecipitate is calculated on the basis of the amount of fibrinogen present in 1 unit of cryoprecipitate, the plasma volume, and the desired increment. The difficulty in determining the correct amount to administer is due primarily to variability in the fibrinogen content of cryoprecipitate, secondary to variable storage volume and pooling methods used. The goal of therapy should be to maintain the measured fibrinogen at greater than 100 mL/dL. This can usually be accomplished by the transfusion of 2 to 4 units/10 kg if the fibrinogen content of the concentrate is low and by 1 to 2 units/10 kg if the fibrinogen content is high. For these doses, the expected increment in fibrinogen should be approximately 60 to 100 mg/dL. Dosing frequency should be determined based on clinical and laboratory response.

Compatibility and Side Effects

Cryoprecipitate can contain anti-A and/or anti-B antibodies and, as such, the American Association of Blood Banks (AABB) Standards recommends ABO compatibility for cryoprecipitate transfusions.[50] However, because of the small amounts of these isohemagglutinins in each unit, "out of ABO group" cryoprecipitate is sometimes administered when "in ABO group" cryoprecipitate is unavailable. As with FFP/F24, compatibility testing is not required and because cryoprecipitate does not contain red blood cells, Rh matching is unnecessary. The risks of fevers, chills, allergic reactions, and infectious disease transmission are similar to those of frozen plasma products.

ALBUMIN

Albumin, an important plasma protein, contributes primarily to the maintenance of plasma colloid oncotic pressure. It is clinically available in three forms: a 5% solution in saline; a 25% solution in distilled water; and purified protein fraction (PPF), which is 5% total protein (88% albumin and 12% globulins). These products are heat treated and unable to transmit viruses. The high cost, periodic shortages, and lack of efficacy in some clinical situations have led to increased scrutiny over the appropriate use of this important plasma derivative.[51,52] In many clinical situations, the use of albumin remains controversial and is the subject of continued debate. Many authorities believe that albumin is extensively overused. Listed in Table 149–3 are our preferences for indications, possible indications, investigational uses, and clinical situations in which administration is contraindicated. Under common usages, the table contains clinical situations in which albumin is frequently used.

Table 149–3 Administration of Albumin

Indicated
After large-volume paracentesis[62–64]
Nephrotic syndrome resistant to potent diuretics[66]
Ovarian hyperstimulation syndrome[68–70]
Volume/fluid replacement in plasmapheresis[109]
Possibly Indicated
Adult respiratory distress syndrome
Cardiopulmonary bypass pump priming[56]
Fluid resuscitation in shock/sepsis/burns[57]
Neonatal kernicterus
To reduce enteral feeding intolerance[110]
Not Indicated
Correction of measured hypoalbuminemia or hypoproteinemia
Nutritional deficiency, total parenteral nutrition[111]
Preeclampsia[112]
Red blood cell suspension
Simple volume expansion (surgery, burns)[57]
Wound healing
Investigational
Cadaveric renal transplantation[113]
Cerebral ischemia[114]
Stroke[115]
Common Usages
Serum albumin <20 g/dL
Nephrotic syndrome, proteinuria, and hypoalbuminemia
Labile pulmonary, cardiovascular status
Cardiopulmonary bypass, pump priming
Extensive burns
Plasma exchange
Hypotension
Liver disease, hypoalbuminemia, diuresis
Protein-losing enteropathy, hypoalbuminemia
Resuscitation
Intraoperative fluid requirement exceeding 5 to 6 L in adults
Premature infant undergoing major surgery

Indications

A decrease in measured plasma albumin is found in many situations and is often not a clinically significant concern. Mild edema due to hypoalbuminemia does not require albumin therapy. However, inadequate synthesis, as seen in severe liver disease and severe malnutrition, or excessive loss, as seen in nephrotic syndrome and protein-losing enteropathy, can lead to significant hypoalbuminemia with intravascular volume depletion, anasarca, ascites, and pleural effusions. Historically, albumin has had a broader use (ie, nutritional support, correction of hypoalbuminemia, volume replacement), but recent studies support its benefit in fewer situations, including nephrotic syndrome resistant to potent diuretic therapy, after large-volume paracentesis, and in ovarian hyperstimulation syndrome (OHSS).[53,54]

The indications and inappropriate uses of albumin are described in detail in the following sections.

Intravascular Volume Expansion

Albumin provides the most (80%) of plasma colloid oncotic pressure. Infused albumin provides colloid oncotic pressure; however, 50% of the infused protein is lost to the extravascular fluid compartment within 4 hours. Crystalloid may also provide volume expansion and is more quickly redistributed into total body fluids. Studies investigating the use of albumin in various situations including volume expansion during and after surgery,[55] as priming solution in cardiopulmonary bypass,[56] or in maintaining colloid oncotic pressure,[57] found no clinical benefit compared with controls. In 1998, the Cochrane Injuries Group performed a systematic review of randomized control trials in albumin treatment of critically ill patients and concluded that there was no evidence that albumin reduces mortality in patients with hypovolemia, burns, or hypoalbuminemia. In fact, they suggested that albumin may increase mortality. On the basis of their findings, the group recommended that hypoalbuminemia be eliminated from the list of indications and called for a large randomized trial to assess the effect of albumin on mortality.[58] Critics of the meta-analysis sharply disagreed with the Injuries Group findings and have extensively disputed each study's individual and cumulative conclusions.[59] At this time albumin therapy cannot be recommended for simple volume expansion or for the maintenance of albumin levels or colloid oncotic pressure. This conclusion is not definitive and *it will not be definitive* until a large, randomized control trial on albumin administration in critically ill patients is performed. Currently, the Australia and New Zealand Intensive Care Society in conjunction with the Institute for International Health of the University of Sydney are embarking on such a study.[60]

Cirrhosis

The use of albumin in cirrhotic patients dates to before 1950. In this setting, albumin is recommended for temporary improvement in hyponatremia, spontaneous bacterial peritonitis, or prevention of the complications associated with paracentesis, including volume shifts and hyponatremia.[61] Several studies demonstrated that after large-volume paracentesis, hyponatremia and renal insufficiency were improved with albumin infusion compared with other volume-expanding agents.[62–64]

Nephrotic Syndrome

Albumin has been used to increase colloid oncotic pressure with the intention of increasing diuresis. This use is currently limited to patients in whom diuretic therapy is poorly tolerated or ineffective or in those with massive ascites or anasarca.[65,66]

Ovarian Hyperstimulation Syndrome

Ovarian hyperstimulation syndrome is characterized by ovarian enlargement and increased capillary permeability that results in ascites and renal impairment with fluid and electrolyte imbalance.[67] This potentially lethal syndrome is associated with exogenously administered gonadotrophins for the induction of ovulation in women undergoing reproductive procedures. Several vasoactive substances, including an unidentified factor released by the hyperstimulated ovary, have been implicated in the pathogenesis of OHSS. In high-risk patients, the use of prophylactic IV human albumin at the time of oocyte retrieval has been shown to decrease significantly the incidence and severity of OHSS,[68–70] although the pregnancy rate may be less than that associated with embryo cryopreservation.[71] Furthermore, a meta-analysis by Aboulghar et al in 2002 demonstrated that albumin administration was effective in the prevention of severe OHSS.[72] However, it is unknown if therapeutic albumin treatment for women with a diagnosis of severe OHSS is effective. It is postulated that albumin exerts its beneficial effect through binding and inactivating the OHSS-associated factor.

Dose

The volume and speed of administration should be determined by the patient's volume status, condition, and response to the product. Albumin 5% is oncotically equivalent to normal human plasma. Albumin 25% provides less infusion volume per amount of albumin and is usually administered to patients with a tenuous volume status.

Compatibility and Side Effects

Albumin is a plasma derivative used widely and associated with rare adverse reactions. Still, allergic reactions, including urticaria, may be encountered. Volume overload may occur with excessive doses, and a decrease in ionized calcium is, at least, a theoretical possibility. Albumin is an excellent growth medium for bacteria, and bacterial contamination can lead to febrile and more serious reactions. Albumin lots are tested for contaminants and pyrogens before shipment. Transmission of infectious diseases is no longer a concern.

INTRAVENOUS IMMUNOGLOBULIN

Intravenous immunoglobulin is prepared by fractionation of large pools of human plasma. There are numerous preparations available in the United States and throughout the world. Each preparation is slightly different and has theoretical advantages and disadvantages and specific licensed indications. Ideally, IVIG should contain each IgG subclass; retain Fc receptor activity; have a normal half-life; demonstrate virus neutralization, opsonization, and intracellular killing; and have antibacterial capsular polysaccharide antibody. Furthermore, vasoactive impurities should be absent, and no transmissible infectious agents should be present.[73]

Indications

Indications, possible indications, and investigational uses of IVIG are listed in Table 149–4.

Primary Immunodeficiency Syndromes

Primary congenital immunodeficiency syndromes have been treated with intramuscular immunoglobulin for the past 30 years. The use of intramuscular immunoglobulin has certain disadvantages: delayed absorption, delivery of inadequate amounts due to small muscle mass, and pain at the injection site. IVIG overcomes these disadvantages, and used prophylactically in patients with primary immunodeficiency[74] has been demonstrated to reduce the number of febrile and infectious episodes as well as improve survival rate.[75] IVIG use in IgG subclass deficiencies is also beneficial.[76]

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) may be associated with hypogammaglobulinemia and complications of repeated bacterial infections (see Chapter 79). IVIG decreases the incidence and severity of bacterial infections in CLL patients with hypogammaglobulinemia and has become accepted prophylactic therapy.[77,78]

Table 149–4 Administration of Intravenous Immunoglobulins

Indicated
Primary immunodeficiency syndromes
Common variable immunodeficiency
X-linked agammaglobulinemia
Severe combined immunodeficiency
Ataxia-telangiectasia
Wiskott–Aldrich syndrome
IgG subclass deficiency[76]
Cytomegalovirus-interstitial pneumonia after bone marrow transplantation[79]
Chronic inflammatory demyelinating polyneuropathy[121]
Chronic lymphocytic leukemia[77]
Guillain–Barré syndrome[123,124]
Idiopathic thrombocytopenic purpura (refractory)[83–88]
Inflammatory myopathies (refractory, dermatomyositis, and polymyositis)[108,128,129]
Mucocutaneous lymph node syndrome[91]
Pediatric HIV infection[82]
Parvovirus infection
Possibly Indicated
Antiphospholipid syndrome in pregnancy[118]
Autoimmune hemolytic anemia (warm type unresponsive to prednisone)[119]
Factor VIII inhibitors (refractory)[151]
Graves ophthalmopathy[132]
Immune neutropenia[126]
Multiple myeloma (stable disease, high risk for infections)[1331]
Myasthenia gravis (refractory, acute severe decompensation)[133]
Pemphigus[152]
Systemic lupus erythematosus (refractory, severe, active)[148]
Thrombocytopenia refractory to platelet transfusion[149]
Vasculitis (refractory to standard therapy)[150]
Investigational
Acquired von Willebrand disease[116]
Amyotrophic lateral sclerosis[117]
Burn patients[120]
Chronic fatigue syndrome[122]
Fetomaternal alloimmune thrombocytopenia[136]
Graft-versus-host disease[81]
Human immunodeficiency virus infection[125]
Immune-mediated aplastic anemia[77]
Inflammatory bowel disease[77]
Intractable childhood epilepsy[130]
Multiple sclerosis[134]
Neonatal hemolytic disease[137,138]
Neonatal sepsis[135]
Prevention of nosocomial postoperative infections[139,140]
Prophylaxis in transplant recipients against cytomegalovirus infection[141]
Recurrent unexplained spontaneous abortions[142,143]
Rheumatoid arthritis[144]
Solid organ transplantation[145–147]

Bone Marrow Transplantation

The use of prophylactic IVIG or cytomegalovirus (CMV)–IVIG in CMV-negative bone marrow transplant recipients during the first 100 days posttransplant has been demonstrated to reduce the incidence of symptomatic CMV-associated disease, including CMV interstitial pneumonia, in some trials.[78] Because of the high cost of this treatment and the increasing use of prophylactic ganciclovir, IVIG is currently not indicated for the prophylaxis of CMV infections in bone marrow transplant recipients. In established CMV-interstitial pneumonia, IVIG in combination with ganciclovir has been shown to reduce the mortality rate and has become the recommended treatment modality.[80] Its role in preventing severe graft-versus-host disease is unclear. Prolonged IVIG therapy during GVHD prevention may suppress humoral immunity recovery.[79,81]

Pediatric Human Immunodeficiency Virus Infection

The defects in humoral and cellular immunity observed in children with HIV infection predispose them to life-threatening bacterial infections. Studies have shown that the administration of IVIG to HIV-infected children can reduce the incidence and severity of bacterial infections as well as the frequency of hospitalization.[82] Prevention of maternal–fetal transmission of HIV infection through the use of hyperimmune HIV-IVIG is being investigated.

Idiopathic Thrombocytopenic Purpura

The use of IVIG represents a major advance in the treatment of acute and chronic idiopathic thrombocytopenic purpura (ITP) (see Chapter 132). IVIG significantly raises the platelet count within 5 days in adults with chronic ITP and in children with acute ITP.[7,83,84] The mechanism of action of IVIG in ITP is unknown, but most clinicians believe that Fc receptor blockade decreases the removal of antibody-coated platelets. Other proposed mechanisms include suppressed antiplatelet antibody synthesis, increased antiviral immunity, and blockage by antiidiotypic antibodies. In general, IVIG induces responses in most patients within 1 to 2 days. Responses are of variable duration and are rarely sustained, although maintenance therapy may be of some value. IVIG may be effective in chronic ITP refractory to corticosteroids or splenectomy[85,86]; may show greater efficacy in conjunction with corticosteroids[87]; and has been demonstrated to be superior to oral corticosteroids in children with acute ITP.[88]

Although IVIG has shown equal efficacy with corticosteroids in pediatric acute ITP and in 75% of adults with chronic ITP, because of the transient responses and high cost, its use is justified only in clinical situations requiring rapid elevation of platelet count or if standard therapy has failed. IVIG is, therefore, indicated in acute bleeding episodes or before urgent surgery, including splenectomy; in patients at high risk of intracranial hemorrhage; and in those in whom corticosteroids are contraindicated or ineffective. IVIG has also been used to treat ITP during pregnancy, postinfectious thrombocytopenia, ITP associated with HIV infection, and neonatal thrombocytopenia. Intravenous anti-D immune globulin has demonstrated efficacy in Rh-positive, nonsplenectomized individuals with ITP. It has been suggested that the mechanism of action may involve a shift in the immune-mediated destruction from platelets to the antibody-coated RBCs.[89]

Mucocutaneous Lymph Node Syndrome

The mucocutaneous lymph node syndrome (Kawasaki disease) has been treated with aspirin with or without concomitant IVIG administration.[90] Coronary artery aneurysm, a serious complication of this disease, was significantly reduced in the IVIG-treated group.[91] However, in a multicenter retrospective survey of all children treated with Kawasaki disease, persistent or recrudescent fever after their first course of IVIG was associated with a statistically significant risk of treatment failure. Furthermore, IVIG retreatment in those patients with persistent fever after IVIG treatment failure was approximately 60%. A call was made for a randomized trial to assess the efficacy of this practice.[92] With regard to the pathogenesis of Kawasaki disease, decreased peripheral blood lymphocyte apoptosis has been demonstrated. Therefore, the effect of IVIG in Kawasaki disease has been postulated to partially reverse inhibited lymphocyte apoptosis.[93]

Dosage

Patients with primary immunodeficiency syndromes and IgG levels less than 200 mg/dL are candidates for immunoglobulin replacement. Most patients require 100 to 200 mg/kg IV every 3 to 4 weeks to achieve adequate IgG levels (usually >800 mg/dL) and protection against infection. Initially, serial IgG level determination may allow

the physician to individualize the dose and schedule. These are affected by the recovery, half-life, redistribution, and catabolism of IVIG, which vary from product to product and patient to patient. Patients with ITP are usually treated with 400 mg/kg daily for 5 days or 1000 mg/kg daily for 2 days (see Chapter 132). Repeat single doses (400 mg/kg) have been used intermittently in some patients (particularly children) to maintain platelet counts greater than 50,000/μL. Kawasaki disease is treated with higher doses ranging from 1800 mg/kg to 2000 mg/kg as a single dose.[90,91,94]

Compatibility and Side Effects

Infusions of IVIG should be started slowly and patients should be closely monitored. If the initial rate (0.5 mL/kg/hour) is well tolerated, the rate can be increased gradually, but not more than eightfold. Fever, headache, nausea, vomiting, fatigue, backache, leg cramps, urticaria, flushing, elevation of blood pressure, and thrombophlebitis may be seen. IgA-deficient patients may have IgG anti-IgA antibodies, which can cause anaphylactic reactions.[94] This complication is rare and may be avoided by using products with a lower concentration of IgA.[95] Aggregated IgG may produce chills, nausea, flushing, chest tightness, and wheezing. Rarely, IVIG preparations contain IgG anti-A and/or anti-B RBC antibodies that can produce hemolysis[96] or interfere with serologic evaluations, including RBC compatibility testing.[97] IVIG treatment will produce a positive direct antiglobulin test (DAT), rendering the DAT test result unhelpful with regard to potential red blood cell autoantibody interpretation. Serum sickness can occur. Improved manufacturing processes currently in place render IVIG free of envelope and nonenvelope viruses.[98] Nevertheless, hepatitis C virus transmission has been reported in certain patient populations.[99,100] High-dose IVIG therapy has been associated with reversible, acute renal failure[101] and aseptic meningitis.[102]

HYPERIMMUNE AND INTRAMUSCULAR IMMUNOGLOBULINS

Hyperimmune immunoglobulin is prepared from large pools of plasma known to contain elevated antibody titers against specific infectious agents. The intramuscular and hyperimmune immunoglobulins[73] are listed in Table 149–5.

Antithymocyte globulin (ATG) is a purified concentrated γ-globulin made from hyperimmune serum of horses immunized with human T lymphocytes. ATG is used in renal transplant patients as an adjunct therapy in the treatment of graft rejection.[102] It is also used in patients with aplastic anemia who are not candidates for bone marrow transplantation (see Chapter 25).[103]

Hyperimmune immunoglobulin is used to prevent the development of specific clinical disease or alter its symptomatology. CMV Ig is indicated in all kidney and liver transplant recipients who are seronegative for CMV and who receive the respective organ from a seropositive donor and in bone marrow transplant patients with CMV interstitial pneumonia.[79] Hepatitis B immunoglobulin is used to provide passive immunity to hepatitis B virus associated with needlestick exposure or sexual contact with HBsAg-positive individuals.

Rh immunoglobulin is used when fetal Rh(D)-positive RBCs may have entered the maternal circulation of an Rh(D)-negative mother. This means that Rh(D) immunoglobulin is given to Rh(D)-negative mothers after abortion or amniocentesis, as well as before delivery and again postpartum if the child proves to be Rh(D) positive.[153] The therapeutic effect is thought to be caused by antibody feedback with T-cell suppression of the B-cell clone responsible for the formation of anti-Rh antibody. Rh immunoglobulin can also be given to prevent immunization in Rh(D)-negative individuals given Rh(D)-positive components, such as platelets. Transfusion of Rh(D)-positive RBCs to Rh(D)-negative recipients is occasionally necessary, and prevention of immunization is not possible unless IV Rh immunoglobulin is made available by the manufacturers. Rh immunoglobulin has also been used to treat ITP.[89]

Experimentally, immunoglobulin has also been administered by oral, intrathecal, and aerosolized routes. Oral administration has been tried with some success in the prevention of rotavirus infection and necrotizing enterocolitis in premature infants, in the treatment of *Cryptosporidia*-associated diarrhea, and in the prevention of viral gastroenteritis after bone marrow transplant. Intrathecal administration has been tried in the treatment of viral encephalitis and tetanus, aerosolized administration in infections with respiratory syncytial virus.

Table 149–5 Hyperimmune and Intramuscular Immunoglobulins

Antithymocyte globulin
Cytomegalovirus immunoglobulin
Hepatitis B immunoglobulin
Rabies immunoglobulin
Rh(D) immunoglobulin
Tetanus immunoglobulin
Vaccinia immunoglobulin
Varicella-zoster immunoglobulin
Western equine encephalitis immunoglobulin

CHAPTER 150

PREPARATION OF PLASMA-DERIVED AND RECOMBINANT HUMAN PLASMA PROTEINS

William N. Drohan and David B. Clark

The development of large-scale methods for the preparation of human plasma proteins began more than 60 years ago. In 1940, after the outbreak of World War II, a meeting was called to discuss the urgent request of the United States Armed Forces for 300,000 units of human whole blood or plasma for transfusion, which at that time seemed an impossibly large amount.[1] Dr. Edwin J. Cohn of the Harvard Medical School was approached to determine whether animal plasma could be made safe for human use. Cohn drew together a task force of investigators and developed a method for the fractionation of bovine plasma based on differential precipitation of various plasma proteins by appropriate combinations of ethanol concentration, pH, low temperature, ionic strength, and protein concentration. Within a short time, highly purified preparations of bovine serum albumin were available for clinical trials. Although there were no immediate reactions, the frequency of severe delayed reactions made it obvious that these preparations were unsuitable for clinical use. Meanwhile, Cohn had arranged with the American Red Cross to provide his laboratory with a supply of human plasma, and the ethanol method was quickly adapted for human plasma fractionation. Although albumin was the only product distributed during the war, the remaining plasma fractions were carefully preserved, and other preparations, including fibrinogen and immunoglobulins, were soon developed.

Since World War II, major improvements have occurred in the preparation of human plasma proteins. The ethanol process has been supplemented by more selective purification techniques to produce a wide variety of products of high purity. Genetic engineering technology has allowed recombinant human plasma proteins to be produced in tissue culture systems and transgenic animals. Most important, the safety of plasma products has been increased significantly by the development of improved methods for the inactivation and removal of viruses, as well as for the screening and testing of donors and donations. Transfusion-transmitted diseases and the safety of blood and plasma products are described in detail in Chapter 154. Today, methods for inactivation or removal of viruses and other pathogens that might be present in the starting materials are integral parts of all manufacturing processes. This chapter describes current methods and future directions for the preparation of plasma-derived and recombinant human plasma proteins for clinical use, mainly for products available in the United States.

FRESH FROZEN PLASMA

Plasma from a single donor that has been separated from the red cells, placed in a freezer within 8 hours after phlebotomy and stored at 18°C or less meets the criteria for labeling as Fresh Frozen Plasma (FFP).[2] Clinical indications for the administration of FFP are described in Chapter 149. FFP has a very low risk of infectious disease transmission[3]; however, its viral safety depends entirely on donor selection and blood screening techniques. One method is currently being used to increase the safety of plasma for transfusion. Fresh Frozen Plasma, Donor Retested[4] is FFP that is held in quarantine for a minimum of 112 days after collection, through the "window" period during which a donor can be infectious but not test positive in the screening tests. Once the donor from whom it was collected has been retested and found negative in all tests, the plasma may be released for use. A similar method is used by most manufacturers to quarantine plasma for fractionation until a donor again tests negative at a subsequent donation.[5]

PLASMA FRACTIONATION
