The proximal sesamoid bones and other components of the suspensory apparatus are subject to tremendous tensile forces and fatigue, especially when under full load at high velocity. Several fracture types occur in the proximal sesamoid bones, but apical fractures predominate. Other fracture types include midbody, basilar, abaxial, and comminuted fractures, but all occur less frequently than fractures of the apex (Figure 9.2).

Apical fractures are articular; therefore, joint effusion is usually observed if the fracture is displaced. There is pain on flexion and on focal pressure of the involved sesamoid. Diagnosis is confirmed radiographically, and there is a good prognosis for return to racing with forelimb involvement (67%) with an even better prognosis for return to racing for hindlimbs (83%).[51] The medial sesamoid of the front fetlock carries the worst prognosis; only 47% return to race.[51] A major determinant in the prognosis is the integrity and degree of damage of the suspensory ligament; therefore, ultrasound evaluation is critical.

Abaxial, transverse midbody, and basilar fractures occur less commonly and carry a guarded prognosis for future racing, with or without surgery. Surgical removal

VetBooks.ir

of abaxial fragments is routinely performed. Generally, if marked displacement has occurred, there are usually excessive suspensory damage and a poor prognosis for return to racing. However, if there is minimal suspensory damage, surgical removal can have a favorable outcome to return to race, but only a fair prognosis for returning at the same level. In general, horses with fractures of the lateral sesamoid bone do better than those with fractures involving the medial sesamoid bone, and hindlimbs do better than forelimbs. Midbody fractures may be managed conservatively or with surgical treatment with lag screw fixation or circumferential wiring.[25] Contrary to literature reports, there is a guarded prognosis for future racing. One report that supports this demonstrated a 44% return to racing when lag screw fixation was elected and 0% when circumferential wiring was elected.[8] Radiographs often indicated that the fractures have completely healed; however, once back in training, lameness often occurred when the horse worked 5/8th of a mile and re-injury was common. Degenerative joint changes often accompanied these injuries and worsened the prognosis. With conservative management, horses usually become sound and are useful for breeding or light athletic use.

Stress-related bone disease of the distal metacarpus or metatarsus is an extremely common cause of lameness in juvenile horses and is also seen in older horses. The most common clinical manifestation is a variable severity of lameness, usually seen when cooling after a workout or on the following day. Nuclear scintigraphy often demonstrates intense focal uptake of radioisotope of the involved condyle. Radiographs generally show some degree of resorption of subchondral bone.[31] At this stage, conservative therapy yields a good prognosis. If continued training is allowed, resorption will progress to a fracture line. Lameness is usually evident at this point, and surgical intervention is necessary if there is any distraction at the fracture site (Figure 9.3). If initial radiographs only show subchondral resorption, it is imperative to perform follow-up radiographs in 3–4 weeks to assess development of a fracture line once resorption is complete. The metacarpi develop fractures of the lateral condyle more frequently than medial, while the metatarsi sustain medial and lateral fractures in approximately equally. There is a tendency for lateral condylar fractures to remain in a relatively simple configuration and exit the metacarpus laterally, whereas the medial fractures tend to spiral proximally and may exit medially or laterally. Prognosis is directly correlated with the extent of articular injury and if the fracture is displaced with concurrent palmar fragmentation or avulsion of the intersesamoidean ligament, resulting in an axial sesamoid bone fracture.

Figure 9.3. Dorsopalmar radiograph of a right front fetlock showing a complete displaced comminuted lateral condylar fracture of the third metacarpus.

Metacarpal Region

The third metacarpal bone is commonly subject to stress-related bone injury. The most common manifestation is dorsal cortical disease that ranges from mild bucked shins to dorsal cortical fracture.[39] Numerous configurations of bone reaction and resorption are recognized, including periosteal reaction, dorsal cortical thickening, vertical resorption lines in the dorsal cortex, and saucer fractures (Figure 9.4).

Diagnosis is based on clinical findings such as palpable sensitivity of the dorsal cortex while holding the limb in a non-weight-bearing frame. Typically the horse will jog very sore when wearing front bandages. Local anesthesia is occasionally necessary to isolate the lameness. Radiographs eventually detect periosteal new bone proliferation or bone resorption, but these changes may not be evident for several weeks. Treatment is based on the severity of the disease and degree of lameness, but the most common and effective treatment is reducing the intensity of training or rest. Ancillary treatments include shockwave therapy, needle periosteal scraping, osteostixis, and cortical screw placement.[9] In general, there is a good prognosis for future racing.

High suspensory lameness in the forelimb presents in a variety of different ways and can be a diagnostic challenge. Clinically these horses demonstrate a shortened cranial phase of the stride. Clinical exam can reveal heat, sensitivity to palpation, thickening of the suspensory ligament, or no abnormalities. Often mild effusion of the middle carpal joint will be noted without heat or sensitivity to palpation of the carpus, and this is believed to be due to referred inflammation. Diagnostic anesthesia of this region is critical followed by several diagnostic modalities to further clarify the disease. An ultrasound exam is important to rule out a primary desmitis or core lesion. If the ultrasound exam is normal and radiographs do not reveal any obvious bony changes, nuclear scintigraphy

VetBooks.ir

Figure 9.5. Dorsolateral palmaromedial oblique radiographic view of the carpus showing a chip fracture of the distal radial carpal bone.

is indicated to determine the degree of bone involvement. When nuclear scintigraphy shows a mild IRU at the origin of the suspensory ligament, these cases respond very well to ESWT, topical Surpass, and Naquasone and can be maintained in active training. However, if there is marked IRU or if a core lesion is appreciated, then a prolonged rest and rehabilitation program is warranted. Proximal palmar cortical fractures may develop at the origin of the suspensory ligament and are a source of significant lameness. Two common types of bone injury occur in this region. The first is a circular resorptive region in which there is usually an avulsion of the suspensory ligament. The other type consists of palmar cortical vertical fractures, which typically do not involve the suspensory ligament. Suspensory injuries have a favorable prognosis with conservative management and monitoring to assess healing unless an avulsion fragment is present, which carries a guarded prognosis. A convalescence period of 3–6 months is usually sufficient for training to restart.

Fractures involving the splint bones are more common in the forelimbs than hindlimbs. Initially a focal swelling is present with heat and sensitivity to palpation. As training continues, a large focal firm swelling becomes evident. Initially an obvious fracture is difficult to appreciate on radiographs; however, based on the reactivity of the bone and periosteum, a fracture is almost always present. Unless the fracture is very distal, surgical removal is rarely indicated. Horses are removed from training, and the splint can be injected with corticosteroids, and sarapin or cryotherapy is useful if the periosteum is highly reactive. Horses are walked for 2–4 weeks before intense training is resumed. The prognosis is good and recurrence is rare.

Carpus

Carpal lameness is extremely common in Thoroughbred racehorses of all ages, especially in juveniles. The carpus is a complex joint that is susceptible to a multitude of injuries associated with training and racing. Stress-related pathology is involved in most of the bone, cartilage, and other soft tissue injuries of the carpus.

Common conditions include synovitis and/or capsulitis, cartilage wear and erosion, and stress-related bone injury of the third carpal bone. Numerous chip fractures of the radial carpal and middle carpal joints also occur (Figure 9.5).[42]

Clinical signs of carpal lameness vary depending on the disease process, but generally the horse tracks in a base-wide manner to facilitate lateral placement of the knee. The middle carpal joint is far more frequently affected than the proximal joint. Young horses with

VetBooks.ir

synovitis of the middle carpal joint display minimal lameness. The joint is often warm and there may be a change in behavior or performance. Radiographs are normal and the condition is self-limiting with a reduction in training. Joint injection is frequently performed using a corticosteroid or IRAP in conjunction with a chondroprotective agent. If the condition persists or recurs after treatment, a rest period of 30–60 days is indicated.

Third carpal bone disease is very common in juvenile thoroughbreds and is considered to be an integral component in the development of third carpal slab or sagittal fractures. Radiographs including a skyline projection of the third carpal bone should be performed and are diagnostic for third carpal disease. Common radiographic changes are sclerosis, bone resorption beginning at the radial facet, and slab and sagittal fractures (Figure 9.6).[21] Prognosis is correlated with the amount of displacement of the fracture and degree of damage to the articular cartilage.[32]

Other fracture configurations of the middle carpal joint include chip fracture of the distal radial carpal bone, the proximal third carpal bone, and the distal intermediate carpal bone. Prognosis for return to racing soundness depends on the extent of damage to the articular cartilage and amount of exposed subchondral bone at the load-bearing surface. Poor prognostic signs include extensive cartilage damage, a void on a load-bearing surface, and third carpal bone involvement. Free fragments in the palmar aspect of the joint are also considered a poor prognostic indicator.[24]

The radial carpal joint is less frequently involved than the middle carpal joint, but pathology affecting this joint occurs routinely. Bone and cartilage injury usually manifests on the distal lateral radius, which often develops large (0.5–1.0 cm), partially or completely displaced fragments. In many cases, the fragment on the distal lateral radius occurs first, and the horse is very lame (grade 4+/5) initially but becomes relatively sound in a couple of days. If the horse continues to train, it will often develop a fragment on the proximal intermediate and/or radial carpal bones as a kissing lesion. Fragments of the distal medial radius and proximal radial carpal bone also commonly occur. In general, there is a good prognosis associated with removal of fragments in the radial carpal joint.

Radius

Lameness associated with the radius is probably the least common location in the forelimb region of the Thoroughbred racehorse. However, an occasional finding on nuclear scintigraphy would be an IRU in the center of the radius classified as an enostosis-like lesion or bone islet. These findings are seen in the radius, with the tibia and cannon bone also affected.[1] Lameness is attributed to this finding in approximately 50% of cases and correlated with the intensity of the lesion. Therefore, it is important to distinguish between a stress fracture and an enostosis-like lesion, as the rehabilitation program is dramatically different (Figure 9.7). Typically, enostosis-like lesions involving the radius rarely result in lameness, whereas these lesions in the tibia are more likely to result in lameness. Horses with enostosis-like lesions are maintained in training on aspirin. These horses typically walk until they are sound and jog for 1 month before high-intensity work is resumed. A repeat nuclear scintigraphy examination

Figure 9.7. Nuclear scintigraphy image demonstrating two focal areas of IRU in the mid-radius corresponding to an enostosis-like lesion that was not associated with lameness.

VetBooks.ir

will often reveal normal uptake, and the prognosis for a successful career is excellent.

Humerus

Humeral fractures are a common type of injury and are a result of an imbalance in stress remodeling. Typically these horses demonstrate a significant lameness that resolves quickly with a couple days of walking. Often a single limb is affected; however, this can be a bilateral condition in which the horse will often demonstrate a reluctance to train and a markedly shortened cranial phase of the stride. Clinically these horses present very similar to a scapular stress fracture; however, stress fractures of the humerus are more common.[32,40] It is important to note that horses with proximal suspensory desmitis will often demonstrate a shortened cranial phase of their stride and diagnostic anesthesia is important in differentiating between the different regions. The most common time to see lameness associated with the humerus is in a horse that is returning to exercise following a lay-up period. It is not uncommon to see this type of lameness while the horse is jogging or galloping and before they complete their first breeze. The author utilizes the humeral snap test to help diagnose horses with humeral stress fractures. The test is performed by holding the radius while quickly flexing the elbow joint. A horse with a humeral stress fracture will often resent this type of manipulation and should increase the index of suspicion (Video 9.1). However, nuclear scintigraphy is the most reliable method for detecting this injury. The most common location for humeral stress fractures is the proximocaudal aspect of the humerus or caudal aspect of the distal humerus (Figure 9.8). Complete fractures of the humerus are more commonly associated with stress fractures of the proximocaudal aspect than the distal aspect of the humerus.[16] Interestingly racetrack surface has an impact on the location of humeral stress fractures. A study performed in Southern California demonstrated that horses on synthetic surfaces had a greater proportion of distal humeral lesions, whereas horses on dirt surfaces had a greater proportion of caudoproximal lesions.[16] Another interesting observation was that none of the horses that sustained a complete humeral fracture and were euthanized underwent nuclear scintigraphy prior to the injury. This suggests that scintigraphy is very good at identifying horses at risk for complete fracture and helps minimize their occurrence in racehorses.[16] Because complete humeral fractures are always fatal, horses with IRU in the humerus are always given a rest and rehabilitation period. Typically these horses are given 3 months off if no callus is seen radiographically and 4 months off if a callus is seen and have an excellent prognosis for making a complete return without recurrence as long as care is taken not to rush them back following rest and rehabilitation.

Scapula

Scapular fractures are the most common type of injury to the scapula although uncommon when compared with all injuries in the forelimb of the racehorse. Typically these injuries are seen in horses 3 years old and older and initially present as a significant lameness that resolves quickly with a couple of days of walking. This is not unique to scapular stress fractures as this is a characteristic that is common with all types of stress remodeling lameness. Often a single limb is affected. The right is more commonly affected than the left; however, it can occur bilaterally.[56] The clinical presentation is very similar to a humeral stress fracture. The most reliable method of identifying a scapular fracture is by nuclear scintigraphy. The most common site for this injury is at the distal aspect of the spine of the scapula (Figure 9.9). Because this injury occurs in a very characteristic location, firm digital palpation at this location can sometimes result in a painful response, and a positive result would increase your index of suspicion. Additionally, ultrasound examination of this location can demonstrate an increase in thickness of the spine of the scapula with a rough bone margin as a result of the woven bone callus that is present. Typically these horses are given 3–4 months off work and have an excellent prognosis to return to race training without recurrence, provided that the rest and rehabilitation period is not rushed.

Figure 9.8. Scintigraphic image that demonstrate an IRU on the caudodistal aspect of the humerus.

Tarsus

Lameness localized to the distal hock joints (TMT/DIT) is a common source of lameness and typically seen with horses that have sickle hock conformation. Clinically these horses demonstrate an exaggerated collected stabby gait. The rider will often complain that the horse is cross-firing or cross-cantering and not changing

VetBooks.ir

Figure 9.9. Nuclear scintigraphy image demonstrating an IRU on the distal aspect of the spine of the scapula.

leads behind. Often nuclear scintigraphy and radiographic abnormalities do not correlate well with clinical disease. However, unless a fracture of the central or third tarsal bone is present, the clinical response to intra-articular corticosteroid and a chondroprotective agent is very good and accompanies a favorable long-term prognosis for a successful career despite radiographic changes. Exceptions include overt pathology such as fracture of the third or central tarsal bones or tarsal crushing or wedging.[30,55] Reports suggest a poor prognosis for return to racing with slab fractures of the third and central tarsal bones; however, clinical experience indicates that the prognosis is favorable as long as healing occurs with preservation of normal articular margins and normal shape of cuboidal bones. If there is advanced distal tarsal disease, internal fixation in conjunction with hock drilling may produce good results.

Lameness associated with the high suspensory region is not as common as distal hock OA and is less common compared with the forelimb. It can be localized with diagnostic analgesia of the lateral plantar nerve or local infiltration. Care should be taken when performing a local infiltration as an impending slab fracture of the central or third tarsal bone can also be desensitized. Because of the retinaculum, horses with primary lameness associated with the high suspensory will often show more improvement in lameness when treated with Naquasone compared with NSAIDs. Treatment options are similar to that of the forelimb, and the prognosis is typically more favorable.

Occasionally horses will demonstrate a stringhalt gait that is most commonly associated with a traumatic event; however, the true etiology is unknown. Typically this abnormality in gait is noticed when the horse is walking at the barn or to the racetrack and is not demonstrated while the horse exercises during high speeds. Oftentimes this exaggerated gait bothers the trainer more than the horse and rarely interferes with their athletic potential. For these traumatic or sporadic cases, a lateral digital extensor tenectomy utilizing a standing approach often results in a good prognosis for improvement in gait; however, the exaggerated flexion of the rear limb is often not completely eliminated.

Tibia

Tibial stress fractures are very common in 2-year-old racehorses as they approach their first race. Occasionally these fractures are seen in older horses; however, this is much less common. Typically horses demonstrate a hindlimb lameness following a gate work. The lameness is most commonly identified 1–2 days following the work, and the affected horse will demonstrate a short-strided, toe-first, heel-slapping gait when jogging in hand in a straight line. Tibial stress fractures can occur unilaterally or bilaterally; however, even in the bilateral cases, one leg is often more severely affected. Nuclear scintigraphy is the most reliable method for diagnosing a tibial stress fracture.[33] Typically these fractures occur proximally or distally. Once a tibial stress fracture is identified on a nuclear scintigraphy examination, a radiographic examination is necessary to confirm the presence of a fracture. If a fracture is visible on radiographs (Figure 9.10), horses are given 60 days of stall rest with hand walking followed by a gradual return to exercise. If a fracture is not visible and only periosteal or endosteal reactivity or callus is noted (Figure 9.11), trainers are instructed to walk the horses until they are sound, which typically occurs within a week. The horses are then jogged for 1 month and are maintained on daily aspirin. The prognosis is excellent and the risk of recurrence is low.

Stifle

Lameness in the stifle is commonly diagnosed by clinical evaluation. It is largely believed to be associated with strain and subsequent injury, primarily of the soft tissue structures of the medial femorotibial joint with occasional involvement of the femoropatellar joint. Manifestations of this lameness include the following gait disturbances: the horse travels wide behind, often does not push off the affected limb normally, and has an unsteady appearance of the hindleg. The medial femorotibial compartment usually has joint effusion, but radiographs are typically normal. Intra-articular anesthesia is not typically performed but does improve the lameness if used as a diagnostic aid. Treatment with intra-articular placement of corticosteroids and chondroprotective agents improves the lameness 5–7 days after therapy. If the gait worsens following initial improvement, a tibial stress fracture should be suspected.

Upward fixation of the patella is usually seen in 2-year-olds but may be seen in older horses as well. Most horses with upward fixation of the patella respond

VetBooks.ir

favorably to treatment with systemic intramuscular administration of 3.0 mL of 30 mg/mL mephentermine hemisulfate (90 mg/horse) for 3 consecutive days. Treatment options for refractory cases include internal blister of the patellar ligaments or quadriceps muscles or hormonal therapy. Prognosis for racing is good after resolution of the fixation. Occasionally a fractured patella is the source of lameness; however, this injury is almost always accompanied by a traumatic event and is far more common in the steeplechase discipline. The skyline radiographic projection of the stifle is critical in order to obtain a complete clinical picture.

Pelvis

The pelvic and sacral regions are plagued with a number of soft tissue and bone injuries, which are usually stress induced by excessive exercise. All types of pelvic fractures described in the literature may occur as a result of some form of acute trauma.[50] However, stress fractures of the wing of the ilium and sacroiliac (SI) injury are the most common sites of bone injury of the pelvis in racehorses.[47] Subjectively, female racehorses tend to have an increased incidence; however, some reports have found no sex association.[50] Often horses

VetBooks.ir

with pelvic stress fractures demonstrate a significant lameness following a gate work and are often pulled up by the rider shortly after breaking out of the gate. Additionally these horses demonstrate a very sore, tucked up hind end, and short-strided gait, and the trainer often believes the horse is tied up. Horses with suspected pelvic fractures should be maintained tied to a wire in the stall to keep them standing for a minimum of 30 days. Recumbency increases the risk of complete fracture, which can result in laceration of closely associated vessels causing fatal hemorrhage. Special care should be taken to monitor these horses for pneumonia as this is a complication of maintaining a horse on a tie wire with the head elevated. The most common location is the ilial wing, and nuclear scintigraphy is the most reliable method of detecting this injury and its location (Figure 9.12). Ultrasound examination is often important in characterizing the type of fracture. Prognosis for most injuries in this region is favorable with rest as long as the fracture is not displaced. Typically horses with ileal wing fractures are given 3–4 months off and have an excellent prognosis with minimal risk of recurrence, whereas fractures that are comminuted, articular, or involve the acetabulum have a poor prognosis for return to racing, and an alternative career should be considered.

Less commonly, lameness will be localized to the SI joints. SI pain is often secondary to a primary lameness lower in the limb, resulting in a change in gait and the way they carry themselves during training. Typically the exercise rider will experience a bunny hop gait when the horse transitions from a jog to a gallop. Often these horses will jog sound when examined in hand. The SI region is medicated with corticosteroids and sarapin; if the primary lameness is identified, this region should be addressed as well.

Soft tissue injuries are recognized in the hip area and are believed to occur during propulsion at fast work. Synthetic surfaces with increased traction have been incriminated in development of this condition; however, there is no current evidence to support this theory. Treatment consists of rest, and the prognosis is good for full recovery.

Tendons and Ligaments

Tendon and ligament injuries in racing Thoroughbreds occur predominantly from intrinsic sources, although extrinsic trauma or injury occasionally occurs. The etiology is multifactorial, but cumulative excessive strain rates in addition to the gradual demise of structural stability incurred with degenerative aging changes that are accelerated by exercise are the primary components.[52] Repetitive loading of a compromised tendon (one that has sustained subclinical, microscopic damage) may be responsible for the often progressive nature of these injuries.[47] Incidence of tendon injury is high and in one study was reported to be responsible for up to 46% of all racetrack injuries,[2] although in clinical experience the rate is not this high.

The forelimb superficial digital flexor tendon (SDFT) is most frequently injured (Figure 9.13) followed by the suspensory ligament, including the origin of the suspensory and medial or lateral branches of the front and hindlimbs, and the distal sesamoidean ligaments. The SDFT develops several characteristic lesions in different locations. A common site is the mid-metacarpal region where it usually develops a core lesion.[45] Central core lesions may be due to unequal strains on fibrils within the tendon. It has been suggested that strain levels on central core fibrils are greater than on peripheral fibers.[3] The second most common lesion of the SDFT recognized clinically involves tearing of the peripheral fibers located on the lateral aspect of the tendon. Juvenile

Figure 9.12. Nuclear scintigraphy image demonstrating an IRU on the right ilial wing.

Figure 9.13. Typical bowed tendon appearance associated with superficial digital flexor tendinitis.

VetBooks.ir

tendonitis presents as uniform enlargement of the SDFT without fiber disruption and is often unilateral, although bilateral involvement does occur. These cases are identified in 2-year-olds within the first several weeks or months when intensive training begins. As long as these cases are identified prior to fiber disruption, the prognosis is excellent for return to training after a 60–90-day rest period, and recurrence is rare.

Physical evaluation often reveals warmth, mild to moderate edema, and pain upon palpation of an affected area. Horses may exhibit palmar metacarpal swelling without SDFT swelling, usually with very low-grade involvement of the tendon.[22] Lameness may be nonexistent, subtle, and transient or overt. Ultrasound examination is the gold standard to gauge the tendon injury. Caution must be used in interpretation, especially in the acute phase, in which fluid accumulation between fibers may resemble a tear. The follow-up ultrasound examination several weeks later is critical for accurate determination of the degree of tendon injury. Tears are recognized as hypoechoic areas within the tendon, range dramatically in diameter and length, and may be partial or complete. Complete tears appear as anechoic areas, and partial tears appear as hypoechoic, or echogenicity is mixed (Figure 9.14). Affected tendons and ligaments may have a larger cross-sectional diameter than unaffected contralateral structures, and periodically this is the only visible indicator of the problem on ultrasound.[22] More refined imaging may be obtained via MRI and most likely will influence the future management of tendon injuries.

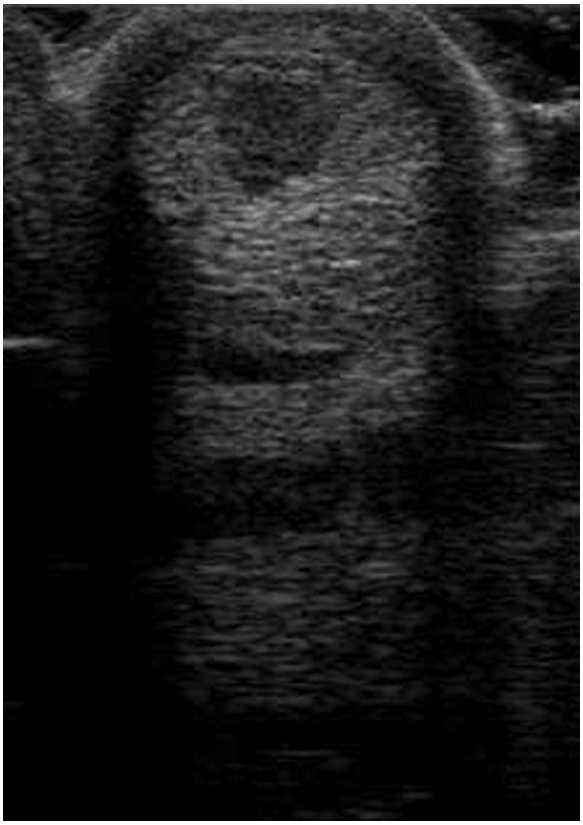

Figure 9.14. Ultrasound image of the flexor tendons showing a core lesion of the superficial digital flexor tendon.

Treatment varies according to the degree of injury. Severe injuries may require complete rest coupled with systemic NSAIDs, hydrotherapy, sweating, regenerative therapies, superior check ligament desmotomy,[28] and gradual return to work, whereas minimal lesions may only need a reduction in training. Serial ultrasonographic examinations help determine the rate of healing and ability to return to full training. Very large defects may benefit from surgical intervention in the form of tendon splitting to permit fluid drainage from the tendon lesion.

The prognosis for return to racing is guarded following tendon injuries. In general, the more severe the tear, or the more distal the location of the lesion, the worse the prognosis. Horses with superficial digital tendonitis in the region of the pastern have a guarded prognosis for future racing. Tendons undergo repair in phases, and the final result is remodeled, mature scar tissue.[45] Frequently, healed areas contain scar tissue that does not have the elasticity of an uninjured tendon, and therefore there is a possibility for repetitive injury. The majority of tendon injuries tend to recur in racehorses, regardless of the treatments employed. Recurrence may be at the original site but is often in a region distinct from the original injury.

Additional Considerations

When considering lameness in the racehorse, one must not fail to consider potential neurologic conditions such as equine protozoal myeloencephalitis (EPM), OA of the cervical vertebral facet joints, or spinal cord compression. EPM is known as the disease that has no characteristic clinical signs. Oftentimes this is seen in young horses that originated from an endemic area, and the stress of shipping and onset of active training may cause enough stress on the individual where the clinical signs become apparent. These horses often present for a lameness issue and failure to train or poor performance. Musculoskeletal evaluation does not reveal any areas of concern, and other diagnostics are unremarkable. The immunofluorescent antibody (IFA) and Western blot blood test is a quick useful way to identify these cases. They typically respond well to treatment and are able to maintain active training once an improvement is noted, which is often within the first week.

OA of the cervical vertebral facet joints is a common cause of hindlimb lameness and poor performance in the Thoroughbred racehorse. These horses demonstrate a stiff neck or altered gait relative to changes in head and neck position and a hindlimb lameness or occasionally a shifting front limb lameness. Diagnosis is typically confirmed with nuclear scintigraphy demonstrating an IRU in the C4–C5, C5–C6, and/or C6–C7 region without any uptake in the hind end. The treatment of choice is ultrasound-guided injection of the articular facet with corticosteroids and a chondroprotective agent. The response to treatment is often very good and rapid. Spinal cord compression cases are relatively uncommon because these cases are often identified prior to active training at the racetrack.

THE STANDARDBRED RACEHORSE

Kimberly Johnston and Frank A. Nickels

VetBooks.ir

DESCRIPTION OF THE SPORT

The name Standardbred originated in 1879 in the United States with registration of horses capable of trotting a mile within a standard time of 2:30 minutes. Now the Standardbred is a distinct breed with foals eligible for registration if both sire and dam are registered Standardbreds, regardless of racing performance. Today's Standardbreds currently race much faster, with pacers completing a mile in less than 1:50 minutes and trotters only a few seconds slower. Racing is done on an oval track, usually a mile in length, and horses pull lightweight carts with a single driver. In the United States racing is counterclockwise and commences from a moving start with horses at their post position behind a vehicle with a collapsible partition. Standardbreds race at either the trot or the pace. In the United States, pacers outnumber trotters 4:1, while in Europe and Australia, races are held at the trot only. A horse may have the ability to perform both gaits, but Standardbreds tend to race at only one gait for their entire career. In general, pacers seem to tolerate lameness better than trotters due to the perpetual swinging motion of the pace itself.

The Standardbred resembles the Thoroughbred; however, it is longer and does not stand as tall, averaging between 14.2 and 16 hands. Adequate body length is essential for a long stride and to allow free movement of the limbs without interference. Conformation plays a pivotal role in the success of the racehorse, and many conformational faults predispose to interference or lameness problems. Toeing out is undesirable in the front limbs, especially when accompanied by a base-narrow stance. This conformation affects the flight of the hoof and can cause interference. Toeing in causes less interference but results in an inefficient gait and increases the strain on the medial side of the limb, leading to carpal pain and the development of splints. Horses that are offset or back at the knees are at risk of carpal chips and slab factures. Sickle hocks used to be common in pacers and were even selected for, but sharp angulation of the hindlimb predisposes to curb and hock arthritis. In contrast, many trotters are cow hocked, but unless severe, this conformation may be advantageous because it allows a passing gait in which the imprint of the hindlimb falls outside the imprint of the forelimb, providing a longer stride.

Standardbreds are broken to harness as yearlings and train for 7–9 months before racing as 2-year-olds. Horses are jogged at a slow trot/pace for several miles daily to gain fitness and stamina. Jogging is done "the wrong way" (clockwise) around the track, and a few times a week, a horse is turned to work "the right way" for short bursts of speed training. During peak season, Standardbreds may race as often as once a week. This pounding on hard tracks for many miles and the fact that Standardbreds race and train in different directions makes them prone to repetitive stress and maladaptive bone injuries (Figure 9.15).

Figure 9.15. Although the pace is a natural gait, horses often wear hobbles to help maintain the gait while racing. This equipment commonly causes hairless areas on the legs, making a Standardbred pacer readily identifiable.

LAMENESS EXAM

Lameness is a leading cause of poor performance that plagues nearly every Standardbred racehorse at some point during its career. Compared with many other disciplines, a high percentage of hindlimb lameness problems are encountered as a result of the Standardbreds' symmetrical gaits and having to pull a draft load.

History taking should include age, stage of training, and whether the horse is a trotter or pacer. Owners should be asked if the horse is lame or simply not performing well. Young Standardbreds experience a subset of problems not commonly seen in the mature horse, and examination of unproven 2- and 3-year-olds with poor performance must be sufficient to rule out the cardiovascular or respiratory systems as the cause.

Lame horses should be examined for signs of localized inflammation (heat, swelling, or pain), and the trainer asked about the duration of the problem. It is important to ask about the size of the track that the horse races on and whether lameness is worse in turns or on the straightaway. Most harness races are a mile long, but track lengths do vary. On smaller tracks, horses must negotiate more turns and the turn diameter is less. Lameness from the medial side of the limb is more evident in the turns, whereas lameness from foot pain, splints, and curbs worsens with distance and is likely more obvious at the end of a race. A change of racing venue may prove successful for horses with chronic lameness issues. For example, a trotter with stifle arthritis may perform better on a 1-mile track where it only has to negotiate two turns.

It should be noted whether the horse "breaks stride" (gallops instead of maintaining the trot or pace), which is a serious fault for the harness horse. Hock pain causes horses to get uneven coming into or out of the turns, but they usually maintain the gait, whereas fetlock and stifle lameness often cause horses to break stride in the turns. Horses can break for many reasons other than lameness, including excitement, immaturity, and incoordination, and interference is a major cause of breaking. In this case, shoeing or tack changes may correct the problem. The "bute test" can be helpful to differentiate lameness from interference: a horse is prescribed a modest course of phenylbutazone and then reexamined. It is believed that lameness improves with the nonsteroidal anti-inflammatory medication while interference remains unchanged. Neurologic disease also must be considered in any horse with unresolved gait abnormalities.

Several terms unique to Standardbred racing provide information about a horse's performance. "Bearing in" or "bearing out" means a horse drifts toward the infield or the outside rail, respectively. Drivers may comment that a horse is "on a line," indicating that they must pull harder on one rein to keep the horse from bearing in or out. Horses drift away from a source of pain, so a horse on the right line is likely to have right front lameness. Alternatively, for rear limb problems, the hindquarters may move closer to one shaft of the sulky, and the horse is then described as being "on a shaft" (Figure 9.16). There are exceptions so this information must only be used as a guide. Horses with right front medial heel pain, for instance, are commonly on the left line during a race because they try to avoid loading the inside of the limb (Figure 9.16).

Figure 9.16. This 2-year-old Standardbred pacer demonstrates being on a shaft. The colt's hindquarters are positioned closer to the right shaft of the sulky. This colt is also on the left line, and its head is turned to the left as the driver pulls harder on the rein in an attempt to keep the horse straight. This combination of findings suggests a left hindlimb lameness.

Interference may mimic lameness if horses alter their stride to avoid hitting another limb, and it can result in bruising and lacerations that do cause lameness. Alterations in gait can also cause horses to overload other limbs and develop compensatory lameness, which is so common in the Standardbred that veterinarians must always consider the possibility that new problems have arisen. Both primary and secondary lameness issues must be addressed to achieve soundness. Trotters tend to develop diagonal lameness problems, whereas pacers may develop ipsilateral or contralateral issues. Tack changes such as the addition of hobbles, boots, or a head pole often indicate high-speed lameness and should be assessed.

Finally, the clinician must know the horse's history, including racing performance, prior lameness, treatments, and response to those treatments. Detailed record keeping is imperative, since many owners and trainers prefer jumping straight to treatment rather than pursuing extensive diagnostic tests. Without a complete diagnosis, response to treatment becomes the barometer of clinical accuracy. Standardbred trainers may try to treat problems on their own, resulting in conflicting clinical findings. It is not uncommon to be presented with a horse that has "had all his joints done" (meaning intra-articular injections) but is still not performing well.

VetBooks.ir

Careful inquiry may reveal that an area has been overlooked or the veterinarian may need to shift the focus to soft tissue structures rather than just injecting the horse again. It is also important to remain aware of the potential for joint infection following intra-articular injections. Onset of clinical signs can be delayed as long as 2 weeks if steroids are used.

An acceptable venue to watch a horse in hand can be difficult to find at the racetrack, and Standardbreds are not always amenable to jogging on a lead, making observation of the horse in the shed row typical. Unsound trotters sometimes prefer to pace at slow speeds; however, the pace is a forgiving gait, and front limb lameness may be difficult to detect. Most horses, including pacers, will finally trot in hand after several attempts. Correlation between lameness seen in hand and that at racing speed is often poor, so observation of horses in harness on the track is routine.

Flexion tests are part of most exams, although their value is dubious. The carpus can be flexed exclusively and this manipulation is generally useful. In the hindlimb, an effort should be made to flex the fetlock separately from the upper limb, because problems are relatively common in this joint.

A few points regarding the use of diagnostic analgesia in the Standardbred deserve mention. Foot pain is so commonplace that blocking of a front limb should always begin with anesthesia of the palmar digital nerves to establish the significance of heel pain in the overall picture. The abaxial sesamoid block is avoided because it can desensitize the foot, pastern, and parts of the fetlock. Inadvertent anesthesia of fetlock pain could be mistaken for lameness of the foot, with dire consequences if a fracture is present. Hindlimb foot pain is infrequent, so digital anesthesia is rarely warranted; however low plantar anesthesia should be used to rule out the distal limb for all but the most obvious cases of hindlimb lameness. Observation of the horse on the track before and after diagnostic analgesia can be useful; but there is risk of further injury, so the driver should be instructed to only drive the horse as far as is necessary to assess the effectiveness of the block and to avoid abrupt stops or turns. Propagation of incomplete fractures or catastrophic breakdown is possible following desensitization of a limb. Finally, the veterinarian must remember to abide by local jurisdictions regarding the use of local anesthetics close to race day.

SPECIFIC LAMENESS CONDITIONS

Foot

Standardbreds race on compacted limestone tracks and are shod frequently, predisposing them to foot pain. It is not uncommon for a horse to be foot sore for several days after a race. The long-toe, low-heel hoof conformation seen in many Standardbreds, along with the repetitive concussion sustained from jogging on hard tracks, predisposes them to corns. Horses that are shod tight or have the heel of the shoe turned in to prevent it from being pulled off if they overreach are likely to develop bruising from the focal pressure placed on the caudal angle of the bars. Fracture of the distal phalanx is a relatively frequent cause of foot pain and should be considered in severely lame Standardbreds that have no localizing signs. Acute lameness is seen after a race, often in the winter months.

Distention of the distal interphalangeal joint is a nonspecific sign that may be noted in conjunction with foot soreness. Radiographic signs of coffin joint arthritis may or may not be present because synovitis can be a reflection of inflammation in nearby structures, including the podotrochlear apparatus. Response to intra-articular medication is generally favorable but often must be repeated, especially if an accurate diagnosis is never made.

Pastern

The pastern region is often overlooked in the Standardbred. Many practitioners are not as familiar with the intricate anatomy of this area, so soft tissue injuries are likely underdiagnosed. Injury to the distal sesamoidean ligaments, collateral ligaments, and flexor tendons in the pastern can all result in lameness and even joint instability, causing ringbone months or even years later.

Fetlock

Synovial or joint capsule inflammation is common and develops as the amount of training increases. The condition can be secondary to altered gait from another lameness issue, and it is frequently seen in horses with sore heels as a result of toe-first landing. Heat and effusion are present along with a positive response to joint manipulation, but overt lameness is not typical. Fibrosis and mineralization of the synovial pad can occur with chronicity resulting in a decreased range of motion.

Osteochondral fragments are frequently encountered in the fetlock, most commonly originating in the dorsomedial proximal margin of the first phalanx.[6] Concurrent thickening of the synovial pad is frequently observed because the two sites make contact during maximal extension of the joint. Small fragments may not be a significant problem, but larger fragments close to the articular surface result in lameness and can produce score lines on the metacarpal condyle. Frequent injection may keep horses going, but fragment removal is the treatment of choice to prevent joint deterioration.

Proximal palmar/plantar osteochondral fragmentation of the first phalanx is a frequent radiographic finding in Standardbreds. These lesions are routinely removed prior to the onset of a racing career. Not all fragments cause lameness, and when they do it is mild. The complaint more often involves an inability to go straight or breaks at high speed. Most fragments are found medially in the left hindlimb, and horses with an outwardly rotated hindlimb axis are predisposed.[6] Demonstration of the lesion requires oblique views angled 30°–45° distad to prevent overlap of the proximal sesamoid bones on the palmar/plantar aspect of the first phalanx. Problematic fragments can often be managed using intra-articular therapy until the end of the racing season without risk of further injury to the joint. Arthroscopic removal of axial fragments is then indicated, but the value of this has come into question.[1]

VetBooks.ir

Abaxial fragments are not articular and surgical removal should not be attempted.

Fractures of the first phalanx occur and are generally straightforward; however, special mention should be made of incomplete sagittal fractures because they are common in the Standardbred and can represent a diagnostic challenge. Marked lameness after a race subsides quickly but recurs with return to work. Heat, swelling, and joint distention may be absent or minimal. This scenario, coupled with a positive response to fetlock flexion, should arouse suspicion. Radiographs prior to diagnostic anesthesia are warranted because propagation of the fracture can occur. Short fractures may not be radiographically visible until bone resorption occurs 3–6 weeks following fracture. Diagnosis is facilitated by observation of linear lucency in the proximal sagittal groove on the AP view and dorsal periosteal remodeling, which is best seen on the lateral to medial projection. Sclerosis near the midsagittal groove often precedes fracture, and nuclear scintigraphy is likely to demonstrate the lesion much earlier. Until an accurate diagnosis can be made, these cases should be managed conservatively in a stall to prevent catastrophic injury. Short fractures may be treated with confinement alone, whereas longer, propagating, or nonhealing fractures benefit from internal fixation. Healing occurs in 4–6 months, and the prognosis for racing is good, provided significant degenerative changes do not occur.[8]

Cyclic bone fatigue occurs in the Standardbred when bone adapts to the miles of low-speed jogging one way of the track and is then unable to endure the intense loads encountered during speed work in the opposite direction. Common sites of stress remodeling in the fetlock include the distal plantarolateral aspect of the metatarsal condyle, distal palmaromedial aspect of the metacarpal condyle, proximal sesamoid bones, and the proximal aspect of the first phalanx.[3] Physical findings are minimal, and affected horses have a variable response to fetlock flexion. Subtle high-speed lameness or frequent breaks in the turns are typical. Minimal improvement is seen with intrasynovial anesthesia, except in the most severe cases, because intact cartilage prevents desensitization of the subchondral bone. Nuclear scintigraphy is a valuable tool to reveal identifiable patterns of uptake for this disease entity. Radiographic findings offer insight for prognosis, because changes are nearly undetectable initially, and then progress to sclerosis and flattening of the palmar/plantar condyle. A skyline view of the palmar aspect of the condyle is obtained by holding the limb in flexion while the X-ray beam is aimed dorsodistal to palmaroproximal through the fetlock joint (Figures 9.17 and 9.18). A characteristic "gull wing" pattern of sclerosis on the condyle provides the diagnosis. Exercise must be reduced to allow the adaptive process to equilibrate and microdamage to heal.

Arthritis is probably the most common condition of the fetlock. Joint distention, most notable in the palmar/plantar recess, is characteristic along with variable lameness exacerbated by flexion. Range of motion may be reduced due to joint capsule thickening and fibrosis. Some horses subsist surprisingly well, and lameness does not become a prominent feature until the disease is advanced. A subclinical condition often becomes apparent after hard training or racing under adverse conditions. Diagnosis is based on the presence of degenerative changes on radiographs, and treatment is primarily palliative.

Figure 9.17. An example of positioning to obtain a flexed 45° dorsodistal to palmaroproximal oblique (skyline) radiograph of the metacarpal condyle.

Proximal Sesamoid Bones

Sesamoiditis is believed to result from minor tearing of the suspensory attachment to the proximal sesamoid bones, causing inflammation. Diagnosis is based on radiographic changes, including the presence of prominent vascular channels and patchy sclerosis within the bones. Many believe that the condition predisposes horses to sesamoid fracture, but in a serial radiographic investigation of 71 young Standardbreds, horses that developed proximal sesamoid bone fractures did not have radiographic signs consistent with sesamoiditis.[7] Rest and NSAIDs are the mainstays of treatment, but prognosis for chronic cases is poor.

Fractures of the sesamoid bone are associated with trauma and generally occur in areas of attachment of the suspensory ligaments. It is believed that the suspensory ligament responds to conditioning faster than the sesamoid bone, predisposing the bone to failure during overloading. Horses present with lameness, joint swelling, and thickening of the branch of the suspensory ligament attached to the fracture. Pain is elicited with digital pressure over the bone. Treatment and prognosis vary depending on the type of fracture and extent of concurrent soft tissue injuries. Surgical removal of apical and abaxial fragments is indicated in acute cases.

VetBooks.ir

Figure 9.18. This radiograph of the metacarpus was obtained using the position described in Figure 9.17. This view is useful to demonstrate small fissures or sclerosis of the palmar aspect of the condyle, neither of which are present in this case.

Metacarpus/Metatarsus

Standardbreds are not prone to the bucked shin complex seen in other racing breeds, although the problem is occasionally seen in forelimbs of 2-year-old pacers during late summer. Bruising of the hind shins may occur in trotters that interfere, with the front foot hitting the dorsal surface of the metatarsus.

Injury to soft tissue structures in this region is common. The majority of cases result from repetitive stress injury, although acute trauma and even tendon rupture can be seen in Standardbreds that race without adequate leg protection. Tendon injuries are relatively easy to diagnose in the Standardbred; swelling and pain prompt ultrasonographic evaluation. Injury to the superficial digital flexor tendon (SDFT) is most common, and the severity dictates the course of treatment. Prognosis for SDFT injury appears better in the Standardbred than other racing breeds. Horses with injury within the tendon sheath often develop constriction by the palmar annular ligament and may require transection of this ligament prior to racing.

Proximal palmar metacarpal pain is regularly encountered in the Standardbred, and differentials must include proximal suspensory desmitis (PSD), injury to the inferior check ligament, and sagittal fracture of the cannon bone, with PSD being most likely. Horses with PSD usually have a head nod that is pronounced when the limb is on the outside of a circle. Affected horses can move in a manner that mimics carpal pain, and lameness may be exacerbated by both fetlock and carpal flexion. In the hindlimb, swelling from PSD is minimal, and horses can be positive to any or all hindlimb manipulations, including the Churchill test, making diagnostic anesthesia critical. In all cases, diagnosis is confirmed with ultrasound, but radiographs should also be obtained to look for bone abnormalities at the ligament's origin, proximal sesamoid bones, and the splint bones, which are frequent in racing Standardbreds.

Suspensory branch desmitis is common in the Standardbred, and it is frequently seen in horses that train on tracks with tight turns or excessive banking. Single branch disease is related to hoof imbalance or poor conformation, whereas biaxial injury results from hyperextension of the fetlock joint. Lameness is not a prominent feature, and many Standardbreds continue to race and train, accumulating damage and propagating injury toward the suspensory body. Injury is easily recognized by the visible swelling at the back of the fetlock and palpation of the enlarged branch(es).

Carpus

Carpal pain represents a significant cause of lameness in the Standardbred. One study revealed its presence in one-third of the population and found it to be the top reason for horses to require a layoff longer than 1 month.[17] Lameness results in a distinctive gait characterized by abduction of the limb and a shortened cranial phase of the stride from a reluctance to flex the carpus. Affected horses often stand in the stall with the knee(s) slightly flexed to reduce tension on the dorsal joint capsule. Heat and swelling are invariably present and often recognized by trainers.

Synovitis and capsulitis are frequently encountered in the young Standardbred. Sensitivity to palpation, pain on flexion, and reduced range of motion are typical. Treatment is aimed at returning the joint to normal as quickly as possible; NSAIDs and ice are helpful in the acute stage. Walking should follow to regain joint mobility and limit fibrosis. In some cases, intra-articular hyaluronan (HA) or steroids are needed to control the inflammatory process. Suppression of synovitis is important to prevent the products of inflammation from compromising the articular cartilage and causing arthritis.

Osteochondral fractures in the carpus are a direct result of race training. In the Standardbred, fragments are mainly seen in the middle carpal joint and are almost exclusively located dorsomedially, coming from either the distal radial carpal bone or the proximal third carpal bone.[14] Sudden onset of carpal swelling with lameness is typical. Flexion exacerbates the lameness, and digital pressure along the dorsal aspect of each bone while the joint is flexed may help localize the source of pain. A complete radiographic study of the carpus should be performed to document any chips as well as subchondral sclerosis. Remodeling occurs in both limbs simultaneously; therefore, the contralateral carpus should also be radiographed to look for concurrent disease. In the racehorse, most chips are clinically important, and arthroscopic removal is the treatment of choice.

The third carpal bone is prone to maladaptive stress remodeling that causes pain and fractures. Evaluation of Standardbreds in training revealed middle carpal joint

VetBooks.ir

lameness in 30% of horses, with severity directly related to the degree of third carpal bone sclerosis.[9] Increased bone density and loss of vascular channels cause ischemic necrosis and predispose to further injury (Figure 9.19).[19] Lucency of C3 is also associated with lameness,[14,17,19] and lesions in bone and cartilage are usually identified at surgery.[14] Etiopathogenesis is similar to that seen in the fetlock and requires similar management.

Incidence of carpal slab fractures is highest in 2-year-olds, with frontal plane fractures of the radial facet of the third carpal bone the most common configuration.[14] Distribution is nearly equal between the right and left limbs. Horses are lame and resentful of flexion, often leaning back or rearing to avoid it. Diagnosis is confirmed using radiography; the tangential view (skyline) of the third carpal bone is the most valuable. Fractures heal with conservative management, but surgery limits the severity of joint deterioration and provides the best chance to return to racing. Up to 77% of Standardbreds return to racing following slab fracture, but earnings may be decreased.[18]

Tarsus

Young Standardbreds with uneven gaits or those subjected to miles of jogging quickly develop tarsitis. Affected horses exhibit a shortened stride and may stab the toe laterally as they land, causing uneven wear to the shoe. Disease is most frequent in the tarsometatarsal joint but can occur solely in the distal intertarsal joint; therefore, these joints should be blocked (and treated) separately. Nuclear scintigraphy of the Standardbred with distal tarsitis reveals increased radiopharmaceutical uptake (IRU) in the dorsolateral region of the joints, in contrast to a medial location seen in most other sport horses.[4] Radiographic findings correlate poorly with disease severity, and they are frequently negative in 2- and 3-year-olds despite a response to diagnostic anesthesia. Intra-articular use of HA and corticosteroids is beneficial, and older horses may require regular injections to remain competitive. Flat shoes with square toes ease break-over, and the removal of all shoe additives (toe grabs) helps to reduce shear strain.

Figure 9.19. A flexed 35° dorsoproximal to dorsodistal (skyline) view of the distal row of carpal bones in a 3-year-old Standardbred filly with grade 2 of 5 right forelimb lameness. Note the generalized sclerosis of the third carpal bone along with focal lucent areas in the radial facet, indicative of bone necrosis.

Distention of the tarsocrural joint is usually associated with osteochondrosis (OCD) that is prevalent in the Standardbred. Frequency and distribution of OCD lesions may differ between trotters and pacers,[11] and early removal of most fragments allows horses to perform equivalently to unaffected counterparts.[11]

Fractures of the central or third tarsal bone are occasionally seen in the racing Standardbred. Lameness can be severe, but other external signs are often limited and do not specifically incriminate the distal tarsus. Both conservative treatment and internal fixation have provided a fair prognosis for return to racing, but arthritis remains an inevitable sequellae.[13,20]

Curbs frequently develop in 2-year-olds as speed training begins. In addition to swelling in the long plantar ligament, injury to the digital flexor tendons, collateral ligaments, and numerous other structures in this region can lead to the appearance of curb.[15] Cryotherapy (freeze firing) is often employed for persistently painful curbs.

Stifle

The stifle is frequently implicated as a source of lameness in the Standardbred, but a thorough work-up is rarely performed at the track, and the true incidence of lameness attributable to this region is unknown. Usually, lameness blocks out lower in the limb. Horses with stifle lameness tend to carry the affected limb wide and land on the toe. Trotters may develop a bunny hop gait, particularly if affected bilaterally.

Standardbreds with so-called loose stifles frequently have quadriceps muscle soreness that makes them resemble horses with intermittent upward fixation of the patella. They develop an abnormal cranial phase of the stride as the patella momentarily "catches" before the limb is brought to the ground. Generally, this is a fitness issue that is cured by trotting up and down hills or working in deep footing to hasten conditioning. Nevertheless, many veterinarians advocate internal blisters over the medial patellar ligament to induce scarring and decrease laxity. Medial patellar desmotomy should be reserved for cases of true upward fixation because fragmentation of the distal end of the patella has been reported following this procedure in normal horses.[12]

Stifle swelling should be a red flag whenever it is found. Marked femoropatellar effusion with minor lameness is characteristic of OCD and should prompt radiographic investigation.[5] The postoperative prognosis is favorable in the Standardbred, as long as lesions are not extensive. Medial femorotibial effusion is a more subtle but ominous sign, often indicating advanced arthritis or injury to the intra-articular support structures of the stifle. These injuries usually end a racing career.

Upper Limb Stress Fractures

Racehorses can experience stress-related bone disease in the proximal appendicular skeleton, including

VetBooks.ir

the radius, humerus,[10] tibia,[16] and pelvis.[3] A high index of suspicion enhances the ability to diagnose these stress fractures, and a combination of nuclear scintigraphy and radiography is often needed. Tibial stress fractures are the most common and are usually seen in 2-year-olds.[16] Lameness is noted after speed work and abates quickly with rest. Palpation is unrewarding but response to upper limb flexion may be dramatic. The fracture location is unique for the Standardbred, with the majority in the mid-diaphysis of the tibia, whereas fractures in Thoroughbreds are usually in the proximal caudal or caudolateral cortex.[16] Bilateral fractures can be seen, even in horses with unilateral lameness (Figures 9.20 and 9.21). Horses with scintigraphic evidence of stress remodeling should be treated conservatively, even if fracture is not radiographically visible. The prognosis is good for return to racing following appropriate rest.

Sacroiliac Pain

Sacroiliac pain is very common in the Standardbred and may present as poor performance or overt lameness. Drivers sometimes describe a horse's reluctance to take hold of the bit and think the problem is related to the teeth. Injury occurs during slips and falls, and damage to either the ligaments supporting the pelvis or the sacroiliac joint results in a similar clinical picture. Treatment includes rest and NSAIDs or injection of the sacroiliac joint. Both types of injury should be followed by a controlled exercise program with specific exercises to strengthen muscles of the back and croup.[2]

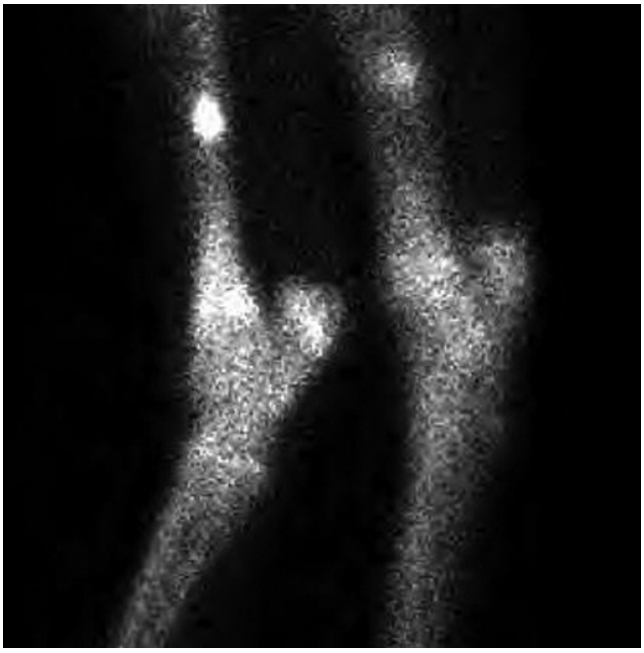

Figure 9.20. A lateral scintigraphic image of the hindlimbs in a 2-year-old Standardbred filly with obscure right hindlimb lameness. Note the focal intense radiopharmaceutical uptake in the mid-diaphysis of each tibia.

Figure 9.21. A dorsolateral to palmaromedial oblique radiograph of the tibia from the same horse as in Figure 9.20. Endosteal sclerosis and callus formation along the caudolateral cortex in the mid-diaphysis indicate the presence of a stress fracture. The horse was rested for 6 months and made a full recovery.

THE RACING QUARTER HORSE

NANCY L. GOODMAN AND LARRY R. OVERLY

VetBooks.ir

INTRODUCTION

Racing Quarter horses are the sprinters of the racing world. They are capable of attaining speeds in excess of 50 mph in less than 21 seconds at a distance of one-quarter mile. The breed originated in colonial Virginia in the 1600s when imported English Thoroughbreds were crossed with native breeds of Spanish descent producing a compact, heavily muscled horse designed for sprinting. They were referred to as Quarter Pathers or Quarter Milers, named after their decided quarter mile racing distance.

The first race records are from 1674 in Enrico County, Virginia, where match races were run down village streets and in small, level fields. The contemporary version of the sport emphasizes 2-year-olds racing in futurities, which run in qualifying heats where horses with the 10 fastest times compete in a final 2 weeks later. Horses must be nominated to futurities, and periodic payments are made in order to maintain eligibility. The same applies to derbies held for 3-year-olds, though the purse money is less than futurities. A very prominent Quarter horse race is the All American Futurity held annually on Labor Day weekend at Ruidoso Downs, Ruidoso, New Mexico, and features a 2-million-dollar purse, with $1 million going to the winner. Los Alamitos racetrack in Southern California, the only predominantly Quarter horse track, offers at least five races during the year with high dollar purses, with the Los Alamitos $2-million-dollar futurity being the richest. The Champion of Champions, which is held at the end of the racing season, is the most prestigious race for older horses. It represents winners of the top races nationwide throughout the year.

Yearling sale prices are driven by precocious, nicely conformed, and well-bred individuals with the potential to compete in these lucrative futurities and derbies (Figure 9.22).

The American Quarter Horse Association (AQHA) studbook has remained open to breeding with Thoroughbreds since the breed was formally established. This outcross has been beneficial in expanding an otherwise small gene pool. It also maintains the classic quarter mile distance of 440 yards, although some Quarter horses run their best at even shorter distances of 300–350 yards.

CONFORMATION RELATING TO LAMENESS

Conformational factors that have been associated with lameness in the forelimb are relatively large body mass, poor carpal conformation (back at the knee and bench-kneed), short upright pasterns, and poor hoof conformation (Figure 9.23). In a scientific study, the most significant finding was that for every inch increase

Figure 9.22. Precocious individuals with popular bloodlines are sought after at yearling sales. This horse (pictured as a sale yearling) won the All American Futurity the following year. *Source*: Courtesy of The American Quarter Horse Racing journal.

VetBooks.ir

in toe length, the odds of sustaining a carpal chip fracture increased by a factor of 40.[14] Major hind end conformational defects (e.g. sickle hocks, cow hocks, too straight in the stifles) are undesirable in the Quarter horse racing breed. Breaking sharply from the starting gate is necessary to be competitive, and any serious hind end lameness may inhibit the individual's ability.

TRAINING THE RACING QUARTER HORSE

Horses are usually started under saddle in the latter part of the yearling year to prepare for racing as 2-year-olds. They are not allowed to race before March of their 2-year-old year, and they are restricted from racing 440 yards until later in the year.[1] In California the horses are required to be truly 24 months of age before their first race. The early races are very short (220 yards), and their training schedule is light compared with the racing Thoroughbred. Most of the 2-year-old Quarter horses are very precocious, big bodied, and naturally fast. They can perform well with a low level of fitness, which is possibly a risk factor for injury. Once they are fit, they gallop fewer days than Thoroughbreds, and many older racehorses spend much of their time on a mechanical horse walker at the barn.

SHOEING

The most serious shoeing considerations in the Quarter horse are probably the same as in the Thoroughbred: long toe, low, excessively sloping heels, and medial to lateral hoof imbalance. Most racehorses are shod close to or on race day; consequently, corrective shoeing is not employed as often as needed in many cases because of the risk of sore feet on race day. Horses race in aluminum shoes and various types of pads are employed for foot-sore horses, including rim pads, wedge pads, full plastic pads, and even full aluminum pads with an assortment of hoof packing. Toe grabs are controversial, especially in Quarter horse racing. They have been associated with catastrophic injury in the racing Thoroughbred, and racing regulators restrict their use in some states. There is very little published data regarding toe grabs in Quarter horse racing, and one study found underrun heels as a more significant risk factor for catastrophic injury than toe grab length.[2] Historically, Quarter horse racehorses have used up to 8-mm-(high) toe grabs to prevent stumbling and slipping from the starting gate, but the norm now is 2- to 4-mm toe grabs, with higher ones used only rarely. Races can be won or lost at the break in Quarter horse racing due to the short distance. The action of the front hooves pointing into the racing surface at the first jump out of the gate is different than that of Thoroughbreds, as is the fact that they actually pull with their front legs as well as push from the hindquarters (Figure 9.24). Some leading trainers feel that the use of higher toe grabs may be necessary for a few individuals after the horses have stumbled or fallen out of the starting gate while wearing a low toe grab. A 2-year survey in California found no adverse effect of toe grabs on the rate of catastrophic injury in racing Quarter horses, with a similar distribution of injury to the control population.[10] Further studies specific to Quarter horse racing and toe grabs correlated to injury rates are necessary, as is investigation into racing surfaces and the condition of the racetrack itself.

LAMENESS RELATED TO TRACK SURFACE

Quarter horses race on varying track surfaces around the country; however, trainers prefer a firmer surface because a loose or sandy surface poses problems with breaking at speed from the starting gate and gaining enough traction for sprinting at high speeds. A different set of injuries is associated with racing on a sandier track, particularly tendinitis of the superficial flexor tendon. Hind end lameness, muscle pulls, back soreness, and suspensory ligament injuries also are more prevalent. Although firmer tracks are preferred, they may lead to a higher incidence of joint and bone injury due to greater concussive forces. There are currently no statistics for Quarter horse injuries associated with synthetic tracks.

LAMENESS EXAMINATION

There is no set procedure for lameness examination, but a systematic approach is essential to assure that it

VetBooks.ir

is thorough. It is important to be efficient because many trainers will have their veterinarian examine every horse before it is entered to race. Soundness is imperative for optimum racing performance in the Quarter horse breed because the races are so short and they are regularly determined by photo finishes. Lame horses may be fractious in the starting gate, and those with hind end lameness may be slow to break from the gate. Quarter horses require a great deal of lameness monitoring to remain at the top of their game. Intra-articular therapy is frequently employed due to the high incidence of joint injury and inflammation associated with speed and concussive forces. Hyperextension of the carpus and metacarpophalangeal joints is common in racehorses and can contribute to lameness (Figure 9.25).

It is very useful to watch the horse walk out of the stall and down the shed row, and this is a good time to obtain a history from the trainer or barn foreman. A sore carpus may be noted immediately by a characteristic wide placement of the leg while walking. Observations such as "The horse gets hotter than usual at the track in the morning" or "He is digging a hole in the stall and standing in it" are useful parts of the history. Observing the horse walk and jog on a hard, level surface may accentuate the lameness and aid in diagnosis. Hoof testers should always be used to define lameness pertaining to the foot. Joint flexion and palpation are particularly useful due to the high incidence of joint problems in the Quarter horse racehorse.

In addition to a conventional lameness examination, the authors pay particular attention to certain examinations

Figure 9.25. A champion 870-yard Quarter horse winning a stakes race at Remington Park. This is a good example of hyperextension of the carpus and metacarpophalangeal joints commonly seen in racehorses. *Source*: Courtesy of Dustin Orona Photography/ Remington Park.

VetBooks.ir

in the racing Quarter horse. This includes flexing the carpus with the leg in a raised position so that the radius is horizontal and looking for an immediate withdrawal response of the neck and shoulder muscles as a response to pain. Directly palpating the carpal joints by placing the thumbs along the individual dorsal borders of the carpal bones while the fingers apply pressure behind the joint can further localize the lameness. The coffin joint is palpated for heat and excessive joint effusion, and the digital pulse should always be checked because it is frequently elevated in horses with acute foot problems. A positive Churchill test may indicate hock soreness and is quickly performed while palpating the distal limb. The medial femorotibial joint is the most common area of soreness in the stifle and may or may not have effusion. The history of a poor performance (especially leaving the gate) usually initiates a more complete examination of the hindlimb. Diagnostic blocks are used when necessary to localize the lameness. See Chapter 2 for more details.

SPECIFIC LAMENESS CONDITIONS

The lameness conditions discussed below are the most relevant for the Quarter horse racing breed. Most of the topics are covered extensively in other chapters; therefore, this section is meant as a review of Quarter horse injuries and how they differentiate from Thoroughbreds.

Arthrosis of the Distal Interphalangeal (DIP) Joint and Problems Associated with the Foot

Coffin joint synovitis is a significant cause of lameness in the Quarter horse.[7] The breed is well known for having undersized feet in relation to the body size, which, coupled with the tendency for racehorses to develop long toes and excessively sloping heels, probably leads to greater stresses to the foot than in other breeds. They also tend to have short upright pasterns, and they race at high speeds on firm track surfaces. Bilateral forelimb lameness is seen, and it can be accentuated by jogging on a hard surface. The stride is shortened with a transfer of weight to the hindlimbs. Horses typically respond to hoof testers over the central third of the frog (as in navicular syndrome). An increased digital pulse is usually evident, and DIP joint effusion may be palpated above the coronet in many cases. Younger horses (2- and 3-year-olds) with synovitis show a greater degree of localizing inflammatory signs than older horses with chronic osteoarthritis (OA).[12]

OA of the DIP joint is occasionally evidenced by the presence of osteophytes involving the distal aspect of the middle phalanx or the extensor process of the distal phalanx. Generalized suspensory soreness as well as soreness in the area of the bicipital bursa is often palpated secondary to inflammation of the DIP joint. Back pain may also be associated with the presence of sore feet and can be detrimental to racing performance due to the horse's reluctance to break sharply and extend its stride.[12] These secondary clinical signs usually disappear after resolution of the foot soreness.

Intra-articular anesthesia may be used to localize the lameness. Radiographs are frequently normal but may show some degree of pedal osteitis, and rarely, navicular syndrome changes. Problems associated with post-racing arthrosis usually occur 1–2 days after racing, when lameness is quite severe. Anti-inflammatories, ice, and systemic corticosteroids tend to correct the lameness within 12–24 hours.

Anti-inflammatory medications and corrective shoeing are often used to treat the condition. The shoeing is in accordance with individual needs, most commonly backing up the shoe as much as possible and protecting the sole. A wide variety of pads are employed with various sole packings. Wedge pads or shoes may be used to correct the low-heel conformation, but care must be taken as often the heel pain is exacerbated. Some horses are trained in bar shoes until they are ready to race. NSAIDs (phenylbutazone in particular) are useful, and the feet are iced twice daily during the acute stage.

Intra-articular corticosteroids are effective in relieving the lameness. Betamethasone esters (Betavet®) or triamcinolone acetonide (Vetalog®) and isoflupredone acetate (Predef®) with or without HA are commonly used, especially if frequent joint injection is necessary. Frequent use of methylprednisolone acetate (Depo-Medrol®) in the coffin joint can produce severe cases of OA over time.

Medial heel bruising is very common. Treatment by quartering shoes short term can become a major source of lameness in the long-term due to the time required to grow out heels and correct shoeing imbalance. Other differential diagnoses of the foot include bruises, abscesses, grabbed quarters, quarter cracks, and laminitis. See Chapters 4 and 11 for further details on lameness conditions of the foot.

The Metacarpophalangeal (MCP) Joint

The MCP joint is another frequent site of lameness in Quarter horses. The most common conditions are synovitis/capsulitis, osteochondral chip fractures, osteochondritis dissecans (OCD), OA, and fractures of the proximal sesamoid bones.

Heat and synovial effusion are the first signs of synovitis, along with a varying degree of lameness. The condition is often bilateral and radiographic examination is negative. Capsulitis does not occur as frequently as in the Thoroughbred because Quarter horses in training gallop less than Thoroughbreds do; therefore, much less stress is placed on the soft tissue structures of the fetlock joint. Symptomatic treatment includes the use of ice, leg sweats or poultice, and NSAIDS. Intravenous HA (Legend®) or IM PSGAG (Adequan®) are often used as systemic treatments. Intra-articular therapy is very effective in these cases, with a good response from corticosteroids with or without HA. If the condition does not resolve with intra-articular therapy or if it recurs after a brief period of time, the training program should be altered or the risk of further joint damage is likely, with OA as the end result.

Many 2-year-olds are entered in multiple futurities, so training revolves around these races. Trainers try to keep horses on schedule for their race dates without sustaining injuries that jeopardize their careers or require extended lay-up periods.

VetBooks.ir

Intra-articular chip fractures of the dorsal aspect of the proximal phalanx are commonly seen in the forelimb of racing Quarter horses (but less than carpal chip fragments). These fractures are considered to be traumatic hyperextension injuries. They occur primarily on the medial aspect, but may also occur laterally.[8] In some cases, they are quite large, especially compared to the fragments that occur in the Thoroughbred, with a long frontal component (Figure 9.26). Horses usually exhibit lameness and synovial effusion, and are positive to flexion of the fetlock joint.

OCD of the sagittal ridge of the metacarpus and metatarsus is usually noticed when the horse is in early training or still at the farm. It may be seen in either the MCP or metatarsophalangeal joints (more commonly, the latter). The joint is radiographed due to synovial effusion, and varying degrees of lameness may be noted. The defects are recognized on the sagittal ridge, along with varying degrees of fragmentation and loose bodies. Not all cases require surgical intervention.

OA may be seen in association with proximal phalanx chip fractures, especially in older horses, and is manifested as wear lines and erosions on the distal metacarpophalangeal articular surface.[8] Defects of the palmar surface of the distal metacarpus are far less common than in the Thoroughbred, but they do occur in older Quarter horses, and the prognosis is similarly poor.

Fractures of the proximal sesamoid bones (apical, abaxial, mid-body, basilar, and comminuted) are relatively common in the Quarter horse, despite such fractures being considered fatigue-related injuries by other authors. Although most often associated with Thoroughbred racing, biaxial and comminuted sesamoid fractures occur in the Quarter horse, resulting in disruption of the suspensory apparatus.

Dorsal Metacarpal Disease

Bucked shins and stress fractures of the dorsal metacarpus are mainly problems of 2-year-old racehorses but are occasionally seen in 3-year-olds. Dorsal metacarpal disease (DMD) is a bone remodeling phenomenon of the dorsal metacarpus along the lines of stress, resulting in various degrees of periostitis and osteoporosis.[15] The incidence is less now that trainers understand this bone remodeling process as it relates to exercise. Stress fractures are most often seen in the 2-year-old year, in contrast to those in Thoroughbreds, which often sustain stress fractures from 3 to 5 years of age.[15] Many of the fractures are longitudinal and cannot be seen to exit the cortex. They may be present bilaterally with the dorsolateral cortex being the most common location, as in the Thoroughbred. Surgery is not indicated with longitudinal fractures because they heal well with rest. Saucer fractures are generally treated with lag screw fixation.

The treatments for DMD are variable, depending on the owner, trainer, and the horse's racing schedule. Some veterinarians are using a treatment combining regional perfusion of tiludronate disodium (Tildren®) with systemic use of clodronate injection (Osphos®) and extracorporeal shockwave. There is no proof at the present time of it speeding healing, and it remains controversial. While extracorporeal shockwave alone is a popular treatment, some of the older methods including electrical hyfrecation, pin firing, and periosteal scraping continue to be employed. They are all used with varying degrees of rest, depending on the level of disease present.

Proximal Suspensory Desmitis

Proximal suspensory desmitis is usually seen as an acute lameness the day after a workout or race, with profound lameness (4 on a scale of 5). Often it is the fastest horse in the trainer's barn that suffers from this injury. In the acute stage, the horse may walk on the toe without dropping the heel down to contact the ground. Perineural anesthesia of the lateral branch of the palmar nerve may be utilized to localize the lameness without blocking the middle carpal joint of the carpus. Radiographs should be taken and an ultrasound examination performed. Treatment of this condition varies depending on severity, ranging from rest to shockwave to subcutaneous injection of corticosteroids depending on the degree of desmitis.

Tendinitis of the Superficial Flexor Tendon

Superficial flexor tendinitis may be seen in the racing Quarter horse but tends to be related to racetrack surface. The incidence increases with sandier tracks, and the condition is more prevalent in horses that race at the 870-yard distance. Diagnosis and treatment are the same as for the racing Thoroughbred.

VetBooks.ir

Arthrosis of the Carpus

Carpal synovitis is the most frequent condition seen in the young racing Quarter horse. Back-in-the-knee conformation is common, and this predisposes to carpal injury during hyperextension of the joint while running. Many 2-year-olds have a large body mass for their age and reach very fast speeds without much prior conditioning. The condition is characterized by heat and synovial effusion of the affected joints with the absence of radiographic changes. Lameness may be present but is generally not severe. Carpal flexion and palpation are used to localize the affected joints. The treatment is the same as for synovitis of the MCP joint.

Osteochondral Chip Fractures of the Carpus

The incidence of osteochondral chip fractures of the carpus is very high in racing Quarter horses. Multiple chip fractures are often seen and many times they are bilateral. The distal radial carpal bone is the most common site for chip fracture, followed by the proximal intermediate carpal bone. It is not uncommon to have distal radial carpal fragments in both middle carpal joints and proximal intermediate carpal bone fragmentation in both antebrachiocarpal joints in the same horse (Figure 9.27).[13]

Figure 9.27. Radiograph demonstrating osteochondral chip fragments off the proximal intermediate and distal radial carpal bones (a common combination in the racing Quarter horse). *Source*: Courtesy of Dr. CW McIlwraith.

The diagnosis is generally made by physical examination and digital radiography. The lameness is fairly obvious; most horses have a characteristic wide placement or circumduction of the involved limb at the walk. Most cases are sensitive to flexion of the carpus and palpation of the dorsal surface of the carpal bones. Heat and synovial effusion are often present.

Arthroscopic surgery is the treatment of choice. Distal radial carpal chips are particularly associated with progressive cartilage damage and OA if the horse continues to race without removal of the chip fracture. Many Quarter horses have multiple surgeries during their racing careers due to the high incidence of osteochondral chip fragmentation.

Other important injuries include the more severe fractures (slab fractures and comminuted fractures), many of which are amenable to surgery. Whenever significant lameness is evident in the carpus, a thorough radiographic examination including skyline views of the carpus is necessary to ensure that degenerative lesions, incomplete sagittal fractures, and any nondisplaced fractures may be seen before a catastrophic injury occurs. All of the reported third carpal bone fractures can be seen in the Quarter horse, with a higher percentage of large frontal slab fractures involving both the radial and intermediate facets (Figure 9.28). The slab is often displaced in these cases, with the distal margin of the radial carpal bone collapsing into the proximal fracture site (Figure 9.29). Lag screw fixation is necessary for proper healing and to prevent further collapse of the joint.

Fractures involving both rows of carpal bones may be seen with some injuries. These can be challenging surgical cases due to the severe damage to the carpal bones and associated joint instability, requiring partial or panarthrodesis and the use of multiple bone plates. Most of these injuries can be managed successfully by using aggressive internal fixation techniques to produce pasture-sound breeding animals. Prompt surgical intervention is necessary due to the high risk of laminitis in the contralateral limb.[9]

Hock Lameness

Effusion of the tarsocrural joint in the hock may be indicative of OCD lesions associated primarily with the distal intermediate ridge or medial malleolus of the tibia. Often these cases are operated before arriving at the track. Lameness associated with the distal tarsal joints, as well as other hind end lameness, is associated with a failure to break sharply from the starting gate. Upper hindlimb flexion tests may be equivocal, but a positive Churchill test along with the history of a poor performance may indicate tarsitis, although a negative test does not rule out the problem. The condition is generally bilateral, and the horse may track close behind or cross midline when observed from behind.

Horses that wear patches behind to protect from scalping or horses with laceration marks seen on the medial aspect of the hock are highly suspect for hock soreness. Radiographs are negative in many instances, or subtle changes may be seen. Intra-articular corticosteroids are effective at relieving the lameness and/or improving performance. Even though the tarsometatarsal and centrodistal joints are low-motion joints, maintaining articular cartilage is important because these joints rarely fuse on their own. Betamethasone esters (Betavet®) and triamcinolone acetate (Vetalog®) have been shown to have fewer deleterious effects on cartilage than methylprednisolone acetate (Depo-Medrol®).[5,6]

Figure 9.29. Radiograph of a collapsing slab fracture of the third carpal bone with the distal margin of the radial carpal bone collapsing into the proximal fracture site. *Source*: Courtesy of Dr. CW McIlwraith.

If methylprednisolone acetate is used, low doses should be considered (20–40 mg).

Stifle Lameness

The most common site of stifle pain is the medial femorotibial joint, which is the same in racing Thoroughbreds. This can be another cause of poor performance. The horse may be positive to upper hindlimb flexion or palpation, but most often intra-articular anesthesia is required to localize the lameness. It is not always clear whether the condition is synovitis or early OA. Radiographs are useful to assess the joint and rule out certain conditions. Ultrasound examination is useful to pick up soft tissue conditions.[4]

Most stifle lameness responds well to intra-articular therapy; however, if lameness persists, diagnostic arthroscopy is necessary to make a definitive diagnosis. Lameness conditions involving the femoropatellar joint are often accompanied by the presence of joint effusion, but in recent years most OCD lesions are operated on before the horse starts racing. Upward fixation of the patella can be an issue in immature racehorses in early training. Subchondral cystic lesions of the medial femoral condyle are a relatively rare but painful condition in the racehorse.

Tibial Stress Fractures

Stress fractures involving the tibia are seen in young horses around the time of their second qualifying work or first race. Diagnosis of the condition has become more common with the advances in imaging techniques and the access to nuclear scintigraphy. The lameness is unilateral and quite severe; the left hindleg is predominantly affected. This may be due to the fact that the horse pulls up quickly from high speed before entering a left-hand turn on the racetrack. If a tibial stress fracture is suspected, nuclear scintigraphy is the best way to demonstrate the injury. Alternatively, digital radiographs taken 1 week to 10 days after injury may show a lesion on the tibia. The horse is usually rested for at least 90 days before resuming training.

Catastrophic Fractures

Proximal sesamoid fractures are the greatest cause of catastrophic injury in the racing Quarter horse. A retrospective study of racing fatalities found that carpal bone and vertebral body fractures were more common in Quarter horses than Thoroughbred racehorses. Sprinting vs. distance racing may play a role in a different distribution of skeletal injuries, but the greatest cause of death for both breeds was found to be fetlock injury.[16]

Lumbar vertebral fractures of the spine have been associated with serious injury to jockeys due to the fall of horse and rider.[3,11] The fractures are located at the L5–L6 vertebral junction. Pathology of the lumbar vertebral region appears to be present before catastrophic injury and is likely associated with maladaptive pathology at the L5–L6 location (Figure 9.30).[3]

THE WESTERN PERFORMANCE HORSE

Robin M. Dabareiner

VetBooks.ir

INTRODUCTION

Western working stock horses are highly talented and bred to be extremely athletic. Its genetic instinct to control a cow, plus overall athletic ability, produces the near-perfect scenario for training- and competition-related injuries with subsequent pathologies. The role of attending veterinarians is to diagnose injuries accurately and initiate appropriate therapy as soon as possible, thereby minimizing recovery time. A thorough understanding of the nature of the horse's competition is necessary for advising the trainer and owner in the proper management of each athlete.

TEAM ROPING HORSES

Description of Event

Team roping is a timed event that begins with a horned steer weighing approximately 200–300 kg that is contained in a chute at the end of the arena. The heading box is to the left of the steer, and the heeling box is to the left of the chute. The first member of the team, the header, asks for the steer to be released from the chute, and the steer is allowed a head start, termed the score. The team is assessed a 10-second penalty if the header leaves the heading box before the steer crosses the score line. When cued by the rider, the heading horse leaves the roping box and chases the steer at maximum speed, much like a racehorse leaving the starting gate. As the header approaches the steer, it "rates off" or slows slightly as it reaches the steer's hip to allow the rider to rope the steer's horns. After the steer is roped, the rider wraps the rope around the saddle horn (dally), and the heading horse drops its hindquarters to slow the steer's momentum. The heading horse is then turned 90° to the left and pulls the steer across the arena, maintaining a constant reduced speed that allows the rider of the heeler to get into position to rope the hindlimbs of the steer. After the heeler's rider ropes the hindfeet and slack is drawn out of the heel rope, the rope is dallied around the saddle horn, and the heel horse is signaled to drop its hindquarters and come to an abrupt stop. The heading horse turns 180° to face the heeler, which signals the end of the run, at which point time is taken. A good time for the completed run is 7–8 seconds; the world record is 3.2 seconds.

Musculoskeletal Injuries

One study that identified the prevalence of specific musculoskeletal injuries sustained by horses used for team roping also showed differences between horses used specifically for heading vs. heeling. Horses used for heading were significantly older (12 vs. 9 years) and heavier (545 vs. 500 kg) and at greater risk of lameness than horses used for heeling.[1] All were Quarter horses, and all that presented for poor or change in performance were lame.

The type of performance change reported by the owners differed between horses used for heading or heeling. The primary owner complaint in horses used for heading was that the horse stopped pulling the steer after it was roped, followed by the horse acting nervous in the heading box and the horse failing to slow down (rate) after reaching the steer to allow the roper to throw his rope. The primary owner complaint in horses used for heeling was that the horse quit stopping after the steer's feet were roped or the horse would nicker when asked to stop.

The right forelimb was most frequently affected by lameness in horses used for heading, whereas the left forelimb was most frequently affected in horses used for heeling. Horses used for heading had significantly more bilateral forelimb lameness, and those used for heeling had significantly more bilateral hindlimb lameness.

As the heading horse sets the steer and initiates the 90° turn to the left, the right front limb is placed cranially and laterally to decelerate and brace against its forward motion and the weight of the steer, placing a tremendous amount of weight and strain on the structures of the right forelimb. These actions and forces may explain the frequency of right forelimb problems in horses used for heading. As the heading horse turns the steer to the left, the heel horse changes directions and makes a quick left turn to position itself to the inside of the steer's left hip so the roper can throw his rope, which may account for the left forelimb involvement. The horse then stops abruptly which could place stresses on the hindlimbs (Figure 9.31).

The most common musculoskeletal problems diagnosed in horses used for heading were:

1. Pain in the navicular area only
2. Navicular area pain with distal tarsal joint osteoarthritis (OA)
3. Soft tissue injury in the pastern region of the right forelimb
4. Carpal joint OA

Heeling horses were most commonly affected by:

1. Navicular area pain
2. OA of the metacarpophalangeal joint
3. Distal tarsal joint OA
4. OA of the left forelimb proximal interphalangeal joint

The joints of the majority of horses were treated with intra-articular medications; the distal interphalangeal joint was most frequently treated.

VetBooks.ir

TIE-DOWN AND BREAKAWAY ROPING

Description of Event

Tie-down roping, previously called calf roping, is another timed roping event; however, it involves only one horse and rider and one calf without horns. Similar to team roping, the rider backs his horse into the roping box located to the right of the calf, which is confined in the chute. The calf is given a head start, the score, which varies depending on the length of the arena and the level of the roping event (professional calf ropers have a longer score compared with amateur ropers). A 10-second penalty is assessed if the horse and rider leave the roping box before the calf reaches the predetermined score line. The horse and rider chase the calf and the rider ropes it around the neck. The rider dismounts as the rope comes tight and must grab the calf's flank and put him on his side on the ground. The roper then ties three legs together with a pigging string that he carries during the run. The rider gets back on his horse, and the calf must stay tied 6 seconds or he is disqualified. As the rider dismounts, the horse comes to a sudden stop (Figure 9.32) and backs up to take excess slack out of the rope. This allows the roper to catch and flank the calf. The calf roping horse constantly works the rope or keeps it tight throughout the entire run, placing a tremendous amount of pressure on the hindlimbs. A good tie-down roping time is 8–9 seconds.

Breakaway roping is similar to tie-down roping except the ropers are women or children and the rider does not dismount and tie the calf. The roper ropes the calf around the neck with a breakaway rope—a normal rope equipped with a breakaway device that releases the calf as soon as the rope becomes tight. Horse and rider chase the calf, the calf is roped around the neck, and the horse stops quickly, allowing the rope to come tight, at which point the breakaway rope opens. Time is stopped when the rope breaks free. A good time is 3–4 seconds for the run.

Figure 9.32. Tie-down roper after roping the calf. As the roper dismounts, the horse comes to a quick stop and backs up to take the slack out of the rope, allowing the roper to tie the calf.

Musculoskeletal Injuries

The stop is critical and demanding in these horses. The horses are running at top speed and then must come to a complete stop very quickly. Hindlimb lameness issues are very common. The most common musculoskeletal injuries seen by the author are:

1. Distal tarsal joint OA
2. Medial femorotibial joint pain or arthritis
3. Hindlimb suspensory ligament desmitis and hindlimb flexor tendinitis

VetBooks.ir

4. Hindlimb fetlock OA
5. Hindlimb pastern joint OA
6. Forelimb foot pain

BARREL RACING

Description of Event

Barrel racing is a timed event. The pattern consists of three barrels (55-gal. steel drums) in a cloverleaf pattern. The distance covered for the pattern varies with arena size, but generally the distance from the starting line to the first barrel is 14–18 m. The distance between the first and second barrel is 21–27 m and between the second and third is 27–32 m. The horse and rider start at the alleyway or entrance into the arena, run at full speed to the first barrel (the contestant chooses to take the right or left barrel first), and then slow down (rate) and complete a 360° turn around the first barrel. The horse and rider then speed up and run toward the second barrel and turn 360° around it (Figure 9.33), repeat the process with the third barrel, and then sprint to the finish line. The fastest time to complete the pattern varies with arena size, but a good run for a large arena pattern is 15–16 seconds. If a rider gets too close to a barrel and tips it over, a 5-second penalty is assessed. If the horse and rider fail to negotiate the pattern correctly, they are disqualified.

Although the event is called barrel racing, it is important for the veterinarian to realize that these horses do not sustain the same type of injuries encountered by flat racing horses. The barrel horse does not run at top speed over long distances like flat and steeplechase racehorses; thus, injuries generally associated with speed and fatigue (such as superficial flexor tendinitis or metacarpophalangeal and carpal chip fractures) are usually not common in barrel-racing horses.

A recent study evaluated musculoskeletal injuries sustained by more than 100 horses used solely for barrel racing.[2] The median age was 9 years and the horses weighed an average of 509 kg. Sixty percent were examined due to an owner complaint of lameness, and 40% because of a change in the horse's performance. The most common performance problem reported by owners was that the horse refused to turn correctly around the first (usually right) barrel or ran past it and down the arena. Other complaints included a decrease in the horse's speed, failure to enter the arena, and failure to take the correct lead around the barrel.

Figure 9.33. Barrel horse and rider turning a barrel.

Musculoskeletal Injuries

The right forelimb was most frequently affected by lameness (48%), followed by the left forelimb (43%), left hindlimb (26%), and right hindlimb (21%). Bilateral forelimb lameness (26%) was more common than bilateral hindlimb lameness (5%). The majority of horses that had a performance problem related to the first (right) barrel had right forelimb lameness.

The most common musculoskeletal problems diagnosed in horses used for barrel racing were forelimb foot pain only (33%), distal tarsal joint OA only (14%), suspensory ligament desmitis (13%), forelimb foot pain with distal tarsal joint OA (10%), and bruised feet (9%). Eighty-one of 118 (69%) horses had the affected joint(s) treated with intra-articular medications.

The majority of barrel horses begin the cloverleaf pattern by going to the right barrel. The horse runs at full speed and then slows to turn 360° around this first barrel. The first barrel is the hardest to turn because at this point in the pattern, the horse is at maximum speed. As the horse turns to the right, the inside right forelimb may be under great strain. As the horse approaches the two left turns (second and third barrels), its speed is slower than it was for the initial approach to the first barrel, which may account for slightly less left forelimb lameness. Perhaps these horses refuse to turn sharply to the right because they have subtle right forelimb lameness and are trying to avoid a painful stimulus. This has been previously suggested by other veterinarians who work on barrel racing horses.

REINING HORSES

Description of Event

Reining horses are judged individually as they complete 1 of 11 specified patterns (Figure 9.34). One or more judges score each horse between zero and infinity, with 70 denoting an average score. Each horse automatically begins the pattern with a 70. The judge can either add or deduct up to 1.5 points on each maneuver in half-point increments based on the quality of the maneuver. Penalties are also allocated for minor deviations from the pattern; major deviations result in a zero score for the go. As the judges watch the execution of the pattern, individual scribes keep track of each judge's maneuver scores as well as penalty marks on a score sheet. Scores are tabulated and announced at the end of each run.

The judge's sheets with individual maneuver scores, penalties, and total scores are then posted for the benefit

VetBooks.ir

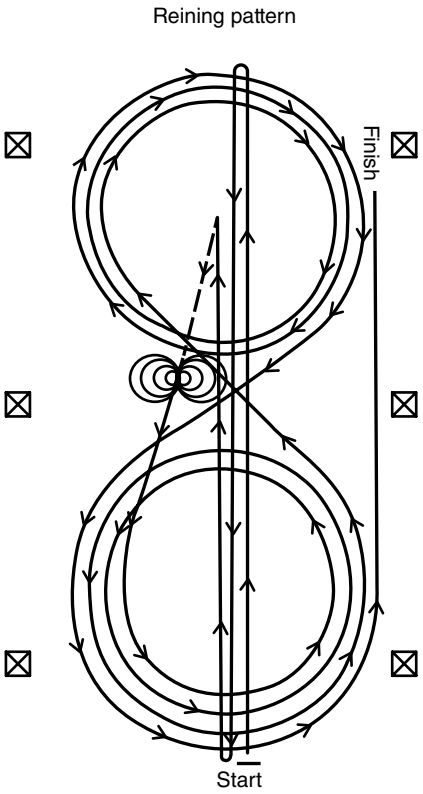

Figure 9.34. Reining horse pattern.

of the exhibitors following each class. In scoring, credit is given for smoothness, finesse, attitude, quickness, and authority when performing the various maneuvers. Controlled speed in the pattern raises the level of difficulty and makes the reining horse more exciting and pleasing to watch. An increased level of difficulty is rewarded with higher scores if the maneuvers are performed correctly.

Musculoskeletal Injuries

The precision maneuvers performed at top speeds by reining horses require implementation of good preventative and balanced shoeing principles. These horses start from a standstill, gallop at top speed, and come to a 30-foot sliding stop. They perform turnarounds in which their body whirls around the inside hindfoot as the forelimbs reach and cross over in a precise and smooth motion.

These horses are often plagued with distal limb bone bruises, fractured splints, and coronary band injuries from the turnaround spins. The high-speed and lateral movements also lead to unilateral hoof impaction and forces that can cause high quarter cracks and blow out cracks.

Half-round shoes are often used on the front feet to ease break-over in all directions, especially with all of the lateral movement that these horses are required to perform. However, some trainers feel that the web of the half round is not wide enough for support and prefer the rounded edges of polo or rim shoes on the front feet. The sliding stops require a sliding plate on the hindfeet

Figure 9.35. Sliding plate used on the hindlimbs of reining horses so that they will slide after a stop. *Source*: Courtesy of Jeff Ridley.

(Figure 9.35). These are usually made from 0.75- to 1.25-inch × 0.25-inch flat steel. The extended heels add support and balance to the stop, and the extended heels rarely extend past the heel bulbs so that they do not cut the opposite leg during the turnaround. Most seasoned horses wear a 1-inch sliding plate throughout the shoe with equal length branches, which provides good support and adequate traction.

Many reining horses are plagued with hindlimb tendon and ligament injuries, of which hindlimb proximal suspensory desmitis is most common. This is likely due to the extensive sliding stop that they are asked to perform.

CUTTING HORSES

Description of Event

Cutting horses were born of necessity on the open grass plains of West Texas. They provided big ranches without barbed wire fences with the only means of working vast cattle herds. The task of the horse was quite simple, at least by definition. Guided by his rider, the cutting horse would enter a herd of cattle quietly and deliberately. A single cow was cut, or separated, from the herd. The cow's natural instinct is to return to the safety of the herd. The cutting horse, through breeding and training, controlled the calf with a series of moves and counter moves. The speed, agility, balance, and quickness of the cutting horse kept the cow from the herd, where other cowboys would hold the cut. The horse and rider would reenter the herd again and again, cutting cattle out until the work was done.

Training of today's cutting horse begins early in its 2-year-old year with the goal of having a competitive 3-year-old futurity horse. After 90 days under saddle, the horse is introduced to cattle. The objective is to have the horse instinctively anticipate and mimic the movements of the cow, using quick stops and turns, while receiving minimal instruction from the rider. Reining the horse is permitted only to make the cut of a single

VetBooks.ir

cow from the herd. After the cut is successfully made, the reins are placed in a relaxed position on the horse's neck, and only leg cues are permitted from the rider during the actual working time. The instinctive ability of the working cow horse to contain the individual cow provides the excitement of competition in cutting. During the competition, the horse and rider are judged on how smoothly the cow is separated and kept from the herd, keeping the cow in the middle of the arena and having the horse work without hand cues from the rider. Each contestant gets three cows per performance. The rider and horse as a pair begin the competition with a score of 72, going up or down from there; a 74–76 is a good score.

Musculoskeletal Injuries

Due to the twisting and quick side-to-side movements (Figure 9.36), these horses are plagued with numerous hindlimb, pelvis, and thoracolumbar problems. One retrospective study has documented poor performance and musculoskeletal injuries in 200 horses used solely for cutting (Dabareiner RM et al., unpublished data). The majority of horses were Quarter horses with a median age of 5 years. The most common performance complaint by owners was that the horse would not reverse direction to follow the cow (55%), followed by improper stopping (18%). On physical examination, 70% of horses were noted to have thoracolumbar pain upon back palpation. Eighty percent of horses had peripheral or intra-articular diagnostic anesthesia performed to localize the source of lameness. One hundred twenty-six of 200 horses (63%) had hindlimb lameness only. The most common hindlimb lameness was pain originating from the medial femorotibial joint in the stifle (40%) followed by distal hock pain (20%) and hindlimb suspensory desmitis. Forelimb lameness was uncommon with proximal suspensory desmitis and foot pain being most common.

Figure 9.36. Twisting and rotation of the body as the cutting horse mirrors the movement of the cow.

Radiographic abnormalities of the joints may not be apparent in young cutting horses with stifle or distal tarsal joint inflammation. Treatment options consist of short periods of rest combined with NSAIDS and often IV sodium hyaluronate. Most trainers and owners prefer to keep the horse in work and elect for intraarticular medication of the medial femorotibial joint and/or both the distal intertarsal and tarsometatarsal joints with a combination of corticosteroids and sodium hyaluronate. Many of these horses will also be painful to palpation in the lumbar region of the back.

In horses with evidence of soft tissue injuries or radiographic changes, longer periods of rest are usually required. Hindlimb proximal suspensory desmitis does occur in cutting horses. Mild cases with minimal sonographic changes respond well to 6–8 weeks of stall rest combined with local injection of hyaluronic acid and corticosteroids. Horses with chronic, severe lesions require additional therapies and usually have a guarded prognosis for returning to athletic function.

Young cutting horses with hindlimb lameness may suffer concurrently with thoracolumbar myositis. These horses are painful on palpation of the back. They are often agitated when saddled or mounted and unwilling to stop or perform. Therapy is aimed at reducing the local inflammation and preventing muscle spasms. Rest is indicated but rarely is an option due to the horse's performance schedule. Systemic use of muscle relaxants such as methocarbamol (10-mg/kg PO BID for 10 days) may be beneficial in mild cases. Others may respond to a single injection of triamcinolone acetonide (12–16 mg, IM) in addition to the muscle relaxants.

Specific localized pain may be treated successfully by injecting anti-inflammatories directly into affected tissues. The combination of methylprednisolone acetate (200–400 mg) and sarapin (50 mL) locally infiltrated aseptically with 2- to 3.5-inch needles is the author's treatment of choice. The injections are placed into areas of palpable pain by local infiltration.

Other management considerations are important to the recovery. Horses with low underrun heels in the hindfeet should be shod to encourage additional heel support and raise the heels. Typically, a 2°–3° lift is indicated in the stock horse. Evaluation of the saddle fit, type of pad, and specific pressure points when ridden should be considered.

Other modalities such as pulse electromagnetic field and ultrasound therapy have been very useful in keeping these horses in competition. Long warm-up periods of ponying the horse at a walk and trot for 30–45 minutes without the rider are always indicated. The trainer must be cautioned to avoid overwork and severe fatigue at all times.

Strain and subluxation of the sacroiliac joint are not uncommon in the working stock horse. Unlike other types of horses that incur sacroiliac desmitis as a result of slipping or falling, the stock horse often incurs this type of injury from the twisting and rotation of the back and pelvis during work. This rotation is complicated by the weight of the tack and rider, who is attempting to maintain balance and remain stationary on top of the horse during sudden hard stops, turns, and bursts of speed.

Many of the symptoms observed with thoracolumbar myositis are also common with sacroiliac desmitis.

VetBooks.ir

A painful reaction to digital palpation of muscles in this region is common because of the bridging effect. The muscles undergo bridging during contraction to provide stability to the traumatized sacroiliac joint. This constant state of contraction leads to muscle fatigue, spasms, and pain. Unlike thoracolumbar myositis, observable pelvic limb lameness is often associated with unilateral sacroiliac strain and subluxation.

Clinical signs are extremely variable but include stiffness and alteration of gait, either bilaterally or unilaterally. Often the horse will show a right hindlimb lameness when the left hindlimb undergoes an upper limb flexion test or vice versa. Infiltration of local anesthetic into the suspected area of trauma may help in diagnosis, but seldom is 100% improvement achieved.

Therapy is similar to previously described treatments for thoracolumbar myositis. Deep intramuscular injections of methylprednisolone (400 mg) and sarapin (50 mL) into the region of the sacroiliac joint have been very effective. Disposable needles at least 4 inches long are necessary to reach the affected area. Strict aseptic technique must be rigidly followed. Concurrent systemic therapy with NSAIDs is beneficial in sacroiliac desmitis. All classes of significantly lame horses with sacroiliac instability and subluxation must have rest. Two to six months out of training is often necessary, with strict stall confinement for the first 30–45 days.

The unpublished study by Dabareiner RM et al. is the first clinical study that documented an increased incidence of hindlimb lameness versus forelimb lameness in any horse discipline. It is also the first to document the stifle as the most common joint affected in a specific discipline. Given the increasing popularity of the cutting discipline, this information should be very useful to clinicians working on cutting horses.

JUMPING, EVENTING, AND DRESSAGE HORSES

Omar Maher

VetBooks.ir

INTRODUCTION AND HORSES USED FOR THE DISCIPLINES

Jumping, dressage, and 3-day eventing constitute the three Olympic equestrian disciplines, included since 1912. Their modern form developed mostly from military institutes and in recent decades became a civilian sport. All three disciplines have become increasingly popular and are widely practiced at various levels of performance. The United States Equestrian Federation (USEF) assures the governance of the sports in the United States, and the Federation Equestre Internationale (FEI) at the international level worldwide.

Many breeds are used for these disciplines, especially at lower levels. As the level increases, particular breeds better suited for the disciplines become predominant.

The degree of specialization, adoption of specific training methods, the structure of the competitions, the selection of horses bred for them, and the level of competition predispose these horses to specific occupation-related injuries.

Dressage

Dressage is a challenge of combining the need for balance, obedience, suppleness, and hindlimb engagement. The objective is to have the horses move as asked giving the impression that the horse is doing it willingly and generously. The horse needs to move upon the slightest command from the rider with rhythm, looseness and suppleness, and energy while remaining straight and in contact with the bit.

Grace, power, athleticism, and balance are needed along with the compatibility for complete obedience. High-level dressage horses are almost exclusively within the Warmblood breeds, with a few Thoroughbred crosses and a few Iberian horses (Spanish and Lusitano).

A study comparing gait and conformation of several Warmblood and Spanish horse breeds (3 years old) including Hanoverians, Westphalians, Oldenburgs, and Selle Francais and Spanish saddle horses concluded that the German Warmbloods, in particular Hanoverians, were the most adapted for competitive modern dressage.[1] This is confirmed in the show rings, as Hanoverians are the most represented breed at the elite level.

Jumping/Hunting

Show jumping involves the athletic effort of jumping added to speed. This will require balance, power, and agility as well as the carefulness not to hit the rails from the horse. The objective is to jump a course obstacle with set distances between them, without knocking rails down or having the horse refuse a jump, in the minimal amount of time.

The level of horse/rider coordination is of extreme importance especially as the courses get more technical (turns and distances between obstacles) and the jumps higher.

Show hunting is specific to North America, and although it still requires jumping of fences without knocking down rails, more importance is given to the elegance of the jumping style of the horse and rider (Figure 9.37). The horses need to travel elegantly, always in balance with barely noticeable command from

Figure 9.37. A show hunter. Manners, way of going, and style of jumping are being judged. *Source*: Courtesy of Dr. Eric Swinebroad.

VetBooks.ir

HORSESthe rider and jump fluidly with ease, style, and scope. Competitions are scored subjectively.

Thoroughbreds, Warmbloods, American Quarter Horses, and their crosses are commonly used as hunters and jumpers. Several breeds of ponies are often used for children. The appearance of the horse, its proportions, and the jumping styles are important, especially for the hunters as they are judged subjectively. Many European Warmblood breeds (Selle Francais, Hanoverians, Dutch Warmbloods, etc.) have been selected for several decades, with the help of government run programs (i.e. Haras Nationaux in France), using objective data and rigorous selection programs to produce competitive show jumpers and are dominating the show circuits.

Eventing

Eventing consists of the consecutive combination of dressage, cross-country (named previously speed and endurance), and jumping tests. Horses must show proficiency in each one of these disciplines with the cross-country being the most important (Figure 9.38). Horses need to show some of the qualities needed for dressage and jumping, with added emphasis on speed and endurance. Competitions especially at higher levels are extremely demanding on the horse's physic as well as relatively dangerous for both the horse and rider.

Partially because of their relative lesser financial value, and because of the need to be proficient at the different tests, event horses often get into eventing as a second career (often after being suboptimally successful racing). Because of the accrued need for endurance and speed for the cross-country phase, most of the elite event horses are Thoroughbreds or Thoroughbred crosses. Australian, New Zealand, and Irish Thoroughbreds are particularly appreciated at the elite level because of their bigger frame.

STRUCTURE OF TRAINING AND COMPETITION

In comparison with racehorses, training of horses used for dressage or jumping starts much later. Horses are usually broken at 3 or 4 years of age. Often it is not until they are 10–12 years old that they reach their prime in performance.

Dressage

Training of the dressage horse after it has been backed follows a pyramid training scale. At the bottom of the pyramid is "rhythm and regularity" (Takt) that should remain the same through the different exercises and their combination.

"Relaxation" (Losgelassenheit) or looseness is the second level: the aim is to have the horse relaxed, loose at the pole, chewing at the bit, swinging his neck and tail along the strides, and making smooth transitions between gaits.

The third level is "contact" (Anlehnung) at the bit and should result from the horse's forwardness instead of the pulling by the rider's hand.

Fourth level is "impulsion" (Schwung), which is created by storing the energy of engagement. "Straightness" (Geraderichtung) and "collection" (Versammlung) are the last two levels. Collection is the horse's ability to move its center of gravity more backward, by taking more weight on the back end, lowering it, and lightening the forehand. This requires more energy and muscular strength and allows the performance of more advanced exercises such as "piaffe" and "passage."

Competition usually starts at the age of 5; these horses can reach medium levels by age 7–8 and for some of them Grand Prix level by age 8 or 9. Under FEI rules, no dressage horse can show under the age of 6. Lower-level competitions require mostly balance and freedom

Figure 9.38. A cross-country obstacle.

VetBooks.ir

of movement, and then as the level raises, so does the demands on lateral work and collection. Under the USEF governance, competitions are progressively ranked as "training" and then first level through fifth level that corresponds to international competitions. In Europe it is divided in three progressive levels (L, M, and S). S corresponds to international competitions. International competitions (under FEI governance) starts at Prix St Georges, Intermediate I, Intermediate II, Grand Prix, and Grand Prix Special. Shows are also classified by order of competitiveness and difficulty as CDI* (Concours de Dressage International) to CDI***. Competitions are judged by anywhere from one to five judges who score each one of the movements/figures, giving a score from 0 to 10. The scores of each figure are added and converted into a percentage.

The training and competition surfaces are usually well cushioned, most often artificial. Between show grounds, the surfaces are very consistent and close to ideal and therefore rarely blamed for contributing to lameness problems.

Dressage horses do not perform any speed work or high impact work, which shields them from acute traumatic orthopedic injuries. Their training does involve repetition of similar exercises, and this makes them more prone to chronic accumulative stresses, resulting in subclinical injuries that can ultimately or periodically cause decreased performance, unwillingness to perform some tasks and sometimes chronic lameness.

The collected and lateral work (Figure 9.39), together with the fact that the saddle is placed relatively far back and that the rider is almost exclusively sitting, places unique strains on the dressage horse. This is accentuated by the fact that they have relatively long careers; as many compete until 15–20 years of age, most are at their peak between 8 and 14 and compete after that at lower levels with less experienced riders (as schoolmasters).

Figure 9.39. A dressage horse executing a half pass.

Jumping

Young jumper prospects are often free jumped before getting broken (between ages 2 and 3). In some breeding programs, weanlings are free jumped, and a first selection is done at 6 months, based on their jumping style. One study found that superior jumping style could indeed be detected at such age, although with some variability.[34] Also, foal jumping technique was found to improve with training and had a positive impact on their jumping technique at age 4 when compared with untrained foals, although the difference did not carry over when horses reached 5 years of age, rendering the early training unnecessary.[35]

After they are broken, training of the hunter jumper involves basic flat training, similar to basic dressage training, emphasizing collection and engagement work. After a few months of training on the flat, they are brought over fences. As the training continues, the fences usually get higher, but also horses are trained to jump combinations of fences and jump fences at different angles, at different speeds, and from different distances. A lot of work is put into teaching them to modulate their stride length and speed while approaching the fences.

Hunters are trained to jump in a relaxed fashion, giving the impression of jumping effortlessly, with the jump being a smooth continuation of the previous strides (jumps "in stride"). Completions are scored subjectively, on the style and cadence of the horse and rider. The height of the jumps starts at 2′6 and increases with the levels but does not exceed four feet. It is not uncommon practice to ride hunters or lunge for a long time just before the competitions to "take the edge off."

For jumpers, less attention is given to the style of moving and jumping. The competitions are scored objectively based on fallen rails, possible refusals and time of completion of the course. Height of rails varies between 0.90 and 1.50 m depending on the level of competition at the USEF level (although can go higher in Puissance), and up to 1.70 m for FEI competitions.

There is a multitude of classes and levels depending on the status of the rider (amateur vs. professional) and his age (adult vs. junior) and the age, experience, and quality of the horse (i.e. young horse classes). As the level rises, so do the height of jumps and the technicality of the courses.

The competition season can be exceptionally long for hunter and jumpers as there are shows running every single week of the year. It has become the norm for

VetBooks.ir

Figure 9.40. A show jumper. Note the hyperextension of the hind fetlocks.

horses to show several weeks every month and often travel long distances in between shows.

At higher levels horses will be conditioned and prepped for a few key events a year. At each show, hunters will tend to be ridden in several classes every day for up to 4 days of the show week. Jumpers will typically only be ridden in one to three classes that week. The longevity of jumpers' and hunters' careers and the particular strains placed by the jumping (Figure 9.40) also contribute to the development of occupational injuries.

Eventing

Event horses start their dressage and jumping training at the age of 4. Some of them have had prior career as a racehorse. The cross-country training includes the familiarization to the cross-country obstacles but more importantly the horse's fitness. Horses start competing at lower levels around the age of 5 and can reach international level by age 7–8.

Competitions start at the lower levels (pre-novice and novice) with 1-day events, during which all three tests are conducted. Different levels for the USEF-regulated competitions include in order of increasing difficulty, pre-novice, novice, training, preliminary, intermediate, and advanced levels.

International competitions are sanctioned by the FEI and are divided between Concours International Combine (CIC) and the more advanced (more jumps and faster rate) Concours Complet International (CCI). CIC competitions are further rated with one to three stars, increasing with the level of difficulty.

The top level of international competition is the 3-day event or "Concours Complet International." It is conducted over 3–4 days: 1 or 2 days of dressage, 1 day for the cross-country, and 1 day for the stadium jumping. The cross-country use is divided in four phases (classic form of the competition), including a trotting warm-up (phase A), the steeplechase (phase B), a cool down (phase C), and finally the proper cross-country course with 30–45 fixed obstacles (phase D). There is significant veterinary involvement before and during each phase of the competition because of how strenuous it is on the horse's physic.

The new format of the CCI competition eliminated phases A, B, and C in an attempt to make this less strenuous on the horses starting in 2002. However, there is still debate on the real effect on the horse by changing the format. The difference between CCI and CIC became only the number of jumps, distances, and level of difficulty.

CCI competitions are rated with one to four (highest-level) stars. There are very few CCI**** worldwide every year: the Olympic games, the FEI World Equestrian Games, the Burghley Horse Trials (UK), the Badminton Horse Trials (UK), the Australian International Three-Day Event in Adelaide (Australia), the Rolex Kentucky Three-Day Event (USA), the Luhmuhlen Horse Trials (Germany), and the Stars de Pau (France). A horse usually competes in only 1–2 CCI**** per year.

Horses competing at this higher level usually use 1-day events and lower-level competitions for training and as fitness indicators.

Overall, fences for the jumping and cross-country phase vary between 1 and 1.30 m in height and 1.40–2 m in spread (Figure 9.41). The cross-country distance varies from 2,500 to 7,200 m. The length and required speed for these competitions, especially at high levels, pushes these horses close to their metabolic and musculoskeletal limits.

TRAINING SURFACES AND SHOEING

Training surfaces between the three disciplines vary considerably. Dressage training and competition arena are relatively standardized, are most often made of artificial material, and provide great cushion. Three-day event horses are at the other end of the spectrum as they have to tackle various surfaces from hard ground to wet mud. Jumpers compete in a variety of surfaces, meant to be somewhat controlled, varying from sandy rings to grass fields, with increasingly synthetic geotextile footings.

Deep soft footing predisposes them to multitude of soft tissue lesions related to fatigue, including suspensory desmitis, superficial digital flexor tendonitis, inferior check ligament desmitis, and gluteal myositis. Hard surfaces predispose to impact injury, such as foot soreness, and joint trauma, bony bruising, and also axial skeleton pain. Competition on grass fields promotes the use of studs. Studs are placed (one to three on each shoe) on the shoes of the front or both front limb and hindlimb. The use of only one stud per foot offsets the lateral medial balance and results in abnormal torque forces.

VetBooks.ir

Figure 9.41. An event horse landing after a cross-country jump. Note the hyperextension of the front fetlocks. *Source*: Courtesy of Dr. Eric Swinebroad.

The use of studs on both sides of the shoe is less problematic from a lateral medial point of view but might exacerbate hyperextension of the forelimbs by preventing, upon landing from a jump, the normal minimal sliding of the front feet. The addition of a third stud usually on the lateral toe side of the shoe is also common in front shoes.

Synthetic geotextile footings are becoming increasingly prevalent. Although they are rarely too deep or slippery, they tend to negate the natural slipping that happens upon landing from jumps, increasing the torque forces and to some extent the impact at that phase.

Typically, a horse will get shod at least 1 week before any significant competitions, which will allow correction and sufficient rest in the case of a shoe set to tight or a nail issue. An added constraint on the competition horses from a shoeing stand point is that the constant traveling to shows may result in various farriers trim and shoe them (when the regular one is not set to travel). This can result in lack of familiarity of the farrier to the particular horse's feet and the loss of subtle fine-tuning.

LAMENESS DIAGNOSIS

Lameness evaluation on performance horses should be preceded by a good knowledge of the medical/orthopedic history, the current and past performances, and any changes in training, riders, or shoeing.

Palpation of the horse's joints, tendons, and back is performed routinely as well as limb flexion tests and finally evaluation of the spinal range of motion. Hoof testers are then applied. Horses are evaluated in motion, at the walk, on straight line, and on short circles and then at the trot and canter, ideally both on hard and soft surfaces. It can be extremely fruitful to evaluate some horses under saddle. Many elite barns have horses evaluated on a weekly basis to detect any small changes enabling them to address problems early on and modulate workload accordingly.

Barring constraints from the timing of future shows or regulations at the particular show (FEI vs. USEF vs. national regulations of other countries, for the limits of detection of traces of local anesthesia agents) and depending on the severity of the gait abnormality, local and/or regional blocks could be performed. Perineural nerve blocks are often combined with synovial blocks as needed to gain more specificity.

This process might take several days as it is often needed to let a block wear off before using more specific ones. This is especially true when trying to gain more information about foot lameness (after a positive PD nerve block, using intrasynovial distal interphalangeal (DIP) joint, navicular bursa (NB), or digital flexor tendon sheath (DFTS) blocks) or differentiating hindlimb proximal suspensory ligament desmitis from lower hock joint pain.

Results of the blocks are evaluated on the horse in hand or ridden. Having a rider is especially helpful for

VetBooks.ir

some mild lameness that are better felt than seen or when the lameness is best seen under saddle. It has been shown that some lameness can be unconsciously well hidden by riders and some would be exacerbated by such riders.[24] Experience of the veterinarian with the particular discipline plays a major role in the detections of such subtleties. This is especially true with dressage horses, when the veterinarian will also have to evaluate the trainer and rider as they could be causing a particular gait irregularity or not be able to guide the horse properly to perform a certain task. Having an experienced rider available to help evaluate such a horse can prove invaluable.

If the lameness cannot be localized, nuclear scintigraphy may be used. If the lameness is localized with nerve blocks, the whole array of imaging modalities could be used beginning with radiographs and ultrasound and when necessary cross-sectional imaging such as magnetic resonance imaging (MRI), computed tomography (CT), contrast-enhanced computer tomography (CECT), and positron emission tomography (PET) scan. MRI performed standing has gained in popularity and is often repeated to follow and monitor pathology even in competing horses.

COMMON LAMENESS PROBLEMS

All three disciplines confounded, the most common sources of lameness are:

1. Foot pain, including heel pain, solar pain, DDFT within the foot, DIP joint synovitis/arthritis, collateral desmitis of the DIP joint and navicular bone, and associated ligament injuries
2. Lower hock pain
3. Suspensory desmitis (fore- and hindlimbs, origin, and branches)
4. Axial skeleton: cervical, thoracolumbosacral, and sacroiliac pain
5. Superficial digital flexor tendon (SDFT) and inferior check ligament injuries
6. Fetlock osteoarthritis (OA)
7. Stifle injuries

There are marked variations regarding lameness problems not only between disciplines but also within disciplines between high- and low-level horses.[28] Dressage horses are significantly more prone to proximal suspensory desmitis (PSD) in the hindlimbs at both low and high level. Those competing at lower levels are more prone to navicular bone and associated ligamentous (impar sesamoidean and suspensory ligament of the navicular bone) injuries. Elite dressage horses are more prone to distal hock OA than the low-level horses. High-level show jumpers are more prone to DDFT injuries within the DFTS and the foot. The low-level horses are more prone to navicular bone and associated ligament injuries. Both have a relatively high incidence of distal hock OA. High-level event horses and high-level jumpers are significantly more prone than others to SDFT injuries. This is likely related to the fact that strain of the SDFT increases significantly with speed, fatigue, and height of the fences being jumped.[5,26]

Foot Pain

Foot pain is the single most common cause of lameness in performance horses. Assessment of foot pain starts with the observation of its conformation. Low-heel, long-toe conformations, underrun heels, and lateromedial imbalances predispose horses to soreness. Evaluation of the symmetry of the collateral ligaments of DIP joint and the presence of DIP joint effusion is better done by palpation. Hoof testers are applied carefully over the heels and sole and across the frog and the heels.

Most of the lameness of the foot will respond to PD nerve blocks, although such a block is not completely specific to the foot as it has been shown to diffuse and block out lesions in the pastern area even when performed the most accurately.[29,37] A positive PD nerve block should be interpreted as the lameness had its origin somewhere in the foot or pastern area. A positive DIP joint block will localize it to the coffin joint and the rest of the foot including the navicular apparatus and the sole, excluding the heels.[10,36,37]

A positive navicular bursa block will localize the origin of the lameness to the navicular apparatus or the sole.[38] A positive DFTS block if interpreted within 10 minutes should limit the origin of the lameness to its content with DDFT lesions[17] and sometimes distal sesamoidean ligament lesions found most commonly.

Heel Pain and Solar Pain

Heel pain and solar pain are more common in the event horses and jumpers than they are in dressage horses. Part of this is probably due to the type of surfaces they work on. Proper farriery guided with radiographs will often be sufficient. For solar pain, the use of full pads is often helpful. Pour-on fillers are very popular as well, but care must be taken not to over fill the shoe or under the plates, as it would cause undue pressure on the sole. Full plates are commonly used on hunter/jumper and dressage horses but pretty unpopular among the eventers as they can promote shoe loosening.

Heel pain and corns can be managed fairly well using onion shoes (open shoe with wide flare at the heels). Occasionally, in more severe cases of underrun heels, loading the frog using dental impression material, taped in without a shoe for 4–6 weeks, may help to promote some heel growth in a more vertical direction. Alternatively using frog-loading pads or a rolled heel can be useful.

Sheared heels affect mostly jumpers and starts often insidiously. The medial heel is often displaced proximally. Floating the affected heel and improving breakover by setting the shoe back and adjusting the lateral medial balance will usually resolve the problem, although this process can take 6 months to a year. Addition of a hoof supplement rich in Biotin seems to speed up hoof growth and improve hoof wall quality but is most often already being used.[23,32]

Navicular Syndrome, DIP Joint, and DDFT Lesions

Navicular bone and associated ligament injuries, DDFT lesions within the foot, DIP joint synovitis/arthritis,

VetBooks.ir

and DIP collateral desmitis can be difficult to differentiate using diagnostic analgesia only. Usually navicular bone and associated ligament injuries (impar ligament and suspensory ligament of the navicular bone) will usually block out not only to a PD nerve block but also to a DIP joint block and a navicular bursa block. Horses with DDFT lesions will block only partially to a PD nerve block and to a DFTS block if located in the distal tendon sheath and will block well to a PD nerve block and to the navicular bursa block or a DIP joint block if located within the navicular bursa and to a PD block and DIP joint block if the lesion is located at the level of the insertion.

Horses with DIP joint arthritis/synovitis will usually display effusion of the DIP joint and block well to a PD nerve block and to a DIP joint block. DIP collateral desmitis rarely displays palpable asymmetry, tends to block only partially to the PD block and a DIP joint block, and often requires a pastern ring block or a basisesamoid nerve block to resolve totally.

Navicular bone injuries such as subchondral bone cysts, fragmentation of the distal border, increased size of vascular channels, and enthesiopathy of the attachment of the suspensory ligament of the navicular bone are common and can be diagnosed easily using radiography. Early and/or less obvious lesions without a radiographic representation could be detected using nuclear scintigraphy or cross-sectional imaging such as CT or MRI. Bone bruising or edema is best seen on MRI STIR sequences.

Abnormalities of the impar ligament and distal aspect of the DDFT could be identified using transcuneal ultrasonography, although image quality is not always ideal, and there is a chance to miss subtle lesions as well as other lesions within the foot.

Effusion within the navicular bursa and some lesions of the DDFT proximal to the navicular bone can be seen with ultrasonography between the heel bulbs. This is enhanced when a microconvex probe is used because of the smaller footprint, which allows for a better contact. Injuries of the suspensory ligament of the navicular bone are harder to evaluate using ultrasonography.

Only 50% of the injuries to the collateral ligament of the coffin joints can be seen using ultrasonography. A small percentage has typical radiographic changes with osteolysis at the site of insertion onto the third phalanx.

Initial management usually entails rest and corrective shoeing, trying to adjust the hoof pastern angles and lateral medial unbalance. Bar shoes or onion shoes are often used as they support the heels and help decrease the sinking of the heels during the caudal phase of the stance on soft ground, theoretically diminishing pressure on the navicular apparatus and coffin joint. For suspect collateral desmitis, asymmetric shoes with a wider bar on the side of the injury are often used. Pads or fillers are often used as well. Onion shoes with a plate open over the frog are becoming increasingly popular.

DIP joint injection and navicular bursa injections with corticosteroids and hyaluronic acid or glycosaminoglycans are often part of the initial treatment. Alternatively, the use of biologics such as interleukin-1 receptor antagonist protein (IRAP),[13] platelet-rich plasma, or protein solutions (Pro-Stride™)[3] is becoming increasingly popular, as it seems to deliver clinical results on cases on which corticosteroids have failed. The other advantage is that you can use these products around shows without the worry about possible testing.

In recent years, polyacrylamide gels (Arthramid™ and Noltrex™) have become available as a new intra articular injection.[42] The gel acts initially as a joint lubricant and then gets integrated in the synovium improving its elasticity. Clinical results on OA cases have been impressive even in cases that were refractory to other modalities.

When this initial management fails or fails to last long enough, cross-sectional imaging such as MRI or CECT is warranted. MRI and CECT are both very valuable imaging modalities for injuries of the foot. In the author's experience both MRI on horses anesthetized and CECT are equally sensitive for most soft tissue lesions and structural bony lesions. MRI on horses standing has been (in the authors' experience) less sensitive and more susceptible to motion artifact. MRI presents the advantage over CECT to detect physiologic bony lesions (bone bruising or bone edema) on STIR. CECT offers the major advantages over MRI to be much faster and more importantly to allow CT guidance of needles to perform intralesional therapeutic injections.

Once a definitive diagnosis is made, the most appropriate treatment is indicated. This can consist in treatment of bone injuries (such as navicular bone edema or bruising or pedal osteitis) using rest, anti-inflammatories, and potentially bisphosphonates (tiludronate, clodronate, zoledronate). Collateral ligaments and DDFT lesions can be further treated using extracorporeal shockwave therapy (ESWT) high-intensity lasers or intralesional injections. Intralesional injections are performed under ultrasound guidance if the lesions can be seen or when available under CT guidance. The reader is referred to Chapter 8 for further information on these therapeutic options.

Lower Hock OA

Lower hock joint OA is also extremely common in sport horses. Most common complaints include lameness but more often the lack of engagement, loss of stride length, and poor impulsion. Complaints about jumpers and eventers will often include loss of scope jumping and the inability to stay centered while jumping. Dressage riders will complain about the inability to perform advanced figures necessitating significant collection such as piaffe or passage. Lameness is usually bilateral. Positive spavin flexion test is usually part of the findings. Radiographs can show various degrees of bone spurring, sclerosis, and joint space thinning with little correlation to the degree of lameness. In most cases intra-articular blocks of the tarsometatarsal (TMT) and distal intertarsal (DIT) joints improve significantly the lameness. In some cases, a tibial and peroneal nerve block is necessary to see an improvement. Most often, these joints are medicated with corticosteroids and hyaluronic acid or glycosaminoglycan as a therapeutic trial without blocking. Using a shoe with a small lateral plantar extension is thought to normalize the landing pattern of the foot and is often used in conjunction with joint injections.

VetBooks.ir

The choice of corticosteroid is often imposed by the show schedule and regulations: e.g. methylprednisolone has to be used at least 60 days prior to an FEI-regulated show, 15 days prior to an USEF-regulated show. Such treatment is often repeated at regular intervals to avoid losing performance and weeks of showing and help prevent the development of secondary issues.

Horses are often treated also with systemic injections of "maintenance" therapy such as glycosaminoglycans or hyaluronic acid.

In some cases refractory to steroids, biologics such as IRAP have been used with some unexpected success. In advanced cases, fusion of the lower hock joints could be performed either chemically (using ethyl alcohol[39] or monoiodoacetate[4,8,33]) or surgically. Horses will usually be able to perform at lower classes in such case.

When hock injections seem to improve the lameness but only for short periods, some thoughts should be given to the possibility of other injuries in the close proximity of the TMT and DIT joints such as proximal suspensory ligament desmitis.

Suspensory Desmitis

PSD is the single most common soft tissue lesion of especially dressage horses and hunter/jumpers. In the hindlimbs, PSD is likely due to the increased load placed by collection work in dressage and by jumping in hunter/jumpers and eventers. In the forelimbs, it is often seen with overzealous movers and related to the marked metacarpophalangeal hyperextension upon landing from jumps. Suspensory branch lesions are most common on the forelimbs in eventers and high-level show jumpers.[14]

PSD appears most often insidiously in the hind limbs, and lameness or loss of performance seems to subside temporarily to small periods of rest. The condition is often bilateral, and this delays recognition of the problem further. In the forelimbs, there is often a more acute lameness initially. Lameness is often more obvious on the circle with the leg on the outside. Palpation often can reveal sensitivity at the site on forelimbs, but interpretation can be difficult. Flexion tests can be positive especially carpal flexion test and spavin test, which can mislead the diagnostician.

Diagnosis is made using diagnostic analgesia: either direct infiltration of the ligament origin or specific nerve blocks. If subtle or no obvious lameness is present, using bilateral nerve blocks and reevaluating the horse for a change in its freedom of movement or seeking the help of an experienced rider to better evaluate the horse's ability to perform particular tasks may be necessary (especially for dressage horses) to aid diagnosis. Analgesia of the lateral palmar nerve at the level of medial aspect of the accessory carpal bone in the forelimb[6] and perineural injection of the deep branch of the lateral plantar nerve in the hindlimb[21] are gaining popularity as they are easy to perform and seem to decrease the incidence of unintentional analgesia of the carpometacarpal and TMT joints. Especially in the hindlimbs, the differentiation of distal hock pain and suspensory desmitis can be difficult. Performing a tibial nerve block can help differentiate between the two as it would theoretically block the proximal suspensory and not the lower hock joints. It also offers the advantage of not interfering with potential ultrasound evaluation. Such blocks could be performed on horses in hand or ridden if the lameness is most obvious then or only felt.

Ultrasonography is the most used way to diagnose PSD, evaluating possible enlargement, loss of fiber pattern, and core lesions. Ultrasound evaluation can be challenging especially when evaluating hindlimb suspensory ligaments, as the lesions are often subtle, and there is significant variation in the muscle fibers of the suspensory ligament that could appear as lesions to even experienced ultrasonographers. The transducer should be applied from medial plantar, and the ligament should be evaluated on cross-sectional and longitudinal planes. Comparisons with the opposite limb should be performed if there are any doubts about potential muscle fibers.

Radiographs could show bony remodeling at the level of the proximal palmar or plantar cortex and in more severe cases avulsion fractures. Nuclear scintigraphy can also be useful detecting increased radiopharmaceutical uptake at the level of the insertion of the proximal suspensory ligament, indicating a bony component to the lameness.

In questionable cases, the use of cross-sectional imaging MRI and CECT is extremely useful, not only to confirm lesions but also to rule out other causes of lameness responding to local analgesia of the site.

Treatment of PSD includes rest and controlled exercise and therapeutic shoeing (shoe with wide toe and thin branches to load the DDFT more), which is often sufficient treating for forelimb PSD but rarely resolves hindlimb desmitis. The addition of ESWT, laser therapy, and intralesional injections (of biological therapies) is helpful when dealing with hindlimb desmitis and has somewhat improved the prognosis. Ligament splitting is performed not only when a fresh core lesion is present but also in chronic cases.[19]

Fasciotomy and neurectomy of the deep branch of the lateral plantar nerve and neurectomy alone[2] have shown extremely promising results in horses with chronic hindlimb PSD as these horses are believed to have a neuropathy accompanying the compartmental syndrome created by the enlargement of the ligament.[43] Both fasciotomy and neurectomy are believed to reduce the compartmental compression: directly with the fasciotomy and indirectly by the neurectomy as it causes atrophy of the muscular fibers within the ligament, resulting in a reduction of the cross-sectional area.[30] Neurectomy of the deep branch of the lateral palmar nerve has also become increasingly used in recurrent front suspensory cases.

Suspensory branch injuries often have an acute onset. Enlargement, heat, and pain to palpation are usually features of the early stages. Definitive diagnosis is made using ultrasonography and periligamentous fibrous tissue; core lesions or enthesiopathy at the insertion on the proximal sesamoid bones can be seen. Rest and controlled exercise programs usually result in improvement. Laser therapy seems to help reduce clinical signs. Large core lesions could be treated with splitting or intralesional injections. Enthesiopathies respond well to ESWT. In some cases, the branch lesions communicate with the

VetBooks.ir

fetlock joints creating some degree of synovitis, requiring intra-articular medication of the joint and in certain cases arthroscopic debridement of the branch lesions.[27]

Axial Skeleton Pain

Cervical Pain

Cervical facet OA is an increasingly recognized condition affecting horses in several disciplines but more common in event horses and jumpers. A wide range of clinical signs can be linked to this condition including decline in jumping quality, resistance to sharp turns, and advanced dressage figures involving exaggerated lateroflexion such as canter pirouette, resistance to work in a frame, resistance to the bit, abnormal head carriage, forelimb lameness, neck stiffness, and in the most advanced cases neurological proprioceptive deficits.

Evaluation of range of motion (lateroflexion, ventroflexion, and extension) should be performed with minute attention to any range limitations, hesitation, or slowness. Some horses will compensate and avoid maximal flexion by turning their heads at the level of the atlantoaxial joint. Radiographs of the cervical column can be difficult to interpret as many horses will have evidence of some degree of OA of the last two intercervical facets (C5–C6 and C6–C7).[9] Nuclear scintigraphy will confirm the suspicion or reveal the sites when evaluating a horse for either poor performance or forelimb lameness that does not block out to the most commonly performed blocks.

Ultrasound is useful to evaluate the articular facets and identify osteophytes and effusion but is most often used to guide needles for therapeutic joint injections.

Horse with cervical pain associated with cervical facets OA can respond to physical therapy and osteopathic and chiropractic work. The vast majority will respond to intra-articular injections of corticosteroids using ultrasound guidance.

Back Pain

Back pain is frequent in performance horses and can manifest clinically through various performance limitations. The riders and trainers most often recognize it when it is accompanied by sensitivity to palpation, grooming, saddling, reactivity to tightening the girth and to the rider's weight, and bucking. Horses with chronic back pain will often loose some of their epaxial muscle mass.

Evaluation of reported behavior, back palpation and manipulation (inducing lateroflexion, dorsiflexion and extension at various levels), and observation of the horse lunging at the canter on soft ground (to evaluate the amplitude of the dorsiflexion) as well as the observation of the horse ridden will provide significant information.

Treatment of back pain will involve treatment of the initiating cause if identified, treatment of the primary lesion, and treatment of the associated muscle spasm and pain. Chiropractic work, physical therapy, and acupuncture, along with training modification, are complementary to the medical management.

The most common causes for back pain include the following.

Hindlimb Lameness Causing a Compensation Muscle Spasm in the Thoracolumbar Area

Treating the lameness usually will result in the resolution of the back pain within a few weeks. Treatment of the muscle spasm and pain will speed up the return to optimal performance and might be needed depending on the timing of shows.

Suboptimal Saddle Fit Creating Pressure Points or Restricting the Horse's Movement

Horses need to be comfortable in their tack to be able to provide optimal performance. The saddle should ideally be fitted to the individual horse. Adjustments should be made when the horse is in a state of fitness, and the fitting should be evaluated at rest but most importantly during work when the muscles are tighter and more voluminous to ensure that the saddle is not constrictive. Saddle should have a good area of contact with the horse and should not create pressure points. A veterinarian or saddle fitter experienced in the particular discipline should perform the evaluation and recommend/perform the adjustments as the movements that the saddles need to allow will vary depending on the discipline. Some saddle companies provide pads with pressure sensors to help evaluate the fitting of saddles. Alternatively, thermography could be used.

Rider

Evaluating the rider as a potential cause of back pain is always a delicate task and requires the veterinarian to be very knowledgeable about the particular discipline. Horses will have back issues that will be treated but would recur regularly. This situation presents itself most often with lower level riders that either sit crookedly or are heavy (relatively to the horse) and unbalanced.

Primary Muscle Strain and or Spasm

Primary muscle strain is usually acute, most common in jumpers and eventers, and presents with significant pain, swelling, and spasm. It usually is appreciated shortly after a significant workout. Treatment will involve anti-inflammatory therapy (icing and NSAIDS or a systemic dose of corticosteroids depending on the severity), rest, and muscle relaxants.

The more insidious and also more frequent muscle spasm requires finer back palpation to identify. Treatments are varied and include NSAIDS, muscle relaxants (methocarbamol), and epaxial muscle injections of trigger points or mesotherapy.

Epaxial muscle injection can be performed using 80 mL of sarapin, 10 mL of DMSO, and a dose of short-acting corticosteroid, injected using a 1.5-inch 21-g needle, following three parallel lines on either side of the dorsal spinous processes spaced inch apart, from mid-thoracic level, caudally to the sacroiliac area.

Kissing Spine

Kissing spines or dorsal spinous process impingement is one of the most common causes of primary back pain.

VetBooks.ir

The pain is chronic, and diagnosis is made using radiography (evidence of overriding spinous processes, with areas of bony sclerosis and bony lysis) or nuclear scintigraphy. The supraspinous ligament can also be affected and should be evaluated ultrasonographically.

Interpretation of radiographs, nuclear scintigraphy, and ultrasound of the supraspinous ligament should be performed with caution as many horses with no clinical signs of back pain will have abnormalities.[12,18] Using local anesthetics around suspected areas could be useful but should also be performed cautiously as it will also increase the amplitude of movement of normal horses.[20]

Treatment of impinging spinous processes involves injections of corticosteroids and sarapin in and around the affected interspinous spaces, muscle relaxants, NSAIDS, and bisphosphonates. Shockwave therapy is efficacious in some cases. Ancillary therapies (acupuncture, chiropractic work, etc.) and adaptation of the training aimed at encouraging dorsiflexion will complement the treatment. Refractory cases can be treated surgically (interspinous ligament desmotomy or partial resection of the spinous processes.[22]

Intervertebral Facet OA

Intervertebral thoracolumbar facet OA is to be suspected when horses have recurring back spasm and pain. Diagnosis can be made using nuclear scintigraphy, radiograph, or ultrasound. Facets are best evaluated on lateral oblique (horizontal 20° ventral–dorsal oblique) views taken from left to right and from right to left.[15] The use of local anesthesia and reevaluation helps confirm the diagnosis.[16] Treatment consists of intra-articular or periarticular injections of corticosteroids under ultrasound guidance and/or bisphosphonates added to the basic treatment of the associated muscle spasm. Physiotherapy to improve muscling is helpful for long-term management. Core strengthening exercises (such as baited stretches), riding or lunging aides to engage the hind end (Pessoa lunging rig, Equi-Band, and equivalents), and functional electrical stimulation (FES) are used most routinely.[31] FES has been really helpful to lower the spasticity of the muscle, as well as the quality of the muscling around the spine.

Sacroiliac Pain

Sacroiliac pain is relatively common, more so in jumpers and eventers than in dressage horses. The disease is usually bilateral but one limb is often more affected than the other. Severity varies widely but the most severely affected horses stand parked out and resent bearing weight on the most affected limb (complaint is often that the farrier is having a hard time shoeing the horse). Mild to moderate lameness is sometimes present, and some of the horses tend to "bunny hop" at the canter. Affected horses will often resist or show pain when the hindleg is picked up and raised enough to tilt the pelvis and are often sore to palpation/pressure over the tuber sacrale region.

Diagnosis can be reached using local analgesia around the joint (this should be done with extreme caution and never bilaterally, because of the risk of anesthetizing the sciatic nerve that will affect the horse's ability to walk and potentially stand). Nuclear scintigraphy using motion correction software can be diagnostic but is somewhat insensitive. Ultrasound evaluation of the dorsal sacroiliac ligament (transcutaneously) and of the sacroiliac joint itself (transrectally) can provide supportive information.

Therapeutic trials using periarticular injections of corticosteroids are used most often to confirm the diagnosis. Such injections are carried out blindly or with ultrasound assistance, using 8–10-inch spinal needles.[7,11] Treatment involves periods of rest for the most severe cases (4–6 months) and periarticular injections using corticosteroids and potentially sarapin for the least affected ones.

SDFT and Inferior Check Ligament Injuries

SDFT Injuries

SDFT injures are most common in event horses, somewhat common in jumpers especially at higher levels and rare in dressage horses. They almost exclusively affect the forelimbs. Presentations range from subclinical progressive tendonitis and peritendonitis (most common in eventers associated with cyclic repetitive loading and damage) to acute severe tendonitis with large core lesions (eventers and high level jumpers) that are most often related to one misstep on deeper footing and especially associated with the use of studs.

Diagnosis is easily made by palpation. Ultrasonography further characterizes the injury and allows follow-up.

Treatment is aimed in the acute stage at minimizing inflammation, using icing and NSAIDS to minimize edema and further fiber disruption. In extremely painful horses, placing the limb in a cast or a supportive boot seems to increase the comfort level. Supportive bandage and local anti-inflammatory ointments such as DMSO or diclofenac cream alternating with icing are helpful for the first few days.

After a few days, ultrasonographic examination is repeated. Large core lesions are treated using transcutaneous splitting. Treatment after that consists of rest and controlled exercise for 3–12 months depending on the extent of the injury, using ultrasonography to monitor progress and gradually increase the workload. The use of intralesional injection is becoming routine for such lesions using a source of stem cells (bone marrow, bone marrow concentrate, fad derived mesenchymal cells, cultured stem cells), a source of growth factors (platelet rich plasma or bone marrow supernatant), a scaffold (porcine bladder submucosa—Acell), or a combination thereof. Such injections are believed to improve the quality and speed of healing and decrease the rate of re-injury. The use of laser and therapeutic ultrasound is also popular.

Inferior Check Ligament Desmitis

This condition affects mostly jumpers and eventers in their mid-teens and younger dressage horses, almost exclusively on the forelimbs. Lameness presents acutely with swelling and heat at the site. Ultrasonography confirms the diagnosis, and treatments involve mostly rest and controlled exercise for 4–6 months.

VetBooks.ir

Intralesional injections of the inferior check ligament have not been rewarding in the authors' experience.

Some cases get complicated with adhesions to the SDFT that can be identified during a dynamic ultrasound examination (holding the leg and ultrasounding the area as fetlock flexion and extension are induced). Management of such complications involves surgical separation and 3–4 repeated injections of corticosteroids in between the SDFT and the check ligament 2 weeks apart.

Metacarpophalangeal and Metatarsophalangeal (MCP/MTP) Joint Injuries

Synovitis and OA of the fetlock joints are fairly common in older jumpers and eventers. Lameness is localized by a positive intra-articular analgesia or a low 4- or 6-point nerve block. Fragmentation of the proximodorsal aspect of the first phalanx is not uncommon and is better treated surgically, removing the fragment arthroscopically. Synovitis, with no evidence of radiographically/ultrasonographically visible pathology, usually responds well to intra-articular injections of corticosteroids and hyaluronan or glycosaminoglycan. Alternatively series of IRAP injections could be used. If the response to intra-articular therapy is incomplete or transient, advanced imaging (such as MRI) or exploratory arthroscopy is warranted. Severe bone bruising visible on MRI STIR sequences should be addressed and probably treated using bisphosphonates and rest to help prevent the development of subchondral bone cystic lesions.

Stifle Injuries

Osteochondrosis and Subchondral Bone Cysts

Osteochondrosis of the trochlea ridges of the femur and of the patella along with subchondral cystic lesions of the medial condyle of the femur is relatively frequent developmental disorders in Warmbloods. Therefore, radiographic surveys of yearlings during prepurchase examination are highly recommended.

Osteochondrosis lesions are treated surgically with debridement using arthroscopy, and prognosis is relatively good if the lesions are not too sizable.

Subchondral bone cysts are treated with either surgical debridement or injections of corticosteroids under the lining of the cyst,[44] but prognosis is not as good for a long career especially if the horse is older.[40] Preoperative treatment with a bisphosphonate reduces in the authors' experience the risk of postoperative enlargement of the cyst when debridement is elected.

Intermittent Upward Fixation of the Patella

This condition affects especially larger young horses and horses after a period of rest. The diagnosis is easy in the most severe cases and necessitates a finer observation in the milder ones who only "catch their patella." The best way to observe mild cases is during a transition from canter to trot or when they are being asked to back up.

Milder cases respond well to blistering of the medial and middle patellar ligament to induce scarring and thickening (injection of 0.5 mL of 2% iodine in almond oils at three levels in each ligament) and an injection (1 mL) in the gluteal muscles. More tenacious cases can be treated by ligament splitting,[41] and medial patellar desmotomy is reserved for the most severe ones as it has been associated with complications such as patellar fragmentation.[25]

Synovitis and OA

Synovitis and OA can affect either one or a combination of the three synovial compartments within the stifle. Ideally each one should be blocked during lameness examination separately. Radiographs and ultrasonography especially to evaluate the menisci are necessary. Osteophytes at the level of the medial tibial condyle are relatively common. If no soft tissue injuries are identified, intra-articular injections using a combination of corticosteroids and hyaluronan or glycosaminoglycan are warranted in each of the affected compartments. Alternatively IRAP could be used. If the injections do not provide soundness or if they do only for a short period, diagnostic exploratory arthroscopy is warranted.

Meniscal injuries are diagnosed after identification of one of the femorotibial joints as source of lameness, using ultrasonography or during exploratory arthroscopy.

Debridement of meniscal tears is warranted unless they are amenable to be sutured, and a period of 3–4 months of rest should ensue.[45]

Patellar Fractures

Patellar fractures are mostly seen in event horses and some jumpers. They are associated with moderate to severe lameness and effusion of the femoropatellar joint. Skyline radiographic view of the patella is necessary to fully evaluate the fracture. Most of the fractures are amenable to arthroscopic debridement, and the majority return to full work.

ACKNOWLEDGMENT

The authors thank Dr. Jack R. Snyder for his contributions to this chapter in the previous edition.

THE ENDURANCE HORSE

Todd C. Holbrook

VetBooks.ir

THE SPORT

The sport of equine endurance has grown substantially since the American Endurance Ride Conference (AERC) was established as the national governing body for long-distance riding in 1972. Under current rules, the AERC recognizes endurance competitions that cover distances of at least 50 miles/day up to a maximum distance of 150 miles in 3 days. Pioneer rides may be up to 5 days in duration; in that case, 1 day must be 55 miles, and the remaining are 50 miles.[8]

The sport originated in the United States, where the Western States Trail Ride 100-mile competition (also known as the Tevis Cup) has been held in the Sierra mountain range since 1955. Endurance events covering distances of 80–160 km have been regulated by the Federation Equestre Internationale (FEI) since 1982. The sport has subsequently undergone tremendous growth internationally. In 2010, a new world record was set in a 100-mile (160-km) endurance competition in Dubai, United Arab Emirates. The winning time was 5 hours, 45 minutes, 44 seconds, at an average speed of 27.77 km/hour.[2] The trend of faster speeds associated with less technically demanding competitions in international events in comparison to national events is well recognized.

Typically, AERC rides are composed of both limited distance competitions (25–35 miles) and AERC-recognized endurance competitions, ranging from 50 to 100 miles. Over the past 10 ride seasons (2007–2016) in the United States, the AERC recognized an average of 269 yearly rides in which 19,575 horses competed each year.[8] While completion rates typically vary with ride conditions and level of competition, the average completion rate over the past 10 AERC seasons has been 86.25%.[8] Completion rates for international competitions are not typically this high. In a recent review of 30,741 horse starts at 100–160 km FEI endurance rides—in 47 countries between 2008 and 2011, completion rate was 50.7%.[5] Furthermore, a notable inverse relationship has been documented between mean competition speeds and completion rate.[10] In both national and international venues, the primary reason for elimination from endurance competition is lameness.

ATHLETES AND EXERCISE CONDITIONS

The suitability of pure Arabians and Arabian crosses is well recognized for long-distance aerobic exercise. However, most endurance rides are open to horses of other breeds, with the exception of breed-sanctioned competitions (i.e. Arabian Horse Association).

Frequently, suitable athletes compete from the age of eligibility for 8–12 years. It is not uncommon for some horses to compete well into their 20s. The current minimum age limit is 5 years for AERC and novice levels of FEI competition.[8,9] FEI competitions are categorized by course difficulty: horses must be 6 years old to enter 1* and 2* rides, 7 years old to enter 3* rides, and 8 years old to enter 4* rides.[6]

Although most competitive horses in the sport are of Arabian influence, their individual conformation can vary widely. Those with a long competitive career usually have few striking conformational flaws; however many horses with less-than-perfect conformation (e.g. toed in or out, high/low heel, contracted heels, post-legged, sickle hocked, etc.) can be competitive in the sport. Coupled with the magnitude of distance covered, the environmental conditions in terms of both topographical terrain variation as well as heat and humidity extremes create exercise conditions that are among the most challenging of any equine sport. Lameness and metabolic disturbances are the two most common reasons for elimination during competitions.

VETERINARY CONTROL

Endurance is one of the most stringently controlled equine sports in terms of veterinary oversight during competition. Horses are initially examined prior to the ride to determine suitability to enter competition. The examination includes a basic physical and lameness examination. At the pre-ride inspection, joint or tendon sheath effusion and abrasions or scars are entered on the ride card horse diagram, similar to markings on a Coggin's form (Figure 9.42).[8]

The ride is divided into segments or phases. An examination determines fitness to continue at the end of each phase at a veterinary check point or "vet gate." Short rides may only have one vet gate, whereas 160-km competitions may have as many as 7. Physical examination parameters evaluated and recorded on the ride card at each vet gate include pulse and respiratory rate (PR), mucous membrane character, capillary refill time, jugular vein refill, skin turgor, gastrointestinal sounds, back and withers sensitivity, rubs or sores from the bit or tack, muscle tone, anal tone, gait, impulsion, and overall impression. Criteria are recorded on a ride card using a scale of A to D, with A considered normal (Figure 9.42).[8] Rectal temperature is often only measured and recorded in horses exhibiting signs of heat stress.

Horses must meet a pulse criterion that is set prior to competition (usually 64 beats/minute within 30 minutes of entering the vet gate). A cardiac recovery index is determined in conjunction with the lameness examination by assessing the heart rate before and 1 minute after initiating an 80-m trot (40 m out and back). After the trot-out, if the horse's heart rate increases by four or more beats, metabolic criteria coupled with other physical exam findings are scrutinized in more depth to

VetBooks.ir

determine fitness to continue competition. Horses with synchronous diaphragmatic flutter coupled with evidence of significant metabolic distress are eliminated from competition. Those eliminated from competition by the control veterinary staff are typically referred to a treatment veterinarian for further evaluation and treatment on site.

Lameness is evaluated on the American Association of Equine Practitioners (AAEP) scale of 1–5 (see Table 2.3). Competitors may not enter or proceed in the ride on a horse with lameness of grade 3 or higher. Typically the footing for lameness examination areas is well planned and controlled at international ride venues, whereas at regional AERC rides, the footing and terrain may be quite variable at the vet gates (Figure 9.43). Occasionally, when level topography is unavailable and the footing is inconsistent, the lameness examination can be more challenging.

Maximum ride times are typically 12 and 24 hours for 50- and 100-mile competitions, respectively. In most rides the top 10 finishers are evaluated 1 hour after completion to determine best condition (BC). In con-

trast to examinations during competition, the BC exam often includes limb palpation and mild flexion. Similar to the routine exams during competition, horses are evaluated for lameness at a trot. In addition, during the BC lameness examination, horses are also frequently evaluated in a circle in both directions. Performance-enhancing medications are not allowed during endurance competitions, and both the FEI and AERC governing bodies use random drug testing for prohibited substances.

THE LAMENESS EXAMINATION

It is not uncommon for an individual to perform several hundred lameness exams during any given ride, depending on entries, ride distance, and number of ride veterinarians. This provides a great training ground for students and new graduates as well as an enjoyable working environment for practitioners who are sports medicine enthusiasts.

As indicated above, lameness examinations during competition are typically limited to observation from a distance, with the exception of the foot evaluation. While limb palpation and joint flexion are used during the BC exam, this depth of examination during competition is typically reserved for horses that are eliminated to direct further diagnostics and treatment. If a soft tissue injury is suspected in horses with only a grade 1 or 2 lameness at a vet gate, the flexor surfaces are frequently palpated when considering elimination. Consistent examination of the foot also is important in these horses because removing a rock lodged in the frog sulcus or replacing a lost, displaced, or bent shoe may resolve or improve the lameness and allow the horse to continue (Figure 9.44). Thus, riders have the option to re-present for lameness evaluation after farriery.

VetBooks.ir

Figure 9.43. (A) Veterinary gate trot-out area for the FEI Young Riders World Endurance Championships in Verona, Italy, in 2017. (B) Veterinary gate trot-out area at an AERC ride near Poteau, OK.

Horses with grade 3 or greater lameness are eliminated from further competition and referred to the treatment veterinarian. Elimination of horses with grade 1–2 lameness is at the discretion of the control veterinarian and depends on the suspected underlying cause. Most horses with undetermined causes of lameness of this grade are allowed to continue, whereas elimination of horses with consistent sensitivity over the suspensory ligament or flexor tendons is prudent. Prior to elimination at FEI and AERC national championship rides, it is common for a panel of three veterinary judges to observe the trot-out and vote with the majority consensus taken.

VetBooks.ir

Figure 9.44. (A) 50-mile endurance horse with grade 3 lameness of the left front limb. Note the displacement of the medial branch of the shoe and the compression of the heel (arrow). (B) Medial heel bruise that was evident after shoe removal. The medial heel was floated and the shoe straightened and replaced. Subsequently, the horse was sound and continued competing.

COMMON CAUSES OF LAMENESS

Lameness is by far the most common indication for elimination from endurance competition. Based on AERC post-ride statistical reports, of 21,933 starts during the 2007–2008 ride season, 1,410 horses were eliminated for lameness, accounting for 44% of all eliminations. Of these, the majority were unlocalized front limb (45.9%) and hindlimb (23.4%) lameness conditions. Keep in mind that diagnoses at the vet gate are based on brief examination only, usually without even the benefit of hoof testers and definitely without the use of diagnostic nerve blocks. Considering the defined causes of lameness, hindlimb muscle comprised 9.4% of all lameness problems, followed by front suspensory (4.9%), front foot (4.4%), front tendon (3.3%), front muscle (2.5%), front joint (2.1%), hind tendon (1.1%), hindfoot (0.78%), other front ligament (0.71%), other hind ligament (0.64%), hind joint (0.57%), and hind suspensory (0.28%).[8]

Many causes of lameness in endurance athletes are transient, leading to elimination from competition on ride day but resolving after rest with or without the benefit of anti-inflammatory treatment. Often, the exact cause of lameness in these situations is not specifically determined. Recurrent problems or significant acute soft tissue or orthopedic injuries are more likely to result in a full diagnostic and therapeutic approach similar to that performed for any other sport horse.

Muscle Disorders

Certain occupational conditions are common in the sport of endurance, including exertional rhabdomyolysis and other muscle disorders primarily of the hindlimbs, back, and neck. While data regarding the prevalence of exertional rhabdomyolysis in endurance horses is limited, a recent prospective study of 101 endurance horses competing in four 50-mile distance races in the Northwestern United States identified a 4% prevalence of exertional rhabdomyolysis.[7]

Subclinical myopathy may also predispose to the development of compensatory lameness. In a study of 36 elite horses competing in a 160-km FEI 3-star competition, 22 horses that successfully completed had abnormally high mean creatine kinase (CK) activity (22,473 ± 41,192 IU/L) compared with pre-ride concentrations (702 ± 720 IU/L). Although there was no difference in CK activity between finishers and nonfinishers, two horses eliminated for lameness had the highest CK values (240,000–400,000 IU/L).[6]

Exertional rhabdomyolysis usually develops early in the ride (fewer than 15 miles), is often associated with anxiety, and may be influenced by cold weather and inadequate warm-up. Myopathy also develops late in the ride (more than 50 miles) and is associated with exhaustion or abrupt changes in footing (i.e. muddy hill work). Most commonly, the gluteals and lumbar epaxial muscles are affected. The gluteal and/or lower lumbar epaxial muscles may be affected asymmetrically, resulting in pronounced unilateral swelling or firmness in a specific area (e.g. middle gluteals). The most common gait abnormality is a shortened anterior stride phase at a walk. Further exercise is contraindicated with significant rhabdomyolysis, and aggressive treatment is warranted in most affected horses. The primary goal of treatment is fluid diuresis until gross pigmenturia is resolved. Analgesics may be necessary in some horses. Doses of flunixin meglumine and other toxic NSAIDs should be minimized in the face of dehydration. Portable biochemistry analyzers are commonly used by treatment veterinarians, at even small local endurance rides. Field evaluation of serum electrolytes, muscle enzymes, and renal parameters in these patients helps to guide therapy. Occasionally, endurance horses develop rhabdomyolysis upon resuming work after long-distance transport (road and air).

Although the efficacy of dantrolene in the treatment of acute rhabdomyolysis in horses has not been well studied, its role in preventing recurrent episodes is established. In treadmill studies, dantrolene sodium (4 mg/kg PO)

VetBooks.ir

reduced biochemical evidence of muscle damage in Thoroughbreds with recurrent exertional rhabdomyolysis.[3] In addition, dantrolene reduced recurrent episodes of rhabdomyolysis in racing Thoroughbreds.[1] Although dantrolene use during competition is prohibited, it is used in an attempt to prevent recurrent myopathy during training and/or long-distance transport of elite Arabian endurance horses predisposed to myopathy prior to resuming work.

Muscle spasms or cramps and muscle strains are also quite common in the sport. The gluteal muscles are commonly affected, but other muscle groups, including the gracilis, lumbar, triceps, biceps, forearm, and pectoral muscles, may be involved. Occasionally horses with muscle spasms are acutely painful; they may collapse and show signs similar to those of acute colic. These individuals usually benefit from prompt analgesic treatment. Most often an α-2 agonist (e.g. detomidine, xylazine) with or without a narcotic (butorphanol) is more effective and safer compared with high doses of NSAIDs, considering the likelihood of significant concurrent dehydration. Massage therapy, stretching or walking, and topical heat may help treat muscle cramps. On-site serum biochemical analysis in these patients is prudent because it may reveal electrolyte imbalances, necessitating correction.

Muscle pain affecting the back and skin sensitivity of the saddle and girth regions is common in endurance horses. It is likely that both are related to rider imbalance and poor saddle fit and compensatory back pain may develop secondary to hock lameness. In the neck region, sensitivity of the strap muscles in front of the shoulder (brachiocephalicus m.) is very common and likely develops as a consequence of forelimb lameness (usually in the feet or ankles) or fatigue.

More rarely, frank muscle tears may cause acute lameness. Occasionally, local hematomas may form. Rest and NSAIDs (post-rehydration) usually lead to full recovery.

Suspensory Desmitis

Forelimb suspensory desmitis (SD) is common in endurance horses, affecting both the proximal area and branches. Hindlimb SD is less common but likely has a similar pathogenesis, and the treatment options are identical. SD usually develops when local footing consists of deep sand, soft soil, or mud. Hence, in areas such the United Arab Emirates, SD is the most common cause of lameness in endurance horses. The diagnosis is suspected based on palpation of the limb and is confirmed by ultrasonography (Figure 9.45). The author's impression is that medial/lateral hoof imbalance predisposes endurance horses to suspensory branch desmitis. With branch lesions, usually only one branch is affected; therefore, notable swelling may be evident on palpation compared with the opposite branch or leg. In contrast, lesions of the proximal suspensory and body may be less obviously swollen, and diagnosis is usually based on sensitivity to palpation and ultrasound. Subtle, recurrent lameness associated with proximal SD may require diagnostic nerve blocks followed by ultrasonography for confirmation.

After an acute injury, the character of the ultrasonographic lesion severity may worsen over time, so serial examinations to follow lesion progression are recommended. Response to topical ice therapy can be dramatic and is warranted for the first 24 hours' post-injury. This should be followed by intermittent ice water or cold-water therapy and bandage support. After rehydration, NSAID treatment for the first 5–10-day post-injury is typical. The prognosis for return to function is good in horses with mild desmitis. Those with minimal to no ultrasonographic changes may only need 3–4 weeks of stall rest and hand walking before gradually returning to work under saddle, with an additional 4–6 weeks of walk/light trot intervals prior to returning to training work. With significant lesion size, long-term rest (minimum 6–8 months) is prudent. Horses with significant desmitis are best managed

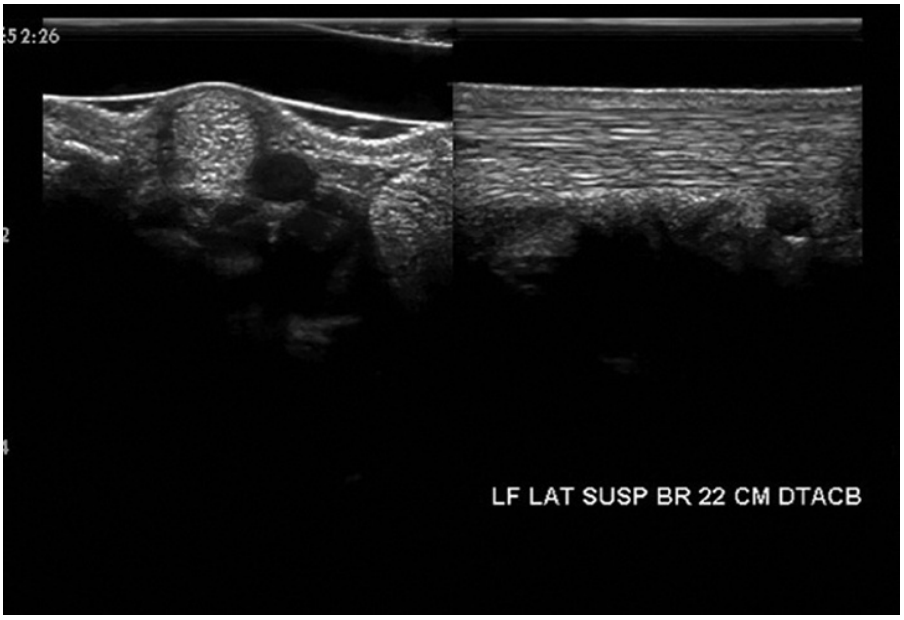

Figure 9.45. Ultrasonographic image of the lateral suspensory branch from an endurance horse that developed grade 3 lameness after 83 miles of competition. Enlargement and fiber disruption were minimal, and the horse returned to work after several weeks of rest. *Source*: Courtesy of Dr. Patty Doyle.

VetBooks.ir

with a well-controlled exercise program in which the intensity and duration of work is gradually increased over 6–12 months. This is often guided by improvement in lameness and ligament healing based on serial ultrasonographic evaluations.

Foot Lameness

Foot conditions are common causes of lameness in endurance horses. If time permitted more routine use of the hoof tester at the vet gate examination during endurance events, the AERC post-ride statistic results mentioned above would likely be quite different. Often evaluation of the digital pulse and comparison of its pre- and post-trot quality can be informative. Common conditions include foot bruising, corns, dislodged or sprung shoes, and heel bulb trauma from overreaching or other sources of injury.

Endurance horses are also subject to acute laminitis that may be related to repetitive concussive laminar trauma or associated with systemic exertional disease syndromes (e.g. heat stress, exhaustion, rhabdomyolysis, and renal failure). Aggressive medical treatment for acute laminitis is indicated in any endurance horse with prodromal signs thereof (shifting weight, forelimb lameness while turning, bounding digital pulses, etc.). Early treatment is important because consistent clinical prognostic indicators are unclear. It is quite common for certain horses to develop bruising at the coronary band and subsequent horizontal hoof cracks as the hoof grows out that serve as a timeline of when laminitis may have occurred at previous competitive rides (Figure 9.46). The majority of these horses complete the ride and do not develop lameness; thus, it is unclear whether this truly represents a laminitic event. Very rarely subsolar hematoma formation can cause acute lameness that can mimic acute traumatic laminitis in endurance horses.

Tendinitis

Superficial digital flexor (SDF) tendinitis is a common cause of lameness in endurance horses, especially in the forelimb. While tendinitis occurs less commonly in the hindlimb, it appears to be more prevalent in the sport of endurance compared with other disciplines. Deep digital flexor tendinitis occurs less commonly than SDF tendonitis but appears to have a predilection for the hindlimb in endurance horses. Clinical diagnosis is based on palpation and confirmed by ultrasonography. Thermography can be used to confirm regional hyperthermia associated with acute soft tissue injuries (Figure 9.47). Similar to other soft tissue injuries, early topical ice therapy and systemic NSAIDs after rehydration are warranted. Rest duration, rehabilitation, and prognosis depend on lesion severity and location.

Other Causes of Lameness

Acute joint sprain is not uncommon and is often influenced by the condition of the trail footing. Although the fetlock appears to be more commonly affected, slipping on trail can potentially result in soft tissue injury of any other joint. Interference injury, especially of the medial fetlock of the hindlimb, is common, and occasionally lameness can result (Figure 9.48).

Splints can cause acute lameness and are likely more common during training, especially in horses with less than ideal forelimb conformation. This condition typically responds well to conservative treatment and rest. Recurrent lameness is uncommon unless there is impingement on the suspensory apparatus that causes chronic desmitis.

Chronic OA affecting the metacarpophalangeal and hock joints is not uncommon. Prognosis in horses with significant degenerative disease is guarded with the exception of distal tarsitis, which may respond well to intra-articular corticosteroids, enabling continued work.

Catastrophic fractures have become more frequent in endurance horses coincident with the increasing speeds of competition, especially in the Middle East and at international venues. Fractures are most common in the forelimb, especially condylar fractures involving the metacarpo(tarso) phalangeal joint and, less commonly, the proximal phalanx.[4] Stress-related bone injury is presumed to play a role in fracture development in endurance horses. While no large-scale

VetBooks.ir

Figure 9.48. Interference lesion at the medial aspect of the right hind fetlock.

epidemiologic studies have been published, the prevalence of fractures per start in elite endurance horses appears to be similar to that seen in flat-racing Thoroughbreds.[4] Therefore, treatment veterinarians at endurance events should be prepared to stabilize distal limb fractures.

THE WESTERN PLEASURE HORSE

Sherry A. Johnson and David D. Frisbie

VetBooks.ir

UNDERSTANDING THE SPORT

Western pleasure remains one of the most popular show events within the spectrum of western performance classes offered by such prominent show associations such as the American Quarter Horse Association (AQHA), National Snaffle Bit Association (NSBA), and the American Paint Horse Association (APHA). From its origin dating back to the 1960s, the western pleasure sport served to showcase working horses' athletic ability to execute performance gaits comfortably and synergistically with their rider. The collected, soft gaits and overall calm demeanor of these horses embody the name of their sport and the enjoyable riding experience they have come to represent. The sport has since evolved into the platform for other western classes including trail, horsemanship, and western riding. As with any specialized equine discipline, an effective veterinarian must be closely familiar with the expected maneuvers, training schedule, and demands placed upon the western pleasure athlete.

Similar to other specialized equine sports, western pleasure has undergone several style transitions throughout the years. Excessively low head carriages characterized pleasure horses in the 1980s, while in the 1990s they are remembered for their extremely slow, mechanical motions. The AQHA has since redefined how the western pleasure horse should ideally move throughout the three judged gaits (walk, jog, and lope).[1] The western pleasure assessment criteria can be most easily grouped into the below three categories:

1. Correctness of each gait
2. Quality of the horse's performance including self-carriage, expression, topline, and softness of movement
3. Ease of performance with minimal cuing from the rider

The quality of movement and consistency of gaits remains the most intrinsic and sought-after trait of an elite western pleasure athlete. It is also a source of intimidation for many equine veterinarians who are not familiar with how the various gaits should appear.

When done properly, a western pleasure horse uses its core stabilizing muscles to round its back, lift its topline, and advance its limbs in free-flowing, coordinated motions with suspension and cadence. The horse should exhibit forward motion with significant hind end propulsion, especially while loping. The speed of movement is determined by the frequency and length of strides taken. According to the AQHA, the stride length in all gaits should be "of reasonable length in keeping with conformation." In addition, the horse should be able to cover a proportionate amount of ground with little effort. In essence, slow, deliberate, long-flowing strides are more rewarded than short, choppy, and uncoordinated gaits. Western pleasure horses should carry their heads and necks in a relaxed, natural position, without excessive motion, while allowing for balance and cadence reinforcement. The neck should be at or slightly above the level of the withers, and the nose should not be excessively behind or in front of the vertical. All of the maneuvers should be able to be performed on a reasonably loose rein, with a bright, willing expression (Figure 9.49).

The sport of western pleasure has been criticized for the appearance of horses performing maneuvers incorrectly, potentially leading to strained, unnatural, and uncoordinated gaits in the show ring. Most commonly, exaggerations of the desired gait qualities include head bobbing, a four-beat lope, and most

Figure 9.49. Western pleasure horse being shown at the jog.

VetBooks.ir

recently an "over-canted" lope. When head bobbing as a consequence of lameness has been ruled out, the abnormal motion is most often the result of decreased forward momentum, lack of self-carriage, and imbalance. Also a consequence of reduced forward momentum is a short, choppy four-beat lope instead of the desired well-defined, three-beat gait. The extra beat has given life to the term "tropping," referring to lack of gait coordination between the forelimbs and the hindlimbs. An "over-canted" lope refers to curvature within the sagittal plane (through the hip) that manifests itself as the outside hindlimb being placed further to the inside of the arena than the inside forelimb (Figure 9.50).[1] This curvature toward the inside of the ring is a tactic employed to enhance the appearance of hindlimb stride length, also known as the "deep hock" appearance. The result of excessive curvature is a labored, mechanical lope instead of the desired fluid, smooth gait. The AQHA has taken proactive steps in establishing judging continuity to ensure that class placements do not favor these altered gaits. As with many equine disciplines, however, there will likely continue to be trends that come and go.

Figure 9.50. An overly canted lope characterized by curvature within the sagittal plane (through the hip) that manifests itself as the outside hindfoot (arrow) being placed further to the inside of the arena than the inside front foot.

WESTERN PLEASURE TERMINOLOGY

In addition to understanding the sport, the equine veterinarian must also be able to effectively communicate with owners and trainers about specific ridden impressions or other lameness-related observations. Being fluent in specific colloquial terms used among horsemen will enable the practitioner to better successfully evaluate, diagnose, and treat the subtleties that distinguish the elite western pleasure athlete.

Western pleasure horses may often present to the veterinarian for decreases in performance, not necessarily overt lameness issues. Common performance complaints include a horse not "holding ground well," or not "engaging behind," for example. "Holding ground" typically refers to the amount of time the forelimb on the outside of the circle remains in late stance phase during a particular gait (usually the lope), before rolling into swing phase (Figure 9.51). Extending the late stance phase of a forelimb increases the amount of time the foot is in contact with the ground, ultimately slowing leg speed. When a horse is not "holding ground" well, the resultant lope can be quicker, choppier, and less fluid than the desired gait. In addition, not "holding ground" can lead to increased carpal flexion while loping, which is in contrast to the preferred "flat knee" or "quiet up front" action (Figure 9.51). Another commonly used phrase in the western pleasure industry is a horse's ability to "engage behind" (Figure 9.52). This phrase refers to the cranial–caudal distance that a horse is driving up underneath of itself (cranial phase of stride), resulting in maximal hind end propulsion and effortless self-carriage. Commonly used expressions will likely vary among horsemen, geographical region, and level of competition.

TRAINING AND SHOWING

Some western pleasure athletes begin their careers as yearling lunge line competitors, while others do not enter the show ring officially until their 2-year-old season. Young horses are first trained to perform the basic transitions and gaits and then are gradually taught the preferred head set and speed while being exposed to different riding environments. Low head carriage is typically reinforced not only through hand cues and exposure to a variety of bits but also through the use of draw reins (Figure 9.53) or martingales. Speed is often controlled through varying amounts of leg and hand pressure and sometimes even with a cue referred to as a "spur stop" where applying leg/spur pressure signals the horse to slow down or stop. Due to the variability in the training methods most commonly used, the AQHA has instituted comprehensive rules that safeguard first and foremost the welfare of the horse.[1]

Asking a horse to perform these gaits with specific limb placement at slow speed adds difficulty to an already technically challenging sport for both horse and rider. A similar comparison can be made to a weight lifter. A weight lifter may easily lift 100 pounds quickly, but when asked to lift that same weight with controlled, slow motion, the task becomes much more difficult. The same applies to western pleasure horses. To master flawless gait transitions with seemingly invisible cues from

VetBooks.ir

Figure 9.51. A western pleasure horse loping in the left lead. The right forelimb is "holding ground," while the left forelimb is "quiet" with minimal carpal flexion. In addition, the hind end is well engaged, allowing for maximal hindlimb propulsion.

Figure 9.52. Western pleasure horse demonstrating the desired hind end engagement that allows for cadence, self-carriage, and forward propulsion while loping in the right lead.

the rider, significant training is required, and fatigue-related soft tissue injuries are not uncommon. In addition, a variety of orthopedic conditions as a result of rigorous training schedules and strenuous physical demands are seen in western pleasure horses.

COMMONLY ENCOUNTERED MUSCULOSKELETAL ISSUES IN THE WESTERN PLEASURE ATHLETE

Because the art of western pleasure derives itself from subtleties, these horses are typically best evaluated for lameness while ridden or lunged. Diagnostic analgesia and the administration of all therapeutics must be performed in accordance with association-sanctioned guidelines for which the practitioner must be astutely aware. The clinician treating actively competing horses faces a unique set of challenges in managing physiologically complex orthopedic conditions; therapeutic plans must not only reflect the most appropriate therapy for the horse but also remain in accordance with existing medication rules.

FOOT PAIN

Not unlike horses of any other discipline, western pleasure horses experience concussive forces throughout their training. Although this concussion is not endured at speed, the repetitive nature and hours required to gain

VetBooks.ir

Figure 9.53. Draw reins that allow the rider to contact the horse's bit through a single, movable, pulley-like system are commonly used as training tools to reinforce the appropriate head and neck carriage required of western pleasure horses.

the slow motor control to perform the calculated gaits are a recipe for foot pain. Some believe that the characteristically small feet of today's Quarter horse, which may not accommodate force dissipation during stance phase, exacerbate the effects of concussion.

Specific farrier approaches are often employed to enhance the western pleasure horse's natural, flowing forelimb movements. Western pleasure horse's front feet are typically shod with aluminum shoes, often with 2°–3° wedges and rim pads to achieve positive palmar angles and weightless solar support. Medial to lateral balance is as important in the western pleasure horse as it is in any other discipline, with often special attention paid to aligning the hoof pastern axis and decreasing the toe distance, also known as "easing the break-over." This combination of shoeing enhances the "quiet" carpal action of the western pleasure horse characterized by minimal carpal flexion. The hindfeet are also typically shod with aluminum shoes.

The forelimb lameness of a western pleasure horse with foot pain can present with varying degrees of severity and is usually exacerbated with the limb on the inside of the circle. The typical differential list for a western pleasure horse with pain localized to a palmar digital (PD) nerve block is no different than that for horses of other disciplines, and the major rule-outs include coffin joint, navicular apparatus, or sole pain as a result of concussive forces/shoeing abnormalities.

In a 7-year demographic review of 17,458 horses that presented to a practice focusing on competing western performance horses, diagnostic analgesia was performed 9,329 times. The forelimb PD and abaxial sesamoid were the two most frequently performed nerve blocks (Table 9.1). Over the 7-year period, 24,910 joints were medicated, with intraarticular coffin joint therapy comprising 4,480 of those cases (Table 9.2). The navicular bursa and pastern joint were medicated in 355 and 113 cases, respectively (Table 9.2).

It is the author's experience that MRI abnormalities that occur within the front feet in this population of horses are similar to those of other disciplines.

Table 9.1. Frequency of diagnostic nerve blocks performed over a seven-year period on 17,458 horses in a western performance equine sports medicine practice.

Diagnostic block	Frequency performed
Forelimb PD	1,867 (20.0%)
Forelimb abaxial	1,695 (18.2%)
Low four-point	724 (7.8%)
Tarsometatarsal joint	704 (7.5%)
Forelimb proximal suspensory	648 (6.9%)
Hindlimb proximal suspensory	575 (6.2%)
Distal intertarsal joint	382 (4.1%)
Femoropatellar joint	362 (3.9%)
Fetlock joint (forelimb and hindlimb)	239 (2.6%)
Femoropatellar, medial femorotibial, and lateral femorotibial joints	235 (2.5%)
Scapulohumeral joint	103 (1.1%)
Medial femorotibial joint	100 (1.1%)
Carpus	91 (0.9%)
Sacroiliac joint	80 (0.9%)
Tarsocrural joint	82 (0.9%)
Lateral femorotibial joint	57 (0.6%)
Bicipital bursa	41 (0.4%)
Distal interphalangeal joint	26 (0.3%)
Elbow joint	24 (0.3%)
Carpal canal	18 (0.2%)
Hindlimb digital tendon sheath	15 (0.2%)
Forelimb digital tendon sheath	13 (0.1%)
TMT and DIT joint	8 (<0.01%)
Total diagnostic blocks	**9,329**

Observed pathologic changes include articular cartilage damage of the coffin joint, deep digital flexor tendinopathy, collateral ligament desmopathy, alterations of the navicular bone itself (sclerosis or bone marrow edema), and navicular bursitis. The array of abnormalities that have been realized with the use of high-field MRI continue to advance what is known about navicular disease in all equine athletes, a paradigm that will continue to evolve with continued research and clinical application.

FETLOCK OSTEOARTHRITIS

Similar to the racing Thoroughbred, the western pleasure horses experience pathologic manifestations due to the chronic, repetitive forms of loaded exercise that they undergo. Condylar fractures are far less common in the western pleasure horse compared with the racing Thoroughbred, but osteochondral fragmentation, synovitis, and eventual osteoarthritis with varying levels of articular damage, sclerosis (Figure 9.54), and bone marrow edema are commonly encountered in western pleasure horses.

In the previously described western performance horse demographic review, the fetlock joint was blocked for diagnostic purposes in 239 cases and was the sixth most frequently medicated synovial structure (N = 912; Table 9.1). Interestingly, the frequency of medicating to fetlock joint with interleukin-1 receptor antagonist protein (IRAP) was second only to the femoropatellar joint (Josh Donnell, Unpublished data).

PROXIMAL SUSPENSORY DESMOPATHY

Suspensory desmopathy of the fore- and hindlimbs is frequently encountered in western pleasure horses, albeit commonly with differing presenting histories. In the western performance practice demographic review, forelimb and hindlimb proximal suspensory analgesia was pursued 648 and 575 times, respectively (Table 9.1).

Horses subsequently diagnosed with hindlimb proximal suspensory desmopathy often present with a historic hindlimb lameness that improves for 2–3 weeks following hock injections. Following the transient improvement, however, the lameness returns and seems exacerbated with work in soft, deep ground. Trainers and riders also usually describe a lack of hindlimb propulsion, but this observation is not specific for only hindlimb suspensory desmopathy. The lameness is not consistently worsened when the hindlimb is on the inside vs. outside of the circle and is broadly characterized by a decreased cranial phase of stride and an unwillingness to push during late stance phase. Once the lameness has been localized to the proximal metatarsal region in accordance with ruling out the distal limb, standard radiographic evaluation of the tarsus is typically pursued, followed by both weight-bearing and non-weight-bearing ultrasonographic evaluation of the proximal suspensory ligament as previously described.[6,7]

Commonly observed pathologic changes include ligamentous enlargement (desmopathy), osseous remodeling (enthesopathy), fascial thickening (fasciitis), and loss of fat/muscle/fiber definition assessed with off-angle imaging. Ligamentous enlargement and osseous remodeling of the plantar aspect of the third metatarsal bone (Figure 9.55) singularly or in combination remain the most consistent, subjective findings in western pleasure horses. However, a portion of acutely lame horses with suspected suspensory injuries show no ultrasonographic evidence of abnormalities. The importance of contralateral limb comparisons cannot be overemphasized, permitting the clinician to more easily evaluate subtle changes that may otherwise go undetected. Of the 1,728 ultrasonographic evaluations performed in the practice demographic review, the forelimb and hindlimb suspensory ligaments were the most frequently evaluated anatomic structures with 871 and 365 exams performed, respectively (Josh Donnell, Unpublished data).

Horses subsequently diagnosed with forelimb proximal suspensory desmopathy commonly present with an acute lameness following a period of uncontrolled (excessive) lungeing or exercise. Alternatively, horses present with an acute-on-chronic, insidious forelimb lameness that worsens with work. A common complaint for these horses is not "holding ground" with the limb on the outside of the circle. Regardless of the history, the lameness is usually exacerbated with the limb on the

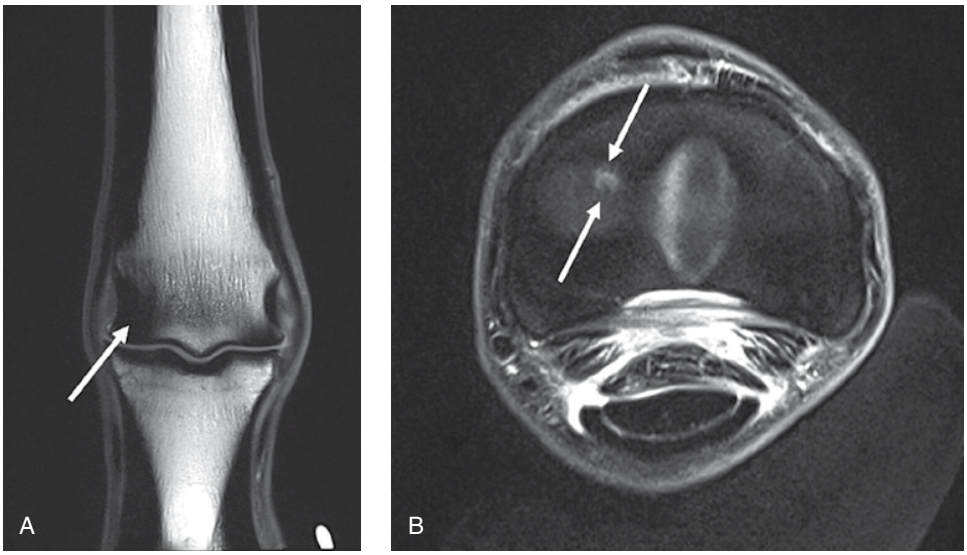

Figure 9.54. Magnetic resonance images from a 9-year-old western pleasure gelding with lameness localized to the fetlock joint that was refractory to intra-articular therapy. (A) Dorsal plane, T1-weighted image demonstrating markedly low signal consistent with severe sclerosis of the medial condyle (white arrow). Image acquisition parameters TR 600 ms, TE 12 ms. (B) Transverse plane, intermediate-weighted, fat-suppressed image demonstrating an ill-defined area of increased signal (white arrows) within the mid to dorsal aspect of the metacarpophalangeal joint. The linear striations in the oblique sesamoidean ligaments (most prominent in the medial distal oblique sesamoidean ligament) are normal architecture. Image acquisition parameters TR 300 ms, TE 40 ms (mildly T2 weighted).

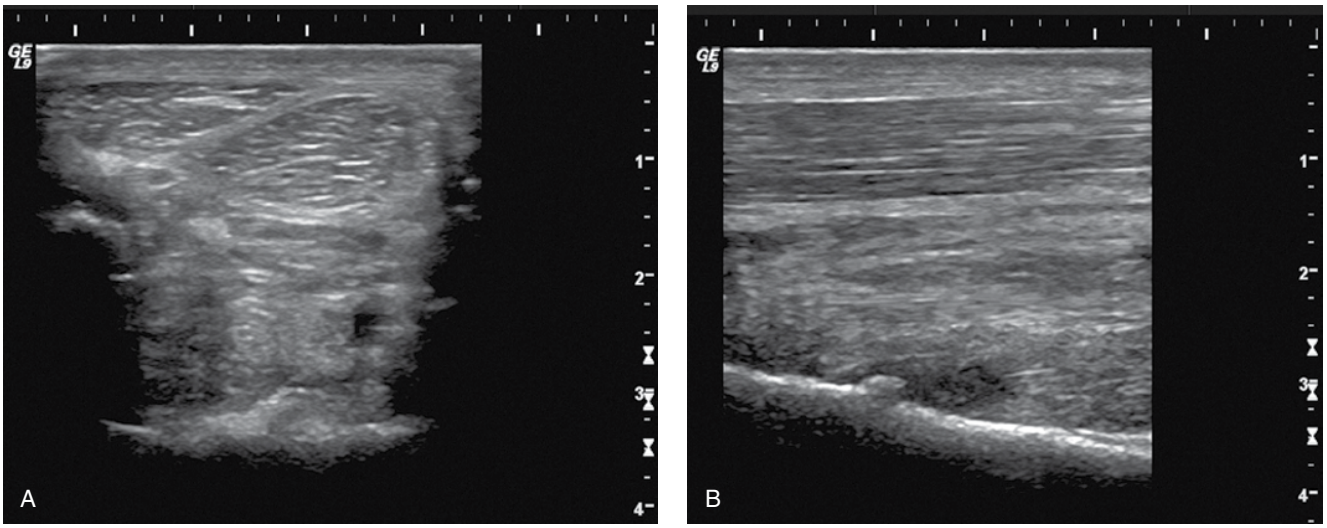

Figure 9.55. Ultrasonographic evaluation (non-weight bearing plantar (A-top) and weight bearing longitudinal (B-bottom)) of a 10-year-old all-around western performance horse with a hindlimb lameness localized to the proximal suspensory ligament. Moderate to severe chronic proximal suspensory desmopathy with associated enthesopathy and fasciitis was subsequently diagnosed and confirmed on MRI evaluation.

outside of the circle and periodically with the foot desensitized.[3] Standard diagnostic analgesia beginning with the distal limb is recommended, followed by radiographic carpal evaluation and ultrasonographic assessment similar to that described for the hindlimb (weight bearing and non-weight bearing).[6,7] Frequently observed ultrasonographic changes of the forelimb suspensory ligament include generalized ligamentous enlargement (desmopathy) with fiber hypertrophy that results in palmar displacement of the fat/muscle tissue. Osseous remodeling at the palmar aspect of the third metacarpal bone (enthesopathy) is also encountered to varying degrees. Subjectively, forelimb enthesopathy changes seem to reflect osseous resorption, resulting in a "scooped" appearance of the palmar metacarpus at the origin of the suspensory. Similar to the hindlimb, however, many western pleasure horses with pain localized to the proximal metacarpus show no ultrasonographic evidence of abnormalities.

If the severity of disease does not warrant cessation of work, forelimb and hindlimb proximal suspensory desmopathy is most successfully medically managed with extracorporeal shockwave therapy in combination with regional corticosteroid treatment, cryotherapy, and

VetBooks.ir

Figure 9.56. Standing stifle arthroscopy being performed with the use of an 18-auge disposable arthroscope. This technique has been used on numerous western performance horses to identify and characterize pathologic changes within the stifle.

rehabilitation. In the western performance practice demographic review, 1,212 cases received shockwave therapy to medically manage suspensory desmopathy (Josh Donnell, Unpublished data).

DISTAL TARSAL DISEASE

Pursuant to a discussion of hindlimb suspensory desmopathy, dialog regarding distal tarsal (hock) disease naturally follows thereafter as the two conditions are both commonly seen in the western pleasure athlete and often simultaneously.[2] In contrast to horses of other disciplines, a considerable frequency of juvenile (2–3 years of age) osteoarthritis is observed in the distal tarsal joints of western pleasure horses. The high prevalence of disease is attributed to the repetitive loading and torsional forces placed on the hocks of western pleasure horses during the collected lope. In addition, all pivots and overall directional changes in western pleasure are to be performed through hindlimb propulsion, of which the hocks and stifles are the driving force. With age and progressing levels of work, juvenile distal intertarsal (DIT) and tarsometatarsal (TMT) osteoarthritis may progress to partial or complete ankylosis.

Western pleasure horses with distal tarsal (DIT/TMT) disease typically present with a standard history of hindlimb lameness and lack of propulsion. A trainer may also specify that a horse is not "engaging" as they are capable of. It is the authors' subjective experience that primary TMT-related lameness is exacerbated with the affected limb on the inside of the circle, while primary DIT-related lameness is exacerbated with the affected limb on the outside of the circle, although the incidence of simultaneous disease is high. The TMT joint was the most frequently blocked synovial structure (N = 704) in the demographic review (Table 9.1). Subsequently, the TMT joint was the most frequently medicated synovial structure. The DIT joint was blocked second most frequently and was the third most medicated joint (Josh Donnell, Unpublished data).

In a study of 103 hindlimbs assessed with MRI, the majority of which were western performance horses, osteoarthritic changes of the DIT and TMT joints were the most common findings.[2] Other degenerative tarsal changes such as subchondral cystic lesions and intertarsal desmopathy that were underappreciated radiographically were identified with MRI.[2] With the increasing frequency of distal tarsal/proximal metatarsal MRI examinations, there will likely be further insight into the range of pathologic changes that occur in this complex region.

Stifle Disease

Similar to equine athletes of other disciplines, stifle disease is a consistent source of lameness for western pleasure horses. The standard clinical and dynamic lameness exam reveals hindlimb lameness of varying degrees with effusion typically present in both the medial femorotibial and femoropatellar joints. Unlike some of the other lameness conditions, stifle disease does not subjectively seem to be consistently worsened with the affected limb on the inside or outside of the circle, as it can be present during either scenario.

Diagnostic analgesia to investigate the source of the stifle lameness is standard as for other hindlimb gait abnormalities, with the authors routinely anesthetizing all three joints of the stifle simultaneously to effectively rule in or out the stifle as the source of lameness. Anesthesia of the individual stifle joints may then be pursued at a later blocking session if warranted. Over the 7-year study period, all three joints of the stifle were anesthetized 235 times, while the femoropatellar, medial femorotibial, and lateral femorotibial joints were individually anesthetized in 362, 100, and 57 cases, respectively (Table 9.1). Likewise, the femoropatellar joint was the most frequently medicated stifle joint being treated in 5,133 cases. Overall, the femoropatellar joint was the second most frequently treated synovial structure behind the TMT joint. The medial and lateral femorotibial joints were individually treated in 960 and 338 cases, respectively, while all three stifle joints were medicated simultaneously in 235 cases (Table 9.2).

Once the lameness has been localized to the stifle, standard diagnostic evaluation is performed both radiographically and ultrasonographically. The standard ultrasonographic assessment of the stifle should include

VetBooks.ir

not only a thorough evaluation of the articular environment but also an exhaustive consideration of the character of the medial meniscus and medial cranial meniscotibial ligament (MCMTL) during the non-weight-bearing portion of the exam. Commonly observed pathologic changes include meniscal degeneration, with MCMTL tearing (desmopathy) and associated osseous (insertional) remodeling (enthesopathy). These changes, in combination with synovitis and suspected articular cartilage damage, comprise the traumatic osteoarthritis complex frequently encountered in not only western pleasure horses but also western horses of many disciplines. Repetitive hindlimb loading and torsional forces are suspected, although the exact etiology and the temporal relationship of articular cartilage damage to meniscal instability (or vice versa) remain unclear.

With or without significant imaging abnormalities, a lameness that has been diagnostically localized to the stifle joint that remains refractory to therapeutic treatment usually warrants diagnostic and therapeutic arthroscopic surgery. The use of an 18-gauge disposable arthroscope to evaluate the stifle joint in the standing horse has been used successfully on horses of many western disciplines (Figure 9.56).[4] Used as a diagnostic tool, this procedure helps identify lesions and allows the clinician to characterize lesion severity in the standing, sedated horse. In turn, these findings can be used to decide whether to continue further medical and rehabilitative management or determine the need for standard, therapeutic arthroscopic surgery.

Axial Skeleton

Because precise head and neck carriage are central to the sport of western pleasure, the neck and associated supporting musculature is commonly investigated in cases of poor performance or perceived stiffness. Following a routine, dynamic lameness evaluation, special attention is paid to assessing the cervical spine for pain and functional restriction. Routine diagnostic evaluation of the cervical spine includes radiographic assessment using both lateral and oblique views, followed by ultrasonographic evaluation. The most frequently observed pathologic change of the cervical spine is facet osteoarthritis characterized by periarticular osteophyte formation, joint capsule thickening, and synovitis. In the demographic review, cervical facets within the neck were medicated 70 times with C3/4 being the most frequently treated articular facet (Josh Donnell, Unpublished data).

Although "back pain" is a common presenting complaint of owners and trainers of western pleasure horses, it is often difficult to fully determine whether the back is a primary or secondary performance issue. Once any contributing role of primary hindlimb lameness and/or saddle fit has been addressed, any remaining back pain is usually treated with combinations of a variety of therapies including systemic muscle relaxants, mesotherapy, acupuncture, regional infiltrations of sarapin and triamcinolone or shockwave therapy. The back/lumbar region was the fourth most frequent site that underwent shockwave therapy in the previously discussed demographic review (the suspensory ligament, hock, and palmar heel region underwent shockwave therapy most frequently). Shockwave therapy was also frequently used on the sacroiliac region, and the sacroiliac region was medicated in 807 cases (Table 9.2).

REHABILITATION AND MANAGEMENT OF THE WESTERN PLEASURE ATHLETE

With the increasing popularity and inherent athletic demands of the sport of western pleasure, there is vested motivation for preventing and managing injuries in the longitudinally competing western pleasure athlete. While owners and trainers still commonly pursue routine therapeutic joint injections, the value of physical therapy is also recognized both at home and during show competitions. Horses with previously diagnosed injuries are often aggressively managed with cryotherapy, systemic and topical non-steroidal anti-inflammatories, and support limb wraps (when indicated and as allowed per sanction guidelines). Similar to other disciplines, western pleasure athletes are also commonly maintained on systemic joint medications such as IV hyaluronate sodium* and/or IM polysulfated glycosaminoglycan.** Numerous commercialized therapeutic modalities are also readily accessible at the larger show competitions including cold-water spas, theraplates, electromagnetic blankets, and lasers of various classes. While the mechanism or role many of these modalities play in the treatment of musculoskeletal disease remains unknown, their increased availability, demand, and use by horsemen warrants mention.

When show horses are not competing, graduated, controlled exercise rehabilitative programs that incorporate the use of focused flexibility training, proprioceptive stimuli and core-strengthening exercises are being utilized with increasing frequency. In addition, with the increased availability of underwater treadmill units and the recognized role aquatic therapy can play in mitigating osteoarthritis, aquatic training is increasingly being used as an exercise alternative to maintain musculoskeletal fitness between competitions.[5] As the field of equine rehabilitation continues to evolve, advancements in tailored rehabilitation programs for specific injuries of various severities can be expected.

CONCLUSION

The sport of western pleasure with its deep-rooted traditions and novel stylistic approaches will likely continue to remain one of the most popular events of the western performance athlete. The specific, rigorous training and showing demands placed upon the western pleasure horse predispose them to sports-specific injuries just as other elite equine athletes. The most effective sports medicine veterinarians are able to recognize the physical stresses these horses endure to perform at the highest level possible. Therapeutic plans must not only reflect the most appropriate therapy for the western pleasure athlete but also remain in accordance with existing medication rules.

GAITED HORSES

David A. Wilson and Kevin G. Keegan

VetBooks.ir

EVALUATING GAITED HORSES FOR LAMENESS

Most horses in the United States move in four specific gaits; walk, trot, canter, and gallop. The walk and trot are symmetric gaits, and the canter and gallop are considered asymmetric gaits. Symmetric gaits are the easiest gaits to analyze for lameness because the earliest sign of lameness is gait asymmetry.

Lameness evaluation is more difficult in horses that typically use a gait that is not a walk or trot. There are many other gaits used by horses, either naturally or artificially by training, and these other gaits can be difficult to evaluate without sufficient knowledge or experience. The trot is by far the most common symmetrical gait, and the majority of horses in the United States are evaluated for lameness at the trot. Therefore, most veterinarians are very comfortable evaluating horses at the trot. There are both practical, meaning it is easier, and principled, meaning it is more accurate, reasons for doing so. The trot has a large vertical suspension phase that occurs twice during each stride, and that vertical suspension phase exacerbates a weight-bearing lameness because of the resulting effects on vertical ground reaction force, which is the kinetic measure most highly correlated with pain on weight bearing. The trot is also a symmetric gait not only by side (left vs. right) but also by forelimb vs. hindlimb, which allows more predictable effects on determination of compensatory lameness. All of these reasons make the trot easier and better to evaluate for most veterinarians.

WHAT IS A GAITED HORSE?

Technically all horses are gaited horses. A walk, trot, and canter are "gaits." However, horses are considered to be "gaited" if they perform a gait that is not a typical walk, trot, canter, or gallop.

Gaited horses typically perform one of the many intermediate speed four-beat gaits, which are collectively referred to as ambling gaits. These horses are selectively bred for their natural gaited tendencies and are generally smooth to ride (Table 9.3).[8] In most "gaited" breeds, the ambling gait is a hereditary trait. The gene DMRT3 controls the spinal neurological circuits related to limb movement and motion.[1,2,22] Even one copy of a premature stop codon mutation in the DMRT3 gene (*DMRT3:Ser301STOP*), which diverged from a common ancestral sequence within the last 10,000 years, will produce gaitedness.[2] However, some members of these breeds may not always gait, and some naturally trotting breeds not listed in Table 9.3 may have ambling or "gaited" ability.

A gaited horse moves at a walk, similar to non-gaited horses. They place all four feet down independently. The change in foot placement occurs as the speed increases. Most horses begin to trot at faster speeds, with forelimb and hindlimb footfall synchrony. However, in gaited breeds at speeds a little faster than a standard walk, they disassociate forelimb and hindlimb footfall. In gaited breeds this faster disassociated gait may be faster than a trot in a non-gaited horse. These faster than walking gaits have many different names, the flat walk, the running walk, the rack, saddle gait … the list goes on and on.

CLASSIFICATION OF GAITS

There are many ways to classify the various gaits of the domestic horse. Gaits may be classified as:

Stepping (walking) vs. leaping
Symmetrical vs. asymmetrical
Two beat vs. four beat
Lateral vs. diagonal sequence
Regular vs. lateral vs. diagonal couplet gaits

Stepping (Walking) vs. Leaping Gaits

Stepping (walking) gaits lack an airborne (suspension) phase in the stride. Each limb is on the ground >50% of the total stride duration.[4,10,17] Stance phases of the forelimb and hindlimb pairs overlap, with no period of suspension and no high vertical displacement of the body and no aerial phases of the stride. These are typically four-beat gaits that have a lateral footfall sequence of LH, LF, RH, RF.[20]

By contrast, leaping gaits have at least one or usually two aerial phases during each stride, when none of the limbs are in contact with the ground. With leaping gaits, primarily the trot and the pace, the concussion or ground reaction forces on the limbs are usually greater than those horses using a stepping gait at equivalent speeds. Therefore, this increased concussion in the leaping gaits tends to exacerbate the differences in weight bearing between limbs with pain and those without.

Symmetrical vs. Asymmetrical Gaits

The rhythm or cadence of the right and left footfalls defines gait symmetry. In symmetric gaits, the footfalls of a pair of feet (forelimb pair or hindlimb pair) are evenly spaced in time.[10,17] The forelimbs and hindlimbs move symmetrically, but the left and right sides are 180° out of phase.[9,12] The movement of each pair of feet (fore or hind) is evenly spaced in time. The symmetric gaits are distinguished from each other by the coordination between the fore- and hind limbs, the speed of progression, the relative duration of stance and swing phases, and the presence/absence of aerial phases.[10]

The trot and pace are at opposite ends of the spectrum considering symmetrical gaits, but they are the closest to total symmetry such that the right and left and fore- and hindlimbs move in virtual symmetry. In other

Table 9.3. Breeds of gaited horses.

Breed	Description/origin
Aegidienberger	Small gaited horse from Germany that performs the tölt gait and was created by crossing the Peruvian Paso with the Icelandic horse
American Saddlebred	Some have one or two, four-beat ambling gaits: the slow gait and the rack. Initially developed in the United States in the early 1700s by crossing imported Thoroughbreds to the native Narragansett Pacer
Campeiro	Small, stout Brazilian horse that has an ambling gait similar to the Marchador and was developed in the 1500s from Spanish and Portuguese imported horses
Campolina	Larger Brazilian breed with an ambling gait called the true marcha or *marcha verdadeira*, developed in 1870 by farmer Cassiano Campolina by crossing a Barb mare with an Andalusian sire. Further refinements were made over the years by crossing to various other breeds
Florida Cracker Horse	Also known as the Seminole and has a single-footed ambling gait, sometimes referred to as a "coon rack." Was developed from ancestors of Spanish horses brought to Florida in the 1500s
Icelandic horse or pony	Has an ambling gait called the tölt and was developed in Iceland from horses imported by the Norway settlers almost 1,100 years ago
Kathiawari	Has a swift, lateral pace and is indigenous to the Kathiawar peninsula in western India
Kentucky Mountain Horse	Has a naturally occurring single-foot ambling gait, was developed in Eastern Kentucky, and is related to the Tennessee Walking Horse.
Mangalarga Marchador	Have two natural ambling gaits—the diagonal *batida* and the lateral *picada*. Are native to Brazil and descended from Portuguese Lusitano stallions and Barb mares
Marwari horse	Has a natural ambling gait that is close to a pace, called the *refaal*, *aphcal*, or *rehwal*, and are from the Mariwar (Jodhpur) region of India
Messara horse	Has a naturally pacing gait, also known as a Cretan horse, found on the island of Crete off the coast of Greece
Missouri Foxtrotter	Has an ambling, four-beat broken diagonal gait, developed in the Missouri Ozark Mountains in the early 19th century
North American Single-Footing Horse	Has an intermediate ambling gait sometimes called the rack or paso largo and originated in the southern United States
Pampa, spotted, or pinto horses	Developed from the Brazilian Mangalarga Marchador, Campolina, and Brazilian crossbred horses
Paso Fino	Has a natural four-beat ambling gait and originated from Barb, Spanish Jennet, and Andalusian horses imported to the Caribbean from Spain as early as the late 1400s
Peruvian Paso	Has a natural ambling gait called a "paso largo," and originated in Peru from Spanish Jennet, Barbs, and Andalusian horses.
Racking Horse	Has a distinctive ambling single-foot gait called the rack which is similar to the running walk of the Tennessee Walking Horse from which it descended in the mid-1800s
Rocky Mountain Horse	Has a natural ambling four-beat single-foot gait and was developed in Kentucky in the late 19th century
Spotted Saddle Horse	Has an ambling gait other than the trot and was developed by crossing Spanish–American type gaited pinto ponies with several gaited horse breeds, including the Tennessee Walking Horse, Morgan, and Standardbred horses
Standardbred Horse	Has a two-beat diagonal gait (trot) or two-beat lateral gait (pace); developed in the 18th century in the United States from English bloodlines
Tennessee Walking Horse	Has a four-beat gait with the same pattern as a regular, flat walk, but significantly faster and was developed in the late 18th century from Narragansett Pacers and Canadian Pacers crossed with gaited Spanish Mustangs from Texas
Walkaloosa	Has an ambling gait other than the trot and has been available for many years but just recently was recognized as a breed registry

VetBooks.ir

words they have a regular rhythm. All other symmetrical gaits move with right and left symmetry (both fore and hind), but the forelimbs do not move in symmetry with the hind limbs.

In asymmetric gaits, the footfalls of a pair of feet are unevenly spaced in time. The canter and gallop are examples of asymmetric gaits.[17] Each asymmetric gait also has two forms; for example, the right and left lead canter. This asynchrony makes it more difficult to evaluate lameness because one must remember the movement in one form and compare it to the other form that must be subsequently observed. It has been shown that weight-bearing pain is displayed at the trot as asymmetry well before the asymmetric gait is substantially altered.[18] Therefore, most descriptions of lameness evaluation are focused on symmetric gaits, most commonly the trot.

The horse performs many symmetric gaits including the walk, running walk, rack, paso largo, paso corto, classic fino, paso llano, sobreandando, marcha picada, marcha batida, fox trot, tölt, pace, stepping pace, trot, passage, and piaffe. The coordination between the hindlimbs and the forelimbs, the speed of progression, the relative durations of stance and swing phases, and the presence or absence of aerial phases distinguish the symmetrical gaits.[10]

Two-Beat Gaits: Diagonal (Contralateral) vs. Lateral (Ipsilateral) Synchrony

The two-beat gaits of horses use a diagonal (contralateral) or lateral (ipsilateral) pattern. In the trot, there is diagonal (contralateral) synchrony, whereby the forelimb and the contralateral hindlimb move in relative synchrony with a period of suspension separating the diagonal stance phases.[11,14]

In the pace, there is lateral (ipsilateral) synchrony whereby the forelimb and the ipsilateral hindlimb move in relative synchrony and each lateral stance phase is followed by a period of suspension.[10,14] Both the trot and pace have a suspension phase, which makes the gaits relatively uncomfortable and more difficult for the rider. Because of the suspension phase, the vertical ground reaction force of each limb is greater than during other gaits at equivalent speed. These gait characteristics increase the severity of the observed lameness, particularly in weight-bearing lameness.

Four-Beat Gaits

Most symmetric gaits, other than the trot and pace, are four-beat gaits. Each hoof contacts the ground separately in a four-beat gait. The footfall sequence may be lateral, diagonal, transverse, or rotary (Figure 9.57).[11] There are no known rotary gates in the horse.

Lateral vs. Diagonal Sequence Gaits

In a lateral sequence gait, the order of footfall is LH, LF, RH, RF. Lateral sequence gaits have the footfall of a given hindfoot followed by the footfall of the ipsilateral forefoot. The fox trot is an example of a lateral sequence gait.

In a diagonal sequence gait, the order of footfall is LH, RF, RH, LF. Diagonal sequence gaits have the footfall of a given hindfoot followed by the footfall of the contralateral forefoot.[17] The marcha batida is an example of a diagonal sequence gait.

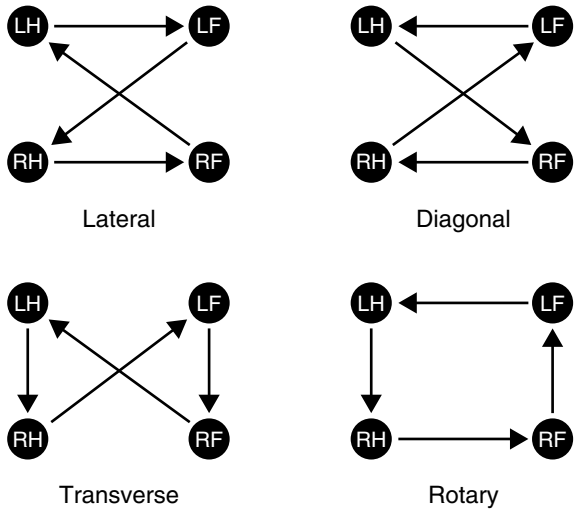

Figure 9.57. Footfall sequences in four-beat gaits. Arrows indicate the order of footfalls. LH, left hind; RH, right hind; LF, left front; RF, right front. *Source*: Reprinted with permission, The Dynamic Horse, Sport Horse Publications, 2004. Reproduced with permission of Cambridge University Press.

Regular Rhythm vs. Lateral Couplets vs. Diagonal Couplets

Lateral sequence gaits can be further divided into regular rhythm vs. lateral couplet vs. diagonal couplet gaits.

Regular (or square) rhythm gaits have a time interval between ipsilateral hindlimb and forelimb footfalls of exactly one-quarter of the stride duration.

Lateral couplets occur when the time between the ipsilateral footfalls of the hind- and forelimbs occurs in less than one-quarter of the stride duration. Lateral couplet gaits, such as the rack, have footfalls of a given fore- and hindfeet on the same side of the body related in time as a pair.

Diagonal couplet gaits, such as the fox trot, have footfalls of the fore- and hindfeet on the opposite sides of the body related in time as a pair. Diagonal couplets occur when the time interval between the ipsilateral footfalls of the hind- and forelimbs occurs in greater than one-quarter of the stride duration (Figure 9.58).[10,17]

Gaits Other Than the Walk, Trot, Pace, and Canter

There are many symmetric gaits that can be difficult to evaluate for a variety of reasons, primarily because most practitioners have not had as much experience evaluating these gaits. In these other symmetric gaits, the fore- and hindlimbs are generally moving symmetrically, but the timing of the fore- and hindlimbs varies depending on the specific gait. These gaits do not have a typical suspension phase and usually have at least one foot on the ground at all times.

These other symmetric gaits fall in a virtual continuum from the trot, which has a diagonal (or contralateral) symmetry, to the pace that has a lateral (or ipsilateral)

VetBooks.ir

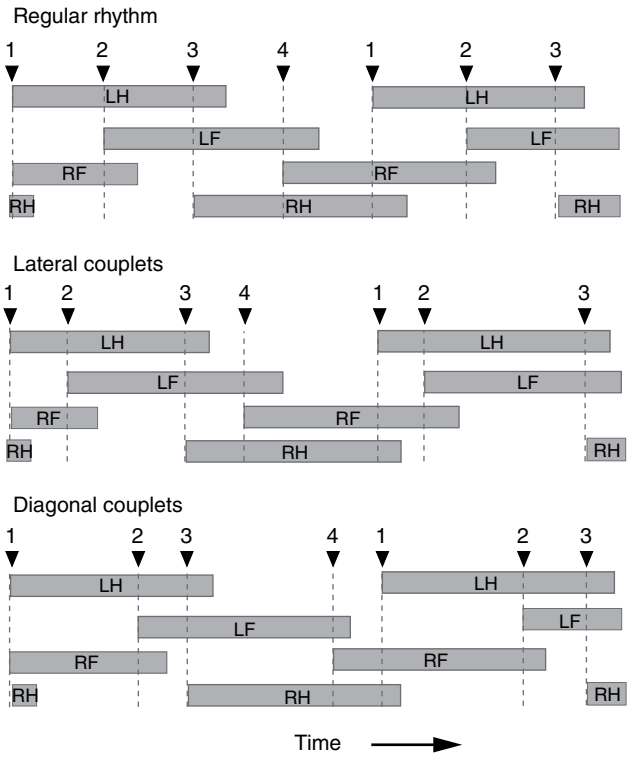

Figure 9.58. Gait diagrams for symmetrical, four-beat, lateral sequence gaits performed with a regular rhythm (above), lateral couplets (middle), and diagonal couplets (below). Shaded bars represent the stance phases of the limbs and open areas between bars represent swing phases. The numbered arrows and vertical dashed lines show the timing of the footfalls. LH, left hind limb; RH, right hind limb; LF, left front limb; RF, right front limb. Note that the contacts of the LH and RH occur at the same time in all three diagrams. *Source*: Reprinted with permission, The Dynamic Horse, Sport Horse Publications. symmetry.[17,21] The gaits along this continuum, shown in the center of Figure 9.59A and B, are usually considered four-beat gaits or stepping gaits. The boundaries between these four-beat stepping gaits are arbitrary and subjective with gait distinction being based mostly on timing of foot placement, breed, and style of movement. They include the walk, the paso gaits, fox trot, the marcha gaits, the various rack gaits, and the running walk[17,20] (Figure 9.59). The gaited horse gait spectrum (https://www.youtube.com/watch?v=aoB6FFP7a84; Phoenix Rising Saddles, accessed 30 January 2020).

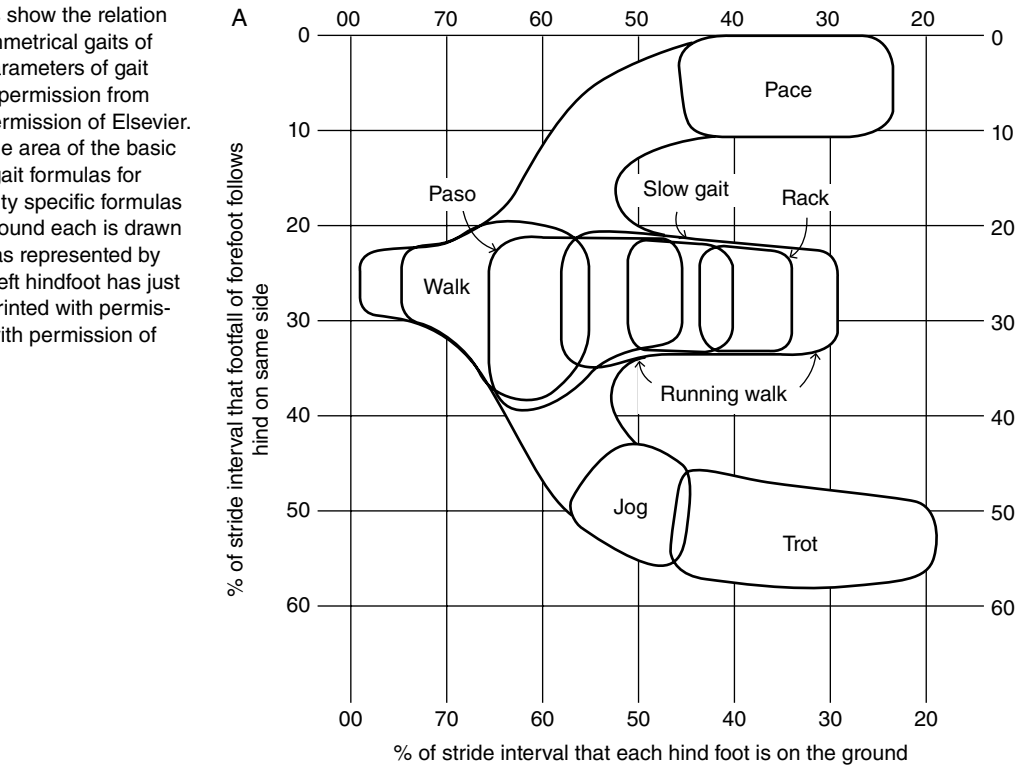
SPECIFIC GAITS IN "GAITED HORSES"

The **fox trot** is a four-beat gait, with an irregular rhythm with diagonal couplets. It is a stepping gait with no periods of suspension.[9] The rhythm of footfalls is characterized by diagonal couplets with forelimb impact being slightly before contralateral hindlimb impact, after an interval of ~15% of the stride duration (https://mfthba.com/education/). The sequence of limb placements is LH, LF, RH, RF. This early forelimb placement and impact causes an amplified vertical movement of the head and damped vertical movement of the rest of the body. It is reported to be an energetically efficient gait. There are typically eight limb support sequences in each stride, which alternates between periods of bipedal and tripedal support (https://mfthba.com/education/).[12] At faster speeds, as seen in the show ring, there may be a suspension phase when both forelimbs are off the ground simultaneously (https://mfthba.com/education/).

The same principles apply for the five-gaited Saddlebred and Tennessee Walking Horse at the rack, slow gait, and running walk (and the Icelandic horse at the tölt), when the hindlimb impacts the ground before the ipsilateral forelimb. The damped vertical movement of the body during these four-beat gaits in these breeds, although creating a more difficult gait to evaluate for lameness, is a desired quality that provides a smooth riding experience. Fortunately, most five-gaited Saddlebred horses readily trot and can be evaluated at this gait when evaluation of the rack or slow gait is difficult.

Running walk is a four-beat stepping gait with lateral couplets (LH, LF, RH, RF) and significant overstep of the forelimbs at speed. The hindfeet overreach the imprint of the front by 15–55 cm in a straight, smooth, gliding motion. It is the classic gait of the Tennessee Walking Horse[7] (https://www.youtube.com/watch?v=usZCp-nJEYI, accessed 30 January 2020).

The racking family of gaits falls into the symmetrical gaits, and almost all have the same sequence or order of footfall. The footfall sequence of the gaits in the rack family is the same as that of the walk (LH, LF, RH, RF). The variation in racking gaits is due to the timing of footfall, the "pick up," and the support sequence. This family of gaits includes the rack, saddle rack, stepped rack, and half rack. These are known by different names in the various breeds: Fino, Corto, Largo, Rocky Mountain Horse, Pleasure Gait, Trippel, Singlefoot, Stepping Rack, Pure Tölt, and Fast Largo.



Rack (single foot) is a four-beat stepping gait with a regular rhythm with lateral couplets. This gait is similar to a pace and paso llano as the lateral limbs move in couplets (LH, LF, RH, RF). Each foot hits the ground at equal, separate intervals[5] (https://www.youtube.com/watch?v=vKHjWSn44ZA, accessed 30 January 2020).

Slow gait (stepping pace) is a four-beat stepping gait that is highly collected with a regular rhythm with lateral couplets (LH, LF, RH, RF), similar to but slower than the rack. The ipsilateral fore- and hindlimbs lift almost simultaneously, but the hindfoot contacts the ground prior to the forefoot.[5]

Paso fino gaits are evenly spaced four-beat lateral gaits with each foot contacting the ground independently in a regular sequence at precise intervals creating a rapid, unbroken rhythm. When executed perfectly, the four hoof beats are absolutely even in both cadence and impact, resulting in unequaled smoothness and comfort for the rider (www.pfha.org, accessed 30 January 2020). All four hooves travel close to the ground while in motion and are lifted equally in height as the horse covers ground. At whatever speed the horse travels, the smoothness of the gait ideally allows the rider to appear motionless with little up and down movement.

The paso largo is a four-beat stepping gait with an irregular rhythm with diagonal couplets. According to the Paso Fino Horse Association (PFHA), it is the fastest speed of the gait, executed with a longer extension and

VetBooks.ir

stride and moderate to minimal collection. Forward speed varies with the individual horse. The paso largo is a fast, lateral, four-beat gait in which the horse can reach speeds up to 25–30 mph, equivalent to a canter or slow gallop. The paso largo is not just an increase in speed but also shows a distinct extension in stride.

The paso corto is a four-beat stepping gait with an irregular rhythm with diagonal couplets. According to the PFHA, its forward speed is moderate, with full to moderate collection. Steps are ground covering but unhurried, executed with medium extension and stride. The speed of this gait is comparable with the speed of a trot but is much smoother.

The classic fino gait is a four-beat stepping gait with a regular four-beat rhythm. According to the PFHA, it is performed at full collection, with very slow forward speed. The footfall is extremely rapid while the steps and extension are exceedingly short. It is a collected gait with rapid footfalls that covers as little ground as possible. It requires a high degree of collection, the most difficult of the three paso fino gaits.

Peruvian Paso performs a natural ambling four-beat lateral gait, in that it has four equal beats and is performed laterally: LH, LF, RH, RF. A unique trait of the Peruvian Paso gait is *termino*, an outward swinging leg action, originating from the shoulder, in which the front lower legs roll to the outside during the forward movement of the stride, similar to a swimmer's arms.[4]

The paso llano is a four-beat stepping gait with a regular four-beat rhythm. It is the slowest gait of the Peruvian Paso other than the natural walk. This gait is similar to a pace as the lateral limbs move in couplets (LH, LF, RH, RF). The Peruvian Paso can also move in a more diagonal gait, which is called the *pasi-trote* and is similar to the fox trot in foot placement and rhythm without the vertical head movement, characterized by diagonal couplets with forelimb impact being slightly before contralateral hindlimb impact. (https://www.youtube.com/watch?v=I3e3Ea0IDz0, accessed 30 January 2020; https://www.youtube.com/watch?v=ST4QgNsfapc, accessed 30 January 2020).

The sobreandando is a four-beat stepping gait with an irregular rhythm with lateral couplets. It is a fast broken pace. It is faster than the paso llano, but instead of four equal beats, the lateral beats are closer together in a 1–2, 3–4 rhythm (LH-LF, RH-RF), with a longer pause between the front foot of one side to the hindfoot of the other side.

The tölt is a four-beat stepping gait with a regular four-beat rhythm. It is a running walk of the Icelandic pony, sometimes said to be more similar to the rack or paso llano. The horse's hindlegs should move well under the body and carry more of the weight on the hind end, allowing the front to rise and be free and loose. This gait is characterized by the movement of the animal's legs in a lateral sequence (LH, LF, RH, RF), with lateral couplets with a rhythm similar to the sobreandando and paso llano.[6] (https://www.youtube.com/watch?v=RV9P0w8vZi8, accessed 30 January 2020).

Mangalarga Marchador, a Brazilian horse breed, has a natural gait called the marcha, which can be either marcha batida (ba-chee-da), a diagonal movement, or marcha picada, a lateral movement. If the horse ambles equally between the two gaits, it is referred to as having centro movement. Centro is not an actual gait but rather a term used to describe where the horse falls on the gait scale. Of the two gaits, the picada is thought to be considerably smoother than the batida. The marcha picada is a four-beat stepping gait with a regular four-beat rhythm. It is a broken pace with little vertical movement. This gait is characterized by movement in a lateral sequence (LH, LF, RH, RF), with lateral couplets and periods of triple hoof support. The timing of footfalls is similar to the paso llano of the Peruvian Paso Horse. The marcha batida is a four-beat stepping gait with a period of triple support and diagonal couplets (LH, RF, RH, LF). This gait is similar to the trot but shows very little suspension as horses are always in contact with the ground. There is no aerial phase (http://www.marchadorsinmotion.co/gaits, accessed 30 January 2020; http://www.namarchador. org/breed/the-marcha-gaits/, accessed 30 January 2020).

LAMENESS IN THE GAITED HORSE

Lameness in the gaited horse is primarily associated with the hindlimbs. The reason is possibly due to the shift in the center of mass caudally when utilizing these gaits, particularly at speed. The distal intertarsal and tarsometatarsal joints are most commonly affected. Stifle joint osteoarthritis and back pain are also associated with the racking gaits, the running walk, marcha picada, fox trot, etc. However, a study by Axelsson et al. revealed no association of the tölt gait in Icelandic horses being a risk factor for osteoarthritis of the distal tarsal joints. Tarsal joint angles being either too small or too large also may predispose gaited horses to distal tarsal osteoarthritis, but this is not unique to gaited horses.[3,13]

The most unique lameness originally associated with gaited horses is the disorder of degenerative suspensory ligament desmitis (DSLD), first described in Peruvian Paso and Peruvian Paso cross horses. However, this lameness is not necessarily associated with gait. DSLD is a heritable, debilitating disease causing an insidious, progressive onset of bilateral to quadrilateral lameness associated with diffuse enlargement of the suspensory ligaments that are not responsive to rest.[16] Exercise may help to improve or at least stabilize the clinical signs of DSLD.[23] DSLD is now recognized as a more systemic disease of proteoglycan accumulation in connective tissue such as collagen fibrils in tendons and ligaments and smooth muscle cells. Halper proposed to change the name to equine systemic proteoglycan accumulation (ESPA) due to its more systemic effects.[16] DSLD has subsequently been reported in other breeds such as Paso Fino, Thoroughbred, Arabian, Hanoverian, American Saddlebreds, Appaloosa, Quarter horse, and Akhal-Teke (www.akhal-teke.org, accessed 30 January 2020; https://en.wikipedia.org/wiki/Akhal-Teke, accessed 30 January 2020) and in some pony and draft breeds. Akhal-Teke horses are from Turkmenistan, thought to be one of the oldest existing horse breeds. Peruvian Paso horses have been reported to develop the disease at an earlier age than other horses.[15,19]

Why Is Evaluating Lameness in Gaited Horses Different (More Difficult)?

The vertical movement trajectories of the head and pelvis during the symmetric gaits other than the trot are identical in concept to the trot, which means that they move down during the first half and up during the second half of stance. Therefore, the same principles of altered movement with lameness apply, with "lowest on sound" for both head and pelvic movement for fore- and hindlimb lameness, as an accurate indicator of side of lameness. Also, with the ipsilateral gaits, there is more rolling from side to side than vertical movement down and then up. So, although in principle vertical movement of the head and pelvis should be good indicators of lameness, they may be more difficult to observe. Certainly, the compensatory lameness patterns for ipsilateral gaits will be different than that for the contralateral trot.

There are many reasons why gaited horses are more difficult to evaluate for lameness. The trot is the most common gait of horses in the United States, and horses that trot or pace have a suspension phase to their stride such that the relative impact is greater in horses that trot or pace. Most equine lameness can be considered weight-bearing lameness, with a decrease in peak vertical ground reaction force as the main effect. Therefore, gaits with higher normal vertical excursion of the center of mass, and higher vertical ground reaction forces experienced by the limbs, will more apparently display lameness. Horses that typically move in gaits without a clear suspension phase are more likely to mask low-grade pain on weight bearing.

Those familiar with evaluating horses at a trot recognize asymmetries of movement such as a head nod, hip hike or hip drop, shortened stride, asymmetric hock height, etc., as well as compensatory lameness (ipsilateral forelimb or contralateral hindlimb). Veterinarians must shift their thinking to evaluate gaits that fall in the continuum between trot and pace. One way to do that is to separately evaluate the forelimb and hindlimbs. The gaits are still symmetric, but they are asymmetric between fore- and hindlimbs. The forelimbs should move symmetrically, and the hindlimbs should move symmetrically. Therefore, the evaluator may want to train their mind to look at each half separately. Some gaited horses have an exaggerated head movement, but it still should be symmetric between right and left forelimbs. Hindlimb lameness can be difficult to evaluate in gaited horses because they do not have a typical suspension phase and therefore their hip movement or gluteal asymmetry may often be minimal compared with horses at a trot or pace.

Due to the rapid movement of the limbs in some gaited horses, particularly for horses performing the rack, classic fino gait, or the paso largo gait, the evaluator may wish to improve their chances of identifying a lameness or asymmetry in gait by having the horse travel over a hard surface. The speed of limb movement is often near the threshold of the human eye's ability to accurately discriminate movement and/or placement of the limbs. The combination of eyes and ears may help the evaluator identify the lameness or asymmetry. The sounding board used to show and evaluate Paso Fino horses can be used to help evaluate horses with a rapid gait.

Gaited horses are often evaluated under saddle in their regular environment. The extra weight of the rider and saddle will increase the ground reaction force and therefore may help to exacerbate a mild lameness. They may also more easily maintain a consistent speed or gait when ridden than when moved in hand.

Using Body-Mounted Inertial Sensors (The Q™ and Lameness Locator®) to Evaluate Lameness in Gaited Horses

Gaited horses can be evaluated for lameness using body-mounted inertial sensors, but there are some unique characteristics for acquiring data and important data interpretation facts that need to be understood when using currently available systems.

With the exception of the standard walk, any symmetrical gait that causes a falling and rising of the body twice per stride can be analyzed with body-mounted inertial sensors. This two-phase, sinusoidal-like vertical movement pattern, with downward movement of the torso during the first half of stance (impact) and upward movement during the second half of stance (pushoff), is generally retained even with the four-beat gaits like the fox trot (forelimb hits the ground slightly before contralateral hind limb, i.e. a broken trot) and the stepping pace (hindlimb hits the ground slightly before the ipsilateral forelimb, i.e. a broken pace). Measurement of head and pelvic trajectory and calculation of differences in maximum (between the stances) and minimum (within the stances) heights remain valid for determining lameness. At the standard walk, with a cadence of 1–2–3–4 (LH, LR, RH, RF), and equal timings between footfalls, this biphasic vertical movement is shifted so that maximum torso heights are highest during stance and lowest between stances. Current software does not include algorithms that detect this shift, and, therefore, they are not valid for the walk. Data can be collected at the walking gaits, and an amplitude of asymmetry may indeed be measured and reported, but the side and timing of lameness may not be accurate. However, weight-bearing lameness is less measurable (and less visible) at the walk than at the faster gaits, and the importance of measuring lameness at the walk is minimal. While it may appear that some lameness is better displayed at the walk than at other gaits, this is really only because the movement is slow enough for the limited temporal resolution of subjective observation to pick up the movement disturbance. A horse demonstrating lameness at the walk will have measurable lameness at the trot.

With the ipsilateral gaits (pace, stepping pace, etc.), hindlimb lameness analyses need to be flipped, i.e. left hindlimb lameness is a right hindlimb lameness and vice versa. This is because hindlimb footfall, which is currently determined by the right forelimb gyroscope and the assumption that the horse is moving in a contralateral gait, is one half-cycle out of phase, i.e. right hindlimb footfall is coded as left hindlimb footfall and vice versa. Correct hindlimb footfall sequence can be accurately determined by pelvic rotation from the sensor on the pelvis (generation 5 Q™ sensors include a three-axis gyroscope), but as of the date of this writing, this has not been fully tested and implemented in Lameness Locator®

VetBooks.ir

software. Amplitude and timing of hindlimb lameness (impact vs. pushoff) are correctly measured, but the side of lameness is opposite of actual. So, why retain the right forelimb gyroscopic sensor? The combination of the right forelimb gyroscope to detect forelimb footfall order and a pelvic gyroscope measuring frontal plane rotation to detect hind limb footfall order allows instantaneous (on-the-fly) determination of ipsilateral from contralateral gait. Future versions of Lameness Locator® are expected to include this capability, so users will not need to specify gait.

Many four-beat gaits are characterized by suppressed vertical torso movement (this is what makes them comfortable to ride) and, especially in the Missouri Foxtrotter, exaggerated vertical head movement. Vertical movement of the head remains the best method of forelimb lameness detection in the four-beat gaits; however a small difference between right and left strides, which, subjectively, are easily seen in a standard trotting horse, may be more difficult to appreciate in the Missouri Foxtrotter and other breeds with exaggerated vertical head movement. It is a question of seeing a small signal against the background of a lot of surrounding noise. Also, because vertical hindquarter movement is damped, detecting small differences in vertical pelvic movement between right and left is more difficult.

These same limitations affect objective measurement with inertial sensors. Lameness Locator® software includes a standardization algorithm that adjusts lameness measures based upon expected vertical movement of the head and pelvis. This is accomplished with algorithms that decompose the vertical movement trajectories into harmonic components, the expected vertical movement being the component at twice stride frequency. This is provided so that a mild lameness measure for a bounding Warmblood in dressage competition (large range of expected vertical movement) will be approximately the same as a mild lameness measure in a miniature horse trotting across the exam room floor (small range of expected vertical movement). Larger asymmetric movements are needed to exceed normal reference ranges when expected vertical movement is high. Smaller asymmetric movements are considered normal reference ranges when expected vertical movement is low. However, at the extreme ends of the total vertical movement spectrum, such standardization may cause discrepancy between what asymmetry is visually apparent and what is actually measured. So, the exaggerated normal vertical head movement in the Missouri Foxtrotter may suppress forelimb lameness results and variation, and the minimized normal vertical pelvic movement (actually in some cases near zero) may exaggerate hindlimb lameness results. Therefore, it is not uncommon for Missouri Foxtrotters (and other breeds that gait with exaggerated vertical head and suppressed vertical torso movement) to measure with forelimb lameness that seems less than and with hindlimb lameness that seems greater than that seen with the naked eye.

Some breeds, most notably the Missouri Foxtrotter and the Standardbred pacer, will not move with a consistent gait when led on a lead shank by a handler, and they do not commonly lunge. Instead, when in hand, they may move at a gait transitional between a walk and fox trot or between a trot and a pace or simply at a very fast walk. Some do not lead at all. This inconsistency of gait is inherently and normally asymmetric, unrelated to pain, so incompatible for determining lameness. For the Missouri Foxtrotter, having the handler force the horse to move faster, by moving faster him/herself, may cause the horse to begin to trot regularly, and the lameness may then be seen or measured. But this may not be ideal, as the owner/trainer is complaining about lameness at the fox trot, and the handler will more quickly tire so that additional observation trials are more difficult to collect. Instead, the lameness evaluation is more likely to succeed if conducted with the horse under saddle and ridden. In this manner, gait and speed are more consistent, and both the fox trot and trot can be evaluated. The Mangalarga Marchador (performing the *marcha batida)* is very similar to the Missouri Foxtrotter both in gait and consistency while led and under saddle (Figure 9.60).

Similarly, it is almost futile to attempt to have a handler lead a Standardbred pacer and expect a consistent gait of either a trot or pace. The best method for evaluating pacers for lameness is to sit behind them in the bike with the horse tacked up fully. Also, simply jogging slowly, even in hobbles, may not cause the horse to gait symmetrically, until a certain speed (usually faster) is attained (Figure 9.61). This can be accomplished with inertial sensors either by placing the receiving tablet computer on the person of the driver or within the sulky, traveling in a vehicle within range of the moving horse, or connecting to and collecting data from sensors as the horse is moving by the data collector holding the receiving tablet. Placing the receiver in the sulky with the driver or traveling next to the horse allows collection of hundreds of strides with low stride-by-stride variability, such that the effect of directional change in the turns is minimized over the entire trial. There is more side-to-side rolling in a Standardbred pacer, but the torso (and head) still rise and fall twice per full stride. However, because the horse is pacing, hindlimb lameness results must currently be flipped, right to left and left to right, but forelimb lameness results are the same as if the horse were trotting at speed. Of course, flipping the hindlimb results is not necessary for the Standardbred trotter and other breeds that trot at high speed, and a more ideal combination of gait (the trot) and circumstance (ability to collect large numbers of contiguous strides at speed) for evaluation with inertial sensors would be hard to find. Because of the presence of the head check and crupper, which occupy the body locations ideal for body-mounted inertial sensors, increased diligence is needed for proper attachment of the head and pelvic sensor. Some users around the world have invented attachment devices that seem to work well.

There is no published information on using body-mounted inertial sensors to evaluate American Saddlebred horses at the rack (an ipsilateral gait) or in other breeds like the Icelandic horse in similar symmetric ipsilateral gaits. These authors have evaluated some American Saddlebred horses for lameness at the rack and have found that the variability in gait is relatively high and trial length (ability to collect multiple contiguous strides) is relatively low, both of which significantly interfere with the ability to find small consistent asymmetries of mild lameness or to detect partial improvements

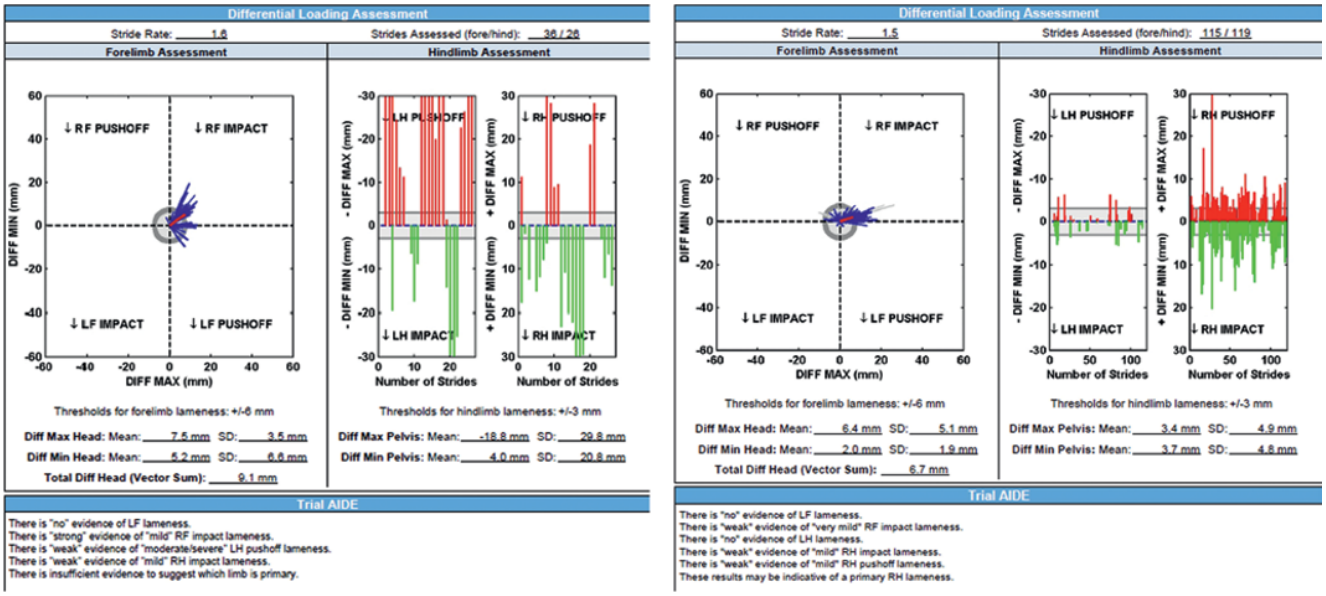

Figure 9.60. (Left) Attempt to measure lameness with inertial sensors in a Missouri Foxtrotter led by a handler. Note: There is no consistent hindlimb asymmetry measured. (Right) Consistent mild right hindlimb lack of pushoff and lack of impact are measured during foxtrot under saddle.

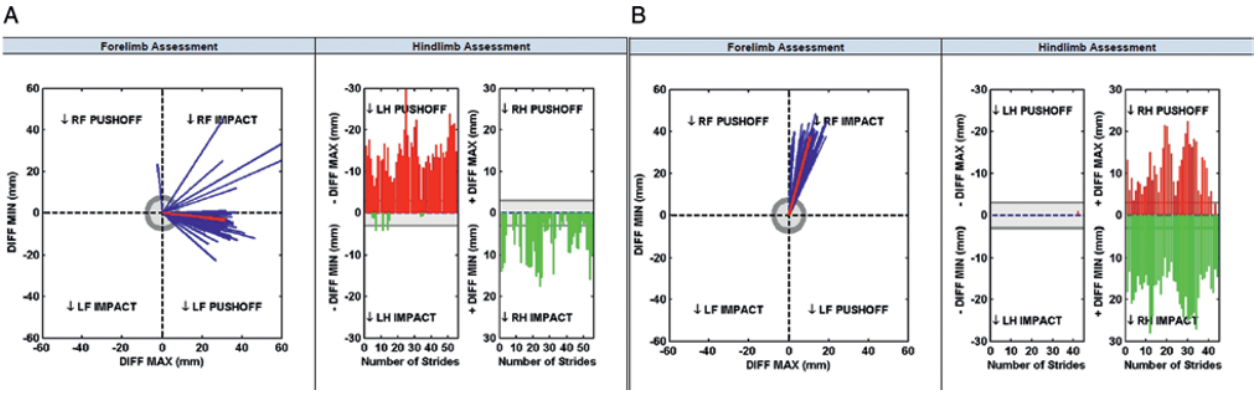

Figure 9.61. Inertial sensor data (A) from pacer that is jogging in hobbles. Note: No clear forelimb lameness, pushing off less in left hind and coming down less in right hind. Difficult to decide which limb is lame. (B) When same horse is pacing at speed. Note: Clear right forelimb lameness with compensatory left hindlimb lameness.

in mild lameness after blocking. Because the rack is an ipsilateral gait, using currently available Lameness Locator® software, the hindlimb lameness results must be flipped for the rack. However, this is of little consequence because most American Saddlebreds trot readily, such that evaluation for lameness at the rack is usually not required (Figure 9.62).

Lameness Locator has been tested in the Missouri Foxtrotter, Standardbred Pace, and American Saddlebred Rack. Based on these findings and clinical observations in these and other gaits, the following general guidelines can be made for some other common gaited breeds.

Tennessee Walking Horse and Rocky Mountain Horse Running Walk

These ambling gaits do not have a small extra duration between second and third footfalls needed to differentiate contralateral from ipsilateral hindlimb foot fall, so they will be OK for forelimb, but hindlimb results may not be reliable.

Paso Finos (Classic, Corto, Largo)

Because the footfall cadence is LH-LF-RH-RF, similar to the walk, the algorithms used in Lameness Locator will have trouble discerning the side of hindlimb lameness. Forelimb evaluation will likely be accurate in the largo, but hindlimb results may be unreliable at all three gaits. The classic is a poor gait to evaluate lameness as the torso is not really moving up and down. It is primarily only the legs moving with no upper body movement. It is like the horse is doing the Irish jig.

The Icelandic Tölt and Flying Pace

The tölt is a four-beat lateral ambling gait and will likely be measured similarly to the Saddlebred rack or

VetBooks.ir

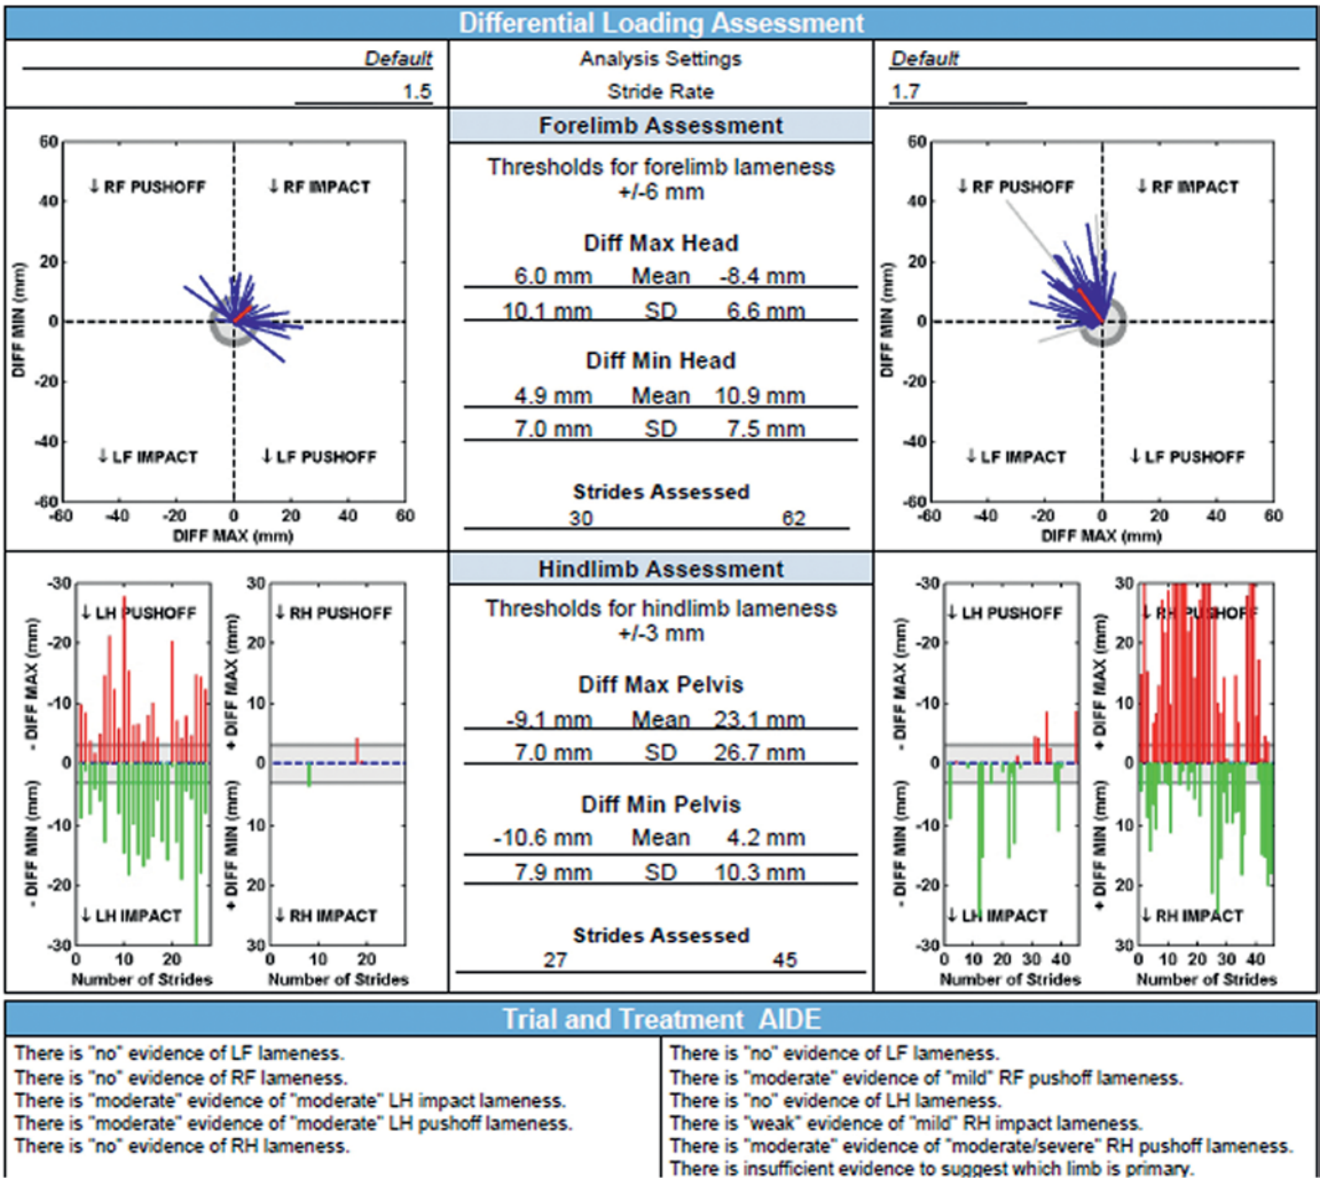

Figure 9.62. (Left) Evaluation of an American Saddlebred for lameness at the trot. A clear left hindlimb lack of pushoff and impact lameness are found with variation (standard deviations) of Diff Max and Diff Min Pelvis less than mean indicating good consistency. (Right) Evaluation of the same American Saddlebred horse at the rack. Note the right hindlimb lameness, which should be flipped to a left hindlimb lameness due to the data collection of an ipsilateral gait. Also, note the relatively high variation compared with means of Diff Max and Diff Min Pelvis, with standard deviations greater than means.

running walk of the Tennessee Walking Horse. Therefore, forelimb results will be reliable, but hindlimb results will be unreliable. The pace is a two-beat, lateralized gait with a moment of suspension between footfalls. Forelimb results will be reliable, and hindlimb results will be opposite of true.

THE DRAFT HORSE

JAN F. HAWKINS

VetBooks.ir

INTRODUCTION

Evaluating lame draft horses presents unique challenges due to of their large size, which complicates handling, routine farriery, and the lameness evaluation. Fortunately, most draft horses are docile and amenable to restraint. Draft horses are rarely exercised at speeds greater than a trot. This can delay the onset of obvious signs of lameness because of the lower amount of athletic demand required. This section reviews the anamnesis, physical and lameness examination findings, diagnostic tests, common lameness disorders, and treatments for lameness in the draft horse.

ANAMNESIS

Knowing the type of athletic demand placed on the horse is useful in determining the most likely cause of lameness. Common uses for draft horses include pulling, farm labor, showing in a hitch (either alone or with other horses), dressage, or broodmare. Young horses (under 2 years of age) presenting with lameness should be evaluated for metabolic bone diseases such as osteochondrosis and subchondral bone cysts.

LAMENESS EXAMINATION

All draft horses should have a complete physical examination because some cases presented for lameness evaluation may have systemic disease (e.g. endocarditis). The lameness examination should begin with a visual examination of the limbs and trunk. Next, the limbs, neck, back, and pelvis should be carefully palpated for evidence of asymmetry and focal pain or swelling. Chronic forelimb lameness can contribute to foot asymmetry and muscle atrophy of the shoulder muscles. Chronic hindlimb lameness can result in gluteal muscle atrophy.

Palpation of the lower extremities is complicated by the presence of long hair (feathers) in the fetlock and pastern regions. Palpation is also hampered because of the thick nature of the skin covering the distal extremity. Picking up the foot for applying a hoof tester can be challenging because not all draft horses willingly allow the examiner to pick up the foot. If necessary, the horse can be placed in stocks and a hobble placed around the pastern of the affected limb. A rope is secured to the hobble and the foot hoisted. Hoof tester application is often not helpful because the soles and hoof walls are typically thick and hard. Nonetheless, hoof testers should be applied to fully evaluate the hoof capsule, sole, and frog.

Lameness should be evaluated at the walk and trot. Horses should be evaluated on a straight line and while trotted in a circle. If possible, competition hitch horses should be evaluated while pulling a cart or wagon. Flexion tests and diagnostic anesthesia are performed as in light breed horses. Diagnostic nerve blocks are more difficult because of the thick skin of the distal extremity. The thick skin may limit diffusion of local anesthetic; therefore, greater amounts of anesthetic solution are often needed, and observation times should be longer to allow for greater diffusion. Higher kVp and mAs are required for radiography due to the increased size and thickness of the foot and distal extremity. Ultrasonography of the lower limb (below the hock or carpus) is complicated by the thick skin and dense hair on the distal extremity, making careful skin preparation necessary.

COMMON CAUSES OF LAMENESS

Lameness of the Foot

The most common cause of lameness in the draft horse involves the foot due to poor hoof wall quality, improper or no trimming, and inadequate hoof hygiene (Figure 9.63). Tie stalls and confinement in wet, manure-contaminated stalls can be risk factors for disorders such as subsolar abscessation and proliferative pododermatitis (canker). It is difficult for owners to regularly pick up and examine the foot, and many farriers are reluctant to provide routine hoof care for draft horses because of the physical demands of holding up a large draft horse.

Farriery can be greatly aided with shoeing stocks. Some owners possess shoeing stocks and perform routine farriery on their own. Feet also can be hoisted with the help of a rope secured to a hobble placed around the pastern. Shoes for draft horses are not readily available

Figure 9.63. Hoof care can be more difficult in draft horses, predisposing to foot problems, including hoof cracks.

VetBooks.ir

because most are custom made, thus adding to the expense of routine hoof care.

Most draft horses not used for athletic use or pulling are frequently left unshod. Those left unshod and not trimmed regularly by a farrier are prone to overgrown hoof walls. Overgrown hoof walls are prone to hoof cracks, which can involve the sensitive laminae, and poor hoof care in general can contribute to chronic foot soreness and lameness (Figure 9.63).

Subsolar Abscessation

Subsolar abscessation is common in draft horses. Risk factors include inadequate hoof care and poor stall hygiene.[8,12,13,27] Hoof testers should be applied to the sole, hoof wall, and frog in an attempt to localize focal areas of pain. In some instances purulent discharge can be expressed with the hoof testers. Feet also should be carefully evaluated for foreign body penetration. Insensitivity to hoof testers does not preclude a diagnosis of subsolar abscessation. Draft horses believed to have subsolar abscessation should have a palmar digital or abaxial sesamoid block performed to confirm the diagnosis and aid in trimming of the foot and sole exploration for an abscess. If necessary, affected horses should be restrained in shoeing stocks or sedated for examination to facilitate foot examination. Inability to find an abnormal region of the sole following hoof trimming does not rule out a diagnosis of subsolar abscessation. Soaking the foot can help soften the sole and aid identification and drainage of subsolar abscessation.

Affected horses should be treated with NSAIDs as needed to facilitate patient comfort. Most abscesses resolve promptly with adequate drainage and do not require antimicrobials. It is important to remove the undermined sections of the sole involved in the abscess to ensure adequate drainage. The author recommends placing a foot bandage initially. Once cornification begins, a shoe with a treatment plate can be substituted for the bandage. The shoe can be removed following complete cornification of the sole defect, if desired, and the horse returned to use. The prognosis for routine subsolar abscessation is good.

It is a rare case (less than 5%) in which extensive subsolar abscessation leads to the development of septic osteitis of the distal phalanx in draft horses. Radiography is required to determine the amount of the distal phalanx involved. Debridement of the third phalanx is accomplished with the horse standing and is combined with perineural anesthesia of the digital nerves.

To access the distal phalanx, a portion of the sole overlying the abnormal area must be removed, and all abnormal bone should be curetted. The defect is packed with sterile gauze and a sterile bandage is placed on the foot. For large sole defects, a shoe with a treatment or hospital plate should be considered to protect the sole and facilitate foot hygiene. The prognosis for septic osteitis of the distal phalanx is fair to good as long as 25% or less of the distal phalanx is involved.[3,10]

Infectious Pododermatitis

Infectious pododermatitis (canker) is commonly diagnosed in horses housed in stalls with inadequate hygeine.[17,30] Various treatments have been described for managing infectious pododermatitis, including topical application of caustic agents such as formalin and hydrochloric acid, topical sulfa drugs and metronidazole, cryosurgery, and limited and aggressive surgical debridement. The combination of limited surgical debridement and topical application of metronidazole results in the best outcome.

Surgical debridement can be performed under general anesthesia or while standing.[11] Debridement under anesthesia is preferred because of improved visualization, lack of patient movement, and superior hemostasis. Standing surgical debridement is facilitated with intravenous sedation (detomidine hydrochloride and butorphanol tartrate) and perineural anesthesia of the palmar digital nerves. A hobble is secured around the pastern, and the leg is hoisted and secured with a rope held by an assistant or attached to stocks. A tourniquet is essential to control hemorrhage and improve visualization. All visible portions of abnormal frog and sole are resected with a sharp hoof knife or scalpel blade. Following debridement, a paste of metronidazole tablets (equivalent to a systemic dose, 15–30 mg/kg) is applied to the debrided foot. A sterile bandage is then placed on the foot. A treatment plate aids postoperative management.

Topical application of metronidazole is performed at least once daily until the debrided area of the sole and frog is completely cornified, which may take 6–8 weeks. Aftercare is time consuming and must be performed daily until the defect has completely cornified. Owners must understand the absolute requirement for good foot hygiene following treatment. If the horse is placed back into the same unhygeinic conditions, the condition will most likely recur. The prognosis following treatment is fair to good.

Sidebone

Ossification of the collateral cartilage occurs to some degree in all draft horses. Fortunately, lameness related to sidebone is rare. Sidebone can be indicative of chronic foot lameness, even though it is not the primary cause for lameness. All suspected cases of sidebone should be confirmed with diagnostic anesthesia to rule out other more common disorders of the foot.

Radiographic findings compatible with sidebone include complete to incomplete ossification of the collateral cartilages.[21,22] Separate centers of ossification are not unusual and should not be confused with a fracture of the collateral cartilage. Bone-phase nuclear scintigraphy can be useful in determining the significance of collateral cartilage ossification to lameness.[22] Corrective farriery is the treatment of choice for management of sidebone. The foot should be balanced medial to lateral, and a long-toe, low-heel conformation should be avoided. Corrective shoeing should include a rolled toe with quarter clips to stabilize the foot, or a bar shoe with clips can be considered. The prognosis for sidebone in confirmed cases is favorable. Nonresponsive horses can be considered for palmar digital neurectomy.

Distal Phalanx Osteitis

Nonseptic osteitis of the distal phalanx is not unusual. Contributing factors include heavy body weight,

VetBooks.ir

poor hoof care, thin soles, broken hoof walls, and exercise on hard surfaces. Horses with distal phalanx osteitis typically present with a history of bilateral forelimb lameness that is worse when worked on hard surfaces (e.g. gravel, pavement, dry ground). Most horses with distal phalanx osteitis have increased sensitivity to hoof testers across the toes, quarters, and sometimes the heels. When trotted in hand, affected horses have clinical signs of bilateral forelimb lameness, which may be worse when trotted in a circle. Approximately 50% of horses improve following a palmar digital nerve block, and the remaining 50% improve following a midpastern ring block or an abaxial sesamoid nerve block. The author prefers a midpastern ring block because it is more specific for the foot and pastern.

Radiographic findings associated with nonseptic osteitis include lucency along the margins of the distal phalanx and proliferative new bone formation along the margin of the distal phalanx, which can extend up the hoof wall. Treatment includes NSAIDs and corrective farriery, which should include the placement of a wide-web shoe with a rolled toe. The inside of the shoe should be filled with shock-absorbing material such as dental impression material. This type of material is very important in managing the lameness because it protects and supports the sole to minimize compression and concussion to the distal phalanx. Cases that do not respond to corrective farriery and sole support may be considered for a palmar digital neurectomy.

Hoof Cracks

Hoof cracks involving the insensitive and sensitive laminae are common in draft horses. This is in part due to the difficulty in keeping the feet trimmed but may also be secondary to previous coronary band trauma. More than 75% of hoof wall cracks in draft horses involve the insensitive laminae, and these cracks can be managed with corrective shoeing and proper trimming of the hoof wall. Grooving the hoof wall at the most proximal aspect of the crack can be useful in preventing crack propagation toward the coronary band. If desired, insensitive hoof wall cracks can be managed with hoof wall staples and epoxy/acrylic repair, with a good prognosis.

Cracks involving the sensitive laminae result in lameness and require stabilization. Acceptable methods of stabilization include staples, acrylic repair, and a bar shoe with clips on each side of the crack.[18,19] If epoxy/acrylic repair is chosen, it is very important that the crack be completely cornified prior to repair to reduce the risk of abscessation. Hoof wall cracks associated with coronary band defects may require surgical reconstruction of the coronary band defect to prevent continued cracks. The prognosis is usually good. The most common complication is infection associated with hoof crack repair.

Laminitis

Laminitis, although not diagnostically challenging, is difficult to manage in draft horses because of their heavy body weight. Common causes of laminitis in draft horses include grain overload, following gastrointestinal disease (e.g. diarrhea, postabdominal surgery), retained placenta, and contralateral weight-bearing lameness. These horses

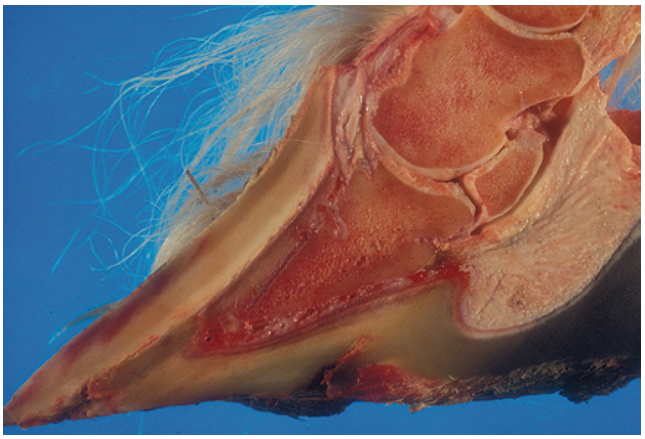

Figure 9.64. Cross section of a Clydesdale's foot demonstrating the long toe and concavity of the dorsal hoof wall that may predispose these horses to laminitis.

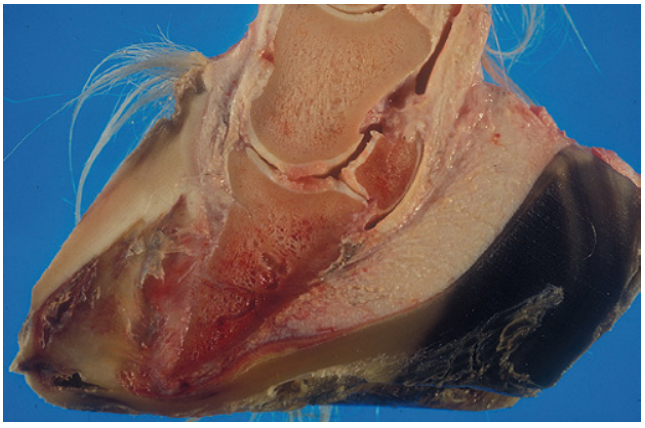

Figure 9.65. Cross section of a Clydesdale's foot with severe chronic laminitis. Significant movement of the distal phalanx is often present at the initial evaluation of draft horses, and preventing further movement can be challenging.

are also commonly shod with long toes and exercised on hard ground, which also may predispose them to laminitis (Figure 9.64). Laminitis can involve rotation, distal displacement of the distal phalanx (sinking), or a combination of rotation and distal displacement of the third phalanx.[1] The author has found no universally successful method for managing laminitis in draft horses. Laminitis is difficult to stabilize so that no further rotation or distal displacement occurs (Figure 9.65). The risk factor that most likely explains this is the large body weight.

The cornerstone of management is corrective shoeing, and working with a farrier is crucial to a successful outcome. The author prefers the application of wedge shoes with sole/frog support to relieve the pull of the deep digital flexor tendon and to support the sole and frog. Because of draft horses' large foot size, custom-made shoes are often required. Some draft horses respond well to application of heart-bar shoes with added sole and frog support. Draft horses with distal phalanx rotation greater than 15° are candidates for deep digital flexor tenotomy.[7] This should not be considered as a salvage procedure but as a useful tool in the management of laminitis. It

VetBooks.ir

can make a significant improvement, along with corrective farriery, in derotating the distal phalanx. Regardless of the treatment chosen, the prognosis for laminitis in draft horses is guarded to poor and is considered to be worse than for light breed horses.

Osteoarthritis of the Distal and Proximal Interphalangeal Joints

OA of the distal (low ringbone) and proximal interphalangeal (high ringbone) joints is not unusual. The greatest risk factor is a combination of large body size and work-related activities that pull and twist the lower limb. Radiographic evidence of ringbone is not unusual and may not be responsible for signs of lameness. The radiographic findings are similar to those found in other breeds of horses. Mild cases of ringbone can be managed successfully with conservative management consisting of corrective shoeing, NSAIDs, and intra-articular injection.

Moderate to severe cases of high ringbone that do not respond to conservative management should be considered for pastern arthrodesis. In draft horses, pastern arthrodesis should include at least two lag screws and locking plate application to ensure a strong enough construct to avoid cyclic fatique.[15,16] Pastern arthrodesis is performed less commonly in draft horses than light breed horses, primarily because of the cost as well as anesthetic concerns related to their large body size. Most owners typically opt for retirement from exercise or use these horses for breeding. The prognosis for ringbone in draft horses is favorable in mild to moderately affected horses. Severely affected horses can only be successfully managed with pastern arthrodesis, with a fair to good prognosis.

Osteoarthritis of the distal interphalangeal joint in mildly to moderately affected horses can be managed with a combination of corrective farriery and intra-articular injections.[6] Surgical arthrodesis for severely affected horses may be considered, but most owners reject this for financial reasons.[2,25] Palmar digital neurectomy also can be considered. The prognosis for distal interphalangeal OA is lower than for proximal interphalangeal joint OA.

Suprascapular Nerve Injury

Suprascapular nerve injury, or shoulder sweeny, is caused by direct trauma to the suprascapular nerve. This condition is not uncommon in draft horses because of repetitive injury to the suprascapular nerve from ill-fitting collars. Clinical signs of shoulder sweeny include muscle atrophy of the supraspinatus and infraspinatus muscles, subluxation of the shoulder joint, and lameness. Nevertheless, all affected horses should have radiographs of the shoulder to rule out traumatic injury, including fracture of the supraglenoid tubercle or proximal humerus. The clinical signs of this type of fracture and shoulder sweeny can be similar. Horses with clinical signs of suprascapular nerve injury but no radiographic abnormalities should be treated conservatively for at least 60 days before deciding on surgical decompression of the suprascapular nerve.

Conservative management consists of stall rest and NSAID therapy if needed.[5] Acute cases of shoulder sweeny can be administered corticosteroids and NSAIDs to decrease perineural inflammation. If following 60 days of conservative management no improvement in clinical signs has been observed, surgical decompression of the suprascapular nerve can be considered. The surgical technique has been described previously and is not detailed here.[23] The surgical success rate has been reported as favorable. However, muscle atrophy can persist in some cases, even though subluxation of the shoulder joint and mechanical lameness resolves. The prognosis for conservatively treated horses is fair to good, whereas the prognosis for horses treated with surgery is guarded. Horses that return to use should be monitored carefully for proper fitting of the collar to prevent recurrent suprascapular nerve injury.

Osteoarthritis of the Lower Hock Joints

OA of the tarsometatarsal or distal intertarsal joints (bone spavin) is a common cause of hindlimb lameness in competitive draft horses, especially in show horse hitches. Intra-articular anesthesia of the lower hock joints is indicated, and the author recommends using mepivacaine in both the DIT and TMT joints to confirm the diagnosis. It is not unusual for affected horses that appear lame in only one limb during baseline evaluation to become lame in the contralateral limb following successful intra-articular anesthesia of the originally lame limb. Radiography is not required but is helpful to determine the amount of radiographic change present and establish a baseline for future examinations.

Mildly affected horses can be managed with corrective farriery and NSAID therapy. Corrective farriery can include a square or rolled toe shoe with a 2°–3° heel elevation. The toe of the hoof should be trimmed short to aid break-over. Moderately affected horses also should be treated with intra-articular injections of corticosteroids. The author prefers methylprednisolone acetate for injection into the DIT and TMT joints. Ethyl alcohol also can be used for intra-articular injection to facilitate bony fusion of the lower hock joints.[26] Ethyl alcohol also is neurolytic, and injected horses frequently are more comfortable following intra-articular injection. Those that do not respond to intra-articular injections can be considered for surgical fusion of the lower hock joints. The author currently prefers to perform surgical ankylosis with intra-articular drilling alone.[31]

The prognosis for conservatively treated horses is fair to good, with the majority responding satisfactorily. In the author's experience, fewer than 5% of horses diagnosed with OA of the lower hock joints require surgery. The prognosis following surgery is good, with most horses improving.

Stringhalt

Stringhalt is caused by hyperactivity of the lateral digital extensor (LDE) muscle. Causes include trauma to the LDE tendon, peripheral neuropathy, ingestion of toxic plants, and idiopathic causes.[4,14,28] The classical clinical sign for stringhalt is hyperflexion of the hindlimb with the limb being quickly moved toward the abdomen while walking or trotting. Clinical signs alone can be used to make the diagnosis. The only conservative treatment for stringhalt is administration of phenytoin

VetBooks.ir

(15 mg/kg, PO, every 24 hours, for 14 days).[14] Phenytoin has been used to improve the gait abnormality associated with Australian stringhalt.

Horses with traumatic injury to the LDE tendon or musculotendinous junction are best treated with LDE myotendonectomy. The author prefers to remove the LDE tendon along with a 5–6 cm of the distal aspect of the LDE muscle belly, thus completely removing the musculotendinous junction. The inclusion of the musculotendinous junction seems to lessen the chance for adhesions between the stump of the resected tendon and extensor tendon sheath, which may contribute to recurrence. The prognosis following surgery is fair to good.

Shivers

Shivers affects draft horses along with other breeds, including Warmbloods.[9,29] It is an unusual problem because the horse typically only does it once it begins to walk or trot. Affected horses pick up their leg quickly, toward the abdomen, and tend to shake the limb before setting it down. It can be confused with stringhalt and upward fixation of the patella. Accompanying the flexion of the hindlimb, the tail head may elevate. The abnormal gait can be exacerbated with lack of exercise, low ambient temperatures, and increased horse anxiety. The condition can be difficult for the farrier to deal with because the unexpected flexion of the limb makes limb restraint difficult. The condition can be unilateral or bilateral and can be progressive. For some horses, the progressive nature of the condition can make it difficult to stand, especially when the condition is bilateral. Clinical signs also can involve the forelimbs.

The cause of shivers is unknown, but equine polysaccharide storage myopathy (PSSM) has been incriminated. A muscle biopsy may be obtained and submitted for evidence of PSSM. Affected horses can be improved with a high-fat, low-carbohydrate diet. No other treatment for shivers has been shown to be consistently effective, and most owners learn to live with the disorder.

DISEASES OF YOUNG DRAFT HORSES

Septic Arthritis

Septic arthritis in draft horse foals is not uncommon and is usually associated with septic omphalophlebitis secondary to a patent urachus. The most commonly affected joints are the hock and stifle, and osteomyelitis is not an uncommon sequelae. The diagnosis and treatment for septic arthritis in draft horse foals is the same as for light breed horses.[24] The prognosis for draft horse foals is similar to that for light breed horses, although the expectations for athletic demand are less.

Osteochondritis Dissecans (OCD)

OCD in draft horses mimics the condition in light breed horses except that the size of the OCD lesion in draft horses is usually larger. The most commonly affected joints are the hock and stifle.[20] Large osteochondral fragmentation of the distal intermediate ridge of the tibia and the lateral trochlear ridge is not uncommon (Figure 9.66). Likewise, for the stifle, large lesions involving the lateral trochlear ridge of the femur are not unusual. Standard arthroscopic techniques for the hock

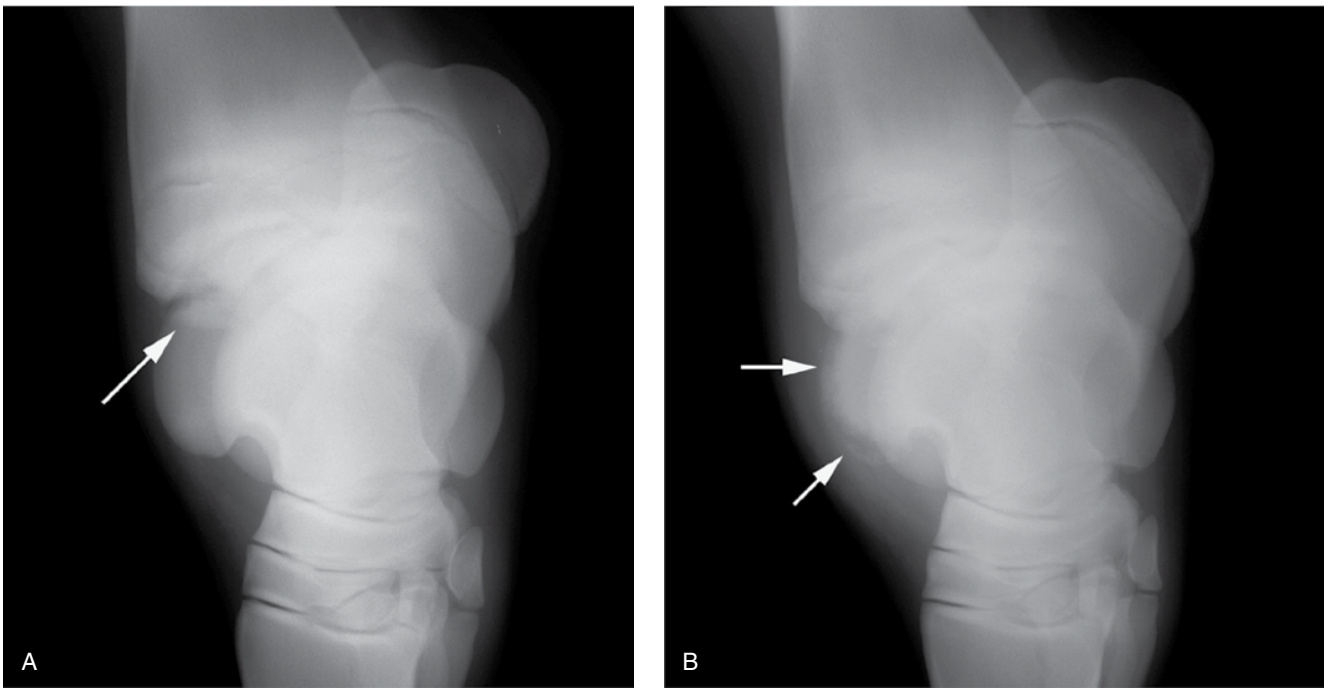

Figure 9.66. Fragmentation or osteochondral defects associated with OCD tend to be very large in draft horses and occur at more than one location within the joint. (A) A large OCD lesion of the distal intermediate ridge (arrow) and (B) an extensive subchondral defect involving most of the lateral trochlear ridge (arrows). The horse in (A) also had a large lesion of the lateral trochlear ridge in the same joint.

VetBooks.ir

Figure 9.67. Tarsocrural joint effusion is a common finding in draft horses and may persist even if the OCD lesions are removed.

and stifle are used. The prognosis following arthroscopic debridement is favorable in most instances due to the lower athletic demand placed on draft horses. However, despite arthroscopic debridement some horses will continue to have persistent joint effusion (Figure 9.67).

CHAPTER

Lameness in the Young Horse

THE PHYSIS/PHYSEAL FRACTURES/PHYSITIS

Dane M. Tatarniuk, Troy N. Trumble, and Gary M. Baxter

THE PHYSIS

Growth and Development of the Musculoskeletal System

During fetal development, equine long bones have two main centers of ossification. The primary ossification center develops first and forms the diaphysis and metaphysis of the bone, while the secondary ossification center will form the epiphysis. In between these two centers of ossification is a specialized, highly cellular region referred to as the physis or growth plate. Most long bones have a physis at each end of the bone, whereas others have only one, such as the third metacarpal/metatarsal bone (distally) and the proximal and middle phalanges (proximally). The function of the growth plate is to increase longitudinal bone growth via endochondral ossification, a process where rapidly differentiating and maturing cartilage cells get replaced by bone.[49]

There are two types of growth plates: discoid and spherical.[4] Discoid growth plates are located in long bones between the metaphysis and the epiphysis (Figure 10.1). In addition, a type of discoid physis is present distal to an apophysis (specific type of epiphysis that is subject to tensile rather than compressive forces) on the olecranon process (Figure 10.1), calcaneal tuber, and tibial tuberosity. These physes contain greater amounts of fibrocartilage to withstand tensile forces.[38] Spherical physes are located in the small cuboidal bones of the carpus and tarsus (Figure 10.2). These growth plates develop into bones by centrifugal expansion around a central cartilage core.[4] The cartilage core begins to ossify in the center and gradually assumes the contours of the bone of an adult as bone development reaches the margins of the cartilage model (Figure 10.3).

The epiphysis forms early in life at one or both ends of long bones between the growth plate and the articular cartilage. These articular–epiphyseal complexes form in a manner similar to ossification of the cartilage models of the small cuboidal bones. This ossification mostly increases the size of the epiphyses but contributes very little to the length of the bone (Figure 10.2). The cellular events consist of vesiculation and chondrocyte death with calcification of matrix, invasion of vessels, and partial resorption and ossification.[38] Eventually, a subchondral bone plate forms protecting the articular cartilage portion that persists throughout life.

Endochondral Ossification of the Physis (Growth Plate)

The metaphyseal growth plate or physis has a characteristic cellular architecture from birth to maturity that allows for simultaneous longitudinal growth and ossification of bone. The cartilage cells of the growth plate can be divided into a number of zones, which vary in height and cell number, histological appearance, and cellular function. They include the resting/reserve, proliferative, hypertrophy, provisional calcification, and ossification zones.[49,50] On the outer periphery of the growth plate is a perichondrial ring of collagen fibers oriented vertically, obliquely, and circumferentially often referred to as the ring of La Croix.[18] It encircles the growth plate and extends from the metaphyseal periosteum to epiphysis (Figure 10.4). Its main function is to provide mechanical support for the growth plate while also acting to constraint the circumferential growth of

VetBooks.ir

the physis.[45] Directly under this perichondrial ring is the zone of Ranvier at the level of the resting and proliferative zones (Figure 10.4).[34] This wedge-shaped zone contains undifferentiated cells, fibroblasts, and progenitor cells for osteoblasts that are supplied to the resting/reserve zone.[52] These cells function to expand the diameter of the growth plate.[52]

Resting/Reserve Zone

The zone nearest the epiphysis (Figure 10.4) contains scattered undifferentiated or resting chondrocytes (similar to those in articular cartilage).[49] These chondrocytes are highly metabolic with high cytoplasmic lipid content that suggest potential for nutrient storage.[1,50] Epiphyseal vessels (arterioles and capillaries) are closely associated with early cellular events and may provide undifferentiated cells that can add to the pool of chondrocytes.[49] Recently it has been shown that this zone contains cells that can act as precursors of the cells in the proliferative zone and it produces an orienting factor that dictates that the cells line up into parallel columns along the long axis of the bone.[1]

Proliferative Zone

The zone of growth or proliferation is where chondrocytes divide rapidly in columns of isogenous groups along the long axis of the bone (Figure 10.4).[49] This orientation directs the lengthwise growth of bone. Chondrocytes farther down the cell columns synthesize and secrete extracellular matrix (predominantly of type II collagen), aggrecan, other proteoglycan aggregates, and type X collagen.[49] Collagen that is randomly orientated in the resting zone becomes more longitudinally oriented between the columns of proliferating cells.[49] Terminal differentiation is

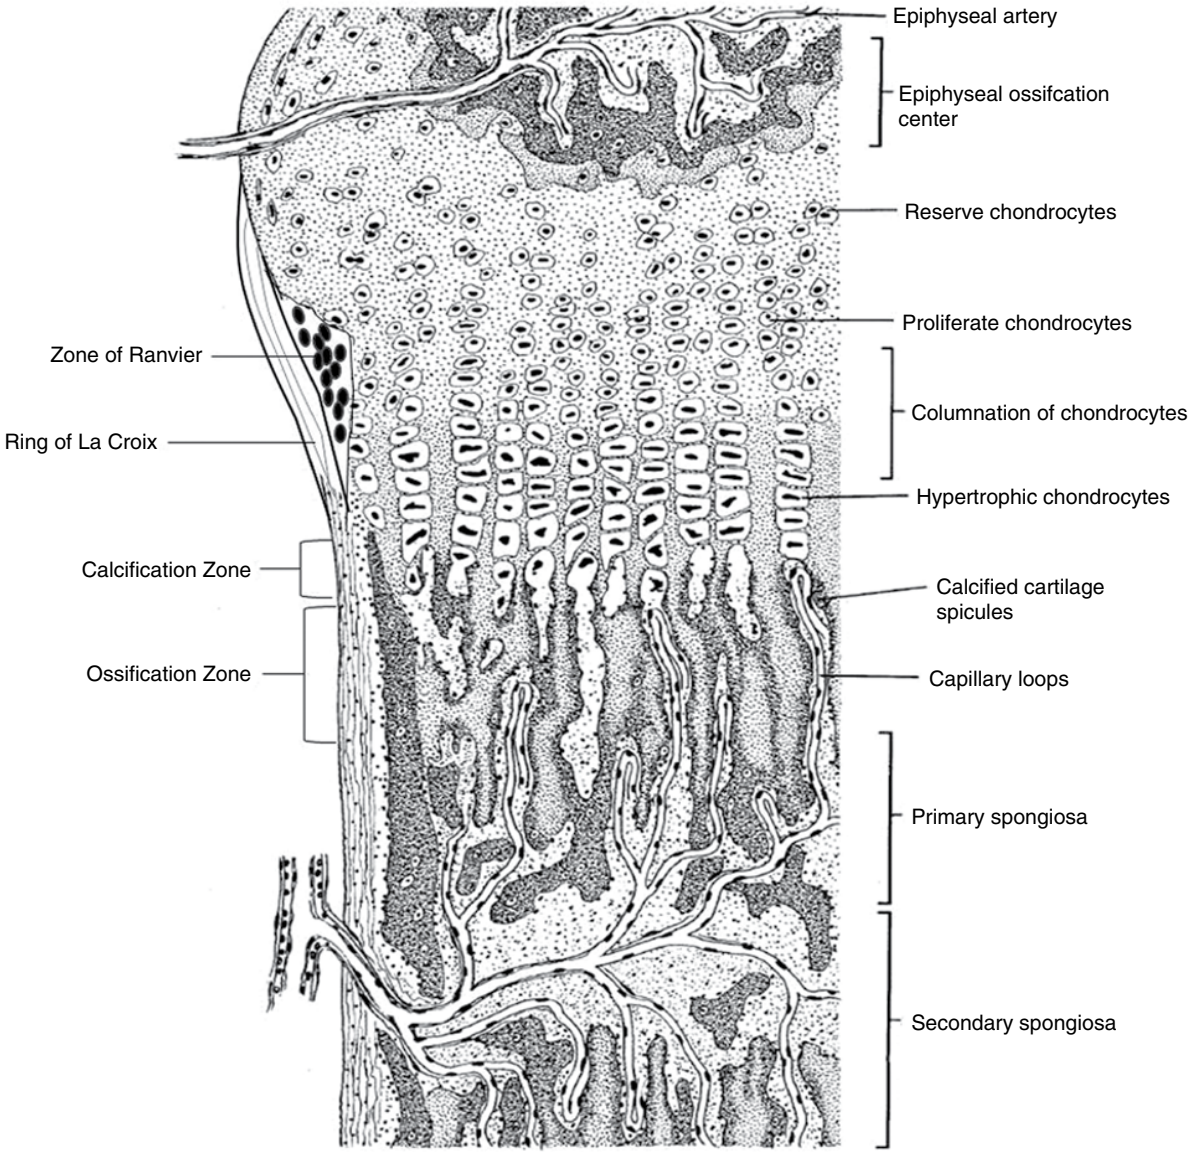

Figure 10.4. Cellular layers of the physis.

VetBooks.ir

inhibited in this zone by a morphogen produced in the resting zone.[1]

Hypertrophy Zone

After the chondrocytes finish cell division, they continue to mature and hypertrophy in the columns established in the proliferating zone. Matrix vesicles begin to form in this region. Matrix vesicles are microstructures that form in the extracellular matrix from the cytoplasmic membrane of the chondrocytes and contain products essential for calcification including alkaline phosphatase and calcium.[49] Type X collagen is also produced from the cells in this zone, which helps set up the matrix assembly for mineralization and helps increase calcium influx into matrix vesicles.[53] Within the zone, cells increase in size from the epiphyseal to metaphyseal side of the physis (Figure 10.4) due to the presence of factors such as insulin-like growth factor.[60] At the base of the hypertrophic zone, the size of the chondrocytes can be five times larger than those cells in the proliferative zone.[8] This increase in cell volume is what increases the rate of longitudinal growth of the physis.[7] The hypertrophied chondrocytes closest to the metaphysis have less metabolic activity, ultimately leading to cell degeneration and death.[9] Cell death triggers vascular invasion and calcification.[12,49] Because this zone is the transition zone between the cellular and bony region of the physis, combined with the relative lack of matrix surrounding the large chondrocytes, the zone of hypertrophy has been considered to be the structurally weak link of the physis.[4,39]

Zone of Calcification/Ossification

The zone of calcification is an ill-defined region that starts in the lowest region of the hypertrophic zone. The matrix between the cells gradually becomes mineralized due to deposition of hydroxyapatite crystals (Figure 10.4). This is thought to be initiated by the matrix vesicles, and it depends on several factors such as the availability of calcium and phosphate ions, cobalt and collagen, the pH, and the enzyme alkaline phosphatase.[49]

The zone of ossification is sometimes called the zone of angiogenesis because the terminal ends of the capillary sprouts impinge on the hypertrophic chondrocytes. Here osteogenic buds, which consist of capillary sprouts and osteoprogenitor cells, invade the columns of calcifying cartilage.[35,49] In the horse, there is approximately one capillary sprout per column of cells.[49] After the vessels come in, osteoblasts deposit osteoid, the organic part of bone, on the matrix surrounding the columns of calcified cartilage. This forms longitudinally orientated bony spicules (with a cartilaginous core inside) that make up the region called the primary spongiosa. Eventually the bone of the primary spongiosa is replaced by secondary spongiosa, which lacks remnants of the cartilage core.[55] As the bone elongates, bone at the diaphyseal end is removed by osteoclasts at the same rate that new bone is being formed on the epiphyseal side of the metaphysis. Thus, there is a continuous sequence of events, with cell division at one end, bone formation, and bone destruction, which is an important process that contributes to the final shape of the bone (Figure 10.4).[55]

Vascularity of the Physis

The blood supply to the growth plate originates from the epiphyseal, metaphyseal, and perichondral circulations.[4,38] Transphyseal vessels (those crossing the growth plate) are present in large epiphyses and may serve as a route for spread of infection from the metaphysis to the epiphysis. The metaphyseal circulation forms a series of loops that penetrate the longitudinal septa, enlarging as they return toward the diaphysis and forming a sinusoid. This produces a sluggish pattern of blood flow within the physis that predisposes this region to bacterial localization and osteomyelitis.[55]

The integrity of the blood vessels within the zone of Ranvier is important for continued appositional growth at the periphery of the epiphyseal growth plate. Disruption of the blood supply in this perichondral region can potentially cause ischemia to the physis, contributing to asynchronous growth and a subsequent angular limb deformity (ALD). In addition, lack of blood supply, particularly to the ossification zone, can prevent proper bone formation and potentially contribute to disruption of bone growth or osteochondrosis (OC).[11,40,41,66]

Biomechanical Aspects of the Physis

Although the exact mechanism is not completely understood, tension and compression on the physis are essential for continued orderly bone development and growth.[55] Each growth plate has a biologic range of both tension and compression within which it will respond. Within this range increasing tension or compression will accelerate physeal growth, while reducing tension or compression will decrease physeal growth. However, beyond the physiologic limits of tension or compression, physeal growth may be significantly decreased or even stopped; this is referred to as the Hueter–Volkmann law of physeal growth.[25,55] This law states that when mechanical compression is applied, growth will be retarded but that tensile forces will stimulate growth. This has an important practical application in the management of foals with ALDs. If we assume that a foal with an ALD of the carpus (carpus valgus) exerts an asymmetric load on the distal radial physis, then the physis will stimulate growth on the concave (tension) side of the physis and slow growth on the convex (compression) side of the physis, serving to straighten the limb without intervention. However, unrestrained exercise may cause physeal compression that is greater than the physiologic range and therefore prevent autocorrection of the ALD. In addition, foals with physitis or physeal dysplasia may have weaker metaphyseal bone than normal, which may be more susceptible to trauma.[4]

Cessation of Physeal Growth

As bone growth ceases, the physis becomes progressively thinner, and finally the epiphysis and metaphysis fuse.[38,39] The cartilaginous growth plate is replaced with

VetBooks.ir

trabecular bone, making it incapable of correcting an ALD. The timing of the physeal closure depends on the specific bone. Some close early in life and others remain open for several years (Table 10.1). However, it is important to note that functional (remaining growth potential) physeal closure occurs well before radiographic closure, and this difference has important bearing on the timing of surgery used to correct ALDs.[55] In general, the further distal on the limb the physis is located, the sooner longitudinal growth will become functionally inactive. For instance, the distal metacarpal/metatarsal physes close sooner compared with the distal radial or distal tibial physes (Table 10.1), making correction of ALDs of the fetlock more important early in life than those of the carpus or tarsus.[19] In addition, any injury to the physis such as excessive pressure, direct trauma, traction, circulatory loss, or shearing forces can lead to premature cessation of growth or asynchronous growth.[4,62] Comparatively, circumferential growth of the epiphysis continues uniformly regardless of anatomical location until the horse is fully mature.[30]

External Trauma to the Physis

When excessive force is applied to a joint and its nearby physis, an epiphyseal or physeal injury is likely to occur because the cartilaginous growth plate is weaker than the surrounding bone, ligamentous structures, and joint capsule. Physeal and epiphyseal injuries are common in foals.[16,17,42] Injuries that would normally produce a ruptured ligament or joint dislocation in an adult may produce traumatic separation of the physis in a young animal. For example, trauma to the fetlock region might cause a fetlock luxation in an adult horse, whereas a foal might sustain a distal metacarpal/tarsal physeal fracture.[55] This is partly why joint luxations appear to be rare in young horses.

CLASSIFICATION AND TREATMENT OF PHYSEAL INJURIES/FRACTURES

The most widely accepted classification of growth plate injuries is based on the Salter-Harris system, which separates the injuries into six specific types (Figure 10.5).[47] The system was designed for humans but has been applied to horses to permit equine clinicians to communicate effectively when describing such injuries.

Physeal fractures are relatively common in foals (accounting for approximately 20% of fractures) and may be considered more serious than diaphyseal fractures because of the risk of disturbed limb growth and articular involvement.[16,17,42] Type I and II physeal fractures are most common in horses. Frequent locations of physeal fractures include the distal metacarpus/metatarsus, distal and proximal radius, proximal humerus, proximal tibia, and distal and proximal femur (Figures 10.6 and 10.7).

These fractures tend to heal quickly but usually reduce the growth potential remaining in the physis via premature closure of the physis at time of injury or during fracture repair. This can lead to premature limb shortening or ALD. Certain locations (distal metacarpus/metatarsus and proximal tibia) have sparse soft tissue coverage and can lead to open fractures and increased risk of implant-associated infection with surgical repair. Concurrent injuries to the surrounding synovial, ligamentous, and tendinous structures can also influence overall prognosis. As with any fracture, the greater the degree of instability, displacement, and

Table 10.1. Range of growth plate closure in equine bone for forelimb and hindlimbs.

Forelimb			Hindlimb		
Growth plate	Age at closure (months)		Growth plate	Age at closure (months)	
	Earliest	Latest		Earliest	Latest
Cranial glenoid cavity of scapula[15]	5.0	5.0	Proximal femur/capital[54]	36.0	42.0
Supraglenoid tubercle and coracoid process[15]	12.0	24.0	Third trochanter[54]	24.0	48.0

duration until stabilization, the increased risk of damage and inadequate healing.[51] Although the prognosis can be very good, it has been shown that only 25% of foals with physeal fractures achieved complete soundness.[16,42]

Overall goals of treatment are to provide stability of the physeal fracture, allow weight-bearing function of the limb, and preserve growth plate function.[51] Stabilization can be tricky to achieve because often there is little bone to purchase, resulting in various methods of internal fixation that can be used and will differ based on individual fracture configuration (Salter–Harris subtype) and anatomical location.[33] Please see Chapters 4 and 5 for additional information on physeal fractures at specific locations on the limb.

Type I

In a type I injury, there is complete separation of the physis without fracture through the bone. This fracture usually occurs due to shearing forces across the physis causing the fracture to propagate through the zone of hypertrophy with the germinal cells of the growth plate remaining with the epiphysis (Figures 10.5 and 10.6).[39] With external trauma, this fracture configuration is common in the proximal femoral physis (slipped capital femoral epiphysis; Figure 10.6B), as well as the proximal radial physis or proximal humeral physis,[4,55] Salter-Harris type I fractures have been reported to occur as a pathological fracture secondary to severe physitis.[27] The prognosis for type I physeal fractures is generally poor.[27]

(B) Lateral radiograph of the stifle of a long weanling with a type II distal femoral physeal fracture. In most situations, these types of fractures should be repaired surgically to prevent malalignment of the limb.

Type II

Type II is the most common type of physeal injury in foals as well as in virtually all domestic animals.[55] The fracture line extends along the physis for a variable distance and then breaks out through a portion of the metaphysis, producing a triangular-shaped metaphyseal fragment (Figures 10.5 and 10.7). Similar to nearly all physeal injuries, the germinal cells remain within the physis. This type of injury is usually the result of shearing and bending forces. The distal third metacarpal/metatarsal physis commonly incurs this injury when the mare steps on the foal. The periosteum is torn on the convex side of the angulation but is intact on the concave side. Thus, the intact periosteal hinge is always on the side of the metaphyseal fragment.[47] A similar injury also occurs in the proximal tibial physis in slightly older foals. Closed reduction with casting alone may be possible in foals with metacarpal/metatarsal type II physeal injuries, but

VetBooks.ir

successful internal fixation with lag screws and casting has been described.[31] Internal fixation (medial bone plate and/or screw and wire transphyseal bridge) is usually mandatory for type II proximal tibial fractures.[42,51]

Type III

Type III fracture is intra-articular and extends from the joint surface, through the epiphysis, into the deep zone of the growth plate and then along the physis to its periphery (Figures 10.5 and 10.8).[46,47] This type of injury is uncommon in foals and is usually caused by an intra-articular shearing force or is secondary to infectious physitis. Open reduction and internal fixation are necessary to reconstruct the joint surface to prevent the development of secondary osteoarthritis (OA).

Type IV

Type IV fractures are intra-articular and extend from the joint surface through the epiphysis, across the entire thickness of the physeal plate, and through a portion of the metaphysis (Figure 10.5). This type of fracture is rare in foals. Open reduction and internal fixation are

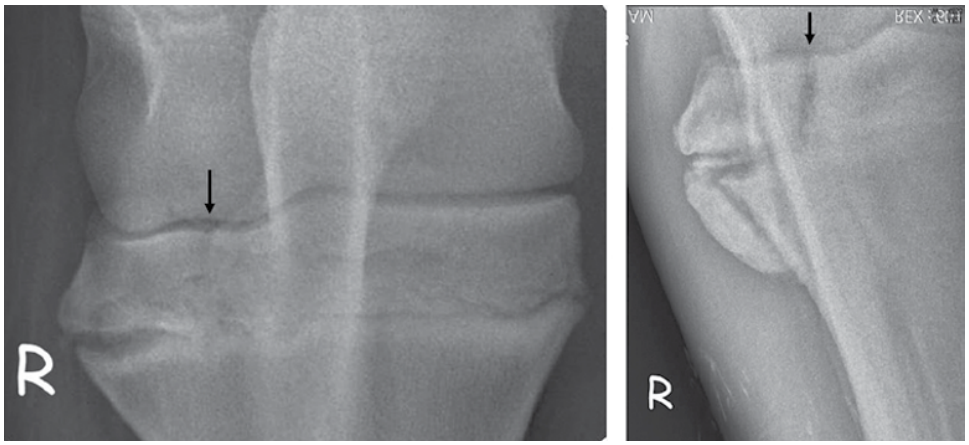

Figure 10.8. Craniocaudal radiographs of a 6-month-old horse at the time of fracture (A = day 0) and after stall rest (B = day 30). A Salter–Harris type III fracture is present that extends from the lateral articular surface (arrow) to the physis and out the lateral side of the physis. Note the extreme periosteal reaction present at day 30 with conservative treatment.

VetBooks.ir

necessary not only to restore a normal joint surface but also to obtain perfect apposition of the physeal plate. It has been observed in children that unless the fractured surfaces of the physeal plate are kept perfectly reduced, fracture healing occurs across the plate and renders further longitudinal growth impossible.[46,47]

Type V

Type V fracture is also an uncommon injury in foals. It results from a severe crushing force applied through the epiphysis to one region of the physeal plate (Figure 10.5). It may be associated with the distal third metacarpal/metatarsal physes in cases of severe varus deformity of the fetlock or the distal radial physis with severe carpal valgus. Excessive trauma to one part of the physis may be responsible for the severity of these deformities, although this is difficult to document.

Type VI

In a type VI injury, a periosteal bridge develops between the metaphysis and epiphysis (Figure 10.5). The new bone restrains growth on the affected side of the physis and has the same effect as a transphyseal staple or screws and wire. This type of injury may occur due to excessive trauma during placement or removal of staples or screws and wire, secondary to local infectious periostitis, or spontaneously from external trauma.[4,55] Removal of the periosteal bridge to help restore further growth in combination with transphyseal bridging on the opposite side of the physis is necessary to correct the problem. This approach has been reported to successfully resolve type VI lesions of the distal radial physis in two yearling horses.[21]

DEVELOPMENTAL ORTHOPEDIC DISEASES

The term developmental orthopedic disease (DOD) has historically been used to describe a comprehensive group of growth disturbances that occurs in foals and growing horses.[29,62] In recent years there has been an attempt to alter this nomenclature.[13,58] Denoix et al. proposed using the term juvenile osteochondral conditions (JOCC) to represent disorders related to the immature joint and growth plate.[13] The reasoning is that even though most joint and physeal lesions in young animals are due to orthopedic developmental issues, some are traumatic in origin based on the unique biomechanics of the developing skeleton.[13] Therefore, this terminology would involve pathology such as physitis/physeal dysplasia, ALD, OC, subchondral cystic lesions (SCL), incomplete ossification or collapse of the cuboidal bones, and juvenile arthritis. The old DOD term would still encompass all of those listed under the JOCC nomenclature, but would also include cervical vertebral malformations (CVM) and flexural deformities.[29,58] Van Weeren et al. may have summarized the nomenclature best by suggesting that the DOD term should be used for developmental disorders that relate to the entire animal, whereas JOCC should be used for pathology of articular structures in the juvenile animal.[58] Since this chapter incorporates all of the DOD conditions except for CVM, the term DOD will still be used throughout.

Regardless of the terminology used, most of these developmental conditions are attributed to alterations in bone growth or development at the metaphyseal or articular–epiphyseal growth plates. Clinical signs of these conditions vary depending on the specific disease and location, but are unique to growing horses.[29] In one survey of Thoroughbreds, 11% of young horses needed treatment for DOD conditions, and ALD and physeal dysplasia constituted 73% of treated cases.[37] Signs include variable degrees of lameness, alterations in posture or positioning of the limb, crooked legs, joint effusion, limb enlargement, and ataxia (CVM only). Although uncommon, multiple DOD conditions may develop in the same animal.

OC is a focal disturbance of endochondral ossification that results in a thickened area of articular cartilage. This may also present with fragmentation, referred to as a dissecans lesion or OC(D). The etiology is multifactorial, with no single factor accounting for all aspects of the disease.[66] The most commonly cited etiologic factors are heredity, rapid growth, anatomic conformation, trauma, and dietary imbalances; however, only heredity and anatomic conformation are well supported by the scientific literature.[49,57,66] Formation of fragile cartilage, failure of chondrocyte differentiation, subchondral bone necrosis, and failure of blood supply to the growth cartilage all have been proposed as the initial step in the pathogenesis.[41,66] High-circulating insulin levels from high-energy feeding has also been suggested to contribute to altered matrix metabolism and faulty mineralization.[28]

Although the exact cause for DOD is unknown, several risk factors predispose young horses to develop these diseases. The major risk factors appear to be nutritional imbalances, trauma, and genetic predisposition.[50] Nutritional imbalances include energy and phosphorus excesses; calcium, phosphorus, and copper (Cu) deficiencies; or any combination of these.[50] Feeding rations high in energy appears to predispose young animals to DOD abnormalities, presumably by contributing to rapid bone growth. However, in a recent study, weanling horses fed a high-starch diet had no increase in OC(D) lesions compared with those fed a medium-starch diet.[43] Defective collagen cross-linking from a deficiency in lysyl oxidase (an extracellular copper-dependent enzyme) may impair the strength of bone collagen, essentially producing a soft bone syndrome, particularly in the metaphyseal regions.[26,49] Trace mineral deficiencies, particularly copper, have been shown to cause clinical signs and joint pathology consistent with OC in foals.[26] However, copper supplementation of mares and foals had no significant effect on the frequency or severity of articular cartilage lesions in foals at 160 days of age.[22,44] The importance of copper deficiency in the pathogenesis of OC(D) is currently thought to be overemphasized.[22] In addition, trace mineral supplementation to yearling horses had no effect on growth and development, and no skeletal abnormalities were detected.[43] It has been suggested that it is likely most important to make sure the mare has adequate copper supplementation in late gestation to help protect the foal from joint pathology.[58]

VetBooks.ir

Trauma to the metaphyseal or epiphyseal growth plates may also contribute to altered growth, subchondral bone damage, avulsion of defective bone, and disruption of the physeal vasculature, all of which may predispose to DOD conditions. Weight, limb conformation, and excessive exercise may be contributing factors.[50, 57] Genetics most likely plays a role in the occurrence of these diseases, but its contribution is difficult to determine. OC is most likely a polygenic trait with a complex method of inheritance.[66] A genetic predisposition has been demonstrated in dogs, pigs, and horses.[49] Populations of risk alleles from two separate populations of OC(D) affected Standardbreds suggested that there is a true risk locus as a contributing etiology.[36] However, in most cases, the underlying cause of the DOD condition is multifactorial, usually obscure, and often never determined.[4,62] Factors that may have contributed to the disease process are often long gone by the time a veterinarian is asked to evaluate the horse. In addition, the timing at which risk factors may exert their effects on bone growth and development is currently unknown. Discussions of each specific DOD condition seen in growing horses are presented throughout this chapter.

EPIPHYSITIS/PHYSITIS/PHYSEAL DYSPLASIA

Physitis or epiphysitis is an important generalized bone disease of young growing horses characterized by inflammation and enlargement of the physeal region of certain immature long bones (Figure 10.9).[4,5] Most cases of physitis occur in young, rapidly growing horses such as weanlings, with a peak incidence between 4 and 8 months of age,[61] but even yearlings and 2-year-old horses may also develop the condition. It may affect a single or multiple growth plates, but is often bilaterally symmetrical.

Physeal dysplasia may be a more appropriate term because the condition is thought to be characterized by a disruption of endochondral ossification within the physeal growth cartilage.[5] However, in one study, physeal cartilage abnormalities and compromise of endochondral ossification were not frequently seen in Thoroughbred foals with visible bony enlargements of the distal metacarpus/metatarsus.[23] This questions the clinical significance of these physeal swellings and suggests that they may be physiological swellings associated with normal bone remodeling.[23]

ETIOLOGY

Although the exact etiology of physitis is unknown, it is most likely multifactorial and may differ from case to case.[4,5] For instance, in foals with multiple limb involvement, a nutritional problem affecting the entire animal seems most plausible. In contrast, physitis involving a single site is likely due to trauma or excessive compression of the affected physis.[4] Secondary ALDs tend to occur more frequently with trauma-induced physitis than from other causes. Foals with severe lameness in one limb may develop physitis and an ALD in the contralateral limb because of excessive weight-bearing (Figure 10.10).[3] However, in many cases, physitis appears to have a mechanical as well as a nutritional component. In young

Figure 10.10. Varus angular deformity of the left front fetlock in a foal that suffered a fracture on the opposite limb. Note the secondary physitis present with sclerosis (arrows) present in the distal medial metaphyseal region of the metacarpus.

foals, inflammation around the physis tends to occur when this newly forming bone is not able to withstand the load being placed on it.[5] This is usually because either the normally growing bone has too high of loads being placed on it as a result of being overfed for rapid growth,[4] exercise, weight, or conformation or because the bone itself is abnormal and cannot withstand normal loads.[5] The metaphysis provides much of the longitudinal growth in the foal and is therefore more prone to inflammation from repetitive loading than the epiphysis.[5] Regions of disturbed ossification within the physis from any number of these factors may predispose the underlying subchondral bone to microfractures.[61] These microfractures could lead to clinical signs of inflammation and potentially stimulate bone production and remodeling that is often seen radiographically as sclerosis in horses with physitis (Figures 10.9 and 10.10).[4,61]

The term physitis is often referred to as physeal compression, which further emphasizes the mechanical component of physitis.[55] When compression is applied to a physis, an increased thickening of the physis occurs due to retardation of provisional calcification and increased

VetBooks.ir

survival of chondrocytes.[4,55] This is an autocorrection phenomenon in which the animal corrects any minor angulation of the limb axis. However, loads on the physis are continually under challenge in the growing animal by the increase in both body weight and activity level.[6] If the compression is beyond the physiologic limits of the physis, complete arrest of endochondral ossification may occur. The end result is asynchronous physeal growth and the development of an ALD together with physitis. This is most commonly seen at the distal radial physis in horses with carpal varus (Figure 10.11).

Septic, or infectious, physitis is a separate etiology that may present similar to traditional aseptic physitis depending on severity. Septic physitis is common in younger neonatal foals (often 1 week to 4 months of age) and occurs secondary to hematogenous sepsis and/or failure of passive transfer. The abundant metaphyseal, physeal, and epiphyseal vasculature combined with slower perfusion can create an ideal environment for infection to establish. Inflammation and osteolysis of the surrounding epiphyseal/metaphyseal trabecular bone adjacent to the physis may ensue (Figure 10.12).[6,24]

Figure 10.11. Physitis of the medial aspect of the distal radius (arrow) in a 12-month-old colt, which occurred after being kicked in the area. A carpal varus deformity developed after the trauma.

CLINICAL SIGNS

The clinical signs in young foals are variable but usually include a stiff gait with a shortened cranial phase to the stride, increased amount of time lying down, and trembling when standing, potentially buckling forward at the carpus or fetlock (Figure 10.13).[5,59,61,63] In general, physitis occurs more commonly in distal versus proximal physes, as distal growth plates have less soft tissue support and are subject to increased biomechanical forces due to the long axis of the limb creating a lever-arm stress.[6] Therefore, the most common locations of physitis are the distal radius, tibia, and third metacarpal/metatarsal bones. It is usually visually apparent as an enlarged physeal region due to the metaphyseal flaring that develops secondary to physitis (Figures 10.9, 10.11, and 10.14). The enlargement is often painful to deep palpation and can therefore result in a progressive increase in muscle tension that can lead to contraction of the flexor tendons.[5,59,61]. In the case where the cause of the physitis is due to the level of exercise or the amount of weight, the physitis is symmetrical (e.g. involves medial and lateral aspect of physis), whereas for those that are due to conformation or cartilage retention, the physitis is asymmetrical (e.g. involves only part of the physis, either medial or lateral).[5]

Physitis of the distal aspect of the cannon bones often involves all four limbs (Figure 10.13), whereas the distal aspect of the radius and tibia is usually not involved concurrently.[4] In addition, foals with metacarpal/metatarsal physitis are usually younger than foals with physitis in other locations. This may be related to the activity of the physes with respect to bone growth at varying ages. Septic physitis usually occurs in young foals that are susceptible to other hematogenous infections and show similar signs with more pain on standing and deep palpation. In severe cases of physitis, secondary Salter-Harris (type I or II) fractures (Figure 10.7B) can occur.[27]

DIAGNOSIS

Radiographs help classify the severity of physitis. Early physitis, related to a transient maladaptation to increased body weight or exercise levels, will have a normal radiographic physis.[6] With chronicity, characteristic radiographic changes develop. The most common radiographic abnormality observed with physitis is paraphyseal bone production, often termed physeal lipping or metaphyseal flaring (Figure 10.14).[5] Increased radiolucency or widening of the physis, asymmetry of the metaphysis, wedging of the epiphysis, metaphyseal sclerosis adjacent to the physis, and asymmetry of cortical thickness due to altered stress on the limb can also commonly be observed (Figures 10.9, 10.10, 10.13, and 10.14).[4,61]

Radiographic abnormalities may be disseminated across the entire physis or be focal within the physis.[6] Concurrent ALDs or OC lesions also may be present. In cases of septic physitis, cystic osteomyelitis of the periphyseal trabecular bone can develop (Figure 10.12).[6,24] In addition, MRI has been shown to be a useful tool for identifying lesions that occur in the epiphysis, metaphysis, and physis with a higher sensitivity than radiographs.[20] MRI can help provide a definitive diagnosis for earlier aggressive treatment (Figure 10.15).

VetBooks.ir

TREATMENT

Treatment of physitis in young foals needs to incorporate treatment of the symptoms (e.g. pain) but also needs to treat the source. For most, nonsteroidal anti-inflammatory drugs (NSAIDs) are indicated to decrease physeal inflammation and improve the animal's stiff gait. NSAIDs help diminish pain and may prevent the development of flexural deformities. NSAIDS are often required for at least 2–3 weeks to completely resolve the inflammation.[6] Monitoring for gastrointestinal and/or renal complications is advisable. Phenylbutazone is a common formulation used for musculoskeletal disorders.[14] Alternatively, COX-2 selective formulations (such as firocoxib or meloxicam) may be preferable due to less risk of adverse systemic effects.[14]

If the source of the physitis is obvious, then it needs to be treated appropriately. For example, if an ALD is present, the greatest degree of physeal abnormalities usually corresponds to the direction in which the limb is deviated. For example, weanlings with significant physitis of the medial aspect of the distal radial physis often develop carpal varus (Figure 10.11). This suggests that the physitis has contributed to arrested growth on the medial aspect of the physis. Autocorrection of these deviations is unlikely, and growth retardation surgery on the opposite side of the physis is often necessary to correct the ALD.

Most of the time, the exact source of the physitis not easily identified, but the amount of exercise can be adjusted since both the intensity and duration of exercise influence physeal stress. If the foal is getting too much exercise, it should be reduced, but not eliminated to prevent further trauma to the physis.[5] This can be accomplished via confinement or by changing the exercise routine such that smaller segments of exercise are delivered multiple times per day instead of one continuous period of exercise, especially in foals and weanlings.[6] If a foal spends the first few weeks of its life recumbent, the bone needs to adapt to the loads placed on it when the foal is standing. If the exercise level increases dramatically in this time frame, adaptation of the bone will not occur quickly enough, resulting in some degree of clinical physitis.[5] Therefore, careful control of exercise is important in these particular foals. In the case of an unstable physis secondary to trauma, some protection with external coaptation may be required. However, completely protecting the physis from weight-bearing forces, as could be achieved with a cast, is contraindicated unless absolutely required, as complete disuse will lead to further weakening of the growth plate.[6]

The feed ration should always be evaluated, especially if it involves multiple locations. Often a geographic nutritional deficiency may exist, especially when multiple animals are affected. The ration should be altered accordingly, and many times it is advised to reduce the animal's body weight or growth rate. However, retardation of growth rate by feeding poor-quality hay is considered irresponsible by many.[32] The recommended approach is a carefully formulated diet that specifically restricts starch and protein while supplying National Research Council (NRC) minimum requirements of other essential nutrients.[32] In general, affected horses should be fed less grain and fewer protein supplements, and the quantity of alfalfa hay should be reduced or replaced with good-quality grass hay.[4] With nursing foals, the milk production of the mare should be decreased if possible. Specific balanced rations for growing horses to minimize the development of physitis and other DOD diseases have been developed and can be considered.

In cases of septic physitis, early recognition and aggressive management with systemic and local (intravenous or intraosseous) antimicrobials are required. In select cases, debridement of osteolytic, necrotic periphyseal bone is required. Premature closure of the growth plate with subsequent ALD or limb shortening may be complicating sequela.[6,24]

PROGNOSIS

Fortunately, the majority of physitis cases are mild and are often self-limiting. Most cases resolve when skeletal maturity is reached and growth of the affected physis ceases. In many cases, a mild amount of physitis may be part of the normal aspects of bone modeling and remodeling; as such, foals simply grow out of the problem.[5,6,23] More severe cases of physitis, such as those that develop concurrent angular or flexural limb deformities or those resultant from sepsis, may cause residual problems severe enough to limit future athletic soundness of the horse.[5,6]

ANGULAR LIMB DEFORMITIES (ALDS) AND CUBOIDAL BONE MALFORMATIONS

Nicolas S. Ernst, Troy N. Trumble, and Gary M. Baxter

ANGULAR LIMB DEFORMITIES (ALDS)

Angular limb deformities (ALDs) are defined as conformational deviations in the frontal plane. These are axial deviations that are based on the relationship of the limb distal to a particular joint. Valgus and varus are the terms used to describe ALDs in foals. Valgus indicates an outward shift of the limb distal to the joint of origin, while varus indicates an inward shift of the distal limb. For instance, carpal valgus refers to a deformity in which the carpus is the site of the lesion and the limb distal to this joint (third metacarpal bone) is deviated away from the midline of the body (Figure 10.16).

A large number of foals examined during the first month of life can present with limb deviations, which will decrease on prevalence and severity with increasing age and exercise. Carpal valgus is the most common ALD seen in foals, followed by fetlock varus, carpal varus, and tarsal valgus.[4,5,15,18,19,22] Tarsal varus is rare, as are deviations of other parts of the limbs.[4,13,20] Foals with ALDs due to asynchronous physeal growth typically are not lame and have few physical examination abnormalities other than crooked legs. If lameness is present, physeal trauma, fracture, collapse, or sepsis of the cuboidal bones should be suspected as the cause of the limb deformity (Figure 10.17).[6]

Figure 10.16. Young filly with bilateral carpal valgus.

ETIOLOGY

Foals can be born with ALDs or can develop them over time. Proposed causes in foals born with ALDs include malpositioning *in utero*, *in utero* chemical insults such as locoweed, and hormonal or nutritional imbalances.[6,21,24,32] However, most ALDs occur over time with 73.2% of acquired deviations appearing between 3 months of age and weaning age, irrespective of the joint.[25] Acquired causes of ALDs in foals include laxity of periarticular supporting tissues, incomplete ossification of the tarsal or carpal cuboidal bones, direct trauma to the physis as with concussion or fractures, traumatic luxation or fracture of the carpal bones (Figure 10.17), and asynchronous longitudinal growth of the metaphysis and epiphysis (Figures 10.10 and 10.16).[4,6,22,32] By far the most common reason for ALDs in foals is asynchronous metaphyseal growth. For often unexplained reasons, one side of the growth plate grows faster than the other, resulting in a deviation of the normal limb axis.[18] Trauma across the growth plate is believed to be one of the main underlying causes of asynchronous growth.[18] Trauma may retard calcification of the matured and dying chondrocytes, resulting in thickening of the physeal plate with an increasing number of chondrocytes at the hypertrophied cell layer.[6] If compression is excessive, chondrocytes may undergo necrosis and the physis may prematurely close or growth is slowed. Any factor that causes asymmetric loading across a growth plate can lead to this sequence of events, resulting in an ALD.[6,15] Such factors include joint laxity, hypoplasia of the cuboidal bones, poor foot trimming, heavy muscling, excessively active foals, or lameness in the opposite limb (i.e. foals develop support limb ALDs instead of laminitis).[4,6,18]

CLINICAL SIGNS

Laxity of Periarticular Support Tissues

Foals with ligamentous laxity are often termed windswept because their limbs are very flaccid and tend to deviate in the same direction. The carpus or tarsus is usually affected, and one limb has a valgus deviation and the

(A) Physical examination of the carpus revealed effusion of the middle carpal joint and pain on flexion. (B) Dorsopalmar radiograph of the carpus, which revealed a fracture of the ulna carpal bone (arrow) and collapse of the lateral aspect of the middle carpal joint.

other has a varus deformity (Figure 10.18). Usually the limbs can be manually straightened, indicating a soft tissue or cuboidal bone ossification problem and not a deviation of the bony column. Affected foals are usually within 2 weeks of birth, may be premature, and usually are not lame. At the walk, the affected joint may deviate inward or outward when weight is placed on the limb (hence the term spaghetti legs) due to the weakness of the supporting soft tissue.

Delayed Ossification of the Tarsal or Carpal Cuboidal Bones

Affected foals are usually born premature or dysmature and may have concurrent ligamentous laxity.[24] The limbs are often straight at birth and then begin to deviate within a few days or weeks due to collapsing of the cuboidal bones (Figure 10.19). Valgus deviation of the carpus and tarsus occurs most commonly.

Physeal or Articular Trauma/Fracture

The majority of foals with physeal or articular trauma/fracture have no history of limb deformities until after a traumatic incident. They may have a single limb involved, are usually lame, and often have joint effusion (Figure 10.17). Lameness and pain on manipulation of the affected joint are the most important clinical findings to suggest trauma as the cause of the ALD. Radiographs are essential to make a definitive diagnosis.

Septic Physitis of Cuboidal Bones

The physis within the cuboidal bones can become septic in young foals. This is most likely from a hematogenous route, but can also be from trauma. Any physis or cuboidal bone can be affected, but most foals only have a single limb involved. The foals are usually significantly lame and have joint effusion or pain localized to the physis. Sepsis can cause significant lysis of the physis or cuboidal bones leading to collapse that ultimately contributes to an ALD (Figure 10.20).

Asynchronous Longitudinal Growth

Foals with asynchronous physeal growth appear clinically normal except for their crooked legs. No palpable abnormalities should be present and the limbs cannot be straightened manually. Varying degrees of outward rotation of the limb often accompany foals with carpal valgus (Figure 10.16).[6,32] Multiple types of ALD may be present in the same foal, especially if it has not been treated. Carpal valgus and fetlock varus may occur concurrently, and the treatment of one deformity most likely affects the other (Figure 10.21).

DIAGNOSIS

Foals with ALD of almost any joint can usually be diagnosed by visual exam. When examining foals for ALDs, it is important to note that correct conformation

VetBooks.ir

Figure 10.19. Radiograph of a newborn foal that has a carpal valgus deformity due to delayed cuboidal bone ossification.

for the foal is not the same as correct conformation for the adult.[2,3,16,26] Foals will undergo changes during growth and maturation that can rapidly change the conformation. In general, examination of the foal for ALDs should start as close to birth as possible, then every week until 1 month of age as this is a critical time in which many changes can occur in response to growth and exercise demands. Examinations should then be continued on a monthly basis until 6 months of age. A complete exam entails examination of the limb of interest in a standing and a flexed position, followed by exercise and radiographs. When examining the limb standing, rotation of the limb can make interpretation of the degree of ALDs more difficult, especially those distal to the fetlock.

Rotation of the limb or torsion around the weight-bearing axis of the limb is often associated and coupled with ALDs. Therefore, when examining a limb for ALDs, it is very important to be directly lined up in front of the limb and not just in front of the foal (Figure 10.22). Being directly lined up in front of the limb will give a more accurate assessment of the ALD, especially when there is a rotational component to the limb as well. Most foals have some degree of external (toed-out) rotation that will generally improve with age as the chest broadens and pushes the elbow outward.

Figure 10.20. Septic cuboidal bones (black arrows) in a 1-month-old colt.

VetBooks.ir

Figure 10.21. Foal with a combination of carpal valgus and fetlock varus. Straightening the carpal valgus would probably make the fetlock varus worse and must be considered when developing a treatment plan.

Elevating or flexing the limb will often help alleviate some of the perceptual problems that can be encountered from rotation of the limb. Flexion of the limb around the joint of interest allows the examiner to compare the relative position of the distal limb to proximal limb by putting them in closer proximity to each other. In addition, it helps to distinguish some of the more complicated cases in which there are ALDs involving both the carpus and fetlock.[19] Picking up and manipulating the limb in a medial-to-lateral direction also allows the examiner to determine whether the limb can be manually straightened or not. If the limb can be manually straightened, it is highly likely that the deformity is centered within the joint and results from delayed ossification of the cuboidal bones or laxity of the periarticular soft tissues. If the limb cannot be straightened, the deformity likely originates at the physeal region. Watching the foal walk is often very useful in distinguishing how much of the ALD is a component of ligamentous laxity. Ligamentous laxity will tend to show more exaggerated movements around the joints of interest, making the ALD more pronounced. In these foals, it is important to make note of the age and exercise level of the foal to know what the best treatment for correcting the laxity so that a better evaluation of the ALD can be made. For example, neonates are often very lax and require more exercise, whereas older foals that have exercised rigorously need to be stall confined for a few hours for the laxity to improve.[4]

If foals are examined on a regular basis, radiographs are not necessarily required unless radical changes have occurred between examinations. However, if it is the first time the foal is examined for ALDs, especially in older foals, radiographs provide the most conclusive evidence about the location and potential cause of the ALD. For ALDs, only dorsopalmar and lateral radiographic views are required unless there is evidence of problems within the joint, and then oblique views should be added. The radiographs should be centered over the joint of interest and include the middiaphysis of the proximal and distal long bones. These views allow identification of the "pivot point" of the ALD by drawing lines down the middle of the long bones on the dorsopalmar view.[6,24,32] Where the lines bisect is where the deformity is thought to originate (Figure 5.4). In the case of asynchronous growth across a distal physis, the deviation arises from the distal metaphyseal region rather than within the joint (Figure 10.23A). Wedging of the epiphysis on the concave side of the deviation, abnormal contour of the cuboidal bones, and displacement of the splint bones often accompany limb deviations of the carpus and tarsus but usually resolve when the limb straightens (Figure 10.23B).[6,22] Epiphyseal wedging is especially prominent with varus deformities of the fetlock (Figures 10.10 and 10.24), and collapse of the lateral aspect of the third carpal bone is common with carpal valgus deformities (Figure 10.23B). However, severe abnormalities such as physeal or cuboidal bone fractures or crushing of the carpal or tarsal bones in conjunction with an ALD are a major concern and may contribute to permanent lameness problems, even if the deviation is corrected.

TREATMENT

Treatment depends on the cause, location, and severity of the ALD, as well as the age of the foal. In general, varus deformities appear to be more problematic for future soundness than valgus deformities. Varus deformities of the fetlock (pigeon-toed) are thought to contribute to pastern and fetlock lameness problems, whereas mild carpal valgus was found to be protective for carpal injuries in racing Thoroughbreds.[3] Most foals have a mild degree of carpal valgus conformation (approximately 5°) that tends to decrease as they grow older.[16,28] Foals tend to grow into the mild carpal valgus as the chest expands during growth.[16,32] If the limb is completely straight as a foal, a carpal varus may develop as the chest expands during growth. In contrast, fetlock varus deviations tend to worsen with age up to 6 months.[28] Therefore, mild carpal valgus deformities should not be treated, whereas minor varus deformities of the fetlock probably should be addressed because of the potential to worsen with age.

VetBooks.ir

Figure 10.22. Images of the right forelimb of a weanling as viewed from directly in front of the horse (A) and lined up with the externally rotated hoof wall (B). Note that the carpal valgus looks similar in both images, but the fetlock looks different (slightly valgus in A and varus in B). It is important to line up with each limb since many limbs are externally rotated in foals.

Conservative Treatment of Asynchronous Physeal Growth

Conservative treatment of asynchronous physeal growth usually involves a combination of time, exercise restriction, and foot care in foals with mild to moderate ALDs. Under normal circumstances, most foals autocorrect their deformity because the bone grows faster on the concave side and slower on the convex side (Wolff's law).[14,17,32] This only occurs under physiologic loads, so the goal of confinement is to minimize overloading of the physis. Overactivity may cause or perpetuate physeal trauma and excessive loading, possibly preventing the limb(s) from autocorrecting. Restricting the foal's exercise by confining the mare and foal to a stall and run or small paddock/pasture is usually adequate. Confinement is usually continued until the limb has straightened.

Foot trimming (or balancing) also may minimize compressive forces on the physis. In foals with varus deformities, the hoof does not wear as much on the medial side and becomes compressed on the lateral side. The opposite occurs with valgus deformities. The goal of trimming is to remove the hoof wall that is overgrown (trim the hoof on the side that the leg goes; inside hoof for varus deformities and outside hoof for valgus deformities) to make the foot flat or balanced.[24,32] This should be done with only a rasp to avoid excessive trimming. Glue-on shoes (Dalric, Advanced Equine Products, Versailles, KY) with lateral or medial extensions also may be helpful to minimize asymmetrical loading of the physis and pull the limb inward or outward. The extensions are placed on the opposite side of where the deformity goes (lateral extension for varus deformities and medial extensions for valgus deformities; Figure 10.18). Frequent reevaluations (e.g. every 2 weeks) with or without radiographic examination should be performed to monitor the progress of conservative therapy.

Confinement and minor foot trimming can correct many foals with mild to moderate ALDs and should always be considered as the initial therapy if possible. However, aggressive and prolonged trimming may lead to concurrent angular deformities elsewhere in the limb that may worsen the overall condition of the foal. For example, a secondary varus deformity of the fetlock may develop in some foals with carpal valgus treated conservatively.[4] Conservative management is usually not recommended or successful with a severe deformity of any physis in any age foal. The asymmetrical loading of the physis is usually beyond the physiologic limits in these cases, making autocorrection unlikely.[17,32] In addition, a severe ALD has a greater likelihood of causing permanent damage to the tarsal or carpal cuboidal bones if not corrected early in life.

Surgical Treatment of Asynchronous Physeal Growth

Surgical treatment of foals with ALDs is directed toward accelerating growth on the concave side or slowing growth on the convex side.[4,5,15,18,19,32] Hemicircumferential transection of the periosteum and periosteal stripping (HCTP+PS) is used to stimulate growth, and various forms of transphyseal bridging (TPB) are used to retard growth.

Physeal growth has been reported to occur by stimulation of the physis with fan-shaped stab incisions and placement of needles directly into the physis.[11] These techniques were reported as another method to treat ALDs and as an alternative to HCTP+PS.[11] The exact mechanism contributing to physeal growth stimulation is unknown but is thought to be a mechanical release of the periosteal restraint of growth.[4,5] However, there is controversy regarding the true benefit of HCTP+PS. In practices where foals can be examined on a consistent basis, clinicians found that most correct on their own, with only changes to the exercise regimen.[29] This has been confirmed by two studies. A controlled model of ALD demonstrated no benefit of HCTP+PS compared with controls treated with confinement and hoof trimming.[25] Another study in nine foals with naturally occurring carpal valgus deviation reported that correction of carpal ALD was not significantly corrected by HCTP+PS.[31] These studies and observations have questioned whether HCTP+PS is a necessary surgical procedure in foals with ALDs. However, many veterinarians remain convinced that it is beneficial because foals with ALDs treated conservatively improve after HCTP+PS is performed.[4,11,18]

TPB is effective and is currently the most reliable surgical technique to correct limb deformities. However,

VetBooks.ir

the advantages of HCTP + PS over TPB techniques are that the procedure is easy to perform, has minimal complications, and is less expensive than TPB procedures and the limb does not overcorrect. In addition, the majority of horses can perform well after surgery, although racing performance has been shown to be reduced if HCTP+PS is performed at two or more anatomic locations.[23] Despite these benefits, HCTP+PS appears to be most useful for mild to moderate cases of ALD that have not responded to conservative treatment. Foals with severe ALD at any location are best treated with TPB.

Retardation of endochondral ossification on the convex side of the deformity can be accomplished with various TPB procedures.[10,13,18,20,22,33] The bridges may consist of staples,[10,18] screws and wires,[4,22] a small plate spanning the growth plate,[18] or a transphyseal lag or positional screw placed across one side of the physis[20,33] (Figure 10.25). A positional screw is currently recommended to avoid screw breakage and difficulties in screw removal. The transphyseal screw technique is especially useful in the tarsus because of the ease of screw placement (the epiphysis is narrow and angled), but can also be used primarily in the fetlock (Figure 10.25B).[20,29,33]

The implants create a static compression across one side of the physis so that bone growth is retarded.[17,32] Slowed growth on one side of the physis and continued growth on the opposite equalize the relative length of the medial and lateral aspects of the distal metaphysis, thereby straightening the limb. Once the limb is straight, the implants must be removed or the limb will over correct. Limb growth usually returns to normal following implant removal. However, continued growth retardation has been seen following removal of the transphyseal screw, and this should be considered when deciding when and where to use this technique. Other considerations for a transphyseal screw are the potential for the development of a physitis that results in metaphyseal collapse (creates an angular deformity in the opposite direction) when used for carpal ALDs.[9] Due to this and the fact that use of a transphyseal screw increased the risk of physitis that required further treatment, surgeons should carefully weigh the pros and cons of using a single screw in the carpus.[9] The advantages of the TPB procedures are that severe deformities can be corrected quickly and most surgeons feel that the results are more reliable than HCTP + PS. The disadvantages include that the procedure is more difficult to perform, there are more wound healing complications (can cause a cosmetic blemish), a second surgical procedure is needed to remove the implants, and the limb can overcorrect if the owners fail to monitor the limb or the implants damage the physis. For these reasons, most surgeons utilize TPB in severe deformities that will not correct with HCTP + PS alone or in older foals/weanlings where the growth potential of the physis may be limited.

All improvements should be made within the time frame for maximal growth for each particular growth plate so that the bone can still respond. The maximal

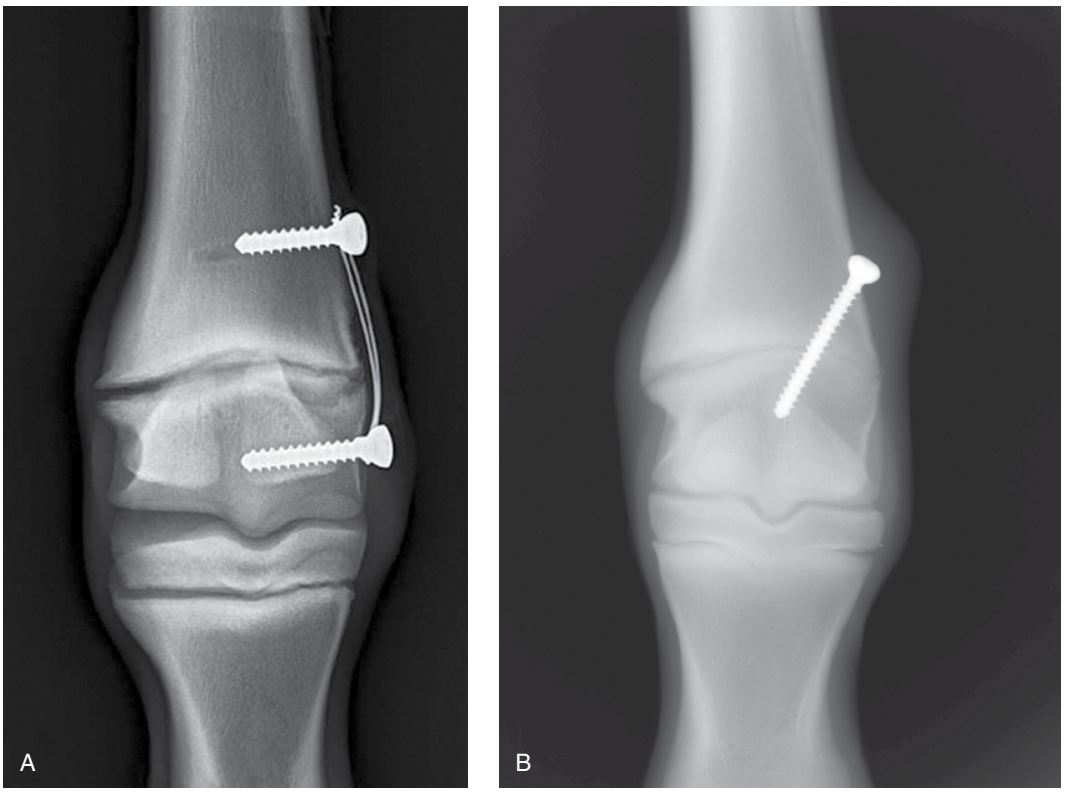

Figure 10.25. Dorsopalmar radiographs demonstrating transphyseal bridging of the distal physis of the third metacarpal bone using (A) screws and wire and (B) a transphyseal screw.

VetBooks.ir

growth in the distal physes is over after 2 months for the metacarpal/metatarsal bones, 4 months for the tibia, and 6 months for the carpus.[4] In most cases, ALDs of the fetlock or phalanges should be treated surgically within 45–60 days of age, or sooner if they are worsening.[4,32] Hunt recommends that HCTP+PS be performed by 1–2 months and TPB by 3–4 months to achieve correction of ALDs at the fetlock.[18] However, some minor limb deviations of the fetlock may be corrected with TPB after 4–6 months of age. The distal radial and tibial physes close at a later age, and therefore conservative therapy can be continued longer (up to 4–5 months). However, if the deformity is severe (more than 15°) or if limb deviation worsens with time, then surgery should be performed earlier.

In most cases of carpal and tarsal deformities, surgery is indicated if the limbs have not corrected by 4–5 months of age.[18,20,33] Carpal valgus deformities of less than 10° in foals less than 4–5 months of age may benefit from HCTP+PS alone.[4,5,18]

The HCTP + PS technique should be performed by 45 days of age to correct fetlock deformities and in one study was most beneficial for tarsal valgus deformities if performed by 60 days of age.[13] TPB techniques are usually recommended for carpal deformities greater than 10°, especially in foals older than 4–5 months, and for most fetlock deformities in foals older than 2 months of age. The transphyseal screw is the recommended TPB technique for the tarsus because it is much easier to place than staples or screws and wires. The mean age of foals in two different studies with fetlock, tarsal, or carpal deformities that were treated with transphyseal screws was 94, 220, and 377 days, respectively.[20,33] These average ages were greater than what is currently recommended for TPB techniques, but several older horses were treated in these studies, which contributed to the greater mean ages. Depending on the severity of the deformity and to ensure correction, the upper age limit for using TPB techniques should be approximately 6 months for the tarsus and carpus and 3 months for the fetlock. However, horses older than these upper limits have been treated successfully with TPB techniques, depending on the severity. TPB can be performed successfully up to 14–16 months of age in the carpus, up to 12 months of age in the tarsus, and up to 7 months of age in the fetlock.[18,33]

Many veterinarians' philosophy about managing foals with ALDs appears to have changed over the last decade. Mild carpal valgus is considered normal, and there is less desire to obtain perfectly straight front limbs at an early age. Furthermore, more foals are being treated conservatively and for longer periods of time before surgery is performed. It also appears that correction of ALDs can be accomplished with TPB techniques in foals and weanlings older than what has been previously thought. All of these findings have led to a more conservative approach to manage foals with ALDs, relying more on normal bone remodeling and growth for correction. However, severe deformities at any location and varus deformities should still be considered problematic, less responsive to conservative treatment, and often an indication for surgical intervention.

PROGNOSIS

Foals with mild and moderate ALDs of any region usually have an excellent prognosis for correction and future athletic soundness. In general, varus deformities appear to be more problematic for future soundness than valgus deformities. As such, even mild varus deviations (1°–8° deviation in the distal aspect of radius) are usually treated surgically with a favorable outcome for sales and racing performance.[30] Varus deformities of the fetlock (pigeon-toed) are thought to contribute to pastern and fetlock lameness problems, whereas mild carpal valgus may be protective for carpal injuries. Severe ALDs have the potential to cause asymmetrical loading of the carpal and tarsal cuboidal bones, contributing to collapse, articular cartilage damage, and future lameness. Early correction of severe ALDs usually helps prevent these problems and improves the long-term prognosis in affected foals.

CUBOIDAL BONE MALFORMATION/INCOMPLETE OSSIFICATION

Incomplete ossification of the cuboidal bones of the carpus or tarsus occurs most commonly in premature, twin, or underdeveloped newborn foals.[6,32] At birth, the cuboidal bones have not ossified sufficiently to withstand the forces of normal weight-bearing, predisposing to variable degrees of carpal or tarsal bone wedging or collapse.[12] In one study of foals with tarsal valgus deformities, 56% had concurrent incomplete ossification of the tarsal cuboidal bones.[13] Incomplete ossification without collapse is not readily apparent clinically in young foals and may go unrecognized until the horse has matured. These horses often develop osteoarthritis (OA) of the distal tarsal joints at an early age and become lame when put into work.[7,8] This condition has been termed juvenile arthritis or spavin.

ETIOLOGY

Cuboidal bone ossification normally occurs during the last 2–3 weeks of gestation.[32] Foals born prematurely or immature may simply have a delay in the normal ossification of the cuboidal bones (Figure 10.26). Others foals with incomplete ossification may have similar congenital or developmental abnormalities that are associated with ALDs and OCD. For example, juvenile arthritis is thought to occur because of a defect in endochondral ossification of the cuboidal bones, similar to OCD. The articular–epiphyseal physes are affected with OCD and the spherical physes of the tarsal cuboidal bones with juvenile arthritis. Cuboidal bones can become crushed or collapse over time with normal biomechanical forces if there is incomplete ossification present. This can result in ALDs and/or accelerate the development of juvenile arthritis.

CLINICAL SIGNS

Clinical signs associated with delayed cuboidal bone ossification may be evident in the newborn foal as an ALD of the carpus or tarsus (Figure 10.19). Concurrent

VetBooks.ir

laxity of soft tissue structures is often present.[24] The limb can usually be straightened manually but often bows inward or outward during weight-bearing. It is usually bilaterally symmetrical, and both the carpi and tarsi may be affected. When collapse or crushing occurs, this tends to affect the tarsal bones more commonly than the carpal bones (Figure 10.27).[12,13] Tarsal collapse is often associated with a sickle or cow-hocked conformation because the tarsus is often deviated cranially (reduced angle to the hock).[1] The tarsus may appear like it has a curb. There is usually no lameness initially, but lameness is inevitable if the cuboidal bone collapse went unrecognized and was not clinically apparent until later in life (Figure 10.27).

Incomplete ossification and mild collapse of the tarsal bones are also thought to predispose to juvenile spavin in young horses (Figure 10.28).[6–8] These horses tend to develop hind lameness and moderate to severe radiographic signs of distal tarsal OA at a young age without a history of exercise.[6] Incongruencies or minor malformations of the central and third tarsal bones are thought to contribute to the development of OA at such an early age (Figure 10.28B).[8] For unknown reasons, the distal intertarsal joint appears to be affected most commonly in horses with juvenile arthritis, with changes in the tarsometatarsal joint being more subtle (Figure 10.28A).

DIAGNOSIS

The diagnosis is based on the history, characteristic limb conformation, and radiographs indicating incomplete ossification of the cuboidal bones. Radiographically, incomplete ossification is observed as wide joint spaces with small, rounded cuboidal bones, with or without compression or crushing (Figures 10.26 and 10.27).[24] Serial radiographs should be performed on a weekly basis to monitor the progression of ossification (Figure 10.2). Ultrasound has also been reported to help diagnose and monitor progression of ossification of the cuboidal bones.[27] In the tarsus, collapse is usually located on the cranial aspect of the distal tarsus, contributing to the cranial deviation of the limb.[6,12] The lesions in the tarsus have been described as incomplete ossification with less than 30% collapse of the affected bones (type I) and more than 30% collapse with pinching or fragmentation of the affected bones (type II).[12] Type II lesions are more common and are associated with a worse outcome than type I lesions (Figure 10.27).[12] In addition, a skeletal ossification index has been proposed to classify osseous immaturity in the carpal bones, but it is not used clinically by the authors.[1]

Milder forms of incomplete ossification may not become clinically apparent until later in life. However, young horses (under 2 years of age) with hindlimb lameness localized to the distal tarsus should be suspected of having malformation/incongruency of the tarsal cuboidal bones (Figure 10.28).[8] Some of these horses also may have a tarsal valgus or sickle-hocked tarsal conformation. The diagnosis is confirmed by radiographs, which may indicate mild cuboidal bone collapse, wedging, or malformation, and signs of OA.[7,8]

TREATMENT

Treatment depends on the age of the foal, severity of the incomplete ossification, and the limbs affected. If diagnosed early, the goal of treatment is to prevent cuboi-

VetBooks.ir

dal bone collapse and maintain axial alignment until bones are fully ossified. This usually involves minimizing compressive (weight-bearing) forces on the bones until they have time to ossify completely. Confinement, sleeve casts, bandages alone, bandage casts, or bandages and splints may be used, depending on the severity.[6,24,32] However, bilateral sleeve casts or bandages can be difficult to manage in newborn foals, and the foals may have difficulty getting up and down. The decision whether to use external coaptation is made on a case-by-case basis. In addition, it is important to remember that the more rigid the coaptation used, the more lax the ligamentous structures will become in newborn foals. Therefore, the type of coaptation and amount of exercise should be reassessed on a weekly basis via the use of serial radiographs to monitor the progression of ossification. If cuboidal bone collapse has already occurred, any form of treatment is unlikely to be of benefit and abnormalities within the joints are inevitable.

PROGNOSIS

Foals that can be managed successfully to prevent cuboidal bone collapse can do well. Foals with only minor tarsal bone collapse (type I) were able to perform as intended, whereas foals with more severe tarsal bone collapse and fragmentation (type II) could not be used for their intended purposes.[12] No study has looked at the prognosis of foals with carpal bone collapse, but it is logical to assume that these foals have a more guarded prognosis than those with tarsal bone collapse.

FLEXURAL DEFORMITIES

Nicolas S. Ernst, Troy N. Trumble, and Gary M. Baxter

Flexural deformities, or contracted tendons, of limbs of young horses are classified as congenital (apparent at or near the time of birth) or acquired (develop during the growth period).[2,23] Limb deformities secondary to trauma also may be considered as acquired flexural deformities.[13] The term contracted tendons is often used synonymously with flexural deformities, but the potential for contraction of dense tendinous tissue is limited and the primary defect is usually not in the tendon itself.[23] For this reason, as well as the fact that other structures such as the suspensory ligaments, distal sesamoidean ligaments, joint capsule, and fascia can be involved,[18] the contracted tendon terminology should be obsolete. The mechanism for development is not well understood,[10] but in many instances the result is an effective functional length of the musculotendinous unit(s) that is less than what is necessary for normal limb alignment. These abnormalities are most accurately discussed relative to the joint(s) around which the deformity is centered rather than the probable affected tendons and ligaments because more than one structure may be involved.

CONGENITAL FLEXURAL DEFORMITIES

Etiology

Several factors have been incriminated as causes of congenital flexural deformities in neonates. This condition primarily has been attributed to uterine malpositioning or overcrowding, but more complex influences have been implicated, such as genetic factors, equine goiter, and teratogenic insults from toxic and infectious agents during the embryonic stage of pregnancy or from malnutrition of the mare.[10,12,23,25] Arthrogryposis, as a cause of congenital flexural deformities, has been well documented in calves but is less well defined in horses.[23]

Clinical Signs

Generally, congenital flexural deformities may affect one or more limbs with the superficial and deep digital flexor musculotendinous units being most commonly affected. Therefore, the carpus and/or fetlock cannot be completely straightened. The carpus is most commonly affected. The fetlock can also be affected with the carpus or on its own (Figure 10.29). With fetlock flexural deformities the foals may be able to stand but knuckle over at the fetlock. In newborns, the fetlock flexural deformity may be combined with laxity at the level of the distal interphalangeal (DIP) joint (Figure 10.30); if the flexural deformity of the fetlock is not corrected, subluxation of the DIP can occur.[12] In severe instances, the foals walk on the dorsal surface of the fetlock. Involvement of the deep digital flexor tendon (DDFT) alone may manifest as a flexural deformity of the DIP joint. Congenital flexural deformities of the pastern and tarsus occur, but much less frequently.[10,23] Tarsal flexural deformities are rarely seen because the deformity often causes a dystocia, leading to stillbirth, but, when present, are often combined with multiple other congenital deformities (Figure 10.31).

Rupture of the common digital extensor (CDE) tendon may occur concurrently with carpal or fetlock flexural deformities (Figure 10.32).[23,38] Occasionally, flexural deformities may not be noted despite evidence of a ruptured extensor tendon. The extensor tendon rupture may occur secondary to flexor tendon contracture, or it may predispose to the flexural deformity. Affected foals may have other associated birth defects including prognathism, underdeveloped pectoral muscles, and incomplete ossification of the carpal/tarsal bones.[23]

Diagnosis

The diagnosis is usually based on the history of being born with the problem and physical examination of the foal. Affected limb(s) cannot be straightened manually, and the foal may have difficulty standing. It is important to try to get the foal to stand, if possible, as the deformity is usually not as bad as it seems when trying to straighten the limb while they are recumbent (Figure 10.33). In more mild cases it may be possible to palpate which tissues tighten while trying to extend the limb, but this becomes increasingly difficult in more severe cases and those with contracture of the carpal fascia and/or palmar ligaments. This contributes to an arthrogryposis-like position of the carpus with minimal flexion or extension capabilities (Figure 10.29A). Radiographs or ultrasound can be performed but are usually not necessary for the diagnosis. Radiographs can be useful though for identifying any underlying abnormality of the cuboidal bones when the carpus is affected.[12] Radiographs should be considered more often in the distal limb since fetlock flexural deformities can lead to subluxation of the DIP joint (Figure 10.30B). In addition, rare pastern flexural deformities are hard to diagnose early in life without the benefit of radiographs.

Concurrent extensor tendon rupture is characterized by the presence of unilateral or bilateral swelling over the dorsolateral aspect of the carpus (Figures 5.8 and 10.32).[38] It may or may not be possible to palpate the enlarged ends of the ruptured tendon. Commonly, the ruptured CDE tendon is not recognized, and the problem is diagnosed as a carpal flexural deformity.

Treatment

Medical treatment usually consists of NSAIDs and IV oxytetracycline and is often combined with bandaging and splinting. Treatment of congenital flexural deformities should be initiated soon after recognition of the problem, with the severity of the deformity dictating how quickly and aggressively treatment should proceed.[10,31] Foals with minor congenital flexural deformities (particularly of the

carpus) may improve spontaneously and do not require treatment (Figures 10.29B and 5.6). In addition, most fetlock flexural deformities usually respond well to bandaging and splinting.[2,10,23] DIP joint deformities may respond to glue-on toe extensions that stretch the DDFT and also prevent excessive wear of the toe. However, these should be used with caution because they may produce excessive tension on the laminae.[10,27]

While NSAID treatment in young foals is not ideal, it can often be necessary to help offset the pain that is produced from the additional therapies such as splinting. It is important to have the foals be comfortable enough to stand as they will improve quicker than if then remain recumbent due to pain (Figure 10.33). Please refer to Chapter 8 for more information on NSAID therapy. Generally, it is recommended to use gastroprotectants while foals are being administered NSAIDs.

Oxytetracycline remains a common treatment for foals with congenital flexural deformities.[1,2,10,19,23] Clinically, it appears to be more effective on congenital than acquired flexural deformities, but can be used for both types. The use of oxytetracycline was first described in 1985 by Lokai and again in 1992 by the same author.[19,20] All foals in the latter study (n = 123) were treated either once or twice with 3 g of oxytetracycline intravenously (undiluted), and no external splinting was used. A 94% overall success rate was reported with the forelimbs responding better (98%) than the hindlimbs (75%).[19] Oxytetracycline's mechanism of action has been hypothesized to result from chelation of calcium in muscle or to decrease the expression of the contractile protein α-smooth muscle actin.[14,19] A recent study found that myofibroblasts made up most of the cells in the distal check ligament and the DDFT in normal foals, supporting this rationale.[14] Oxytetracycline was also found to inhibit normal collagen organization in equine myofibroblasts through a matrix metalloproteinase-1 mechanism.[5] However it works, oxytetracycline appears to be an effective method to obtain a short-term moderate decrease in metacarpophalangeal (MCP) joint angle in newborn foals. Two controlled studies have documented changes in MCP joint angles following treatment with oxytetracycline.[16,21] A significant decrease in mean MCP joint angles at rest was observed in foals 24 hours after treatment, and these angles returned to pretreatment value by 96 hours.[21] In another study, maximum MCP joint angles that occurred during the stance phase of the stride at a walk and range of joint motion were significantly increased in treated foals compared with controls.[16]

Currently, 1–3 g (or 44 mg/kg) of oxytetracycline diluted in a small amount of saline IV is recommended for the average-sized foal.[12,18] The 44 mg/kg IV dose was used in one experimental study with good effects and no alterations in blood chemistry values.[21] It is generally ideal to perform this treatment within the first few weeks of life. One or two repeat treatments may be given, but the risk of renal problems should be considered with multiple dosing or overdosing.[10,37] The authors usually combine splinting with IV oxytetracycline treatment, especially in moderate to severe cases of congenital flexural deformities.

Splints may be made from PVC pipe tubing or fiberglass cast material. The PVC pipe can be bent with heat to whatever conformation is desired while the cast material can be molded over a padded bandage. In addition, IV simplex tubing has also been used,[18] acting as a rubber band over the dorsal aspect of the limb. It is often easiest to apply bandages and splints with the foal sedated and positioned in lateral recumbency. Regardless of the method, splinting increases tensional forces to the flexor units during weight-bearing, which induces flexor relaxation through the inverse myotatic

VetBooks.ir

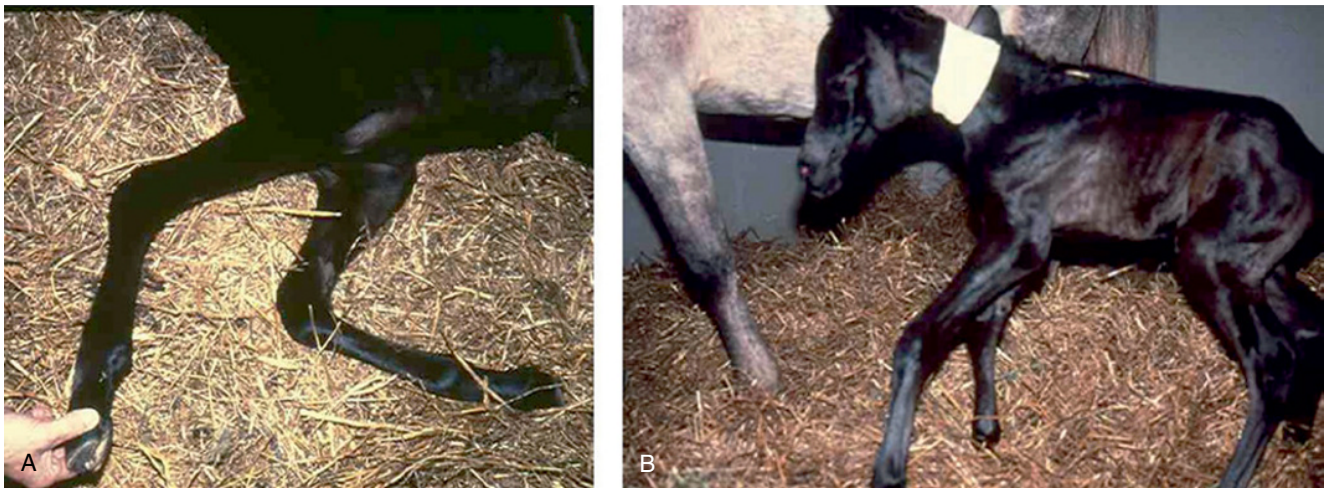

Figure 10.33. Images of a newborn foal with a carpal flexural deformity. (A) The clinician is attempting to straighten the left forelimb while the foal is recumbent. (B) Notice that the foal can straighten the left forelimb more when standing than with manual force being applied while recumbent.

reflex (stretching the musculotendinous unit leads to relaxation).[23] All splinting devices require strategic placement of padding, constant evaluation, and changing of the splints to prevent complications, as the skin can be easily irritated in foals (Figure 10.34). To help prevent decubital ulceration of the skin, many clinicians will keep the splints on for 6, 12, or 24 hours, followed by an equal amount of time out of the splint (bandage only).[12] In more severe cases where the splint needs to remain on, the angle of the splint will often need to be changed every 1–2 days as the foal starts to improve to prevent rotation and unequal pressure sores and to continue to provide constant tension to the limb.

Concurrent rupture of the extensor tendon usually responds spontaneously with stall rest, but bandaging and splinting may be needed to prevent knuckling over at the fetlock.[23,38] There is no need for surgical intervention in these foals as the ends will reappose naturally over about 6 months, with minimal swelling.[11,26] Exercise is usually restricted initially because the foals often have difficulty walking, but exercise may actually increase strength and tone in the flexor muscles.[10]

Surgical treatment of congenital tendon contractures is usually the last resort and often unnecessary. Flexor tendon tenotomies and carpal (inferior) or radial (superior) check ligament desmotomies have been used successfully but are not commonly indicated.[10,23] Transection of the superior check ligament may benefit some foals that are chronically over at the knees because the carpus becomes more hyperextended following transection.[3] Transection of the palmar carpal ligament in the palmar carpal joint capsule has been used to treat foals with severe carpal flexural deformities.[35] Tenotomy of the ulnaris lateralis and flexor carpi ulnaris 2 cm proximal to the accessory carpal bone has been used to treat less severe carpal flexural deformities with a very favorable outcome.[2,9] It is important to know that if tenotomies of the superficial or deep digital flexor tendons are performed in severe cases, then the surgeon usually cannot manually straighten the limb at surgery. This should not dictate cutting more tendons or ligaments as many will straighten within a week after surgery. Over correction is possible. Arthrodesis of the fetlock joint has also been used to correct severe flexural deformities of the fetlock in a donkey and miniature horse and may be used as a salvage procedure in some cases.[2,36] For most flexural deformities of the pastern, surgical realignment and arthrodesis of the pastern joint are usually performed with a fair prognosis for soundness.[22] Desmotomy of the peroneus tertius has been reported to improve a foal with a tarsal flexural deformity.[30]

Figure 10.34. Image of a distal limb of a foal that had multiple palmar splints applied to help straighten a fetlock flexural deformity. Notice the decubital ulceration of the skin due to pressure from the splinting.

ACQUIRED FLEXURAL DEFORMITIES

Acquired flexural deformities can be unilateral or bilateral and usually affect the DIP joint (club foot) or MCP joint (dorsal knuckling of the fetlock). Flexural deformities tend to occur in fast-growing horses or in those following a growth spurt. Flexural deformities of the DIP joint typically occur in foals and weanlings, and flexural deformities at the MCP joint are more typical of 1- to 2-year-old animals (Figures 10.35 and 10.36).[24,32,33,35]

VetBooks.ir

Figure 10.36. Visual (A) and radiographic (B) appearance of a yearling Quarter horse with a flexural deformity of the left front fetlock. The deformity did not respond to a previous inferior check ligament desmotomy.

VetBooks.ir

However, the relationship between age and the type of flexural deformity is not absolute.

Etiology

The cause of acquired flexural deformities is multifactorial. Historically, acquired flexural deformities have been grouped within the DOD complex because the potential causes and risk factors (overfeeding, nutritional imbalances, trauma, and genetics) are similar.[23] In addition, other types of DOD conditions such as physitis and OCD can often be seen concurrently in these animals and may actually contribute to the development of flexural deformities (Figure 10.37). This is because pain in the limb for any reason may initiate a flexion withdrawal reflex causing flexor muscle contraction and an altered position of the joint.[23] Chronic unweighting of the leg also may contribute to foot contracture, high heels, and the development of a club foot. Lack of exercise has been suggested to prevent proper stretching of the tendons and ligaments, contributing to limb contracture.[23] Severe trauma to a flexor tendon or its associated muscles is also known to cause tendon contracture due to fibrous tissue deposited during the reparative process.[13] The authors have seen flexural deformities of both the DIP and MCP joints develop subsequent to trauma to the elbow region.

The mechanism by which the suggested risk factors produce flexural deformities is still uncertain. Suggested hypotheses include the failure of tendons and ligaments to develop at the same rate as bone lengthening and a discrepancy between bone growth and the capacity for lengthening of the check ligaments.[13,23] Flexor muscles are stronger than extensor muscles, and the foal consequently develops a flexural deformity. These theories are not entirely compatible with our knowledge of bone growth since the majority of bone growth occurs early in life (first few months) and many flexural deformities develop later than that time period.

Clinical Signs

Flexural deformity of the DDFT centers around the DIP joint and results in a raised heel with a "club foot" appearance (Figure 10.35). The heel may be completely off the ground in severe cases (walking on the toe; Figure 10.38), but usually the heels maintain contact with the ground and grow excessively long (Figure 10.35). Most foals should not be lame, and a pronounced

VetBooks.ir

Figure 10.38. Young foal with a flexural deformity of the DIP joint, in which the hoof wall is beyond vertical and the heels are completely off the ground. Surgical treatment is recommended for these types of deformities. An inferior check ligament desmotomy was performed in this foal.

lameness should cause wariness of other problems in the limb. Dishing or concavity of the dorsal hoof wall may occur in chronic cases (Figure 10.35B), and tearing of the dorsal laminae may lead to seedy toe and toe abscesses.

The severity of the deformity may be subdivided into stages I and II based on the visual position of the dorsal hoof wall.[23,24] Stage I contracture is when the dorsal hoof wall does not go beyond vertical (Figure 10.35A), and stage II is when the dorsal surface of the hoof passes beyond vertical (Figure 10.38). The more severe the deformity, the more shortening of the musculotendinous unit, and the more aggressive treatment should be. With severe contracture, pathologic changes may develop in the joint capsule and other tissues of the coffin joint, making permanent correction less likely.[13,23] With chronicity, more changes can happen to the hoof capsule due to the pressure being placed on the toe. The degree of concavity at the toe and discrepancy in growth rings from dorsal to palmar have been categorized into different stages.[8,27]

Flexural deformity of the MCP joint has been classically referred to as contracture of the superficial digital flexor tendon (SDFT). It is characterized by dorsal knuckling of the fetlock with the hoof itself remaining in normal alignment (Figures 10.36 and 10.37). The term SDFT contracture is a gross oversimplification because the SDFT, DDFT, both the SDFT and DDFT, and the suspensory ligament in chronic cases may the involved with the deformity.[2] Early in the condition, the fetlock and pastern may begin to appear more upright with the fetlock angle approaching 180° measured from the dorsal surface (the normal angle is approximately 140°).[2] In more severe cases, the fetlock knuckles forward with every step, and the horse may stand with a dorsal fetlock angle of more than 180° (Figure 10.39).

VetBooks.ir

As with flexural deformities of the DIP joint, when the deformity goes beyond vertical (constant dorsal knuckling of the fetlock), more aggressive treatment is usually required. In chronic cases, the suspensory ligament becomes involved, fibrosis of the joint capsule may occur, and osteoarthritic changes may develop in the fetlock joint.[23]

Diagnosis

A tentative diagnosis of flexural deformities of the DIP or MCP joints usually can be made based on the characteristic foot and limb conformation. Flexural deformities of the DIP joint only involve the DDFT. Determining which soft tissue structure(s) is involved with deformities of the MCP joint is more difficult. Since these acquired deformities can developed secondary to a painful focus, such as physitis, it is important to identify any potential sources of pain, as without eliminating those, it will be very difficult to treat the flexural deformity.

The horse should be examined from a distance in its natural environment and then on flat ground to determine how much the limb can straighten while moving or standing flat. Standing palpation should then be performed to determine the presence of any asymmetries that could be related to physitis or joint effusion (possible OCD). Similar to congenital cases, the clinician can attempt to manually straighten the limb while simultaneously palpating the flexor surface of the limb to see if any specific structure becomes more taught. For instance, the DDFT, SDFT, and the suspensory ligament may all contribute to an MCP deformity.[2] Careful palpation of the limbs in both the standing and flexed positions may suggest that the DDFT or SDFT is more taut on palpation. However, if this cannot be determined, it is probably best to assume that both the DDFT and SDFT are involved to avoid failure in treatment. It is also the authors' opinion that younger horses with MCP joint deformities usually have primary DDFT involvement (Figure 10.40), whereas older horses often have both SDFT and DDFT involvement (Figure 10.36). This decision is very important when selecting surgical treatment.

Radiographs can be used to confirm the diagnosis and assess any changes in the joints involved or those affected by the abnormal stance. Lateral-to-medial and 60° dorsopalmar views of the foot should be performed in foals with DIP joint deformities and at least two views of the phalanges/fetlock for MCP deformities. The degree of DIP joint subluxation, angle of the dorsal hoof wall, and abnormalities at the apex of the distal phalanx should be observed. Varying degrees of osteolysis in the distal part of the distal phalanx is not uncommon, and the foals with the most pronounced clinical signs usually display the most prominent radiologic changes (Figure 10.41A).[4] Radiographs of the phalanges/fetlock in horses with MCP deformities usually reveal dorsal knuckling of the fetlock with no other bone abnormalities of that joint, but can have varying degrees of DIP joint subluxation (Figures 10.36B and 10.41B).

Figure 10.40. This 6-month-old Quarter horse filly with flexural deformities of both front fetlocks responded well to bilateral inferior check ligament desmotomies.

Treatment

Nonsurgical Treatment

Nonsurgical treatment may consist of changes in diet and exercise, corrective trimming and shoeing, splinting for MCP deformities, IV oxytetracycline, and the use of NSAIDs if pain is considered to be a contributing factor.[1,2,23] Mild deformities or those in the early stages of the disease are the most appropriate candidates for conservative treatment. Foals with DIP joint deformities that cannot touch the heel to the ground or MCP joint deformities that constantly knuckle forward at the fetlock are not candidates for nonsurgical treatment (Figures 10.38 and 10.39).

Animals with flexural deformities of the DIP joint should have the heels trimmed to increase tension on the palmar flexor tendons (primarily the DDFT). Trimming of the heel combined with a toe extension or elevation also may be used. Extension of the toe may be accomplished with a steel shoe, glue-on shoe, or acrylic applied to the bottom of the foot, depending on the age of the foal.[8,27] In general, toe extensions are not as well tolerated in foals as they are in older individuals.[27] Application of acrylic at the toe of foals helps maintain the health of the toe as well as the concavity of the foot while shifting

VetBooks.ir

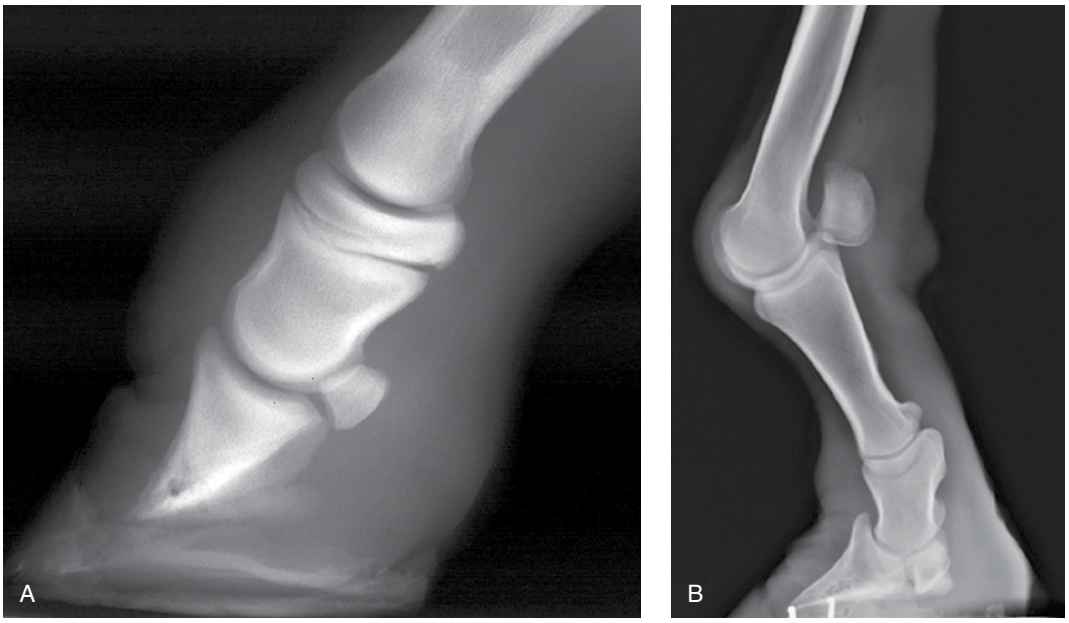

Figure 10.41. (A) Lateral radiograph of a foal with a club foot. Remodeling and lysis of the distal aspect of the distal phalanx was present, and the foal had a concurrent abscess in the toe. (B) Lateral radiograph of the distal phalanges on a yearling with a chronic MCP flexural deformity. Note that even though the fetlock joint has no changes, the DIP joint is chronically subluxated.

Figure 10.42. Rocker shoe placed on a 2-year-old horse after trimming its heel so that it could rest it forward if painful but would transfer weight to the palmar structures when walking. Walking on flat surfaces is crucial for this type of shoe to be effective.

the force palmarly.[27] As the heel is trimmed, the horse may experience pain related to stretching the DDFT and may require NSAID administration. In older individuals, another way to help counteract this pain is to use a rocker shoe that can serves to slowly stretch the DDFT (Figure 10.42) after the trim, but the horse must be walked on a firm surface to ensure that downward force goes through the heel.

It is generally recommended to raise the heels with corrective shoeing to treat horses with MCP joint deformities. This is thought to relax the DDFT and cause the fetlock to drop.[23,32] However, each case should be evaluated individually by placing wedges under the foot to either elevate the heel or elevate the toe to observe which scenario improves the angle of the fetlock (Figure 10.43). Whether heel elevation reduces strain on the SDFT and suspensory ligament is debatable, but most clinical cases respond best to heel elevation in contrast to lowering the heels.[2,23] Heel elevation (2–3 cm) combined with a 1- to 2-cm toe extension also has been advocated.[2] Corrective shoeing is often combined with splinting of the MCP joint to prevent dorsal knuckling of the fetlock. The PVC splint is applied to the palmar aspect of the distal limb to pull the fetlock in a palmar direction. Conforming the PVC splint (using heat) to the palmar aspect of the limb or use of fiberglass cast material may improve the effectiveness of the splinting.[2]

Corrective trimming and shoeing, and splinting if used, may contribute to lameness in some horses by increasing tension on the palmar soft tissues. In addition, horses must bear full weight on the limb(s) to achieve the maximum benefit of nonsurgical treatment. Therefore, low doses of oral NSAIDs are recommended for 1 to 2 weeks to help stretch the musculotendinous unit. Oxytetracycline IV can be used as an adjunct treatment similar to that in foals with congenital flexural deformities, but appears to be less effective in older animals.

Surgical Treatment

The decision for surgical treatment of DIP and MCP joint flexural deformities depends on the severity of the deformity, age of the horse, and response to conservative treatment. Surgical intervention is the only alternative in cases that do not respond to conservative methods.

Surgical options for foals with deformities of the DIP joint include an inferior check ligament desmotomy or DDFT tenotomy at the level of the pastern or mid-metacarpus.[1,2,15,29,33] Foals treated at a younger age (younger than 6–8 months) with an inferior check ligament

VetBooks.ir

Figure 10.43. Elevation of the heel vs. the toe with a wedge in horses with flexural deformities of the fetlock can help guide both surgical and conservative treatment. In most horses, heel elevation causes the fetlock to drop and improves the angle of the fetlock.

desmotomy have an improved prognosis for normal hoof conformation and for athletic performance.[29,35]

Surgical options for horses with deformities of the MCP joint include an inferior check ligament desmotomy, a superior check ligament desmotomy, both inferior and superior check ligament desmotomies, and SDFT tenotomy in the mid-metacarpus.[1,2,17,32] There is scarce information regarding the prognosis of horses with MCP flexural deformities following surgery. However, in the authors' experience, lack of response to surgery and recurrence of the flexural deformity is much more common with MCP joint deformities than with DIP joint deformities. In addition, multiple surgeries may be required since the source of the deformity is harder to initially identify. There should be at least 2 weeks between surgeries, since some horses will improve more a few days after surgery than they did immediately post-op.

The majority of DIP deformities can be corrected with an inferior check ligament desmotomy. This includes all type I and many type II deformities if the surgery is performed at a young age (younger than 6–8 months) and if combined with corrective shoeing such as a toe extension and/or toe elevation.[23,35] An inferior check ligament desmotomy is recommended in foals with hoof-ground angles of 90° or less and in most foals with deformities between 90° and 115° (Figure 10.44).[2] An inferior check ligament desmotomy is highly recommended in foals and those older than 1 year of age that have not responded to conservative therapy, with hoof deformities approaching or beyond vertical, with osteolysis of the distal phalanx, and that cannot touch the heel to the ground.

The surgery can be performed with the traditional open approach in the proximal metacarpus or with ultrasound guidance through a 1- to 2-cm incision.[15,23,24,29,33] Trimming the heel and using a shoe with a toe extension, toe elevation, or rocker shoe is recommended following surgery in most cases (especially older horses) to achieve a normal hoof conformation as quickly as possible. Normal limb alignment may be obtained almost immediately following surgery, but relaxation may progress for 7–10 days postoperatively.[23] Normal hoof conformation should be achieved within 2 weeks of surgery in most cases. Several studies have documented that the majority of foals treated with an inferior check ligament desmotomy develop a normal hoof conformation and can be used for their intended purpose.[24,29,33,35] Experimental studies also have documented that transection of the inferior check ligament causes minimal changes in locomotion, joint angles, or strains to the palmar soft tissue structures in normal horses.[6,7] The surgery itself should have minimal effects on future performance.

Tenotomy of the DDFT is usually reserved for older horses (older than 1 year) with severe deformities of the DIP joint. A DDFT tenotomy is recommended if the hoof-ground angle is more than 115° (Figure 10.44).[2] Foals with deformities between 90° and 115° may respond to an inferior check ligament desmotomy, and this should be attempted initially. However, the response to surgery is less predictable in these cases.[2,23] The DDFT tenotomy may be performed in the mid-metacarpus or

VetBooks.ir

the palmar aspect of the pastern. Greater release of the DDFT and correction of the DIP joint deformity can usually be obtained with transection in the pastern, but the wider separation of the tendon ends is more of a concern with later function. Fewer complications and a better functional outcome are usually achieved with DDFT tenotomy in the mid-metacarpus compared with the pastern region.[2] Tenotomy of the DDFT should be considered a salvage procedure; however, many of these horses can be used for light riding.[1,2]

The results of surgical treatment of MCP joint deformities are less predictable than those of deformities of the DIP joint. The recommended surgery also is less defined and is often based on the clinical experience of the veterinarian and the physical examination findings of the horse. Surgical guidelines have been recommended based on the angle of the MCP joint (Figure 10.39).[2] Mild deformities have a fetlock joint angle of less than 180°, and an inferior or superior check ligament desmotomy is recommended. Moderate deformities are those with a fetlock angle of 180° (straight upright), and performing both an inferior and superior check ligament desmotomy is recommended. Severe deformities have a fetlock angle of more than 180° (knuckled forward), and an inferior check ligament desmotomy combined with a superior check ligament desmotomy or SDFT tenotomy is recommended (Figure 10.39). Splinting is recommended after surgery for both moderate and severe MCP joint deformities.

Often the decision of which desmotomy (or both) to perform is based on which tendon feels more taut on palpation. If the SDFT is most taut, then a superior check ligament desmotomy may be appropriate, or an SDFT tenotomy if the deformity is severe. If the DDFT is most taut, then an inferior check ligament desmotomy is indicated. However, this approach is very subjective, and little information is available regarding its appropriateness. In one report of 15 cases of MCP joint flexural deformities, mild deformities were treated nonsurgically, moderate deformities were treated with an inferior check ligament desmotomy, and severe deformities were treated with both inferior and superior check ligament desmotomies.[23] In a more recent report of using tenoscopy to transect the superior check ligament, both desmotomy procedures were performed on horses with MCP flexural deformities.[17]

One author has found that younger horses (younger than 1 year) with MCP joint deformities respond better to inferior check ligament desmotomy alone than older horses. A combination of inferior and superior check ligament desmotomy is usually recommended by the author in yearlings or 2-year-olds with MCP joint flexural deformities. However, successful results have been reported with inferior check ligament desmotomy alone by some authors.[23,32] A tenoscopic approach is currently recommended for superior check ligament desmotomy to minimize the complications seen with the open approach.[17,28]

Horses with severe MCP deformities have a poor prognosis and often do not improve with either or both check ligament desmotomy surgeries.[32] Transection of the SDFT in the mid-metacarpus in the standing sedated horse is often the quickest, least expensive, and most beneficial procedure in these cases (Figure 10.45). However, an SDFT tenotomy combined with an inferior check ligament desmotomy has been recommended in these cases (Figure 10.39).[2] Suspensory ligament/branch desmotomy also may be considered when the MCP joint deformity is refractory to other surgical treatments, but is often unsuccessful due to fibrosis and scarring of the soft tissues around the fetlock that often accompany chronic cases.[23] In addition, it has been one author's experience that once the suspensory ligament is transected, there is a risk of the fetlock dropping several weeks after surgery.

Figure 10.45. Before (A) and after (B) images of a 2-year-old with severe flexural deformities of the front fetlocks that had the SDFT transected in the mid-metacarpal region. This horse had been treated previously with an inferior check ligament desmotomy.

VetBooks.ir

Prognosis

In general, the prognosis is much better for foals with DIP joint flexural deformities than older horses with MCP joint deformities. Most reports indicate that young (under 5–6 months) horses with a DIP joint deformity treated surgically have a better prognosis for future athletic use than older horses.[29,35] In one report, 33 of 40 horses treated with an inferior check desmotomy were used for their intended purpose.[33] In addition, foals treated surgically with an inferior check desmotomy had an improved prognosis for racing than those treated conservatively.[29] In another report, Thoroughbreds with a mean age of 151 days that underwent inferior check ligament desmotomy were less likely to start in a race compared with their maternal siblings. However, for those who raced, the longevity of career and earnings per race were not different than controls.[34] In contrast, the response to surgery is often unpredictable in horses with MCP joint deformities, and these horses often have a guarded to poor prognosis for soundness. In one report, horses with mild and moderate MCP joint deformities returned to useful work, but none of the horses with a severe flexural deformity became athletes.[32] Similar to DIP joint deformities, it is the author's opinion that MCP joint deformities respond much better to either nonsurgical or surgical treatments in younger horses. The sooner treatment can be initiated in either type of deformity, the better the prognosis for correction and future athletic use.

OSTEOCHONDROSIS

C. Wayne McIlwraith

VetBooks.ir

INTRODUCTION

Osteochondritis dissecans (OCD) is arguably the most important entity within the developmental orthopedic disease (DOD) complex. It is a frequent cause of lameness in young athletic horses and is the most frequent condition of the complex requiring surgical intervention. OCD has been classically considered as a manifestation of osteochondrosis.[10] Rejno and Stromberg[22] described the first stages of osteochondrosis as a disturbance of cellular differentiation in the growing cartilage and the second as involving the process of basal forces within the joint, giving rise to fissures in the damaged cartilage. The terms osteochondrosis, osteochondritis dissecans, and osteochondrosis dissecans have been regularly used as synonyms, but this is misleading. Poulos[18] distinguished them as follows: osteochondrosis is the disease, osteochondritis is the inflammatory response to the disease, and OCD is the condition in which a flap can be demonstrated. This is a simple but fairly appropriate representation.

Subchondral bone cysts (SBC) or subchondral cystic lesions (SCLs) were also proposed by Rejno and Stromberg[26] as a manifestation of osteochondrosis. The author considers that SCLs showing up clinically in the first 2 years of life are indeed manifestations of osteochondrosis. However, they represent quite a different disease than OCD. Examination of the lining of enucleated SCLs in the medial femoral condyle showed that they produce increased levels of PGE_2, neutral metalloproteinases, and nitric oxide (NO) and that there was enhanced osteoclastic resorption activity attributable to the tissue.[20] *In situ* hybridization of sections of fibrous tissue of SCLs showed that mRNA of IL-1β was upregulated at the periphery of the cystic lesion and IL-6 was upregulated in the fibrin tissue of the center.[21] Other work showed that SCLs could be produced after 5-mm-diameter, 3-mm deep defects were created in the subchondral bone plate at the central weight-bearing of the medial femoral condyle,[19] leading to an alternative pathogenesis for clinical cases in older horses.

Other diseases in the DOD complex have sometimes been referred to as osteochondrosis, but the important clinical manifestations of osteochondrosis (and the primary ones that fit this pathogenesis) are OCD and SCLs, and discussion will be limited to those conditions. Osteochondrosis also can occur in the physis, but it is uncommon and rare for it to cause a clinical problem. Figure 10.46 illustrates the proposed pathways of osteochondrosis leading to both OCD and SCLs. More details on the osteochondrosis process can be found elsewhere.[28]

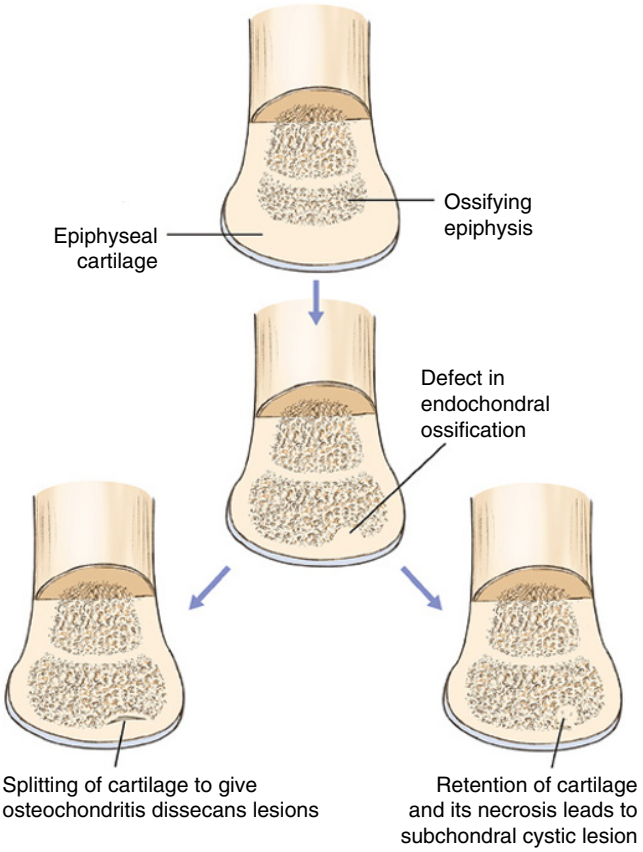

Figure 10.46. The proposed pathways of osteochondrosis leading to both OCD and SCLs.

OSTEOCHONDRITIS DISSECANS (OCD)

Disease Manifestation

Three categories of OCD lesions are recognized:

1. Those showing clinical and radiographic signs.
2. Those showing clinical without radiographic (but arthroscopic) signs.
3. Those showing radiographic, but no clinical signs.

Data from the first two categories of disease have been tabulated from the most commonly selected joints from the author's surgical case reports.[9] The relative incidence of clinical signs vs. radiographic lesions also has been documented in the femoropatellar joint by McIntosh and McIlwraith.[15] The third category of radiographic lesions has become increasingly important because of the common use of presale radiographs of yearlings.[6,7]

VetBooks.ir

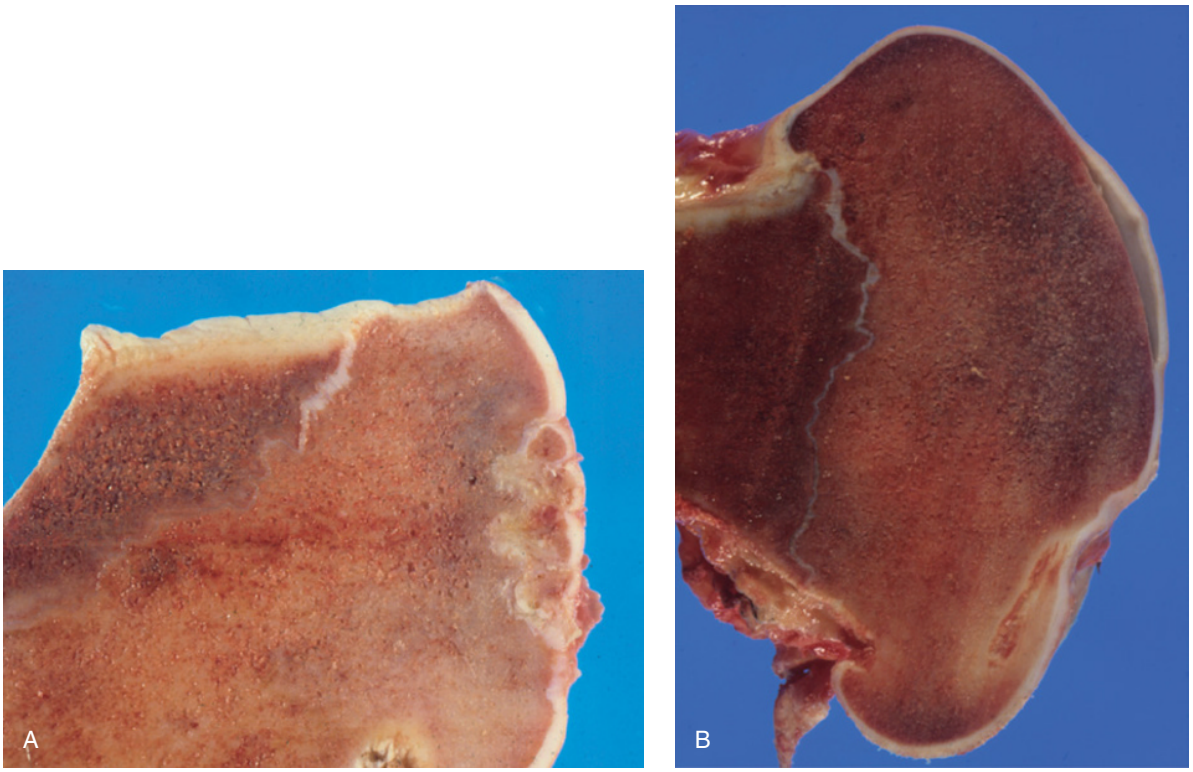

Figure 10.47. Variation in depth with which OCD lesions can extend on the lateral trochlear ridge of the femur. (A) This is a typical lesion with fragments within pathologic cartilage in a clear defect in the subchondral bone (this will be easily discernible radiographically). (B) Less commonly (and usually on the medial trochlear ridge of the femur), there can be elevated cartilage, which has normal fragments with normal bone contour and no evidence of an endochondral ossification defect.

Osteochondrosis affects the articular (joint) cartilage and often involves the subchondral bone beneath the cartilage surface (Figure 10.47A). Generally, a dissecting lesion develops that involves cartilage, or cartilage and bone, and the defection plane ultimately reaches the joint surface. It is theorized that clinical signs develop when the joint surface is reached by the dissecting lesions. Sometimes the OCD fragments can detach and become a loose body or joint mouse. In most instances, however, the fragments remain loosely attached to the bone of origin, but the debris that is released into the joint from the flap results in synovitis or joint inflammation and the clinical signs of pain and lameness that are seen with the disease.

In some instances there is no defect in the subchondral bone, but merely separation of cartilage (normal thickness) from a normal subchondral bone contour (Figure 10.47B). These manifestations not only lead to questioning of the classical defects in the endochondral ossification concept but also provide diagnostic challenges because there is no defect identified on radiographs.

OCD can affect a number of joints, but the most commonly involved are the femoropatellar, tarsocrural, and fetlock joints. Shoulder joints also are affected, but less frequently. Each of these entities is discussed separately.

Osteochondritis Dissecans of the Femoropatellar Joint

The femoropatellar joint is one of the principal joints affected with OCD. Although stifle OCD can be diagnosed in almost any breed, it seems to be more common in Thoroughbreds than in other breeds (Table 10.2).[4] Approximately 60% of affected horses are 1 year of age or younger when the condition becomes symptomatic, and younger animals that develop clinical signs often have more severe damage within the joint (Table 10.3).[4] However, incidental radiographic lesions are sometimes

identified in older horses in which no clinical signs have ever been observed.

Clinical and Radiographic Signs

Animals usually present with a sudden onset of joint swelling and lameness. A recent increase in the level of exercise is sometimes part of the history. Lameness may be very mild, with a stiff action and shortened stride observed, rather than the horse having a prominent lameness. Some more severely affected horses have a bunny hop action behind, and severe cases can sometimes be confused with a neurologic problem due to an inability to flex the stifle and may appear to be circumducting the limb. Joint distention, however, is the most consistent clinical sign seen in horses with OCD of the stifle (Figures 2.90 and 5.110). Careful palpation of the joint may identify free bodies or the surface irregularity associated with the damage within the joint. Bilateral involvement is common in the femoropatellar joint, so both joints should be examined carefully. Flexion of the limb usually exacerbates the lameness, and anesthetic placed into the joint improves or eliminates the lameness. However, intra-articular anesthesia is usually not necessary to confirm a diagnosis.

Lateral-to-medial radiographs provide the most useful information regarding specific lesion location and size (Figure 10.48). The most commonly identified defect is a variably sized irregularity or flattening of the lateral trochlear ridge of the femur. The area of the ridge that comes in contact with the distal aspect of the patella is most commonly involved. Partial mineralization of the tissue within the defect or fragment formation is often seen, and free bodies are also occasionally identified. It is rare to see OCD primarily affecting the patella, but secondary radiographic changes in the patella resulting from the trochlear ridge damage are often seen at arthroscopy (Figure 5.113). The medial ridge of the femur is less commonly involved.

Generally, the extent of damage to the joint identified at surgery is more extensive than would be predicted from radiographs.[25] Although other joints may be involved concurrently, this is uncommon. In one study of 161 horses with stifle OCD, 5 also had OCD affecting the rear fetlocks, 4 had hock OCD, and 1 had OCD of a shoulder joint.[4]

Treatment

It is generally accepted that surgical debridement of the lesions using arthroscopic surgery is the treatment of choice.[4,11,15] However, smaller lesions in younger horses may respond to rest and resolve radiographically.[15] It has also been shown in a study taking radiographs once a month for the first year of life in a group of Warmblood foals that femoropatellar OCD lesions can resolve.[3] They can develop into obvious lesions radiographically, but then completely heal. In the case of the femoropatellar joint, healing is completed (if they are going to heal) by 8 months of age. These are generally lesions that are not causing severe clinical signs. If lameness and swelling are prominent and the horse is older than 8 months, arthroscopic surgery is indicated.

As for all joint surgery, the joint is thoroughly explored, and suspicious lesions are probed. Loose or detached tissue is elevated and removed (Figure 10.49), and loose bodies are removed. The defect site is then debrided down to healthy tissue. Care must be taken to not be overly aggressive with bone debridement in young animals that have soft subchondral bone. Salvage and reattachment of OCD cartilage flaps in the stifle have been reported.[15,17] While not common, an OCD cartilage flap that is relatively smooth and is not detached on its entire perimeter can be elevated and the underlying necrotic cartilage and marrow fibrosis debrided. The flap can then be replaced and secured with polydioxanone (PDS) pins (OrthoSorb, Ethicon, Johnson and Johnson) or PLLA tacks (Chondral Dart, Arthrex, Naples, FL).

Prognosis

In one study of 252 stifle joints in 161 horses with follow-up information available for 134 horses, 64% returned to their previous use, 7% were in training, 16% were unsuccessful, and 13% were unsuccessful due to reasons unrelated to the stifle.[4] The success rate was higher in horses with smaller lesions and in older horses. However, the age factor was considered to be due to the fact that the most severe lesions were generally identified in younger horses.

Osteochondritis Dissecans of the Tarsocrural (Hock) Joint

Tarsal OCD most commonly involves the intermediate ridge of the tibia.[13] However, lesions can also develop on the trochlear ridges (the lateral ridge is much more common than medial ridge) and the medial malleolus of the tibia.

Clinical and Radiographic Signs

The most common clinical sign of tarsal OCD is effusion of the tarsocrural joint. Lameness also can be seen but it is uncommon and rarely prominent. Racehorses usually present as 2-year-olds, but nonracehorses usually present as yearlings prior to beginning training.

On radiographs, lesions, in order of incidence, can occur on the distal intermediate ridge of the tibia (DIRT) (Figure 10.50), followed by the lateral trochlear ridge of

(D) A lesion on the medial trochlear ridge of the femur manifesting as elevated cartilage of normal thickness without a subchondral defect beneath.

the talus (Figure 10.51) and then the medial malleolus of the tibia (Table 10.4). Lesions are identified as defects alone or defects containing fragmentation. The radiographic appearance often underestimates the extent of damage identified at surgery, particularly for lateral trochlear ridge lesions. The hock is also a joint in which radiographically silent lesions (those identified at surgery and in which no abnormality was seen on radiographs) occur more commonly than in other joints.[13]

Treatment

Although lameness is usually minimal with hock OCD, surgery is the recommended treatment. Lameness may only be a problem at racing speeds, or at upper levels of performance, and this cannot be determined during a clinical examination. Resolution of the effusion cannot be expected without removal of the abnormal tissue. However, not all horses need surgery. Those with small lesions, minimal effusion, no lameness, and a potential career as a pleasure horse or light use horse may not require surgery. Sequential radiographs of Dutch Warmblood tarsocrural joints showed development (and resolution in most cases) of lesions of the DIRT and lateral trochlear ridge of the talus over the first 5 months of life.[3] Surgery should be considered early enough in the course of the disease (but after 5 months of age) so that the joint capsule is not unduly stretched, which makes resolution of the joint effusion less likely. Arthroscopic surgery with removal of fragments and debridement of defective tissue is recommended.

Prognosis

In a study involving 183 horses, 76% raced successfully or performed at their intended use after surgery.[13] Only 11% were unsuccessful because of a persistent hock problem. If degenerative changes were identified at surgery in the cartilage remote from the OCD lesion (wear lines on the medial trochlear ridge of the talus), the prognosis was less favorable. Complete resolution of effusion was inferior for lesions involving the lateral trochlear ridge and medial malleolus compared with the intermediate ridge of the tibia; however, this seemed to have no

effect on subsequent performance (but can be a cosmetic issue for show horse owners). Further studies have confirmed the success rate with arthroscopic surgery.[1,8]

Osteochondritis Dissecans of the Fetlock Joint

The most common manifestation of OCD in the fetlock joint is fragmentation and irregularity that occurs on the dorsal aspect of the sagittal ridge and the condyles of the metacarpus or metatarsus (cannon bone). A second manifestation involving the fetlock is fragmentation of the dorsal aspect of the proximal phalanx. A third manifestation that has been considered by some to be osteochondrosis related is plantar/palmar fragments of the proximal phalanx. However, the consensus now is that these are avulsion fragments.

Osteochondritis Dissecans of the Dorsal Aspect of the Distal Metacarpus/Metatarsus

Clinical and Radiographic Signs

Joint swelling (effusion) is the most common clinical sign, with lameness variable in both appearance and severity. Fetlock flexion tests are usually positive. It is not unusual for all four fetlocks to be involved, and bilateral forelimb or hindlimb involvement is quite common.

The diagnosis is confirmed on radiographs, and clinically silent lesions (no effusion or baseline lameness) are often identified along with the lesions causing clinical signs. Lameness can sometimes be induced by flexion in these clinically silent joints. A variety of radiographic presentations are seen with fetlock OCD. Some joints show only flattening or a defect in the sagittal ridge (type I OCD), others have a fragment in place within the area of flattening (type II OCD), and others have flattening with or without a fragment in place, but also have free or loose bodies within the joint (type III OCD).[15,30]

Treatment

A conservative approach is initially recommended for type I lesions. Many of these cases have resolution of clinical signs, as well as improvement or disappearance of radiographic signs[12,15]; however, surgery is eventually necessary in a small number of these cases. Surgical debridement is recommended for type II and III lesions, where fragmentation or loose bodies are present.[12]

Prognosis

The prognosis is quite favorable for type I lesions, but more guarded for type II and type III lesions. In one study involving 42 horses, the success rate was approximately 60%.[12] Horses with other signs of articular cartilage erosion or wear lines within the joint had a less favorable prognosis. If the lesion extended onto the condyle of the metacarpus/metatarsus from the sagittal ridge, the prognosis was also less favorable. It was determined that clinical signs would persist in approximately 25% of cases.

OCD Fragments of Proximal Dorsal Aspect of Proximal Phalanx

Joint swelling (effusion) is the most common clinical sign, with lameness variable in both appearance and severity. Quite often these fragments are identified on survey radiographs and are presented for removal. The fragments are usually rounded in appearance and are off the proximal medial eminence of the proximal phalanx. Arthroscopically they show a typical OCD appearance with separated cartilage and defective cartilage underneath.

Osteochondritis Dissecans of the Shoulder Joint

OCD involving the shoulder joint is the most debilitating form of OCD affecting horses. Generally, large areas of the joint surfaces are involved, and secondary joint disease is common. However, it is unusual to have free or loose bodies develop. OCD of the shoulder is less common than for the other joints described and seems to affect Quarter horses and Thoroughbreds with a similar incidence.

Clinical and Radiographic Signs

Most horses with shoulder OCD present at 1 year of age or younger, with a history of forelimb lameness of variable severity. Many of these horses have prominent lameness, and if lameness has been present for many weeks, shoulder muscle atrophy is also seen. Because of the altered gait and use of the limb, many cases develop an upright or club-footed appearance to the foot, and the foot may appear smaller on the affected limb. Deep pressure over the shoulder joint often causes discomfort,

VetBooks.ir

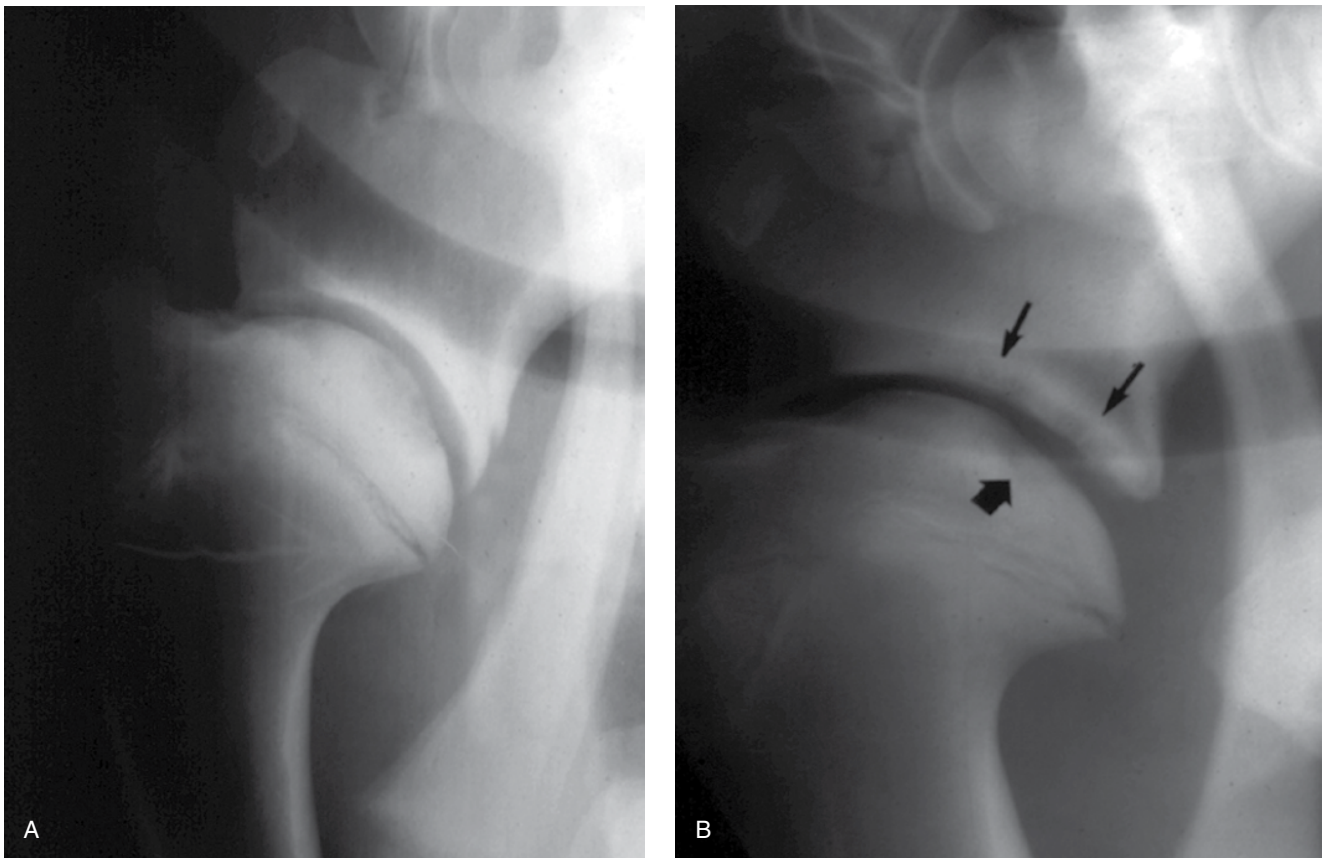

Figure 10.52. Radiographic manifestations of OCD of the shoulder. (A) This defect in the humeral head is the only lesion. (B) Defects in the humeral head (large black arrow) and glenoid of the scapula (2 black arrows).

and forced flexion/extension of the limb sometimes accentuates the lameness that is seen. Intra-articular anesthesia improves or eliminates the lameness.

On radiographs, the most common sign is flattening or indentation of the humeral head (Figure 10.52). Often, defects or cystic-type lesions are also identified in the glenoid cavity of the scapula. Productive remodeling changes are commonly identified along the caudal border of the glenoid cavity.[2]

Treatment

Historically, the author had advocated that conservative treatment is never associated with a successful outcome. More recently it has been recognized that in selected cases the radiographic obvious lesion can resolve without secondary osteoarthritis (OA) with conservative management.[15] The typical case will be localized to the glenoid, which is recognized early, and follow-up radiographs taken regularly to ensure that resolution is occurring. In the majority of cases arthroscopic surgery is necessary to achieve athletic activity, and dramatic improvement in the clinical signs in most affected cases is the norm.[2,15,16] If extensive degenerative arthritic change is present on radiographs at the time of the initial examination, the prognosis for an athletic career is unfavorable, and surgery should only be considered for relative improvement in the degree of lameness. For more localized lesions, the prognosis is favorable for a successful outcome.

The shoulder is probably the most difficult joint on which to perform arthroscopic surgery, due to the depth of the joint below the muscles in the area, and there is a learning curve.[15] Surgery is easier on younger animals due to their relative muscle mass. Problems encountered in the shoulder are inaccessibility of lesions due to their location within the joint and extravasation or leakage of fluid outside the joint, which impairs visibility within the joint.

Prognosis

A large series of cases having surgery for shoulder OCD has not yet been reported, although preliminary results from 80 cases compiled at Colorado State University suggest that the overall prognosis is approximately 50%. The prognosis seems to be less favorable if lesions are present on both the humeral head and the glenoid cavity. In unsuccessful cases, further deterioration of the joint surfaces on subsequent radiographs is common.

SUBCHONDRAL CYSTIC LESIONS

SCLs have been mentioned previously as a manifestation of osteochondrosis, at least in young horses. The most common location for clinically significant SCLs is within the medial condyle of the femur in the medial femorotibial joint (Figures 10.53 and 7.17). Other areas

VetBooks.ir

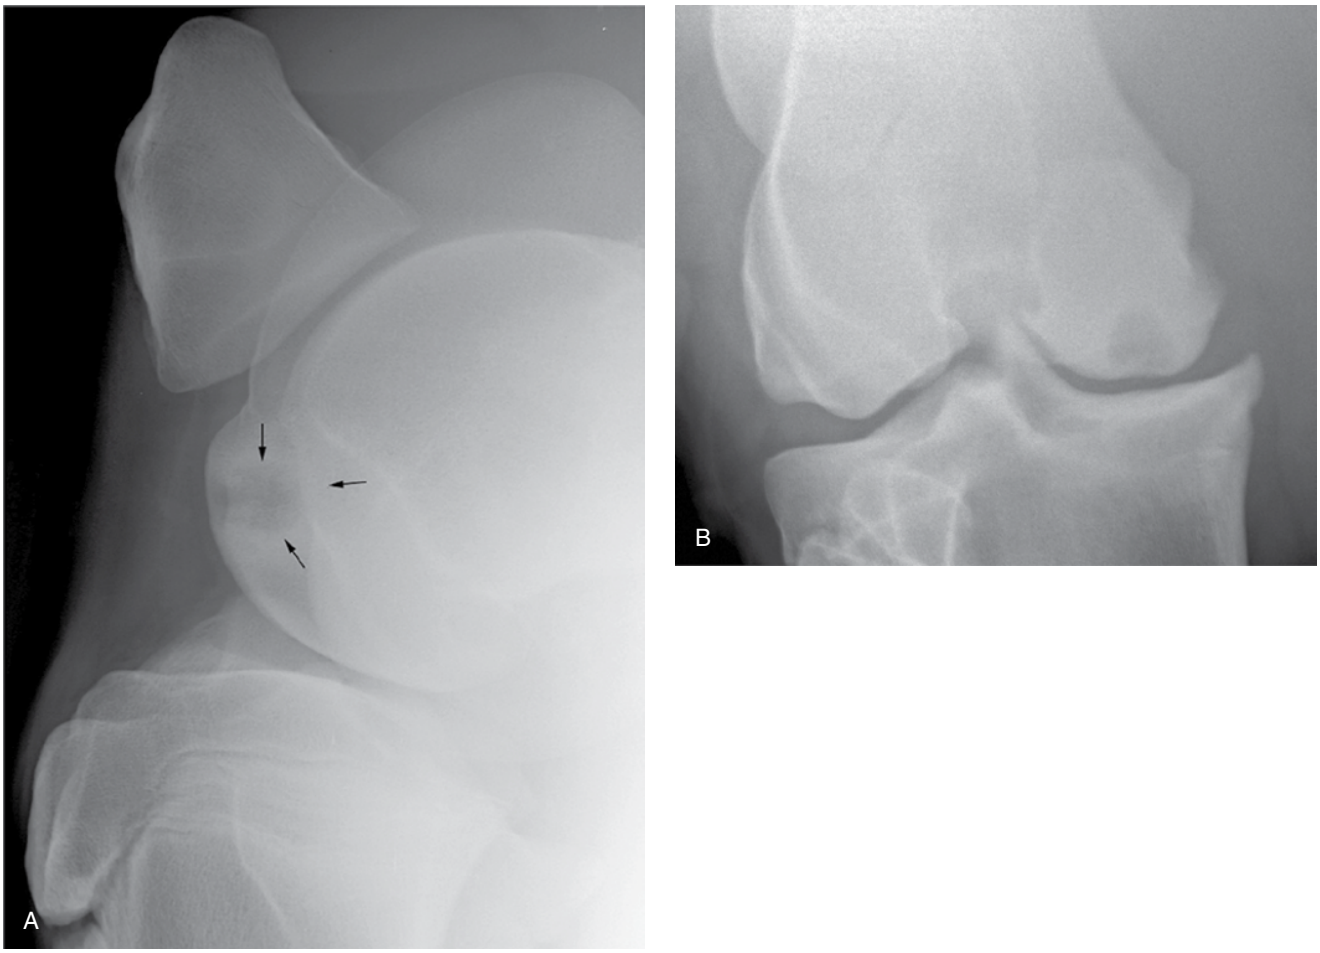

Figure 10.53. (A) Flexed lateral–medial radiograph and (B) caudal–cranial radiograph of subchondral cystic lesions (arrows in A) of the medial femoral condyle of the femur.

of importance are the distal metacarpus or metatarsus in the fetlock joint, the distal proximal phalanx in the proximal interphalangeal joint, and shoulder, elbow, carpus, distal phalanx, and talus. Principles of diagnosis and treatment will be restricted here to the most common entity, the medial condyle of the femur.

With regard to radiographic appearance and classification of SCLs of the MFC, there has been an evolution. Initially there were two types: type 1 was a radiographically domed-shaped lucent area that was confluent with a flattened joint surface, and type 2 had a circular lucent area within the condyle with a thinner radiolucent track connecting the cyst to the articular surface of the condyle (the typical manifestation as seen in Figure 10.53).[29] This early classification evolved into type 1, 10 mm or less in depth, type 2 more than 10 mm in depth, and type 3 flattened or irregular contours of the subchondral bone. More recently five different types were described by Wallace et al. in 2008 (Figure 5.127).[27] Type 1 lesions were defined as being concave and smaller than 10 mm in depth and were usually dome shaped. Types 2A and 2B were typical cystic lesions over 10 mm in depth, and the width of the surface communication was the only difference. Type 3 lesions (noted incidentally on survey radiographs of yearlings) were defined as condylar flattening or small defects in the subchondral bone usually noted in the limb contralateral to that of the clinically significant SCL, and type 4 lesions were defined as those that had a lucency in the condyle with or without an articular defect but no radiographic evidence of an opening in the subchondral bone plate (less common). Digital radiographs and surveys have led to increased scrutiny of radiographs, and type 1 lesions have now evolved into two sizes of concave defects as well as including flattening of the condyle.

The decision for surgery based on the authors' experience is based on the presence or absence of clinical signs. Most cases with clinical signs referable to the medial femoral tibia joint when there is an SCL present are typical SCLs (type 2 under the Wallace classification). Type 1 lesions are occasional associated with clinical signs and treated with arthroscopic surgery as well. Historically, SCL lesions in the medial femoral condyle have been treated with curettage,[5,24,29] but this technique is quite rarely done now. Based on recent agreement to a treatment algorithm,[14] it had arthroscopic surgery. If the SCL is found to have stable margins, the treatment of choice is intralesional injection of triamcinolone acetonide into the contents of the cystic lesion.[27] This technique was developed based on work previously cited by von Rechenberg et al.,[20] in which the lining of SCLs produced increased levels of PGE_2, MMPs, and NO, as well

VetBooks.ir

as enhanced osteoclastic resorption activity. Recently published results have shown a 90% success rate with unilateral SCLs and 67% success rate with bilateral SCLs. Some instances of SCLs (other than type 2) have been treated with debridement, but intralesional therapy with triamcinolone acetonide is attempted in the first instance and any debridement is limited to a loose flap associated with the SCL defect.

Most recently a technique of lag screw fixation across the cystic lesion has been described.[23] Promising results have been reported. The author has done a number of cases with this technique after encouraging results were reported in this paper and favorable results have been experienced by other surgeons including the author.

LAMENESS IN FOALS

Robert J. Hunt

Lameness in foals is common and may be recognized shortly after birth or at any time during development. The economic impact of foal lameness in the equine industry is tremendous. With proper treatment the outcome is usually favorable, but with improper management, the consequences may be disastrous and result in permanent debilitation, compromised economic value, or loss of the animal. Even with proper clinical management, some diseases are destined to clinical failure; it is important for the clinician to recognize these to avoid prolonged and unnecessary suffering. This chapter focuses on foals up to approximately 6 months of age.

By nature of their physical makeup, behavior, and environment, foals are particularly vulnerable to events resulting in lameness. There are multiple causes of lameness, including infectious and noninfectious etiologies. Several clinical entities are unique to foals and will be addressed. Because of the often rapid clinical progression of lameness with potentially life-threatening consequences, timely recognition along with accurate diagnosis and treatment is critical for a favorable outcome.

DIAGNOSIS

The correct diagnosis of lameness in foals begins with an accurate history, signalment including age, sex, and breed of the foal, and knowledge of the housing and husbandry practices of the farm. Also relevant is an understanding of the turnout schedules and environment, in addition to recent changes in the paddock size or the duration of turnout. Observation of the behavior of the mare and foal and herd size and temperament is important for assessing risk factors for injury to the foal. The medical history of the lame foal as well as others on the farm is vital for determining the possibility of exposure to pathogens. Information should be obtained about the mare's general condition, the presence of any medical or reproductive problems during pregnancy or parturition, and possible insufficient immunoglobulin transfer to the foal. The presence or absence of any febrile episodes and any alterations in the hemogram are important, and evidence of any infectious disease on the premises and equine traffic on the farm should also be noted.

There are specific age ranges in which the foal is most susceptible to certain disorders. For example, lameness in the post-foaling period is commonly associated with trauma during foaling or *in utero* sepsis, resulting in early-onset septic arthritis/osteomyelitis. Excessive traction during delivery of the foal may result in musculoskeletal injury involving bone or soft tissue of the extremity or injury to the ribs. Other examples are illustrated throughout the chapter in their respective areas.

The physical evaluation is the primary means of isolating lameness. A comprehensive evaluation of the entire foal should be performed to determine its overall condition and development compared with other foals on the premises. Visual observation, physical evaluation, and locomotor assessment are utilized in locating, defining, and isolating lameness and obtaining a preliminary diagnosis. Observing the foal at rest and unrestrained in the stall will allow assessment of the demeanor of the foal and allows manifestation of any subtle postural changes and gate alterations. Observation of the restrained foal may be difficult if the foal is not acclimated to a handler and it may be necessary to assess locomotion following the mare. Most present-day breeding operations handle foals at an early age to allow assessment of the foal walking while restrained. With the foal walking in a straight line, careful attention should be given to stride length, foot and limb flight pattern and placement, head and neck carriage, height of the shoulders and elbows, and symmetry across the hips as well as any tail deviation. All articular structures and all regions of the limbs and the trunk should be carefully inspected for swelling or alterations in contour.

Routine palpation of the foal should begin with gaining familiarity with the foal by rubbing and allowing contact with the foal so it is relaxed for the examination. If the rectal temperature has not yet been obtained, it should be performed. Limb palpation should commence with a normal limb to avoid confusion between a behavioral and a pain response. Unless there is an obvious area of pathology, a complete palpation should begin at the foot and extend proximally. Inspection of the foot includes observing for changes in the shape and integrity of the capsule, the presence of wall cracks, wall separation, or sole cracks. The digital pulse should be carefully assessed for intensity and compared to the opposite limb. The coronary band should be palpated thoroughly for any swelling or regions of sensitivity possibly indicating sepsis. Circumferential swelling of the coronary band is commonly associated with advanced sepsis of the distal interphalangeal joint that often requires prompt treatment. Palpation of the hoof wall includes detection of focal regions of temperature elevation or reduction. Hoof compression with a hand placing pressure across the heels will detect heel pain commonly observed with wing fractures of the distal phalanx. Commercial hoof testers may also be used here and on the rest of the foot. A painful response at the toe is commonly associated with bruising, sepsis, or fracture. In foals less the 1 month of age, abscess of the toe along with a type VI distal phalangeal fracture is common, especially in the hindfeet.

Advancing proximally the fetlock should be assessed for articular or periarticular swelling and surface temperature changes or areas of increased sensitivity to

VetBooks.ir

digital compression and flexion or manipulation of the joint. The surfaces of the proximal sesamoid bones during extension and flexion are palpated for sensitive areas. Sequential and methodical palpation of the entire limb including surfaces of the articular as well as nonarticular structures should be routinely performed. Most articular structures affected with sepsis yield a response of the foal with digital compression of the joint margins and should raise suspicions of the clinician. Likewise, focal areas of injury typically produce a pain response to digital compression and warrant further investigation with imaging procedures. Deep palpation of the proximal forelimb, vertebral column, proximal hindlimbs, and pelvis should be a routine part of the examination. Each compartment of the stifle should be isolated and palpated for effusion, pain, and temperature alteration. The entire rib cage should be carefully examined especially in the young foal that may have sustained rib fracture with subsequent forelimb lameness.

Isolation of the lame limb and the specific origin of pain may be challenging if subtle, but in general foals readily display locomotor evidence of the location of pain. Most foals attempt to avoid the painful component of the gait and usually display more exaggerated lameness reactions than adults. Observation of the young foal at rest and unrestrained in the company of the mare may be useful in detecting mild gait alterations or postural changes. Special attention should be given to the stance of the foal, particularly any trends in abnormal posture. Young, untrained foals may require gait evaluation while unrestrained and following the mare. The gait should be assessed at a slow walk in a straight line and in turns in both directions. Placement of the foot as well as limb and body carriage during ambulation is important in localizing lameness. Although there are some common findings with certain conditions (see below), there are few absolutes regarding gait characteristics and location of lameness in foals. Conventional lameness diagnostic anesthesia is often necessary to isolate the location of the source of lameness.

NONINFECTIOUS CAUSES OF LAMENESS

There are a multitude of events that may affect any part of the musculoskeletal system resulting in lameness; several disorders are unique to foals and occur routinely. Categorically lameness may be divided into infectious or noninfectious causes. Noninfectious causes include trauma, metabolic (DOD), or afflictions of vascular or neurogenic origin. For discussion purposes disorders causing lameness will be mentioned by anatomical region involved.

Virtually all components of the musculoskeletal system are susceptible to injury and lameness. Intrinsic and external sources of trauma commonly result in structural compromise to tissue of the musculoskeletal system. Other conditions resulting in lameness include those associated with DOD and disorders of vascular or neurogenic origin. Several disorders specific to foals occur routinely and are worth mention.

Foot Lameness

Distal phalangeal fractures in horses have been classified into seven types.[10,40] Although any of these may occur in foals, type VII fractures are unique to foals and occur very commonly on Thoroughbred breeding operations. There is a reported prevalence of 19%–74% that are recognized predominantly between 2 weeks and 5 months of age.[5,13,48] Fractures involve the nonarticular margin dorsal to the palmar/plantar process. They have been described as ossicles or osseous bodies but are commonly referred to as "wing" fractures.[25] The lateral palmar process is almost always involved, but occasionally they occur biaxial or bilateral; seldom is only the medial wing involved. Although factors such as hard or soft surfaces, changes in turnout schedules, and hoof conformation and application of external hoof acrylics are incriminated, no single factor has been substantiated as causative.[13,14] Because many type VII fractures are recognized as incidental findings, they have been considered separate centers of ossification; however this has not been documented.[40]

The degree of lameness associated with type VII fractures varies from non-apparent to non-weight-bearing but generally display a 3/5 lameness acutely that improves in a matter of days. While ambulating in a straight line, the foal will display a characteristic abduction of the limb during contact with the ground, presumably to reduce loading on the painful region. The lameness is more exaggerated on turns as well.

There is usually a palpable increase in the intensity of the digital pulse, but only a mild increase in the temperature of the foot. The most consistent clinical finding is an increase in reaction to medial-to-lateral compression of the hoof wall at the quarters and heels (Figure 10.54). Palmar digital anesthesia of the involved side will eliminate the lameness. The diagnosis is confirmed radiographically using the 45° dorsal–ventral

proximolateral to distal–medial oblique projections, although fractures may be seen on the lateral–medial, horizontal dorsal–palmar, and 45° dorsal–ventral projections (Figure 10.55).

Treatment for type VII fractures of the coffin bone is conservative and consists of confinement to a small area on soft, uniform bedding for 2–3 weeks or until the horse is comfortable enough for paddock turnout.[48] Rigid coaptation of the foot with a shoe is unnecessary but has become popular. Two complications of shoe application include creating limb length discrepancy resulting in the contralateral limb overload and possibly contracting the hoof capsule if the shoe remains long. Improvement in lameness is usually seen with application of a soft foot bandage, which may be changed daily or every other day for 2–3 weeks. The prognosis for future soundness is good; rarely are there any long-term ramifications or gait deficits. Differentials include other types of coffin bone fracture, foot abscess or bruising, septic osteitis, and a septic coffin or pastern joint.

Subsolar abscess with or without involvement of the coffin bone is common. It is discussed here because it is generally associated with trauma rather than hematogenous. Lameness may be recognized as early as 3–5 days of age or older. In the young foal, the hindfeet are more commonly involved, and the abscess likely begins with bruising and subsolar hematoma beneath the soft keratinized sole that is present during the first few days of life. It is common for the abscess to involve a large portion of the subsolar tissue or dissect proximally up the dorsal hoof wall or involve the coffin bone (Figure 10.56) with possible sequestration.[2,37] Subsolar abscess generally causes a severe non-weight-bearing or minimally weight-bearing gait. Treatment includes draining purulent material and protecting the foot.

It is common to for abscesses to involve the solar margin of the distal phalanx (type VI fracture), which often requires surgical curettage if sepsis is present.[34–37] Regional perfusion with antimicrobials is frequently performed and clinically appears to be beneficial. Broad-spectrum systemic antimicrobials are routinely administered once drainage is established, or in refractory cases, or if surgical curettage is necessary.

It is not uncommon for the coffin joint to become secondarily involved through extension; arthrocentesis and copious joint lavage are indicated in addition to the above treatments. Generally, with joint involvement subsequent to hoof abscess, there is a guarded to poor prognosis because this is often associated with an aggressive and rapidly spreading infection.

Proximal Sesamoid Bone

Fracture of the proximal sesamoid bones is another common lameness condition on commercial breeding farms. These are most commonly seen in foals younger than 6–8 weeks of age; they are often associated with overexertion from running.[11] Essentially all configurations of proximal sesamoid bone fracture described in the literature occur in foals, but the most common types are apical and basilar fractures with a smaller number having midbody or comminuted fractures (Figure 10.57). It is common for the fractures to be unilateral and involve only one sesamoid, or to be bilateral and uniaxial, although sometimes they are biaxial.

VetBooks.ir

(C) Dorsomedial to palmarolateral radiographic view of a mildly displaced medial basilar sesamoid fracture in a foal at time of injury. (D) Radiograph of the same foal shown in C at 16 months of age after healing.

VetBooks.ir

The degree of lameness varies from mild and perceptible only on turns to non-weight-bearing. Gross instability of the suspensory apparatus resulting in a dropped fetlock only occurs with biaxial fractures of the body with extreme distraction. Foals are at the highest risk for biaxial fractures when turned out to a paddock after being confined for a period of time.[40] Depending on the fracture configuration, there may be a soft tissue profile over the involved sesamoid. There is often joint distension, especially with the basilar sesamoid fractures. Fetlock flexion and direct manual pressure applied over the involved sesamoid usually elicits pain.[11] The diagnosis is confirmed by radiographs and may be facilitated by ultrasound evaluation.

Treatment for proximal sesamoid bone fractures in foals is conservative and consists of confinement to a stall-sized area for 4–8 weeks, followed by a graduated turnout schedule. The prognosis for future athleticism is good, but the sesamoid commonly heals in an elongated manner, which is often criticized if the horse is sold at public auction.

Only in rare instances is external coaptation with a cast or splint indicated.[40] Most devices are contraindicated for fear of promoting laxity of the flexor tendons. Likewise, surgical repair is usually futile and applies to salvage cases with total compromise of the suspensory apparatus that have marked distraction of the fracture fragments and dropping of the fetlock. The logical surgical technique is circumferential wiring or suturing of the fractured sesamoid bones. External coaptation and intensive rehabilitation to allow gradual loading of the limb are necessary. Irrespective of treatment, after severe separation, the sesamoid bones remodel in a distorted and deformed configuration, and an athletic and sale future is unlikely. Alternatively, surgical arthrodesis of the fetlock may be performed to achieve comfort; however, this is considered only for salvage and not for athletic use.

Carpus and Tarsus

Lameness associated with the carpus is usually from trauma or sepsis. Trauma may be associated with compression injury, and dysmature neonates are at higher risk. Chip fracture also may occur as a result of trauma and is often accompanied by soft tissue trauma. There are almost always outward physical signs of carpal involvement, such as pain on manipulation and palpation, heat, joint effusion, and swelling of periarticular tissue. Most carpal injuries involving cartilage, bone, and intra-articular soft tissue carry a guarded prognosis, and management depends on the type of injury. Displaced fragments that are unstable require removal and have a poor prognosis depending on the degree of articular involvement.

Tarsal lameness may be associated with wedging or crushing of the cuboidal bones as a result of dysmaturity (Figure 10.58).[8,9] Accompanying clinical features include a boxy appearance of the distal tarsus when viewed from the front and a curby or sickle-hocked appearance when viewed from the side. Radiographs should be performed on all dysmature foals to establish a baseline of the degree of mineralization of the cuboidal bones as well as the shape of the bones. Premature and dysmature foals are normally confined to a stall until 6–8 weeks of age or until acceptable mineralization has occurred to minimize wedging or crushing. Tarsal wedging or crushing usually does not cause lameness in the neonate. Gait abnormalities are recognized only after periods of exertion following turnout with other foals or after athletic activity begins. If lameness is present in the neonate with a lack of mineralization of cuboidal bones, septic osteomyelitis must be ruled out.

Figure 10.58. Lateromedial radiographic view of the tarsus of a foal showing collapse of the third tarsal bone.

Common injuries of the tarsocrural joint result in fracture of the distal lateral trochlear ridge of the talus and malleolar trauma with or without fracture. Marked synovial effusion is associated with these injuries, and the diagnosis is confirmed radiographically. If there is displacement of the fragment, surgical removal is the treatment of choice and the prognosis is favorable.

Soft tissue injury is common. A decubital wound of the lateral aspect of the tarsus overlying the lateral digital extensor tendon is the most frequently observed condition. This injury often occurs in young foals less than 2–3 weeks of age that have spent significant time in lateral recumbency as neonates, but it may be recognized in clinically normal foals as well. The condition causes mild lameness unless secondary sepsis extends into deeper bony structures or the tendon sheath, in which case lameness may be severe. Once the tissue opens and begins draining, the lameness resolves. There is a good prognosis with proper conservative wound management and good hygiene. These wounds should be allowed to heal by second intention, which may take weeks to months.

VetBooks.ir

Elbow and Shoulder

Lameness of the elbow may be associated with trauma or infection. The presenting appearance may range from a subtle shortening of the gait to the classic dropped elbow recognized with olecranon fracture and disruption of the triceps apparatus (Figure 10.59).

Lameness involving the shoulder region of the foal is common and may be of septic or traumatic origin. It is not unusual to have two foals present simultaneously with shoulder injuries from colliding with one another while running head on. They may also undergo collision with a tree or sustain a kick injury. Many collision injuries result in nerve paralysis involving the radial nerve or brachial plexus, whereas kick injuries commonly cause fracture of the supraglenoid tubercle or other portions of the scapula.

Differentiating between nerve injury and fracture can be accomplished with physical exam and radiographs. With nerve injury, the foals are not painful on palpation and manipulation, the shoulder is dramatically dropped, and the limb may be physically placed and maintained in normal position while applying pressure to the dorsal aspect of the carpus. There is usually less swelling over the point of the shoulder with nerve injury than with fracture. Radiographs are normal with nerve injury; however, they may be confusing to interpret because of the physes. Likewise, if a supraglenoid tubercle physeal fracture is initially nondisplaced, it may go undetected. Follow-up radiographs in several days to weeks may be necessary for an accurate diagnosis.

Prognosis for nerve injury is guarded, depending on the extent of injury. Foals with neuropraxia improve in a matter of hours to days, although it may take weeks to return to normal. There is often some degree of muscle atrophy that gradually improves. Ruptured and avulsed nerves do not improve, and these cases may undergo prolonged treatment attempts before the involved limb develops severe contraction or there is breakdown of the contralateral limb. The prognosis for supraglenoid tubercle fracture is good for survival, pasture soundness, and light use, but poor for athletic use. Surgical removal of the fragmented tubercle and open reduction with internal fixation have been performed, but there is little difference between aggressive and conservative management in the long-term outcome regarding athletic potential of these animals.

Stifle

Lameness of the stifle in foals is commonly septic in nature; traumatic injuries and developmental orthopedic disease (DOD) of the stifle in foals occur less frequently. The proximal tibial physis is subject to fracture in a predictable configuration, which produces a Salter-Harris type II fracture.[3] There is frequently accompanying soft tissue trauma that precludes athletic soundness after reduction and surgical repair, but these animals are most often sound for breeding as adults. Other traumatic injuries of the stifle are usually severe and result in intra-articular soft tissue injury involving the cruciate ligaments, collateral ligaments and menisci, or severe bone injury, necessitating destruction.

Pelvis

Injuries of the pelvic region are common and may be difficult to diagnose with great specificity because they

Figure 10.59. Typical dropped elbow appearance seen in fractures of the humerus and olecranon. Notice that the limb is also abducted and held in slight flexion.

VetBooks.ir

may involve bone, cartilage, muscle, tendon and ligament, nerves, and blood vessels. There is no age limitation on pelvic injuries, which may occur as early as a few days or at any time later; however, most traumatic and septic causes of pelvic lameness occur prior to 4 months of age.[23] Traumatic injuries of the pelvis and coxofemoral joint may result from rearing, twisting, and falling over, with torsional load causing the injury. Tuber coxae injuries are typically associated with external trauma such as a kick from another horse or striking the area during a fall or against a gate post or other fixed object. Injuries of the tuber ischii may occur from falling backward or accelerating backward and directly striking or landing on this bony prominence.

The gait and degree of lameness depends on the structures involved and their location. Fractures of the pelvis almost always involve both sides, with one side more extensively damaged than the other. Displaced pelvic fractures are generally non-weight-bearing lame during ambulation on the side with the most damage. When standing, however, foals generally bear weight on both limbs and may electively stand on the primary fracture side. Generally, the tail is set away from the most severely affected side. If the injury is caudal to the coxofemoral joint, the caudal phase of the stride is prolonged and there is resentment during the cranial phase, whereas the opposite is true for injuries of the tuber coxae. Foals with injuries to the superficial bony prominences such as the tuber coxae, tuber ischii, or greater trochanter of the femur as well as injury to the coxofemoral joint display a pain response on digital palpation. Deeper injuries of the pelvic floor or pubic symphysis may be more difficult to detect on physical palpation.

Radiographs are necessary to confirm the presence of a fracture, and ultrasound may facilitate identification of other injured tissue. Nuclear scintigraphy is occasionally used to evaluate pelvic injuries and can effectively identify regions of injury, but does not allow identification of specific fracture types. Injuries of the physes and accompanying soft tissue are more effectively identified by magnetic resonance imaging.

Treatment for pelvic injury includes stall rest, and the duration depends upon the severity of the injury.[30] Once full weight-bearing returns, controlled exercise in the form of hand walking is beneficial for rehabilitation. The prognosis for pelvic injury depends upon severity. In general, the prognosis is favorable, but severe displacement accompanied by marked soft tissue trauma or significant involvement of the coxofemoral joint carries a poor prognosis. The main differentials for pelvic trauma are septic arthritis, osteomyelitis, septic physitis, and pelvic abscess.

Less severe lameness of the hip region is associated with tearing of the fascia of the lateral aspect of the biceps femoris or the vastus lateralis muscle. These injuries produce a transient lameness that manifests as a shortened gait at a walk. A palpable 3- to 5-cm deficit, oriented obliquely and parallel to the muscle fibers, is present, and an associated hematoma may be observed. Treatment is rest and confinement for 1–2 weeks to allow any hemorrhage to stop. These tears should not be drained or opened for fear of sepsis. Rarely, if ever, do any long-term residual effects of these tears manifest, and future athletic potential should not be affected.

Physeal Fractures

Physeal fractures are common due to the relatively weak physeal bone compared with the diaphyseal bone. Diagnosis of physeal injuries is made on clinical and radiographic findings. Clinical signs vary depending on the degree of instability; they include lameness of varying degrees, pain on palpation, swelling, and occasionally angular deviation of the limb distal to the fracture. The primary differential for a stable physeal fracture is infectious physitis. Fracture of pressure physes (those that contribute to longitudinal bone growth) have been categorized and defined using the Salter-Harris classification scheme, covered elsewhere in the text.[3,6,12] Surgical repair is necessary in foals with displaced, unstable physeal fractures.[29] If adequate reduction and stabilization are achieved, the prognosis for future soundness is good.

Long Bone Fractures

Long bone fractures usually result from external trauma such as a kick or having the limb pinned beneath an object while rolling. Rearing and misloading a limb may result in fracture of the tibia, femur, or pelvis.[21,23] Physical evaluation may be diagnostic in foals with lameness of traumatic origin because unstable fractures or severe soft tissue injuries cause obvious, immediate clinical signs.[47] If a fracture is suspected, radiographs are necessary to confirm the diagnosis and determine the severity of the injury. The prognosis for a foal after fracture depends on the anatomical location of the fracture; the complexity, orientation, and degree of soft tissue injury around the fracture; and whether the fracture is open.[17,21] Secondary problems associated with contralateral limb overload from prolonged lameness or from immobilization often dictate the degree of long-term soundness.

Although mechanical laminitis is not as common as in adult horses, it occurs in foals. More common problems include excessive laxity of the metacarpophalangeal or metatarsophalangeal joint, varus deviation, or deformity of the foot, such as underslung or crushed heels and overgrowth of the toe. Contracture or excessive laxity of the fractured limb associated with disuse may prevent future soundness.

Developmental Orthopedic Disease

Lameness may be associated with DOD in foals.[7,39] In a group of 378 foals evaluated radiographically at 6 months of age, 47% were affected by DOD and 36% by osteochondrosis with some evidence showing Warmbloods may be at higher risk.[26] Although osteochondrosis does not typically manifest until the late weanling and yearling period, it is occasionally recognized clinically as a cause of lameness in foals less than 6 months of age.[40] The development of DOD is multifactorial, but there may be some association with exercise conditions and rapid growth.[27] See earlier sections of this chapter for specific DOD conditions.

VetBooks.ir

Perinatal and Congenital Conditions

Foals may be born with musculoskeletal conditions that result in lameness or they may develop them shortly after birth. These conditions are relatively infrequent but worthy of mention because historically they have either been misdiagnosed or erroneously given a poor prognosis. As a result, foals that might have matured and had normal athletic potential have been humanely destroyed. Lameness may be directly caused by these conditions or it may be secondary to their occurrence.

Two such conditions of the neonate are flexural limb deformities and excessive laxity of flexor tendons, both of which are relatively common and may result in secondary lameness. Flexural limb deformity may produce mechanical limitations on ambulation, or it may cause pain associated with attempts to correct the deformity. The most common cause of lameness from flexural deformity is excessive trauma to the sole of the foot at the toe region, which causes bruising and abscess formation.

Flexor tendon laxity causes lameness from decubital sores, bruising, and abscess in the heel bulbs of the hindfeet. These may be prevented by lightly bandaging the heel bulbs for protection and preventing luxation of the distal limb by applying extended heels.

Certain structures in the neonate and young foal are prone to rupture, including that of the common and lateral digital extensor tendons of the forelimb, which usually occurs within 72 hours of birth. Foals with mild flexural deformities may be predisposed to develop these problems. In these contracted individuals, the condition may develop at 2–3 weeks of age. The predominant clinical sign is knuckling forward on the ankle and carpus and initially failure to advance the limb. This pathology is frequently mistaken for flexural limb deformity.

The two conditions may be differentiated with physical evaluation. Lateral and common digital extensor tendon rupture may be recognized by the presence of a characteristic swelling over the dorsal lateral surface of the carpus at the musculotendinous junction where the rupture occurs. The limb also may readily be placed in a normal position, whereas this is not possible in foals with flexural deformity.

Treatment is aimed at protecting the limb from excoriation of the dorsum of the fetlock with bandaging until the foal acclimates to walking. Continuous splinting or casting is not usually necessary but may be applied intermittently to facilitate use of the limb. Surgery is not necessary or advisable because the tendons generally heal uneventfully over several weeks.

Ruptured gastrocnemius muscle is recognized in neonates following both normal deliveries and dystocias, but larger foals appear to be predisposed to this condition.[24] Rupture may be partial or total. With partial rupture there is moderate flexion of the tarsus, but the foal can still bear weight on the limb. With a complete tear the foal is unable to extend the limb and will collapse with weight-bearing, and the excessive flexion of the hock with the stifle in a fixed position results in a typical, crouched position on the affected side (Figure 10.60). Prognosis for future soundness is good with conservative treatment, providing the foal is not compromised with other concomitant disease processes.[24,44] Splinting is usually required, and bandages must be changed frequently to prevent focal pressure necrosis, adequately support the limb, and support ambulation while healing occurs.

Figure 10.60. Excessive flexion of the hock in a foal with rupture of the left gastrocnemius muscle.

INFECTIOUS CAUSES OF LAMENESS

Lameness in foals caused by infectious agents is extremely common, so much so that it is a safe to assume that all lameness in foals is septic in origin until proven otherwise. Foals may be affected shortly after birth or up to 4 months of age, although such lameness may sporadically occur in older foals; approximately half the foals are affected by 60 days of age.[36] It is perplexing that foals appear to be plagued with these conditions more than other species with similar housing and hygiene practices.

The most common infectious conditions causing lameness include the complex of osteomyelitis, septic arthritis, septic physitis, and/or septic tenosynovitis.[15,18,19,32–34,41,45] Although there are numerous pathways by which these conditions may occur, such as external injury, the most common is believed to be hematogenous spread from a primary source.[20] Such sources include the urachus or urachal remnants, gastrointestinal tract, respiratory tract, or a distant site in the musculoskeletal system.[22,36] It is commonly thought that there is a propensity for bacterial colonization in the extensive vascular plexus composed of venous sinusoids, metaphyseal loops, and epiphyseal, metaphyseal, and physeal vessels in growing long bones. The slow and sluggish blood flow and relative vascular stasis in this region allow bacteria to proliferate at or close to the cartilage interface.[6,15] Cartilage matrix degradation and proteoglycan loss may occur within 2 days, and loss of collagen within 9 days after inoculation by bacteria.[4,6,35] The chance of infection is increased in high-risk individuals such as a foal with failure of passive transfer or exposure of a naïve immune system to an aggressive pathogen.

Hematogenous osteomyelitis and septic arthritis have been classified into five types based on the structure involved and location.[15,46] Infectious synovitis, or S-type, most commonly affects younger (under 2 weeks) foals and involves only the synovial structure. Epiphyseal type (E-type) involves the joint and adjacent epiphysis. Involvement of subchondral bone results in eventual radiographic changes, although these may not be evident for a week or more. P-type involves the physis and is seen in foals 1 week to 4 months of age. Lesions are seen radiographically as lytic changes in the physis, metaphysis, or epiphysis.[19] T-type involves the tarsal or carpal cuboidal bones and may result in collapse of these structures. These most commonly occur in neonates that suffer from dysmaturity, although normal foals may be affected. I-type involves periarticular soft tissue abscess infecting a physis or joint and often involves the hip or stifle, or more commonly the distal metacarpus or metatarsus. Foals older than 6–8 weeks are most often involved. The clinical appearance of the involved region is diffuse pitting edema, with eventual abscess development and drainage.

The common presenting complaint of osteomyelitis and/or septic arthritis is acute onset of lameness, and there is often a pyrexic episode at presentation or in the recent past. The degree of lameness varies from mild to non-weight-bearing and largely depends on the severity of the infection and structures involved. The foal may be noted in recumbent positions more often than normal. With joint involvement there is synovial distension as opposed to the diffuse swelling typically seen with osteomyelitis. The region is usually warm to hot and is painful on manipulation. Occasionally, the area may be cold if the swelling is excessive enough to create vascular compromise, or there may be vascular thrombosis associated with the sepsis.

Hemogram is often normal on presentation because of the localized and acute nature of the infection. When hemogram alterations occur, there is an elevation in the white blood cell count, with or without a left shift and an increase in fibrinogen of 500–800 mg/dL or higher. Plasma fibrinogen concentration of more than 900 mg/dL may be useful as an indicator of physeal or epiphyseal osteomyelitis, and values may reach 1500 mg/dL.[38] Serum amyloid A (SAA) has more recently proven beneficial as a marker to identify inflammation associated with sepsis.[31]

If joint involvement is suspected, diagnosis is confirmed through arthrocentesis, joint fluid analysis, and culture and sensitivity. Unfortunately, culture results are often negative because of the bacteriostatic properties of synovial fluid and previously administered antimicrobials.[4,36] Fluid analysis typically reveals more than 20,000 white blood cells and an elevation in total protein. Diagnosis may be more challenging without articular involvement; however, ultrasound evaluation coupled with aspiration and analysis of any fluid pockets may facilitate accurate diagnosis.[22] Radiographs are helpful in establishing a diagnosis, prognosis, and treatment plan. Initial radiographs are often normal but begin to show areas of lysis within a few days of onset. Aspiration of a lytic area may be performed with a needle; however, if this technique is not productive, a sample may be acquired via passage of a drill into the lesion and shavings from the drill may be cultured.[22,32] This portal may also be used for therapy by instillation of antimicrobial agents through a needle or through a cannulated bone screw placed in the hole.

Treatment of septic arthritis includes systemic broad-spectrum antimicrobials while waiting on culture results. Pain control, protection against gastric ulceration, and overall support for the foal regarding hydration and nutritional intake are important, especially in young foals. In cases with joint involvement, local treatment by joint lavage using sterile polyionic fluids is important; alternatively, constant rate infusion therapy with antimicrobials has recently proven beneficial.[1,28] Joint lavage is not necessary if the lesion is isolated to bone. Regional perfusion has proven beneficial, as has intraosseous antimicrobial administration.[22]

Anecdotally, the use of chondroprotective agents parenterally, orally, and intra-articularly is believed to be beneficial in restoring and maintaining joint health, especially in systemically ill foals. Hyperbaric therapy for treatment of osteomyelitis has likewise gained favor for the benefits of revascularization of ischemic tissue and increasing the effectiveness of antimicrobial therapy.[16] In debilitated or cachectic foals, the common clinical impression is that immediately following hyperbaric treatment, the animal is usually brighter and has an improved appetite.

With early diagnosis and appropriate treatment, the prognosis for the survival of foals with septic osteomyelitis is favorable, and a return to function in Thoroughbred racehorses reported between 37% and 48.3%[22,36,42,43];

VetBooks.ir

however, with a delay in therapy, the prognosis is guarded to grave. Younger foals (under 30 days) that display involvement of bone have a worsened prognosis because of a high incidence of multisystem disease.[18,36,42,43] Multiple sites of involvement have a significant detrimental impact on survival as well as future athletic potential.

CHAPTER

Foot Care and Farriery

BASIC FOOT CARE

STEPHEN E. O'GRADY

INTRODUCTION

The equine foot is unique in that it is a biological entity (hoof structures) that follows the laws of physics (biomechanics). Biomechanics is the study of the mechanics of a biological structure, and it is essential that the veterinarian and the farrier have a working knowledge of the foot's biomechanics to implement appropriate farriery.[3,5,7] Proper farriery promotes a healthy, functional foot, provides biomechanical efficiency, and prevents lameness.[6]

The structures of the hoof complex comprise the hoof capsule, sole, frog, digital cushion, ungual cartilages, and deep digital flexor tendon (DDFT). The equine foot has numerous functions: supporting the weight of the horse, dissipating the energy of impact as the foot strikes the ground, protecting the structures contained within the hoof capsule, and traction.

The veterinary and farrier literature often describes the "normal" foot. However, the concept of normal may be misleading because it does not consider genetics, breed, foot conformation, environmental influences, and the athletic pursuits of the individual horse. Thus, the terms good, ideal, healthy, and functional foot may be more appropriate (Figure 11.1), because they describe a foot that comprises:

1. A thick hoof wall
2. Adequate sole depth (thickness)
3. Solid heel base
4. Growth rings below the coronet that are of equal size at the toe and heel
5. Acceptable foot conformation

Farriery (trimming and shoeing) affects not only the external hoof capsule but also the internal structures of the foot. Often trimming and shoeing methods are based on theoretical assumptions and aesthetic decisions derived from empiric experience rather than consistent guidelines that can be applied to each foot on an individual basis. Farriery assumes the dominant role in maintaining the health of the foot and preserving the integrity of its structures.[6]

The hoof care provided by the farrier depends on that individual's knowledge, training, experience, and skill level. Because the equine veterinarian is responsible for the overall soundness of the horse, a working knowledge of farriery is essential. A thorough knowledge of traditional horseshoeing enables the veterinarian to interact with the farrier at the farrier's level, which ultimately enhances the professional relationship and promotes quality hoof care.[2,4,6] This chapter focuses on basic, fundamental farriery: evaluation of the foot, foot trimming and preparation, shoeing principles, and farriery for common hoof disorders.

For clarity in this discussion, the hoof is defined as encompassing the distal end of the middle phalanx, the hoof capsule, and structures within the hoof capsule. The digit refers to the limb distal to the metacarpophalangeal/metatarsophalangeal (fetlock) joint.

EVALUATION OF THE FOOT

Before any type of foot care or farriery is initiated, the hoof and digit should be visually evaluated, and the observations recorded mentally or as a written record. Many of the smartphones or tablets are ideal for recording this evaluation and can then be stored as part of the horse's permanent record. This evaluation should begin with the horse in the static position on a firm, flat surface and then in motion in a straight line, again on a flat firm surface.

Static Observation

With the horse standing still and viewed from the lateral side, the hoof-pastern axis (HPA) should form a

VetBooks.ir

straight line. The dorsal hoof wall should be parallel to the dorsal surface of the pastern. In the ideal foot, the angle of the hoof wall at the heel should approximate the angle at the toe of the dorsal hoof wall. However, this approximation of the toe and heel angle is generally not an accurate assessment because during movement, the heels of the hoof wall expand or move outward against the shoe—and to a lesser extent against the ground—when the animal is barefoot. This causes the hoof wall at the heels to wear relative to the hoof wall at the toe. Depending on the conformation of the foot and the amount of hoof mass present, this abrasive wear generally causes the hoof angle at the heel to be less than the angle at the toe. The angle of the foot appears to have taken on less importance recently since the hoof angles do not take into consideration the conformation of the horse's individual limbs.

It is generally thought that the foot is trimmed and/or shod appropriately and the hoof angle is correct when the dorsal hoof wall and the dorsal surface of the pastern are parallel.[1] The terms low hoof angle and high hoof angle describe a nonlinear relationship between the dorsal hoof wall and the dorsal pastern region (HPA). An imaginary line that bisects the third metacarpus (MC3) should intersect the ground at or near the most palmar aspect of the weight-bearing surface of the heels of the hoof capsule (Figure 11.2A). Furthermore, an imaginary vertical line extending midway between the dorsal and palmar borders of the middle phalanx (palpated just above the coronet) to the ground should bisect the hoof capsule at approximately the widest part of the foot. The coronet should have an even, gentle slope from the toe to the heel with no focal displacement.

Figure 11.1. A shod foot that demonstrates what is considered good or ideal foot conformation. *Source*: Courtesy of Jeff Ridley.

Viewed from the dorsal aspect, a line bisecting the third metacarpus should bisect the phalanges and hoof so that the hoof is approximately symmetrical, including the mass of the hoof on either side of the line and the heights and angles of the walls. The distal phalanx is often offset to the lateral side within the hoof capsule, which leads to disproportionate weight-bearing. A line drawn between two comparable points on the coronet should be parallel to the ground, and a vertical line bisecting the third metacarpal bone should be perpendicular to a line drawn across the coronet or the ground surface of the foot (Figure 2.37).

Viewing the hoof from the palmar aspect can help to note the height of the heels, whether there is a disparity between the heel height or heel conformation when compared to the contralateral limb, a condition termed mismatched foot; also note whether there is a disparity in the heel bulb height when measured from the ground surface of the hoof to the hairline at the heel bulb on an individual foot. The difference in heel bulb length appears to arise from disproportionate weight-bearing and should be considered when trimming and shoeing the foot.

Viewed from the ground surface of the foot, the width and length of the hoof capsule of the forefoot should approximate each other, although the hoof capsule may be slightly wider than it is long.[6] Stated another way, if a line is drawn across the widest part of the foot, a line from the widest part of the foot to the base of the frog at the heels and a line from the widest part of the foot to the toe should approximate each other (Figure 11.2B). The weight-bearing surface of the heels of the hoof capsule should extend to or coincide with the base of the frog.

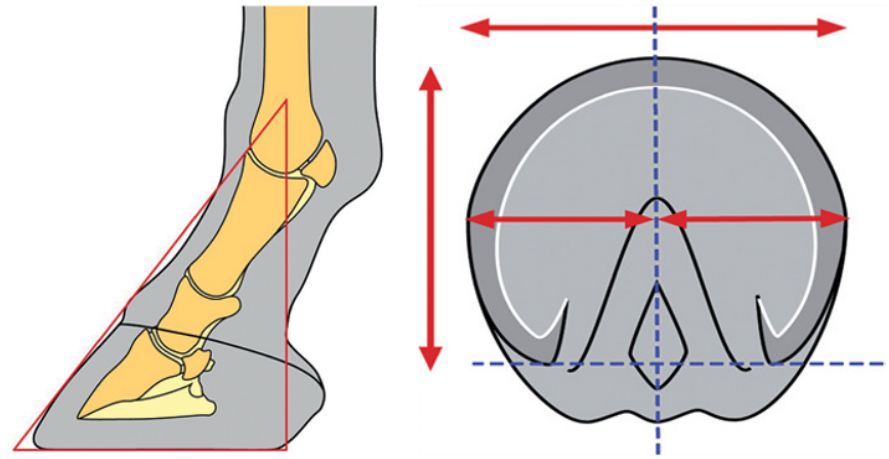

Figure 11.2. Schematic drawings showing the ideal hoof-pastern axis (A), extent of weight-bearing surface, and ideal proportions for the solar surface of the foot (B).

VetBooks.ir

A line drawn across the widest part of the foot can be used to evaluate both the shod and unshod foot and help determine whether previous farriery was appropriate.

Break-over is the phase of the stride between the heel lifting off the ground and the toe lifting off the ground. The point of break-over is best assessed from the ground surface and should be located in the center of the toe. However, the ideal point of break-over is widely disputed. In a traditionally trimmed and shod horse, break-over is positioned where the margin of the dorsal hoof wall intersects the ground. In a biomechanical sense, there are many situations in which it may be beneficial to position the break-over more palmarly.

The relationship between the longitudinal axis of the frog and the overlying distal phalanx is more constant than the longitudinal axis of the frog to the ground surface of the hoof. The relationship of the untrimmed frog to the sole indicates the position of the distal phalanx within the hoof capsule (i.e. the palmar angle). For example, if the apex of the frog is deeply recessed and the incline of the frog appears to be angling toward the coronary band at the toe, the distal phalanx is generally similarly positioned, creating a negative palmar angle. The central sulcus of the frog should be wide, solid, and shallow so that the index finger or ring finger fits easily into it. Contraction of the central sulcus is so common that it is widely ignored by clinicians. Another important reference point is the dimensions of the frog; the width of the frog should be 67% of the frog length.[8] Ideally, the medial and lateral aspects of the ground surface of the foot should be symmetrical on either side of the central axis of the frog.[6] The sole of the foot should be concave and possess sufficient depth such that it does not deform when pressure is applied.

Dynamic Observation

The key to observing the horse in motion is defining the placement of the foot as it strikes the ground. The strike pattern should be viewed from the side, and ideally the horse should either land slightly heel first or flat, with the toe and heel contacting the ground simultaneously. Marked heel-first landing generally denotes decreased ground surface in the palmar section of the foot or a shoe that is too small. Toe-first landing is considered abnormal, and it may be an attempt by the horse to avoid landing on its heels if they are painful or a club foot conformation where there is a shortening of the musculotendinous unit of the DDFT. Viewing the horse in motion from the front or from the rear allows the examiner to assess the mediolateral orientation of the heels as they strike the ground. Ideally, both heels should contact the ground simultaneously, but often horses with a narrow chest and a rotational limb deformity impact the ground on the lateral hoof wall and then load the medial side. This type of strike pattern results in the medial (or lateral) heel being displaced proximally; this type of hoof capsule distortion is termed a sheared heel.

Hoof Balance

Veterinarians and farriers often use the term hoof balance to describe the theoretically "ideal" shape or conformation of a foot, the position of the hoof relative to the limb above, and how the foot should be trimmed; however, hoof balance lacks an intrinsic definition.[3] The term has been further subdivided to describe various proposed methods for achieving balance, including geometric, dynamic, three-dimensional, and natural balance. In practice, no single method of balance will achieve optimum foot conformation for every horse. For example, a problem may arise with the exclusive use of either geometric or dynamic balance to address both dorsal palmar/plantar and mediolateral trimming. If the landing pattern or limb conformation deviates from normal, one method of achieving hoof balance may produce a foot with a different shape from another, or if the conformation of the limb causes the foot to assume a disproportionate load when landing, trimming the foot to land flat may be detrimental.[3,6]

"Hoof balance" is often used to communicate aspects of hoof care to the farrier. A more effective option is to use a set of biomechanical principles or landmarks that can be used as guidelines that have a universal meaning that can be applied to every horse, allowing the individual foot to be evaluated, trimmed, and/or shod in a consistent, reproducible manner (Table 11.1).

These guidelines standardize the basic approach to farriery by both veterinarians and farriers. Furthermore, they do not interfere with nor contradict the traditional concepts of static, geometric, or natural balance. The guidelines can also be used to modify existing hoof conformation and improve hoof capsule distortions and the landing patterns of the foot.

The guidelines or landmarks described in this chapter are applicable to both the forefeet and hindfeet, but for simplicity, only the forefeet are considered here. In the section on foot preparation (trimming), the connotation of balance is replaced with anatomical landmarks along with dorsopalmar/plantar and lateromedial orientation.

Removing the Shoe

Removing the shoe may appear elementary, but it is extremely important that veterinarians master the technique to avoid damaging the hoof capsule during removal. Shoes are removed during lameness examinations to examine the solar surface of the foot that is covered by the width of the shoe and during pre-purchase examinations to evaluate the entire perimeter of the sole–wall junction (white line) for abnormalities. Shoes should also be removed for radiographs; otherwise, they prevent some of the hoof structures from being imaged.

The first step in removing the shoe is to raise the clinch—the small square section of the nail that exits on the outer surface of the hoof wall and is bent over to secure the shoe—on the outer hoof wall. A clinch that is not straightened prior to pulling the shoe may damage the hoof wall as the shoe is removed. The clinch can be raised using a clinch cutter, a small chisel-type tool

Table 11.1. Hoof parameters to use as guidelines to evaluate and trim the foot.

Figure 11.4. Shoe pullers. Note the knobs on the ends of the handles, which distinguish this tool from hoof nippers (compare with nippers in Figure 12.15). *Source*: Courtesy of FPD Farrier Products Distribution, Shelbyville, KY 40066.

(Figure 11.3). The clinch cutter is placed under the clinch, and a nylon hammer, which is quiet and prevents shock, is used to tap the clinch cutter upward and straighten the bent clinch. An alternative method is to file the clinches off with a hoof rasp.

Shoe pullers (Figure 11.4) are then placed between the shoe and the hoof, starting at the heel; the pullers are placed between the shoe and the hoof and levered forward, alternating from side to side toward the toe. The shoe is either removed in its entirety, or the shoe can be tapped back in place, exposing the head of the nail above the surface of the shoe just in front of where the

Figure 11.5. Creased nail pullers. Note the short handles, which can be readily used by veterinarians. *Source*: Courtesy of FPD Farrier Products Distribution, Shelbyville, KY 40066.

shoe was levered. The nails are then removed individually and the levering process repeated behind each nail until all nails are removed. Another method is to use a creased nail puller (Figure 11.5) to grasp the nail head and remove each nail from within the crease or fuller of the horseshoe. The creased nail puller should always be used when removing therapeutic shoes to minimize trauma to an already compromised foot. If a horse loses a shoe or if the shoes must be removed and a farrier is not available, a layer of deformable impression material (Equilox Pink Equilox International, Inc., Pine Island, MN) can be placed on the solar surface of the foot and attached by wrapping the foot with a roll of 2- or 3-inch elastic tape. This provides comfort and prevents damage to the hoof wall until the farrier replaces the shoe.

PRINCIPLES OF TRIMMING AND SHOEING

Stephen E. O'Grady

VetBooks.ir

GUIDELINES FOR TRIMMING

The Importance of Hoof Conformation

Foot conformation (shape) is defined by the structures and is important because of its relationship to the foot's biomechanical function. Any changes made to the bottom of the horse's foot through farriery affect the angulation of the hoof, the hoof-pastern axis (HPA), and the alignment of the hoof capsule under the center of rotation (COR).[6] Hoof conformation embraces the shape and function of the foot in relation to the ground, as well as the skeletal structures of the lower limb both at rest and in motion.[2,3,6] Each foot's conformation should be strong and protective and should maximize biomechanical efficiency. When this ideal conformation is theoretically achieved, it has been termed hoof balance. At present, there is no universal method to assess appropriate foot conformation or balance, nor is there a uniform method that implements guidelines when trimming the equine foot.

The Palmar Foot

The soft tissue structures that comprise and form the palmar/plantar section of the foot are often the limiting factor when trying to achieve and maintain good hoof conformation or shape.[11] The primary structures of the palmar foot include the frog, digital cushion, ungual cartilages, and deep digital flexor tendon (DDFT) (Figure 11.6).

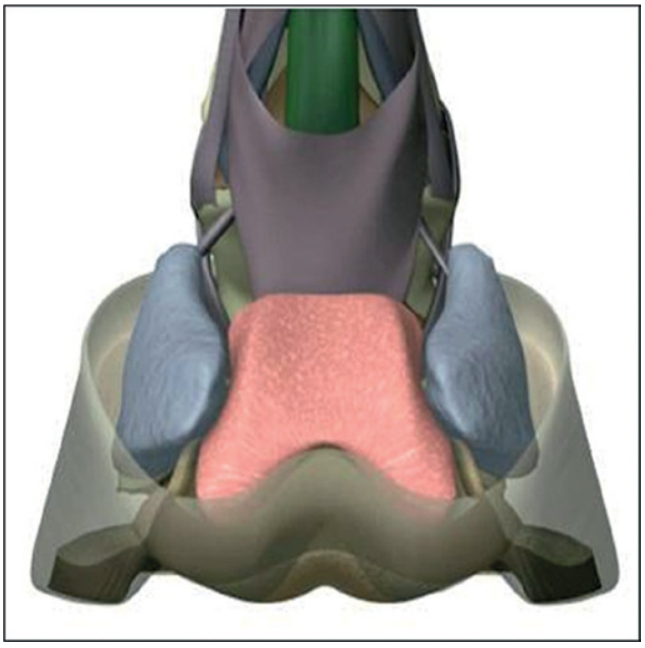

Figure 11.6. Foot model illustrating the structures in the palmar foot responsible for palmar foot conformation. Gray, ungual cartilages; pink, digital cushion; brown, frog. *Source*: Courtesy of Dr. Andrew Parks.

The conformation of the palmar/plantar section of the foot is contingent on the accumulated mass or density provided by these structures. Unfortunately, attaining sufficient mass for good conformation is not always possible because the structures are influenced by genetics (certain breeds such as Thoroughbreds often have decreased structural mass), improper development or maturity, continuous repetitive overload when the structures are immature (especially common in young horses in training), and inappropriate farrier practices. Farriers generally need to address the heel area (trimming, manipulating, or supporting) to achieve the desired HPA, position of the COR, and hoof capsule extending to the base of the frog.

The Hoof-Pastern Axis

The HPA should be the first guideline considered when trimming the foot. With the horse standing on level ground, the metacarpus/metatarsus should be perpendicular to the ground, and when viewed from the lateral side, the HPA should form a straight line along the dorsal surface of the pastern and the dorsal hoof wall from just below the fetlock to the ground. When the HPA is parallel, a linear line passes through the middle of the phalanges (proximal, middle, and distal) from the metacarpophalangeal joint to the ground. The straight alignment of the phalanges places the dorsopalmar orientation of the distal phalanx within the hoof capsule such that the solar surface of the distal phalanx assumes a similar alignment relative to the ground surface of the hoof capsule/ground. Ideally, the palmar angle of the distal phalanx should be 3°–5° greater than the dorsal angle of the distal phalanx; this allows the distal phalanx to descend in a distopalmar direction during weight-bearing and utilize the physiology in the palmar/plantar section of the foot (Figure 11.7).[9]

The angle of the solar border of the distal phalanx generally depends on the conformation of the palmar/plantar section of the foot. The dorsopalmar/plantar orientation of the distal phalanx within the hoof capsule helps prevent disproportionate load concentration on the solar surface of the hoof capsule and changes in the position of the ground reaction force (GRF).[14,16,17] Changes in the GRF in a dorsal direction, such as the broken-forward HPA, or in a palmar direction, such as in the broken-back HPA, suggest disproportionate weight-bearing on the solar surface of the hoof capsule when the foot is loaded. Additional detrimental effects of either a broken-back or broken-forward HPA have been well documented.[1,7,17]

Changes in HPA are generally associated with two common hoof capsule distortions: low or underrun heels or upright or clubfeet. A broken-back HPA is often caused by a low heel or excessive toe length combined with a low heel or underrun heel. The low heel is generally correlated with a lack of soft tissue mass in the

VetBooks.ir

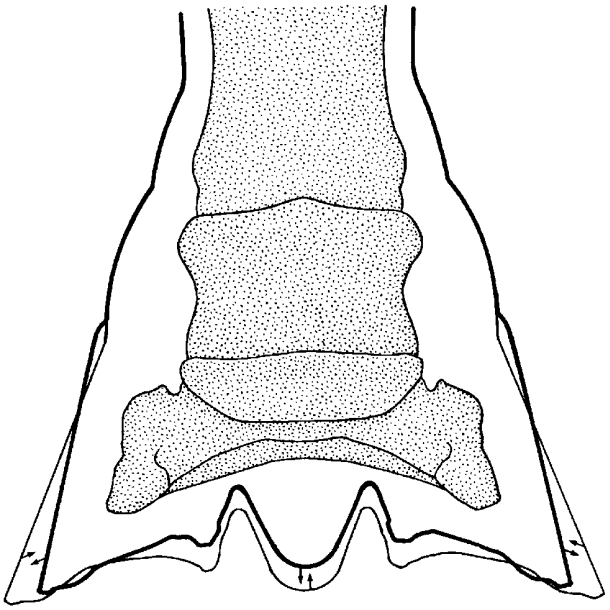

Figure 11.7. During weight-bearing, the frog and sole are forced downward, causing expansion of the hoof wall. The reverse occurs when the foot is unweighted.

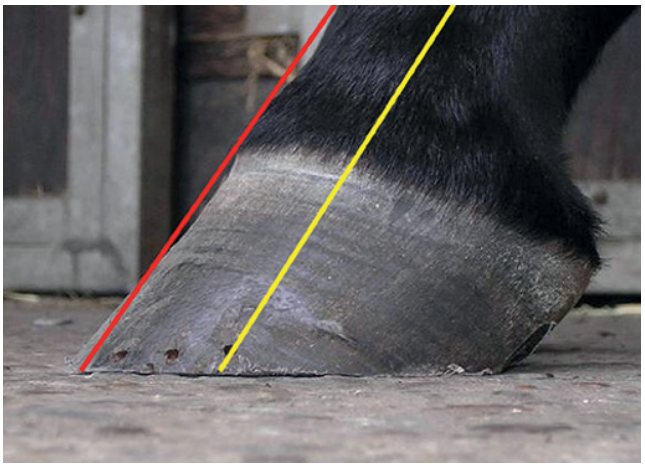

Figure 11.8. Hoof-pastern axis. Note that the dorsal surface of the pastern and the dorsal surface of the hoof wall form a straight line (red line). The yellow line depicts the corresponding digital alignment.

palmar/plantar section of the foot. This lack of soft tissue mass decreases the ability of the foot to dissipate the energy of impact during landing and the forces acquired during the stance phase of the stride, thus shifting some of these forces to the laminar interface and the bone. The broken-back HPA also places the distal interphalangeal (DIP) and to a lesser degree the proximal interphalangeal (PIP) joints in dorsiflexion, promotes load bearing in the heel area of the foot, and increases the stresses in the DDFT.

In a broken-forward HPA, the heels grow long while the frog generally recedes below the hoof wall, causing the energy of impact generated during weight-bearing to be transferred directly through the laminar interface to the bone, bypassing the soft tissue structures in the palmar/plantar section of the foot. The DIP and PIP joints are placed in flexion, which promotes load bearing on the dorsal margin of the DIP joint. The flexed DIP joint results in excessive weight-bearing to be placed on the dorsal section of the foot.

Until recently, the veterinary and farrier literature recommended that the normal hoof angle be 48°–55° for the forefeet and 52°–60° for the hindfeet. These recommendations have been shown to be erroneous, because they do not take into consideration the conformation of the horse's individual limb. Therefore, the foot is trimmed appropriately, and the hoof angle is correct for the individual horse when the dorsal hoof wall and the dorsal surface of the pastern region are aligned in parallel planes (Figure 11.8).[2,3,14] A parallel HPA is easy to access visually and can be confirmed radiographically when necessary.

The Center of Rotation

The second guideline or landmark used for trimming the foot is the COR. A vertical line drawn on a lateral radiograph from the center of the lateral condyle of the distal middle phalanx to the ground should bisect the bearing surface just palmar/plantar to the middle of the foot (Figure 11.9A).[4,6,7,10,11,14] This line demarcates the biomechanical COR of the DIP joint and should be in close proximity with a line drawn across the solar surface of the foot through the middle one-third of the frog or the widest part of the foot. The widest part of the foot is located 5–10 mm dorsal to the COR and forms a reliable landmark on the solar surface of the foot that is repeatable, can be used as a reference point when trimming, and can also be used in the evaluation of foot conformation and the current farriery that has been performed on the horse (Figure 11.9B). The widest part of the foot is also what farriers refer to as "Ducketts" bridge (Duckett D, Ambler PA. Personal Communication, 2008).

The widest part of the foot is the one point on the solar surface of the foot that remains relatively constant regardless of the shape or length of the ground surface that is dorsal or palmar to this point. In a biomechanical sense, because the widest part of the foot is just dorsal to the COR or the biomechanical pivot point, there are moments created on either side of the COR (Figure 11.10). Therefore, when considering biomechanical efficiency, the distance and force (moment) on either side of the line drawn through the widest part of the foot should approximate each other (equilibrium) when the horse is standing at rest. Following the trim, the ground surface of the ideal foot should be as wide as it is long, and the ground surface of the hoof capsule at the heels should not project dorsal to the base of the frog.[8,14,16]

Heels of the Hoof Capsule Extending to the Base of the Frog

The third guideline is the heels of the hoof capsule extending to the base of the frog. Located within the hoof capsule dorsally are osseous structures that accept load through the lamellae interface and soft tissue structures palmarly/plantarly that are thought to absorb concussion during load bearing and dissipate the energy of impact.

VetBooks.ir

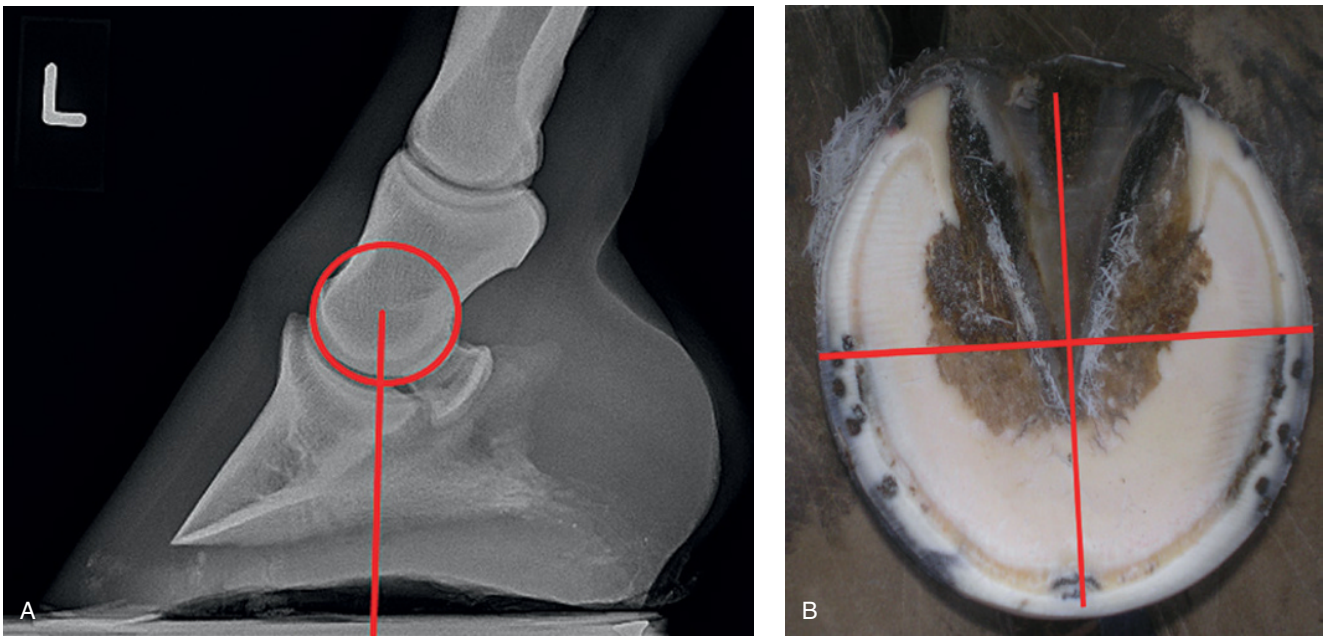

Figure 11.9. (A) Lateral radiograph demonstrating the center of rotation that should approximately bisect the weight-bearing surface of the foot (red line). (B) Solar surface of the foot showing the middle or widest part of the foot, which should be just dorsal to the center of rotation. Note that the foot is basically as wide as it is long.

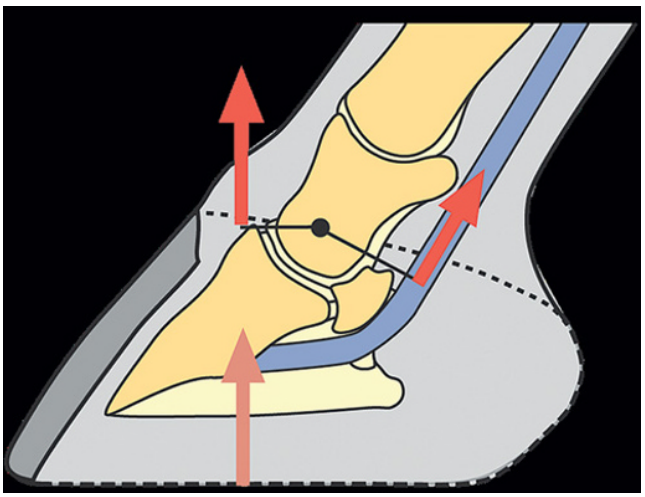

Figure 11.10. Schematic drawing illustrating the moments about the DIPJ. Note the extending force (dorsal red arrows) and a flexing force (palmar red arrow) on either side of the center of rotation.

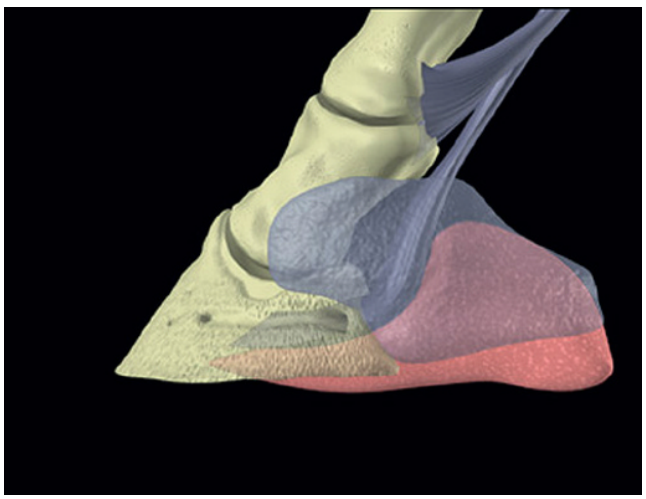

Figure 11.11. Model illustrating the necessity for the hoof capsule to approximate the frog to enclose the structures in the palmar foot. *Source*: Courtesy of Dr. Andrew Parks.

Within the hoof capsule, the distal phalanx occupies approximately two-thirds of the space, and the soft tissue structures occupy one-third. For effective physiologic functioning of the foot, the osseous and soft tissue structures must be located on the same plane within the hoof capsule and complement each other (Figure 11.11). The hoof wall at the heels of the hoof capsule should extend to or approximate the base of the frog.

Appropriate or consistent trimming of the palmar/plantar section of the foot has always presented problems for the clinician, for a variety of reasons. Variations in hoof conformation, farrier training, empiric considerations, and owner pressure not to trim the heels often dictate how the heels are trimmed. Due to the normal angulation of the horn tubules, the heels of the hoof capsule grow forward rather than tall. If the heels are not trimmed appropriately and are allowed to migrate dorsally toward the center of the foot, the laminar interface and the bones of the digit assume the function of the soft tissue structures. Often, the hoof conformation does not allow the heels of the hoof capsule to be trimmed to the base of the frog for anatomical reasons but an attempt should always be made to trim the heels of the hoof capsule to the same horizontal plane as the frog. If the hoof wall at the heels cannot be trimmed to the base of the frog, the branch of the shoe or some other form of farriery can be used to extend the ground surface of the hoof capsule to the base of the frog. Farrier methods for the palmar section of the foot are discussed later in the chapter.

VetBooks.ir

TRIMMING THE FOOT

The hoof care performed by the farrier is perhaps the most important routine procedure for maintaining and promoting the health of the equine foot. Farriery is a difficult occupation, and in order to provide the best service, the farrier should be provided with the best possible working conditions. The owner, client, or trainer should respect the farrier by providing a clean environment in which to shoe the horse. If an acceptable place is not provided, then the farrier should request one. The farrier should carry a good-quality fly spray and spray the horse as needed to control flies with the owner's permission. It is important to keep the area clean while working. Sweeping the floor after each foot is trimmed can be effective. The foot trimmings and manure should always be swept at least 6 feet behind the horse. Sweeping to the front or the side of the horse should be avoided as the debris will still attract flies to the horse's face or body. The broom is an important tool that every farrier should carry in his/her vehicle. Another helpful tip is to place an ordinary wood clamp in the tail hairs at the base of the tail to decrease tail swishing as the tip of the tail may injure your eyes when an odd fly lands on the horse. The farrier should have shade in warm weather and protection from cold weather in the winter. The area must be well lit and have an adequately sized space with a firm flat surface. Often the horse's owner or trainer must hold the horse to keep it quiet while being shod. If physical restraint is necessary, the client rather than the farrier should always perform it. Sedation or tranquilization should be discouraged when shoeing the horse, but if required, it is always best to have a veterinarian administer the medication.

The basic trim is the most significant aspect of good basic farriery. The farrier can use landmarks—the HPA, COR, and heels of the hoof capsule extending to the base of the frog—to carefully evaluate each foot and apply the appropriate trim. Using these three guidelines allows the farrier to be consistent with each foot trimmed. Sometimes good-quality radiographs are useful to locate or confirm the guidelines and provide additional parameters for applying the appropriate farriery.

The first observation should be the HPA in the standing horse, as described previously. To confirm that the HPA is straight or parallel, the horse should stand squarely on all 4 feet with the third metacarpal bone positioned vertically to the ground, on a hard, level surface, and be viewed from the side. If the HPA is either broken forward or backward, the initial trimming can be used to address this condition. The COR also can be located and marked on the outer surface of the hoof capsule if desired. A very practical technique is to palpate the dorsal and palmar border of the middle phalanx just above the coronet. Half the distance between the borders of the middle phalanx is determined, and from this point, a vertical line is dropped from the coronet to the ground (Figure 11.12). This line appears to have a good correlation with the widest part of the foot on the solar surface.

A leather apron should always be worn when trimming or shoeing the horse to protect the operator's legs. Trimming begins with picking up the foot and cleaning the solar surface with a hoof pick followed by using a wire brush, which allows the farrier to evaluate the structures on the solar surface. Before placing the foot between the farrier's legs, the ground surface of the foot is sighted by placing a hand on the medial side of the dorsal distal surface of MC3 just above the fetlock and allowing the distal limb (digit) to hang freely. The farrier's line of vision should be over the hoof to assess the lateral to medial orientation of the solar surface relative to the ground (Figure 11.13). If either the lateral or medial side of the hoof is excessively high or low relative to the opposing side, this can be addressed during the

Figure 11.12. The vertical line, as shown, usually approximates the center of rotation and the middle of the foot.

Figure 11.13. The examiner's line of vision should be placed over the hoof, which is permitted to hang in a relaxed natural position rather than being pulled outward. This permits accurate assessment of mediolateral orientation and inspection of the bottom of the foot.

VetBooks.ir

trim. It is equally important to evaluate the height of the heel bulbs (measured from the hoof wall at the heel to the hairline) and note any marked disparity between them. A notable difference in height (greater than 5 mm) denotes a sheared heel hoof conformation and should be addressed during the trim.[18]

The size and position of the frog should be noted on the ground surface of the foot. The width of the frog should be 67% of its length, and the surface of the frog should be on the same plane as the lateral and medial hoof wall at the heels of the hoof capsule.[14] The author believes that if the surface of the frog protrudes below the level of the hoof capsule at the heels or is recessed below the heels of the hoof capsule, this should be noted, addressed, and corrected, if possible, during the trim. If the frog protrudes below the hoof capsule, as is often seen in horses with low or underrun heels, the frog can be trimmed lightly to remove any excess horn and then the horse can be placed on a solid surface for 12–24 hours without shoes. This allows some compression of the frog and allows the heels of the hoof capsule to migrate distally, placing all of the structures on the same horizontal plane. If the frog is recessed below the level of the heels, an attempt should be made to trim the heels of the hoof capsule to the point where all structures located on the ground surface of the palmar foot are on the same horizontal plane. The length of the frog far exceeding the width is a clear indication of a chronic foot problem in which the proper physiology in the palmar foot has not been utilized. In this case the frog is usually accompanied by narrow heels and bars that show curvature instead of being straight; this condition is referred to as contracted heels.

Next, a line is imagined or drawn (with a magic marker or felt tipped pen) across what is judged or measured to be the widest part of the foot. This point can be measured with a ruler if desired. As described above, this line approximates the COR (Figure 11.9) and can be used to determine the dorsal and palmar proportions of the foot.

Before beginning the trim, the ground surface of the foot is aggressively cleaned again with a wire brush. The author removes no horny material from bulk of the solar surface of the foot other than any loose or exfoliating horn that is present over the frog or sole. In most cases, all horn material that remains after the foot is cleaned with a wire brush is left intact.

Excess length of the hoof wall at the toe and quarters of the hoof is determined by paring the sole–wall junction (white line) to live solid sole with an appropriate hoof knife (Figure 11.14), and then the excess horn relative to the trimmed sole is removed using hoof nippers (Figure 11.15), being careful to leave the adjacent sole for protection. The author removes the excess hoof wall length beginning just dorsal to the heel quarters with the nippers placed in a tapered position to start the cut and then moving in sequential increments to the opposite heel quarter. Using a hoof rasp (Figure 11.16), the heels of the hoof capsule are trimmed to the same horizontal plane as the frog and then blended into the toe and quarters, creating a flat level surface.

The author prefers to use the rasp in a side-to-side motion rather than in a forward motion except at the toe. This allows better control and prevents uneven

areas of the foot from being created. Attention is paid to extending the heels of the hoof capsule to the base of the frog when possible, with the intention of creating a solid heel base. If there is insufficient hoof wall for the end of the heel to reach the base of the frog, or if the heels are damaged, this distance can be lengthened by extending the branches of the shoe or by some other farriery method. The key to trimming the heels is to complete the trim at the heels with the hoof wall and the frog on the same horizontal plane if possible (Figure 11.17). The medial or lateral hoof wall can be trimmed cautiously relative to the other when changes to the lateral medial

VetBooks.ir

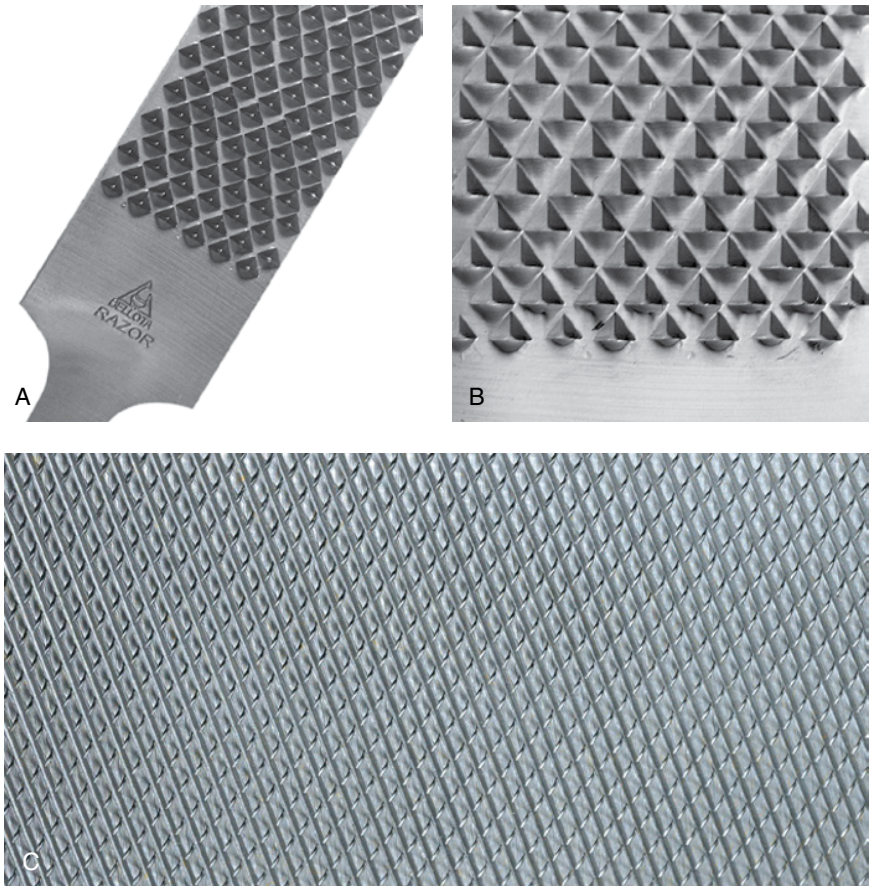

Figure 11.16. Hoof rasp (A). Note the coarse side of the rasp (B) that is used to remove hoof wall and the smooth side (C) that is used to level the foot. *Source*: Courtesy of FPD Farrier Products Distribution, Shelbyville, KY 40066.

orientation of the foot are necessary, such as in the case of sheared heel conformation.

An imaginary line drawn from the initial line across the widest part of the foot to the base of the frog should approximate another line drawn from the widest part of the foot to perimeter of the hoof wall at the toe. When making this final assessment, the distance from the middle of the foot to the toe is generally greater than the distance to the base of the frog. When this occurs, the foot can be placed on a foot stand, and the outer perimeter of the distal dorsal hoof wall at the toe can be reduced with a rasp. This places the COR in the middle of the foot or in the middle of the shoe when shod. The foot is further shaped by removing flares from the outer surface of the hoof capsule to concentrate weight-bearing on the hoof wall under the limb. Following the trim, a shoe can be applied to complement the trim, protect the trim, and change the biomechanics of the foot when necessary.

TRIMMING THE BAREFOOT HORSE

Recently, it has become popular to maintain horses in the barefoot or natural state. The author favors horses being maintained without shoes when possible. On the other hand, the author believes that horses can be shod in a physiologic manner such that minimal damage to the hoof capsule will occur. Factors to consider when making this decision to leave the horse barefoot include:

- Protection for the before ground surface of hoof capsule when hoof wear exceeds growth
- Traction that is necessary for athletic activities in performance horses and safety for horse and rider
- Therapeutic shoes or devices to treat lameness or diseases of the hoof or to address limb conformation

VetBooks.ir

Any one or a combination of the above factors may dictate the necessity for shoes. The decision also depends on the intended use of the horse, the owners' expectations, and the type of hoof care the horse receives, especially during the transition period from shod to barefoot. Much of the horse industry is involved in competitive athletic disciplines, and the question arises, "Can this horse compete and perform at a given standard without shoes?"

Wear vs. hoof wall growth takes into consideration the genetics and breed of the horse, structure and conformation of the hoof, working surface, farriery practices, and, most importantly, the horse's intended use, all of which influence wear of the feet. The quality and integrity of the structures of the foot is usually the determining factor.

Maintaining the horse barefoot is best accomplished when—or potentially when—the hoof wall is thick and solid, there is good sole depth, and there are soft tissue structures in the palmar/plantar section of the foot that are of sufficient mass. Breeding practices have influenced the structure of the feet, and unfortunately, this has not always been for the better. Quarter horses have been bred for fashion, whereas Thoroughbreds have been bred for speed, and the result is often poor-quality feet. Usually, and especially in Thoroughbreds, the foot is often prevented from growing and maturing into a so-called good or functional foot due to husbandry or training practices.[14]

Hoof development, particularly during the first 3 years, depends on stimulation from regular exercise and turnout. Yearlings are often shod for sales for purely cosmetic reasons or in an attempt to alter faulty foot conformation. The majority of racehorse's feet remain healthy until the time they are broken and enter training, usually as 2-year-olds. As training begins, the hoof capsule and its related structures are still immature, the animal is confined to a stall or small paddock with exercise severely limited, a rider is placed on its back that leads to additional weight-bearing on the feet, and the horse begins to work. Training leads to abnormal stresses being placed on an underdeveloped foot along with excessive wear. Next, the horse shows discomfort, and shoes are then placed on the feet for protection. The first thing that happens when shoes are applied is that the solar surface of the foot loses contact with the ground and its ability to adapt. Furthermore, the method of foot trimming and the size and placement of shoes by the farrier must be considered.

The combination of the above factors can and often does change the structures of the foot forever, or the factors can lead to a weak foot that is hard to maintain without shoes. Taking a digital photo of a horse's foot at the start of training and then taking another photo 6 months to a year later and comparing the difference can confirm this observation. The feet are often overtrimmed and shoes are placed on young horses too early and often unnecessarily if just a few modifications were made to the farriery and the training program to allow the feet to continue to develop.

The anticipated exercise program is also a key factor. Many horses fare well without shoes, if they are not asked to perform. Whereas light riding of barefoot horses may be feasible, competition may not be possible. Finally, the surface upon which the horse is kept and exercised influences the wear on the feet. A hard or abrasive surface, such as sand, is not as forgiving as a soft, deformable footing.

The need for traction on certain ground conditions such as wet grass can also dictate the choice of barefoot vs. shod. Shoes themselves act as a traction device by providing additional cup to the horse's foot. Shoes, and various traction devices that are added to shoes, allow horses to hold their footing, prevent slippage, enhance propulsion with the hindfeet, and improve overall performance in competitions such as eventing, jumping, steeplechase racing, and polo. Winter equestrian sports such as fox hunting are aided by traction devices because of the diverse weather and footing conditions. Traction devices protect the horse and give the horse and rider confidence while performing. Often overlooked is the fact that they also protect the rider, whether trail riding or competing. Borium or studs provide additional safety from slippage and allow a horse to be ridden, to pull a carriage up and down hills, or to pull a sleigh on snow and ice.

Sliding plates used in reining horses may be considered anti-traction devices because they decrease the friction between the ground and the hoof.

Finally, therapeutic shoeing generally is a component of or sometimes even the entire treatment for lameness localized to the foot. Lameness results from repetitive stresses or overload placed on a given structure(s) of the hoof capsule or within the hoof, leading to damage. Shoes can be used to change the forces/stresses on a given structure and unload damaged areas of the foot. They are used for realignment of the distal phalanx in laminitis, provide continuity of the hoof capsule after resection in white line disease (WLD), stabilize hoof cracks and distal phalanx fractures, and provide protection following a puncture wound or foot surgery. Angular or flexural deformities in young horses may be treated or aided by several types of shoes.

A transition period to allow the foot to adapt is generally needed when changing from shod to barefoot.[12] The hoof wall must toughen and the sole must become thicker and stronger to compensate for not wearing shoes. Horses are much easier to maintain in a barefoot manner if they have never had shoes. Another factor in the transition period is the length of time that the horse has worn shoes; this affects the length of time needed for the horse to develop the necessary sole protection once the shoes are removed. Often, the foot structures have inadequate mass or are irreversibly damaged and thus incapable of adaptation.

The horse should be taken out of work if a decision is made to remove the shoes. The author recommends a 30- to 90-day transition period during which time the structures of the horse's feet can toughen and adapt to going without shoes. At this point hoof care changes from trimming the foot to shaping the foot.[13] The only tools necessary are a wire brush and a rasp. Nothing is removed from the bottom of the foot. Using a rasp, the heels are moved back to the base of the frog (when possible) such that the heels of the hoof wall and the frog are on the same plane. Unlike when applying shoes, the hoof wall is rasped on an angle (instead of a flat plane) to create a rounded edge. The angle of the hoof wall is

VetBooks.ir

created with the rasp placed at a 90° angle, starting on the outer side of the sole–wall junction (white line). This manner of rasping reduces the hoof wall length and creates a sharp edge that is then smoothed with the rasp used in a horizontal direction, resulting in the rounded perimeter. Flares, or excess toe, are removed from the outer hoof wall (shaping). The shaping is finished by slightly beveling the toe on the ground surface of the foot from the toe quarters forward to decrease leverage, which promotes sole growth and to toughen the sole–wall junction. This bevel should not be created if firm pressure (using thumb pressure or hoof testers) on the sole causes the sole to deform.[13]

The length of the adaptation phase often can be predicted according to the initial structure of the horse's foot and should be modified as necessary. When there is minimal sole depth (as evidenced by hoof testers applied to the sole), the horse should be confined or placed in a small area of soft footing and walked daily on a firm surface until the structures of the foot begin to change and adapt. Placing the horse in a protective boot will protect the foot but may not provide the necessary stimulation for adaptation. At no time should the horse show marked discomfort, because this defeats the purpose. If the horse's sole has not become firmer and noticeable growth of sole does not appear on the inner border of the sole–wall junction after 30 days, then it may be worthwhile to take lateral radiographs to assess sole growth or reconsider whether this method of hoof care is in the best interest of the horse.

THE HORSESHOE

The basic configuration of a horseshoe is a curved bar made from a variety of materials that is rectangular in cross section and shaped to conform to the contour of the ground surface of the hoof wall. The shoe should be wide enough to cover the ground surface of the hoof wall, the sole–wall junction (white line), and the sole adjacent to the sole–wall junction. The shoe has four surfaces: the foot and ground surfaces and the inner and outer perimeter or margins. The parts of the shoe are named after the corresponding section of the hoof: toe, quarter, and heel. Each shoe has two branches, medial and lateral, that extend from the center of the toe to the medial and lateral heels, respectively. The width of the shoe is often referred to as the web. The shoe is punched or machine stamped with nail holes, three or four in each branch, 2–3 of which are generally used in each branch.

Materials and Size

Horseshoes may be made from steel, aluminum, titanium, synthetic polymers, or various composites; the construction material dictates the shoes' weight and durability. Most horseshoes are made of steel due to their durability, cost, and workability. However, aluminum is used frequently because of its lighter weight and ease of shaping for many farriers. Recently, shoes made from various synthetic polymers and composites have been recommended for specialty uses, but they have not replaced the traditional materials.

Shoes may be hand forged from steel or aluminum bar stock or manufactured. Handmade shoes offer few advantages over the manufactured shoes that are available on the market today. It is more important that the farrier be skilled at forging, so he/she can modify manufactured shoes to fit the foot and hand forge a shoe from bar stock when necessary. Heating the shoe makes altering the shape much easier, and it has advantages when fitting the shoe, such as seating clips (when used) and detecting uneven sections on the ground surface of the foot. Excessive heat generated by repeatedly placing a red-hot shoe on the horse's foot should be avoided, as the heat appears to damage the inner structures of the sole–wall junction.

Bar stock is usually rectangular in cross section and available in sizes from 0.6 to 1.2 cm thick and 1.2–3.1 cm wide. The most common size is 0.8–1.9 cm. Concave bar stock has a crease stamped in the bar stock and is tapered from the crease toward the inner margin on the ground surface of the shoe. A shoe made from this type of bar stock is thought to increase traction on all terrains and possess a self-cleaning action. It is frequently used in Europe but has also become popular in the United States. Pre-made concave shoes can also be purchased.

Manufactured shoes, also referred to as keg shoes, are catalogued using numerical sizes. Although the sizes are usually consistent within and between a given manufacturer's product lines, there is no universal standard for sizing keg horseshoes. Manufactured shoes may be generically shaped to the general shape of a horse's foot or specifically designed for a forefoot or hindfoot. The dimensions of the stock of both manufactured and hand-forged shoes affect the weight and stiffness of the shoe, coverage of the ground surface of the foot, height to which the shoe elevates the foot off the ground, and rate at which the shoe wears.

Shoe weight influences the biomechanics of movement. The heavier the shoe, the more energy is expended accelerating and decelerating the limb at the beginning and end of each stride. Therefore, the lightest possible shoe should be used that is compatible with protecting the wall and adjacent sole and providing the stiffness and wear required. Shoes made from concave stock are lighter than those made from regular bar stock. The width and thickness of the shoe usually is uniform around the circumference of the shoe so that the biomechanical influences of shoe weight and the stresses imposed are generally balanced about the axis of the limb. Although the width or web of a shoe is related to the thickness of the hoof wall, and at least in part the size of the foot, it is common to increase the width of the web of the shoe to provide increased protection to the margins of the sole. The thickness of the shoe is related to the rate at which it is expected to wear and to a lesser extent the rigidity needed to prevent the shoe from losing shape. The height that the shoe raises the foot off the ground also is influenced by the thickness of the shoe, but this is usually a secondary consideration.

Several common modifications are made to the ground surface of the shoe by forging, and some modifications can be made with an electrical grinder or sander. Softening the 90° angles at the junction of the shoe's

VetBooks.ir

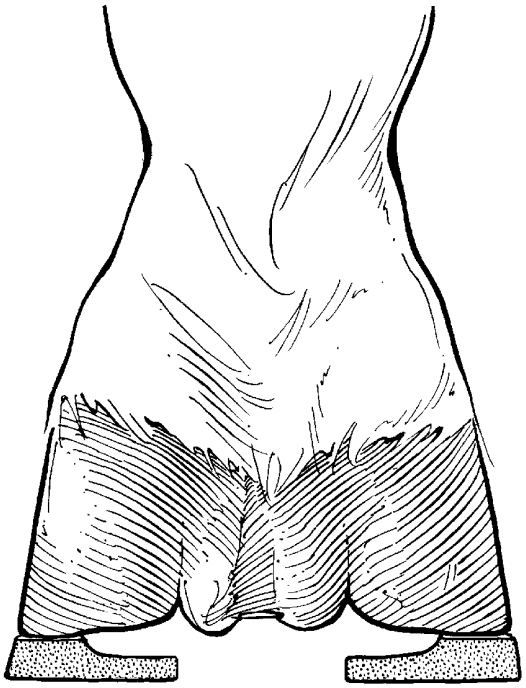

Figure 11.18. A wide-web shoe with a concave solar surface covers and protects the sole without applying pressure to it.

Figure 11.19. Half-round shoe.

ground surface and outer margin by beveling or rounding, called safing, increases the ease of break-over. A shoe with a rounded outside perimeter is thought to improve the ease of break-over in any direction. A similar modification used by the author is achieved by using a half-round shoe, which is made from half-round bar stock that resembles a semicircle in cross section (Figure 11.19). Half-round shoes can be purchased, but the semicircle does not have the same curvature as a shoe made from bar stock.

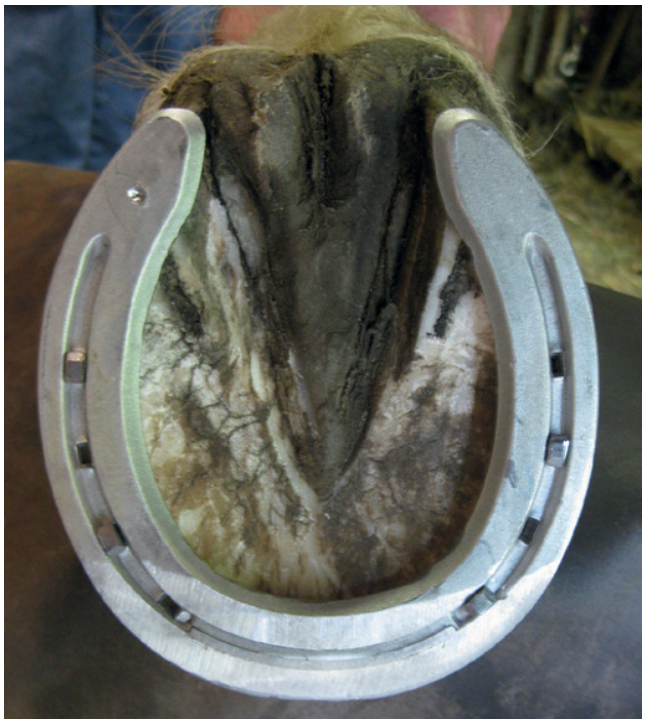

Figure 11.20. Using an electric grinder, break-over can be created in any shoe beginning at the inner margin of the shoe creating a tapered effect toward the outer margin.

The toe section of flat shoes frequently is rolled or beveled only at the toe to improve the ease of break-over. This modification can readily be accomplished by forging. For enhancement of break-over, the author uses a grinder and begins the roll at the inner margin of the ground surface of the horseshoe and creates a tapered roll from this point to the outer margin. This decreases the thickness of the outer margin of the shoe by half the thickness of the material (Figure 11.20).

A similar effect can be achieved by rockering the toe, which is accomplished by bending the full thickness of the toe area of the shoe proximally from toe quarter to toe quarter. When rockering the toe of a horseshoe, it is important to leave sufficient hoof wall mass at the toe to accommodate the rocker created in the horseshoe with the result being an intimate fit between the shoe and the toe area of the foot. This intimate relation is created by burning the rocker in to the toe or by using a hoof rasp to create the bevel in the toe of the hoof to accommodate the rocker in the shoe. Less commonly, a flat shoe may be asymmetrically beveled or rounded to improve the ease of break-over in a desired direction or toward a given side of the shoe to encourage a horse to break-over toward that side and direct or accommodate the flight of the foot. Rounding the outer margin of the medial branch of a shoe on the ground surface of the shoe with a hammer or grinder is called boxing. See Table 11.2 for a list of commonly used farrier terms.

There is little traction between the flat surfaces of steel or aluminum shoes and the ground. Grooves are created in the ground surface of the shoe, called fullering or creasing, to increase traction. A similar modification

VetBooks.ir

Table 11.2. Basic farriery terms.

Term	Definition/explanation
Bar shoe	To increase the ground surface area of the shod foot. It allows weight-bearing to be redistributed from one area of the foot to another
Patton bar shoe	A Patton bar shoe is designed to add significant length and varying degrees of elevation to the palmar/plantar section of a hoof capsule. The initial shoe may be designed as an egg-bar, a straight-bar, or an open-heel shoe
Square toe	A square toe is a shoe modification made to a hind shoe. The material in the toe of the shoe is forged to be square across the dorsal border allowing the shoe to be fit underneath the dorsal toe of the hoof capsule. The square toe shoe gives a foot direction as it breaks over, looking for the path of least resistance. By setting the shoe underneath the toe, the point of break-over is changed, and the flight of the foot is altered to a more upright animated stride
Rolled toe	A rolled toe is a shoe modification that may be applied to the ground surface of both front and hind shoes. It may be forged into a shoe or crated with a grinder from the dorsal border of the shoe back to the inside of the web of the shoe at the toe in a graduated or tapered manner. This modification allows one to change the point of break-over in a shoe
Rocker toe	A rocker toe is a shoe modification where the outer 2/3 dimension of the branch of the shoe at the toe is forged in a manner that is on a different plane than the rest of the shoe. The toe plane would be forged upward, emulating the base of a rocking chair. This modification is applied to both front and hind shoes and may be considered a more aggressive manner of changing the paint of break-over and the flight of the foot via break-over
Forging	Forging is a process where a piece of metal is heated in a forge to increase its malleability. The metal is then forged between an hammer and an anvil, manipulating the material in a manner that it may be drawn, stretched, or creased and nails hole punched into it, as it is shaped into a specific horseshoe. Forging would also encompass the development of numerous shoe modifications such as bar shoes, trailers, clips, etc.
Fullering/ creasing	The shoe modification is used regularly to create a groove in the approximate middle of the branch on each side of a horseshoe where nail holes will be placed in the shoe. The crease is forged into a shoe with a hammer and creaser that is driven into heated steel displacing the steel, crating the groove. This crease creates an opportunity to remove a shoe utilizing a tool called a creased nail puller. Removing one nail at a time eliminates pressure applied to the sole during the removal process. Additional creases may be applied to a shoe to increase traction. In addition, as the crease fills with dirt, it will increase traction and widen an area of the shoe, offering increased ground surface
Swedging	Swedging is a forging exercise where you are changing the shape and dimensions of a piece of bar stock by placing heated steel into a swedge block, striking it with a sledge/power hammer to change the shape and dimensions of the original metal used. A swedge block is generally designed with a 3″ × 3″ × 3″ block of mild steel with a post welded in place to be fit into an anvil's hardy hole. The block may be designed into numerous variations or configurations depending upon the section of the steel desired
Boxing	Boxing is a modification where material is removed from the outer perimeter of the hoof surface of a horseshoe, creating a beveled or slanted edge rather than a sharp flat edge. This process allows the shoe to be fit wider than the margins of the hoof capsule itself. Boxing reduces the likelihood that the horse will step on its own shoe and pull it off
Safing	Safing is a shoe modification where material is removed from the ground surface of the outer perimeter of the medial branch of a shoe from the widest part of the foot back to the heel. This modification creates a beveled or slanted edge on the ground surface of the horse shoe on the inside branch where a horse is likely to step on himself. The beveled edge makes the shoe less likely to injure the horse, if the horse steps on the opposite foot or interferes during limb flight
Clip	A clip is a thin portion of material of a horseshoe that is forged toward the hoof surface of a shoe in a vertical manner from the outer edge of the shoe. The clip should be approximately the same height and width as the dimension of the branch of the horseshoe. Clips are descriptive in nature such as toe clips (would be drawn in the toe of the shoe), quarter clips, and side clips drawn relative to where they are located on the side of the shoe. A clip's sole purpose is to be fit against the hoof wall and minimize the shearing action encountered on horseshoe nails as the horse applies torque when turning or stopping in an abrupt manner
Trailer	A trailer is a shoe modification that is applied to the lateral branch of a hind shoe. The length of a trailer is approximately the same length and width as the dimension of the branch of the shoe that it is being applied to, i.e. a 3/4-inch trailer is appropriate on a shoe that is made from 3/4-inch bar stock. The trailer is forged so it deviates laterally at the heel of the lateral branch of the shoe, thus increasing lateral support to the foot during the weight-bearing phase of the stride. The added length is designed to give the foot direction as it lands

in racing or training plates is termed swedging. The fullering in the horseshoe becomes compacted with dirt; the friction between the dirt in the fullering and the dirt on the ground is greater than steel on dirt, thus aiding in traction. In addition, the nail heads are embedded within the crease with 1–2 mm of the nail head protruding above the crease, which also aids traction and helps to keep the nails tight.

The full circumference of the shoe may be fullered as in the concave shoe, or it may be limited to the branches of the shoe and less frequently just the toe. Fullering a single branch of the shoe enhances traction on one side

VetBooks.ir

and delays break-over on that side of the foot. When the branches of the shoe are fullered, the nail holes are centered in the groove, which conforms with the inside and outside of the nail heads. A classic example of a shoe that uses two of these modifications is a half-round, half-swedge shoe worn on the hindfeet by harness horses. The inner branch is half round in cross-sectional profile and the lateral branch of the shoe is swedged. Thus, the medial branch, enhanced by the half round, breaks over rapidly, whereas the break-over of the lateral branch is delayed by the swedge.

The only common modification to the solar surface of the shoe is beveling of the inner half of the web toward the inside with a hammer or a grinder, called seating out or concaving. Horses with flat, thin soles benefit from a seated-out or concave shoe to decrease pressure on the sole adjacent to the wall (Figure 11.18). Safing decreases the likelihood of the shoe being stepped on by another foot and pulled off. Boxing the heels allows the farrier to fit the shoes with more expansion (width) at the heels without a ledge being present, which can easily be stepped on by another foot.

Clips are triangular-shaped projections that extend proximally from the periphery of the shoe (Figure 11.21). Clips are preformed on manufactured shoes or they may be forged in the shoe at the time of fitting. When a shoe is fitted, the outer surface of the clip is congruent with the surface of the hoof wall. Movement between the shoe and the hoof capsule is reduced, which decreases the shear stress on the hoof nails. A single clip placed in the center of the toe or side clips placed at the toe quarters can be used on front shoes, while side clips placed at the toe quarters or quarters are generally used on the hind shoes. Clips may be positioned elsewhere around the periphery of the shoe when additional stability of the hoof capsule is necessary.

Extensions

An extension on a horseshoe is any projection of the shoe that extends outward beyond the perimeter of the foot in the horizontal plane. Extensions may be placed anywhere around the circumference of the foot. They may be forged into a shoe or welded onto the outside margin. An extension such as a wide lateral heel branch in a hind shoe is available as a manufactured shoe. A similar effect is obtained by using an oversized shoe fitted either forward or backward or by setting one branch of the shoe wide.

Every extension has the potential to cause the shoe to act as a lever. This lever action may be static, when the animal is not moving and the foot is bearing weight, or dynamic, particularly during the landing and break-over phases of the stride. When force is exerted on the extension by the ground, the forces are increased in the adjacent wall and decreased in the opposite wall as the center of pressure of the GRF shifts. In addition to acting as levers, extensions increase the surface area available for ground contact, which decreases the amount of shoe that descends into soft footing at that point in the circumference of the foot. The term floating or flotation effect refers to the web width of a section of the shoe that limits the amount of this part of the shoe that descends into soft footing (Figure 11.22).

Lateral or medial extensions may be used to force the opposite wall of the hoof capsule to the ground or support the wall adjacent to the extension. In doing so, the lever decreases the compression in the opposite wall and increases the compression in the side of the hoof on which the extension is being used. Heel extensions frequently are used on one side of the foot or biaxially (Figure 11.23). When used in performance horses, extensions are continuations of the heel of the shoe and are called trailers.

Trailers are used almost exclusively on the lateral branch of hind shoes. Egg-bar shoes that extend palmar/plantar to the heels of the hoof capsule act as heel extensions. They are most commonly used on the front feet but can also be used on the hindfeet when necessary. Force applied on the butt of an egg-bar shoe decreases the moment about the DIP joint and the tension in the DDFT. Therefore, horses convalescing from a DDFT injury may benefit from heel extensions used in conjunction with some type of heel elevation. The egg-bar shoe acts as a palmar extension, and when the horse is on a soft surface, it reduces the sinking of the heels into the surface at the beginning of the stride and acts as a heel wedge during the support phase of the stride.[5] On the

Figure 11.21. A steel hind shoe with quarter clips (A) and a clipped steel hind shoe fitted to the foot (B).

VetBooks.ir

other hand, egg-bar shoes can be fitted too long, and the extension beyond the heels acts as a lever, causing excess pressure on the heels of the hoof capsule. Heel wedges are known to decrease the force on the navicular bone.[5] However, the consequence of this benefit is that it is often used on horses with damaged heels and the heels are then placed under greater compressive stress. Heel extensions alter the way the foot strikes the ground. If, as happens frequently, the heels are closer to the ground at impact, the extension or butt of the egg bar contacts the ground first. A lateral trailer, either in line with or diverging up to 45° from the midsagittal plane of the foot, forces the foot to pivot toward the side of the trailer as the foot lands. The toe of the foot is directed laterally after impact and break-over is redirected.

Bar Shoes

A bar is the part of a shoe that extends from one branch of a shoe toward the other, forming a closed unit. In a complete bar shoe, one branch extends to the other. In a partial bar shoe, the bar extends part of the way across the shoe. Most bars extend from one heel to the other to form a closed shoe. A bar may extend from one quarter to the other, or even diagonally across the shoe. Several patterns of complete bar shoes are commonly used, including the straight-bar, egg-bar, heart-bar, heart-bar–egg-bar (or full-support shoe), and Z-bar shoe (Figure 11.24).

Indications for a bar shoe include increased stability to the hoof capsule, increased ground surface area, local protection, recruitment of additional weight-bearing area of the foot, and ability to unload a section of the foot. Some type of bar shoe is frequently used, often in conjunction with other shoeing methods, to increase stability within the hoof capsule or distal phalanx. Bars that extend palmar/plantar to the normal position of the heel of the shoe act as a palmar/plantar extension. Bars that are set under the ground surface of the foot can be adjusted to protect that part of the foot from ground contact, apply pressure to that part of the foot, unload that part of the foot, or recruit that part of the foot for weight-bearing. A straight-bar shoe may decrease pressure on the palmar/plantar third of the frog and protect the underlying navicular bone. The heart-bar shoe is used to recruit or increase the role of the frog in weight-bearing, thus using the frog to create a weight-sharing relationship with the hoof wall and

laminar interface. Heart-bar shoes also may be used to support the palmar/plantar aspect of the foot to reduce the stress in the adjacent wall and permit unloading of one or both heels but only if the integrity of the soft tissue structures of the frog and digital cushion have sufficient mass and are intact.

A partial bar shoe extends part of the way across the ground surface of the foot, most commonly from one heel onto the frog, which increases or reduces weight-bearing on a single heel. Farriers refer to this type of shoe as a half-bar or G-bar shoe. The bar of a Z-bar shoe is shaped with two 90° bends that are incorporated into a three-quarter shoe so that one leg of the Z is attached to the heel of one branch and the other is attached to the quarter of the opposite branch. It is very important that when the Z-bar shoe is fabricated, a frog plate is used to recruit the frog to share the load. The author is reluctant to use a Z-bar shoe as this type of shoe does not unload or protect the section of the foot that is not covered by the shoe.

Traction Devices

Various devices can be added to the ground surface of a shoe to increase traction. Traction devices also can influence the speed and direction of landing and break-over. Calks are projections of almost any size and shape—although most are round, square, or rectangular—on the ground surface of a shoe (Figure 11.25). Blocks, stickers, and studs, made of steel or steel with a tungsten carbide core, are all different types of traction devices or calks. Toe grabs on racing plates are essentially curved, elongated calks. Borium, tungsten carbide particles in a brass matrix, is brazed onto the surface of a shoe with an acetylene torch to create a roughened surface to prevent slippage as well as wear of the shoe. Horseshoe nails with tungsten on the heads of the nail can be used to attach the shoe and simultaneously apply traction. These nails are helpful in cold areas with ice and snow.

Some calks are permanent, whereas others are temporary and can be removed. Permanent calks are forged into the heel of the shoe, molded into the shoe at the time of manufacture, or welded or brazed onto the shoe at the time of fitting. Drive-in calks are semipermanent (can be changed if necessary) and are driven into a pre-drilled hole in the shoe. Temporary calks, called screw-in calks or studs, are screwed into drilled holes that have been tapped (create threads) so they can be inserted and removed as needed. Plastic inserts or cotton can be used to plug the hole when not in use. The size and shape of the studs may be changed with the various athletic pursuits or ground conditions. Calks may be positioned at any point around the circumference of the shoe. The choice of whether to use calks, which type to use, and where to position them is usually based on trainer and farrier preferences and the horse's performance discipline. Bilateral heel calks typically are used on jumpers and event horses. Racehorse plates may be equipped with toe grabs, with or without one or two heel calks (blocks or stickers). Draft animals usually have shoes with biaxial heel calks and less frequently a large toe calk.

Any traction device placed on the surface of the shoe inevitably alters the mechanics of the foot by altering the way it contacts the ground. The harder the ground surface or the taller the calk, the greater the effect. Calks concentrate stress in the wall immediately proximal to the calk. Therefore, the lowest, broadest calk compatible with adequate traction is recommended. A single calk at

VetBooks.ir

either the heel or toe alters mediolateral and dorsopalmar orientation. A single heel calk acts in much the same way as an extension or trailer, causing the foot to turn toward the side with the calk as the foot lands. Symmetrical placement of two pairs of calks, one pair on either side of the toe and one pair at the heels, encourages the foot to break-over in the center of the toe.

PLACEMENT AND APPLICATION OF THE SHOE

When a shoe is placed on the solar surface of a horse's foot, the horse is no longer standing on its foot; rather, it is standing on a shoe. Therefore, it is logical to place a shoe with biological congruency such that it conforms to the trimmed foot. For example, most horses have a natural wear pattern on the toe of the front shoe; therefore, the shoe should incorporate some form of break-over enhancement to simulate the animal's natural wear pattern. The shoe should be accurately fitted to the outline of the properly prepared hoof wall with the shoe placed central to the widest part of the foot (Figure 11.26). The shoe should be constructed from the lightest and simplest material that provides traction, protection, and adequate support to the foot for the work being performed.

The ground surface of the foot and the solar surface of the shoe must be flat and level to provide a tight fit between the surfaces. The shoe is fitted so that its outer margin closely follows the perimeter of the hoof wall from the toe to the last nail hole in the shoe. It is acceptable to fit the shoe marginally palmar or planter to the perimeter of the hoof wall at the toe. From the last nail hole to the end of the branch, the shoe should extend 0.0625–0.125 cm beyond the wall; or this distance can be varied according to the conformation of the foot. This protrusion of the shoe beyond the hoof wall is termed expansion. The author prefers the branches of the shoe to extend 1–2 cm beyond the end of the trimmed heel.

The shoe should be placed (or the nail holes punched such that they allow the nails to be placed) in the white line. Nail hole location is important to prevent interference with the movement of the palmar/plantar foot—the last nail hole in the branch of the shoe should be located at or forward of the widest part of the foot. The abaxial end of the branch at the heel should be rounded to provide sufficient space between the frog and branches of the shoe to pass a hoof pick to clean the sulci. The solar surface of the shoe can be concaved toward the inner margin to prevent sole pressure. The fitted shoe should lie central to the widest part of the foot with similar approximate distances from this point to break-over and from this point to the base of the frog. If the heels of the hoof capsule are damaged or do not correlate with the base of the frog, the branch of the shoe can be used to increase the ground surface of the foot by extending the branch to the base of the frog. If the shape of the solar surface of the foot is not ideal, the shoe should be fitted to provide even distribution of weight and, when possible, the shoe should be placed to accentuate the ideal shape.

Preparing the nail holes and driving the nails is often an overlooked part of farriery. If the hoof capsule is thought of as a cone, the necessity of driving the nails at the same angle becomes apparent. In this regard, hand-forged shoes provide an advantage of being able to angle the nail holes when the shoe is punched; this is called nail pitch (Figure 11.27). The nail holes in manufactured or machine shoes are stamped in bulk, so the opening on the solar surface of the shoe is closer to the outer margin of the shoe and the nail hole is not angled. When a nail

Figure 11.27. Nail pitch. Note the slope of the first two nails and the decreased pitch of the heel nail.

VetBooks.ir

is placed through a nail hole in a manufactured shoe, the shank of the nail exits straight rather than being angled to the slope of the hoof capsule. This prevents the nail from gaining solid purchase and height within the hoof wall. Low nailing is usually a precursor to cracks and fissures in the hoof wall. This should and can be easily corrected by re-punching the nail hole at an angle and by back punching the nail hole on the solar surface of the shoe.

Back punching is accomplished by using a pritchel placed on an angle adjacent to the inner side of the nail hole and directed toward the outer side of the shoe. The pritchel is used to create a small notch by removing a tiny piece of steel or aluminum material from the opening. This allows a nail inserted in the re-punched hole to immediately assume an appropriate angle.

The nail head must also have a tight fit within the nail hole. There should be no movement of the nail shank when the nail head is tapped down in the nail hole because movement will cause the shoe to loosen shortly after it is applied. If movement occurs, either a different nail with a different size or style of nail head should be used or the nail hole should be altered to accommodate the desired style of nail. The fewest number of nails and the smallest size of nail that will hold the shoe securely in place during the shoeing interval should be used to attach the horseshoe. Clips on the shoes will prevent shear on the nails and thus allow fewer nails to be used.

The horseshoe nail is unique in that there is a bevel next to the point that forms a short, single-sided wedge with the slanting side directed from within to without. On the same side of the bevel, there is a pattern or trademark located on the head of the nail that can be seen and sometimes felt. To be driven into the foot properly, the bevel and roughened side of the nail head must face toward the inside or midsagittal section of the foot. Another way to remember this is that the frog must be able to see the pattern or trademark on the head of the nail. If the nail is placed with the bevel to the outside, the nail will not exit the hoof wall and may enter the sensitive structures of the foot.

Before nailing the shoe, the author removes a thin slice of sole adjacent to the white line from quarter to quarter to discourage sole pressure. Two or three nails are driven into each branch of the shoe without excessive pounding, paying strict attention to the sinking and sound of the nail as it is driven through the hoof wall. Nails should be driven in the direction in which it is desired that they pass through the hoof wall and exit approximately 2–3 cm above the junction of the shoe and the hoof or approximately one-third of the distance from the ground surface of the hoof to the coronary band. The ends of the nails that exit the hoof wall should be immediately wrung off or bent over against the hoof wall to prevent injury to the horse or farrier if the horse pulls its foot away. After the desired numbers of nails are placed in the shoe, the nails can be tightened or drawn up by placing a clinching block under the bent edge of the nail and striking the head of the nail with a hammer. The author does not perform this step because it often draws the shoe too tight against the sole–wall junction, which can cause discomfort in a horse with a thin sole or hoof wall.

Finishing the foot is generally accomplished with the horse's foot placed on a foot stand. On the outer surface of the hoof wall, the bent ends or points of the nails should be cut with nail cutters so that approximately 3–4 mm of the nail protrudes, which will form the clinch. A rasp or a hoof gouge is used to clean or remove the disrupted horn from under the nail where it emerges from the hoof (Figure 11.28). Using clinching tongs, the end of the nail or clinch is pulled down firmly against the hoof wall or into the small channel created by the gouge (Figure 11.29). A clinch is sufficiently long when it equals the width of the nail at the bend. The holding power of the clinch is in the bend rather than the length of the clinch itself. Finally, the hoof wall and clinches are smoothed with a rasp, and the entire area is sanded with a commercial sanding block to remove any rasp or file marks. This gives the finished hoof a natural appearance without rasp marks, especially if hoof dressings are applied.

NON-NAIL ALTERNATIVES IN FARRIERY

The use of various adhesives to attach shoes has become popular. The glue-on shoe can be attached to the hoof with an adhesive either applied directly to the hoof wall or by tabs or a cuff that are attached to the circumference of the shoe and extend proximally. The cuffs are made of semirigid plastic or synthetic cloth. Alternatively, the adhesive may be directly interposed between an aluminum shoe and the ground surface of the wall and immediately adjacent to the sole.[15]

VetBooks.ir

Attaching a shoe with adhesives may offer several advantages over nailing, such as when nailing is painful, when there is insufficient wall for nailing the shoe, and as a therapeutic option. However, there are disadvantages as well. Recently, it has been shown that adhesive attachment of a shoe significantly limits the expansion of the palmar section of the foot.[19]

Glue-on shoes are more expensive and more time consuming to apply, and the application of adhesives to the side of the wall decreases the quality of the underlying horn over time. There is also a perception that glued-on shoes do not stay on as well as nailed-on shoes, but this impression is in part the result of poor case selection or poor application. Glue-on shoes should be considered a transient device to produce hoof mass or to treat a hoof disease or defect before reverting back to applying traditional shoes or leaving the horse barefoot.

Glue-on shoeing has been used extensively since the introduction of the acrylics (polymethylmethacrylate) (Equilox International, Inc., Pine Island, MN) and urethanes (Vettec Hoof Care Products, Oxnard, CA). These composites consist of a resin and a catalyst that polymerize in a matter of minutes when mixed together, forming a bond between the hoof wall and the shoe. Heat is generated in this process because it is an exothermic reaction. Once the composite has cured, it has a flexible consistency very similar to the outer hoof wall of the foot.

Indications for Glue-On Shoes

Glue-on shoes can be used for damaged hoof walls, hoof walls with poor horn consistency (especially during the summer months), or hoof walls that are thin and benefit from not using nails to attach the shoe. Occasionally, a horse will have its feet trimmed too short while being shod and become sore. In this case glue-on shoes lift the sole off the ground without placing nails in a short foot with minimal hoof wall thickness. Soundness can be restored almost immediately. However, it appears that the use of glue-on shoes has increased due to lack of farriery skills to apply appropriate traditional farriery.

In horses with chronic laminitis, realignment of the distal phalanx within the hoof capsule can be readily achieved with glue-on technology. Combined with the appropriate trim, glue-on shoes permit realignment of the solar surface of the distal phalanx with the ground. In WLD, the accepted treatment is resection of the affected hoof wall along with thorough debridement. Often the farrier is left with inadequate hoof wall to attach a shoe with nails, in which case glue-on shoes provide a means to attach the shoe while leaving the resected area open for observation and daily treatment. Long-toe, underrun heel foot conformation often leads to a persistent low-grade lameness and has always presented a challenge for veterinarians and farriers to manage. In this case, a composite can be used to extend the heel further palmarly to increase ground surface, and when combined with the appropriate shoe, the extended or created heel is placed in a better functional position under the limb. Furthermore, the composite that is placed between the shoe and the foot prevents the abrasive movement of the heel of the hoof capsule against the shoe. This lack of movement prevents further wear, allowing regrowth of the hoof wall and bars at the heel. However, the composite between the foot and the shoe appears to inhibit normal heel expansion and may lead to contracted heels if this practice is continued for any length of time.

Methods of Glue-On Farriery

There are two accepted methods to glue on a shoe. In the direct method, an aluminum shoe is attached with an adhesive (Equilox International, Inc., Pine Island, MN) to the ground surface of the foot (Figure 11.30). An aluminum horseshoe is pre-shaped to the hoof, and the hoof-bearing surface of the shoe is roughened with a grinding disc to increase cohesion. A two-part acrylic combined with fiberglass strands is used to bond the prepared shoe to the hoof wall. Meticulous attention to preparation of the hoof is essential because the heat from the exothermic reaction may lead to an abscess and the outer hoof wall may degenerate with continued use.

The second method is the indirect method. Here, a patented aluminum, rubber-soled horseshoe attached with a fabric cuff (Sound Horse Technologies, Unionville, PA) or an aluminum shoe, which is enveloped in rubber, forming a one piece unit with a cuff (GluShu, Gateshead, United Kingdom). The appropriate size shoe is selected, the cuff is trimmed as necessary, the outer hoof wall is prepared, and a composite is applied to the outer wall to bond to the cuff. Sole depth may increase with these shoes as the fabric or rubber cuff becomes the hoof wall and a urethane rim pad inserted between the shoe and the solar surface of the foot provides an interface to decrease concussion and eliminate sole pressure. However, the constrictive nature of the cuff encompassing the hoof wall must be questioned. Another indirectly applied shoe is an aluminum shoe encased in plastic with attached tabs around the circumference of the horseshoe; the shoe is glued to the hoof wall with cyanoacrylate adhesive (Equilox International, Inc., Pine Island, MN).

Glue-on shoes can be expensive and time consuming to apply. Success depends on proper hoof wall preparation, shoe fit, and composite application. Glue-on shoes

Figure 11.30. Direct method to apply a glue-on shoe in which the shoe is attached with a composite to the ground surface of the foot.

VetBooks.ir

should not be used to replace the necessary farrier skills that are used to resolve routine and difficult foot issues, nor should glue-on technology be used to replace the basic fundamentals of good basic horseshoeing.

All composites cure with an exothermic reaction; therefore, caution should be exercised when repeatedly applying these products to a thin or compromised hoof wall because the long-term effects on the hoof wall have not been determined nor has marked improvement been reported. Nevertheless, glue-on shoe technology offers another option to attach horseshoes to the ground surface of the equine hoof when a non-nailing, non-traumatic alternative is indicated.

ACKNOWLEDGMENT

The author would like to thank Derek Poupard, CJF, DipWCF and Jeffery Ridley, CJF, TE for their contributions.

FARRIERY FOR COMMON HOOF PROBLEMS

STEPHEN E. O'GRADY

VetBooks.ir

CONDITIONS OF THE FOOT THAT RESPOND TO FARRIERY

The biomechanics of therapeutic shoeing and its scientific application have been described in Chapter 8. In this section the basic principles of farriery will be applied to help resolve several types of abnormal hoof conformation or hoof capsule distortions that can occur in both lame and non-lame horses. Farriery approaches to some of the common clinical hoof problems encountered in equine practice will also be discussed. Hoof capsule distortion and the four types of abnormal hoof conformation that will be addressed include the long toe and/or low heel, the club foot, sheared heels and mismatched feet.

Radiography and Farriery

One of the main diagnostic tools besides physical examination that can help assess hoof wall distortions and abnormal conformation is radiography. Radiography can be used to assess both the external hoof conformation and many of the internal structures of the foot.[4,5,22,31,39] Considerable information can be obtained from the image regarding the overall shape and mass of the hoof capsule, the soft tissue structures, and the position of the distal phalanx within the hoof capsule. Lack of performance or many subtle lameness conditions that are localized to the foot are caused by hoof capsule distortions, poor foot conformation, improper landing patterns, and soft tissue damage that result from excessive biomechanical stresses being placed on the hoof capsule, the podotrochlear apparatus, and the DIP joint.

Lateral to medial and dorsopalmar 0° horizontal (DP) views of the foot can be used as a precise guide to implement basic or therapeutic trimming and shoeing (Figure 11.31). From the lateral medial view, the hoof-pastern axis (HPA), center of rotation (COR), sole depth, the angle of the solar border of the distal phalanx, break-over, and the proportions of the ground surface on either side of the COR can be assessed. When the solar plane of the distal phalanx shows a negative palmar angle, the need for heel elevation and the amount to apply, as well as whether the integrity of the structures of the heel will accept the pressure, can be determined. The dorsopalmar 0° horizontal view allows the clinician to evaluate the lateral medial orientation of the distal phalanx within the hoof capsule, the position of the distal phalanx relative to the ground, and the effect of the position of the distal phalanx on the joint spaces of the digit. The need to assess the position of the hoof capsule relative to the long axis of the digit is often overlooked. The DP radiographic view allows the position of the coronary bands to be assessed in the case of sheared heels and the position of the distal phalanx relative to the disparity in heel heights.

Hoof Capsule Distortion

The hoof capsule is composed of the hoof wall, sole, frog, and bulbs of the heels. Its unique continuous bond between its components form a casing on the ground surface of the limb that affords protection to the soft tissue and osseous structures enclosed within the capsule.[13,33,36] The hoof wall is a viscoelastic structure that has the ability to temporarily deform under load and then return to its original shape when the load or weight

VetBooks.ir

is removed due to its elastic nature. It is well accepted that abnormal weight distribution on the foot or disproportionate forces placed on a section of the hoof wall, over time, cause it to assume an abnormal shape.[6,7,13,33–36] These abnormal stresses within the foot will also predispose the foot to injury or disease. Increased stress or weight-bearing placed on a section of the hoof capsule may originate from a single source or from multiple contributing factors such as weight of the horse, abnormal limb conformation, strike pattern of the foot, amount of work, type of footing, and inappropriate farrier practices. The responses of the foot to stress and differing patterns of weight-bearing are threefold: change in position of the coronary band, change in hoof growth rate, and deviation(s) of the hoof wall.

Excess stress placed on a section of the hoof capsule can manifest itself in a variety of ways including compressed growth rings, flares or underrunning of the hoof wall, dorsal migration of the heels, and either focal or diffuse displacement of the coronary band.[34,36] As hoof capsule distortion of the forelimbs is commonly associated with lameness and various disease processes, only the forelimbs will be considered in this chapter. As the "normal" foot has not been defined, each view of the foot will begin with what is perceived to be an ideal, good, or healthy foot.[2,31,33–36,39] Palpation of the hoof capsule often complements the visual examination, and the areas where palpation is relevant will be included. The goal of evaluating the hoof capsule is to identify deformation and changes in the growth pattern that may indicate abnormal distribution of forces (stresses) on the foot. As hoof capsule distortion and abnormal loading usually accompany lameness, farriery will form part of or sometimes the entire treatment to reverse the process. Farriery is used to help redistribute the load and help improve or resolve the hoof capsule deformation.

The Mechanism of Distortion

Evaluation of the hoof capsule morphology will indicate where the hoof wall is unduly stressed; however, the evaluation has to be coupled with an understanding of the abnormal distribution of forces that lead to hoof capsule deformation. Understanding the biomechanical forces leading to hoof capsule distortions is also helpful for the clinician when applying the appropriate farriery to modify these stresses. There are many excellent reviews of basic biomechanics of the hoof in the veterinary literature.[6,7,13,33,35] Increased load or weight-bearing by a portion of the wall has three potential consequences: (1) deviation of the wall outward (flares) or inward (underrunning) from its normal position, (2) movement of the wall proximally, or (3) decreased hoof wall growth.[33–36] A reduction in load or weight-bearing on the foot generally has the opposite effect. Briefly, in the standing horse, the weight of the horse borne by the limb is supported by the ground, which opposes the weight with an equal and opposite force. The force exerted on the foot by the ground is termed the ground reaction force (GRF). The term center of pressure (CoP) is the point on the ground surface of the foot through which the GRF acts on the foot. The CoP varies among horses but is approximately located in the center of the solar surface of the foot in the standing horse.[6,7,13,33,35] However, when the horse is moving, the location of the CoP changes dynamically. The position of the CoP at any point in the stride determines the distribution of forces between the medial to lateral and the dorsal to palmar aspects of the foot. When the CoP is moved to one side of the foot, that side of the foot will be subject to increased forces. If the CoP is moved in a palmar direction, the weight-bearing or load on the palmar hoof wall will be increased.

Relating the CoP to hoof capsule distortions, if the CoP is located more medially, over time, a medial hoof wall flare (bending) and a lateral wall underrunning will develop. If the CoP is moved dorsally due to increased tension in the DDF tendon (DDFT), the hoof capsule will likely develop a higher heel with a flare in the dorsal hoof wall. Farriery is used to change the location of the CoP (to some extent) and change the distribution of forces on the ground surface of the foot. When evaluating hoof capsule deformation, limb conformation should be considered as abnormal limb conformation affects the landing pattern and stance phase of the stride. Few horses have ideal limb conformation, and any change in conformation is likely to change the distribution of forces within the hoof capsule leading to deformation.

Low-Heel Foot Conformation

The palmar section or heel area of the foot plays a critical role not only in soundness but also in the health and maintenance of the horse as a whole. It is subject to almost incomprehensible external and internal biomechanical forces, which inherently predispose the palmar foot to injury or disease.[2,19,20,22,31] However, the application of farriery for this section of the foot, whether routine, or for addressing abnormal conformation or prevention remains controversial. Long toe, low heel is the generality used to describe this foot conformation, but low heel accompanied by a long toe may be the preferred term. A low or underrun heel conformation is defined as the angle of the heels being considerably less than the angle of the dorsal hoof wall. When this difference is considerable, it is characterized by a broken-back HPA—the angle of the dorsal hoof wall being lower than the angle of the dorsal pastern. A common cause is not trimming the heels appropriately, which causes them to grow forward and lose their angle. The low-heel foot conformation is so common in equine practice, especially in Thoroughbred horses, that it is thought to be normal. In one study of foot-related lameness, low-heel conformation was found in 77% of the horses,[47,48] whereas in a different group of horses that where lame without evidence of navicular disease, 73% had underrun heels.[52] In another study of Thoroughbred racehorses, underrun heels were found in 52% of the horses.[14]

A low hoof angle results in dorsiflexion of the DIP joint, which concentrates weight-bearing on the palmar section of the foot and increases strain on the DDFT. The low-heel conformation changes the angle of insertion of the DDFT on the distal phalanx, which places increased stresses on the navicular apparatus.[8] When excessive toe length is present, the increased stresses in the palmar foot are potentiated at break-over. This abnormal hoof conformation also removes the foot's ability to absorb concussion and dissipate the energy of impact, thus

VetBooks.ir

contributing to all forms of palmar foot pain, chronic heel bruising, and DIP joint synovitis. There is also experimental evidence that a low hoof angle compromises circulation in the palmar section of the foot.[38,50]

The terms low heel and underrun heels or even collapsed heels are often use interchangeably; however, it may be helpful to distinguish between the two. In the case of a low heel, the angle of the heel is markedly lower than the angle of the dorsal hoof wall; however, the structure of the heel is relatively good in that the buttress, angle of the sole, tubular horn, and bars (termed the heel base) that comprise the heel structure are intact. With the underrun heel, the structure of the heel is compromised such that the hoof wall at the heel is thin, separated from the adjacent sole and rolls under the hoof in an axial direction, the angle of the sole is missing, the bars are compromised, and the heel–ground surface of the hoof wall does not reach the base of the frog.

As low or underrun heels progress, this condition can be readily observed both visually and radiographically, the point at which the angle of the solar border of the distal phalanx is lower palmarly than it is dorsally. A common error in routine farriery is not continually trimming the ground surface of the hoof wall at the heels to the base of the frog or not trimming the hoof wall at the heels to the same plane as the frog. This type of trimming is potentiated by applying a shoe that is too small. A negative angle of the solar border of the distal phalanx, as noted radiographically, indicates that the soft tissue structures (frog, digital cushion) in the palmar foot are underdeveloped or have decreased in mass, usually due to damage from overloading (Figure 11.32).[2,8,20,22,31] The compromised structures of the palmar section of the foot allow the palmar margins of the distal phalanx to descend distally. This type of hoof conformation alters the structural mass of the foot as the compromised heels lose the ability to accept weight and dissipate the energy of impact. Furthermore, it appears that sufficient soft tissue structures in the palmar section of the foot are necessary to act as a framework for the regrowth of any significant hoof wall in this area. Biomechanically, it changes the angle of insertion of the DDFT on the distal phalanx and increases the peak force on the navicular bone and navicular bursa.[8]

The farriery for low or underrun heels is difficult, and often the conformation of the heels can only be maintained rather than improved.[2,22,31] The traditional treatment for underrun heels is to use an egg-bar shoe, often accompanied by some form of heel elevation to raise the angle of the heels and correct the broken-back HPA that is associated with this condition. Traditionally, these shoes have been fitted long to help extend the heels with the idea that the increased ground surface of the shoe supports the palmar section of the foot and the egg bar supports the heels. However, it is questionable whether support can be applied to compromised structures (heels) that no longer have the structural mass or integrity to accept weight. The egg-bar shoe moves the GRF palmarly, but the length of the bar acts as a moment arm or lever on the heels, creating excessive pressure. The egg-bar shoe places the bulk of the weight-bearing on the soft tissue structures of the already compromised palmar foot, thus preventing further hoof wall growth at the coronet. Furthermore, the length of the bar creates a heel-first landing that when coupled with the leverage puts excessive pressure on the compromised heels.

Farriery for this condition should be directed at improving the heel structures when possible, utilizing all of the structures in the palmar foot to share the load and heel elevation when possible. Allowing the horse to remain barefoot for a period of time with controlled exercise can markedly improve the heel structures. This will eliminate the movement of the hoof wall against the heels of the shoe to friction against the ground and will

VetBooks.ir

load all of the structures in the palmar foot, both of which will tend to increase the ground surface of the hoof wall at the heels.[24]

Foot preparation for low heels begins by visualizing the two basic landmarks on the ground surface of the foot: the widest part of the foot and the base of the frog. The palmar section of the foot is trimmed using the widest part of the foot as a starting point; using a rasp the heels are then trimmed to healthy horn, making sure that all of the structures of the heel and the frog are on the same horizontal plane. The toe is shortened accordingly, again using the widest part of the foot as a guideline. With low-heel conformation, the frog is often situated distally below the level of the hoof wall at the heels. When a prolapsed frog is present, the shoe should be removed, any loose or exfoliating horn is trimmed from the frog, and the horse stood on a hard surface such as a rubber stall mat for 24–48 hours. An alternative to this is to fabricate a frog pad from a full wedge pad to place focal pressure on the frog, tape it on the foot, and stand the horse on a hard surface. This technique creates a level, flat surface in the palmar foot with all structures on the same plane. Having the structures, regardless of their integrity, on the same horizontal plane redistributes the weight creating a "load-sharing" effect.

The trim is complemented by a shoe that attempts to place the load over the entire palmar foot, not just on the hoof capsule at the heels (load sharing concept), and provides heel elevation to correct the HPA when possible. If the structures of the heel are intact and the hoof wall angle simply needs to be raised, an open aluminum wedge shoe or an open steel or aluminum flat shoe with a wedge pad can be used to achieve the desired heel angle. If the heels are damaged or compromised, a load-sharing effect can be accomplished by using a straight-bar shoe with a pad or degree pad placed between the shoe and the foot. A properly fitted heart-bar shoe is useful if the frog and digital cushion have sufficient structural mass to withstand the pressure from the frog plate. An open steel or aluminum shoe with a plastic or aluminum stability or "spider" plate riveted to the shoe, a thin heel plate welded or riveted between the branches of the shoe, or a plastic bar wedge attached to the shoe can be used to distribute the load. Holes are drilled in the heel plate or bar wedge, and some form of silastic material is placed underneath the plate or wedge to create a deformable interface to spread the weight-bearing function over all the structures in the palmar foot. The holes drilled in the plate or pad are necessary to keep the impression material in place. Impression material is placed on the ground surface of the entire foot, in the case of the spider plate or starting in the middle of the frog and extending palmarly as far as desired with the others. The shoe and plate or pad are placed on the foot, and the heel of the shoe is pressed gently into the impression material, forming a slight wedge. Two nails are placed in the toe of the shoe, and the foot is held off the ground until the impression material cures in the desired position (Figure 11.33). Glue-on technology may be helpful to improve the structures in the heel but should not be applied long term because damage to the hoof wall is thought to occur from the heat generated by the composite.[53]

Farriery for low-heel conformation is often based on trial and error and combinations of various methods but depends on assessing the integrity of the structures present, the footing, and the athletic pursuit of the horse. Any form of heel elevation should be accompanied by

VetBooks.ir

enhancing break-over to remove any leverage at the toe. Moving break-over palmarly can be accomplished in a variety of ways such as rolling or rockering the toe of the shoe or creating a rolled toe in the shoe using a hand grinder where the break-over begins at the inner branch of the shoe and extends dorsally in a tapered fashion. Moving break-over palmarly/plantarly decreases the moment applied to the DIP joint and appears to decrease the maximum tension in the DDFT, which occurs toward the end of the stance phase at the beginning of break-over.

Club Foot

A club foot has a high hoof angle associated with a flexural deformity of the DIP joint, while an upright foot will have a high hoof angle but has a straight HPA. A club foot is characterized by a broken-forward HPA, which occurs when the angle of the dorsal hoof wall is greater than the angle of the dorsal pastern (Figure 11.34).[12,26,29] This broken-forward HPA or flexural deformity is created by some degree of shortening of the musculotendinous unit (DDFT and associated muscle bellies), causing the DIP joint to be drawn into a flexed position.

Flexural deformities have been reported as a cause of decreased athletic performance, a shortened stride length, and chronic low-grade lameness in the mature horse.[29,48,53] A shortening of the musculotendinous unit causes more hoof wall growth at the heel (compensating for the shortened muscle tendon unit) than at the toe, and the frog generally recedes below the ground surface of the hoof wall due to the excessive heel height. The energy of impact is now assumed by the hoof wall, bypassing the soft tissue structures in the heel area and transferring the load directly onto the bones of the digit through the laminar interface. Hoof abnormalities associated with a club foot conformation are thin flat soles, poor dorsal hoof wall consistency, toe cracks, hoof wall separations, and white line disease (WLD). A club foot promotes toe-first landing, a decreased cranial phase of the stride, and increases weight-bearing in the dorsal aspect of the foot. Poor performance and injuries associated with a high hoof angle are thought to include DIP joint inflammation due to abnormal position/loading of the joint, sole bruising, and increased strain on the suspensory ligaments of the navicular bone.

High hoof angles with no or mild phalangeal misalignment can generally be improved by gradually lowering the heels in a tapered fashion from the apex of the frog to the heels. Shortening the intervals between trimmings is helpful as it will minimize excessive heel growth. This increases the ground surface of the foot and attempts to reestablish weight-bearing on the entire solar surface of the foot. Break-over is moved palmarly at the same time to compensate for any increased tension in the DDFT created by lowering the heels.

Farriery for a club foot or high hoof angle with concurrent phalangeal misalignment is a greater challenge. Flexural deformities are usually diagnosed and treated while the horse is immature, although mild flexural deformities are often ignored or treated improperly in foals. When these animals enter training, mild flexural deformities can be exacerbated by chronic foot bruising, the type and the amount of exercise, ground surface, inappropriate farrier care such as improper or infrequent shoeing, or some type of underlying pathology.[29] The objective of farriery is to load the palmar section of the foot, compensate for the shortening of the DDFT, and improve the HPA when possible. Therefore, farriery is directed at trimming the heels, but the amount to remove can be difficult to determine. In mild to moderate club feet, the amount of heel to be removed can be estimated by placing the thick end of a 2° or 3° wedge pad under the toe of the foot and allowing the horse to stand on it. If the horse does not resent the tension placed on the DDFT, the heels can be trimmed the thickness of the wedge pad in a tapered fashion starting at the widest part of the foot. The toe is shortened by decreasing the length and removing the concavity from the dorsal hoof wall with a rasp. The

VetBooks.ir

trimmed foot is fitted with a shoe that extends 1–2 cm beyond the end of the heel and has the break-over forged or ground into the shoe starting just dorsal to the apex of the frog and tapering toward the toe to further decrease the stresses on the DDFT.

With a more advanced club foot, the heels should still be trimmed to load the heels and unload the toe, but heel elevation must be added to compensate for the shortening of the musculotendinous unit of the DDFT. This can be determined after the trim by placing the trimmed foot palmar to the contralateral limb to observe whether there is a space between the heels of the foot and the ground. If a space is noted, the author uses a wedge shoe or attaches a wedge pad or a bar wedge to the shoe in order to load the palmar section of the foot and to compensate for the shortening of the musculotendinous unit (Figure 11.35). This method allows the heel area to be weight-bearing but at the same time decreases the stresses in the DDF muscle tendon unit. Break-over is applied as described above.

Severe flexural deformities that result in chronic lameness can be treated by performing a desmotomy of the accessory ligament of the DDFT combined with the appropriate farriery.[29,46] See "flexural deformities" in Chapter 10 for further information regarding this procedure.

Sheared Heels

Sheared heels are a hoof capsule distortion resulting from displacement of one heel bulb proximally relative to the adjacent heel bulb (Figure 11.36).[18,19,22,30] This disparity between the lateral and medial heel bulb is generally 0.5 cm or greater. Sheared heels appear to develop as an adaption/distortion of the hoof capsule as a consequence

Figure 11.35. The foot can be placed palmar to the contralateral foot to observe whether there is a space between the heels and the ground, which corresponds to shortening of the DDFT muscle tendon unit (A). Heel elevation applied to a club foot after trimming (B).

Note the disparity between the length of the two heels and the deformation of the structures on the medial side of the foot (red arrow). (B) DP radiograph of a horse with sheared heels. Note the disparity in the height of the coronary bands (red arrows), yet the plane of the distal phalanx remains parallel with the ground.

VetBooks.ir

of limb conformation that results in an abnormal strike and loading pattern of the foot on the ground.[30] When the weight of the horse is not distributed uniformly over the entire hoof during the landing and stance phase of the stride, one focal area of the foot, usually a heel or heel and accompanying quarter, receives a disproportionate amount of the total load during impact and displaces proximally. Although a number of sound horses have this type of hoof capsule distortion, the author believes that when the adaptive ability of the hoof capsule is surpassed by the excessive load on one section of the foot, this type of hoof conformation can be the sole source of unilateral palmar foot pain. This pain could originate from the compression of the soft tissue located between the middle phalanx and the hoof wall when the heel is displaced proximally. The continual disproportionate loading and increased compressive stresses on one quarter/heel predispose the foot to subsolar bruising, corns, quarter/heel cracks, fracture of the bar, and a deep fissure within the base of the frog that is susceptible to thrush (Figure 11.36). This type of foot conformation is readily observed by picking up the foot and noting the relative disparity in distances from the heel of the hoof capsule to the hairline at the bulbs of the heels between the lateral and medial heel (Figures 11.36 and 11.37).

The etiology of this condition is not completely understood. Inappropriate lateral to medial orientation (balance) of the foot where the foot does not land flat has always been implicated, but this has not been substantiated. A correlation with rotational limb deformity (lateral) that changes the flight pattern of the limb and ultimately the manner in which the foot lands has also been suggested.[2,29] Furthermore, there appears to be a correlation between an offset distal phalanx within the hoof capsule and sheared heels. Commonly, the distal phalanx is offset laterally within the hoof capsule, which places additional load on the medial side of the foot, causing the medial heel to displace. The unequal distribution of vertical forces on a given side of the foot over time appears to result in a biological remodeling rather than the heel being pushed proximally or "jammed" to use the common farrier term (i.e. the heel is "growing out of shape rather than being pushed out of shape").[4,5,22,23,30].

Figure 11.37. Sheared heel with a fissure through the base of the frog (yellow arrow). Note the opposite direction of forces applied to the walls during landing (red arrows).

Biomechanically, the position of the coronary band is related to a balance between hoof wall growth at the coronary band and the rate of migration of the hoof wall distally. Furthermore, the rate of migration of the hoof wall is also a balance between an active process occurring in the lamellae to cause them to move distally and the force on the wall from the GRF. This appears to be the mechanism of displacement in horses with sheared heels/quarters (Denoix and Parks. Personal Communication, 2012). Proximal displacement of the soft tissue structures occurs palmar to the distal phalanx and appears to result from mechanical stress. To substantiate this statement, the author reviewed 50 DP radiographs on horses' feet with at least one heel bulb that was displaced proximally 0.5 cm or greater. In each case, the solar surface of the distal phalanx was basically horizontal (parallel) with the ground, indicating the disparity in heel height did not originate from the lamellae within the hoof wall located adjacent to the distal phalanx (Figure 11.36).[4,5]

Farriery is directed toward unloading the hoof wall and decreasing the forces on the displaced side of the foot. This is accomplished by improving the shape of the hoof capsule and landing pattern by applying the appropriate shoe. Intuitively, if the heel is longer on the displaced side (measured ground surface to hairline), it is reasonable to trim the displaced side and create additional ground surface under the affected side.

Again, when possible, the author will remove the shoes and trim the heels of the palmar foot such that the hoof wall and frog are on the same plane. The horse can be left without shoes for 24–48 hours or longer if necessary. Leaving the horse barefoot for a brief period allows the displaced heel to descend, the compressed area between the coronet and middle phalanx will widen, and the palmar section of the foot will assume a more relaxed position.

With the heels in a more acceptable position, the author uses a double trim method to address sheared heels in an attempt to improve and unload the displaced quarter/heel. The foot is trimmed appropriately using the guidelines of a parallel HPA, the COR, and the heels trimmed to the base of the frog.[22,23] If the displacement of the heel is significant, a wide-web steel or aluminum straight-bar shoe is fitted as symmetrically as possible underneath the long axis of the limb using the apex of the frog as a central marker.[4,5] The bar shoe effectively increases the surface area of the foot, provides more expansion (ground surface) on the displaced side that has a straighter wall, and decreases the vertical movement of the heel bulbs. Before applying the shoe, a second trim is performed under the proximally displaced quarter heel, which goes from 0 mm at the ipsilateral toe quarter (e.g. inside toe quarter for medial sheared heel) to an average of 7 mm at the affected heel. The amount of heel that can be removed with the second trim depends on the sole depth at the seat of corn and on the severity of the proximal displacement of the coronary band at the sheared heel.

VetBooks.ir

This amount of heel ideally corresponds to the difference in length/height between the two heels. Lowering the hoof wall at the quarter/heel will create a wedge-shaped space between the shoe and the hoof wall on the displaced side of the hoof, permitting the displaced heel to descend distally and settle into a more acceptable configuration. No nails should be placed in the shoe palmar to the origin of the second trim as this would inhibit the displaced section of wall from descending distally. This type of selective trimming combined with a straight-bar shoe effectively unloads the section of the heel/quarter that is being displaced and decreases the disproportionate forces on the foot (Figure 11.38). In less severe cases, an open steel or aluminum shoe can be used instead of a bar shoe adhering to the principles of trimming described above.

Mismatched Feet

The management of mismatched hoof angles remains a controversial subject for both the farrier and veterinarian. Mismatched feet are usually defined as forefeet conformation that have a high or upright hoof angle on one foot and a low hoof capsule angle on the contralateral foot (Figure 11.39).[13,35,36] The difference between the forefeet conformation of mismatched feet is variable in severity and can range from a high hoof angle with a straight HPA or a club foot with a flexural deformity in one foot to an overloaded low heel on the contralateral limb. The mass, integrity, and difference in heel height is usually the main contributing factor in creating the mismatched dorsal hoof angles (Figure 11.40). Limb length disparity has been suggested as a cause for mismatched feet although it has not been substantiated. Mismatched feet may contribute to poor performance, subtle lameness, and a shortened cranial phase of the stride. Traditional farriery seeks to elevate the heel on the low foot and therefore match the hoof angles of the forefeet. However, this practice should be discouraged, and treatment should be based on farriery principles to improve the structures and function of the individual foot.

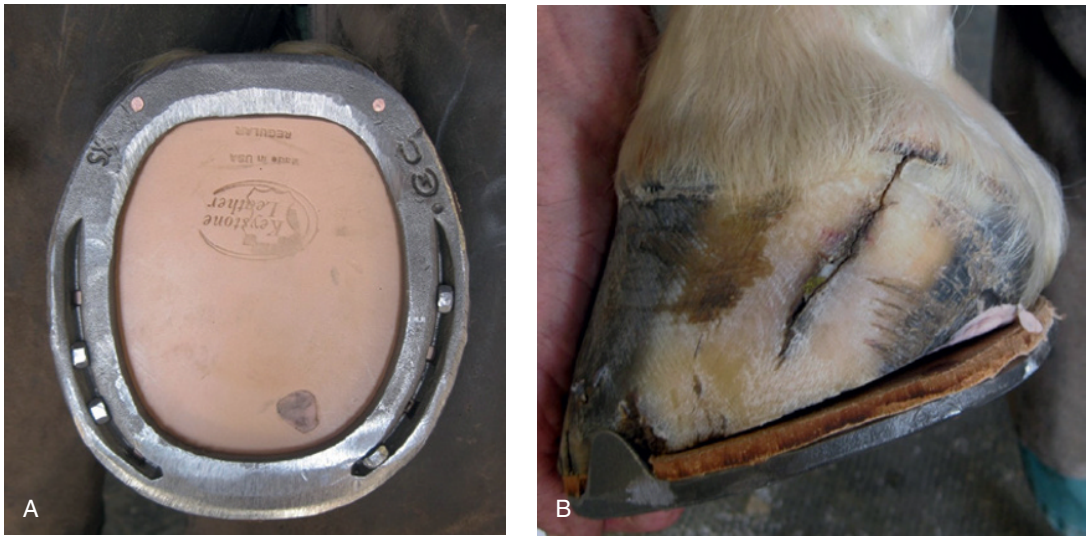

Figure 11.38. Straight-bar shoe used to stabilize the hoof capsule and decrease the vertical movement of the heels (A) shoe with the medial heel unloaded (B). Note the quarter crack, which is often present with a sheared heel.

Figure 11.39. A pair of mismatched forefeet. Note the different hoof angles (A, B) and the mild broken-forward hoof-pastern axis on the upright foot on the left (A).

VetBooks.ir

Horses with a disparity between dorsal hoof wall angles will generally have a straight HPA, and the hoof wall growth below the coronet from the toe to the heel will be uniform. In this case, the author suggests using good farriery principles to apply the appropriate trim and shoe each foot on an individual basis. Managing horses with mismatched feet where one foot has a markedly high hoof angle or a club foot becomes more complex, and the reader should refer to the previous section on the club foot. Horses with mismatched feet will present with a shortened cranial phase of the stride on the limb with the upright foot often coupled with a discernible lameness. Low or compromised heel structures may be noted on the opposite foot from overloading the heel secondary to excess weight on the contralateral foot over time. Managing these horses can be difficult, and the proper shoeing protocol may not be inherently obvious. It is common to see horses with mismatched feet shod with two different size shoes; often a smaller shoe is used on the upright foot with the misguided thought that the shoe will not be pulled. This practice should be discouraged as the ground surface on both forefeet should be the same.

Figure 11.40. A pair of mismatched feet shows the difference in the structural mass in the palmar section of the foot, which is primarily responsible for the difference in toe angle.

One of the objectives of trimming the upright or club foot is to redistribute the load to the palmar aspect of the foot to restore functionality and increase stride length. When approaching the foot with the low angle, the clinician is often inclined to wedge up the heels to improve the HPA and match the other foot. However, this will place additional stress on the already compromised heel structures. Although the HPA will appear improved immediately following the shoeing, the long-term effect is exacerbation of the low angle, further crushing of the heels, and prolapse of the frog below the ground surface of the foot. The heels should be trimmed back to the widest point of the frog if possible, and the toe length should be reduced as described in the section on long-toe, low-heel conformation. It is extremely important to obtain good-quality radiographs of the foot prior to trimming to determine the amount of heel and especially sole that can be removed. The CoP on a low angle foot is further palmar than that of the upright hoof, and therefore the shoeing protocol is directed at moving the CoP away from the overloaded heels. Additionally, redistributing the load or load sharing with the weight-bearing structures of the low angle foot may help decrease the forces directed to the heels. This can be accomplished with impression material, a pour-in pad, and a spider plate or a heel plate added to the palmar aspect of the shoe (Figure 11.41).

Figure 11.41. Mismatched feet showing a spider plate and impression material on the foot with the low heel (A) and a 2° wedge insert on the other foot with the high heel (B).

CLINICAL CONDITIONS AFFECTING THE HOOF

Hoof Wall Defects

Hoof wall defects constitute structural damage to the hoof capsule and can range from superficial to full thickness. The defect can be vertical or parallel to the horn tubules or horizontal, which is perpendicular to the horn tubules of the hoof wall. Defects or cracks can be classified according to their location in the hoof capsule, such as toe cracks, quarter cracks, and heel cracks, and also according to their depth within the hoof capsule (i.e. full vs. partial thickness).

A horizontal hoof wall crack originates at the coronet as a disruption of the coronary corium and moves distally as the hoof wall grows. The disruption of the coronary corium is caused by a rupture at this site usually from an abscess or infection traveling proximally from the solar surface of the foot to the coronary band. Direct trauma to a section of the coronet can also occur contributing to a horizontal crack. Once the coronet is healed, horizontal cracks do not generally enlarge, and they grow out uneventfully. Vertical hoof wall cracks can either originate at the ground surface and extend proximally or begin at the coronet and extend distally. Contributing factors include direct hoof wall trauma or overloading and hoof capsule distortions.

Quarter Cracks

Quarter cracks are the most common hoof wall defect encountered and often cause foot lameness and/or decreased athletic performance in racehorses and sport horses. A true quarter crack is a full-thickness defect (extends into the dermis) that originates at the coronary band and travels distally, causing hemorrhage, instability, inflammation, and/or infection. Quarter cracks often bleed as a result of the invasion and movement within the dermis (Figure 11.42). Causes of quarter cracks may include trauma to the coronary band, preexisting damage to the corium from previous cracks or infection, abnormal hoof conformation, short shoes, or an abnormal landing pattern when the foot strikes the ground asymmetrically. Any one of these causes may place continuous excessive stress or pressure on a focal area of the proximal hoof wall. Quarter cracks result when excessive forces placed on a section of the hoof wall exceed the hoof capsule's ability to deform and accept additional load (Figure 11.38). Various techniques for stabilizing and repairing quarter cracks have been described; however, in the author's opinion, the most important aspect is to determine and correct the cause of the hoof wall defect.

Farriery

The author prefers, when possible, to remove the animal from work and apply the necessary farriery to address the hoof capsule distortion, rather than to repair the crack initially. If the appropriate farriery is applied, there can be substantial solid hoof wall growth proximal to the defect at the next reset in 4–5 weeks, indicating the abnormal forces or stresses in the wall with the defect have been reduced. Obviously, this approach is not an option in performance horses that must continue to compete.

Abnormal hoof conformation and any inappropriate farriery should be evaluated and corrected. Short shoes leave insufficient ground surface under the heels and put the weight-bearing surface in front of the vertical axis of the limb. In such instances, a vertical line drawn from the origin of the quarter crack invariably coincides with the end of the shoe (Figure 11.42B). Abnormal foot landing patterns are often contributory as many horses contact the ground asymmetrically, landing first on one side of the hoof and then impacting on the opposite side. This strike pattern is generally related to a rotated limb conformation and can result in the sheared heel foot conformation. In fact, it is extremely rare to see a horse with a full-thickness quarter crack that is not accompanied by a sheared heel. The foot should be trimmed and shod with the affected quarter below the crack unloaded in the same manner as described previously for a sheared heel. Any horse with a full-thickness quarter crack should be placed in a bar shoe until the crack has grown at least halfway down the hoof wall. Various configurations of bar shoes such as a straight bar, egg bar, or heart bar can be used. All of these shoes effectively increase

Figure 11.42. (A) Acute quarter crack with hemorrhage. Note the tightly packed growth rings distal to the coronet as a result of chronic overload. (B) Chronic quarter crack. The origin of crack coincides with the end of shoe that is too small (arrow), and the coronet is displaced proximally.

VetBooks.ir

the ground surface of the foot on the affected side, provide palmar support, and decrease the independent vertical movement at the bulbs of the heels.

The Repair

If the horse must continue in work, a repair should be performed along with the appropriate farriery. The objective of the repair is to stabilize the crack distal to the coronet and promote healing. If a full-thickness crack is present, just placing a composite over the defect generally does not provide stability; an implant should be used and then covered with a composite patch. Infection at the origin of the quarter crack is characterized by marked lameness, pain when pressure is applied to the defect, and a swollen, discolored coronary band above the defect. Occasionally, exudate can be expressed when digital pressure is applied to the coronet. If infection is present, the crack should be opened and bandaged with a suitable disinfectant agent for at least 48 hours before the repair. If the crack needs to be stabilized at the same time the farriery is performed, the clinician should wait at least 24 hours before repairing the defect to permit the coronet to descend distally to a more suitable position. Repairing the defect with the coronet displaced proximally will compress the horn tubules necessary to produce solid horn above the defect.

A very easy and consistent repair technique will be described.[23,30] Before starting the repair, the hoof wall surrounding the defect should be thoroughly cleaned and dried. The entire length of the defect is explored using a Dremel® tool with a tungsten carbide bit, being careful not to create any unnecessary hemorrhage. All loose undermined horn should be removed, the defect is widened, and the burr is used to create a solid ledge on either side of the trough. The hoof surface on either side of the defect should be sanded with a coarse sanding block.

Two sets of paired 3/64th-inch holes, one-quarter inch apart, are then drilled across from either side of the crack beginning at least 3/8 to 1/2 inch from the margin of the crack and ending within the ledge of the trough. Stainless steel 21-gauge wire is formed into a "hairpin" shape 2.5 inches long with a small steel tab on the closed end of each wire unit. One wire unit is passed through the holes from a palmar to dorsal direction, and another wire unit is passed through the opposing holes in a dorsal to palmar direction into the depth of the crack. The ends of the wires are pulled tight and bent outward. The steel tab placed on the wire unit will now lie against the outer hoof wall. Additional sets of wire units can be used depending on the length of the defect or until the desired stabilization is achieved. Medicated hoof putty or some type of drain is placed in the trough, and the ends of the opposing wires are joined together and twisted until resistance is felt (Figure 11.43). The excess wire in front of the twist is cut off within the defect. The implant is then covered with an acrylic composite combined with fiberglass strands to form a patch.

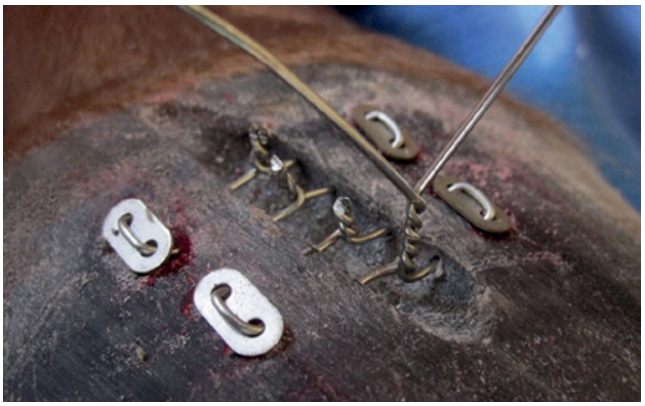

Figure 11.43. Placement of wires for a quarter crack repair.

Toe Cracks

Full-thickness toe cracks occur in the dorsal hoof wall extending from the coronet distally but rarely reach the ground surface. The defect is usually movable, opening when load is removed from the foot and closing when load is applied. The defect is usually associated with excessive length of the dorsal hoof wall with marked concavity, which can be seen with either a long-toe or club foot conformation. Farriery is directed toward correcting or improving hoof conformation if possible, decreasing the length of the toe, and shifting the weight-bearing function palmarly in an attempt to unload the toe.

Unloading the toe can be accomplished by beginning the trim at the apex of the frog and trimming palmarly in a tapered manner until the hoof wall at the heels and the frog are on the same plane. This creates two planes on the ground surface of the foot, so when a shoe is placed on the foot, there will be a space created between the hoof and the shoe at the toe. Farriers refer to this as "floating" the toe. Excess toe length with the concavity is removed from the dorsal surface of the hoof wall. The appropriate size shoe, fitted palmar to the perimeter of the dorsal hoof wall, is then applied. As this condition is often seen with a club foot conformation, if the heels are trimmed to improve the foot conformation, heel elevation may need to be included to compensate for the shortened muscle tendon unit of the DDFT. Moving the break-over palmarly in the toe of the shoe will further decrease stresses in the dorsal hoof wall. The trim and application of a shoe in a manner that unloads the toe are often sufficient to stop the movement of the defect and promote healing. If further stabilization is needed, a metal or brass band can be fabricated and attached to the dorsal hoof wall with screws (Figure 11.44). The band should match the contour of the coronet and be placed at equal distances on either side of the defect. The band should always be attached to the dorsal hoof wall with the foot in the unloaded position with the crack open so the horn papillae at the origin of the defect are not compressed, which allows them to produce solid horn.

Heel Cracks

Heel cracks are generally associated with poor palmar foot conformation secondary to lack of foot mass such as low or underrun heels.[15,31] This type of foot does not have sufficient ground surface under the heels to accept weight. This type of crack is not as common as a toe or quarter crack, but can be difficult to treat. Some type of bar shoe with or without a "spider" plate

VetBooks.ir

Figure 11.44. Brass band attached to dorsal hoof wall to stabilize a toe crack. Note that the contour of the band matches the coronet. Also note that the defect does not extend distally to the ground surface of the foot.

is recommended to increase the ground surface in the palmar foot, redistribute the weight-bearing on the solar surface, and unload the affected heel. The horn in this section of the foot is generally too thin to accept an implant, and therefore the hoof wall palmar to the defect is either removed or the heel can be rebuilt using an appropriate composite material.

White Line Disease

WLD is a keratolytic process that originates on the solar surface of the hoof and is characterized by a progressive separation of the inner zone of the hoof wall.[15,17,21] The separation occurs in the nonpigmented horn at the junction between the stratum medium and stratum internum. A separation in the hoof wall is considered to be a delaminating process potentially brought on from mechanical stress, inappropriate farriery, environmental conditions affecting the inner hoof wall attachment, and possibly some toxicity such as selenium.[15] The separation, which can originate at the toe, the quarter, and/or the heel, appears to be invaded by opportunistic bacteria/fungi leading to infection that can progress to varying heights and configurations proximally toward the coronet. Interestingly, WLD does not invade the coronet, and the disease process nearly always occurs secondary to hoof wall separation.

Etiology

WLD can affect a horse of any age, sex, or breed. One or multiple hoofs may be involved and the affected hooves can be barefoot or shod. One or multiple horses on the same farm may be affected and the problem occurs worldwide. Multiple causes of WLD have been proposed, but none have been proven. Causes include excessive moisture or dryness that initiate and perpetuate separations or allow pathogens to invade the white line area, poor hygiene, and infectious organisms (bacteria, fungi, or a combination of these organisms). The fact that WLD can be resolved with debridement alone further detracts from infection as a primary cause. Mechanical stresses placed on the inner hoof wall that lead to a separation appear to be the most logical cause, although it does not explain why only certain horses are affected. These mechanical stresses may include excessive toe length and various hoof capsule distortions such as long-toe/underrun heel, club foot, or sheared heels.

Clinical Signs and Diagnosis

WLD presents no threat to the soundness of a horse until damage is sufficient to allow mechanical loss of the attachment between the external lamellae and the inner hoof wall (stratum medium), resulting in displacement of the distal phalanx in a distal direction (rotation and/or sinking). In the early stages of WLD, the only noticeable change on the solar surface of the foot is a small separation containing powdery material located at the inner part of the hoof wall adjacent to the sole–wall junction (white line). This area may remain localized or it may progress proximally to form a larger separation in the hoof wall. As the separation becomes more extensive and extends into a quarter, a concavity (dish) can be seen forming along one side of the hoof, and a bulge is present on the opposite side directly above the affected area at the coronary band (Figure 11.45). The distal phalanx is stabilized or held in place within the hoof capsule by the

Figure 11.45. Extensive separation under lateral hoof wall causing a shift of the distal phalanx in the hoof capsule. Note the concavity in the medial wall, bulging of the lateral wall, and the soft tissue enlargement above the coronet on the lateral side.

VetBooks.ir

lamellae; therefore, any significant loss of epidermal lamellae on the side with the separation allows the distal phalanx to shift toward the side with the separation. Other clinical signs may be evident including slow hoof wall growth dorsal to the separation, poor consistency of hoof wall, and a hollow sound noted when the outer hoof wall over the separation is tapped with a hammer.[17,21] Unfortunately, the disease often goes undetected until the horse begins to show discomfort.

Radiography can be very informative and should be considered necessary if WLD is advanced and causing lameness. Good-quality radiographs can show the extent of the hoof wall separation and whether rotation of the distal phalanx within the hoof capsule has occurred. Radiography is helpful to differentiate between WLD and laminitis and can also be used as a guide when trimming and shoeing the horse.

Farriery

Correction of any hoof capsule distortion that may have contributed to the hoof wall separation is essential in the management of WLD. Treatment for WLD is directed toward protecting and unloading the damaged section of the foot with therapeutic farriery combined with resection of the hoof capsule overlying the affected area(s). Resection disrupts the continuity and weight-bearing strength of the hoof wall; therefore, some type of shoe or device should be applied to stabilize the hoof wall and transfer the weight-bearing to a non-affected section of the foot. If the separated area of the foot is determined to be extensive, it is important to plan the method of support, the design of the shoe, and method of attachment prior to the outer hoof wall being resected.

The type of shoe used and the method of support depend on the extent of the damaged hoof wall to be removed. As the toe is involved in most cases of WLD, it is helpful to move the break-over in a palmar/plantar direction. The ground surface of the foot is trimmed from the apex of the frog palmarly, thus creating two planes on the bottom of the foot, which effectively unloads the toe. The shoe is fitted, so break-over is just dorsal to the distal phalanx in an attempt to unload the dorsal hoof wall and remove any leverage at the toe. Unloading the hoof wall distal to the resection is essential to remove the stresses from the inner hoof wall and promote good growth. This also minimizes pain by preventing the "pinching" effect at break-over that often occurs at the junction of normal hoof wall and the proximal aspect of the resection.

If the resection is extensive and/or if rotation of the distal phalanx is present, some type of support shoe or a wooden shoe should be used to stabilize the foot.[25] An alternative method is to use a bar shoe or open shoe and pad combined with some type of silastic material to redistribute the weight on the foot (Equilox International, Inc., Pine Island, MN). If necessary, attaching glue-on shoes to the ground surface of the foot is another useful option for shoeing the horse with WLD.[28] However, acrylic repair of the defect following the resection is not recommended and should only be considered after all tracts are resolved.[15,17,21,37] The composite hides and/or fosters the organisms under the repair, and the composite may weaken the surrounding normal hoof wall. Commitment from the owner to institute environmental changes and continue the treatment schedule for WLD as the hoof wall grows down is essential for success.

Figure 11.46. Dorsal hoof wall resection. Note the solid margins around the periphery of the resection.

Complete hoof wall resection (removal of outer hoof wall to expose diseased area) and debridement of all tracts and fissures in the affected area are often necessary. The debridement should be continued proximally and marginally until there is a solid attachment between the hoof wall and external lamellae (Figure 11.46). The veterinarian or farrier should not reach blood during debridement.

Treatment with topical disinfectants and medications following hoof wall resection has been described and remains controversial.[17,21,37] None of the topical preparations being used to treat WLD have any proven efficacy. Various antiseptics and astringents such as merthiolate or 2% iodine may be helpful not only as a drying agent but as a dye marker to outline the remaining tracts that should be removed in subsequent debridement. After thorough hoof wall resection, the affected area is left to grow out with debridement performed at frequent intervals. A wire brush can be an effective method for owners to keep the resected area clean daily. The clinician should explore and debride any remaining tracts at 2-week intervals. When all tracts are resolved and grown out, a continued examination is indicated at routine re-shoeing intervals every 4–5 weeks to prevent recurrence.

Equine Canker

Equine canker is described as an infectious process that results in the development of a chronic hypertrophy of the horn-producing tissues.[16,27,41] It generally originates in the frog and may remain focal but has the capacity to become diffuse and invade the adjacent sole, bars, and hoof wall. Canker can occur in one or multiple feet. The disease was initially described in draft breeds but can commonly affect any breed or sex. The etiology remains elusive, but wet environmental or moist, unhygienic conditions have traditionally been thought to act as a stimulus. However, canker is commonly seen in horses that are well cared for and in horses that receive regular hoof care.

Clinical Signs and Diagnosis

Canker generally originates in the frog and can be mistaken for thrush in the early stages. Thrush is limited

VetBooks.ir

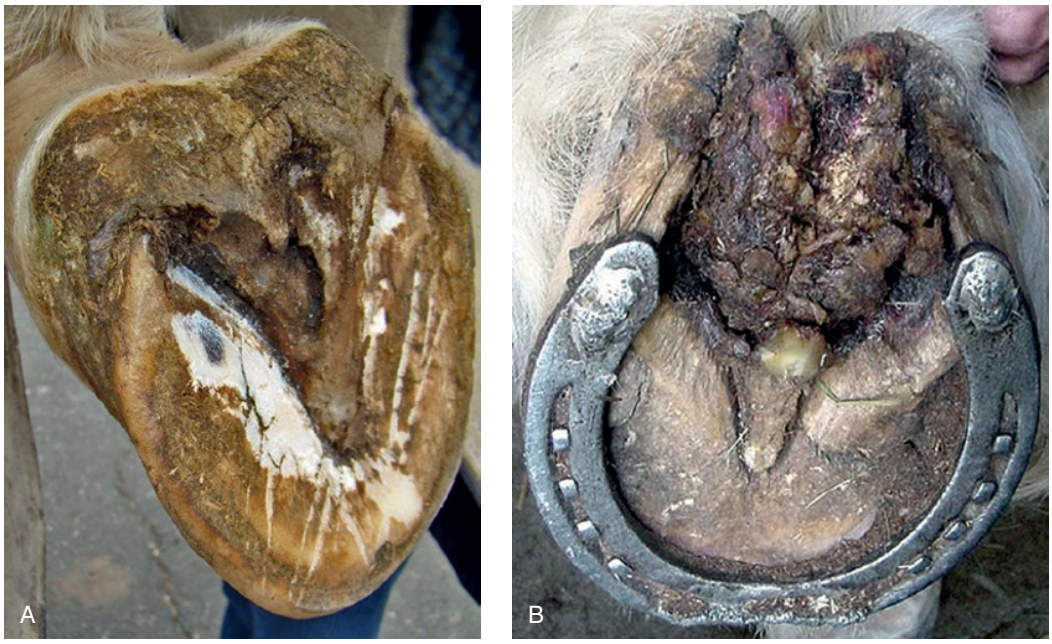

Figure 11.47. (A) Thrush. Note the deterioration of the frog that is recessed below ground surface of foot. (B) Severe canker. Note the proliferation of the diseased horn.

to the body or the base of the frog if a fissure is present, whereas canker invades the horn of the frog anywhere throughout its structure. There is often a proliferation of tissue with canker vs. a loss of tissue with thrush (Figure 11.47). In the early stages, canker may present as a focal area of granulation tissue in the frog that bleeds easily when abraded. Canker is characterized by numerous small fingerlike papillae of soft off-white material that resembles a cauliflower-like appearance.[27,41] The condition is frequently but not always accompanied by a foul odor and is usually covered with a caseous white exudate that resembles cottage cheese.

A presumptive diagnosis of canker is based on the gross appearance of the affected horny tissue along with a fetid odor; however, a definitive diagnosis may be confirmed with a biopsy. Histologically, the lesion is usually interpreted as a chronic hypertrophic moist pododermatitis of the frog.[51] Cultures per se are unrewarding as they typically produce an assortment of environmental organisms such as *Bacteroides* sp. and *Fusobacterium necrophorum*, the usual opportunistic bacteria found in the solar surface of the horse's foot.

Treatment and Prognosis

Historically, horses with canker have had a guarded prognosis. More recently, consistently successful treatments have been described.[27,32,41] Treatment consists of thorough, careful debridement of the affected tissue followed by a regimen of topical therapy applied daily that is continued until the disease has resolved. Recently, the use of corticosteroids during the treatment phase has improved the results. An important aspect that is often overlooked at the onset of treatment is to trim the foot appropriately prior to surgery. All loose exfoliating sole should be removed from the solar surface of the foot. The bars and sole of the hoof capsule adjacent to the frog are explored to be sure the horn in this area is not involved; all underrun or loose horn is removed down to solid structures. The heels are trimmed such that the hoof wall at the heels and the frog are on the same plane or approach the same plane. The frog should not be recessed between the heels of the hoof wall at the beginning of treatment or the affected tissue will not heal.

The debridement of the cankerous tissue can be performed standing under local anesthesia or under general anesthesia if considered necessary. The use of a tourniquet is important to create a bloodless field to better delineate the demarcation between normal and diseased tissue. All abnormal tissue should be removed until the tissue resembles a pink velvet color with numerous pinpoint hemorrhages that corresponds to the dermal papilla. Debridement should be careful, gentle, thorough, and wide rather than aggressive, deep, and radical. Unnecessary removal of the dermal tissue under the lesion should be avoided as this tissue is necessary for regrowth of healthy horn and cornification. Cryotherapy of the debrided area is then recommended to remove residual bacteria from the surface in a double freeze–thaw pattern.

In large defects where the debrided tissue is recessed below the ground surface of the hoof wall, impression material should be used to form an insert over the surgical site in the bottom of the foot. It should extend to the plane of the ground surface of the foot but not above the surface to avoid excessive pressure and discomfort. The impression material ensures contact of the medication against the tissue in the depths of the wound, exerts mild pressure to minimize the production of exuberant granulation tissue, and helps promote physiologic function of the frog.

There are a variety of topical preparations that can be used following debridement, but the astringents (drying agents) appear to play the most important role. Gauze

VetBooks.ir

sponges moistened in a solution of 10% benzoyl peroxide in acetone and sprinkled with metronidazole powder are used by the author. Other topical products that may be equally effective include a solution of tricide/gentocin/lincomycin or an oxytetracycline/metronidazole paste. No caustic preparations should be used on the debrided site as they will burn or damage the dermal tissue that is necessary to restore healthy horn and cornify.

The use of systemic antibiotics such as chloramphenicol or oxytetracycline has been advocated, but the author questions this practice as the majority of cases resolve with local treatment only. All horses should be treated orally with systemic prednisolone at a dose of 1 mg/kg q24h for 7 days, 0.5 mg/kg q24h for 7 days, and then 0.25 mg/kg q24h for 7 days.[32] The author uses this approach as an adjunct to the local treatment discussed above and has found it to be beneficial.

Aftercare performed by the owner daily or at least every second day is extremely important for success. The foot should be cleaned vigorously using a gauze pad soaked with a suitable antiseptic solution, any suspected area of disease is debrided with a dry gauze pad, the foot is rinsed with saline, topical treatment is reapplied, and the foot is rebandaged. The foot should remain bandaged until the affected area has cornified. A shoe with a treatment plate has become popular with canker cases, but the author feels it is contraindicated as it neither keeps the foot as clean or dry as necessary post-debridement. Once the surface has a complete layer of thin cornification, a treatment plate can be used if desired. A commitment from the owners is necessary for success, because aftercare takes several weeks, depending on the stage of the disease, until the affected tissue becomes cornified.

Thrush

Thrush is a degenerative condition that affects the body and base of the frog generally caused by a bacterial infection. The disease begins when bacteria penetrate the outer horn or epidermis of the frog and is characterized by deterioration of the frog and the presence of black necrotic exudate with a foul odor.[1,3,41] In severe cases, the bacteria can reach the frog dermis, causing pain and lameness. Blood may be encountered when the frog is cleaned with a brush or on the end of hoof picking during routine grooming. Severe cases of thrush must be differentiated from canker, which is a proliferative disease where abnormal frog tissue increases in comparison with thrush, which is a degenerative disease where the horn of the frog deteriorates (Figure 11.47A and B).

Etiology

The overall health of the frog is an important component of the etiology of thrush as it does not occur in a healthy frog. A healthy, well-formed frog is broad and firm and deforms with thumb pressure. The frog should fill the space between the heels of the hoof capsule, and, when measured at its base (the widest part), the frog width should be at least 70% of its length.[49] A large healthy frog acts as an expansion joint that holds the heels apart, shares the load-bearing function with the other structures of the palmar foot, and helps to absorb concussion. Under normal conditions, weight-bearing stimulates the normal physiology of the frog, ensuring its continued health. A well-shaped frog that fills the space between the heels also promotes a natural self-cleaning mechanism such that when the foot is loaded, the frog expands, expelling any accumulated dirt or debris from the frog sulci.

An unhealthy frog is markedly smaller in size and recessed below the level of the ground surface of the hoof, thus creating a void in which debris can accumulate. This can occur for a variety of reasons including many of the recognized hoof capsule distortions such as the low heel, club foot, or sheared heels along with inappropriate farriery practices. Other contributing factors for thrush include wet, unhygienic stable conditions, especially when horses continually stand in urine and manure-soiled bedding, neglecting daily routine foot care and lack of exercise.[1,3,34,41]

A fundamental problem with palmar foot conformation involves the frog being below the level of the heels, which reduces the stimulation from the ground, causing the frog to atrophy further. As the frog recedes within the hoof capsule, the frog losses its "self-cleaning mechanism," which allows material (dirt/manure, etc.) to accumulate over the frog, creating excessive pressure. Over time, this constant pressure on a compromised frog leads to increased deterioration and atrophy. Weakened by the reduced protective horn of the epidermis, the frog tissue becomes susceptible to penetration by bacteria and, consequently, development of the disease. Furthermore, the accumulation of debris over the frog creates an environment conducive to bacterial growth, especially for anaerobic bacteria. The recessed frog often loses its ability to act as an expansion joint and the heels begin to contract. The diseased frog can no longer share in supporting the horse's weight, which shifts most of the load-bearing function solely onto the heels of the hoof capsule.

No specific organism has been identified as the sole cause of thrush. Two anaerobic bacteria species, *Bacteroides* sp. and *F. necrophorum*, are opportunistic organisms found in the soil and are commonly isolated from the bottom of the horse's foot. On the positive side, when the necrotic tissue of the frog is debrided and the conformation of the structures in the palmar foot is improved, the anaerobic conditions will be improved, and bacterial growth will be decreased. Furthermore, if antimicrobials are required, these organisms are quite susceptible to most topical preparations.

Clinical Signs and Diagnosis

The diagnosis of thrush is usually straight forward and based on examination of the frog and surrounding structures. There is usually an increased amount of moisture on the bottom of the foot and a black exudate in the sulci of the frog. This exudate, which varies in quantity, usually has an offensive odor.[3,34] The affected sulci of the frog are often deeper than usual and may extend into the sensitive tissues of the foot causing them to be painful. The frog will generally be small, recessed within the hoof capsule, lack a solid firm consistency, and have a necrotic appearance. There may be a fissure present in the central sulci extending from the base of the frog to the hairline at the bulbs of the heels (Figure 11.48). The frog may also be undermined, and areas of necrotic horn can often

VetBooks.ir

be detached from the underlying tissue.[49] Lameness is present in severe cases that involve the dermis, and swelling of the distal limb may be seen.

Figure 11.48. An untrimmed foot with thrush, the frog recessed below the ground surface of the foot, sheared heel conformation, and a fissure present in the central sulci of the frog extending to the hairline.

Fissure in Central Sulci of the Frog

There will often be a fissure located in the central sulcus of the frog in horses that have thrush. The author feels the fissure is a primary structural defect in the soft tissue structures in the palmar/plantar section of the foot that secondarily becomes infected leading to thrush. The fissure is often seen in horses with a hoof capsule distortion (such as low heels with instability and sheared heels), a recessed frog, compromised soft tissue structures, and an abnormal strike pattern. The asymmetrical landing pattern results in an unequal force placed on each heel, causing the heels to move in opposite directions. This movement in opposite directions causes a fissure to form in the weakest part of the soft tissue, which is the central sulcus of the frog (Figure 11.49A and B). Significant movement in the fissure can often be demonstrated by moving the heel bulb in opposite directions.

Treatment

Farriery

Treatment for thrush begins with improving the hoof capsule, the conformation of the palmar/foot, and the health of the frog. Thrush will not be resolved as long as the frog remains recessed below the ground surface of the foot. The amount of improvement in the frog is correlated with the amount of chronic damage especially involving the frog dermis. If the horse can be given time off work, the shoes should be removed, the heels trimmed to the same plane as the frog, the perimeter of the hoof wall rounded, and the horse left barefoot. When barefoot, load is shared by all the structures of the palmar foot, and the integrity of structures improves rapidly and it appears to promote regrowth.[24] Treatment of the thrush as described below is performed daily.

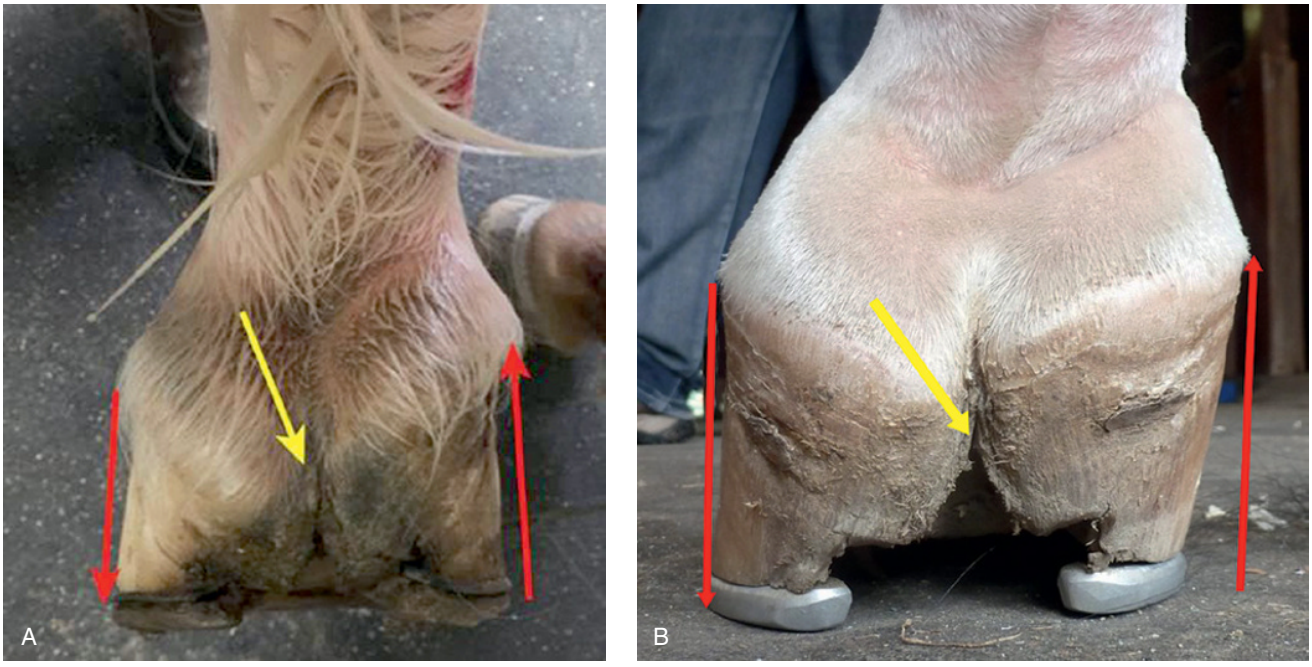

Figure 11.49. (A) Foot conformation showing the frog receded and asymmetric foot landing leading to sheared heels. The difference in force on each heel exerted in the opposite directions (red arrows; A and B) results in the formation of a fissure in the base of the frog (yellow arrows; A and B) (B) A horse with severe club foot combined with a sheared heel. Note the loss of frog mass between the heels.

VetBooks.ir

If shod, the basic trim begins by drawing a line across the widest part of the foot and trimming the heels of the hoof capsule such that they are on the same plane as the frog. This can generally be accomplished in most cases. The toe length is reduced dorsally to the line drawn across the foot, resulting in approximate proportions on either side of the line.[22,24] If significant heel is removed from an upright or club foot, heel elevation may be necessary to accommodate the resultant stresses placed on the DDFT. When a fissure is present in the central frog sulcus, it should be stabilized to decrease the vertical movement of the heels that will inhibit healing. This can readily be accomplished by applying a straight-bar shoe.

Medical

Any detached areas of necrotic horn on the surface of the frog should be debrided with a sharp hoof knife. The frog is cleaned initially by soaking the foot in a saturated (add salt until it no longer dissolves) solution of Epsom salts ($MgSO_4$). Topical antiseptics/astringents including 2% iodine, merthiolate, chlorohexidine, and various copper sulfate solutions can be applied on a daily basis. Topical antibiotic ointments/solutions appear to be unnecessary, and caustic preparations that contain phenol, formalin, or formaldehyde should be discouraged.

Daily Aftercare

Horses should have their feet cleaned and the frogs brushed vigorously with a stiff brush after which an astringent is applied on a daily basis.[1,3,41] If there is a fissure present in the central sulcus, the area above the fissure should be flooded with the antiseptic/astringent solution to allow penetration into the fissure and then packed with a folded gauze pad. The horse should be kept in a dry, clean stall, bedded on wood shavings or sawdust, and turnout should be in a dry paddock. Exercise should be encouraged to maintain/improve the normal physiology of the foot. Repeated trimming of any detached horn on the frog may be required until the infection is controlled. Routine farriery should be scheduled every 4–5 weeks paying close attention to the trim, the foot conformation, the frog, and the integrity of the soft tissue structures of the foot. Prevention is always superior to treatment; therefore, emphasis should be placed on good farriery as the primary means for preventing this disease.

Fractures of the Distal Phalanx

Fractures of the distal phalanx are not an uncommon injury in equine practice. Although this fracture is quite common in racehorses, it can occur in any breed. Causes include racing on a hard track, kicking an unyielding object, landing on blunt objects while exercising, and penetration of the hoof with a foreign body. The involvement of the DIP joint influences the outcome of the case and future soundness. Fractures that involve the articular surface of the DIP joint usually account for increased lameness, a longer convalescence, and a poorer prognosis for a return to full athletic soundness. On the other hand, nonarticular wing fractures carry a much better prognosis. Distal phalanx fractures are classified into 7 distinct categories based on their configuration and location. More detailed information regarding distal phalanx fractures can be found in Table 4.1.

Affected horses show a variation in lameness from a toe touching lameness to a moderate to severe supporting limb lameness that is acute in onset. Trotting on a hard surface generally accentuates the lameness. Increased digital pulse, sensitivity to hoof testers over the sole, and swelling around the coronary band can be noted. With time, the sensitivity of the hoof testers generally becomes localized to the area distal to the fracture. Clinical signs are similar to those displayed with a subsolar abscess or a severe subsolar bruise. Once the clinical examination has isolated a foot-related problem and no abscess is isolated, high-quality radiographs will often confirm a fracture. Nuclear scintigraphy often reveals the fracture in the acute stage before it becomes apparent on radiography. It is the author's opinion that digital nerve anesthesia should not be used prior to radiographs in acute lameness situations, even if clinical signs are minimal, because full weight-bearing on the foot may cause the fracture line to increase in length, become comminuted, or cause nonarticular fractures to become articular. See Chapter 4 for further information on distal phalanx fractures.

Farriery

External stabilization of the hoof can be used to treat some horses with distal phalanx fractures. The distal phalanx can be stabilized within the hoof capsule using one or two methods: a bar shoe with a continuous rim or contiguous clips or a foot cast. A straight-bar shoe with a continuous rim attached to the perimeter of the shoe, encasing the basal border of the hoof wall, prevents or limits expansion of the hoof wall, decreases the independent movement of the heels, and stabilizes the distal phalanx. The solar surface of the foot is packed with impression material before applying the continuous rim shoe for a number of reasons. First, when any form of restrictive shoe is applied to the outer hoof wall, the foot tends to contract, especially at the heels, over a short period of time. Solar/frog support in any form appears to lessen this process quite markedly. Second, the distal phalanx descends in a distal palmar/plantar direction when weight is placed on the foot with no form of counterpressure below. Also, if the fracture is articular with the larger fragment being displaced ventrally, this added support may increase the stabilization in this direction. The full rim shoe is relatively easy to construct and has advantages over the bar shoe with side clips, which are placed randomly and apply limited focal pressure to the outer hoof wall.

The second method is to apply a foot cast. Foot casts are relatively simple to apply and effectively stabilize the distal border of the hoof capsule. In preparation for casting, the hoof capsule should be clean and trimmed if needed. A piece of casting felt is cut to size to cover the heel bulbs both medially and dorsally, and second piece of felt is applied to the proximal pastern just distal to the fetlock. A roll of 2- or 3-inch fiberglass casting tape is then wound around the perimeter of the ground surface of the foot. The concavity of the sole and the frog sulci should be filled with impression material to distribute the load of weight-bearing across the solar surface of

VetBooks.ir

Figure 11.50. Fiberglass foot cast extending to the level of the proximal pastern.

Figure 11.51. Lateral radiograph of a horse with thin soles that would be prone to sole bruising.

the foot. One to two additional rolls of 3-inch fiberglass casting tape are used to envelop the foot and extending to the proximal pastern (Figure 11.50). An acrylic composite may be applied to the toe on the ground surface of the cast to prevent the cast from wearing through the ground surface.

Foot casts should be changed approximately every 3 weeks or as needed. The prolonged application of foot casts will cause some contraction of the hoof capsule and may cause pressure sores on the skin immediately proximal to the heel bulbs.

Marginal fractures (type VI) occur at any site along the solar margin of the distal phalanx and are commonly secondary to another condition such as chronic sole bruising, chronic laminitis, or osteomyelitis. In general, these solar margin fractures are not of primary concern themselves, but rather an indication of another underlying condition such as foot with limited protection due to very thin sole thickness. These horses respond to shoeing with a wide-web straight-bar shoe that is well concaved (using a grinder or skilled forging) on the inner solar surface of the shoe.

MISCELLANEOUS CONDITIONS OF THE FOOT

Sole Bruising

Foot bruising and foot infections are two common causes of acute onset of severe foot lameness. Feet that lack sufficient sole depth to afford adequate protection are susceptible to bruising (Figure 11.51).[44] Sole depth for a good foot should be greater than 15 mm, and the sole should not deform when digital pressure or hoof testers are applied.[39] Bruising can occur when the ground surface of the foot strikes a hard object or excessive trauma from working on a hard surface. It appears to cause diffuse hemorrhage or edema formation in the dermal tissue above the horny sole, the increased pressure being responsible for the discomfort. Clinical signs can range from mild to severe lameness, increased digital pulse, and marked response to hoof testers. Hoof tester response generally is diffuse rather than isolated to a small focal area. The diagnosis is made by ruling out the other common differentials, including laminitis, hoof abscesses, puncture wounds, and distal phalanx fractures.[10,11] The old adage of finding signs of bruising such as red discoloration in the sole of a lame horse at the time of examination or during farriery is not accurate, because this discoloration is generally seen in a white foot and may result from previous hemorrhage in the solar corium that has permeated into the horny sole over time.

The bruising resolves with stall confinement on deep sawdust bedding and a 3- to 5-day course of NSAIDs followed by a period of controlled exercise. The most important part of treatment is a farriery plan to improve sole depth. Farriery options include leaving the sole intact during trimming, evaluating the length of the toe when placing the shoe, modifying break-over, and adding some mild heel elevation. Placing a leather or plastic pad between the ground surface of the foot and the shoe protects the thin sole and provides comfort, but generally does not improve the structures of the foot. The use of a rim pad between the foot surface and the shoe is a common farrier practice to raise the foot off the ground. This practice may provide transient improvement; however, it concentrates the weight-bearing on the wall. When the horse's foot loads, the weight of the horse pushes the sole toward the ground, thus inhibiting any further sole growth (Figure 11.52).

Sole pressure often leads to sole bruising, and this type of bruising is usually noted shortly after the horse is trimmed or shod. In this case the hoof wall is trimmed shorter than the adjacent sole so that when a shoe is applied to the foot and clinched or when the horse stands on a hard surface, excess pressure is placed on the sole.

VetBooks.ir

Treatment for sole pressure is to concave the inner foot surface of the shoe to relieve the pressure on the sole or, in the case of the horse without shoes, apply a shoe with the inner foot surface of the shoe concaved or deep seated to raise the solar surface of the foot off the ground.

The last form of bruising is the so-called corn, which is focal hemorrhage that occurs in the angle of the sole at the heels between the hoof wall and the bar (seat of the corn). The hemorrhage results from trauma, originates from the dermal lamellae, and appears as a small, focal, red discoloration in the seat of the corn. It may be present in one or both heels. There may be a marked hoof tester response, and the source of pain can be confirmed using unilateral local anesthesia. Confusing the diagnosis are abscess, hoof wall separation, and fracture of the bars. Treatment of corns involves removing the pressures on the affected heel by unloading the heel with some form of bar shoe.

Figure 11.52. Foot with a rim pad placed between the solar surface of the foot and the shoe, which raises the sole higher off the ground. The weight of the horse forces the sole through the branches of the shoe toward the ground.

Hoof Abscesses

Hoof abscess, a localized accumulation of purulent exudate located between the germinal and keratinized layers of the epithelium, most commonly subsolar or submural, is probably the most common cause of acute lameness.[42] Entry is either through a break or fissure in the sole–wall junction (white line), a misplaced nail, or a puncture wound somewhere in the solar surface of the foot. Organisms also may enter the foot by way of a full-thickness hoof wall defect or crack.

Most horses with a foot abscess show an acute onset of lameness. The degree of lameness varies from being subtle in the early stages to non-weight-bearing. The digital pulse is usually bounding, and with careful observation, unless the abscess is in the middle of the toe, the intensity of the digital pulse is much stronger on the side of the foot where the abscess is located. If the abscess is long standing, there may be soft tissue swelling in the pastern or above the fetlock on the side of the limb corresponding to the side of the foot where the abscess is located. The site of pain can be localized to a small focal area through the careful use of hoof testers.

The most important aspect of treating a subsolar/submural abscess is establishing drainage. The opening should be sufficient to allow drainage but not so extensive as to create further damage to the hoof capsule. When pain is localized with hoof testers, a small tract or fissure will commonly be found in the sole–wall junction (white line) (Figure 11.53A and B). The wound or point of entry may not always be visible, because some areas of the foot such as the white line are somewhat elastic and wounds in this area tend to close. In this case, a suitable poultice should be applied to the foot daily in an attempt to soften the affected area, and eventually a tract will become obvious.

Figure 11.53. Foreign debris will gain entry and accumulate in a small separation (red arrows) or fissure located in the sole–wall junction (white line) anywhere around the perimeter of the foot (A) including a fissure (circle) on the abaxial surface of the bars adjacent to the sole (B).

VetBooks.ir

Figure 11.54. Small loop knives, 2 mm bone curettes and other suitable probes used to explore a tract in horses with suspected abscesses (A). A horseshoe nail also makes an excellent tool to establish and promote drainage (B).

The offending tract or fissure located within the sole–wall junction is followed using a thin, small loop knife, hoof or bone curette, or another suitable probe (Figure 11.54). Just a small opening is necessary to obtain proper drainage. Under no circumstances should a subsolar or submural abscess be approached through the sole. The application of a medicated poultice (3M Animal Care Products, St. Paul, MN) that has been soaked in hot water is applied to the foot for the first 24–48 hours. The author prefers the sheet version of this poultice rather than the poultice pad because the whole foot, including the coronet, should be enveloped in the poultice. Another method to encourage drainage is to apply a soak bandage. In this method, layers of practical cotton are crisscrossed to form a heavy bandage to envelope the foot. Magnesium sulfate (Epsom salts) is placed on the inner foot surface of the bandage, and the bandage is attached to the foot. The bandage is saturated with hot water and saturated periodically over the next 24–48 hours. Using either of these methods eliminates the need for continued foot soaking.

The horse should show marked improvement within 12–24 hours. Following the poultice or foot soak bandage, the hoof is kept bandaged with an appropriate antiseptic until all drainage has ceased and the wound is dry. The opening is filled with medicated hoof putty (Keratex Medicated Hoof Putty, Brookeville, MD), and the shoe is replaced when the horse is sound. Often an abscess tract is identified, but drainage cannot be established at the sole–wall junction. A small vertical channel can be created adjacent to the abscess tract in the outer hoof wall using a small pair of half-round nippers. Drainage can usually be established using a small probe in a horizontal plane (Figure 11.55).

Figure 11.55. Small channel created in the hoof wall with small half-round nippers or rongeurs, so infection can be approached in a horizontal direction.

Puncture Wound in the Sole

Another common cause of a perceived subsolar abscess is penetration of any region of the horny sole by a sharp object. This is not actually an abscess but rather a diffuse infection caused by the solar corium being inoculated with organisms from the penetrating object. Pain is immediate and usually followed by infection within 3 days. Using the hoof testers for guidance, the site of the puncture wound is easily identified. Radiographs can be helpful to rule out a fracture of the distal phalanx. Drainage is the treatment of choice, and the wound should be opened carefully in a conical configuration using a small, thin loop knife.[9,40,42,43,45] The conical shape of the wound prevents the wound from closing prematurely and prevents dermal tissue from prolapsing and becoming trapped in the wound. The foot is bandaged with an appropriate antiseptic, and the use of systemic antibiotics is at the discretion of the clinician. When the wound has cornified, a shoe with a pad between the foot and the shoe is applied. See Chapter 4 for further details on puncture wounds of the foot.

VetBooks.ir

Nail Abscess

Another form of abscess results from a horseshoe nail driven deep to the stratum corneum into dermal tissue. Dermal tissue can be inoculated by bacteria from a misplaced nail in two ways. First, the nail can be driven directly into the laminar corium. When the nail enters dermal tissue, the horse shows discomfort as the nail is driven into the foot and there is hemorrhage present where the nail exits the outer hoof wall. Blood observed at the exit of the offending nail alerts the farrier of the misplaced nail. The blood also acts as a physiologic rinse to dilute or eliminate bacterial contamination. Removal of the nail and application of an appropriate antiseptic usually prevent infection.

The second scenario that occurs frequently is when the farrier is driving a nail; the horse shows pain, indicating the nail is invading sensitive tissue. The farrier then generally removes the nail, places it in another spot or direction, and again drives it into the foot. The original nail (even if removed) may inoculate the dermis with organisms and contribute to an abscess. If the nail has entered the foot inside the sole–wall junction (white line), the owner should be alerted by the farrier to potential problems. To avert an abscess, the horse may be placed on an oral broad-spectrum antibiotic for 3–5 days as a prophylactic measure.

Finally, there is a "close nail," in which the nail is placed such that it lies against the border of the dermal corium just inside the hoof wall. Pressure against the corium and the movement of the hoof wall structures combined with the organisms introduced with the nail often lead to an abscess as described above. There is usually a lag period of 7–14 days or even longer before clinical symptoms or lameness is observed. Treatment again revolves around removing the nail and establishing drainage.

ACKNOWLEDGMENT

NATURAL BALANCE TRIMMING AND SHOEING

GENE OVNICEK

VetBooks.ir

INTRODUCTION

The term "natural balance" has been used for both labeling commercial products and describing an established protocol for trimming and shoeing horses. Natural Balance® shoes have been developed and marketed by Equine Digit Support System, Inc. (EDSS), since the mid-1990s as a treatment and performance product. Additionally, EDSS has developed other complementary treatment and performance products with the Natural Balance name. The Natural Balance products are simply tools for farriers that are consistent and manufactured with specific design features to produce a given result.

Natural balance hoof care protocols, on the other hand, are hoof evaluation and preparation guidelines that farriers can use to treat hoof distortions that can lead to lameness or performance issues. The natural balance guidelines complement most good, conventional hoof care practices. The basic goal of the natural balance trimming and shoeing protocols is to establish equilibrium in and around the distal interphalangeal (DIP) joint by recognizing and eliminating hoof distortions that cause undue leverage and strain on the DIP joint and the hoof itself.

The structures that are used to evaluate distortions, balance the foot, and determine the quality of foot function include the frog, bars, exfoliated sole, and hoof wall. Other considerations that are employed when evaluating distortions and foot function are how the foot engages the ground (e.g. toe first, flat, or heel first), effort or leverage incurred at the time of break-over, and the use or discipline of the horse. For example, horses that are asked to turn sharp corners or circles at high speed may require a different amount or type of leverage reduction built into the shoe than those that only travel in a straight line. Moreover, horses that live and work in a consistent terrain may maintain better foot function and health if they are left barefoot rather than shod.

Many factors influence the decisions that farriers make in terms of how the foot is prepared and what shoeing application is used, if any. Natural balance hoof care protocols are designed to help farriers make those decisions using simple guidelines that are directed by the individual horse and each individual foot.

DISTORTIONS OF THE HOOF

Most of the original information behind natural balance was gleaned from the study and observation of feral horses and how they maintained their feet in their own natural environment.[3] Although there is much that we can take from the self-maintained feet of horses living in the wild, there are environmental and use considerations that must be factored in when applying that information to domestic horses.

In the wild, hoof wall wear depends upon the terrain. For example, in a very hard, dry, and abrasive terrain, the ground does not yield to the hoof wall. Rather, the outer hoof wall yields to the ground and becomes worn all the way around the foot to the level of the sole (Figure 11.56). In soft, sandy terrain, the ground yields to the hoof wall, so hoof wall wear occurs differently and more slowly. In this case, the wall is allowed to grow beyond the level of the sole. The further the wall grows beyond the level of the sole, the more susceptible it becomes to bending and breaking. Without the strength and support of the sole, the wall becomes vulnerable and eventually bends and breaks off systematically until it is again down to the level of the sole. Therefore, self-maintenance does occur in a softer environment; it is just a longer and less kind process.

Horses that live in both a soft and wet environment have an even more difficult time with self-maintenance. The hoof wall is less brittle due to the moisture, so breakage does not occur until the leverage becomes great. In these conditions, bacterial tracts or abscesses may be the vehicles that mother nature uses to initiate the maintenance process. In other words, a curled, badly distorted heel and bar can develop a bacterial tract that works its way to the sole corium and eventually causes a heel abscess. If the heel abscess is severe enough, it can eliminate the entire heel, thereby eliminating the distortion. It is not kind or aesthetically pleasing but effective for carrying out the necessary maintenance.

In addition to terrain factors, horses in the wild do not routinely turn circles repeatedly or at high speeds. They tend to travel at low to moderate speeds and in straight lines for the most part, yet the outer edge of

Figure 11.56. Lateral view of a feral horse's foot that lives in a dry, abrasive environment. Notice the rounded outer hoof wall in the front half of the foot.

VetBooks.ir

their wall is rolled from one quarter, around the toe to the other quarter (Figure 11.56). Even with these conditions and activities, self-maintained horses have reduced some leverage from a medial and lateral perspective. In the domestic equine world, we not only add the weight of a rider and tack, but we also ask horses to turn in repetitive circles at high speeds. With that, we see many soft tissue strains and injuries on the medial and lateral aspects of the distal joints.

Perhaps it is not possible to use the self-maintained horse as a model for the domestic equine. Maybe the parameters established in feral horse's feet still place too much stress and leverage on the distal joints of the domestic horse. Perhaps we need to relieve even more strain and leverage in domestic horses based on the increased loads and demands that they incur.

Most of the current natural balance guidelines and protocols have been adapted more specifically to the domestic equine through further anecdotal and field research and observations over the last 15 years. The Equine Lameness Prevention Organization (ELPO) is one group that has taken the basics of natural balance guidelines and have further developed and improved upon them over the last 10 years. Practical applications by a large number of farriers in both treating lameness and improving performance over the last decade have helped to fine-tune these methods of balancing feet as well. Through a better understanding of healthy foot function and anatomy, the natural balance and ELPO guidelines have become a more widely used approach to trimming and shoeing domestic horses.

One difference between self-maintained feral horses and our domestic horses is the fact that domestic horses do not typically have the terrain, space, or activity to maintain their own feet and are therefore susceptible to excess hoof growth and hoof distortions. Hoof distortions are generally the result of hoof structures (primarily hoof wall) that grow beyond the level of the sole in a direction that reduces support to the foot or cause increased leverage to the foot. For example, a heel that grows beyond the level of the functional sole and forward becomes unstable and unable to support the weight and force of the horse as the foot engages and loads into the ground. A toe that grows much beyond the level of the sole can become a flare, which further increases the leverage at the time of break-over. A frog that fails to contact the ground and has become narrow and atrophied from lack of use because the heels have been allowed to grow beyond the level of the sole fails to absorb concussion and dissipate energy at the time of ground contact and load.

It is apparent that hoof distortions have a direct influence on function, support, and strain on the internal components of the foot and distal limb.[6,7] When a foot is subjected to increased strain on the soft tissue in and around the distal limb, lameness and pathology are likely to follow. Therefore, it is the job of the veterinarian and farrier to recognize these common hoof distortions and eliminate them at the time of trimming or shoeing to improve or eliminate lameness. Moreover, if these distortions can be dealt with early, or even avoided, then the prevention of lameness in horses can become a more realistic goal.

NATURAL BALANCE HOOF CARE GUIDELINES

A general understanding of the term functional sole plane is needed before discussing the detailed protocol. References have been made previously to the amount of wall that grows or extends beyond the level of the functional or live sole. The functional sole plane is established by scraping or paring the chalky or flaky appearing sole out of the foot until the smooth, waxy-appearing surface is revealed. It is important that when exfoliating the sole, it is approached slowly and methodically so that the functional sole is not invaded or penetrated. If you go too far into the functional sole material, you will not only invade possible sensitive sole, but it also compromises the structures that will be used to balance the hoof wall and distal phalanx to the ground. The live functional sole has been found (with few exceptions) to be an equal thickness beneath the medial and lateral aspect of the distal phalanx.[5] Therefore, if the goal is to balance the distal phalanx medially to laterally parallel to the ground surface, the functional sole is a very reliable guide.

NATURAL BALANCE EVALUATION, EXFOLIATION, AND MAPPING PROTOCOL

Recognizing Hoof Distortions

The first step in the natural balance hoof mapping protocol is to visually recognize hoof distortions in the heels, bars, frog, and toe (Figure 11.57). Heels that are curled, rolled over, crushed, or end dorsal to the widest part of the frog are distorted. Typically, the further dorsal the heels end to the back of the frog, the more distorted and less functional they have become. Similarly, the more curled, laid over, and fractured the bars are, the more distorted and less functional they are. The bars typically terminate into the frog commissures near the widest part of the foot (WPOTF). If the heels are allowed to grow forward, the bars must curve and bend, because the termination point of the bar cannot be moved forward, at least not at the corium level. Like hoof wall and sole material, bars can become overgrown. The overgrowth at the surface can grow forward of the WPOTF and in some cases, such as laminitis, can grow completely around the frog apex. However, actual bar termination maintains its position near the WPOTF.

A frog that has become atrophied and narrowed, and has the central sulcus closed up is often lacking in function and has become distorted. At the same time, if the frog apex has become narrow and pointed, it is likely stretched and distorted as well. Furthermore, if the wall is allowed to grow much beyond the level of the sole, it will start to bend, flare, and become stretched forward. A thickened outer dorsal wall, inner wall, and white zone of the foot indicate that the extra leverage is stretching the components. It may be necessary to look closely at the dorsal wall to see a slight deviation below the coronary band, within the proximal 1 inch of the dorsal hoof wall. As a rule, noticeable flares start about halfway down the hoof wall.

Identifying distortions and evaluating the degree of distortion in all aspects of the foot helps determine the overall health of the foot. Having guidelines to overcome these distortions can help prevent lameness and improve performance. The ELPO has further developed this concept of

VetBooks.ir

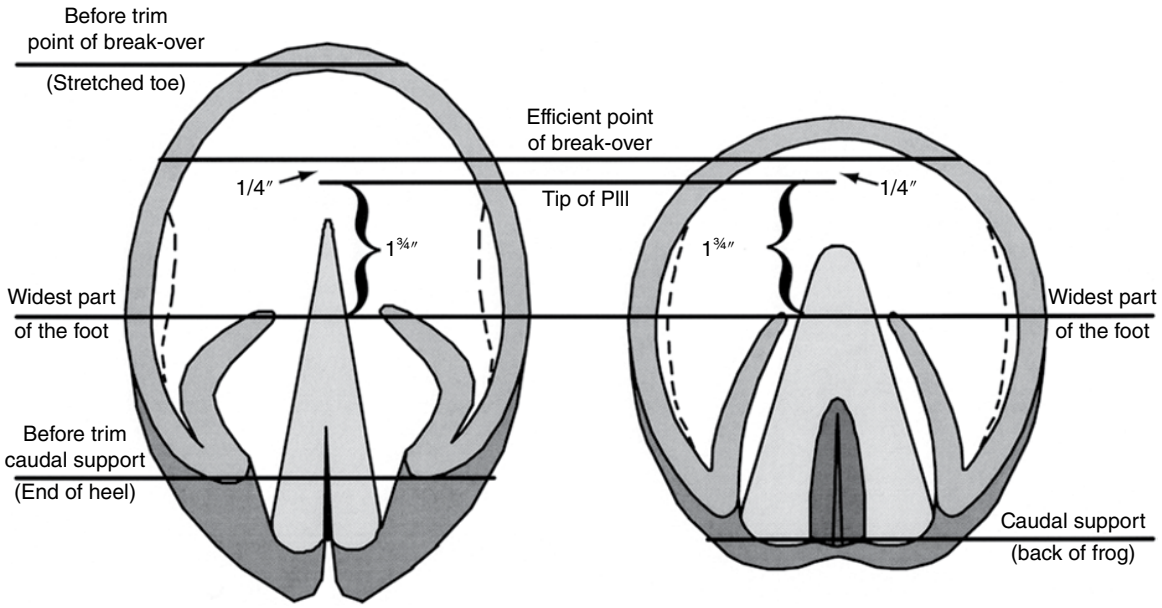

Figure 11.57. Drawings of two solar views. The solar view on the left is a foot with common hoof distortions. The solar view on the right is a non-distorted foot. Lines are drawn on the pictures to illustrate the point of break-over and where it should be on each foot, as well as the widest part of the foot (WPOTF) and caudal most aspect of support (either heels of the foot or back of the frog, depending on which structure contacts the ground first and primarily).

Table 11.3. ELPO hoof evaluation grading protocol.

Grade	Description/abnormalities
0	Considered to be a perfectly natural, normal foot, free of hoof distortions, that is expected to be functioning at its optimum efficiency. Hoof structures with this grade would also be representative of a foot that either requires no maintenance or has just been trimmed and/or shod and again is free of hoof distortions
1	Indicative of a natural normal foot that is at the end of a trimming/shoeing period and requires basic maintenance. Minor hoof distortions seen are the result of normal growth and with basic maintenance will be returned to a grade 0 status. If a #1 status is achieved after trimming/shoeing, then this grade would be representative of hoof structures that possesses only minor hoof distortions that would still allow the foot to function efficiently
2	Indicative of hoof distortions that can start to affect proper foot function. Although these are commonly seen at the end of a shoeing cycle, this rating is suggestive of distortions that generally were not fully dealt with at the beginning of the shoeing/trimming cycle. Feet and structures in this condition can start to negatively affect performance, but may not be recognized as problems by everyone
3	Indicative of hoof distortions that can cause minor to moderate lameness issues. Foot function is often being compromised and common gait faults such as stumbling, forging, and landing toe first are prevalent, and signs of DIP joint pathology may be recognized and even diagnosed by veterinarians. These types of distortions challenge the soft tissues around the DIP joint
4	Indicative of moderate to severe hoof distortions that are often associated with serious lameness issues. These feet have been subject to long-term hoof distortion, and often, irreversible damage can occur. Foot function can be at least somewhat restored with shoes, pads, and detailed hoof trimming
5	Indicative of the most severe hoof distortions that contribute to both soft tissue and bony damage. Horses are often severely lame or debilitated as a result of the distortions. These types of distortions are sometimes irreversible, but can be improved with the use of various prosthetics and more detailed hoof preparation

distortion evaluation by classifying or grading these structures that most commonly distort the foot (Table 11.3 and Figure 11.58).[1] The goal of the ELPO Hoof Evaluation Protocol is to accurately and consistently, in accordance with established standards, be able to determine the amount and/or location of hoof distortions in individual equine feet. Although an overall rating for each foot may be achieved, individual attention to primary hoof structures is the key. Through the systematic evaluation of the external hoof anatomy, a more accurate and meaningful evaluation of the foot can be achieved, as well as a determination of the overall health and soundness of the horse.[1]

VetBooks.ir

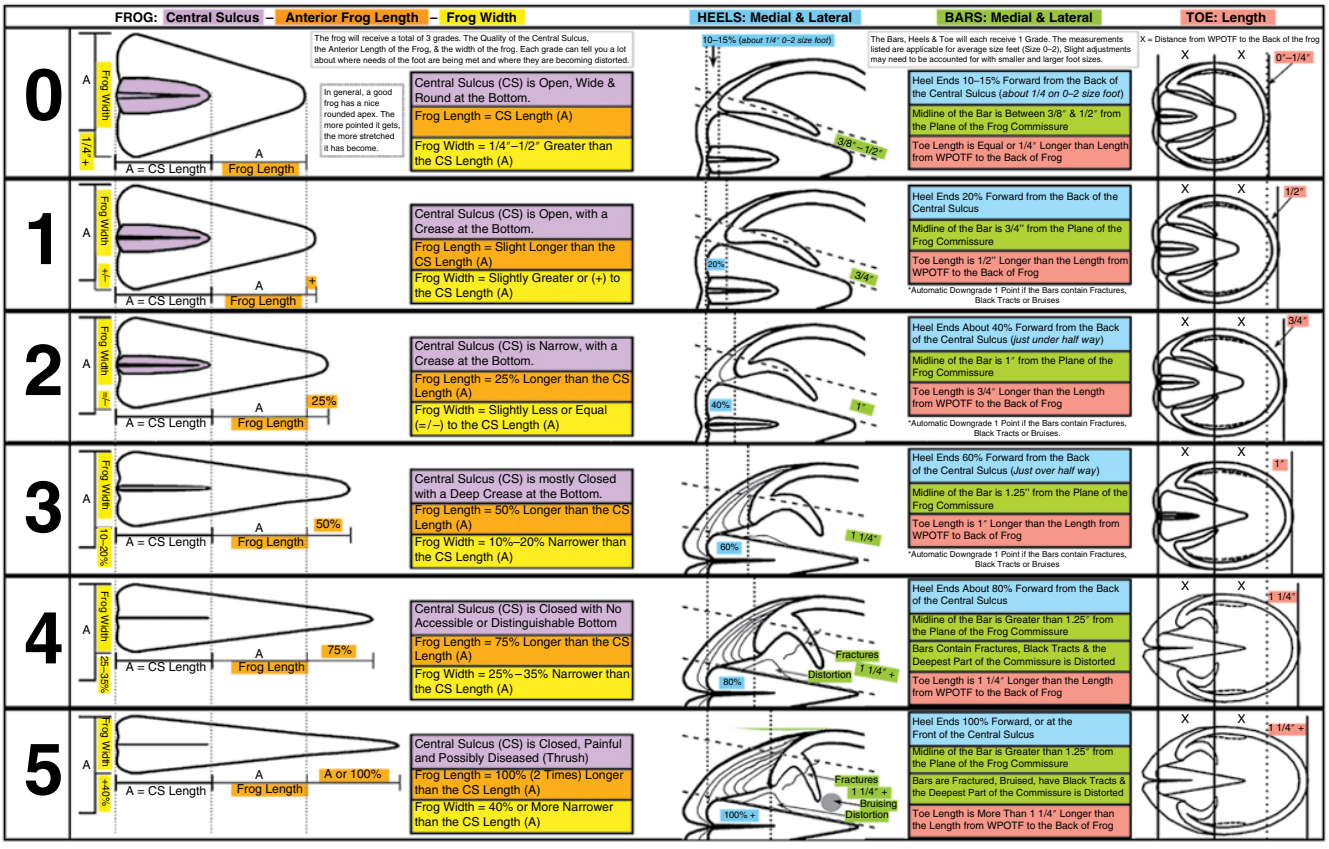

Figure 11.58. Detailed description of the grading protocol that is used for the frog, bars and heel, and the toe of the equine foot by the ELPO. (Disclosure: The information presented in this evaluation protocol are only general guidelines designed for equine professionals as a means to have a standardized formula for recognizing common hoof distortions that exist in many feet with basically "normal" conformations. This evaluation protocol is not intended to diagnose any lameness, nor is it intended as instructional guidelines for trimming or shoeing. For details on hoof care guidelines, look at the "ELPO Hoof Trimming & Shoeing Protocols" offered by the Equine Lameness Prevention Organization, Inc. [www.LamenessPrevention.org].)

VetBooks.ir

The primary hoof structures that are specifically evaluated are the frog, bars, heels, and toe and are evaluated from the viewpoint of the sole. A basic overview of the grading parameters is contained in Table 11.3, and a detailed description of the grading protocol for each structure is available through the ELPO and illustrated in Figure 11.58.

Exfoliating the Foot

When leaving horses barefoot, the amount of exfoliating sole material to remove varies from one environment to another. To assess how much sole exists, first exfoliate and uncover the true frog apex where it blends in with the sole. This provides an idea as to how much nonfunctional sole exists. As a general rule, very little exfoliating in the toe region is tolerated by horses that live in hot, dry climates. Slightly more exfoliation can be done in soft, sod environments where horses get moderate amounts of moisture. In very wet or swampy environments, most feet need very little exfoliation, and most of the time simply wire brushing the bottom of the foot handles most of the exfoliation needs.

Usually when horses are left barefoot, it is a good idea to be conservative when exfoliating the sole. However, it is fairly safe to exfoliate the sole from the WPOTF back, so it is important to find the waxy-appearing functional sole in this region on each side of the foot. This will later be the guide for establishing medial/lateral (M/L) balance.

When applying shoes to horses, it is important to be more specific about removing the majority of exfoliating sole materials to get a clear picture of the functional sole plane. Nevertheless, starting in the back half of the foot is always recommended because it is a relatively safe zone in which to work. Once a clear picture of the functional sole is established in the back half of the foot, move forward and exfoliate the sole in the toe region. Be extremely specific and careful when exfoliating the sole in the toe quarter (pillar) region of the foot. This is the primary guide when trimming the wall to balance the distal phalanx medially and laterally.

Mapping the Foot

The goal of mapping the foot is to gain an appreciation for the location of the distal phalanx and DIP joint within the hoof capsule. As part of their assessment to balance the foot, farriers have always tried to locate or picture the position of the distal phalanx within the hoof capsule but have largely had varying results when using the hoof capsule itself as a guide. The hoof wall can become distorted and more easily lose its relationship to the distal phalanx. However, more static references on the bottom of the foot help establish where the distal phalanx and DIP joint are relative to the hoof capsule.

Once the foot is exfoliated, a primary goal is to locate the WPOTF; there are three methods for locating this position:

Measure back approximately 1 inch from the true, exfoliated frog apex (on a medium size foot #00 to #2), and make a mark (Figure 11.59A).

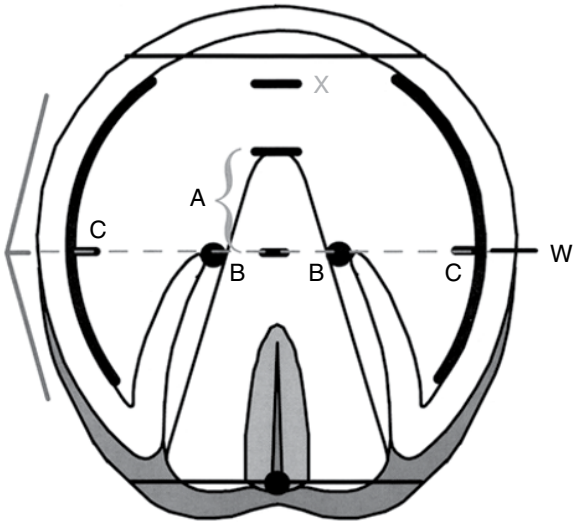

Figure 11.59. Drawings of the solar view of a foot that has the lines and marks used to locate (map) the widest part of the foot, which is generally the center of articulation. (A) Measurement back from the true frog apex. (B) The termination point of the bars into the frog commissures. (C) The actual widest part of the sole. (W) The widest part of the foot using the best 2 out of 3 marks. (X) The tip of the distal phalanx as determined by a given distance forward of the WPOTF.

Follow the bars to their termination point into the frog commissures. There is usually a slight bump or swelling in the commissures to indicate this location. Make marks at these termination points (Figure 11.59B).

Scribe a line at the sole–wall junction in the quarters of the foot on each side. The peak or apex of this arc that has been drawn should be the widest part of the sole. Make a mark at the apex on each side of the foot (Figure 11.59C).

If all three locations line up, then draw a line connecting all of the marks that have been made (Figure 11.59W). If only two of the three locations line up, use those two and disregard the third set of marks.

Radiograph studies have shown that from the marked WPOTF, the dorsal tip of the distal phalanx is a consistent and predictable distance ahead of this mark.[2] On foot size #1 (5-inch-wide foot), measure 1.75 inches ahead of the WPOTF and make a mark. This is approximately the tip of the distal phalanx (Figure 11.59X). For foot sizes smaller and larger, the distance measured forward varies by no more than 1/8 inch/foot size. For example, a #00 foot is approximately 1.5 inches, while a number #2 foot is approximately 1.875 inches. These distances are accurate to within ±1/8 inch.

As a standard starting point for the location of the point of break-over, measure forward 1/4 inch from the tip of the distal phalanx mark (Figure 11.57). In general, this position for the point of break-over (not the front of the shoe) seems to be effective for relieving excess strain and leverage on the DIP joint and excess tension on the deep digital flexor tendon at the time of break-over.[4]

Once the WPOTF and the point of break-over is established, the before-trimming and after-trimming ratios can be evaluated to compare how the foot has been and will be balanced around the WPOTF

VetBooks.ir

(Figure 11.57). The WPOTF is generally below the center of articulation (±1/4 inch), depending on the angle of the distal phalanx.[5] If the distance from the WPOTF to the "before trim" heels is shorter than the distance from the WPOTF to the "before trim" point of break-over, then there are most likely hoof capsule distortions that can negatively affect the performance and soundness of the horse (Figure 11.57). Changing the ground surface ratios around the WPOTF or center of the foot so that there is equal or slightly more mass behind the WPOTF has been shown to improve the function of the foot and soundness of the horse.

Again, the ELPO has taken the lead in developing the mapping protocol further to help improve accuracy and consistency.

NATURAL BALANCE BAREFOOT TRIMMING

The following natural balance hoof trimming procedure is used only on horses that will be left barefoot. The hoof preparation protocols for horses that are to be shod are slightly different and will be covered later.

Once the foot is exfoliated and mapped, it is time to trim the hoof wall to eliminate any distortions and achieve D/P and M/L balance. Begin by trimming the back two-thirds of the foot. Start just behind the toe quarter (pillar) region and follow the contour of the exfoliated sole, staying about 1/8 to 1/4 inch above the line of the sole (Figure 11.60). Next, trim the wall around the toe. Again, start behind the pillar and cut from one toe quarter around the toe to the other toe quarter. Stay at least 1/8 inch above the level of the sole all the way around the toe.

Once the rough cut has been made with nippers, a rasp is used to file the heels down to a flat landing that joins with a portion of the bar to form a solid base. The finished heel should be at or slightly lower than the ground surface of the frog and should end close to the back of the frog. Both the medial and lateral heel should have a similar curvature and end at the same position relative to the back of the frog and at the same height above the level of the functional sole plane. If the frog is atrophied, do not rasp the heel down so low that the functional sole plane in the heel region is invaded. With more use, the frog will eventually fill out and become a larger presence in the back of the foot.

With the heel prepared, a rasp is used to flatten the wall in the toe quarters so there is approximately 1/16 inch of gap between the sole and the ground surface of the wall. Make sure the gap is the same on both the medial and lateral sides. Once the toe is balanced with respect to the sole, bevel (or roll) the wall at a 10°–15° angle from the break-over line forward (Figure 11.60). It is OK to touch some of the sole ahead of this point, because it is not sensitive. The objective is to produce a slight pivot point at the point of break-over that was marked earlier.

After the break-over roll is produced, a flattened area of wall about 3/4 inch to 1 inch in length should be left in the toe quarter region on each side of the foot. Behind that flattened area, relieve the wall in the quarters slightly to avoid flaring and chipping (Figure 11.60).

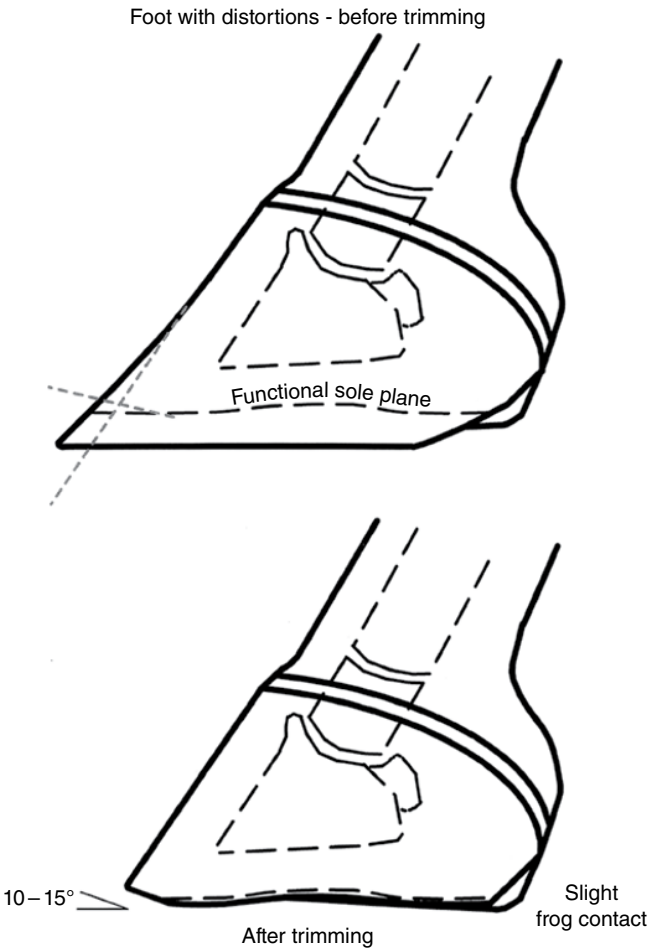

Figure 11.60. Drawings of two lateral views. The top illustration is a foot with common distortions before trimming. The dashed line near the bottom of that foot is the functional or live sole contour used as a trimming guideline. The lighter, shorter dashed lines indicate how the flare is removed and how the toe is to be rolled (beveled). The bottom foot is an illustration of a natural balance barefoot trimmed foot. The wall has been prepared close to the level of the sole, the frog is in slight contact with the ground, and the toe has been rolled at a 10°–15° angle to reduce leverage on the internal structures.

The final step in the barefoot trim is to dress the outer hoof wall to eliminate flares and produce a uniform wall thickness all the way around the foot (Figure 11.60). To eliminate sharp edges and avoid chipping, angle the rasp at a 45° angle to the wall and chamfer the distal border of the wall all the way around the foot.

NATURAL BALANCE SHOEING

The following procedure is used for preparing feet that will have shoes applied to them.

Once the foot has been properly exfoliated and mapped as outlined previously, it is ready to be trimmed (Figure 11.61). Begin with nippers and trim the wall in the back half of the foot first. Unlike barefoot trimming, the exact contour of the sole is not followed through the quarters. Instead, start with the nipper blades just behind the toe quarters and trim toward the heel, leaving a gap of

VetBooks.ir

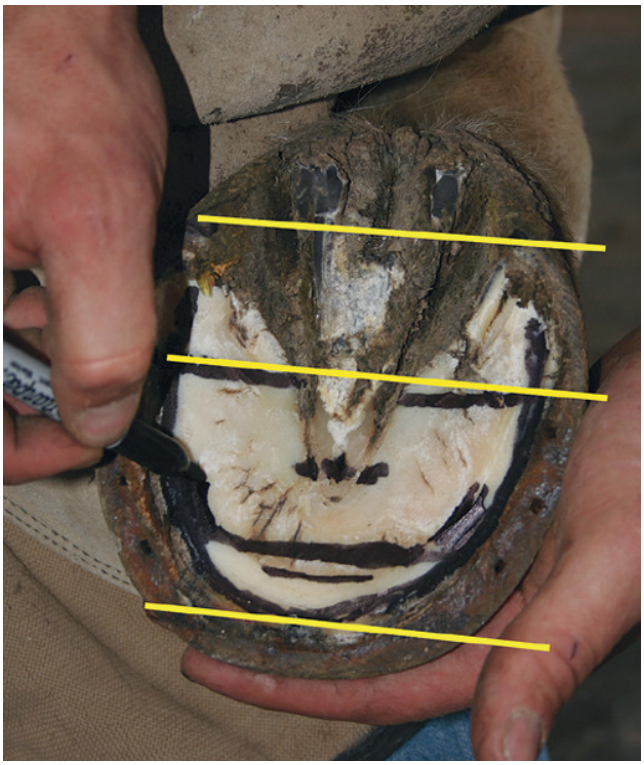

Figure 11.61. Sole view of a foot that has been exfoliated and mapped and is ready to be trimmed for shoes. Yellow lines have been drawn at the end of the heels, widest part of the foot, and at the "before trim" point of break-over.

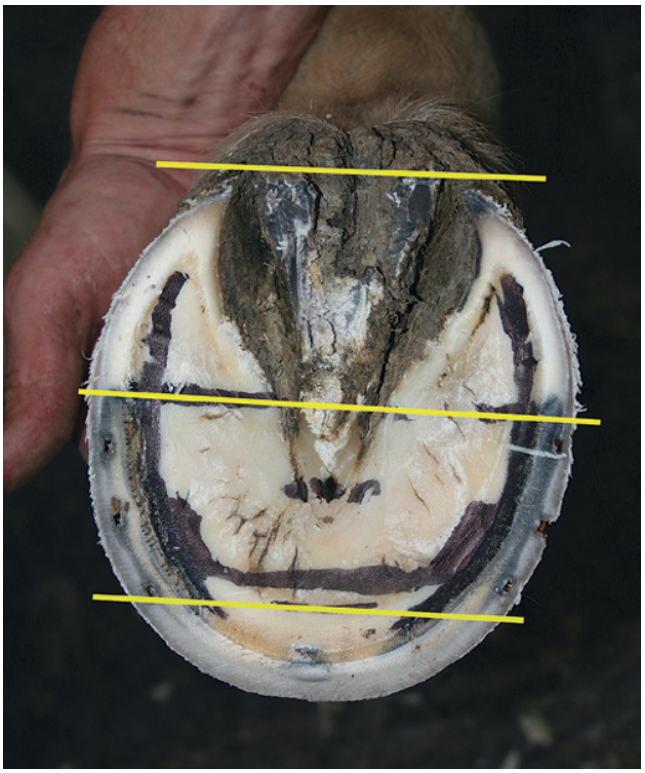

Figure 11.62. Solar view of a foot that has been exfoliated, mapped, and trimmed and is ready for a shoe to be applied. Lines have been drawn at the end of the heels, widest part of the foot, and the position that the point of break-over of the shoe will be placed.

approximately 1/4 inch above the sole in the quarter region. Do the same on each side of the foot.

With the initial heel trim finished, start in the toe quarter region just behind the previous cut and trim the wall from toe quarter to toe quarter. Make sure to leave at least 1/8 inch of wall above the level of the sole all the way around.

Once the rough-in trim is complete, use a rasp to file the heels so they are about 1/8 inch above the level of the functional sole in that region. Both the medial and lateral heel should have a similar curvature and have the same gap from the sole to the wall. The heels should also end evenly near the back of the frog. In cases of severely underrun and contracted heels, it may be necessary to rasp the heels down to the level of the sole to produce a good supportive landing and encourage better heel conformation. However, this should not need to be done every time the horse is shod. Once the heel growth becomes stronger and at a better angle, this more aggressive heel trimming should be stopped.

Once the heels are prepared exactly where desired, it is time to move to the toe. File the wall in the toe region so that there is a gap of approximately 1/16 inch from the exfoliated sole to the ground surface of the wall in the toe quarter region on each side. Although some horses are OK if the wall is rasped level with the sole, for safety measures it is recommended to leave a bit of wall above the sole. Either way, the gap should be exactly the same on both the medial and lateral sides, as this determines the balance of the distal phalanx to the ground once the shoe is applied.

When the heels and toe have been accurately prepared, proceed to rasping the wall in the quarters so that the finished surface is perfectly flat to accept the flat shoe (Figure 11.62).

The final step before applying the shoe is to dress or groom all flares on the outer hoof wall to obtain a uniform wall thickness all the way around the foot (Figures 11.62 and 11.63). By dressing the wall prior to fitting the shoe, the chances of fitting the shoe to hoof capsule distortions are minimized.

Shoe fitting and design is an important part of dealing with lameness issues and improving performance. Basic shoe design for Natural Balance® applications should fit the following criteria:

1. Fairly symmetrical foot surface mass around the widest part of the shoe—the length of foot surface of the shoe should be the same ahead of and behind the widest part of the shoe.
2. Some leverage reduction considerations should be built into the toe of the shoe (i.e. rolled toe). In most lameness and performance situations, the roll should continue around the toe quarters for medial and lateral leverage considerations (Figure 11.64).
3. Wear plates in the toe of the shoe should be avoided so that the point of break-over is allowed to wear back into the shoe as the foot grows longer.

Shoe fitting is extremely important, so good forging skills are always necessary. When sizing the shoe, the heels of the shoe must extend to the back of the frog, and the point of break-over of the shoe should align

VetBooks.ir

Figure 11.63. Lateral view of a foot in which the dorsal hoof wall has been groomed to a flat plane from the coronary band to the ground surface. All noticeable flares have been removed and uniform wall thickness has been achieved (as seen in Figure 11.62).

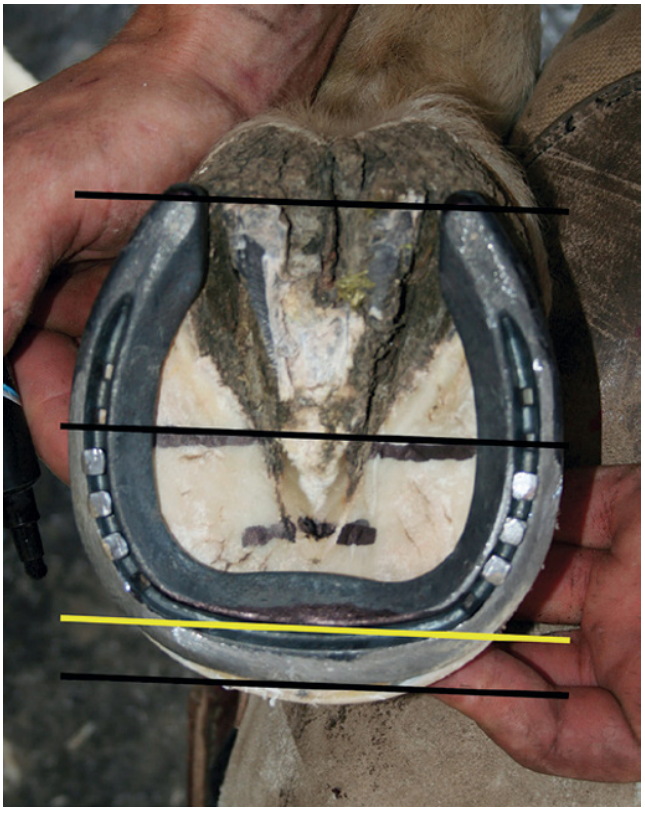

Figure 11.64. Solar view of a foot that has a Natural Balance® shoe applied to it. Black lines have been drawn at the back of the heels, the widest part of the foot, and the front of the shoe to illustrate that the foot surface of the shoe is divided up 50/50 around the widest part of the foot. The yellow line indicates the point of break-over of the shoe.

closely with the break-over line marked on the foot. The foot surface of the shoe should be divided equally around the WPOTF (Figures 11.64 and 11.65). The toe quarters of the shoe should fit to the groomed toe quarters of the foot, and the widest part of the shoe must align with the WPOTF.

When shaping the heels, they should have a gradual bend that follows the contour of the hoof, with the shoe becoming slightly wider than the heels as they progress from the widest part back. The finished heel of the shoe should be around 1/8 inch wider than the heel at the buttress.

The general shape of the shoe should be round on the foot surface with a slight boldness to the toe. However, the toe quarters of the shoe should maintain a width that is basically the same as the heels, meaning the toe quarters and heels should form a box (Figure 11.64).

Nailing on shoes and finishing the foot is basically the same as in any good conventional shoeing job. A quality nailing pattern with three or possibly four nails/side is generally required. Once the nails are clinched, grooming the wall is minimal, because the flares have been dressed prior to fitting the shoe. If there is any amount of toe that sticks out over the front of the shoe, simply position the rasp at a 30° angle and undercut the toe slightly (Figure 11.65).

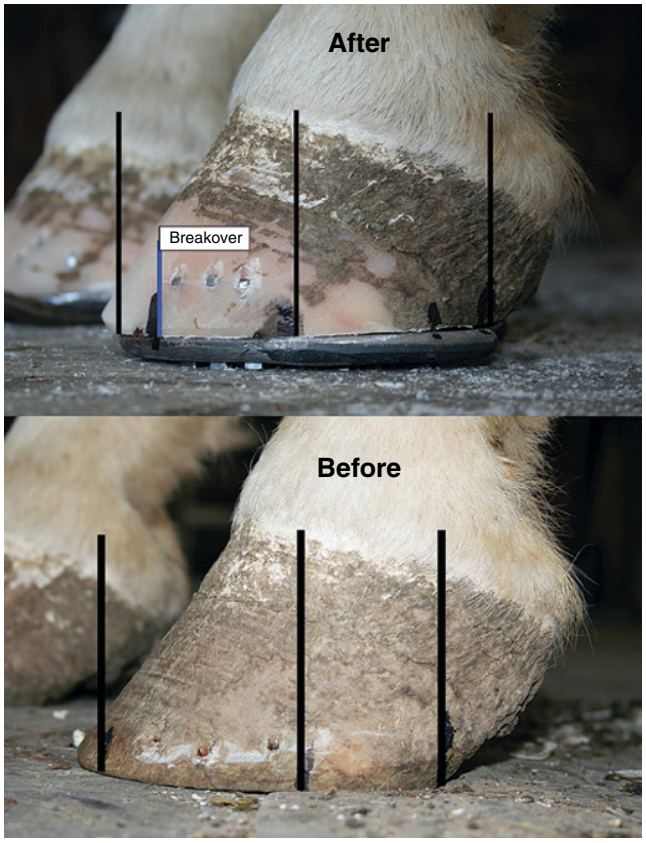

Figure 11.65. Lateral view of the same foot. Before trimming (bottom) and after trimming and shoeing (top) using natural balance guidelines. The black lines on the top image have been drawn at the front of the shoe, widest part of the foot, and back of the heels. The blue line is at the point of break-over of the shoe. The black lines on the bottom picture are at the "before trim" point of break-over, widest part of the foot, and the "before trim" back of the heels. The top picture illustrates better balance after trimming and shoeing around the widest part of the foot, which is generally the center of articulation of the DIP joint.

VetBooks.ir

The angle of the undercut should be similar to the angle of the roll in the shoe. The amount of toe that extends ahead of the shoe depends on the amount of hoof capsule distortion that exists. Normally within three or four shoeing periods, the amount of toe over the front of the shoe will be minimal, as the wall regains a better parallel relationship with the dorsal surface of the distal phalanx.

SUMMARY

Natural balance is a term used within the hoof care industry with both positive and negative connotations. Many of the negatives or failures associated with Natural Balance shoes have in large part been the result of inappropriate or misapplied hoof preparation techniques and/or incorrect shoe placement. The fact is that poorly prepared feet or an inability of a hoof care provider to read and understand the foot, regardless of the shoe applied, is a key factor in the ability to keep horses sound. Understanding the basic structures of the foot and how to locate them inside the hoof capsule and how the foot grows, and developing the ability to see and evaluate when the foot is distorted or overgrown will improve our success at preparing feet to maintain soundness. As the ELPO has continued to improve and develop the natural balance guidelines for mapping, barefoot trimming, and shoeing, the ability to not only get horses sound but keep them sound and prevent future lameness has greatly improved.

CHAPTER

Miscellaneous Musculoskeletal Conditions

MUSCULOSKELETAL EMERGENCIES

KATHRYN A. SEABAUGH

INTRODUCTION

Musculoskeletal (MSK) emergencies such as fractures, tendon/ligament lacerations, and septic synovial structures can occur in any type of horse and may be career ending or potentially life threatening if not treated appropriately. Forty percent of horse owners responding to a survey in the United Kingdom reported that their horse had suffered an injury within the previous 12 months and 54% of those injuries were wounds.[39] It is important to recognize significant MSK injuries early to provide the horse with the best opportunity for recovery. Every veterinarian should be prepared to stabilize a fracture or unstable limb and to quickly identify a laceration that involves a tendon, ligament, or synovial structure. Being prepared for these emergencies can help ease the stress of the situation and can lead to successful assessment and management of the injury. Prompt attention and treatment can often mean the difference between survival and euthanasia of a patient.

Assessment of the Patient

Regardless of the type of MSK emergency, the first and most important step should always be to stabilize the overall systemic condition of the horse. Many of these patients are in significant pain, often anxious, and potentially in shock. Depending on the type of injury, the patient may have also suffered extreme blood loss. Patient assessment and stabilization should include a thorough physical exam and potentially a packed cell volume (PCV) and total protein (TP) measurements. Based on these preliminary findings, pain management with nonsteroidal anti-inflammatory drugs (NSAIDs) and/or opioids should be utilized. Sedation may be used to calm the patient. Phenothiazine tranquilizers, such as acepromazine, should be avoided in horses with hypotension because they may cause an exacerbation of the hypotension.[34] Tetanus prophylaxis is also indicated in cases where wounds are present if the horse is not up to date or has an unknown vaccination status. Once the patient is calm and systemically stable, further evaluation of the injury can be pursued.

FRACTURE MANAGEMENT

Fractures frequently require emergency first aid treatment (Table 12.1). Significant blood loss is rare in equine fractures but can occur with some femoral fractures or pelvic fractures[52] and occasionally proximal tibial fractures.[36] Antimicrobial therapy is typically not necessary for initial equine fracture management. It should be instituted however if the skin has been penetrated by the fracture or if there is an open wound associated with the fracture. Whenever possible, gross debris should be removed from the wound/puncture site prior to placing in a bandage.

Clinical Signs

The most common clinical sign associated with a fracture is an acute non-weight-bearing lameness. Frequently this is associated with a traumatic event that occurred during competition. Swelling often follows the injury, and palpable or audible crepitus is frequently

Table 12.1. Recommended contents of fracture first aid kit for horses.

Material	Purpose	Examples
Rigid material	To stabilize the fracture	PVC splints (varying lengths), aluminum rods, fiberglass cast material, wooden boards
Cotton	Padding for under the splint or cast Robert-Jones bandage	Roll cotton Sheet cotton Combine roll
Brown gauze Vetrap	Compress the bandage/padding	
Sterile gauze	Cover any open wounds	Kerlix AMD
Razor and/or portable clippers	To remove the hair from around any open wounds	
Elastic tape	Secure the top and bottom of the bandage/padding	Elasticon
Nonelastic tape	Secure the splint to the bandage/padding	Athletic tape Duct tape
Pre-made splints	Stabilize lower limb fractures	Kimzey splint
Sedation	Ease anxiety Decrease activity	Xylazine, detomidine Butorphanol Acepromazine
Pain management	Reduce inflammation, pain, swelling	Phenylbutazone Flunixin meglumine
Antibiotics	To initiate if there is a wound or if the fracture has punctured the skin	Parenteral and oral options Dictated by case and veterinarian
Antibiotic ointment	Topical dressing for open wounds	Silver sulfadiazine Triple antibiotic ointment

PVC = polyvinyl chloride.

present. Unfortunately, not all cases are this straightforward especially when the incident that led to the fracture may not have been witnessed or minimal swelling is apparent such as with fractures of the axial skeleton.

Diagnosis

Most fractures in horses can be easily localized and diagnosed with radiographs. If the patient is quiet and comfortable, a full radiographic study should be taken before limb immobilization as the splint may decrease image quality. If the patient is in shock or if the fracture is completely unstable, limb immobilization should be performed prior to image acquisition. A complete radiographic study will usually provide important information on prognosis that allows for better preparedness by the referral center. An initial prognosis can often be developed based on two simple criteria: complete or incomplete fracture and open or closed fracture.[36]

Radiographs may not be diagnostic for fractures of the axial skeleton or in the case of nondisplaced or incomplete fractures where the fractures are too subtle to be seen radiographically. Nondisplaced or incomplete fractures will present with acute onset of lameness, but identification of the fracture lines can be very challenging. If the injury is the result of trauma (i.e. kick from another horse), skin trauma will indicate the area to radiograph. Frequently, multiple radiographs will be needed to identify the fracture line, and even more commonly, the fracture lines may not appear for 14–21 days (Figure 12.1).

Identification of fractures of the axial skeleton can be even more challenging. Nuclear scintigraphy can be useful but is obviously not available in the field nor at all veterinary hospitals. Ultrasound can be very helpful to identify steps in bone contour and is frequently more accessible. Geburek et al.[15] found 73% agreement between ultrasonography and standing radiography for pelvic–femoral disorders.

Fracture Stabilization

Next to patient assessment, fracture stabilization is the most important step in the emergency first aid treatment of fractures. Horses are not readily ambulatory on 3 limbs and often become very anxious when they are unable to place weight on a fractured limb, and any attempt to weight-bear can result in further injury. Appropriate fracture stabilization can mean the difference between euthanasia and successful repair and

VetBooks.ir

recovery. First aid measures should be directed toward minimizing further damage to the fractured limb and maintaining it in a position and condition that will facilitate repair. The primary goals of fracture management should be as follows[4]:

1. Prevent damage to neural and vascular elements
2. Keep the fractured bone from penetrating the skin and becoming and open fracture or protecting the limb from contamination through any existing skin opening
3. Stabilize the limb to relieve anxiety that accompanies an uncontrolled limb in a horse
4. Minimize any further damage to the fractured bone ends and surrounding soft tissues

An important purpose of fracture stabilization is to prevent the development of an open fracture. Loss of intact skin coverage over a fracture is thought to predispose to infection, especially if internal fixation is performed. Equine skin is thin and readily penetrated by sharp bone fragments, and there is very little soft tissue support, such as muscle, below the carpus and tarsus. In general, fractures of the distal (phalanges) and proximal (humerus, ulna, and femur) aspects of the horse's limbs rarely become open, suggesting that fractures involving the metacarpus/metatarsus, radius, and tibia are the most critical to proper immobilization during transport. Immobilization or splinting techniques depend upon the fracture location and the forces applied to the fracture site.[52] A good rule of thumb is that the joint above and below the fracture site should be immobilized. In no circumstance should the splint end at the same level as the fracture because the splint will act as a fulcrum and further disrupt the fracture.[52]

For immobilization purposes, the forelimb and hindlimb of the horse can be divided into four functional segments based on anatomy and biomechanical forces (Figure 12.2).[4,52]

Phalanges and Distal Metacarpus

The phalanges and distal metacarpus are probably the most common sites for fractures to occur in horses, and biomechanically they are dominated by the angle of the fetlock joint[4] with minimal medial/lateral forces. Therefore, proper splinting techniques should attempt to counteract the bending force at the fetlock. This is achieved by creating dorsal cortical alignment (Figure 12.3). A compression bandage combined with a dorsally placed splint or a fiberglass cast applied with the limb maintained in a straight line from the carpus to the hoof provides the optimal dorsal cortical alignment (Figure 12.3). Large diameter polyvinyl chloride (PVC) pipe cut into thirds along its length is a common material used for splints. The curve of the PVC pipe cradles the bandage and the material is lightweight. Minimal padding (light bandage) should be used beneath the splint because fracture fragments can move within a large bulky bandage, and the bulk can sometimes make it difficult for the horse to ambulate efficiently. The splint is applied to the dorsal aspect of the limb from the carpus to the hoof and secured with nonelastic tape. A bandage cast is another alternative—fiberglass casting material placed circumferentially over a lightly padded bandage striving to maintain dorsal cortical alignment. To facilitate application of the splint or bandage cast, an assistant should hold the forelimb proximal to the carpus and let the limb hang (Figure 12.4). Commercially available splints such as the Kimzey Leg Saver (Kimzey Welding Works, Woodland, CA; Figure 12.5) are also available and can be utilized for distal limb fractures.

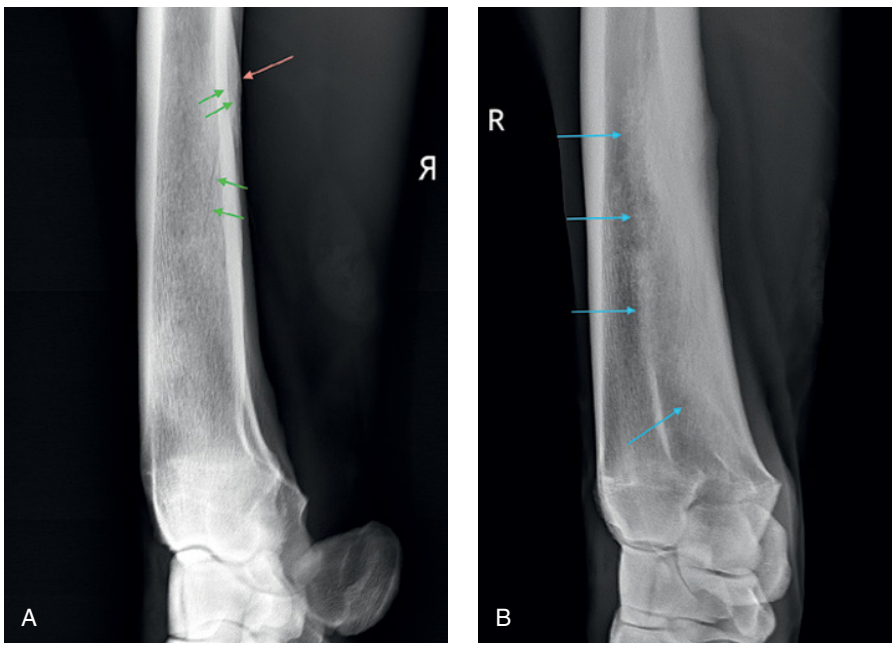

Figure 12.1. Incomplete, nondisplaced fracture of the radius. Fracture lines were not identified until nearly 4 weeks after the initial injury (hoof strike from another horse; red and green arrows in A). Most notable change was the amount of intramedullary sclerosis (blue arrows in B).

VetBooks.ir

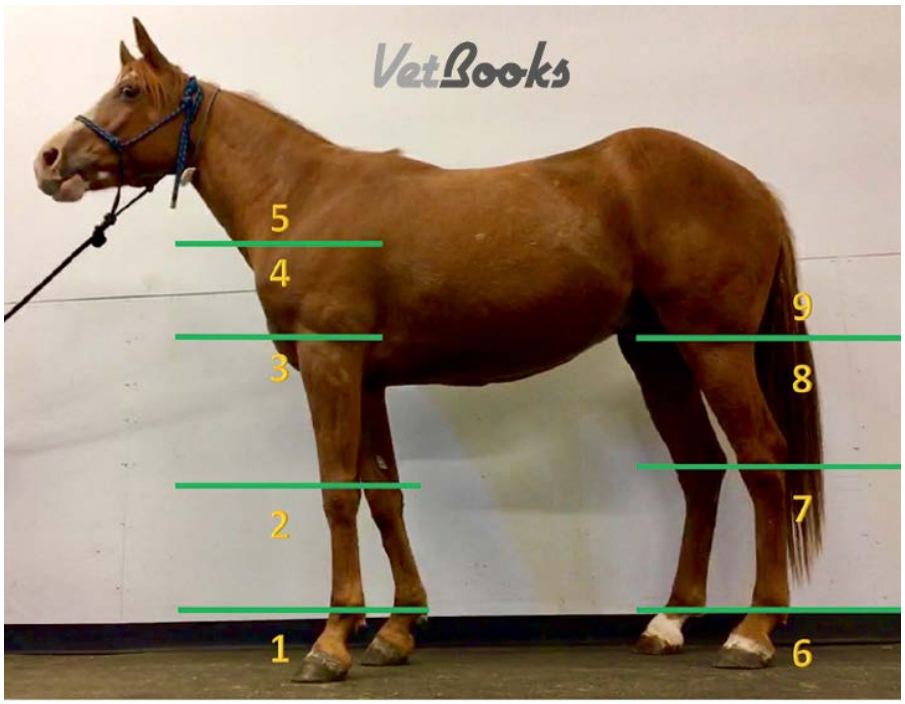

Figure 12.2. Functional divisions of the horse's limbs that can be used as a guide for appropriate application of external support to stabilize fractures for transport. They can be divided into five regions in the forelimb and four regions in the hindlimb. Forelimb: (1) dorsal splint, (2) compression bandage with caudal and lateral splint, (3) compression bandage with extended lateral splint, (4) caudal splint to the level of the elbow to lock the carpus in extension, (5) no immobilization necessary, (6) plantar splint, (7) compression bandage with plantar and lateral splint, (8) compression bandage with extended lateral splint, (9) no immobilization necessary.

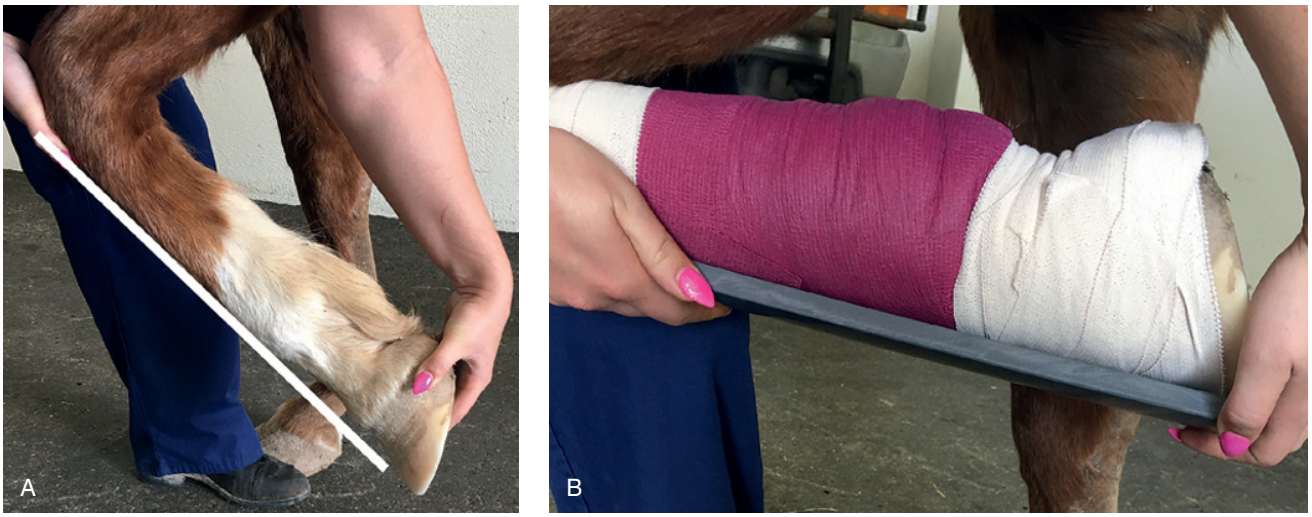

Figure 12.3. Dorsal cortical alignment is represented by the white line on the left image (A). This can be achieved with PCV placed on the dorsal aspect of the limb over a compression bandage (B). This stabilization is ideal for phalangeal fractures. The splint should be held in place with nonelastic tape.

Mid-forelimb (Mid-metacarpus to Distal Radius)

Fractures of this region include subluxation or luxation of the carpus as well as fractures of the proximal metacarpus and distal radius. Goals of immobilization are to establish a straight bony column, stabilize the joints above and below the fracture, and stabilize the limb in multiple planes. This requires two splints, one placed caudally and one placed laterally (Figure 12.6).[3,4] The underlying compression bandage should be applied in several layers, with each layer of padding (cotton) no more than 1 inch in thickness and compressed with elastic or brown gauze to increase its stiffness. Each layer is applied more tightly than the previous one.[14] The bandage should contain only enough padding to help reduce swelling in the limb and protect the limb from the splint material. These fractures have a high risk of displacing further during transportation if the bandage becomes loose due to excessive padding. The bandage and splints should extend from the ground to the elbow. The splints should be at 90° to each other to help prevent movement of the fracture during transport and should be tightly secured to the bandage using nonelastic white tape. If PVC material is not available, any lightweight, rigid material such as wood, aluminum, or flat steel may be used effectively for splinting. Fractures in this location have the advantage of having portions of the forelimb above and below the

VetBooks.ir

Figure 12.4. If a splint is not available, cast material may be placed over a compression bandage to create dorsal cortical alignment and immobilization of a distal limb fracture. An assistant can hold the limb at the back of the carpus and with the toe in extension in a non-weight-bearing position for application.

Figure 12.5. The Kimzey Leg Saver splint is a commercially available device used to stabilize phalangeal fractures or breakdown injuries in the distal limb of racehorses.

fracture site, which can facilitate fracture stabilization. However, because of the sparse soft tissue coverage of the metacarpal region, closed fractures in this location can easily become open if not adequately splinted. This is especially true for foals because their thin skin provides little resistance to bone penetration.

Middle and Proximal Radius

Fractures in the middle and proximal radius result in abduction of the limb distal to the fracture by the upper musculature of the forearm.[3,4] Abduction of the limb distal to the fracture can lead to the proximal fracture fragment penetrating the skin on the medial side of the antebrachium because of the lack of soft tissue coverage. Prevention of abduction of the distal limb is the goal when immobilizing fractures in this location. This is best achieved by applying a Robert-Jones bandage similar to that used with mid-forelimb fractures, but the lateral splint is extended up the lateral aspect of the shoulder, scapula, and chest and taped securely to the proximal forelimb at the level of the axilla. A wide board (15–20 cm) or metal rod appears to work better than PVC for this lateral splint because it can lay flat against the muscles of the upper limb, but PVC can also be used (Figure 12.7). The upper extension of the lateral splint should lie as tight against the shoulder and scapula as possible so that it prevents abduction of the distal limb during ambulation. A PVC splint that extends from the ground to the elbow should also be placed on the caudal aspect of the limb to provide additional stability of the fracture.

Proximal to the Elbow

The humerus, ulna, and scapula are well protected with muscles, which inherently stabilize and protect fractures of these bones. However, complete fractures of these bones disable the triceps muscle apparatus, making it impossible for the horse to fix the elbow in extension for weight-bearing. Restoring the triceps apparatus reduces the anxiety of affected animals and enables them to use the limb for balance during transport. A full-limb cotton bandage with a caudally applied PVC splint keeps the carpus extended and helps restore triceps muscle function (Figure 12.8). Some horses with ulna fractures bear considerable weight on the limb after splinting, but walking may be difficult. Not all fractures in these locations require stabilization. Foals may not have the upper forelimb strength to move the limb with a splint in place, and therefore a splint may be contraindicated. Caution should be taken when dealing with ulnar fractures to not end the caudal splint at the level of fracture as it can result in pressure over the sharp fracture fragments and the development of an open fracture.

VetBooks.ir

Figure 12.6. Placement for a caudal and lateral splint for a mid-forelimb fractures. Both splints should extend from the ground to the proximal radius/ulna. They can then be held in place by nonelastic tape or casting material.

Phalanges and Distal Metatarsus

Fractures in the distal hindlimb can be managed with a single splint, similarly to those in the forelimb except that the splint is best placed on the plantar surface of the limb. A splint/cast combination may be beneficial to provide more support, but a splint held in position with nonelastic tape should be sufficient for transport (Figure 12.9). Dorsally applied splints on the hindlimb appear to be less useful than in the forelimb. Due to the reciprocal apparatus, the distal limb is in flexion when non-weight-bearing, making it difficult to achieve true dorsal cortical alignment, and dorsally placed splints tend to break more readily. Also due to the reciprocal apparatus, application of a bandage cast in the hindlimb can be difficult because of inability to keep the limb steady and in proper alignment while the cast material hardens (Figure 12.10). The Kimzey Leg Saver splint may be used to stabilize fractures in this location, similar to the forelimb.

Middle and Proximal Metatarsus

A Robert-Jones bandage with PVC splints applied laterally and caudally using the calcaneus as a caudal extension of the metatarsus provides adequate support for fractures in this location.[3,4] The Robert-Jones bandage should be less extensive than in the forelimb because it is difficult to secure the splints to the limb if the bandage on the distal aspect of the metatarsus is too bulky. Robert-Jones bandages consist of multiple layers of padding each compressed with brown gauze or elastic tape, and each layer should be applied more tightly than the previous one.[14]

Tarsus and Tibia

Fractures in the tarsus and tibia are particularly difficult to adequately stabilize because of the reciprocal apparatus and its effect on joint motion in the tarsus and stifle.[3,4] Fractures in this location tend to collapse when the stifle flexes, and the tarsus remains in a fixed position. The main principle for stabilization is similar to that of the radius, which primarily involves preventing abduction of the distal aspect of the limb (Figure 12.11). There is very little muscle coverage of the medial aspect of the tibia, and this is the site that is prone to becoming open. To prevent abduction, a single laterally placed splint that is bent to follow the angulation of the limb and extends proximally above the stifle joint works well. The splint is most effective if it is bent back on itself to mirror the hindlimb contour back to the ground, creating a double splint. The splint is applied over a full-limb Robert-Jones bandage and is best made of lightweight metal such as aluminum (Figure 12.12) that can be bent into the proper position, similar to the lateral support of a Schroeder-Thomas splint. An alternative to the metal splint is a wide board (15–20 cm) that extends from the ground to the ilium and is applied to the lateral aspect of the bandage.

Transportation

Appropriate immobilization is very important in the management of fractures, but modes of transportation should be evaluated and discussed prior to splint application. Horses can still be ambulatory with distal limb splints, but often the splints required for more proximal fractures can make ambulation difficult and loading into a trailer even more difficult. Ideally, horses should be loaded into a trailer with a ramp to minimize the effort. When possible, horses should be traveled facing forward for hindlimb fractures and facing backward for forelimb fractures. This concept should be ignored if turning the horse around in the trailer will cause more manipulation of the fracture than to simply allow them to travel facing forward. The use of dividers is also recommended as the horse can brace against them.

MUSCULOSKELETAL WOUND MANAGEMENT

Horses are prone to deep lacerations of their distal limbs due to their flight response, kicking defense, and high speeds. Horses may jump sharp objects or fences or often pull excessively if their lower limb is trapped, inciting significant injury. These lacerations frequently involve tendons and ligaments as well as synovial structures. Early recognition of synovial involvement and/or tendon/ligament injury is paramount to the management of these cases.

Preventing Infection in Traumatic Wounds

The ideal treatment for infection is to prevent or limit infection in the first place. Lameness resulting from a traumatic injury is common, and the sequelae of infection can have a devastating consequence. The initial management of such injuries often determines the outcome. Limb wounds require a thorough examination to determine the structures involved and the degree of injury. Prior to invasive palpation, wounds should be clipped and cleaned in an aseptic manner. A sterile lubricant may be applied to the wound to prevent hair from getting into the wound while being clipped.

Povidone iodine or chlorhexidine-based scrubs remove most debris from the area, minimizing further contamination.[53] Copious lavage with a similar povidone iodine (0.1%) or chlorhexidine (0.05%) solution under moderate pressure (10–15 psi) removes bacteria but does not drive them into the damaged tissue; this is accomplished with a 35- or 60-mL syringe and an 18-gauge needle.[60]

Debridement can be done with a scalpel, removing superficial tissue until all notably contaminated or denuded tissue has been removed. Exposed bone usually needs superficial debridement as well (Figure 12.13). Debridement has been shown to be important in the management of traumatic wounds. Tissue that is contaminated beyond 10^5 microorganisms/g of tissue is likely to become infected.[18,44] Contamination with soil can result in a 25-fold greater infection rate,[42] and specific soil factors can result in as few as 100 microorganisms/g causing infection.[43] Once debrided, the wound can be explored with a sterile instrument such as a probe or with sterile gloved hands (Figure 12.14). Thorough exploration and a solid knowledge of anatomy will help determine the important structures involved.

TENDON AND LIGAMENT LACERATIONS

Clinical Signs

Complete severance of tendons of the distal limb may result in characteristic gait deficits. If the extensor tendons are severed, the lower foot may move more freely,

and the horse may intermittently knuckle forward at the fetlock due to inability to extend the digit during limb placement. Lacerations or rupture of the flexor tendons results in visible changes to limb conformation during weight-bearing (Figure 12.15). Loss of just the superficial digital flexor tendon (SDFT) usually causes the fetlock to drop with normal foot placement. Loss of the deep digital flexor tendon (DDFT) will result in elevation of the toe during weight-bearing (Figure 12.16). Complete severance of both the SDFT and DDFT will likely cause a hyperextension of the fetlock and the toe coming off the ground during limb placement. If the suspensory ligament is also severed, the fetlock drops almost to the ground. Lacerations of collateral ligaments and sesamoidean ligaments do not always result in a characteristic gait but can be detected during manipulation of the limb while non-weight-bearing. Horses are often not lame while weight-bearing with extensor tendon injuries.[31] More lameness is present with lacerated flexor tendons.[9] The degree of lameness for lacerated flexor tendons, and ligaments can be highly variable and can be dependent upon the extent of other injuries.

Diagnosis

Digital palpation of the wound can help reveal the extent of the laceration to the tendons and ligaments in many cases (Figure 12.17). Wounds should be prepared aseptically prior to digital exploration, and sterile gloves

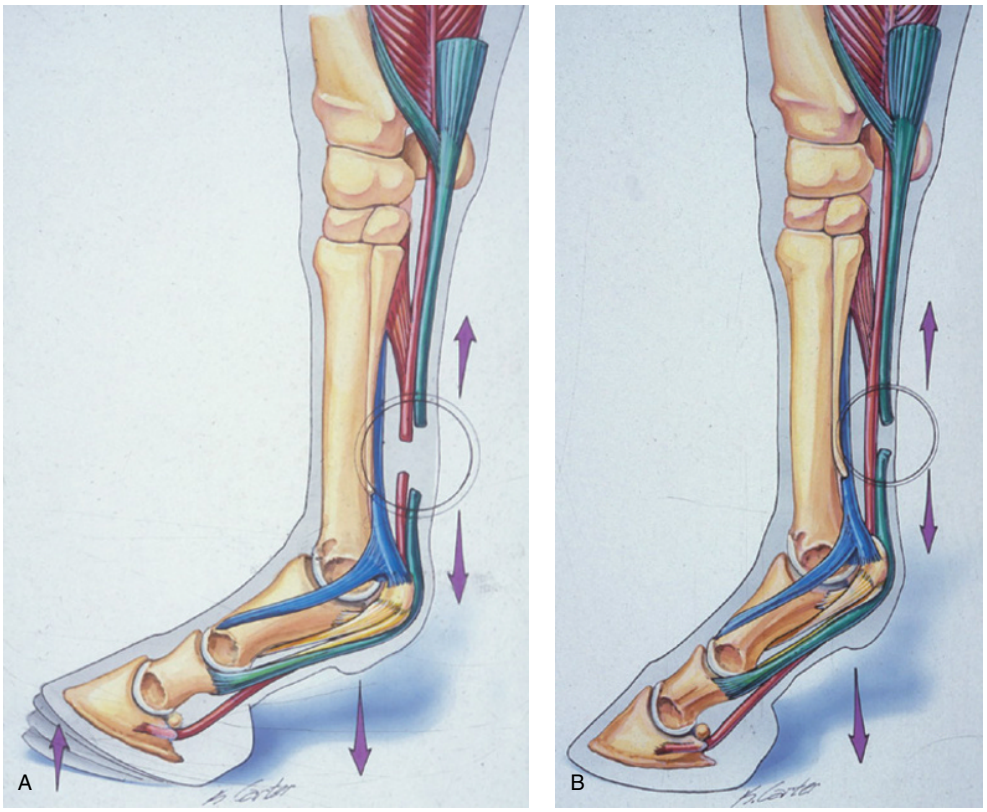

Figure 12.15. Illustration of the biomechanical effects of lacerations of both the SDFT and DDFT (A) and just the SDFT (B) in horses with flexor tendon lacerations. VetBooks.ir

should be worn. Care should be taken to not push foreign material deeper into the wound and to not further separate soft tissues, because vital structures such as an artery, tendon sheath, or joint could be damaged or entered. Extensor tendon injuries are often avulsion-type trauma with loss of skin over the dorsal aspect of the cannon bone. Secondary bone trauma with the development of surface sequestra of the cannon bone often accompanies these severe injuries (Figure 12.18).

Ligament lacerations are commonly accompanied by tendon lacerations. Rarely is a suspensory ligament or sesamoidean ligament lacerated without the overlying tendon also being affected. Lacerations of collateral ligaments can occur alone although they are often accompanied with a lacerated synovial structure. Manipulation of the joint in all directions may be necessary to determine if ligaments are damaged, and imaging (ultrasound or a stressed radiographic view of the joint) may be required to make the diagnosis. Discrete palpation determines whether bone has been exposed or if neighboring tendons are also lacerated. Ultrasound examination can help define partial ligament tears and possibly locate foreign material in the wound.

Treatment

Routine first aid management of all wounds is recommended initially. Immobilization of limbs with lacerated DDFT and SDFT to support the fetlock and prevent further injury should be performed similar as with fractures of the distal limb. This also applies to ruptured tendons and/or ligaments.

For complete extensor tendon lacerations, and if indicated by duration of injury and other criteria, the optimal approach is to reappose the tendon ends, close the wound, and provide support to the fetlock, such as a caudal splint to prevent knuckling, for at least the first 4–6 weeks of healing. This approach will result in the most rapid healing and return to function and best cosmetic outcome. However, many lacerations involving the extensor tendon cannot be closed due to the severity of the trauma, and reapposition of the extensor tendon ends is not required for successful outcome. Conservative management of the wound and extensor tendon laceration with second intention healing can result in complete return to athletic use. Weight-bearing can be permitted for extensor tendon lacerations, so splints, soft casts, or resin-reinforced bandages can suffice to provide fetlock support. The primary goal of immobilization is to prevent dorsal knuckling of the fetlock. Removal of sequestra from the dorsal cannon bone may need to be performed to permit healing in severe injuries.

In general, flexor tendon lacerations are a much more serious injury with greater implications regarding soundness than lacerations of the extensor tendons and are therefore more challenging to treat. For flexor tendon lacerations, the optimal approach is wound debridement, tendon apposition with suture, wound closure, and cast application for 6 weeks.[12] Double locking loop, 6-strand Savage, or the three-loop pulley suture patterns have been described for repair of the flexor tendons. Recent literature has found that the 6-strand Savage has improved strength and resistance when compared with the 3-loop pulley.[11] Occasionally the tendon ends cannot be reapposed for a variety of reasons. Jordana et al. found that tenorrhaphy did not influence the survival of cases or their return to use.[21] Wound debridement and skin closure can still be performed because the tendons will heal with gap healing, provided they are adequately immobilized with a half-limb cast. For wounds that cannot be closed, use of boots and immobilizing splints (Kimzey splint) can achieve acceptable results, but management of these wounds is much more difficult than if casts are used.[9] If the digital sheath is concurrently involved with the laceration, tenoscopic exploratory of the digital sheath or lavage of the sheath should be performed to improve the prognosis.[13] Closure of the tendon laceration together with the digital sheath is indicated in most cases unless gross contamination is present.

Antibiotic therapy is dictated by the extent and duration of contamination. Systemic antibiotics should be considered for all wounds. More intensive antibiotic therapies are strongly recommended in more involved cases. These antibiotic options are discussed in more detail later in the chapter when discussing treatment of contaminated synovial structures.

Prognosis for Tendon and Ligament Lacerations

Extensor tendon lacerations have a good to excellent prognosis (better than 70%)[31] for return to full function with minimal intervention. Complications include prolonged healing and recurrent treatment of wounds and excessive granulation tissue and scar. Horses that are left untreated or turned out without fetlock support can develop permanent flexural deformity of the fetlock.

Flexor tendon lacerations have a good prognosis for pasture or breeding soundness and a fair prognosis for athletic soundness. Foland et al. found that 59% of horses with flexor tendon lacerations returned to riding soundness and that 57% of horses with both SDFT and DDFT involvement returned to some level of riding.[12] Jordana et al. reported 55% of horses with tendon and/or ligament lacerations returned to work.[21] This was lowered significantly by the number of structures affected. Complications include restrictive fibrosis, infection, fetlock hyperextension, and chronic delayed healing due to tendon sheath involvement. Management of flexor tendon lacerations is an expensive proposition due to the long-term care and continual shoe support out to 6 months after surgery. Details on the surgical technique can be found in other texts.[9]

MUSCULOSKELETAL INFECTIONS

Clinical Signs

MSK infections often begin with a traumatic wound, although iatrogenic synovial sepsis following joint/tendon sheath/bursa injections can also occur. In the early hours after injury, wounds involving synovial structures typically do not result in significant lameness. Initial clinical signs are associated with the severity of the

VetBooks.ir

Figure 12.16. Characteristic elevation of the toe during weight-bearing following laceration or rupture of the deep digital flexor tendon.

wound and typically involve swelling, lameness associated with soft tissue and/or bone injury, and potentially hypovolemia due to blood loss. The onset of synovial sepsis coincides with significant worsening of lameness. Osteomyelitis will usually develop much later, but it should be considered with any wound that has bone involvement (Figure 12.19).

Figure 12.18. Sequestrum of the dorsal proximal third metatarsal bone. This radiograph was taken 6 weeks after a traumatic wound. The wound has since healed aside from a small draining tract. The radiopaque marker within a gauze sponge is seen over the site of the sequestrum. *Source*: Courtesy of Dr. Deb Straker.

Diagnosis

If synovial cavities are suspected to be involved, additional diagnostics such as radiography and ultrasonography may be necessary. This should be done prior to synoviocentesis whenever possible. Early introduction of a needle may result in gas gaining entry into the cavity, which potentially complicates a radiographic or ultrasonographic diagnosis. Synoviocentesis combined with cytological evaluation of the fluid will provide additional information regarding synovial involvement (Table 12.2). When performing synoviocentesis, the needle should be placed at a site remote from the wound using sterile technique to minimize the risk of iatrogenic contamination. Caution should be taken if a cellulitis is present. It is often advisable in these horses to bandage the limb and initiate antimicrobial therapy prior to performing synoviocentesis.

If a synovial sample cannot be obtained, sterile isotonic fluid can be injected into the joint to facilitate aspiration of fluid.[54] The urea concentration in the synovial fluid should be compared with that in the serum as this will determine the amount of dilution that occurred and aid in determining the relative synovial fluid parameters.[54] After aspirating synovial fluid for culture and cytological examination, the synovial structure should be distended with sterile fluid to determine if it communicates with the nearby wound.

VetBooks.ir

Traumatic wounds that involve a bony surface or chronic synovial sepsis are most likely to result in osteomyelitis or osteitis. Osteomyelitis refers to the inflammatory or infective process of the cortex and marrow components of bone.[17] If only cortical bone is infected, it is classified as osteitis.[17] Penetrating wound tracts that lead to bone should be treated aggressively. The presence of osteomyelitis/osteitis is significantly associated with nonsurvival in cases with synovial sepsis (Figure 12.20).[57,61] Radiography is commonly used to diagnose osteomyelitis/osteitis, but unfortunately, 30–50% of bone demineralization must occur before it can be observed on plain radiographs. This may require 14–21 days, resulting in very low sensitivity and a delayed diagnosis. magnetic resonance imaging (MRI) and scintigraphy are the modalities of choice for suspected cases of human osteomyelitis and septic arthritis and may also provide for an earlier diagnosis in horses.[20] Ultrasonography also can be effective in helping to diagnose osteomyelitis by imaging fluid pockets in and around the infected bone.[41]

Figure 12.19. This traumatic wound was associated with an open comminuted fracture of the fourth metatarsus. Wound debridement and lavage are important to prevent osteomyelitis in these horses. *Source*: Courtesy of Dr. Gary Baxter.

Treatment

Acute wounds involving synovial structures, including joints, bursae, and tendon sheaths, often directly introduce bacteria and other contaminants into the synovial space. The clinician's primary concern is removing the bacteria from the space before infection can become established. Early recognition and treatment of a synovial penetrating wound are imperative to reduce the risk of developing septic arthritis. One study reported that horses treated within 24 hours had a lower risk of developing septic arthritis compared with those treated after 24 hours.[16] Wereszka et al.[58] found that horses with septic tenosynovitis were significantly more likely to survive if treated during the first day after clinical signs of synovial infection were observed than horses that did not receive treatment within 10 days after clinical signs of infection appeared. However, more recent publications reported that the duration of time until treatment may not affect survival[33,57] or the ability to return to athletic function.[57] Logically, it would still be advised that the quicker or earlier these cases are treated, the better the success (Figure 12.21).

Any wound that communicates with a synovial structure or bone should be considered contaminated. Therefore, early treatment with antimicrobials may help decrease the progression to synovial sepsis and/or osteomyelitis/osteitis. Antimicrobials can be administered parenterally, regionally, locally, or a combination of all. Additional therapies for preventing infection in a synovial cavity include some form of synovial lavage, drainage or endoscopic exploration, and wound debridement with or without closure. Small wounds with minimal contamination can be managed conservatively, but the clinical response should be monitored closely, and any deterioration should be met with more aggressive treatment.

Systemic antibiotics can be initiated for any infected wound, regardless of the structures, to provide a broad spectrum of activity against common microbes. These antibiotics are maintained until sensitivity of the cultured organism is obtained or concerns about sepsis have diminished. Most commonly, a combination of penicillin (22,000 IU/kg every 6 hours IV, every 12 hours

Table 12.2. Synovial fluid parameters used to aid diagnosis of synovial sepsis.

IM) and gentamicin (6.6 mg/kg every 24 hours IV) is used initially. Oral antibiotics can also be utilized (trimethoprim-sulfa, 15–30 mg/kg orally every 12 hours; doxycycline 10 mg/kg orally every 12 hours).

Enrofloxacin is relatively commonly used when indicated; it is broad spectrum and often effective when aminoglycosides are ineffective. However, there is concern that articular cartilage damage may occur with its use in foals and younger horses.[19] Chloramphenicol also has a wide spectrum of activity and has good tissue penetration. The concern associated with this drug is the risk to human health due to the possibility of aplastic anemia in exposed people.[5] Vancomycin has been used successfully in cases of methicillin-resistant staphylococcal infections.[38] Due to concerns about antimicrobial resistance, it is only recommended to use this drug when culture and sensitivity results warrant its use.

If osteomyelitis is suspected, aggressive debridement is warranted. The infected bone should be exposed, curetted, and effectively removed. Osteomyelitis can be challenging to treat and often requires a multifaceted antimicrobial plan.

For both synovial sepsis and osteomyelitis, systemic antibiotic therapy can be supported with regional antibiotics. Regional perfusion by intravenous or intraosseous techniques can be utilized. In some cases, when the osteomyelitis is closely associated with a joint, such as in some cases of septic physitis, it may be prudent to treat the joint with IA antibiotics as well. Research has shown that IA administration of antibiotics provides adequate concentrations in the subchondral bone.[59] Antibiotic-impregnated materials such as polymethyl methacrylate (PMMA) or sponges will provide prolonged release of antibiotics locally.

For wounds that are obviously infected but do not appear to involve bone or synovial structures, principles similar to preventing infection of a wound are followed. The wound can be cleaned and then debrided. Once the extent and nature of the wound has been established, a decision can be made to allow for secondary intentional healing or to close the wound primarily. In general, infected wounds are chronic and primary closure usually is not attempted. Instead, once adequate cleaning and debridement of the wound have been performed, the wound should be bandaged with an appropriate dressing.

Regional Antimicrobial Delivery Systems

Intrasynovial Antimicrobials

The administration of intrasynovial antibiotics is a cost-effective way to attain high concentrations of drugs (above minimum inhibitory concentration [MIC] values) in synovial fluid for at least 24 hours. Antimicrobials commonly are injected into a synovial cavity on a daily basis, or they can be deposited after a synovial lavage. They also can be delivered to the joint using a constant infusion system.[25] Initial studies using a single dose of 150 mg of gentamicin provided concentrations above the

VetBooks.ir

MIC for common pathogens for 24 hours.[27] A 150-mg dose of ceftiofur also has been shown to provide adequate concentrations for more than 24 hours.[32]

Amikacin has recently become one of the most widely used intrasynovial antibiotics; it has also been shown to be effective against a broader spectrum of bacteria than gentamicin and has concentrations above MIC values for common pathogens for up to 34 hours.[51] A dose of 250–500 mg is commonly administered. Other antibiotics that have been used are cefazolin, timentin, methicillin, and imipenem cilastatin.[2,48]

Regional Limb Perfusions

Regional limb perfusions have become the accepted method of providing increased tissue concentrations of antibiotics for the treatment of synovial and osseous infection, as well as for preventing the establishment of infection. The two main methods of delivery are intravenous (IVRLP) or intraosseous (IORLP). Both involve the application of a tourniquet proximal to the infected tissues, and the antibiotic is infused distal to the tourniquet (Figure 12.22B). A distal tourniquet should also be utilized if the infected tissues are proximal on the limb.[50] Several studies have shown that antimicrobial concentrations reach up to 100 times the MIC values for common pathogens.[6,35,40,46,47,59]

The technique is simple to perform and can be done under field conditions in the standing sedated horse or under general anesthesia. A pneumatic tourniquet is preferentially used (Figure 12.22A), and wide rubber tourniquets (i.e. Eschmarch) are acceptable, but narrow rubber tubing is not.[10,26] To assist in applying pressure to the digital vessels in the standing horse, gauze rolls can be applied against these vessels under the tourniquet. The perfusate should include an antibiotic diluted in a balanced polyionic solution. The most common antibiotic used is amikacin; also used are gentamicin, penicillin, ampicillin, cephalosporins, enrofloxacin, and vancomycin. Doses vary considerably, but in most clinical situations 1000–2000 mg of amikacin is used in adult horses diluted to a volume of 30–60 mL.[8,24,37] A smaller volume (30 mL) is recommended in foals.[22] For IVRLP, a 20- to 25-gauge butterfly catheter is used, the vein accessed, and the solution slowly infused. Application of the tourniquet for 15 minutes was found to be adequate to achieve maximum concentrations of amikacin in the coffin joint following IVRLP.[24] One study using a contrast medium showed maximal dye uptake in the soft tissues at 30 minutes.[23]

For intraosseous perfusion, a hole is drilled in the cortical bone of the third metacarpal/metatarsal bone for distal limb treatments. A 3.2- to 5.5-mm cannulated bone

Figure 12.22. Intravenous regional limb perfusion using a pneumatic tourniquet. The tourniquet is placed above the site of the lesion and a vessel is selected to infuse the antimicrobials. (A) The palmar vein. (B) The saphenous vein. Rolls of gauze can be applied over the vessels for extra pressure; these can be seen under the tourniquet in figures A and B. *Source*: Courtesy of Dr. Jeremy Hubert.

VetBooks.ir

screw with a Luer lock head is placed in the drilled and tapped hole. Alternatively, the end of a catheter extension set fits securely into the drilled hole. The remainder of the process is very similar: a tourniquet is placed proximal to the third metacarpal/metatarsal bone. The infusate, of similar volume and concentration as with IVRLP, is slowly injected avoiding excess pressure. The tourniquet should be left in place for 20–30 minutes following the injection. Intraosseous perfusion may be favored over IVRLP in cases that lack easy venous access or the presence of osteomyelitis. Data suggests osteomyelitic lesions may respond better to intraosseous perfusion.[29]

Antibiotic-Impregnated Materials

Antibiotics can be effectively delivered by slow release from impregnated materials. These products are left *in situ* to release the drug over an extended period of time, resulting in high local tissue concentrations. The most common depot material used for local antibiotic delivery in horses is PMMA, or bone cement.[37] It can be formed into beads, and the beads are incorporated in a strand of nonabsorbable material for ease of later removal, although they can be left in place unless they become a source of clinical concern themselves. Elution rates of incorporated antibiotics are highly variable and depend upon a number of factors. Based on the most common pathogens encountered in equine orthopedic infection, 0.5–1 g of amikacin added to 10 g of PMMA and made into smaller cylindrical beads provides the ideal vehicle for drug elution in most clinical scenarios.

SPECIFIC TREATMENT STRATEGIES FOR MUSCULOSKELETAL INFECTIONS

Lavage and Drainage for Synovial Cavities

Through-and-Through Needle Lavage

A simple, quick way to lavage a synovial cavity is to place large-bore needles (14 or 16 g) into the joint at multiple sites and lavage a solution such as normal saline solution through the joint, alternating the ingress needle (Figure 12.23).[1] The horse must remain sedated and the area desensitized to facilitate the procedure. Fourteen-gauge needles are placed into the cavity at appropriate locations, and a fluid line is attached under a pressure system. A recent cadaver study using microspheres found that the greatest recovery of microspheres occurred with the first liter of lavage fluid through the tarsocrural joint.[28] This would suggest that the volume of fluid used is less important than the number or placement of needles/portals. A solution of 10% DMSO (110 mL in a 1-L bag of normal saline) can also be considered. Though a greater recovery of microspheres was found following needle lavage than following arthroscopic lavage,[28] needle lavage is usually not effective in more chronic infections because clots of fibrin and proliferative synovium block the needles. Furthermore, needle lavage cannot be used to assess further damage to the joint and is likely best suited for acute simple punctures of synovial cavities.[45]

Figure 12.23. Through-and-through needle joint lavage is performed using hypodermic needles. The ingress needles are alternated during the lavage, and all synovial pouches should be lavaged if possible.

Arthroscopic/Endoscopic Lavage

Infected synovial cavities are usually best lavaged and debrided through arthroscopic/endoscopic visualization. Foreign material, fibrin, and bone fragmentation if present can be seen and removed, and the joint itself can be debrided accordingly. A more accurate prognosis can also be provided.[61] Lesions to the cartilage, tendons, and bone can be identified and treated appropriately. Partial synovectomy can be performed to aid in debridement of the joint by allowing better visualization of the entire space. Most joints, bursae, and tendon sheaths are accessible for an arthroscopic/endoscopic lavage, and this is the preferential treatment for any synovial injury that is more than 24 hours old.[2] Wounds that have large puncture holes are not suitable for this technique, however, because this precludes adequate distension and visualization of the joint.

After arthroscopic lavage, the arthroscopic portals can be left unsutured to allow for continued passive drainage and repeat lavage in the standing horse. One clinical study showed good results using open wound drainage.[49] It may be especially helpful in chronic synovial wounds. The portals are allowed to close by second intention, but close attention to bandaging is critical.

A variation to this technique is to place an ingress system within the synovial cavity with a smaller egress arthrotomy. This permits repeated lavage and instillation of antimicrobials into the cavity with continued passive drainage. This technique is commonly used for tendon sheath infections. Soft fenestrated drains, such as a Jackson Pratt drain (Jackson Pratt Hubless, American Hospital Supply, Chicago), are placed within a cavity with the drain distad and sutured in place. This same system can be used for constant infusion systems of antimicrobials.[30] A balloon reservoir containing antimicrobials can be attached to the system, allowing a constant infusion.[25] One concern of this system is the potential

VetBooks.ir

for development of a superimposed infection if the system is not kept very clean with sterile bandaging and skin preparations.

Prognosis for Musculoskeletal Infections

With appropriate treatment, horses with MSK infections have a good prognosis. Cousty et al.[7] reported 90.3% of horses (foals and adults) with septic synovial structures had a favorable outcome (no lameness, mild synovial effusion, and return to function). Another report found 84% of horses with infection of a synovial structure survived to discharge and 54% returned to athletic function.[57] Factors that had a negative impact on prognosis were increased intrasynovial concentration of TP at the time of admission[33] and positive bacterial culture of synovial fluid.[56] Radiological evidence of osseous involvement in cases of synovial sepsis has been associated with a poorer long-term outcome.[55]

THE POORLY PERFORMING HORSE

Elizabeth J. Davidson

VetBooks.ir

INTRODUCTION

Evaluation of the poor performer is one of the most challenging aspects facing the equine clinician. Because all body systems in the horse must function in a coordinated and harmonious way for good athletic performance, it bears to reason that the number of potential performance limiting abnormalities is extensive. When clinical signs are obvious, for example, a loud abnormal respiratory noise during exercise, selecting the appropriate diagnostic tools to accurately identify the causative abnormality is straightforward. However, many poorly performing horses present with subtle, inconsistent abnormalities only during exercise, which greatly complicates the diagnostic process.

The type of clinical complaints often reflects the horse's specific equestrian sport.[2,3] For example, a Thoroughbred racehorse may present for lugging out down the homestretch, whereas a Warmblood dressage horse may fall out of rhythm during canter pirouettes. Although it is not necessary for the examining veterinarian to be an accomplished rider or trainer, a solid working knowledge of the horse's discipline is important. It can be difficult to assess a horse with poor-quality extended trot without prior knowledge of what a good extended trot should look like. Additional examples of complaints based on athletic endeavors are given in Table 12.3.[2,3]

Evaluation of these difficult cases is time consuming and requires comprehensive assessment including an accurate history, a detailed clinical examination, complementary diagnostic tools, and specialized techniques.

SIGNALMENT AND HISTORY

Poor performance evaluation starts with obtaining the horse's signalment including the horse's occupation. Some underlying conditions are more common in young horses, while others are more common in older horses. For example, developmental bone diseases such as osteochondrosis frequently hinder young horse athleticism, while wear-and-tear conditions such as degenerative joint disease afflict the older horse. Other conditions such as exercise-induced pulmonary hemorrhage are associated with exercise intensity and affect a variety of horse breeds and ages. The horse's occupation may also influence injury type. For example, stress fractures are common in the racing performance horse, while hindlimb suspensory desmitis is common in dressage horses. It is also important to recognize that to some extent the horse's signalment affects its innate ability to perform and lack of ability is often misinterpreted as poor performance by owners/trainers. In older horses, age-related physiological changes decrease their athletic capacity. Their exercising VO_2max is approximately 25% less than the younger horse[8]; old horses just cannot run as fast as young horses. In the untested young horse, a lack of talent from physical or mental incapacity may be misperceived as poor performance; good breeding does not ensure good performance. The horse's breed and occupation are also important factors in performance. Certain breed characteristics are more desirable for specific equestrian events. For example, Quarter horses typically have a shorter length of stride combined with low head carriage, which makes them well suited for western performance; however, these characteristics are less suitable for upper-level dressage work. When there is a mismatch between horse type and its intended use, the owner's complaint of poor performance may be due to the horse's natural inability to perform desired gait qualities based on its conformation rather than an underlying medical condition, i.e. the wrong horse for the job.

The value in obtaining a thorough and accurate history cannot be overstated. This includes not only a detailed description of presenting complaint(s) and the duration but also past and present performance history. Information from the owner/trainer can provide valuable insight into the potential abnormalities affecting their horse since it relays the magnitude of the problem(s) and whether the horse was ever a good performer. Response to medications and/or exercise modifications and previous lameness are also important historical data. If possible, the veterinarian should determine the answers to the following questions:

1. What is the training schedule and have there been changes? Rapid increases in training intensity may be "too much too soon." For example, the horse being reintroduced to exercise after lay-up for injury may require additional time for sufficient healing or be suffering from physical fatigue due to lack of fitness. Young and/or unproven athletic horses that are objecting to recent increases may have reached their mental or physical limit.
2. Has there been a traumatic event? Recent falls or trailer accident may indicate an underlying musculoskeletal injury.
3. Under what circumstances does the problem occur? Are there consistent factors that are more likely to induce the complaint? The owner should try to determine exactly when the problem occurs and if it is related to a specific reason. For example, the horse trips during downward transition from canter to trot.
4. Is the problem consistent? One of the biggest obstacles when evaluating the poor performer is the inability to reliably reproduce the abnormal clinical signs. This is especially true when the inciting factors are unknown or the owner has empirically rested the horse prior to veterinary evaluation. Ideally, the horse should be fit and abnormalities consistent prior to evaluation.

Table 12.3. Types of poor performance problems.[2,3]

Horse occupation	Clinical problems	Potential cause(s)
Jumpers (hunters, eventers, show jumpers)	Refuses to jump and/or knocks down rails	MS pain or rider error
	Drifts to one side over fences	MS pain, lameness
	Prefers to land on 1 lead	FL lameness, less commonly HL lameness
	Switching leads in the hind end	HL lameness or occasionally neurologic
	Takes a small or ½ canter stride immediately prior to fence ("chips in")	MS pain or rider error
	Rushes fences	MS pain, ±behavioral in anxious horses
	Switches lead in between or immediately prior to fence	HL lameness or rider miscue
	Difficulty with related distances between combination fences	MS pain
	Loss/lack of power	Bilateral HL lameness or sacroiliac pain
	Change in jumping style, usually loss of bascule or jumps flat	Back pain, FL lameness, HL lameness, or combination
Team roping	**Header**	
	Lunges across arena when pulling the steer for heeler to rope	HL lameness, such as distal hock pain
	Acts up in roping box (rears, spins, looks away from steer)	MS pain or behavioral if the horse is tired and has had too many steers roped on him
	Refuses to run fast to the steer	Bilateral FL or HL lameness
	Heeler	
	Refuses to stay in stop position and/or bounces out of stop position	HL lameness such as distal tarsal joint pain
	Stops at an angle instead of square to the steer	FL lameness
	Poor turning after header ropes the steer horns	MS pain
Tie-down and breakaway	Does not stay in the stop or quits working the rope	MS pain, ±HL pain
	Drifts to the side, backs up at an angle after stopping	If the horse drifts right, left HL MS pain
	Decreased running speed	FL lameness
Barrel racing	Runs past the first barrel or takes wide turns	FL lameness
	Decreased speed	MS pain or EIPH
	Refuses to enter arena or acts up (rears, spins)	MS pain or behavioral
Cutting	Does not stay down when stopping or changing directions to mirror cow movement	HL pain such as distal hock joint or medial femorotibial joint pain
	Difficult moving to the right or the left	MS pain; desmitis, sacroiliac pain, and/or thoracolumbar myositis
Dressage	Resists or kicks out at rider aids	Usually MS pain
	Behind the bit	Bilateral limb lameness or bit problems
	Lack of impulsion	HL lameness or sacroiliac pain
	Open mouth, teeth grinding	MS pain or gastric ulcers
	Inability to perform medium or extended trot, may break into canter	FL or HL lameness
	Difficult for lateral movements	FL or HL lameness
	Becomes disunited at the canter	HL lameness or neurological disease or lack of fitness
	Late flying lead changes or difficult changing leads	HL lameness
	Heavy on one rein, crookedness, or reluctance to take even bit contact	FL lameness
	Bucking, rearing, bolting	MS pain, either lameness or back/sacroiliac or both
	Saddle slip	HL lameness
Reining	Bouncing, sideways, or rough stops	HL lameness such as distal tarsal pain or proximal suspensory
	Backing sideways	MS pain
	Choppy, frantic circles	FL or HL lameness
	Over bent when circling	MS pain
	Late or early lead changes	HL lameness
	Spins off center, loss of pivot foot position	HL lameness
	Does not pivot on hind end in rollbacks	HL lameness
	Wrings tail, flips head, mouthing the bit	Lameness or back pain
Endurance	Shortened or choppy gait on hard ground	Sore feet or coronitis or traumatic laminitis
	Stiff or rigid across the back	Bilateral lameness or back pain or exertional myopathy
	Easily fatigued	Chronic lameness or lack of fitness or respiratory disease
	Unbalanced gaits	MS pain

VetBooks.ir

VetBooks.ir

Table 12.3. (Continued)

Horse occupation	Clinical problems	Potential cause(s)
Racehorse: Thoroughbred	Lug in or out, especially during final stretch	Lameness
	Decline in speed	Lameness, respiratory, or cardiac abnormalities
	Does not cool out normally	Chronic lameness or respiratory disease
	Plaiting (hindlimbs travel close together)	HL lameness commonly upper limb
	Stiff hindlimb gait	HL lameness or back pain or both
	Not using the hindlimbs or weak behind or slipping/falling out behind	Lameness or neurologic deficits
	Shorts choppy trot	Bilateral lameness
	Gait improves with exercise	Bilateral lameness such as distal hock pain
Racehorse: Standardbred	Drifts in or out	Lameness, most horses bear away from pain site
	Decline in last quarter mile speed	MS pain or respiratory disorder or atrial fibrillation
	Makes breaks in gait	MS pain
	Interference	Compensatory limb lameness
	Will not take a hold of the bit	Bilateral lameness or fatigue
	Worse on turns	Carpal, fetlock, or stifle lameness
	Off when jogging but improved when racing	FL pain such as carpal lameness
	Stiffness and soreness when walking to the track	Bilateral FL or HL lameness

MS = musculoskeletal, FL = forelimb, HL = hindlimb.

5. What is the current management of the horse? Have there been changes? Modification in the horse's diet such as switching to a higher protein feed or from grass to alfalfa may impact its performance especially in high strung horses. Older horses with low-grade chronic osteoarthritis might be less tolerant of long periods of stall confinement.
6. Has the horse received any medications? If so, have the clinical signs changed? Improvement in performance with nonsteroidal anti-inflammatory therapy, such as phenylbutazone (2.2 mg/kg) twice a day for 7–14 days, is strong indication that the problem is pain related. This information helps to rule out behavioral or other non-orthopedic issues.
7. Has an alternative rider been tried? Changes in performance may be related to the rider's skill. Professional riders may be able to improve the overall quality of the horse's performance, while less experienced riders may be unable to consistently give the horse the proper rider commands or miscue or be unable to navigate specific patterns or jumping courses with proficiency. Unbalanced riders or heavy riders may induce hindlimb and/or back problems.
8. Have there been recent tack changes? Horses may object to a poor fitting saddle or saddle pad. A new bit or mouthpiece may be too harsh for the individual horse's mouth.
9. Has the horse ever performed well? This is key information when trying to sort out if a horse simply lacks physical and mental capacity for its intended occupation. This is a common scenario with owners that have a limited budget and buy young untrained or minimally trained horses or off-the-track Thoroughbreds because they are inexpensive. Despite the horse's potential based on breeding or conformation, unproven performers may not be able to live up to their owner's expectations.

CLINICAL EXAMINATION

The most common cause of poor performance in the athletic horse is musculoskeletal injury. Although overt lameness is easily recognized and an accepted cause for poor performance, mild or subtle lameness is often overlooked or not identified as a potential cause of decreased performance by their owners. In fact, a high proportion of "owner-sound" horses are lame when assessed by a skilled lameness diagnostician.[5,7] Therefore, comprehensive orthopedic evaluation is recommended in any poorly performing horse even without a history of lameness.

Examination starts with thorough physical examination including inspection of body for symmetry (or asymmetry), limb palpation, assessment of hoof conformation and horseshoe, static joint flexion testing, and palpation of the horse's topline. Gait assessment, i.e. the lameness examination, should be performed in a systemic manner preferably with the horse exercising on hard and soft surfaces. Subtle lameness may be more apparent on a specific surface or in small tight circles. This is particularly important for the horse with bilateral limb lameness since they often appear to be sound in straight lines.

Assessment of the horse's gaits while lunging at the walk, trot, and canter is also indicated. Head/neck position, overall body flexibility, willingness to exercise, and balance of gaits should be keenly observed. Low-grade musculoskeletal pain often manifests as subtle uneven gait or a preferred gait in one direction. Horses with cervical pain may preferentially exercise with its head/neck tilted to one side or hold the neck in a straightforward neutral position with limited bend at the poll. Horses with mild hindlimb lameness may canter with its hind end to the inside or outside of the circle, usually drifting away from the lame limb. Horses with bilateral hindlimb lameness and/or sacroiliac may exhibit overall lack of impulsion, stiff/stilted joint movement when

VetBooks.ir

cantering, or simultaneous hindlimb push off at the canter ("bunny hopping"). Assessment of gait change after implementation of tack can also be helpful. Fit of the saddle and bridle and their suitability can be assessed. Systematic application of one or more pieces of tack, side reins at various degrees of tension, or weighted surcingle may induce axial skeletal pain and/or exacerbate lameness.

Since many poor performance abnormalities are only apparent or exacerbated with a rider, the next step is the ridden evaluation. This is particularly true in sport horses when the abnormalities occur only during specific movements, sport-specific gaits, and/or changes of pace such as canter-to-trot transitions. In these horses, ridden exercise is critical. Traditionally, gait abnormalities noted with the application of a saddle and rider have been attributed to back pain. Affected horse may exhibit shortened length of stride, lack of hindlimb impulsion, reluctance to work, and/or a stiff back. However, these clinical signs are not pathognomonic for back pain. Lame horses, especially those with bilateral hindlimb lameness, also exhibit the same abnormal gait characteristics. Lame horses adapt their gaits by decreasing extension of the thoracolumbar-sacral region.[6] This resultant trunk stiffness is often perceived as back pain by the rider even though the underlying pain and decreased back flexibility are due to limb lameness. Nervous or anxious horses may also exhibit short choppy gaits and stiffen or tense their backs until they are more comfortable with their surroundings.

The addition of a rider's weight increases the load applied to the horse's limbs, which many explain why many horses with subtle lameness, especially hindlimb lameness, are only visibly apparent when ridden.[1] Complaints of horses being more comfortable when trotting in one direction or posting on one diagonal may be associated with unilateral hindlimb lameness. Peak forces are higher on the sitting trot diagonal compared with the rising trot diagonal,[9] and hindlimb lameness is often worse when the rider sits on the diagonal of the lame leg.[4] In addition to uneven load stresses on the limbs, rising trot also creates asymmetrical stresses on the back. Increased lameness and/or back stiffness is frequently more obvious during sitting trot vs. trotting in the jumping position. Horses with back pain or bilateral hindlimb lameness may be resistant to collected movements or other maneuvers that require the rider to sit deeply in the saddle.

Based on what the owner feels when riding, they often formulate assumptions regarding the underlying cause of the horse's clinical signs. However, rider preconceptions should be interpreted cautiously since they may be incorrect. For example, difficulty bending correctly in a circle or the horse being heavy in the bridle is often perceived as neck pain by the rider. Although horses with cervical pain can exhibit these abnormalities, more often these gait abnormalities are due to forelimb lameness. In response to pain, horses with mild forelimb lameness will shift their head and neck to one side prior to overt limping and obvious head/neck nod. For riders, this uneven head and neck position results in increased rein pressure or heaviness in one hand. Horses with mild bilateral symmetrical forelimb lameness may feel like they are "heavy on the forehand" to the rider. Saddle slip where the saddle consistently slips to one side of the horse back has been blamed on ill-fitting saddles; however, current research indicates that lameness influences the presence of saddle slip, with most saddles slipped to the side of the lame hindlimb.[3,7] In these horses, comprehensive evaluation including keen observation by the attending veterinary is paramount to distinguish inciting causes from their resultant gait abnormality.

DIAGNOSTICS

Diagnostic analgesia can help determine if the horse's poor performance is due to musculoskeletal pain vs. behavioral, training, or other problems. In addition, nerve and joint blocks can elucidate the authentic site of underlying pain. Neck, back, and pelvic abnormalities are commonly incriminated by their riders; however, the presenting clinical signs in these horses such as body stiffness, resistance to rider aids, and unwillingness to bend are also exhibited in horses with limb lameness. In these horses, resolution of the abnormal gait following palmar digital analgesia is definitive evidence that the clinical signs are due to foot pain and not due to axial skeleton pain. In horses with bilateral symmetrical lameness, simultaneous blocking of both limbs may be diagnostic. For example, in Thoroughbred racehorse with short choppy hindlimb gait, blocking the distal plantar metatarsal nerves in both hindlimbs may be indicative of plantar osteochondral disease of the distal third metatarsus. Alternatively, response to joint therapy may be used for diagnosis. However, not all horses with painful joints will respond favorably to intra-articular medications, and limited or no improvement in clinical signs does not necessarily eliminate those sites as the source of problem.

Comprehensive nuclear scintigraphic evaluation can be beneficial in the poor performer. It is particularly useful in the racehorse with intermittent lameness, appeared to be "sore all over," and those with mild bilateral gait abnormalities. Common abnormalities include distal palmar/plantar fetlock pathology, bilateral upper limb stress fractures, and pelvic fractures. Scintigraphic imaging in riding horses may also be a valuable diagnostic aid. Axial skeletal disease, sacroiliac abnormalities, and rib lesions can be identified with this modality. Albeit frustrating, a "negative" bone scan does not necessarily indicate the horse does not have a musculoskeletal problem. Horses with stifle synovitis and soft tissue injuries such as proximal suspensory desmitis frequently do not have associated areas of increased radiopharmaceutical uptake.

There are many other reasons for a horse to experience decline in performance, and additional investigations may be necessary. Subtle neurological problems can have a dramatic effect on gait. For horses that trip or exhibit disunited gaits or incoordination, a complete neurological evaluation is indicated including cervical imaging and cerebrospinal fluid analysis. Testing for muscle conditions such as polysaccharide storage myopathy or exertional rhabdomyolysis may also be beneficial. Abnormalities of the cardiac and respiratory systems are also common in poor performers. Previously

VetBooks.ir

restricted to treadmill evaluation, upper airway endoscopy and telemetric electrocardiogram can be readily performed in the field, a considerable advantage for the riding horse. Numerous other cytological, serological, and metabolic testing may also be necessary.

TREATMENT

After diagnosis(es) has(have) been established, appropriate treatment strategies can be employed. Given the magnitude of potential causes of poor performance, concerted and exhaustive efforts in the evaluation and diagnostic process may be necessary for diagnosis. However challenging, an accurate diagnosis is paramount since the best therapeutic practices are targeted at the causative underlying injury site(s). Whole horse treatments such as repeated or frequent systemic anti-inflammatory treatment and indiscriminate joint injections should be avoided since they may prolong diagnosis, resulting in further deterioration of injury and decreased likelihood of return to performance.

In summary, the poorly performing horse is a diagnostic and time-consuming challenge. These horses often require a comprehensive multisystem evaluation. Musculoskeletal abnormalities prevail, and most horses that are lame are often sore in more than one limb and/or have axial skeleton pain. In the riding horse, any part of the horse–rider–saddle combination can be problematic and should be investigated thoroughly. Some horses do not have underlying medical abnormalities and simply lack the physical ability to achieve owner's expectation for desired athletic events. Recognition of the underlying cause(s) of poor performance is crucial for successful management and return to athletic function.

EVALUATION OF PROPER SADDLE FIT

Kevin K. Haussler

VetBooks.ir

INTRODUCTION

Proper saddle fit and use is a critical component of optimum athletic performance and the prevention of back pain or discomfort in horses. Unfortunately, it is not always clear what is meant by "good saddle fit," and objective parameters for assessing saddle fit and function during dynamic activities are lacking and often difficult.[2] In an English study of sport horses, 18% had poor fitting saddles defined to be in uneven panel contact, and 33% had unbalanced saddles with either cranial or caudal angulation of the tree.[4] Even for qualified saddle fitters, agreement has been reported to only be fair (kappa = 0.32) for measures of overall saddle fit among members of the Society of Master Saddlers.[5] Saddles are often fit for the seat of the rider; however, the correct width or length of the saddle for a particular horse, adequate padding, and stirrup attachment or positioning, which influence a rider's leg positioning and balance on the horse, are often overlooked.[9] Considerable interactions between the rider, saddle, and horse's back influence the rider's comfort and effectiveness in the saddle and the movement patterns of the horse's back and saddle.[8] Poorly fitting or improperly used saddles and saddle pads often contribute to back pain and poor performance. It is imperative to understand the basic principles of assessing proper saddle fit and the effects of proper vs. poorly fitting saddles on both the rider and the horse.

CLINICAL SIGNS OF POOR SADDLE FIT

Signs of asymmetric rider positioning in the saddle include uneven wear patterns on the seat from asymmetric rider contact with the seat bones (tuber ischii) or asymmetrical leather wear over the stirrup irons or stitching under the rider's legs. Horses with back pain related to poor saddle fit may display adverse or abnormal behavioral signs such as ear pinning, teeth grinding, head tossing, tail swishing, unwillingness to stand still during saddle or saddle pad placement, or biting or kicking while being saddled or while tightening the girth.[7] Asymmetric sweat patterns on the horse or saddle pad, asymmetric dirt patterns on the saddle pad, regional hair loss in areas of saddle contact, local edema, and open sores are all acute signs of poor saddle fit. Chronic signs of poorly fitting saddles include white hairs or granulomas and muscle atrophy in the saddle region.

Ill-fitting saddles can cause horses to hollow their backs (i.e. induced lordosis) and resent mounting. Affected horses often have reduced spinal mobility and are slow to warm up or relax during initial riding but may be completely normal during lunging or work in the round pen due to unweighted exercise. Regular bucking or rearing, resistance to work that worsens with time, difficulty with collection or maintaining impulsion, and resentment or ignoring training aids also may be indicative of poor saddle fit issues related to ridden exercise. Reduced protraction of the thoracic limb (i.e. shortened stride), stumbling or tripping, or obvious lameness can be produced by poorly fitting saddles. Upper pelvic limb lameness and lack of impulsion also may be exacerbated by increased saddle pressure.[4]

SADDLE EXAMINATION

To evaluate proper saddle fit, the saddle is assessed for manufacturer defects or signs of wear, and the rider–saddle and saddle–horse interfaces are evaluated during static and dynamic examinations. The ideal saddle provides uniform contact and pressure across all regions of the back during both static and dynamic assessments.[2] There should be no elevated or depressed areas that predispose to increased pressure and no left-to-right or craniocaudal asymmetries. The most common saddle fitting faults include bridging, increased pressure over the withers at the front of the saddle, high overall pressure, and asymmetric or localized pressure points.[10]

Examination of the saddle begins with assessing saddle construction and wear. The seat is evaluated for asymmetric wear, which often indicates that the rider is uneven in the saddle. Uneven flaps and stirrup bar placement are manufacturing defects, and an affected saddle should be returned for replacement. Worn or dried out leather straps must be replaced due to safety concerns.

Because the tree forms the foundation of the saddle, any saddle with a broken or asymmetric tree must be repaired or discarded. Saddles with broken trees have reduced stability and support, allowing the saddle to deform and causing localized increased pressure. Broken and twisted trees are evaluated visually by inspecting the symmetry. Excessive flexibility is assessed by applying craniocaudal forces to the bars or by applying lateral compressive forces to the head of the tree. The ventral surface of the panels is inspected for adequate flocking, left-to-right angular symmetry, and craniocaudal symmetry in the flocking. Horses with asymmetric withers often affect the symmetry of the cranial portion of the panels. The caudal edge of the panels should be wide and flat to maximize comfort for the horse, rather than narrow or pointed, which can cause localized pressure at the back edge of the saddle. In Western saddles, the fleece along the ventral surface should be palpated carefully with a flat hand to identify any protruding screws, nails, or plant burrs that can produce localized pressure or wounds. The width of the gullet should be two to three fingers wide along the entire length to allow positioning and movement of the dorsal spinous processes.[6]

STATIC EXAMINATION OF SADDLE FIT

The static examination of saddle fit on the horse's back is accomplished by visual inspection and palpation of the saddle–horse interface in the standing horse. A useful analogy for assessing saddle fit and proper saddle pad

VetBooks.ir

use is that the saddle should fit the horse's back like a well-made shoe and the saddle pad functions like a sock.

In a well-fitting saddle, the addition of a thin saddle pad should result in optimal saddle and saddle pad function and should not produce increased pressure or back pain. However, a proper fitting saddle used with an excessive number or increased thickness of saddle pads will likely produce localized pressure and back problems. In poor fitting saddles, the addition of a thin pad will likely not improve saddle fit. Likewise, the use of several saddle pads to compensate for a poor fitting saddle (such as a poor fitting shoe with several socks) will likely exaggerate saddle pressure and produce back pain. That said, wide fitting saddles may benefit from the use of several pads as a temporary solution to mismatched saddle horse sizes.

The static examination of saddle fit begins with the owner placing the saddle on the horse's back. The saddle is initially evaluated without any pads or girth to limit influence by other confounding variables. The owner is instructed to place and position the saddle on the horse's back in the usual manner. This provides an opportunity to qualitatively assess the horse's response and behavior to saddle placement and to evaluate saddle fit and positioning. Horses that pin their ears or attempt to bite or kick with saddle placement likely have or have had issues with poor fitting saddles and secondary back pain. As noted above, the tree provides the framework for the saddle and acts to transfer the rider's weight to the back of the horse. Therefore, the length, width, angles, and twist (or shape) of the tree ideally must match the contour and symmetry of the individual horse's back. The flare at the front of the tree should fit over the withers and allow free scapular movements. The width and angle of the tree must match the lateral slope of the withers.

In English saddles, the cranial edge of the saddle should rest at the caudal edge of the scapula. In Western saddles, the saddle normally covers the dorsal aspect of the scapulae, but the skirt should flare cranially to allow caudal rotation of the scapula during thoracic limb protraction. New saddles often have very stiff and inflexible skirts that may occasionally rub on the dorsal scapula cranially or lumbar region caudally. The length of the saddle should be proportionate to the length of the horse's back and the size of the rider. Saddles that are too short localize pressure and likely cause back pain. Saddles that are too long tend to bridge across the horse's back and localize pressure at the withers and caudal saddle, with little or no contact in the middle of the saddle where most of the rider's weight is located. Saddle bridging is a common problem in lordotic horses; this can be temporarily managed by placing additional padding or shims to fill in the noncontact areas at the center of the saddle to provide uniform saddle contact. Proper skirt length in Western saddles should provide 4–6 inches of clearance in front of the tuber coxae. Long skirts can cause friction rubs on the cranial aspect of the tuber coxae and restrict lateral bending of the trunk.

Stability of the saddle on the horse's back can be estimated by applying cranial-to-caudal, side-to-side, and diagonal rocking motions to the saddle. Properly fitting saddles are very stable and allow no displacement of the saddle. Wide saddles or the use of too many saddle pads causes instability and excessive displacement of the saddle during these induced movements.

In properly fitting and positioned saddles, the pommel and cantle of most saddles are horizontally level, and the deepest portion of the seat should be located near the center of the seat.[2] Saddles that slope downward in the front cause the rider's weight to be shifted over the withers. In contrast, caudally sloping seats cause the rider's weight to be shifted caudally, away from the horse's center of gravity. The position of the girth or cinch should correspond to the narrowest portion of the chest; otherwise, the saddle tends to constantly slide forward or backward, producing back pain and altering performance.

Properly fitting saddles should have two to three fingers wide (4–6 cm) of vertical clearance between the pommel gullet and the dorsal withers (Figure 12.24). Narrow saddles tend to sit higher and produce a taller saddle–wither gap, whereas wide saddles come close to resting on the dorsal spinous processes due to lack of lateral contact and support over the withers (Figure 12.25). Gliding a flat hand under the front edge of a well-fitting saddle and over the withers should provide a sensation of a smooth, uniform, soft contact bilaterally (Figure 12.26). The angle of the head of the tree should coincide with the lateral slope of the withers. Asymmetric trees or scapulae can produce left-to-right differences in saddle contact over the lateral wither region. Gliding a flat hand under the panels or skirt of a well-fitting saddle should also provide a smooth, uniform contact bilaterally, which closely follows the contour of the horse's back. The flocking in English saddles should be symmetric, of uniform firmness, and evenly distributed with no prominences or depressions. Overstuffed panels form round, firm cylinders that do not readily conform to the shape of the horse's back. Underflocked panels are flat and provide no cushion. The panels at the back edge of an English saddle should be flat and in contact with the horse's back. Some saddles have pronounced upward curving panels that cause a substantial reduction in the surface area over which to distribute a rider's weight. The gullet can be visualized from behind the horse and should provide ample clearance for the dorsal spinous processes.

Figure 12.24. Proper spacing between the saddle and dorsal aspect of the withers, with a saddle pad in place.

VetBooks.ir

Figure 12.25. Poorly fitting Western saddle with too close of contact between the pommel gullet and the dorsal aspect of the withers.

Figure 12.26. Evaluation of smooth, uniform contact between the front portion of the panel and the underlying dorsal aspect of the scapula. The contact pressure should be symmetrical from left to right.

STATIC EXAMINATION OF SADDLE PADS

Static evaluation of the combined saddle and saddle pad fit is accomplished by repeating the above examination with the saddle pad in place. If more than 1 saddle pad is typically used by a rider, then pads or blankets are sequentially added or exchanged during the examination to assess the influence of select saddle pads or saddle pad combinations on proper saddle fit. The size, shape, thickness, and material of the saddle pad should correspond to the intended use of the horse. Saddle pads should also be selected for specific temperature, moisture absorption, friction reduction, shock absorption or cushion, and uniform pressure distribution characteristics.

Saddle pads for a short-term dressage test have different requirements than saddle pads used for racing or during extended ridden activities (e.g. a 100-mile endurance ride). One method for indirectly assessing saddle fit and pressure is to ask the rider to ride the horse in a clean, white saddle pad prior to saddle fit assessment. Properly fitting saddles produce symmetric and uniform dirt or sweat patterns on the saddle pad in the shape of a butterfly. Regions of increased dirt and lack of dirt are noted bilaterally, which can help determine where the saddle fit should be examined more closely.

The size and shape of the saddle and saddle pad should be compared. Half pads or pads that are too small can cause increased localized pressure along their margins, especially if the edges are not tapered. Again, like wearing socks in a well-fitting shoe, it is important to have no foreign objects, wrinkles, or step defects in the saddle pads, which can cause discomfort and localized pressure. Saddle pads should always be pulled up into the gullet of the saddle in an effort to reduce friction and pressure over the dorsal withers. Saddle pads should also be evaluated for excessive wear, cleanliness, and moisture.

DYNAMIC EXAMINATION OF SADDLE FIT

Dynamic examination of saddle fit and saddle pad use involves assessing both horse and saddle movement during unridden and ridden exercise. The horse initially should be assessed for pain reactions or abnormal behavior in response to saddle placement and tightening of the girth. Saddle movement and the influence of saddle fit and saddle pads can then be assessed during locomotion in hand, on the lunge, or in a round pen.

Proper saddle fit should allow fluid movements of the thoracic limb without restricting any flexion/extension or lateral bending motion of the thoracolumbar spine. Proper saddle fit provides seamless interactions between the rider and the horse during dynamic activities and intended use. Poorly fitting saddles often cause horses to guard their back due to pain or muscle hypertonicity.[7] Scapula or spinal movement asymmetries can produce obvious one-sided or uneven saddle movement or saddle pad migration.

Evaluation of uniform sweat or dirt patterns on the saddle pad after both unridden and ridden exercise can provide insight into saddle fit and pressure distribution underneath the saddle. Recent research has used pressure-sensitive mats to obtain pressure distribution patterns and areas of peak pressures under both normally and abnormally fitting saddles.[1,3,9] The effects of saddle pad thickness and weight distribution of the rider in the saddle can also be quantified and monitored over time. Evaluation and knowledge of saddle and saddle pad construction and fit as well as rider–saddle–horse interactions is important in assessing causes of poor performance and back pain in horses. A saddle that does not fit the rider may alter the rider's position and balance and precipitate back pain for the rider.[2]

PREPURCHASE EXAMINATION

Randy Eggleston

VetBooks.ir

The prepurchase examination (PPE) is the most comprehensive examination a veterinarian will perform on a horse. It is not only an examination of overall health and soundness of a horse, but the information obtained is used to help make decisions about the ability and capability of performing an intended purpose for the prospective buyer(s).[24] However, the purpose of the PPE is not to evaluate or guarantee a horse's future behavior, trainability, or athletic ability.[26] The horse's future performance cannot be predicted or guaranteed by the PPE; it can only attempt to ascertain any current or potential problems that may affect future soundness.[11] The PPE is a collection of information used by the buyer to help make an informed reliable decision for purchase. The veterinarian's focus should be to be a facilitator in the transaction while always representing the buyer's best interests. Therefore, the veterinarian's role in performing the PPE is to evaluate and advise on the serviceability of a horse for a prospective buyer's intended purpose and to provide guidance on how any existing conditions may affect the future performance of the horse.[15,21] Evaluating and determining the suitability of a horse is generally considered the task of the prospective buyer, agent, and/or trainer.[21]

The veterinarian should be well informed as to the responsibilities and potential risks of performing PPEs. If the veterinarian is not comfortable with all aspects of performing and interpreting the PPE, it would be in their best interest to refer the examination to a colleague that has these skills. Performing the examination is not necessarily the most complicated component of the process as much as the interpretation, documentation, and reporting of the examination findings—crossing the t's and dotting the i's, as they say. The PPE is one of the most common claims brought against equine veterinarians for malpractice or veterinary negligence.[13] Issues recognized in some claims have included (1) owner and agent pressures resulting in compromise to the veterinarians normal procedures and standards, (2) overinterpretation of radiographs or laboratory results when an incomplete history was obtained or an inadequate physical examination was performed, (3) misunderstanding on the part of the prospective buyer as to the PPE not providing warranty to the transaction, and (4) incomplete or inaccurate information obtained from agent or trainer directly involved in the transaction.[13]

There are numerous parties involved in the PPE. At minimum there is the prospective buyer, seller, and examining veterinarian. In many cases there may also be an agent for the prospective buyer and agent for the seller or trainers, and the buyer may also have a trusted veterinarian that they wish to have involved. Throughout the process it should remain clear to everyone that the prospective buyer is the owner of information gained from the PPE. If a legal agent is representing the prospective buyer, then communications may be between the examining veterinarian and the agent; however the prospective buyer must be kept informed and receive the final PPE report. It is important to realize that all parties involved in a potential sale have a role in the process and that their roles should be acknowledged, respected, and addressed in one shape or form.[26]

The prospective buyer is the person financially obligated to the PPE and responsible for making the decision to purchase or to decline purchase. The relationship between the veterinarian and prospective buyer should be established early and clearly stated in the record. Pre-exam communication with the prospective buyer should outline the structure of the PPE, available ancillary testing, cost of services, limitations of the PPE, any financial limitations, and any and all conflicts of interest. The veterinarian is working for the prospective buyer; the prospective buyer is the owner of all information gained from the PPE.[11,15,21,23,26] If the PPE does not end in a change of ownership, it should be made clear to the prospective buyer that the findings of the PPE are privileged information and should not be discussed with anyone beyond the parties involved so as not to hinder any future potential sales.

The seller is the legal guardian of the horse being examined. This individual plays a critical role, in that anything done to the horse during the examination (i.e. riding under saddle, pulling blood for potential drug screening, sedation for imaging, etc.) can only be performed following consent from the seller. The seller is also the source of any pertinent history or medical records that should be collected prior to performing the PPE. If the seller is not present at the time of the PPE, signed consent forms or witnessed consent should be obtained prior to performing the PPE.[2,15,21,26] Although the PPE contract is between the prospective buyer and the veterinarian, the seller should remain well informed throughout the examination. Keeping in mind that the information gained from the PPE is the property of the veterinarian and the prospective buyer, consent from the prospective buyer must be granted before any sharing of materials.[15,21,26]

The veterinarian is the individual actually performing the PPE and plays a tremendous role in the collection, interpretation, and dissemination of PPE results. Another important role of the veterinarian is to recognize and alleviate any areas of conflict of interest. According to the American Association of Equine Practitioners (AAEP) Professional Conduct and Ethics Committee, the most common potential conflict of interest that is encountered in practice is when the seller or the buyer and seller are clients of the practice asked to perform the PPE.[4] It has commonly been recommended that a veterinarian should refuse to perform a PPE on a horse owned by their client. In many instances this can be difficult, and oftentimes both the seller and buyer are comfortable having the established veterinarian perform the examination. The AAEP Professional Conduct and Ethics Committee has addressed this issue and states

VetBooks.ir

that, if in this situation, there must be full disclosure to all parties that this relationship exists and that the seller give full disclosure of all medical records and history. All conflicts of interest and written agreements from all parties should be documented. The veterinarian should not act as the prospective buyer's agent and should not hold any responsibility for the prospective buyer's decision to complete or reject the transaction.[25]

The agent for the buyer or trainer may be separate individuals or one in the same. It is important to establish their role and legal powers prior to initiating the PPE. The agent or trainer will play a role in evaluating the suitability of the horse for their particular client and the horse's intended purpose. Werner recently published his approach to the PPE and outlined service maps that he established to help guide the examination and define the roles of all the individuals' involved in a successful PPE.[26] The reader is referred to this manuscript for further details on the PPE.

STRUCTURE OF THE PREPURCHASE EXAMINATION

The PPE should be broken down into different steps to make the examination progress more efficient and reduce the potential for deletions or inaccuracies in the examination.

Step One: Pre-examination

This step should be performed prior to the PPE appointment. A request should be made to obtain previous medical records and all pertinent history (performance career, current level of work, etc.) either from the seller or through permission from the seller, from the seller's primary veterinarian.[24,26] It is also during this step that all potential conflicts of interest be acknowledged, discussed, accepted, and documented. At this stage, if there is any refusal of information from the seller, or the veterinarian perceives any significant reason to doubt the seller's integrity, the veterinarian should document any conflicts and refuse to perform the examination due to a conflict of interest.[23,26] If the veterinarian has prior knowledge of the horse including any existing problems, they should insist that the seller gives permission to reveal all information to the prospective buyer. If permission is not granted, the veterinarian should graciously refuse the examination.[2]

Developing a PPE package of information that can be sent to the prospective buyer and seller prior to the PPE can save time on the day of the PPE and help to identify any potential conflicts prior to initiating the PPE. Prospective buyer and seller information should include all contact information (buyer, seller, agent, trainer), horse identification (name, breed, sex, age, markings, tattoos, freeze brands, and height), conformation of availability on the day of the PPE, and the appropriate prospective buyer/seller consent and waiver forms.[15,26] A detailed description of the PPE format can also be included. Once the information has been collected, the veterinarian can review the information in preparation for the appointment, and any conflicts can be resolved at this time.

Scheduling of the appointment time and location should also be carefully considered. Points of consideration should include the availability of all involved parties and competent help to perform the exam, scheduling conflicts of the examining veterinarian, location of the exam, and weather conditions.[23] If any of these conditions risk the quality and completeness of the examination, the veterinarian should consider postponing the examination. Documentation of any less than satisfactory conditions should be included in the final PPE report.[13] Additionally, the PPE can require considerable time to perform properly, and if not scheduled appropriately, the veterinarian can find himself/herself rushed and distracted from the task at hand. There are advantages to performing the PPE in the horse's home environment, but there cannot be distractions that will not allow for an accurate assessment of the horse. Space and footing is also very important especially when examining a performance horse. Working the horse on multiple level footings and having adequate space to exercise the horse on the lunge and under saddle are often imperative.[24]

Step Two: Review and Define PPE

Prior to initiating the PPE, the veterinarian should take the time to acknowledge all parties that are present and review the Step 1 information. Any questions or requests that the prospective buyer(s) might have pertaining to the examination should be answered at that time. The veterinarian should confirm the prospective buyer's expectations of the PPE and make it clear that although the PPE is a very complete and comprehensive examination, it may not identify all potential abnormalities.[11,21] It should be made clear that the PPE is a short-term contract lasting the day of the examination and not a warranty.[13,16] The ability of the veterinarian to predict the future soundness and suitability of the horse is impossible.[15] Recommendations for imaging or testing based on pre-exam information, signalment, intended purpose of the horse, and requests made by the prospective buyer can also be discussed at this stage. Additional specialty testing (i.e. reproductive ultrasound, upper airway endoscopy, advanced imaging, etc.) should also be outlined, and the indications for performing and costs associated with each test should be discussed. If a test is recommended or requested but not available at the examining practice, potential referral and its expense should be discussed.

Step Three: Prepurchase Examination

The PPE can be designed and carried out in various formats. A detailed description of the complete PPE will not be discussed, as this will vary greatly from case to case. Within any equine practice, a PPE may vary depending on the type of equine population, economics, and the needs of a particular client base. Regardless of the horse's value and the wants and needs of the client, it is important that the quality of the exam, communication, and reporting of findings be held to the utmost standard of care. The veterinarian should develop a systematic approach to perform each and every PPE using that system to help avoid overlooking portions of the exam.[11,21,24] It is common practice to use a dedicated worksheet that is designed specifically for the PPE and can be tailored to the veterinarian's methods. The worksheet should include patient identification (age, breed, sex, color, markings, tattoos, and brands), checkboxes and comment areas referring to general body condition, conformation, inspection of all body systems, soundness

VetBooks.ir

evaluation, general comments, communication comments, imaging interpretation, and comments concerning any specialty testing that was performed.[26] The worksheet should be maintained in the medical record. Use of a dedicated PPE worksheet will help to reduce the risk of an incomplete exam and inaccurate recall of findings in the formulation of the final report. There are a number of forms online that can be used as a guide for designing a PPE worksheet that is specific for the veterinarian's needs and wishes.

The basic PPE should include a visual inspection of the horse both in and out of the stall, during work, and following work. Any noted abnormal behavior or vices should be noted. This will give the veterinarian an idea of the horse's response to an unfamiliar environment and personnel, recovery from exercise, and any changes in stance or movement throughout the exam. Overall body condition and conformation should be closely evaluated and recorded.[2,11,15,21,24,26]

Physical Examination: An overall general examination of the horse should be performed using a muzzle to tail inspection of all body systems. It is also important to have knowledge of a horse's age based on dentition. Confirming that the horse's dentition corresponds to the age on record is important, as it is not uncommon to have marked discrepancy between the two in some cases.[21] Auscultation of the thorax and abdomen is performed during the initial exam. Auscultation of the lungs using a rebreathing bag is often performed following the dynamic exam. Palpation at this stage concentrates on skin health, identifying any lumps, bumps, or swellings, and careful inspection for common surgical scars (ventral midline, neurectomy, laryngeal, etc.). In the gray horse careful inspection for melanoma lesions at the base of the tail, in the perianal region, and in the region of the parotid salivary glands is important. If firm swellings are identified in the parotid region, consideration of upper airway endoscopy including inspection of the guttural pouches is advised. It is common to find melanotic plaques in the guttural pouches of gray horses with melanoma affecting this region.[5,7,27] In geldings and stallions it is advised to obtain permission to sedate the horse to allow close inspection of the penis and prepuce.[27] Small precancerous or cancerous lesions cannot be identified without close visual inspection. In mares, the seller should be questioned as to the mares' potential for pregnancy. If the response is unclear, it should be suggested to the prospective buyer that an examination for pregnancy be performed.[26]

The ophthalmic examination should be performed in a dark quiet space with an ophthalmoscope.[12] The goals of the ophthalmic examination should be to identify the presence of an abnormality, state if an abnormality will or will not have a significant effect on functional vision, and state whether the abnormality is likely or unlikely to progress over time.[12] The veterinarian should not document any quantitative comments concerning visual impairment or subjective statements with respect to the horse's suitability for riding with suspected visual impairment.[12] It is generally viewed as inappropriate and unnecessary to routinely dilate a horse's eyes during the PPE. The exception to this is if an abnormality is identified and the veterinarian, with the owner's permission, wishes to more fully examine the eye.[12]

Thorough evaluation of the cardiovascular system is important especially in sport horses. Accurate assessment of the heart and identification of heart murmurs can be challenging depending on the veterinarian's equipment and ability to detect subtle murmurs. Evaluating the horse before and after exercise can be useful; however the effect of exercise is a poor guide to the significance of a murmur.[17] A murmur may be physiologic or may be due to disease, not all of which affect a horse's performance negatively, depending on the nature of the murmur. Key factors to take into consideration include (1) the intended use of the horse, (2) safety to horse and rider, (3) the prospective buyer's understanding and willingness to accept risk, (4) the horse's past performance record, (5) age of the horse, (6) if the prospective buyer considering resale, and (7) insurability.[17] If a heart murmur is identified and the veterinarian cannot be confident that it is a physiologic murmur (i.e. second-degree atrioventricular block), further investigation utilizing echocardiography and electrocardiography is recommended.[17] If the intended use for the horse is breeding, many horses with moderate to severe cardiac disease are perfectly suitable for breeding purposes.[17]

Any abnormalities that are identified during this initial stage of the physical examination should be discussed with the prospective buyer and referral offered if the veterinarian is not familiar with the findings and uncomfortable with the interpretation.

Musculoskeletal Examination: Physical examination of the musculoskeletal system should follow a systematic approach and be detailed and methodical to avoid straying from the system. In the equine athlete it is very common to identify or palpate abnormal variations of normal that are considered blemishes (mild fetlock, tendon sheath, and tarsocrural effusion) and insignificant to the horse's future soundness. Recognizing obvious asymmetry between like effusive structures is of greater clinical significance than symmetry between structures.[15] For example, eliciting a mild response to deep palpation of the proximal suspensory in the front limbs of horses in work is a common finding; eliciting the same response in the hindlimbs should be of greater concern, depending on the degree of response.[20]

Step Four: Dynamic Examination

This portion of the examination is best performed over multiple level surfaces in an area with minimal distractions.[24] Having an assistant employed by the veterinarian who is familiar with PPEs and soundness evaluation is helpful and can help assure an efficient and uncomplicated examination. To accurately evaluate a horse's gait, the horse should be relaxed and trot freely on a loose lead. The basic PPE should include observing the horse at the walk and trot on the straightaway, at the trot and canter on the lunge, and after upper and lower flexion tests of all four limbs. The response to flexion tests is highly variable and should be interpreted with caution. A positive flexion test does not always correlate with the presence of lameness in a particular limb.[6] Many horses will trot off asymmetrically following flexion, but the response should resolve within 2–3 strides to be considered a negative response.[6,22] As long as all parties agree, and owner and rider consent is obtained, it is advised to also observe the horse under saddle.[11,15,26] It is recommended to use the horse's own tack to reduce any

VetBooks.ir

unwanted variables.[24] A percentage of horses will not display lameness until they are ridden.[6] This may bring subtle lameness to the surface that may not otherwise be visible. The horse can also be put under more strenuous demands giving the examiner the opportunity to perform a post-exercise physical examination.

A particularly difficult and oftentimes uncomfortable situation is recognizing and confidently documenting the presence of subtle neurologic deficits. During the static exam, evaluating for such signs as symmetric or asymmetric muscle atrophy, abnormal posture, or abnormal hoof wall wear can give clues to possible central, peripheral nerve, or muscle disease.[3] In the standing horse, the veterinarian can evaluate the cervicofacial/auricular and cutaneous trunci reflexes as well as tail tone, perineal, and anal tone reflexes.[9] The veterinarian should closely observe the horse during the dynamic exam for subtleties that might indicate proprioceptive deficits. Evaluation of stops and starts from the walk, transitions from the walk to trot and trot to the walk, tight turns, and backing the horse can help detect subtle neurologic deficits. The goal is to determine if the horse travels symmetrically, smoothly, and with appropriate stride length and foot flight, if the horse appears strong and consistently places the feet appropriately, and if the horse moves in a balanced and coordinated fashion.[3] It can be difficult to differentiate whether asymmetry and weakness are due to musculoskeletal pain and weakness or neurologic deficits.[3] Horses with musculoskeletal pain tend to be consistently irregular, whereas horses displaying neurologic gait deficits tend to be much less consistent and make variable mistakes when positioning their limbs.[18]

Step Five: Diagnostic Testing

There are a number of factors to be considered when requesting or recommending additional diagnostic testing. Knowledgeable buyers often come to the PPE requesting specific ancillary testing regardless of the examination findings. Less knowledgeable buyers may be advised by their primary veterinarian, trainer, or friends as to what type of ancillary testing to request. The examining veterinarian will usually discuss with the prospective buyer ancillary testing that he/she recommends based on the findings of the basic examination. Their recommendations are often based on a number of factors, such as age, breed, intended purpose of the horse, and abnormalities that were identified during the PPE. The decision to perform the recommended testing is up to the prospective buyer. If the prospective buyer refuses additional testing, the conversation, decision, and reason for the refusal should be documented in the final report.

Following completion of the basic PPE, any additional testing that was recommended or requested in Step 1 or 2 can be performed. Depending on the veterinarian's capabilities and facilities, additional testing that is commonly performed may include upper airway endoscopy, musculoskeletal ultrasound, and echocardiogram. Advanced imaging can be considered if a specific finding is to be investigated further. In the future nuclear scintigraphy and magnetic resonance imaging (MRI) may become common practice in PPEs.[10,14,15] Obtaining blood for the purpose of drug screening should also be addressed with the prospective buyer and the blood acquired prior to administering any sedation. Ancillary testing procedures must be interpreted relative to the physical exam findings and relevant to the history of the animal being examined.

There are no required standards for imaging in the PPE. The recommendations for imaging are based on a number of factors including the signalment of the horse, past and present performance, previous medical history, intended purpose for the horse, results of the initial PPE, communication with the prospective buyer, and budgetary constraints.

Radiography is the most utilized imaging modality in the PPE.[8] It is common for a prospective buyer to come to the exam with a list of requests for imaging, regardless of the exam findings. If left up to the recommendations of the veterinarian, the question of if or what to radiograph is generally based on the same above criteria. If the initial examination fails to identify any abnormalities, radiographic evaluation is used to scan for preexisting or potential future issues. The most thorough evaluation would include complete studies of the front feet, bilateral carpi, tarsi, and stifles, all four fetlocks, and cervical and thoracolumbar spine. This number of imaging studies would add considerable expense to the exam, and the veterinarian must keep in the mind radiation safety issues.

A few examples of radiographic studies that might be recommended by a veterinarian assuming relatively normal physical examination and dynamic examination are given below:

- 14-year-old Quarter horse gelding: Bilateral front feet navicular series, bilateral tarsi, and bilateral stifles
- 4-year-old Warmblood mare: All four fetlocks, bilateral tarsi, and bilateral stifles
- Young off-the-track Thoroughbred: Bilateral carpi, all four fetlocks

Recommendations for cervical spine and thoracolumbar radiographs should be discussed with the buyer if evidence of back pain and reduced range of motion in the neck are discovered during the examination particularly in jumpers and dressage horses.[14,15] Shoes should be removed if radiographs of the feet are to be taken preferably by someone that is skilled in properly removing horseshoes or by a farrier. Regardless of who removes the shoes obtaining the owner's signed consent is necessary, and if consent to remove the shoes is refused, a refusal statement should be signed and included in the report.[25]

All radiographs should be of high quality, well positioned, and labeled correctly. Including poor-quality radiographs in a PPE is inappropriate and a potential source of litigation.[13] If the radiographic studies are performed by technical personnel, the veterinarian should approve each image before including them and signing off on the final PPE report.

Abnormalities are commonly identified on PPE radiographs that do not correlate strongly with potential lameness. This can make interpretation and reporting difficult in the final report. In this instance, if the veterinarian is not comfortable interpreting the findings as it relates to continued soundness or potential unsoundness, seeking a second opinion is advised. The relative importance of any radiographic finding that is considered abnormal, or not

VetBooks.ir

within normal limits, must be put into perspective based upon clinical findings in order to place appropriate relevance on the finding. For example, a study that correlated radiographic findings and the presence of lameness in PPEs found 85.5%, 70.0%, 37.5%, and 22.7% of horses with grade 0–3 navicular bones, respectively, to be sound.[8] It is important to communicate to the prospective buyer that these findings can be identified in the absence of lameness. In contrast, it is important to communicate and document that the absence of radiographic abnormalities does not guarantee the absence of future lameness. These situations support the importance of obtaining the horse's past medical history and records, including previous imaging, for comparison. If previous radiographs are available, comparing studies can help determine the significance of an abnormal finding.[14] In cases where there are concerns with abnormalities identified on the physical examination or radiographs and the prospective buyer wishes to continue with the PPE, the veterinarian can recommend additional imaging (ultrasound, nuclear scintigraphy, MRI, etc.) to further evaluate the findings. Permission from the owner must be obtained before performing advanced imaging.

Ultrasound is used commonly in PPEs either as a request of the prospective buyer or for evaluation of an abnormal finding identified on the examination. Ultrasound is a necessary skill for the equine practitioner to have but a skill that is difficult to perfect. Having good-quality equipment capable of producing high-quality musculoskeletal images is also important. If the veterinarian is not comfortable performing or interpreting an ultrasound study, referral to a skilled ultrasonographer should be offered to the prospective buyer.

Because of the large variation in ultrasonographic appearance between horses and even within the same horse, ultrasound is probably best used for investigating areas of concern identified in the PPE or follow-up in horses with a history of having soft tissue injuries.[14] The metacarpal and metatarsal regions are the most common areas to have ultrasound performed in the PPE. It is common in the aged athlete to find subtle or chronic changes in, for instance, the proximal suspensory, in an otherwise sound horse. In a horse that has joint effusion and no radiographic abnormalities, ultrasound can be used to evaluate the surrounding soft tissues. Subtle bony changes may also be evaluated more effectively with ultrasound vs. radiographs. Similar to abnormal radiographs, these findings must be discussed with the prospective buyer along with their significance to future soundness or lameness. The reader is referred to the chapter on performing and interpreting ultrasound.

Nuclear scintigraphy may be considered when further investigation of a particular finding is of concern to the potential buyer(s). It is usually not useful as a screening tool. Depending on a horse's level of activity, scintigraphy commonly results in a number of areas of increased radiopharmaceutical uptake that are not associated with pathology or lameness.[14] This can cause confusion in communication with the prospective buyer, difficulty in interpretation and reporting, and potential termination of an otherwise good purchase. Examples for indications for recommending scintigraphy might include further investigation of radiographic abnormalities in the feet, or neck and back pain.[14,15]

Although the gold standard of equine imaging, MRI should not be used as a scanning tool in the PPE. As with nuclear scintigraphy, abnormal MRI findings, in a sound horse, can be potentially confusing to communicate to a prospective buyer. However, MRI for the purpose of investigating lameness gives the veterinarian much more detailed information to communicate the potential risk to the prospective buyer.[10] The limitations of MRI are its narrow area of focus, making it inadequate as a screening imaging modality, and, if standing MRI is not available, the need for general anesthesia. MRI is useful for investigation once an area of interest has been isolated.[14,15]

Step Six: Interpretation of Findings and Reporting

Once the examination is completed, the veterinarian is tasked with interpreting their findings and communicating the findings to the prospective buyer in a well-organized understandable format, both verbally and written.[1,2,11,13,15,16,21,23–26] The initial verbal report should be between the veterinarian and prospective buyer directly or via the phone. If an agent represents the prospective buyer, the communication is directed toward the agent with the understanding that the prospective buyer will receive a copy of the written report. With permission from the prospective buyer, findings of the PPE can be discussed with the seller.[15,16,24–26]

There are numerous recommendation and examples of what the final PPE report should contain and what the format should be. The AAEP has established guidelines to help the examining veterinarian formulate a report that is complete, concise, and accurate (Table 12.4). These are available at https://aaep.org/guidelines/reporting-purchase-examinations. While compliance with all of these guidelines helps to ensure a properly reported purchase examination, it remains the sole responsibility of the veterinarian to determine the extent and depth of each examination. The AAEP recognizes that for practical reasons, not all examinations permit or require veterinarians to adhere to each of these guidelines (Table 12.4).

SUMMARY

The PPE exam is the most complete comprehensive examination that the veterinarian will be requested to perform. The information gained from the PPE will be used to aid a prospective buyer in making a purchase decision. Obtaining the information (the PPE) and delivering that information in a way that the client understands and can use to make an informed decision is the sole responsibility of the veterinarian. The veterinarian should be well versed in performing and documenting PPEs and be aware of the potential risks. It is the veterinarian's responsibility to determine the horse's overall health and serviceability to perform the prospective buyer's intended purpose for the horse. The veterinarian should not hold any responsibility for determining the horse's suitability for the prospective buyer.

The key to avoiding an unpleasant and potentially litigious PPE is clear and open communication between all parties involved in the transaction. The owner is responsible for willingly supplying any and all performance and medical history. The prospective buyer is responsible for clearly communicating their goals of the PPE, their

VetBooks.ir

Table 12.4. AAEP guidelines for prepurchase report.

- All reports should be included in the medical record.
- The report should contain:
  - A description of the horse with sufficient specificity to fully identify it.
  - The time, date and place of the examination.
- The veterinarian should list all abnormal or undesirable findings discovered during the examination and give his or her qualified opinions as to the functional effect of these findings.
- The veterinarian should make no determination and express no opinions as to the suitability of the animal for the purpose intended. This issue is a business judgment that is solely the responsibility of the buyer that he or she should make on the basis of a variety of factors, only one of which is the report provided by the veterinarian.
- The veterinarian should record and retain in the medical record a description of all the procedures performed in connection with the purchase examination, but the examination procedures need not be listed in detail in the report.
- The veterinarian should qualify any finding and opinions expressed to the buyer with specific references to tests that were recommended but not performed on the horse (X-rays, endoscopy, blood, drug, EKG, rectal, nerve blocks, laboratory studies, etc.) at the request of the person for whom the examination was performed.
- The veterinarian should record and retain the name and address of parties involved with the examination (buyer, seller, agent, witness, etc.).
- A copy of the report and copies of all documents relevant to the examination should be retained by the veterinarian for a period of years not less than the statute of limitations applicable for the state in which the service was rendered. Local legal counsel can provide advice as to the appropriate period of retention.

The following is a list of recommended information that should also be included in the final PPE report in addition to the AAEP's guidelines[16,23,25]:

- List of all medical records and pertinent information received prior to, or at the time of the examination, and if known, a list of individuals given access to the information. Any refusal to supply medical records or pertinent information should be clearly documented along with the reason for refusal.
- Include a brief summary and risk assessment of any relevant past medical history.
- Brief synopsis of pertinent verbal and written communications that occurred during the examination.
- The horse should not "Pass" or "Fail" the PPE. When stating PPE findings using phrases such as "in my opinion," "I cannot predict the future," and "I do not know" should be used when appropriate.
- If a second opinion is obtained to clarify unfamiliar or debatable exam findings that opinion should be solicited from an expert in the area in question, and the second opinion report documented in writing and included in the report.
- Any signed consent forms or statements.

Also available at https://aaep.org/guidelines/reporting-purchase-examinations.

intended purpose for the horse, any limitations they might have, and any misunderstanding they might have with any aspect of the PPE. The veterinarian is responsible for clearly outlining the goals, structure, and limitations of the PPE, discussing all available ancillary testing and the indications for their use, outlining the cost of services, and generating the final report. It is important that all parties are willing to give full disclosure of any conflicts of interest prior to initiating the PPE.

Performing the exam under the ideal conditions as dictated by the veterinarian, in the appropriate settings, and using the right equipment will help reduce the risk of performing an inadequate and incomplete PPE. Performing a PPE at the local performance arena, in the middle of a thunderstorm, to accommodate the trainer's hectic schedule can result in inaccurate assessment of lameness and misinterpretation of radiographic findings. Having the knowledge and experience to perform a thorough PPE and interpret and report the results accurately will help reduce the risk of a poor uninformed purchase decision and future complications for the veterinarian. Reporting that a horse was healthy and serviceably sound only to find out later that squamous cell carcinoma of the penis was identified following purchase and stating that a horse was suitable for the intended purpose only to find out later that the horse refused a jump due to a lack of training, injuring the new owner, are situations that can be avoided by properly and carefully performing and documenting a PPE.

STANCE AND GAIT ANOMALIES CAUSED BY NEUROLOGICAL DISEASE

Lutz S. Goehring

Neurological disease in horses is actually quite rare, particularly if we compare the frequency of occurrence to lower airway disease, lameness, or colic prevalence in the general horse population. Neurological disease results from dysfunctional signaling along neurons and/or of synapses in the central and peripheral nervous system (CNS and PNS, respectively). As the nervous system of the horse stands for interaction with its environment, major tasks of CNS and PNS are the control of body position, stance, and motion through their combined control of muscle activity. Therefore, many nervous system diseases will have significant influences on a horse's stance and gait. For the less experienced owner, any gait anomaly is rather an orthopedic lameness with a suspected pain component than a neurological problem. This is why the veterinarian needs to pay detailed attention to the presenting complaint by careful examination. The common denominator of a neurological gait is unpredictability of limb placement. A neurological gait is typically irregularly irregular, which makes it different of the repeatable, regularly irregular lameness.

From a neuroanatomical standpoint, neurological gait anomalies can be caused by diseases that affect the CNS and/or PNS, either rostral or caudal of the foramen magnum. Lesions in brain areas and therefore rostral to the foramen magnum can be within the vestibular system, the cerebellum, and/or the forebrain/basal nuclei/motor cortex. Lesions in the spinal cord, its segmental spinal nerves, and neuromuscular junctions, however, are causing most of the neurological gait anomalies in horses. In general, a lesion or lesions interfere with electrical or chemical signal transmission along nerve cells and their synapses, while a successful signal transmission is necessary to initiate, activate, fine-tune, terminate, and provide feedback to various nervous system structures for any coordinated activity. Depending on the noxious cause, it will result in single focal, multifocal, or diffuse lesions. Multifocal lesions can be regional and contained to a specific structure, or they can be disseminated. Only immune-mediated disease or specific toxins will affect a distinct structure, cell type, or cellular mechanism, resulting in a distinct deficit (e.g. toxins of *Clostridium botulinum* or *Clostridium tetani*).

For the veterinarian it is usually easy to recognize moderate to severe neurological gait anomalies. Minor gait changes are more difficult to be distinguished from lameness. Furthermore, neurological and musculoskeletal conditions may coexist independently or share a common pathophysiological background, and both conditions will contribute to an abnormal gait while confounding the diagnosis. Osteochondrosis is a perfect example of gait problems resulting from both musculoskeletal and neurological causes. It can lead to limb lameness through joint problems, while facet joint (osteo)chondropathy of the cervical vertebrae can result in compressive cervical spinal cord disease. See the section on cervical vertebral stenosis later in this chapter.

NEUROLOGICAL GAIT AND (NEUROANATOMICAL) LESION LOCATION

The first question veterinarians should ask themselves when a horse presents with suspected neurological gait anomalies is: "Is what we observe caused by neurological disease?" To make a certain diagnosis of neurological disease, it is important to take a thorough history and conduct physical and neurological exams, each and every time. Furthermore, a neurological examination should always be complete, including an assessment of the patient's level of consciousness, cranial nerve function testing, and brief examination of both eyes, and observe eating, drinking, and, ideally, defecation/urination prior to a gait evaluation.[1,10] A neurological gait is the result of upper (UMN) and/or lower (LMN) motor nerve malfunctioning, either directly or indirectly, and can be described in terms of three distinct features of anomaly: ataxia, dysmetria, and weakness. The neurological gait that is observed may be the result of a single, a combination of two, or all three descriptors. Each limb must be observed and evaluated for presence of these findings and graded using a predetermined scale.[5]

Ataxia—The word is derived from the Greek word for indiscipline or "lack of order." An ataxic gait is irregular and lacks predictability when it comes to limb protrusion and placement; it is best described as being "irregularly irregular." Ataxia results from a decreased perception of proprioceptive information ascending from the peripheral sensors, Golgi (tendon) organs in all limbs, trunk, and neck to the cerebellum. The cerebellum receives proprioceptive information also from the vestibular organ and vestibular nucleus in the brain stem. As a result of proprioceptive disruption, the horse can no longer correctly perceive its position, posture, or equilibrium, which leads to mal-interpretation in the (fore)brain/basal nuclei, resulting in delays/absence of movement initiation, maintenance, and control through upper motor neuron (UMN) tracts. Thus, ataxia is typically combined with dysmetria (see below), and ataxia is noticed in a horse if one of the following four components of the nervous system is affected: (1) spinal cord; (2) vestibular organ, vestibular nerve, or nucleus; (3) cerebellum; and (4) fore brain. Each component adds specific detail to the clinical presentation. Vestibular ataxia is usually accompanied by a head tilt and asymmetrical ataxia. Horses with one-sided vestibular ataxia show a head tilt toward the side of the lesion. These horses typically bend their neck and trunk in a concave fashion and tend to circle toward that side. In addition, nystagmus may be present. Cerebellar ataxia is characterized by a

VetBooks.ir

symmetrical ataxia and hypermetria in all four limbs, but without loss of strength. It is routinely accompanied by an intention tremor of the head, a base-wide stance, and absence of a menace response. Forebrain ataxia is accompanied by abnormal mentation and, sometimes, cranial nerve deficits. Spinal ataxia is the most frequently encountered form of ataxia in the horse. Its cause is a disruption of ascending proprioceptive flow of information toward the cerebellum. As a result, descending information cannot appropriately be fine-tuned, which influences initiation/maintenance/termination of motion through muscle tone and motor function in neck, trunk, or limbs. Alternatively, as the descending motor pathways are most likely damaged by the same processes as the ascending pathways, ataxia and dysmetria occur simultaneously. If fore- and hindlimbs are affected, this is either caused by a focal cervical or by multifocal lesions throughout the spinal cord.[1,2,5,10]

Dysmetria—Dysmetria collectively describes a state of rigidity, spasticity, and decreased or exuberant limb flexion. It is associated with UMN conduction disruption in the spinal cord, interneuron circuits, or cerebellar disease. UMN tracts have two major functions: some are involved in the initiation of movement, whereas others have an inhibitory effect on a peripheral reflex loop (e.g. a patellar reflex). Dysmetria is caused by a reduced inhibition of the peripheral reflex loop, and the uninhibited reflex is observed. A hypermetric gait is characterized by an increased range of motion and excessive joint flexion. A hypometric gait is typified by limb stiffness and reduced joint flexion, particularly of the tarsal and carpal joints.

Weakness or Paresis/Paralysis—Weakness or paresis is the decreased ability to initiate gait, maintain posture, or resist gravity. Paralysis is the inability to do all three. Paresis can be further divided into UMN and lower motor neuron (LMN) paresis. UMN paresis, or flexor weakness, presents with a delay in initiating movement, followed by longer and, typically, lower stride. LMN paresis is usually observed as an antigravity or flexor weakness, presenting as short-strided, poor swing-phase gait; trembling due to muscle fatigue (muscle fasciculations); and lowered neck carriage while standing. Muscle atrophy is more pronounced and often more localized in LMN than in UMN paresis; for both forms it may take 2–3 weeks before the muscle atrophy becomes noticeable. Toe dragging and abnormal hoof wear can be seen with either form of paresis. Weakness in all four limbs, but no ataxia or dysmetria, indicates diffusely affected neuromuscular units and is by definition an LMN weakness.[1,2,5,10]

FINDINGS FROM A NEUROLOGICAL EXAM THAT CAN HELP IN LOCALIZING A LESION

Level of Consciousness and Body Position

The normal horse is quiet or bright, alert, and responsive (QAR or BAR); it pays attention to its surroundings, recognizes visitors, and finds water and food. A horse puts weight on all four limbs, which are vertically placed underneath the body (aka the columns of a Greek temple). The exception to this is a standing horse with a locked stifle. In a QAR or BAR horse, the poll of the head should be above the level of the withers. The normal recumbent/resting horse is usually found in a sternal position or in a flat lateral position. Minimal disturbance is typically sufficient for arousal and getting up. A horse extends its forelimbs first, followed by an abrupt extension and lift-off with both hindlimbs. An abnormal horse is either stuporous or (semi)comatose; wanders in circles within its confined space; may appear blind, agitated, or violent; or has a seizure. All clinical signs relate to a problem rostral to the foramen magnum. An abnormal stance can be wide based (sawhorse stance) or narrow based (horse-on-a-ball or goat-on-a-rock stance). The sawhorse stance is typical for a horse with a cerebellar lesion, whereas the horse-on-a-ball stance is seen with diseases collectively affecting the LMN. Whenever a horse places its limbs randomly, once it comes to a standstill (hence, an asymmetrical limb placement), this may be a sign for a lack of ascending proprioceptive information or interpretation in the forebrain. A conscious horse that cannot rise from recumbency is probably affected by profound weakness, which can be (focal/multifocal) UMN or (diffuse) LMN weakness. Whether the horse can or cannot lift its neck from the ground, maintain a sternal position, or sits like a dog is a critical observation in determining where the lesion of the problem is located—the cranial or caudal neck, thoracolumbar spinal cord, multifocal, or diffusely involving gray and white matter of the spinal cord. Horses with a head tilt and vestibular ataxia often stand slightly wide based, and the body may be concavely bent toward the side of the lesion. If recumbent, a horse with a head tilt is more comfortable while lying on the affected side. These clinical signs worsen when the horse is blindfolded.

Head and Body Symmetry

The normal horse shows symmetry in the head position and the posture of the neck, limbs, and trunk. Symmetry also extends to facial expression and the carriage of the tail. A head tilt (a sign of central or peripheral vestibular damage), a dropped ear, and paralysis of facial muscles (facial nerve paralysis) are examples of head asymmetry. Regional muscle atrophy or complete unilateral atrophy is more likely a sign of UMN paresis. Defined muscle atrophy of a single muscle belly is best explained by peripheral nerve damage. However, generalized symmetrical muscle atrophy without signs of ataxia or dysmetria is the result of diffuse LMN disease if neurological and needs to be distinguished from a horse with chronic malnutrition.[1,2,5,10]

Manipulations in the Standing Horse

The normal horse is able to extend and flex its head and neck dorsally and ventrally. During lateral flexion of the head and neck, the horse's muzzle should touch its ribs at either side. Some horses with cervical vertebral stenotic myelopathy (CVSM) may be reluctant or resent lateral flexion due to pain in the intervertebral (facet) joints. Both sides of the horse's neck and back musculature, from front to back, should be probed with a blunt instrument such as the handle of a neurology hammer or

VetBooks.ir

a ballpoint pen. Mild stimulation of the chest and abdomen elicits a cutaneous trunci muscle response, but not in all horses. A two-pinch technique with forceps is used to elicit this local reflex first, and then a pain response may be noticed with a deeper pinch.

The dorsal processes of the thoracic and lumbar vertebrae must be palpated and (gently) percussed. No pain response or crepitus should be observed or palpated. With both hands placed over the withers, the horse is pushed away and pulled toward the examiner. A normal horse quickly activates the extensor or antigravity muscles in the forelimbs to maintain a solid stance. An abnormal horse can easily be pushed away or pulled toward the examiner because of LMN weakness or a lack of proprioception.

Hopping can be done by picking up one forelimb at a time; however, caution is advised in the obviously severely affected horse. The examiner faces the same direction as the horse, holds the lifted forelimb at the pasterns, and pushes the horse away with his/her shoulder. The normal horse will hop one jump at a time with a nice lift-off and landing. The abnormal horse will have a delayed lift-off and a short, rigid jump followed by a clumsy landing. "Hopping" allows to test several aspects of the nervous system: muscular strength, proprioception, and dysmetria.

Stimulating the axial musculature of the back usually elicits a ventrodorsal movement of the vertebral column, lordosis followed by kyphosis. The abnormal horse shows scoliosis or it appears stiff in the back. A normal horse has at least some degree of a tail tone and a perineal reflex. A completely flaccid tail is a sign of LMN weakness. A tail should not continuously be held off the body. This can be a clinical sign of tetanus or tetany, if the horse is unable to clamp its tail upon stimulation of the perineum.

The (standing) tail pull is a very important test during a neurological examination in the standing horse (Figure 12.27). It can help to distinguish between UMN and LMN weakness. The square standing horse is gradually pulled at its tail laterally until the examiner notices a contraction of the quadriceps muscle. The horse will be pulled fairly easily toward the examiner if there is lumbar LMN dysfunction.

A normal horse walks with a regular four-beat movement. Limb placement should be graceful and regular, and a solid surface allows the examiner to listen to hoof placement. The hindlimbs follow the forelimbs, and the hindlimbs typically overreach the imprints of the forelimbs.[10]

Key abnormalities in the neurological horse are revealed in unpredictable limb placement, a shortened stride length, toe dragging, pacing, and generalized rigidity or stiffness resulting in a truncal sway. All of these signs can result from ataxia, weakness, or dysmetria. These may be mild and unobservable during a straight-line exam when walking the horse on a flat hard surface. In such cases the signs can be exacerbated by circling or spinning the horse, backing it up for several steps, and walking it, with and without head elevation, up and down a slope. A horse with a neurologically affected gait may exhibit circumduction (an exaggerated movement of the outer hindlimb) or pivoting (planting a forefoot and turning around without lifting it) during spinning. During backing, the limbs of a normal horse should move diagonally, with simultaneous placement of the contralateral fore- and hindlimbs. During uphill and downhill walking, a normal horse places its limbs solidly and securely, without knuckling in the fetlocks or carpal/tarsal joints. Insecure placement of limbs is a sign of ataxia. Particularly when walking downhill, simultaneous elevation of the head exacerbates insecurity with limb placement. Neurologically abnormal horses also should be examined during a trot and, if not too severely affected, during canter. A good test for proprioception is to trot a horse and bring it to a sudden stop. A smooth collection of all limbs underneath the body will be observed in a normal horse.[1,2,5,10]

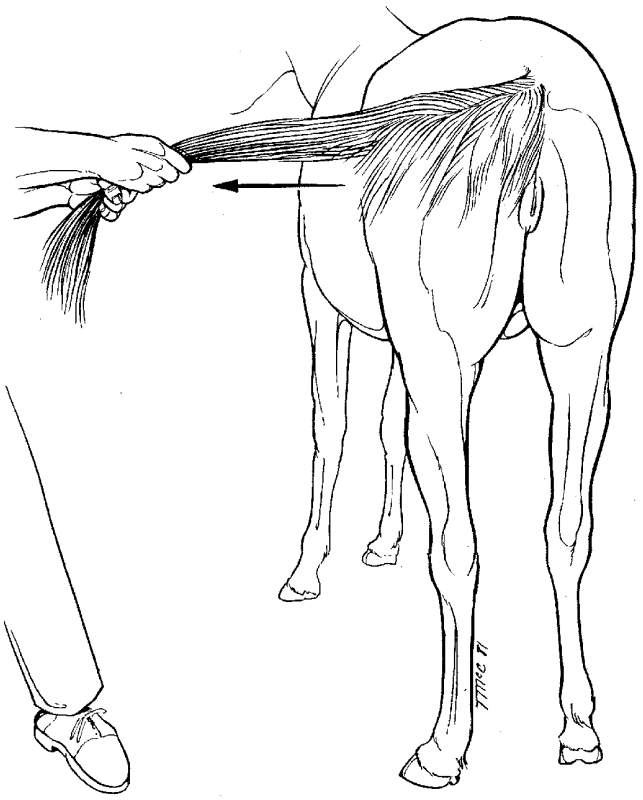

Figure 12.27. Tail pull (arrow) in a standing horse tests the strength of the quadriceps muscle and the reflex activity of the femoral nerve as a part of the lower motor neuron system. A gradually increasing pull on the tail toward the examiner should result in a quadriceps muscle contraction, and the hindquarter of the horse should not move significantly. For example, a horse with a cervical spinal cord lesion showing a grade 3 out of 4 ataxia of the hindlimbs still has a strong response to the standing tail pull. Pulling on this horse's tail during a walk will show incoordination or ataxia.

PITFALLS OF NEUROLOGICAL EXAMINATION

The clinical presentations discussed above suggest neurological damage that affects the gait. However, the signs also can arise from illnesses or problems unrelated to the nervous system. These should be considered when making the diagnosis, and possible explanations for suspect neurological findings are listed in Table 12.5.

VetBooks.ir

Table 12.5. Alternative explanations for presentations with a suspected neurological presentation.

Clinical finding	Alternative, non-nervous system-associated explanations
Generalized muscle atrophy	Starvation, emaciation, (intestinal) nutrient absorption disorder, paraneoplastic syndrome, chronic myopathies
Regional muscle atrophy	Lameness-associated disuse
Low head–neck carriage	Nuchal ligament desmitis or rupture, exhaustion, emaciation/starvation, fever, use of sedatives
Ataxia	Fever, sedation
Stiffness, short strided	Lameness, myopathy
Hindlimb hypermetria	Laminitis, *Chorioptes* spp. infestation, fibrotic myopathy
Recumbency	Exhaustion, colic, rhabdomyolysis, pain, laminitis

SELECT NEUROLOGICAL SYNDROMES AFFECTING THE GAIT

Cervical Vertebral Stenotic Myelopathy (CVSM)

CVSM is probably the most frequent cause of neurological gait abnormalities in performance horses. In general, CVSM is a condition of compression of the cervical spinal cord by malformed cervical vertebrae. This focal compression has its greatest impact on white matter proprioceptive and UMN tracts, resulting in neurologic deficits. Hallmark findings are generally a symmetrical ataxia and dysmetria in front limb and hindlimb. The layperson terminology refers to this condition as "wobbler," which should be avoided, as a "wobbler" could be any ataxic horse with numerous causes responsible for its clinical presentation. Cervical spinal cord compression leading to CVSM is a frequent cause of sudden ataxia in the tall breeds (Thoroughbred, Warmblood, etc.) and is typically recognized either in the young, fast-growing horse (6 months to 2–3 years of age) or in the middle-aged performance horse. Differential diagnoses include trauma (to the neck), NAD/EDM, EPM (Americas), and rarely neoplasia (lymphoma, melanoma). In the young horse, spinal cord compression can be a dynamic or static condition. Dynamic compression occurs due to vertebral instability and usually affects intervertebral sites C3–C4 and C4–C5. Dynamic compression is usually seen in younger horses associated with developmental orthopedic disease and osteochondrosis at the intervertebral facet joints. Mal-articulation of the facet joints can cause abnormal movement between two vertebrae resulting in spinal cord compression. Static compression causes continuous spinal cord compression usually due to vertebral malformation associated with osteoarthritis and bony remodeling that affects the more caudal cervical region. Both causes of compression can occur in the same animal, although static compression is more likely in the middle-aged performance horse. The diagnosis is usually made based on clinical findings together with cervical radiographic and myelographic confirmation of the site(s) of spinal cord compression. Advanced imaging (CT, contrast CT, and MRI) may be used instead of a myelogram depending on the suspected lesion location in the neck and the specific capabilities of the advanced imaging unit. Treatment options include conservative management with anti-inflammatories, exercise restriction, and dietary changes or surgical intervention to either remove the source of compression (dorsal laminectomy) or to stabilize the area(s) of spinal instability/compression. In general, surgery is the most widely reported treatment for CVSM and is often indicated to prevent repetitive trauma to the spinal cord. Excellent and more extensive reviews of CVSM can be found in these references.[7,8,12]

Botulism

Botulism is a feed-borne intoxication associated with *C. botulinum* toxin. If several horses are on a property, botulism usually manifests as a herd outbreak. Botulism toxin blocks the acetylcholine release at presynaptic neuromuscular junctions, postganglionic parasympathetic nerve endings, and peripheral ganglia. Posture and gait deficits are noted initially, with muscle fasciculations and a short-strided gait, followed by recumbency. Hallmark findings of botulism are generalized weakness, resulting in an abnormal gait and recumbency, and cranial (motor) nerve dysfunction (tongue tone, mastication, swallowing). Excellent reviews of botulism are available in other texts.[4,14]

Equine Motor Neuron Disease (EMND)

Equine motor neuron disease (EMND) is a rare, slowly progressive disease that usually affects only a single animal in a herd. Although its etiology is unknown, lack of antioxidants, particularly vitamin E, has been associated with its development. EMND causes a gradual and progressive loss of LMN of the entire spinal cord, leading to signs of symmetrical neurogenic muscle atrophy and weakness without ataxia. Horses with EMND are described as having a loss of muscle mass in combination with a good appetite, and cranial nerves are not affected.[3,11]

Equine Protozoal Myeloencephalitis (EPM)

Equine protozoal myeloencephalitis (EPM) is a disease of the Americas, most commonly caused by a protozoan organism, *Sarcocystis neurona* (and to a lesser degree by *Neospora hughesi*). The geographical restriction of *S. neurona* is linked to the habitat of its definitive host, the American opossum (*Didelphis virginiana*). *S. neurona* oocysts are produced in the opossums' gastrointestinal tract. After horses ingest the oocysts through contaminated feed, sporulation occurs, and asexual

VetBooks.ir

replication of *S. neurona* merozoites may follow. In a small but poorly defined number of horses, the protozoan enters the central nervous system, where replication can be prolonged and progressive, leading to multifocal disease of the brain and spinal cord. The most common presentation of EPM is asymmetrical gait anomaly, with a gradual worsening over weeks to months. Cranial nerve abnormalities are also common. EPM is well reviewed in several textbooks.[1,5,15]

West Nile Virus and Eastern/Western/Venezuelan Encephalitis Viruses

The implementation of a good vaccination program against West Nile virus and eastern, western, and Venezuelan encephalitis viruses means that disease should only be expected in poorly or nonvaccinated horses. Hallmark clinical findings of these viruses are active muscle fasciculations, tremors, and hyperesthesia. Cortex or general brain involvement appears to be more common with eastern, western, and Venezuelan encephalitis viruses, whereas the spinal cord and basal ganglia are frequent targets of West Nile virus.[9]

Equine Herpesvirus Type 1-Associated Myeloencephalopathy (EHM)

EHM is a rare syndrome that can follow infection with equine herpesvirus type 1. It causes multifocal ischemic damage, primarily to the spinal cord, usually in adult horses of the tall breeds. Only horses that develop a cell-associated viremia during infection are at risk of EHM. The clinical presentation varies with the number of ischemic infarcts. A low to moderate number of infarcts results in asymmetrical ataxia and both upper and lower motor weakness; a high number leads to coalescing disease with profound weakness, often resulting in tetraparalysis.[9,13]

Ryegrass Staggers

The clinical signs of ryegrass staggers present shortly after ingestion of a preformed toxin from an endophyte closely associated with perennial ryegrass (*Lolium perenne*), although a few other grasses are associated with a similar syndrome. The endophyte (*Neotyphodium lolii*) is in a symbiotic, lifelong relationship with the grass plant and may produce significant amounts of the toxin, lolitrem B, under specific growth-related and environmental conditions. The syndrome has a regional occurrence, reflecting its close association with (infected) perennial ryegrass occurrence and feeding. Lolitrem B affects the cerebellum and the inhibitory (inter)neurons in the spinal cord. The clinical signs are very typical: tremors, base-wide stance, oscillating eyeball, and a staggering, hypermetric gait. The signs worsen with exercise and persist as long as there is further toxin intake. Once toxin-free feed is provided, there is usually a fast recovery and return to full function.[6]

Stringhalt and Shivers

Although recognized as neuropathies, the etiology for and location of a neurological lesion for both stringhalt and shivers remain poorly understood. A hyperreflexia seems to be involved in both syndromes, and interneuronal disease would be most plausible. In stringhalt is a hyperreflexia of the lateral digital extensor muscle of the hindlimbs, typically hyperflexing one or both hindlimbs during a walk. Stringhalt is typically less prominent or absent at the trot or canter. Stringhalt is differentiated as a plant-associated form involving a toxin, in which case several horses sharing pasture may become affected simultaneously, and an idiopathic sporadic, single-animal form. A peripheral axonopathy may be found in combination with a neurogenic myopathy with the plant-associated form of stringhalt. Shivers, more common in draft and Warmblood breeds, is a hyperreflexia of the flexor muscles of the pelvic limbs, which becomes most noticeable when the horse is backed. Rarely, we see the movement pattern at the forelimbs. The affected hindlimb, often in combination with the tail base, shows jerky, trembling movements that are due to cyclic contraction followed by relaxation of the involved musculature.[5]

metacarpophalangeal (MCP) joint, racing Quarter horses, 975–976
metacarpophalangeal and metatarsophalangeal (MCP/MTP) joint injuries, jumping/eventing/dressage, 996
metacarpophalangeal joint, radiography, *224–236*
metacarpophalangeal/metatarsophalangeal joint
osteoarthritis (OA), 550–552
clinical signs, 550
diagnosis, 551
etiology, 550
prognosis, 552
treatment, 552
metacarpophalangeal/metatarsophalangeal joint (fetlock luxation)
luxation, 556–558
clinical signs, 556–557
diagnosis, 557
etiology, 556
prognosis, 558
treatment, 557–558
metacarpus/metatarsus, 563–592
accessory ligament of the deep digital flexor tendon (distal check ligament) (ALDDFT)
clinical signs, 591
etiology, 591
prognosis, 592
treatment, 591–592
bucked shin complex and stress fractures of the dorsal third metacarpus, 563–567
clinical signs, 564
diagnosis, 564–565
etiology, 563–564
other stress fractures of the third metacarpal/metatarsal bone, 566–567
prognosis, 566
treatment, 565–566
deep digital flexor (DDF) tendinitis, 590–591
clinical signs, 590–591
etiology, 590
treatment, 591
enostosis-like lesions (ELLs), 580
fractures of the condyles of the third metacarpal/metatarsal bones (condylar fractures, longitudinal articular fractures), 567–571
clinical signs, 568
diagnosis, 568–569
etiology, 568, *569*
prognosis, 571
treatment, 569–571
fractures of the small metacarpal and metatarsal (splint) bones, 576–580
clinical signs, 577
diagnosis, 577–578
etiology, 577
prognosis, 579–580
treatment, 578–579
fractures of the third metacarpal/metatarsal (cannon) bone, 571–572
clinical signs, 571–572
diagnosis, 571–572
etiology, 571
prognosis, 572
treatment, 572
functional anatomy, *14*, *15*, 17–19
dorsal aspect, 17
medial and lateral aspects, 17–18
palmar aspect, 18–19
metacarpal/metatarsal exostosis (splints), 572–576
clinical signs, 573–574
diagnosis, 574
etiology, 573
prognosis, 576
treatment, 575–576
nuclear medicine
abnormal conditions, 363–364, *364*, *365*
normal bone, 351, *351*
radiography, *237–240*
Standardbred racehorses, lameness conditions, 968
superficial digital flexor (SDF) tendinitis (bowed tendon), 585–590
clinical signs, 586–587
diagnosis, 586–587
etiology, 585–586
prevention, 590
prognosis, 589
rehabilitation, 589–590
surgical management, 588–589
treatment, 587–588
suspensory ligament desmitis, 580–585
clinical signs, 581–582
degenerative suspensory ligament desmitis (DSLD), 584–585
diagnostic analgesia, 582–583
diagnostic imaging, 583
etiology, 581
prognosis, 584
treatment, 583–584
ultrasonography, 303–312

tibia, 958
diagnosis of lameness, 950–951
risk factors for injury, 949–950
thrombosis of the caudal aorta or the iliac arteries, 775
clinical signs, 775
diagnosis, 775
prognosis, 775
treatment, 775
tibia
see also crus (leg or gaskin)
fracture management, 1148, *1151*
fractures, 703–707
diaphyseal fractures, 706
incomplete fractures, 704–705
proximal physeal fractures, 705–706
tibial tuberosity fractures, 706–707
palpation and manipulation, 107–109
Thoroughbred racehorses, common conditions, 958
tibia/crus, 701–708
clinical conditions, 701–702
diagnostic analgesia of the crus, 701
enostosis-like lesions (ELLs), 702–703
imaging, 701
tibial stress reaction, 703
toe-in or pigeon-toed, forelimb conformation, 81–82
toe-out or splay-footed, forelimb conformation, 82
topical/local therapies, 881–884
counterirritation, 883–884
dimethyl sulfoxide (DMSO), 882
electromagnetic therapy, 883
extracorporeal shockwave therapy (ESWT), 882
intravenous regional limb perfusions (IVRLPs), 882–883
laser therapy, 883
regional perfusion, 882–883
topical first aid (cold therapy and bandaging), 881–882
topical NSAIDs, 881
ultrasonography, 883
transcutaneous electrical nerve stimulation (TENS), rehabilitation/physical therapy, 940
traumatic joint disease
synovial joints, radiography, 210, *211*
triamcinolone acetonide (TA), intrasynovial therapies, 887
trimming and shoeing, 1095–1111
see also farriery; natural balance trimming and shoeing; therapeutic trimming and shoeing
center of rotation (COR), 1096, *1097*
farriery terms, **112**
guidelines for trimming, 1095–1097
heels of the hoof capsule extending to the base of the frog, 1096–1097
hoof conformation, 1095
hoof-pastern axis (HPA), 1095–1096
horseshoe, 1102–1108
bar shoes, 1106–1107
extensions, 1105–1106
materials and size, 1102–1105
traction devices, 1107–1108
non-nail alternatives in farriery, 1109–1111
indications for glue-on shoes, 1110
methods of glue-on farriery, 1110–1111
palmar foot, 1095
placement and application of the shoe, 1108–1109
trimming the barefoot horse, 1100–1102
trimming the foot, 1098–1100
trochanteric bursa, intrasynovial anesthesia, 185–186
trochanteric bursitis (trochanteric lameness, whirlbone lameness)
femur, 750
clinical signs, 750
diagnosis, 750
etiology, 750
prognosis, 750
treatment, 750
trotting, evaluation of the horse for lameness at the trot, 126
trunk (barrel), examination for lameness, 74
tuber coxae fractures, 771–773
tumoral calcinosis (calcinosis circumscripta), 844
femur, 749–750
clinical signs, 749
diagnosis, 749
etiology, 749
prognosis, 750
treatment, 749–750

UFP *see* upward fixation of the patella
ulna fractures, 627–630
clinical signs, 627
diagnosis, 627–628
etiology, 627
prognosis, 630
treatment, 628–630
ultrasonography, 301–339
angled contrast ultrasound technique (ACUST), *306*, 314
artifacts, 322
bone, bone evaluation, 332
characteristics, 301–302
foreign bodies evaluation, 334
identifying incomplete ossification, 331
joints, 323–331
articular cartilage and subchondral bone surface, 328
equipment and technique, 324–325
immature cartilage and bone, 328
incomplete ossification, identifying, 331
indications for ultrasonography of joints, 324
joint capsule, 327
joint injury assessment, 323–324
menisci, 329–331, *331*
normal variations, 328
osteoarthritis (OA), 328–329
osteochondral lesions, 328, *329*
subchondral bone cystic lesions, 329, *330*
synovial fluid, 327
synovium, 327
ultrasonic appearance of the joint, 327–331
ultrasonographic appearance of periarticular structures, 326
lacerations and punctures evaluation, 332–333

VetBooks.ir

VetBooks.ir

ultrasonography (*cont'd*)
ligaments, 302–303
collateral ligaments, 326, *326*
ultrasonographic assessment of ligament pathology, 316–323
limitations, 321–323
metacarpus, 303–312
muscle disorders, diagnosis of specific muscle disorders, 861
muscle evaluation, 333–334
musculoskeletal system, indications for ultrasonography, 332–334
new directions in the use of ultrasound, 335–339
color doppler ultrasound to evaluate tendon and ligament injury, 338–339
elastography to evaluate soft tissue injuries, 337–338
MRI/ultrasound fusion: navigational ultrasound, 335–336
ultrasound-guided injections, 335
pastern, 303–304, *314*, *319*, *320*
patient preparation and scan protocol, 303–314
prepurchase examination (PPE), 1174
punctures and lacerations evaluation, 332–333
sacroiliac region diseases, 779–780
soft tissue structures, 337–338
suspensory ligament, *313*, 314, *320*
tarsus, diagnosis of tarsal lameness, 660
tendons, 302–303, 326
ultrasonographic assessment of tendon pathology, 316–321
topical/local therapies, 883
ultrasound-guided injections, 335
underwater treadmill (UWT), rehabilitation/physical therapy, 941–942
ungular cartilages lesions, magnetic resonance imaging (MRI), 407
United Kingdom Lameness Scale, subjective assessment of lameness, 137, 139
upper limb long bones, nuclear medicine, normal bone, 351
upper limb stress fractures, Standardbred racehorses, 969–970
upward fixation of the patella (UFP), 717–719
clinical signs, 718
diagnosis, 718
etiology, 717–718
prognosis, 719
subjective assessment of lameness, 125–126
treatment, 718–719
UWT (underwater treadmill), rehabilitation/physical therapy, 941–942

vedaprofen *see* nonsteroidal anti-inflammatory drugs
vertebral articulations, functional anatomy, 62
vertebral column, functional anatomy, 60–61
vertebral fractures, 787–788
clinical signs, 787
diagnosis, 787
etiology, 787
prognosis, 788
treatment, 787–788
vertical pelvic movement (VPM), hindlimb lameness, 124, 129–131, 132, **133**, *133*
visual examination at rest, examination for lameness, 71, *72*
vitamins, minerals, trace elements, and herbs, nutraceuticals, 907
VPM *see* vertical pelvic movement

walking, evaluation of the horse for lameness at the walk, 124–126
WBV (whole body vibration) therapy, rehabilitation/physical therapy, 942–943
western performance horses, 980–985
barrel racing, 982
description of event, 982
musculoskeletal injuries, 982
cutting horses, 983–985
description of event, 983–984
musculoskeletal injuries, 984–985
reining horses, 982–983
description of event, 982–983
musculoskeletal injuries, 983
team roping horses, 980, *981*
description of event, 980
musculoskeletal injuries, 980
tie-down and breakaway roping, 981–982
description of event, 981
musculoskeletal injuries, 981–982
western pleasure horses, 1006–1013
axial skeleton, 1013
commonly encountered musculoskeletal issues in the western pleasure athlete, 1008
distal tarsal disease, 1012–1013
fetlock osteoarthritis, 1010
foot pain, 1008–1009, **1010**
proximal suspensory desmopathy, 1010–1012
rehabilitation and management of the western pleasure athlete, 1013
stifle disease, 1012–1013
training and showing, 1007–1008
understanding the sport, 1006–1007
western pleasure terminology, 1007
West Nile virus and eastern/western/Venezuelan encephalitis viruses, 1181
whirlbone lameness
femur, 750
clinical signs, 750
diagnosis, 750
etiology, 750
prognosis, 750
treatment, 750
whole body vibration (WBV) therapy, rehabilitation/physical therapy, 942–943
withers movement, subjective assessment of lameness, 129
wound management, musculoskeletal, 1148–1149, *1151*, *1152*
preventing infection in traumatic wounds, 1149, *1151*, *1152*

X-ray machines, 189–191
see also radiography
accessory X-ray equipment, 192–193, *194*
