Wiley also publishes its books in a variety of electronic formats and by print-on-demand. Some content that appears in standard print versions of this book may not be available in other formats.

Limit of Liability/Disclaimer of Warranty
The contents of this work are intended to further general scientific research, understanding, and discussion only and are not intended and should not be relied upon as recommending or promoting scientific method, diagnosis, or treatment by physicians for any particular patient. In view of ongoing research, equipment modifications, changes in governmental regulations, and the constant flow of information relating to the use of medicines, equipment, and devices, the reader is urged to review and evaluate the information provided in the package insert or instructions for each medicine, equipment, or device for, among other things, any changes in the instructions or indication of usage and for added warnings and precautions. While the publisher and authors have used their best efforts in preparing this work, they make no representations or warranties with respect to the accuracy or completeness of the contents of this work and specifically disclaim all warranties, including without limitation any implied warranties of merchantability or fitness for a particular purpose. No warranty may be created or extended by sales representatives, written sales materials or promotional statements for this work. The fact that an organization, website, or product is referred to in this work as a citation and/or potential source of further information does not mean that the publisher and authors endorse the information or services the organization, website, or product may provide or recommendations it may make. This work is sold with the understanding that the publisher is not engaged in rendering professional services. The advice and strategies contained herein may not be suitable for your situation. You should consult with a specialist where appropriate. Further, readers should be aware that websites listed in this work may have changed or disappeared between when this work was written and when it is read. Neither the publisher nor authors shall be liable for any loss of profit or any other commercial damages, including but not limited to special, incidental, consequential, or other damages.

Library of Congress Cataloging-in-Publication Data

Names: Baxter, Gary M., editor.
Title: Adams and Stashak's lameness in horses / [edited by] Gary M. Baxter.
Other titles: Lameness in horses
Description: Seventh edition. | Hoboken, NJ : Wiley-Blackwell, 2021. | Includes bibliographical references and index.
Identifiers: LCCN 2019046203 (print) | LCCN 2019046204 (ebook) | ISBN 9781119276685 (hardback) | ISBN 9781119276692 (adobe pdf) | ISBN 9781119276708 (epub)
Subjects: MESH: Horse Diseases | Lameness, Animal | Horses–injuries
Classification: LCC SF959.L25 (print) | LCC SF959.L25 (ebook) | NLM SF 959.L25 | DDC 636.1/089758–dc23
LC record available at https://lccn.loc.gov/2019046203
LC ebook record available at https://lccn.loc.gov/2019046204

TABLE OF CONTENTS

List of Contributors **xv**
Preface to the Seventh Edition **xix**
Preface to the Sixth Edition **xxi**
Preface to the Fifth Edition **xxiii**
Preface to the Fourth Edition **xxv**
Acknowledgments **xxvii**
Common Terminologies and Abbreviations **xxix**
About the Companion Website **xxxi**

1 Functional Anatomy of the Equine Musculoskeletal System 1

ANNA DEE FAILS

Anatomic Nomenclature and Usage **1**
Thoracic Limb **1**
Hindlimb **34**
Axial Components **60**
Acknowledgment **64**

2 Examination for Lameness 67

History, Visual Exam, and Conformation 67

GARY M. BAXTER AND TED S. STASHAK

Introduction **67**
Adaptive Strategies of Lame Horses **67**
Classification of Lameness **68**
Signalment and Use **71**
History (Anamnesis) **71**
Visual Examination at Rest **71**
Conformation **72**
Conformation Components and Traits **74**
Acknowledgment **91**

Palpation and Manipulation 93

GARY M. BAXTER AND TED S. STASHAK

Foot **93**
Pastern **96**
Fetlock **97**
Metacarpus/Metatarsus (MC/MT) **97**
Suspensory Ligament **99**
Flexor Tendons **100**
Carpus **100**
Forearm (Antebrachium) and Elbow **101**
Shoulder and Scapula **102**
Tarsus (Hock) **105**
Tibia **107**
Stifle **109**
Femur **112**
Hip **112**
Pelvis **113**
Back **113**
Neck **115**
Flexion Tests/Manipulation **115**
Distal Limb/Phalangeal/Fetlock Flexion **115**
Carpal Flexion **117**
Elbow Flexion **117**
Shoulder/Upper Forelimb Flexion **117**
Tarsal/Hock Flexion **117**
Stifle Flexion **119**
Full-Limb Forelimb and Hindlimb Flexion **119**
Navicular Wedge Test **119**
Direct or Local Pressure plus Movement **120**

Subjective Assessment of Lameness 123

KEVIN G. KEEGAN

Evaluation of the Horse for Lameness at the Walk **124**
Evaluation of the Horse at the Trot **126**
Evaluation of Vertical Movement of the Head for Forelimb Lameness **126**
Withers Movement **129**
Evaluation of Vertical Movement of the Pelvis for Hindlimb Lameness (the *V*ertical *P*elvic *M*ovement [VPM] Method) **129**
Evaluation of Pelvic Rotation for Hindlimb Lameness (The *P*elvic *R*otation *M*ethod [PRM]) **131**
Bilateral Lameness **132**
Observing Movement of the Limbs **134**
Joint Angle Measurements Associated with Lameness **134**
Stride Timing and Length Variables Associated with Lameness **134**
Hoof Trajectory Associated with Lameness **135**
Lameness Evaluation During Ipsilateral Gaits **135**
Evaluation of Lameness at the Lunge **136**
Evaluation of Lameness Under Saddle **136**
Subjective Scoring Methods **137**

VetBooks.ir

Objective Assessment of Lameness 139
Kevin G. Keegan

Measurement of Ground Reaction Forces (Kinetics) **139**
Measurement of Movement (Kinematics) **140**

Perineural and Intrasynovial Anesthesia 157
Gary M. Baxter

Types of Local Anesthetics **157**
Skin Preparation and Restraint **157**
Perineural Anesthesia **157**
Intrasynovial Anesthesia **167**
Acknowledgment **187**

3 Diagnostic Imaging 189

Radiography 189
Myra Barrett and Elizabeth Acutt

Equipment **189**
Digital Radiography Systems **191**
Radiation Safety **194**
Contrast Examinations **195**
Principles of Radiographic Interpretation **198**
Limitations of Radiography **210**
Normal Radiographic Anatomy **211**
Acknowledgments **299**

Ultrasound 301
W. Rich Redding

Introduction **301**
Ultrasound to Evaluate Tendons and Ligaments **302**
Patient Preparation and Scan Protocol **303**
Ultrasonographic Assessment of Tendon/Ligament Pathology **316**
Limitations of Ultrasonography **321**
Ultrasound to Evaluate Joint Injury **323**
Indications for Ultrasonography of Joints **324**
Equipment and Technique **324**
Ultrasonographic Appearance of Periarticular Structures **326**
Ultrasonic Appearance of the Joint **327**
Conclusions **331**
Other Indications for Ultrasonography of the Musculoskeletal System **332**
New Directions in the Use of Ultrasound **335**

Nuclear Medicine/Scintigraphy 342
Kurt Selberg, Elizabeth Acutt, and Alejandro Valdés-Martínez

Principles of Nuclear Medicine **342**
Radiation Safety and Protection **343**
Imaging Equipment **343**
Method for a Scintigraphic Exam of the Musculoskeletal System **344**
Indications for Nuclear Scintigraphy of the Musculoskeletal System in Horses **347**
Normal Bone Scan **348**
Scintigraphic Signs of Disease **356**
Abnormal Conditions for Specific Anatomical Regions **361**
Limitations of Nuclear Medicine **373**

Computed Tomography 376
Mathieu Spriet

Introduction **376**
Equipment and Principles of CT **376**
Clinical Use of CT in Equine Orthopedic Imaging **378**
Contrast-Enhanced CT **380**
Positron Emission Tomography **383**
Conclusion **383**

Magnetic Resonance Imaging 387
Michael Schramme and Emilie Segard-Weisse

Introduction **387**
General Principles and Physics of MRI **387**
Equipment, High- and Low-Field Magnets, and RF Coils **387**
Sequences and Protocols for Equine MRI **389**
Artifacts of MRI **390**
Interpretation of Musculoskeletal MR Images **393**
Contrast MRI Techniques **396**
How to Read an Equine MRI Study **397**
Indications, Case Selection, Advantages, and Disadvantages of MRI **397**
Magnetic Resonance Imaging of the Foot and Pastern **397**
Magnetic Resonance Imaging of the Fetlock Region **409**
Magnetic Resonance Imaging of the Metacarpal and Metatarsal Regions **416**
Magnetic Resonance Imaging of the Carpal Region **420**
Magnetic Resonance Imaging of the Tarsal Region **421**
Magnetic Resonance Imaging of the Stifle Region **424**

Thermography 431
Tracy A. Turner

Thermographic Instrumentation **431**
Principles of Use **431**
Specific Applications for Lameness Diagnostics **433**

4 Lameness of the Distal Limb 439

Navicular Region/Palmar Foot 439
Randy B. Eggleston and Gary M. Baxter

Navicular Syndrome/Disease **439**
Fractures of the Navicular (Distal Sesamoid) Bone **454**
Soft Tissue Injuries in the Foot (DDFT and Podotrochlear Apparatus) **456**
Acknowledgments **459**

Coffin Joint and Distal Phalanx 463
Gary M. Baxter

Osteoarthritis (OA) of the Distal Interphalangeal (DIP) Joint **463**
Fractures of the Distal Phalanx (P3, Coffin Bone) **465**
Subchondral Cystic Lesions of the Distal Phalanx (P3) **471**
Collateral Ligament Injuries of the Distal Phalanx **472**
Ossification of the Collateral Cartilages of the Distal Phalanx (Sidebone) **474**

Miscellaneous Conditions of the Foot 477
Gary M. Baxter

Sole Bruises, Corns, and Subsolar Abscesses **477**
Septic Pedal Osteitis **479**
Penetrating Injuries of the Foot **481**
Keratoma **483**
Avulsion Injuries of the Hoof **485**
Acknowledgments **489**

VetBooks.ir

Laminitis 490

James Belknap, Andy Parks, and Katy Dern

- Overview **490**
- Relevant Anatomy **490**
- Pathogenesis: Pathophysiologic Considerations **491**
- Pathogenesis: Structural Considerations of the Equine Digit **492**
- The Clinical Presentation: The Horse at Risk of Laminitis **494**
- Clinical Signs: The Acute Onset of Laminitis **496**
- Hoof Wall Resections **509**
- Coronary Band Grooving and Resection **509**

The Pastern 512

Ashlee E. Watts and Gary M. Baxter

- Osteoarthritis (OA) of the PIP Joint (High Ringbone) **512**
- Osteochondrosis (OC) of the PIP Joint **517**
- Luxation/Subluxation of the Proximal Interphalangeal (PIP) Joint **518**
- Fractures of the Middle (Second) Phalanx (P2) **522**
- Fractures of the Proximal (First) Phalanx (P1) **525**
- Desmitis of the Distal Sesamoidean Ligaments (DSLs) **532**
- Desmitis of Digital Annular Ligaments **535**
- SDFT and DDFT Abnormalities **536**

The Fetlock 541

Matt Brokken and Alicia Bertone

- Osteochondral Fractures and Fragmentation of the Proximal Phalanx **541**
- Fractures of the Proximal Sesamoid Bones **543**
- Sesamoiditis **548**
- Axial Osteitis/Osteomyelitis of the Proximal Sesamoid Bones **549**
- Osteoarthritis of the Metacarpophalangeal/Metatarsophalangeal Joint **550**
- Palmar/Plantar Osteochondral Disease **552**
- Fetlock Subchondral Cystic Lesions (SCLs) **553**
- Traumatic Rupture of the Suspensory Apparatus **554**
- Luxation of the Metacarpophalangeal/Metatarsophalangeal Joint (Fetlock Luxation) **556**
- Constriction of or by the Fetlock Palmar/Plantar Annular Ligament **558**
- Acknowledgments **560**

The Metacarpus and Metatarsus 563

Kyla F. Ortved and Alicia L. Bertone

- Bucked Shin Complex and Stress Fractures of the Dorsal Third Metacarpus **563**
- Fractures of the Condyles of the Third Metacarpal/Metatarsal Bones (Condylar Fractures, Longitudinal Articular Fractures) **567**
- Fractures of the Third Metacarpal/Metatarsal (Cannon) Bone **571**
- Metacarpal/Metatarsal Exostosis (Splints) **572**
- Fractures of the Small Metacarpal and Metatarsal (Splint) Bones **576**
- Enostosis-Like Lesions **580**
- Suspensory Ligament Desmitis **580**
- Superficial Digital Flexor (SDF) Tendinitis (Bowed Tendon) **585**
- Deep Digital Flexor Tendinitis **590**
- Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon (Distal Check Ligament) **591**

5 Lameness of the Proximal Limb 597

The Carpus 597

Chris Kawcak

- Developmental Abnormalities of the Carpus **598**
- Miscellaneous Carpal Swellings **604**
- Dorsal Carpal Swelling **605**
- Intra-articular Fractures **607**
- Accessory Carpal Bone Fracture **612**
- Carpal Luxations **613**
- Soft Tissue Damage to the Carpus **614**
- Osteoarthritis **615**
- Carpometacarpal Osteoarthritis **616**
- Osteochondrosis of the Carpus **617**
- Osteochondroma of the Distal Radius **617**
- Desmitis of the Accessory Ligament (Radial or Superior Check Ligament) of the Superficial Digital Flexor Tendon **619**

The Antebrachium, Elbow, and Humerus 623

Jeremy Hubert

- Fractures of the Radius **623**
- The Elbow **627**
- Fractures of the Humerus **633**
- Neoplastic Lesions of the Humerus **637**
- Paralysis of the Radial Nerve **637**
- Acknowledgment **638**

The Shoulder and Scapula 641

Jeremy Hubert

- Inflammation of the Intertubercular Bursa (Bicipital Bursitis) **641**
- Inflammation of the Infraspinatus Bursa **643**
- Osteochondrosis (OC) of the Scapulohumeral (SH) Joint or Shoulder **644**
- Osteoarthritis (OA) of the Scapulohumeral Joint **646**
- Luxation of the Scapulohumeral (Shoulder) Joint **648**
- Suprascapular Nerve Injury (Sweeny) **650**
- Fractures of the Scapula **652**
- Fractures of the Supraglenoid Tubercle (Tuberosity) **653**
- Acknowledgment **655**

The Tarsus 657

W. Rich Redding

- Introduction **657**
- Diagnosis of Tarsal Lameness **657**
- Articular Diseases of the Tarsus **662**
- Cunean Tenectomy **672**
- Fractures and Luxations of the Tarsus **680**
- Soft Tissue Injuries of the Tarsus **687**
- Periarticular Tarsal Cellulitis **697**

Tibia and Crus 701

W. Rich Redding

- Introduction **701**
- Diagnostic Analgesia of the Crus **701**
- Imaging the Tibia/Crus **701**
- Clinical Conditions **701**
- Enostosis-Like Lesions **702**
- Fractures of the Tibia **703**
- Incomplete Fractures **704**
- Proximal Physeal Fractures **705**
- Diaphyseal Fractures **706**
- Tibial Tuberosity Fractures **706**
- Gastrocnemius Disruption in Foals and Adults **707**

VetBooks.ir

The Stifle: Femoropatellar Region 709

GARY M. BAXTER and KEN E. SULLINS

Introduction **709**
Femoropatellar Joint **711**
Upward Fixation of the Patella (UFP) **717**
Desmitis of the Patellar Ligaments **719**
Patellar Luxation/Subluxation **721**
Synovial Osteochondroma in the Hindlimb **722**

The Stifle: Femorotibial Joint Region 725

CHRIS KAWCAK

Subchondral Cystic Lesions (SCLs) of the Stifle **726**
Fractures **729**
Femoral Condyle Lesions **731**
Collateral Ligament Injury **734**
Cruciate Ligament Disease **734**
Meniscal Injuries **735**
Synovitis/Capsulitis/OA **737**

Femur and Coxofemoral Region 740

NICOLAS S. ERNST AND TROY N. TRUMBLE

The Femur **740**
Diaphyseal and Metaphyseal Femoral Fractures **740**
Fractures of the Third Trochanter **744**
Fibrotic and Ossifying Myopathy **744**
Femoral Nerve Paralysis (Crural Paralysis) **748**
Calcinosis Circumscripta **749**
Trochanteric Bursitis (Trochanteric Lameness, Whirlbone Lameness) **750**
Ruptured Quadriceps Muscle **750**
The Coxofemoral Joint **750**
Osteochondrosis or Osteochondritis Dissecans (OCD)/HIP Dysplasia of the Coxofemoral Joint **752**
Infectious Arthritis/Physitis of the Coxofemoral Joint **752**
Partial Tear/Rupture of the Ligament of the Head of the Femur (Round Ligament) **753**
Coxofemoral Subluxation and Luxation (Dislocation of the Hip Joint) **754**
Osteoarthritis (OA) of the Coxofemoral Joint **757**
Capital Physeal Fractures of the Femoral Head **758**
Intra-articular Acetabular Fractures **758**
Acknowledgment **759**

6 Lameness Associated with the Axial Skeleton 763

The Axial Skeleton 763

ROB VAN WESSUM

Anatomy and Biomechanics of the Vertebral Column **763**
Primary vs. Secondary Back Pain **767**

The Pelvis 770

ROB VAN WESSUM

Fractures of the Pelvis **770**
Specific Types of Pelvic Fractures **771**
Thrombosis of the Caudal Aorta or the Iliac Arteries **775**

Sacroiliac Region 777

ROB VAN WESSUM

Etiology **778**
Clinical Signs **778**
Diagnosis **779**
Treatment **782**
Prognosis **783**

Thoracolumbar Spine/Back 784

ROB VAN WESSUM

Overriding/Impingement of Dorsal Spinous Processes **784**
Supraspinous Ligament Injuries **785**
Fractures of the Spinous Processes **786**
Vertebral Fractures **787**
Facet Joint Arthritis and Vertebral Facet Joint Syndrome **788**
Discospondylitis **792**
Spondylosis **793**
Scoliosis, Kyphosis, and Lordosis **794**

The Neck and Poll 796

ROB VAN WESSUM

Nuchal Ligament **796**
Cervical Facet Joints **797**
Radiculopathy **798**
Discospondylitis **798**
Cervical Fractures **798**

7 Principles of Musculoskeletal Disease 801

Joint Injuries and Disease and Osteoarthritis 801

C. WAYNE MCILWRAITH

Anatomy and Physiology of Joints **801**
Pathobiology of Joints and Their Reaction to Insult and Injury **808**
Primary Disease of Subchondral Bone **816**

Bone Injuries and Disease 820

CHRIS KAWCAK AND GARY M. BAXTER

The Immature Skeleton **820**
Local Diseases of Bone **825**
Systemic Diseases of Bone **841**

Tendon and Ligament Injuries and Disease 849

LAURIE R. GOODRICH

Anatomy **849**
Functions of Tendons and Ligaments **851**
Biomechanical Properties **852**
Types of Tendon and Ligament Injuries **852**
Effect of Aging and Exercise on Tendon Injury **853**
Mechanisms of Tendon Degeneration **854**
Response of Tendons and Ligaments to Injury: Phases of Healing **854**
Monitoring Tendon Injury **856**
Biomarkers for Tendon Disease **857**
Common Clinical Conditions of Tendons and Ligaments **857**

Muscle Injuries and Disease 860

STEPHANIE J. VALBERG

Classification of Muscle Disorders **860**
Diagnosis of Specific Muscle Disorders **860**
Muscle Soreness **862**
Exertional Rhabdomyolysis **865**

VetBooks.ir

8 Principles of Therapy for Lameness 875

Systemic/Parenteral 875
Drew W. Koch and Laurie R. Goodrich

Parenteral NSAIDs **875**
Polysulfated Glycosaminoglycans (PSGAGs) and Pentosan Polysulfate (PPS) **875**
Hyaluronan **876**
Bisphosphonates **877**
Tetracyclines **877**
Estrogen **878**
Methocarbamol (Robaxin) **878**
Gabapentin **878**

Topical/Local 881
Drew W. Koch and Laurie R. Goodrich

Topical NSAIDs **881**
Topical First Aid (Cold Therapy and Bandaging) **881**
Dimethyl Sulfoxide **882**
Extracorporeal Shockwave Therapy **882**
Regional Perfusion **882**
Therapeutic Ultrasound, Lasers, and Electromagnetics **883**
Counterirritation **883**

Intrasynovial 886
Lauren E. Smanik and Laurie R. Goodrich

Corticosteroids **886**
Hyaluronan **888**
Corticosteroid and HA Combinations **889**
IA Polysulfated Glycosaminoglycans **889**
Polyglycan® **890**
Autologous Conditioned Serum **890**
Platelet-Rich Plasma **890**
Autologous Protein Solution **891**
Bone Marrow- or Fat-Derived Mesenchymal Stem Cell Therapy **891**
Polyacrylamide Hydrogel **891**
Miscellaneous **892**
Intrasynovial Therapy: Practical Considerations **892**

Intralesional 896
Sara K.T. Steward and Laurie R. Goodrich

Introduction **896**
Hyaluronan and Polysulfated Glycosaminoglycans **896**
Autologous Cell Therapies: Mesenchymal Stem Cell Therapy, Autologous Bone Marrow Aspirate, Tendon-Derived Progenitor Cells **896**
Blood-Derived Biologics: Platelet-Rich Plasma, Autologous Conditioned Serum, Autologous Protein Solution, and Bone Marrow Aspirate **897**
Corticosteroids **898**
Miscellaneous **898**

Oral/Nutritional 900
Nicolas S. Ernst and Troy N. Trumble

Nonsteroidal Anti-Inflammatory Drugs **900**
Nutraceuticals **903**

Therapeutic Trimming and Shoeing 911
Andrew H. Parks

Introduction **911**
Examination of the Limb for Therapeutic Shoeing **911**
The Trim **912**
Shoeing **912**
Protection and Support **917**
Clinical Applications of Principles **918**
Summary **920**

Acupuncture Treatment of Limb Lameness and Back Pain 921
Kevin K. Haussler

Introduction **921**
Techniques of Stimulation **921**
General Indications for Treatment **922**
Lameness **922**
Chronic Back Pain **923**
Adverse Effects **924**

Manual Therapy Techniques 925
Kevin K. Haussler

Introduction **925**
Therapeutic Touch **925**
Massage Therapy **925**
Passive Stretching Exercises **925**
Mobilization **926**
Joint Mobilization and Manipulation **926**
Contraindications **927**

Rehabilitation/Physical Therapy 929
Melissa King, Katherine Ellis, and Narelle C. Stubbs

Introduction **929**
Clinical and Client Demand for Rehabilitation/PT **929**
Manual Therapy **930**
Proprioceptive Facilitation/Neuromotor Control Techniques **934**
Physical Modalities **936**
Conclusion **943**

9 Occupational-Related Lameness Conditions 949

The Thoroughbred Racehorse 949
Ryan Carpenter

Risk Factors for Injury **949**
Diagnosis of Lameness **950**
Common Conditions **951**

The Standardbred Racehorse 964
Kimberly Johnston and Frank A. Nickels

Description of the Sport **964**
Lameness Exam **965**
Specific Lameness Conditions **966**

The Racing Quarter Horse 972
Nancy L. Goodman and Larry R. Overly

Introduction **972**
Conformation Relating to Lameness **972**
Training the Racing Quarter Horse **973**
Shoeing **973**
Lameness Related to Track Surface **973**
Lameness Examination **973**
Specific Lameness Conditions **975**

The Western Performance Horse 980
Robin M. Dabareiner

Introduction **980**
Team Roping Horses **980**
Tie-Down and Breakaway Roping **981**
Barrel Racing **982**

VetBooks.ir

Reining Horses **982**
Cutting Horses **983**

Jumping, Eventing, and Dressage Horses 986

OMAR MAHER

Introduction and Horses Used for the Disciplines **986**
Structure of Training and Competition **987**
Training Surfaces and Shoeing **989**
Lameness Diagnosis **990**
Common Lameness Problems **991**
Acknowledgment **996**

The Endurance Horse 998

TODD C. HOLBROOK

The Sport **998**
Athletes and Exercise Conditions **998**
Veterinary Control **998**
The Lameness Examination **1000**
Common Causes of Lameness **1002**

The Western Pleasure Horse 1006

SHERRY A. JOHNSON AND DAVID D. FRISBIE

Understanding the Sport **1006**
Western Pleasure Terminology **1007**
Training and Showing **1007**
Commonly Encountered Musculoskeletal Issues in the Western Pleasure Athlete **1008**
Foot Pain **1008**
Fetlock Osteoarthritis **1010**
Proximal Suspensory Desmopathy **1010**
Distal Tarsal Disease **1012**
Rehabilitation and Management of the Western Pleasure Athlete **1013**
Conclusion **1013**

Gaited Horses 1015

DAVID A. WILSON AND KEVIN G. KEEGAN

Evaluating Gaited Horses for Lameness **1015**
What Is a Gaited Horse? **1015**
Classification of Gaits **1015**
Specific Gaits in "Gaited Horses" **1018**
Lameness in the Gaited Horse **1020**

The Draft Horse 1026

JAN F. HAWKINS

Introduction **1026**
Anamnesis **1026**
Lameness Examination **1026**
Common Causes of Lameness **1026**
Diseases of Young Draft Horses **1030**

10 Lameness in the Young Horse 1033

VetBooks.ir

PREFACE TO THE SEVENTH EDITION

Welcome to the seventh edition of *Adams and Stashak's Lameness in Horses*. The seventh edition is a full-color edition, and therefore a major effort was made to include new color images and illustrations. The goal was to have every image meet the standard of digital quality and clearly illustrate what the author had intended. Another major goal was to update existing material and add new information without expanding the size of the book. This required reorganization, consolidation, and addition and subtraction of material throughout the text. You will notice that the previous Chapters 2 and 3 were consolidated into a single chapter to permit the addition of more material on objective lameness diagnosis by Dr. Kevin Keegan. The large Chapter 5 in the sixth edition was condensed and divided into two individual chapters that focused on lameness problems of the distal vs. proximal aspects of the limbs. Additionally, the references throughout the book were grouped at the end of each major subheading instead of listed after each topic to prevent repetition of the references within chapters.

Also available to the reader are short "how to" video clips that demonstrate a variety of different physical examination (palpation, hoof testing, flexion tests) and perineural and intrasynovial injection techniques. The clips will be available on a companion website intended to complement the text within the book. The goal is for the reader to use the video clips to better interpret and understand the text by being able to clearly see the procedure being performed on a live horse. The select perineural and intrasynovial injection video clips contain extensive anatomic details inserted directly into the live demonstrations to better illustrate the techniques. Important anatomic landmarks are clearly labeled on the videos for further clarity.

I wish to thank all of the authors that have contributed to the seventh edition as well as those that have contributed in the past and for the medical illustrators that helped create the new images and videos for the book. I would also like to thank all of the horses, clients, and veterinarians that have provided the case material, knowledge, and experiences that have been included within this text. I hope that the seventh edition continues to exemplify the excellent tradition that has been characteristic of the previous editions of Adams and Stashak's Lameness in Horses.

VetBooks.ir

PREFACE TO THE SIXTH EDITION

Welcome to the sixth edition of *Adams and Stashak's Lameness in Horses*. When Dr. Stashak approached me about being an editor for the new edition, I failed to realize the complexity of the endeavor. However, I have tried to modify the book with the specific goal of providing the most current information as concisely as possible. You will notice that Dr. Stashak's name has been added to the book title to reflect his numerous contributions to this text over the last few editions.

The primary objectives of the sixth edition were to update existing information and add new information without expanding the size of the book. This required reorganization, consolidation, and deletion of existing material in some cases. Expansive text on surgical procedures was condensed or eliminated in the sixth edition to focus on lameness and not surgery in horses.

You will notice that only Chapters 1–5 and 12 are similar in content to previous chapters in the fifth edition. However, Chapter 4 (Diagnostic Procedures) has been expanded considerably to reflect the advances that have been made in this important area over the last several years. Chapters 6–11 are new, although much of the information from the fifth edition has been reorganized into a different format within these chapters. Chapter 6 was added because of the growing importance of the axial skeleton in lameness and poor performance, especially in certain occupations. Chapters 7 and 8 focus on the principles of musculoskeletal diseases and treatments, respectively, and hopefully permit the reader to better understand these basic disease processes as well as the multitude of treatment options that are available for the numerous disease conditions covered elsewhere in the text. Chapter 9 contains a wealth of information from experienced equine veterinarians regarding lameness conditions unique to a horse's specific sport. Knowing these specific occupation-related conditions can be extremely helpful in lameness diagnosis. Chapter 10 is a "catch all" for many conditions and situations that do not fit neatly within another chapter yet are important aspects of the musculoskeletal system in the horse. Examples include prepurchase examinations, saddle fit, headshaking, and assessment of the neurologic horse. Chapter 11 discusses the unique features of the musculoskeletal system in the growing horse and serves to remind us of the numerous differences between the immature and mature horse with respect to lameness.

A major effort was also made to include as many new color images and illustrations within the sixth edition as possible. Several older anatomical illustrations were converted to color, but many of the black and white illustrations were retained because they remain excellent examples. Conventional radiographs were replaced with digital images whenever possible due to their improved quality and reproducibility. The goal was to have every image clearly illustrate what the author had intended.

An instructional DVD titled The "How to" Guide for Equine Lameness Evaluation complements the sixth edition. Its primary purpose is to demonstrate physical examination procedures, manipulative tests, and other diagnostic techniques that are somewhat unique to the horse. Perineural and intrasynovial anesthetic techniques are illustrated both with still images and live demonstrations. Examples of lameness cases were included, so the observer could translate written text to the live horse regarding what to look for when evaluating a lame horse. Specific examples of uncommon musculoskeletal problems were also included with the idea that once you see one, you will never forget it. Finally, an example of how to evaluate lameness using objective data was included to make readers aware of the possible future of lameness diagnosis in the horse.

I wish to thank all who contributed to the text in any way, including the numerous horses, clients, and veterinarians who have provided me with the case material, knowledge, and experiences that have been included within this text. I hope that the sixth edition continues in the rich tradition of excellence that has been provided by previous editions of *Adams' Lameness in Horses*. However, as the specialty of equine lameness continues to evolve, ideas to further improve the text are always welcomed. Thank you.

VetBooks.ir

PREFACE TO THE FIFTH EDITION

First and foremost, I want to extend my sincere thanks to the veterinary profession, veterinary students, students in related equine science programs, paraprofessionals in the equine industry, and horse owners throughout the world for their wide acceptance of the fourth edition of *Adams' Lameness in Horses*. The many favorable comments I received throughout the years have, to a large degree, provided me with the impetus to embark on the much-needed revision of the fourth edition. That being said, it pleases me to provide the veterinary profession and persons in equine-related fields with the extensively revised fifth edition of *Adams' Lameness in Horses*. As with the fourth edition, the changes are substantial, including the addition of new authors, the reorganization of material, and the reduction in the number of Chapters from 14 to 9. As with the other editions, the fifth edition is designed to appeal to a wide audience in equine-related fields.

Chapter 1 has been revised to provide the reader with an updated version of the functional anatomy of the equine locomotor system. The latest information regarding the dermal microcirculation of the foot and the anatomy of various joint capsules and their distribution has been added with detailed illustrations to support the discussion. As usual, Dr. Kainer's attention to detail provides a complete reference for the various regions of the musculoskeletal system. I would like to thank Dr. Robert Bowker for his contributions to this chapter.

Chapter 2 has changed considerably and covers a discussion of conformation and locomotion. The part on conformation has been extensively revised and updated with as much reference material as possible in hopes of providing objective data from which to draw conclusions. Additionally, the discussion of normal movement, movement abnormalities, and factors that affect movement, which expands on the material from Chapter 13, "Natural and Artificial Gaits," from the fourth edition, has also been included. Cherry Hill's coauthorship has provided much needed insight from a certified (carded by the U.S. breed associations) equine judge's standpoint. Cherry's background as a professional horse trainer and instructor has also added a practical perspective that I believe will appeal to veterinarians and horsemen alike.

Chapter 3 is presented in the same format as in the previous edition, with the addition of new material to make it as current as possible. Most of the anecdotal material has been removed except where personal experience was interjected to provide another perspective. Many new illustrations have been added to facilitate the discussion.

Chapter 4, the imaging chapter, has been completely updated and includes two new parts, one on ultrasound and one on nuclear medicine. The discussion of these two imaging modalities, used extensively for lameness diagnosis, has greatly increased the amount of material presented. Chapter 4 is divided into three parts. Part I, authored by Dr. Richard Park, provides an updated discussion of radiography in the diagnosis of equine lameness. This is followed by Part II, a comprehensive discussion by Dr. Robert Wrigley on the usefulness of ultrasound in lameness diagnosis. This part's many illustrations provide a useful and clear understanding of the anatomy being imaged. In Part III, Dr. Phillip Steyn provides a comprehensive discussion and presentation of illustrations on the value of nuclear medicine in the diagnosis of equine lameness. I would like to thank Dr. Richard Park for his leadership role in the development of this chapter.

Chapter 5 has also been completely updated with the addition of a new first author, Dr. Kate Savage, with Dr. Lewis acting as second author. This chapter provides the most current information regarding the role that nutrition plays in musculoskeletal development and disease.

Chapter 6 has also been completely revised and updated. With the departure of my colleague, Dr. Simon Turner, from the clinical arena to research, Dr. Gary Baxter has taken over as the first author of this chapter, with Dr. Turner serving as second author. A significant addition to this chapter is a comprehensive and practical discussion of the emergency ("first aid") management of equine fracture patients for transport and/or treatment. Many illustrations have been added to support the discussion.

VetBooks.ir

Chapter 7 has been extensively revised by Dr. Wayne McIlwraith. The addition of much research material to this chapter provides the reader with the most current information on the etiopathogenesis, diagnosis, and treatment of the various causes of joint disease and related structures. Many new illustrations have been added to augment the discussion of these various entities.

Chapter 8 has been extensively revised and greatly expanded, with the addition of new diseases. Dr. Alicia Bertone has updated discussion on the diseases associated with the fetlock region, including the metacarpus and carpus. Dr. Ken Sullins has updated discussion on the diseases of the hindlimb up to the coxofemeral joint. Dr. Dean Hendrickson has revised discussion on the diseases associated with the pelvis, back, and axial skeleton. The addition of these authors has greatly improved my ability to provide the reader with the most comprehensive and current discussion of the various diseases that cause lameness. As with the fourth edition, Chapter 8 concludes with discussion of "wobbler syndrome" and the various diseases of the spinal cord that can produce locomotor disorders that appear similar clinically. Dr. Alan Nixon has completely revised this section and, of note, has added a comprehensive discussion of the most current information on the diagnosis and treatment of equine protozoal myeloencephalitis (EPM).

Chapter 9 has been completely reorganized and updated and is presented in an entirely different format from that presented in the fourth edition. It incorporates information from Chapters 10 to 12 of the fourth edition. The addition of Cherry Hill, Richard Klimesh, and Gene Ovnicek as co-authors has greatly improved the presentation of this material, which should make this chapter most useful to all who read it. (Chapter 14, "Methods of Therapy," from the fourth edition has been eliminated, since most of this material is covered throughout the fifth edition for specific lesions or diseases and because many other texts cover the topic more completely than I possibly could in one chapter.)

With the expansion of the literature pertaining to lameness diagnosis and the recognition of new diseases, the reader will soon recognize that the reference lists have expanded in all portions of the text. In all cases the authors tried to include reference material from journals and text sources other than those of English-speaking countries. This was difficult at times, since frequently only summaries and abstracts were written in English.

I am grateful and indebted to Mark Goldstein for his untiring efforts and the many tasks he performed to make the fifth edition possible. Mark scanned the entire fourth edition onto computer. This unfortunately had to be done because the majority of the fourth edition text was lost in the archives of computer services. Following scanning, Mark proofread the material word for word, including checking superscripts and reference formatting. This had to be done, since the accuracy of the scanner at that time was only about 70%. Mark also did all the literature searches for the entire text and copied and organized the literature for distribution to contributing authors. Additionally, Mark combined new and old references for the fifth edition and added their numbered callouts in the text. Mark, thanks for your loyal and untiring effort; without you it would have been very difficult to complete the fifth edition.

The addition of numerous illustrations and photographs represents a tremendous time commitment and effort on behalf of the Computer-Assisted Teaching Service laboratory at Colorado State University. For the majority of the new illustrations, I am deeply indebted to Jenger Smith for her skill and expertise in producing these fine illustrations for the fifth edition. Her desire to produce the best possible image and her untiring efforts are most appreciated. Additionally, I am grateful to Gale Mueller from Visible Productions for the excellent illustrations she made for Chapters 1, 3, and 7.

I am grateful to my colleagues, Drs. Baxter, Hendrickson, McIlwraith, and Trotter, including referring practitioners, for allowing me the courtesy of using some of their case material as examples. I also acknowledge the contribution of my colleagues and the surgical residents who have contributed to the care and treatment of some of the cases presented in this text. A special thanks is extended to the many practitioners who have referred cases that have been used in this text. Without their continued support, the accumulation of the case material would not have been possible. Additionally, I am grateful to the technicians who provided support in the care of these patients.

Dana Battaglia, managing editor, and the entire staff at Lippincott Williams & Wilkins have been most patient and helpful in the preparation of the fifth edition. I am grateful for their support and guidance. I also wish to thank Carroll Cann, former veterinary editor for Lippincott Williams & Wilkins, who provided early encouragement for this edition.

I hope the new fifth edition meets all the expectations and needs of those who read it. As always, I look forward to your cooperation in making corrections and suggested revisions for future editions.

Ft. Collins, CO TED S. STASHAK

VetBooks.ir

PREFACE TO THE FOURTH EDITION

When I was contacted by Mr. George Mundorff, executive editor for Lea & Febiger, regarding the possibility of revising the third edition of "Lameness in Horses" by Dr. O. R. Adams, I was excited but naive to the task at hand. Dr. Adams had, in his previous three editions, established the state of the art of lameness diagnosis and treatment, presenting it in a unique manner that appealed to veterinarians, horse owners and trainers, and farriers. Without a doubt, he defined and directly influenced the course of this subject more than any other individual during this time. I was truly fortunate to train under him during my internship and surgical residency at Colorado State University. His never-ending thirst for knowledge, his humor, his friendship, and his love of the veterinary profession have inspired me throughout this endeavor. I only hope that I have served his memory well and that he would be proud of this fourth edition.

After considerable discussion with Lea & Febiger and the assurance of Mrs. Nancy Adams, Dr. Adams' widow, I embarked on the revision with some basic changes in format in mind. These included the addition of new authors, changes in chapter sequence and presentation, the addition of new chapters and deletion of some old ones, and the transition from a monograph to a reference text. Because I wanted the fourth edition to represent the school where Dr. Adams attended and taught, I selected mostly authors from our faculty on the basis of their expertise and their ability to provide a broad base of opinion for the reader.

With the idea of approaching the discussion of lameness as one would approach a lameness examination itself, I changed the sequence of presentation. Using the newest accepted nomenclature, Chapter 1 deals with the functional anatomy of the equine locomotor system and represents a complete revision of Chapter 2 in the previous edition. Dr. Kainer starts with the forelimb, advancing from the foot up the limb, describing the regional anatomy of each site. The hindlimb is covered in similar fashion. The nomenclature may be confusing initially to older graduates of American veterinary schools, but recent graduates as well as foreign veterinarians will be well versed in this terminology. We felt it was time to make this transition since the new nomenclature has been in use for at least 4 years. (Older terms are included parenthetically.)

Following a format similar to the previous edition, Chapter 2 deals with the relationship between conformation and lameness. I have eliminated "The Examination for Soundness," which was Chapter 3 in the previous edition, because it discussed many topics unrelated to lameness and, simply, because the subject of soundness is so comprehensive it could be covered in a separate text. The present Chapter 3 deals with the diagnosis of lameness. After defining lameness and establishing how to determine which limb is lame, the description of the physical examination begins at the foot of the forelimb and proceeds upward. Emphasis is placed on recognition of problems peculiar to the region examined. Following this is a description and illustration of perineural and intrasynovial anesthesia.

The next logical step in the diagnosis of lameness is radiology, which is discussed in Chapter 4. This chapter is comprehensive; nothing like it has been published elsewhere. The format of the text and illustrations should answer any question the reader may have regarding the techniques for taking radiographs and interpreting them. The artwork beautifully illustrates the different structures seen on various radiographic views, and the illustrations are labeled so that anatomic sites are easily identified.

Chapters 5–7 are new. Discussing the role of nutrition in musculoskeletal development and disease, Chapter 5 illustrates a unique approach not used elsewhere. Dr. Lewis provides a comprehensive review of specific nutritional disorders, their causes, and their treatment for all phases of growth and development in the foal, during pregnancy and lactation in the mare, and during maintenance of the working horse. This information will benefit both the horseman and the veterinarian. Chapter 6, by Dr. Turner, starts with a brief review of endochondral ossification and then discusses the diseases associated with bones and muscles and their treatment. In Chapter 7, Dr. McIlwraith describes the developmental anatomy of joints and related structures, disease processes, clinical signs, and treatments. Both of

VetBooks.ir

these chapters present in-depth reviews, with major emphasis on the pathogenesis and pathobiology of the diseases. They are heavily referenced and will be of major interest to the veterinary profession.

Representing a complete revision of Chapter 8, "Lameness" updates the reader on new diseases as well as new findings and treatment for previously recognized entities. Unlike past editions, this material is heavily referenced. Information regarding the prevalence of the disease within various breeds according to sex and age introduces each subject. The format of the chapter has been changed to start with diseases relating to the foot region and then proceeding upward anatomically, consistent with the way most equine practitioners approach a systematic examination. Specific diseases of each region are discussed separately. This chapter, though referenced heavily and written technically, should be of interest to the horseman as well as the veterinary profession. I am particularly grateful to Dr. Alan Nixon for his thorough and comprehensive review of the diagnosis and treatment of the "wobbler's syndrome" in horses. His presentation is clear and well illustrated, giving the reader the confidence to differentiate among the diseases that cause this syndrome.

Chapters 9–12 were written primarily for the horseman and farrier, though they will also be of interest to the veterinarian, particularly the equine practitioner. I have updated these chapters with new information, as well as listing what the horseman should look for when the horse is properly trimmed and shod. Chapter 13, "Natural and Artificial Gaits," is essentially unchanged. Chapter 14, "Methods of Therapy," has been updated and includes an extensive revision of different methods of external coaptation. This chapter is primarily directed toward the veterinary profession, though the horse owner will obtain insight into why different treatments are selected.

With the explosion of literature pertaining to musculoskeletal disease in the horse and the demands put on authors and editors alike, it became obvious that a transition from a monograph to a reference text was timely. To this end the authors have attempted to provide the latest information. As with any large text, however, authors and editors alike feel somewhat frustrated because at the time of publication some of this information will be out of date. With few exceptions, we stopped referencing material published in 1985. Occasionally publications in 1985 changed the presentation of the materials so much that it could not be denied and therefore was included.

I am grateful to Dr. Robert Kainer, professor of anatomy and author of the first chapter, for taking the time to review and advise me on the nomenclature used in this book. A special thanks is extended to Dr. A. S. Turner for his review and comments on Chapter 8. The fine contributions of all the authors are sincerely appreciated. I want to thank Dr. Robert Perce (California) and Mr. Richard Klimesh (farrier, Colorado) for their advice on the chapters dealing with trimming and shoeing horses.

The addition of many new illustrations and photographs represents a tremendous time commitment and effort on behalf of the Office of Biomedical Media at Colorado State University. For the illustrations, I am indebted to Mr. Tom McCracken and Mr. John Dougherty for their expertise and the cooperation they have given me. For the photographs I am grateful to Mr. Al Kilminster and Mr. David Clack, for their expertise, cooperation, and commitment to excellence. For the design of the book cover, I thank Mr. Dave Carlson.

Most of the manuscript was typed by Mrs. Helen Acevedo. Her cooperation and patience with the many revisions necessary to complete this text are gratefully appreciated.

I am also grateful to my many colleagues who took the time to personally reveal their thoughts regarding certain topics. A special thanks is extended to the following: Dr. Joerg Auer (Texas), Dr. Peter Haynes (Louisiana), Dr. Larry Bramlage (Ohio), Dr. Joe Foerner (Illinois), Dr. Dallas Goble (Tennessee), Dr. Robert Baker (Southern California), Dr. Robert Copelan (Kentucky), and Dr. Scott Leith (deceased, Southern California).

Mr. Christian C. Febiger Spahr Jr., veterinary editor; Mr. George Mundorff, executive editor; Mr. Tom Colaiezzi, production manager; Ms. Constance Marino; Mrs. Dorothy Di Rienzi, manager of copy editors; and the entire staff at Lea & Febiger have been most helpful in the preparation of this book. I am grateful for their support and guidance.

I hope this book will be useful to all who read it. I hope to receive your cooperation in making corrections and suggested additions for further revisions.

Ft. Collins, CO TED S. STASHAK

VetBooks.ir

ACKNOWLEDGMENTS

A big thank you to the numerous people that have been involved with creating the seventh edition of *Adams and Stashak's Lameness in Horse*. These include the staff at Wiley-Blackwell—Erica Judisch, Susan Engelken, Melissa Hammer, and Purvi Patel to name a few—Dave Carlson for creating several new images, and Thel Melton at the Educational Resource Center (ERC) at the University of Georgia for creating the perineural and intrasynovial injection video clips. Thel and others at the ERC spent numerous hours of detailed video editing to complete these clips, and for that I am truly grateful. And lastly, I would like to thank my colleagues at both the University of Georgia and Colorado State University for providing images, case material, and illustrations that may have been included in the new text.

ABOUT THE COMPANION WEBSITE

This book is accompanied by a companion website:

www.wiley.com/go/baxter/lameness

The website includes: Short "how to" video clips that demonstrate a variety of different physical examination (palpation, hoof testing, flexion tests) and perineural and intrasynovial injection techniques. The goal is for the reader to clearly see these procedures being performed on live horses. The select perineural and intrasynovial injection video clips contain extensive anatomic detail inserted directly into the live demonstrations to better illustrate the techniques. Important anatomic landmarks are emphasized and clearly labeled within the videos.

CHAPTER 1

Functional Anatomy of the Equine Musculoskeletal System

Anna Dee Fails

ANATOMIC NOMENCLATURE AND USAGE

Veterinary medical anatomists have been using the Nomina Anatomica Veterinaria, created by the International Committee on Veterinary Gross Anatomical Nomenclature since 1968 to standardize the names of anatomical structures.[46] This chapter endeavors to use the most current, correct terms as outlined in that publication. Nonetheless, equine practitioners need to be equally fluent in older terminology, which is likely to be in wide usage among horse owners and equine professionals. This chapter will provide useful and common synonyms for many structures, along with their more technically correct terms.

Figure 1.1 provides the directional terms for veterinary anatomy that will be used in this chapter. With the exception of the ocular and oral cavity structures, the terms anterior, posterior, superior, and inferior are not applicable to quadrupeds.

THORACIC LIMB

Digit and Fetlock

The digit is composed of distal (third), middle (second), and proximal (first) phalanges and associated structures (Figure 1.2). The fetlock consists of the metacarpophalangeal (fetlock) joint and the structures surrounding it. Because the digits and fetlocks of the thoracic limb and the pelvic limb are similar in most respects, the following descriptions pertain to both limbs unless otherwise indicated. When referring to structures of the forelimb, the term "palmar" is used; this will obviously be replaced with "plantar" when referring to the hindlimb. Likewise, such terms as metacarpophalangeal and metatarsophalangeal are counterparts in fore- and hindlimbs, respectively.

Foot

The foot consists of the hoof and all it encloses: the connective tissue corium (dermis), digital cushion, distal phalanx (coffin bone), most of the cartilages of the distal phalanx, distal interphalangeal (coffin) joint, distal part of the middle phalanx (short pastern bone), distal sesamoid (navicular) bone, podotrochlear bursa (navicular bursa), several ligaments, tendons of insertion of the common digital extensor and deep digital flexor muscles, blood vessels, and nerves. Skin between the heels is also part of the foot.

Hoof Wall, Sole, and Frog

The hoof is continuous with the epidermis at the coronet, and the underlying corium of the hoof is likewise continuous with the dermis of the skin. The ground surface of the hoof comprises the sole, frog, heels, bars, and ground surface of the wall (Figure 1.3). The ground surface of the forefoot is normally larger and rounder than that of the hindfoot, reflecting the corresponding shape of the distal surface of the distal phalanx (coffin bone).

The hoof wall extends from the coronary band (also called the coronet), the transition between skin and hoof, distad to the ground. The surface of the wall is divided into the toe, medial and lateral quarters, and heels (Figures 1.3 and 1.4). From the toe, where it is thickest, the wall becomes progressively thinner and more elastic toward the heels, where it thickens again when it reflects to become the bars. Ranges for the angle of the toe between the dorsal surface of the hoof wall and the ground surface of the hoof vary widely.[1,16] In the ideal digit, the dorsal surface of the hoof wall and the dorsal surface of the pastern should be parallel, reflecting the axial alignment of the phalanges.

The vascular and densely innervated collagenous connective tissue deep to the hoof is the corium. The corium

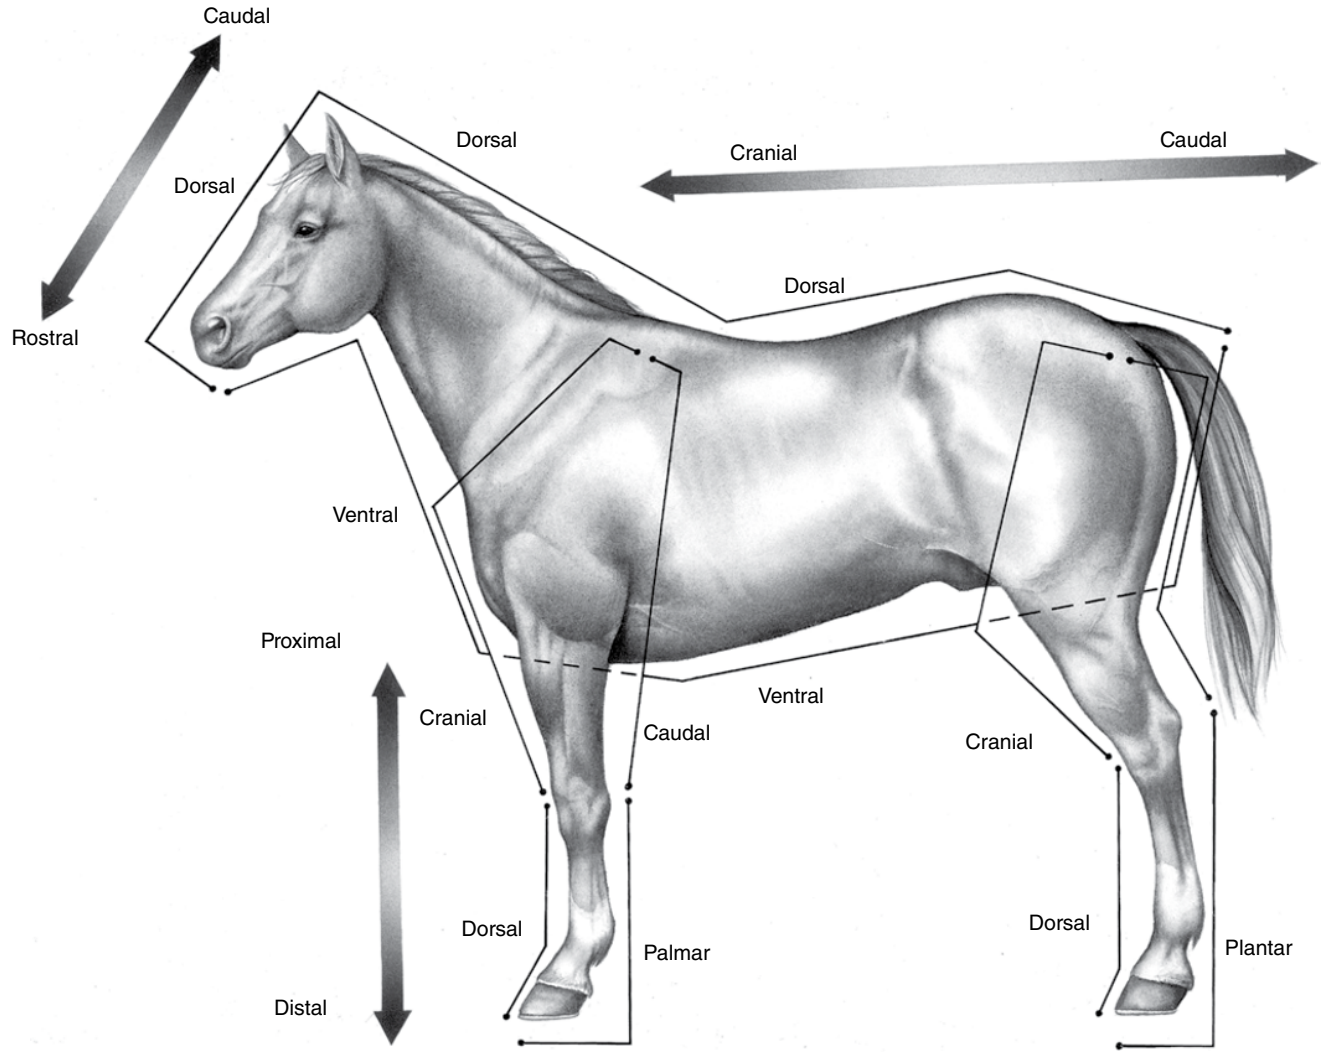

Figure 1.1. Positional and directional terms.

provides sensation, vascular supply, and attachment for the overlying stratified squamous epithelium that constitutes the hoof or ungual epidermis (*L. ungula*, hoof). Regions of the corium are named according to the parts of the hoof under which they are located: perioplic corium, coronary corium, laminar corium, corium of the frog (cuneate corium), and solar corium. Histologically, coronary corium gives rise to elongated, distally directed papillae. Laminar corium forms a series of sheets that interdigitate with epidermal laminae of the stratum internum of the hoof wall. Shorter papillae extend from the perioplic, solar, and cuneate coria.

In the coronary region, the deepest layer (the stratum basale) of the ungual epidermis is a single layer of proliferating keratinocytes lying upon and between long dermal papillae. Cellular division here pushes cells distad into the stratum medium of the hoof wall, forming the epidermis that undergoes cornification.[2] Nearly the entire hoof is composed of a thick layer of anucleate squamous keratinocytes.

For the most part, the keratinaceous tissues of the hoof are devoid of nerve endings; as a consequence it is the "insensitive" part of the foot. However, a few sensory nerve endings from nerves in the corium penetrate between cells of the deepest layer of the epidermis.

Three histological layers comprise the hoof wall: the stratum externum, stratum medium, and stratum internum (Figure 1.5). The superficial stratum externum, commonly called the periople, is a thin layer of horn extending distad from the coronet a variable distance; this thin, soft layer wears from the surface of the hoof wall so that it is present only on the bulbs of the heels and the proximal parts of the hoof wall. The bulk of the wall is the stratum medium consisting of cornified horn.[2] The stratum internum comprises the epidermal laminae.

Distal to the coronary sulcus (Figure 1.4), about 600 primary epidermal laminae of the stratum internum interleave with the primary dermal laminae of the laminar corium (Figures 1.6 and 1.7). Approximately 100 microscopic secondary laminae branch at an angle from each primary lamina, further binding the hoof and corium together (Figures 1.3–1.6). The epidermal laminae are routinely referred to as "insensitive," whereas the dermal laminae are called "sensitive." In the strictest sense, though, only the *keratinized* parts of the primary epidermal laminae are insensitive; the deepest layer of

VetBooks.ir

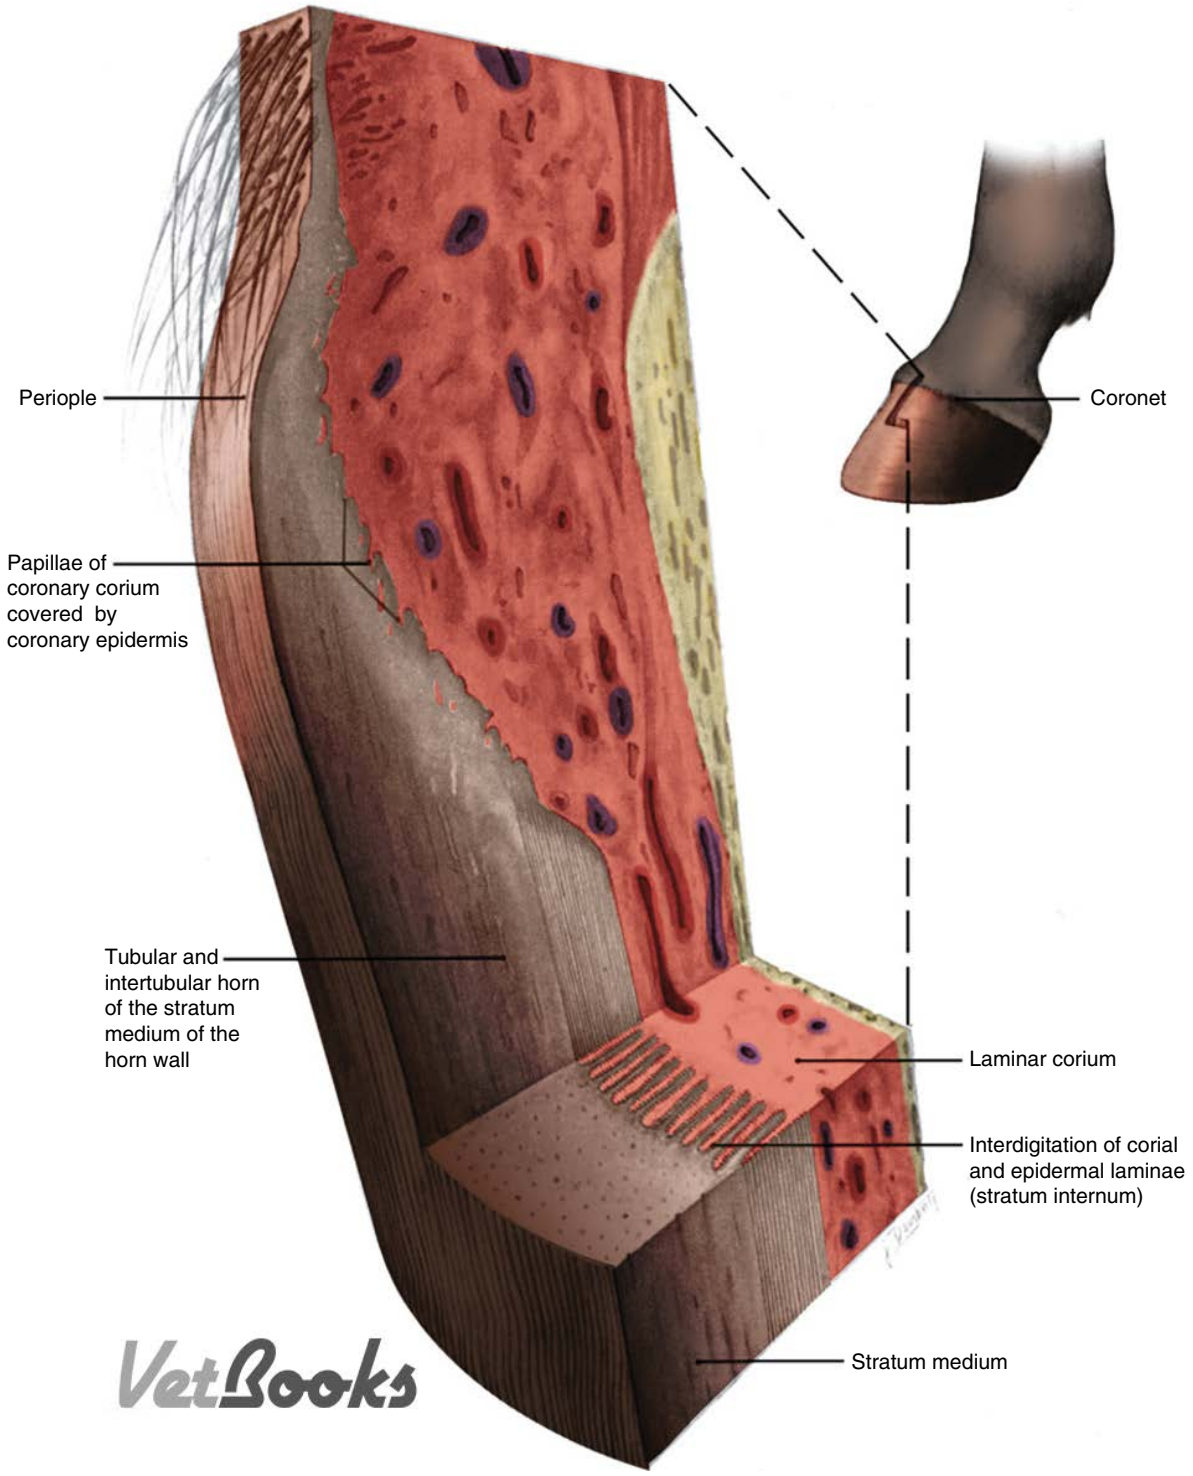

Figure 1.5. Three-dimensional dissection of coronary region of the hoof wall.

the epidermis, the stratum basale, including all of the secondary epidermal laminae, and the laminar corium are both innervated and therefore "sensitive."[42]

Growth of the hoof wall is primarily from the coronary epidermis toward the ground. Trauma or inflammation stimulates greater production of horn. Ultrastructural studies indicate that during growth of the hoof, primary epidermal laminae move past the secondary epidermal laminae by breaking and then reforming desmosomes between the two cell populations.[23] The relationship between the epidermal and dermal laminae plus the blending of the laminar corium with the periosteum of the distal phalanx suspend and support the bone, aiding in the dissipation of concussion and the movement of blood.

The growth of the wall progresses at the rate of approximately 6 mm per month, taking from 9 to

VetBooks.ir

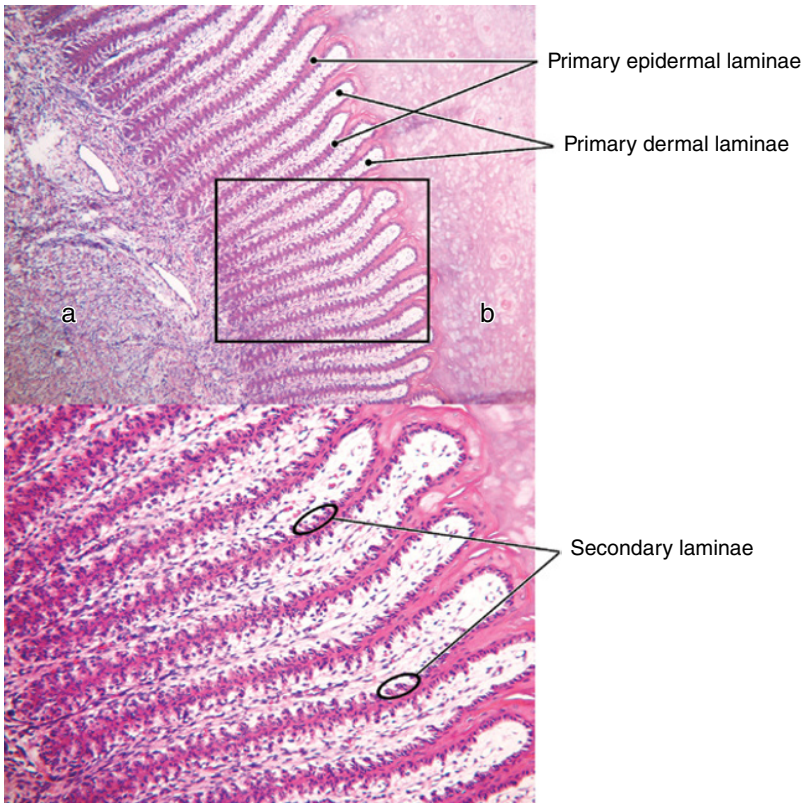

Figure 1.6. Photomicrograph of laminae of the equine hoof. In the top image, a indicates corium; b is the epidermis (hoof wall). Laminae extending from the corium (primary dermal laminae) are the so-called "sensitive laminae." Laminae extending from the epidermal portions of the hoof (primary epidermal laminae) are the "insensitive laminae." The box indicates the region enlarged in the lower image. Here, smaller interdigitating projections, the secondary laminae, can be seen arising perpendicular to the primary laminae.

12 months for hoof generated at the coronary band to reach the ground. The wall grows more slowly in cold and/or dry environments. The hoof wall grows evenly distal to the coronary epidermis so that the youngest portion of the wall in contact with the ground is at the heel (where it is shortest). Because this is the youngest part of the wall, it is also the most elastic, which allows it to accommodate heel expansion during concussion.

Stratum medium may be pigmented or nonpigmented. Contrary to popular belief, there is no difference in the stress–strain behavior or strength properties of pigmented versus nonpigmented equine hooves.[21] It has also been demonstrated that pigmentation has no effect on fracture toughness of hoof keratin.[3] On the other hand, water content of the hoof significantly affects its mechanical properties. In the natural hydration gradient in the hoof wall, the moisture content decreases from deep to superficial.[21] Very dry or extremely hydrated hoof wall is more likely to crack than normally hydrated hoof wall. A normally hydrated hoof is better able to absorb energy without mechanical failure.[4]

The slightly concave sole does not normally bear weight on its ground surface except near its junction with the white line, but it bears internal weight transmitted from the distal phalanx through the solar corium. In the unworn, untrimmed hoof wall, insensitive laminae can be seen on the internal surface of the wall where it makes contact with the ground (Figure 1.3). When the hoof is trimmed, the white line where the wall meets the sole is more clearly discerned. The sensitive corium is immediately internal to the white line that serves as a landmark for determining the proper position and angle for driving horseshoe nails.[14]

The frog (cuneus ungulae) is a wedge-shaped mass of keratinized stratified squamous epithelium made softer than other parts of the hoof by its greater water content.[21] Apocrine glands, spherical masses of tubules in the corium of the frog, deliver secretions to the surface of the frog.[25] The ground surface of the frog presents a pointed apex and central sulcus bordered by two crura. Paracuneal (collateral) sulci separate the crura of the frog from the bars and the sole. The palmar aspect of the frog blends into the bulbs of the heels. Compression of the frog during weight-bearing is transferred to the fibrofatty digital cushion deep to the heels; this force assists with movement of venous blood from the interior of the hoof capsule to the veins of the distal limb.

The corium blends with the periosteum of the distal phalanx, serving (particularly in the laminar region) to connect the hoof to the bone. The corium, the hoof's homolog to the dermis of skin, is composed of dense white fibrous connective tissue that is rich in elastic fibers, highly vascular, and well supplied with nerves. Corial arterial supply derives from numerous branches radiating outward from the terminal arch in small canals extending from the solar canal in the distal phalanx and from the dorsal and palmar branches of the distal phalanx, themselves branches of the digital arteries (Figure 1.8).

The coronary and perioplic coria and the stratum basale of the coronary and perioplic epidermis constitute

VetBooks.ir

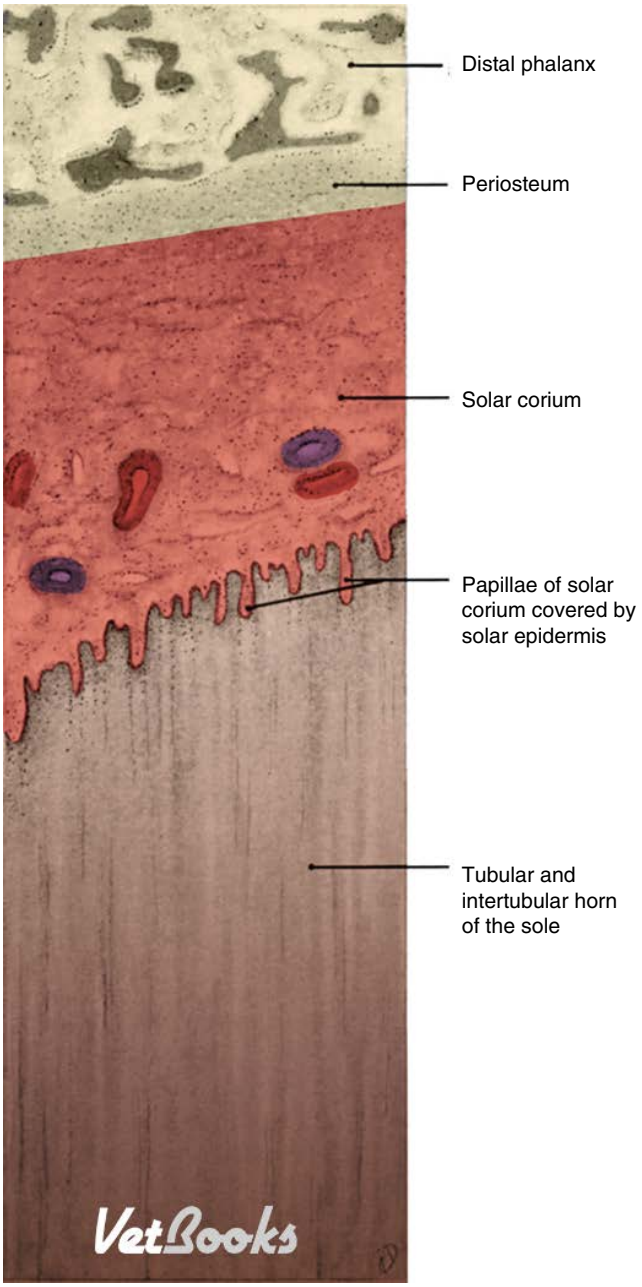

Figure 1.7. Histological relationships of periosteum, corium, and horn of the sole.

the coronary band (Figure 1.5). Deep to the coronary band, the subcutis is modified into the highly elastic coronary cushion. The coronary band and cushion form the bulging mass that fits into the coronary sulcus of the hoof (Figure 1.4). Part of the coronary venous plexus is within the coronary cushion. The plexus receives blood from the dorsal venous plexus in the laminar corium.

Internal Structures of the Foot

The "collateral" cartilages of the distal phalanx (often "lateral cartilages"; most correctly ungual cartilages) lie deep to the hoof and the skin, covered on their abaxial surfaces by the coronary venous plexus. They extend from each palmar process of the bone and project proximad to the coronary band of the hoof where they may be palpated (Figure 1.9). The cartilages are concave on their axial surfaces, convex on their abaxial surfaces, and thicker distally where they attach to the bone. Each cartilage is perforated in its palmar half by several foramina for the passage of veins connecting the palmar venous plexus with the coronary venous plexus.

Five ligaments stabilize each ungual cartilage (Figure 1.9):

1. A short, prominent ligament extends from the dorsal surface of the middle phalanx to the dorsal part of the cartilage.
2. A poorly defined elastic band extends from the side of the proximal phalanx to the proximal border of the cartilage and also detaches a branch to the digital cushion.
3. Several short fibers attach the distal part of the cartilage to the distal phalanx.
4. A ligament extends from the dorsal aspect of the cartilage to the termination of the tendon of insertion of the common digital extensor muscle. The dorsal part of each cartilage also serves as part of the distal attachment for the respective collateral ligament of the coffin joint.
5. An extension of the collateral sesamoidean ligament (CSL) attaches the end of the navicular bone to the cartilage of the distal phalanx.

Between the cartilages on the palmar side of the foot is the digital cushion, a highly modified subcutis consisting of a meshwork of collagen, elastic fibers, adipose tissue, and small masses of fibrocartilage (Figure 1.10). Only a few blood vessels ramify in the digital cushion. Dorsoproximally the digital cushion connects with the distal digital annular ligament. The apex of the wedge-shaped digital cushion is attached to the deep digital flexor tendon (DDFT) as the latter inserts on the solar surface of the distal phalanx. The base of the digital cushion bulges into the bulbs of the heels. The digital cushion serves an anticoncussive function.

As the DDFT courses to its insertion on the distal phalanx, it is bound down by the distal digital annular ligament, a sheet of deep fascia supporting the terminal part of the tendon and sweeping proximad to attach on each side of the proximal phalanx (Figure 1.11). The tendon passes over a complementary fibrocartilaginous plate on the proximal extremity of the palmar surface of the middle phalanx; this is the middle scutum (*L. shield*), which provides a smooth gliding surface for the tendon. Then the tendon gives off two small secondary attachments to the distopalmar surface of the second phalanx; these are part of the so-called T ligament (Figures 1.10 and 1.12).

Continuing toward its primary attachment on the flexor surface of the distal phalanx, the DDFT passes over the navicular (podotrochlear) bursa, interposed between the tendon and the fibrocartilaginous distal scutum covering the flexor surface of the navicular bone. From the exterior of the foot, the navicular bursa lies deep to the approximate middle third of the frog on a plane parallel to the coronet over the quarters of the hoof wall.

The proximal border of the navicular bone (distal sesamoid bone) possesses a groove containing foramina for the passage of small vessels and nerves. The distal border of the bone has a small, elongated facet that

VetBooks.ir

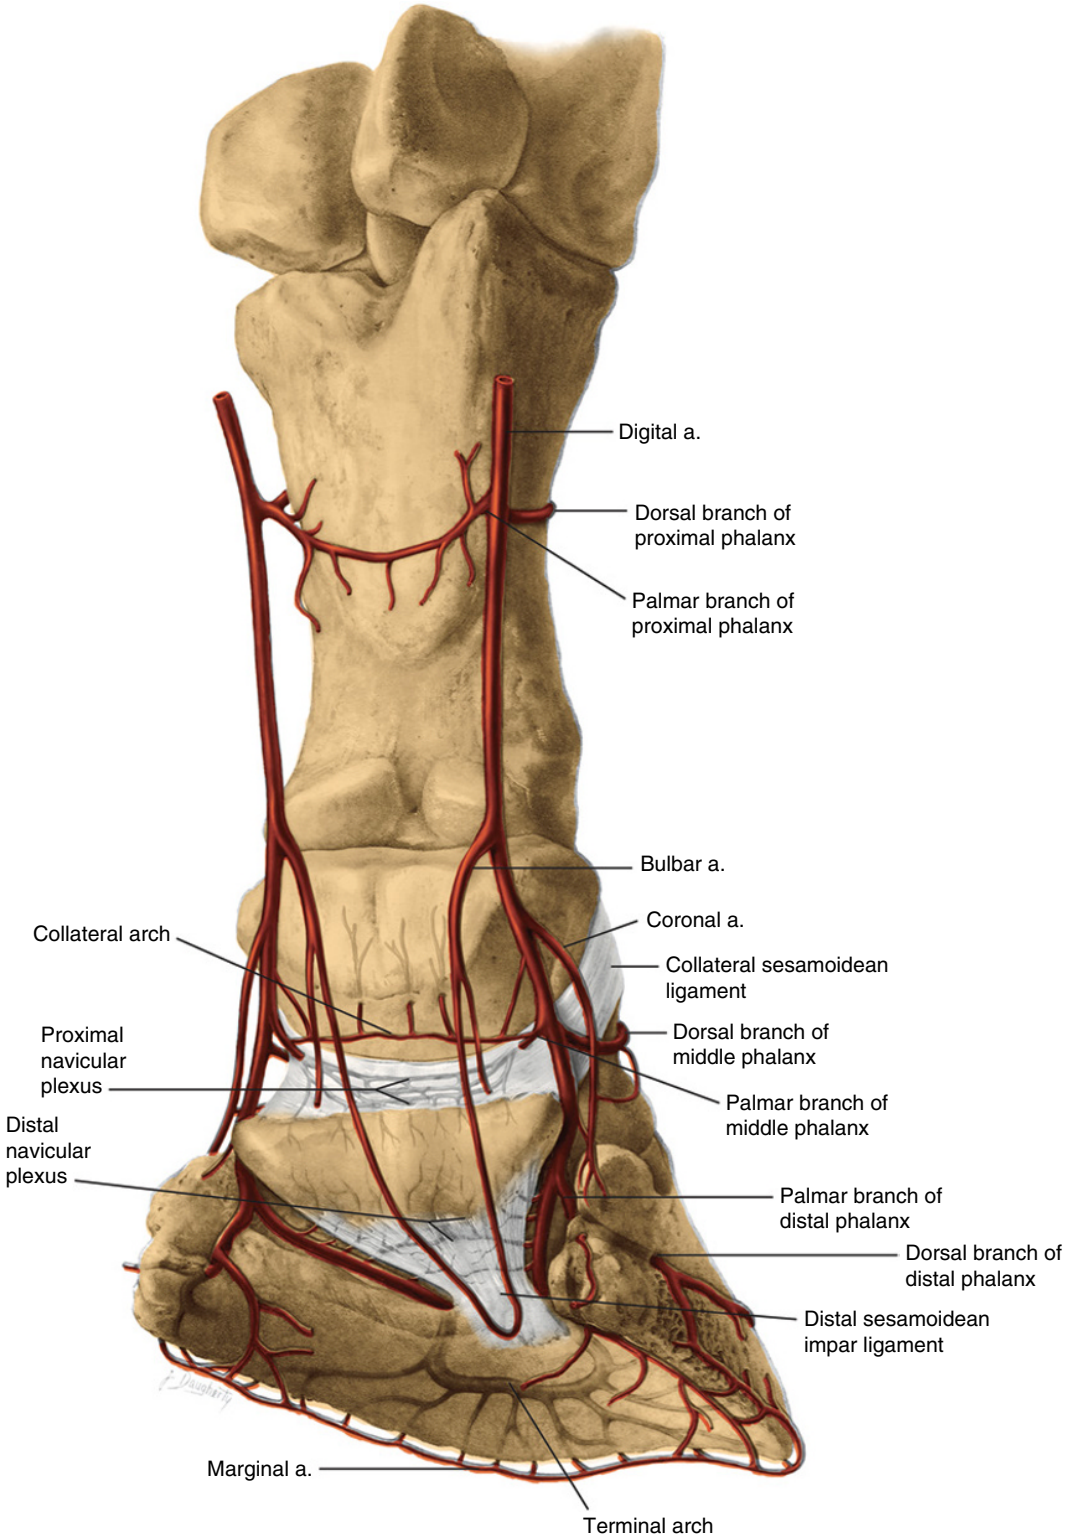

Figure 1.8. Arterial supply to the digit of the forelimb.

articulates with the distal phalanx. Several large, irregular fossae lie in an elongated depression palmar to that facet (Figure 1.13). The main articular surface of the navicular bone contacts the middle phalanx.

The navicular bone is supported in its position by three ligaments comprising the navicular suspensory apparatus. Medial and lateral collateral sesamoidean (suspensory navicular) ligaments arise from the distal end of the proximal phalanx (Figure 1.12). These sweep obliquely distad, each ligament crossing the pastern joint and attaching broadly along the proximal border of the navicular bone. Along this border, each ligament

VetBooks.ir

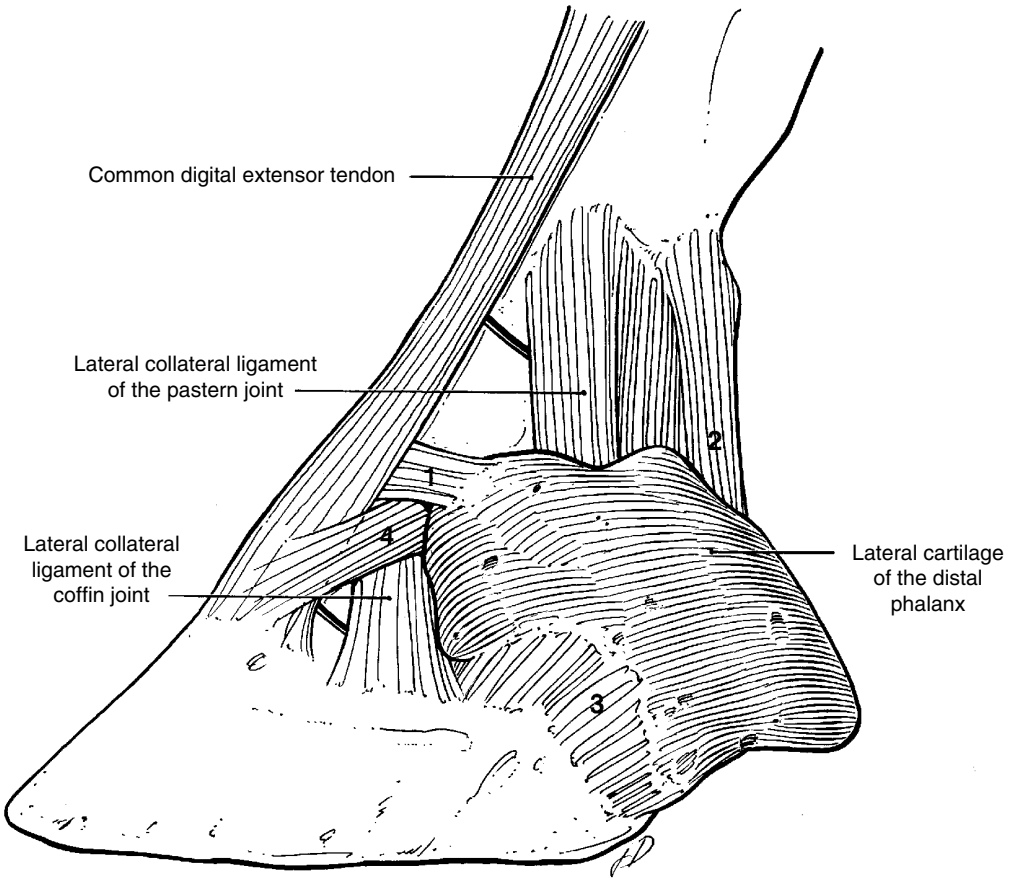

Figure 1.9. Four of the ligaments (1, 2, 3, and 4) that stabilize the cartilage of the distal phalanx. The fifth ligament listed in the text is not depicted as it attaches to the medial aspect of the cartilage.

meets and blends with its contralateral partner. This attachment on the proximal border is joined by branches from the deep digital flexor; together, these constitute the "T ligament" that attaches to the palmar surface of the middle phalanx. Fibers of the CSLs also attach the end of the navicular bone to the palmar process and cartilage of the distal phalanx.

Distally, the navicular bone is stabilized by the distal sesamoidean impar ligament, extending from the distal border of the bone to intersect with the insertion of the DDFT (arrow, Figure 1.10).[6]

The distal articular surface of the middle phalanx, the articular surface of the distal phalanx, and the two articular surfaces of the navicular bone form the coffin joint, a hinge joint of limited range of motion. Short collateral ligaments arise from the distal end of the middle phalanx, pass distad deep to the cartilages of the distal phalanx, and terminate on either side of the extensor process and the dorsal part of each cartilage.

The synovial membrane of the distal interphalangeal (coffin) joint has a dorsal pouch that extends proximad on the dorsal surface of the middle phalanx deep to the common digital extensor tendon nearly to the pastern joint. The synovium has a complex relationship on its palmar side to the ligaments and tendons that are found here. The proximal portions wrap around the distal ends of the CSLs. The distal pouch forms a thin extension between the articulation of the navicular bone and the distal phalanx. This pouch's synovial membrane surrounds the distal sesamoidean impar ligament on each side where the distal interphalangeal joint is closely associated with the neurovascular bundle that will enter the distal phalanx. Although a direct connection between the distal interphalangeal joint and the navicular bursa is rare, passive diffusion of injected dye and anesthetic occurs.[7]

The common digital extensor tendon terminates on the extensor process of the distal phalanx, receiving first branches from the suspensory ligament at the level of the pastern and then an additional ligament from each ungual cartilage as it inserts (Figure 1.9).

Pastern

Deep to the skin and superficial fascia on the palmar aspect of the pastern, the proximal digital annular ligament covers the superficial digital flexor as it bifurcates. In this location, it binds down both digital flexor tendons.

Two distinct ligaments of the ergot diverge from beneath the horny ergot on the palmar skin of the fetlock. Each ligament descends obliquely just deep to the skin. Distally it widens and blends into the dense connective tissue of the distal digital annular ligament.

The superficial digital flexor tendon (SDFT) terminates by bifurcating into two branches that insert on the

VetBooks.ir

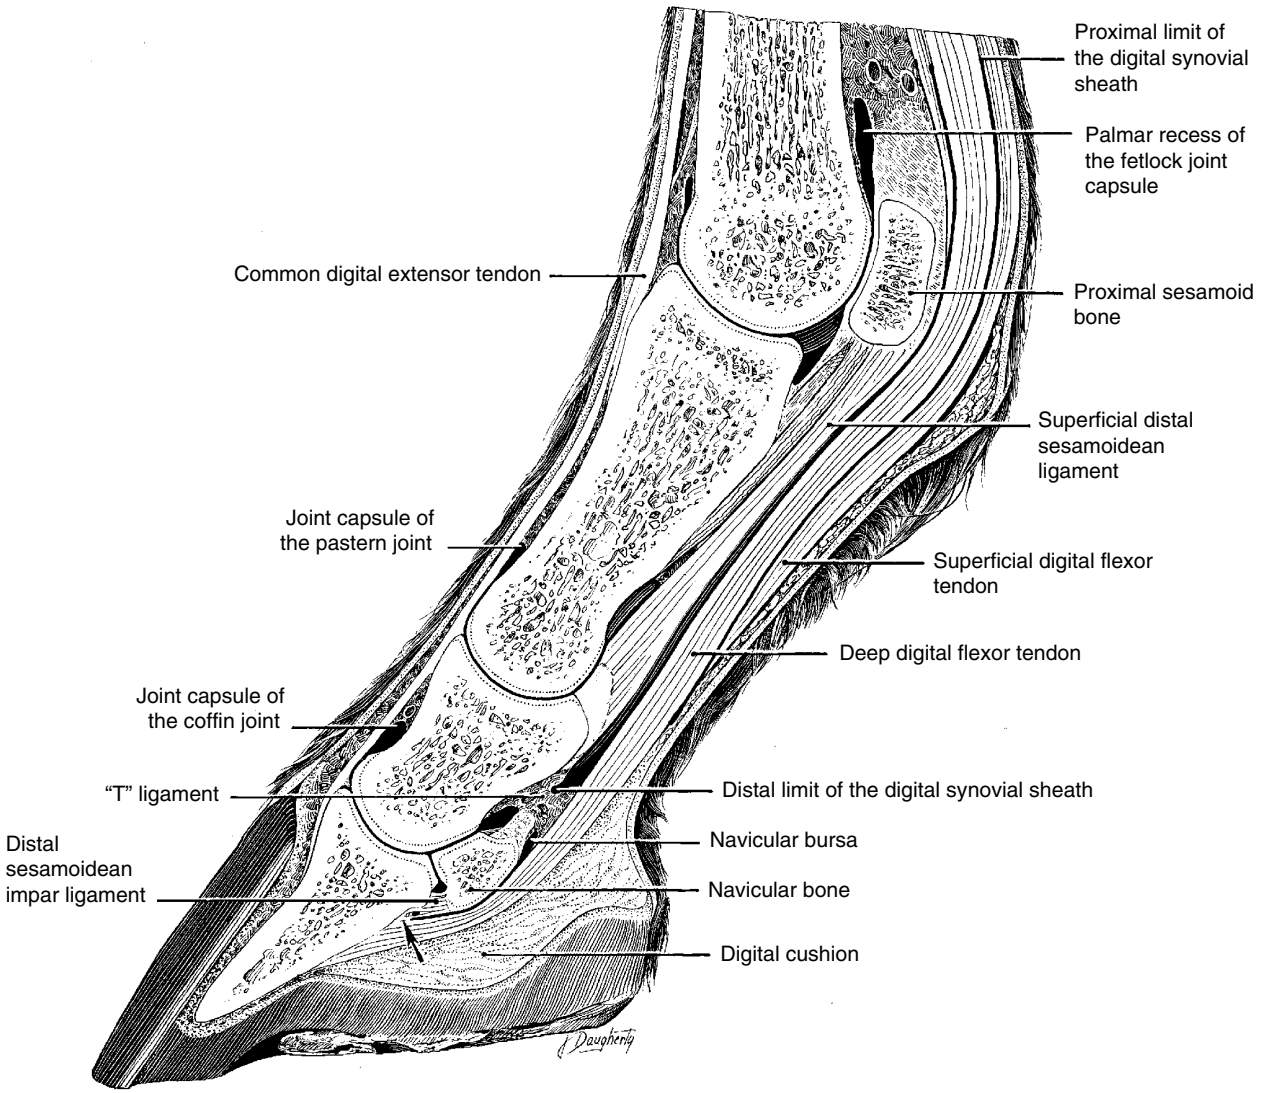

Figure 1.10. Sagittal section of equine fetlock and digit.

proximal extremity of the middle phalanx just palmar to the collateral ligaments of the proximal interphalangeal joint. Traditionally, the insertion of the SDFT has been described as also having additional attachments on the distal extremity of the proximal phalanx; radiographic studies have concluded that these attachments are not strictly part of the flexor tendon and instead represent associated palmar ligaments.[44] The DDFT descends between the two branches of the SDFT. A digital synovial sheath surrounds both tendons and continues in association with the DDFT as far as the "T ligament" (Figures 1.10 and 1.11).

Deep to the digital flexor tendons, a series of ligaments (often collectively referred to as the distal sesamoidean ligaments) extend distad from the bases of the two proximal sesamoid bones (Figure 1.11). These are the functional continuation of the suspensory apparatus into the digit. The most superficial of these is the straight sesamoidean ligament, which attaches primarily to the palmar aspect of the middle phalanx and less robustly to the palmar first phalanx. The wedge-shaped middle (oblique) sesamoidean ligament attaches distally to a rough area on the palmar surface of the proximal phalanx. Deep to these is the pair of cruciate ligaments that cross midline, each attaching distally to the contralateral eminence on the proximal end of the proximal phalanx. Deepest of the distal sesamoidean ligaments are a pair of short sesamoidean ligaments extending from the dorsal aspect of the base of each proximal sesamoid bone to the edge of the articular surface of the proximal phalanx (Figure 1.11).

An extensor branch of the suspensory ligament passes from the abaxial surface of the respective proximal sesamoid bone dorsodistad obliquely across the proximal phalanx to the dorsal surface where each branch blends with the common digital extensor tendon near the distal end of the proximal phalanx. An elongated bursa under each extensor branch is extensive enough to be considered a synovial sheath.[16]

In the dorsal aspect of the pastern, the common digital extensor tendon is attached to the proximal ends of the proximal and middle phalanges on its way to its definitive insertion on the extensor process of the distal phalanx. A bursa often occurs under this tendon near its union with the extensor branches of the suspensory ligament. The tendon of the lateral digital extensor muscle

VetBooks.ir

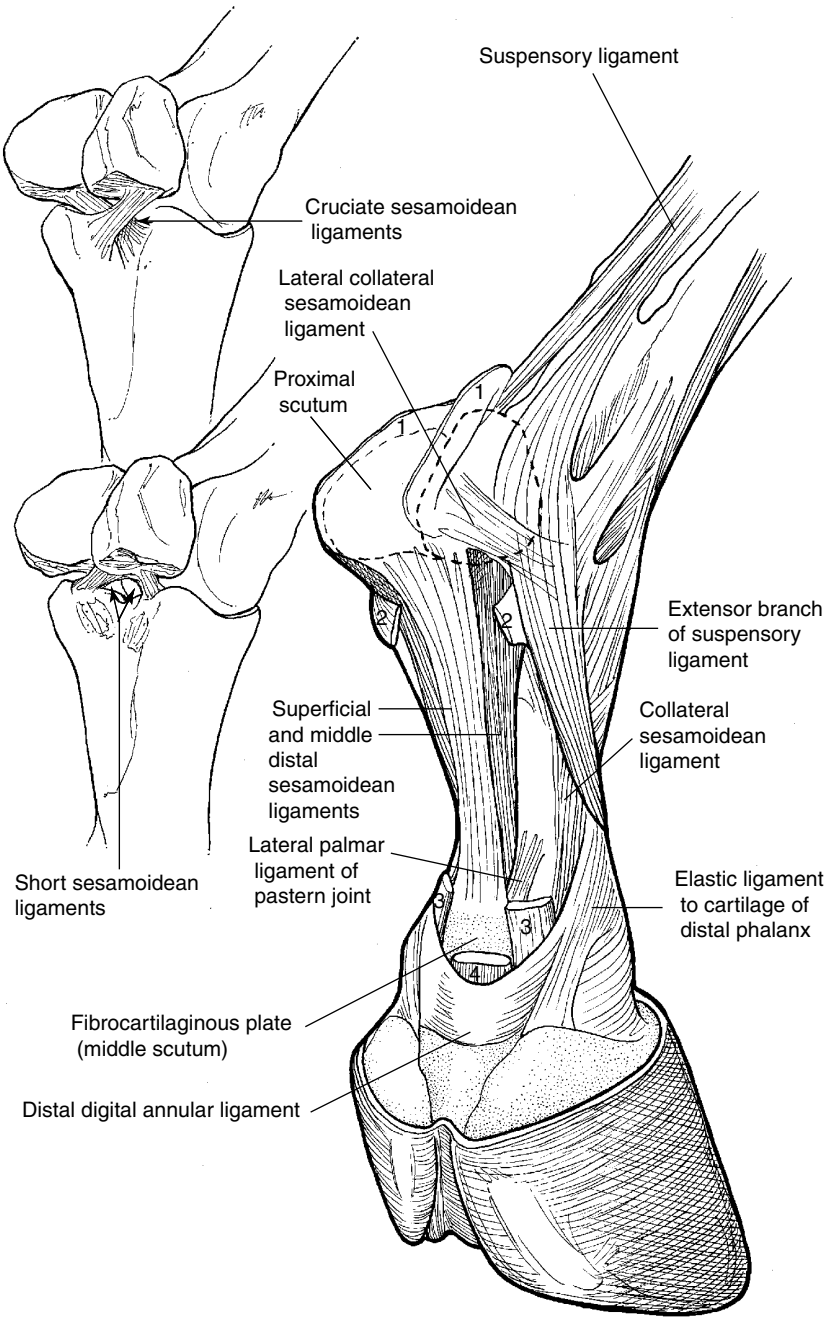

Figure 1.11. Sesamoidean ligaments. Dashed lines indicate positions of the proximal sesamoid bones embedded in the metacarpointersesamoidean ligament. Numbers indicate cut stumps of (1) palmar annular ligament, (2) proximal digital annular ligament, (3) superficial digital flexor, and (4) deep digital flexor tendon.

inserts lateral to the common digital extensor tendon on the proximal dorsal surface of the proximal phalanx.

The proximal interphalangeal (pastern) joint is formed by the condyle on the distal end of the proximal phalanx and two corresponding concave articular foveae on the proximal end of the middle phalanx. Two short collateral ligaments and four palmar ligaments stabilize these bones. The collateral ligaments are oriented vertically between the eminences on the bones rather than parallel to the axis of the digit. The axial pair of palmar ligaments extends from the ridges on the palmar side of the proximal phalanx to the region on each side of the straight sesamoidean ligaments' attachment on the middle phalanx. The abaxial palmar ligaments pass from the lateral aspects of the proximal phalanx to the palmar surface of the middle phalanx. The axial ligaments blend somewhat with the branches of the SDFT and the straight sesamoidean ligament, and they may be difficult to discern as individual entities.

The joint capsule of the pastern joint blends with the deep surface of the common digital extensor tendon dorsally where it is accessible for arthrocentesis (Figure 1.10). It also blends with the collateral ligaments of the joint. The palmar aspect of the capsule extends slightly proximad, compressed between the middle phalanx and the terminal branches of the SDFT and the

straight sesamoidean ligament. These taut overlying structures subdivide the capsule into medial and lateral pouches that are accessible for arthrocentesis.

Fetlock

The fetlock of the thoracic limb is the region around the metacarpophalangeal (fetlock) joint. On the palmar aspect of the fetlock, the ergot is a prominent cutaneous feature. Its dermal base gives origin to the two distally diverging ligaments of the ergot. Deep to the skin and superficial fascia, the palmar annular ligament of the fetlock encircles the digital flexor tendons and their digital synovial sheath, binding them in the groove between the proximal sesamoid bones. Distally, the palmar annular ligament of the fetlock blends with the proximal digital annular ligament.

The fetlock joint is formed by the distal end of the third metacarpal bone (the cannon bone), the proximal end of the proximal phalanx, the two proximal sesamoid bones, and the extensive fibrocartilaginous palmar ligament that the proximal sesamoids are embedded. The articular surface on the third metacarpal bone, its trochlea, is sharply divided by a sagittal ridge, and this ridge fits into a complementary sagittal groove in the articular surface of the proximal phalanx.

Collateral ligaments of the fetlock joint extend distad from the eminence and depression on each side of the distal cannon bone. The superficial part of each ligament attaches to the edge of the articular surface of the proximal phalanx; the shorter, stouter deep part of the ligament attaches to the abaxial surface of the adjacent proximal sesamoid and the proximal phalanx.

The smooth depression between the proximal sesamoid bones through which the digital flexor tendons pass is formed by the fibrocartilage of the palmar ligament that covers the flexor surfaces of the proximal sesamoid bones. Immediately distal to the canal formed by the encircling annular ligament and the groove between the proximal sesamoids, the DDFT perforates through a ringlike opening in the SDFT, the manica flexoria.

The common and lateral digital extensor tendons pass over the dorsal aspect of the fetlock joint where a bursa

VetBooks.ir

lies deep to each tendon. Small but common subcutaneous bursae may occur on the palmar surface of the fetlock joint and on the lateral aspect of the joint just proximal to the extensor branch of the suspensory ligament.[30]

The palmar part of the fetlock joint capsule is thicker and more voluminous than the dorsal part. A consistent bursa deep to the digital flexor tendons at the distal end of the cannon bone lies against the thickened capsule and may communicate with the joint cavity.[16] The palmar recess (pouch) of the fetlock joint capsule extends proximad between the cannon bone and the suspensory ligament. This pouch is palpable and even visible in the presence of joint effusion.

Support for the fetlock and stabilization during weight-bearing and locomotion is rendered by the suspensory apparatus, a part of the stay apparatus. The suspensory apparatus of the fetlock comprises the suspensory ligament (interosseus medius muscle) and its extensor branches to the common digital extensor tendon, the proximal sesamoids embedded in the palmar ligament, and the distal sesamoidean ligaments extending from the bases of the proximal sesamoid bones to the proximal and middle phalanges.

Blood Vessels of the Digit and Fetlock

Arterial Supply

The arterial supply to the digit and fetlock of the thoracic limb is derived principally from the medial palmar artery. This substantial vessel divides in the distal fourth of the metacarpus between the digital flexor tendons and the suspensory ligament into the medial and lateral digital arteries. An anastomotic branch from the distal deep palmar arch unites with the lateral digital artery to form the superficial palmar arch. Branches from this arch directly supply the fetlock joint (Figure 1.8).

Each digital artery becomes superficial on the fetlock. The artery lies palmar to its satellite vein, running between the palmar digital nerve and its dorsal branch (Figures 1.14 and 1.15). As each digital artery courses distad over the fetlock, it gives off branches to the fetlock joint, digital extensor and flexor tendons, digital synovial sheath, ligaments, fascia, and skin.

Distal to the fetlock, the digital arteries run parallel with the borders of the DDFT, giving off branches that create encircling anastomoses around the proximal and middle phalanges. The anastomosis associated with the proximal phalanx is created from dorsal and palmar branches of the proximal phalanx that encircle the digit (Figure 1.8). The palmar branch joins the contralateral vessel between the straight and oblique sesamoidean ligaments. The dorsal branch anastomoses with the contralateral vessel deep to the common digital extensor tendon.

At the level of the middle phalanx, dorsal and palmar branches again arise. The dorsal branch of the middle phalanx anastomoses with the contralateral branch deep to the common digital extensor tendon to form a coronary arterial circle. This vascular complex supplies branches to the distal interphalangeal joint, common digital extensor tendon, perioplic and coronary coria, fascia, and skin. The palmar branches of the middle phalanx run parallel to the proximal border of the distal sesamoid bone, uniting to complete the arterial circle around the middle phalanx. Branches from the palmar portion of the arterial circle supply an anastomotic proximal navicular plexus; this gives rise to several small arteries that enter the foramina along the proximal border of the navicular bone.[9,18] The bone receives approximately one-third of its blood supply from this plexus.

Immediately distal to the distal sesamoid bone, each digital artery gives off one to three small arteries that supply the distolateral border of the navicular bone. The digital arteries further give rise to branches that form a distal navicular plexus within the distal sesamoid impar ligament. Six to nine distal navicular arteries from the plexus enter the distal sesamoid bone through the distal border. These supply the distal two-thirds of the distal sesamoid bone.[18]

Near the level of the pastern joint, a prominent bulbar artery (artery of the digital cushion) arises from each digital artery (Figure 1.8). Their branches supply the frog, the digital cushion, palmar part of the cuneate corium, laminar corium of the heel and bar, and palmar parts of the perioplic and coronary coria. A small coronal artery arises from either the digital artery or the bulbar artery, and its branches supply the heel and perioplic corium.

Within the foot opposite each end of the navicular bone, an artery to the dermal laminae of the heel arising from the digital artery has been noted on radiographic angiograms.[10,18] At the level of the palmar process of the distal phalanx, the digital artery gives off the dorsal branch of the distal phalanx and then continues distad to form the terminal arch within the distal phalanx. The dorsal branch of the distal phalanx gives off a small artery supplying the digital cushion and corium of the frog and then passes through a notch or foramen in the palmar process. Emerging onto the dorsal side of the distal phalanx, the dorsal branch of the distal phalanx bifurcates. One branch supplies the corium of the heels and quarters; the other courses dorsad in a bony sulcus to supply the corium of the toe and to form anastomoses with other arteries on the distal phalanx (Figure 1.8).

The continuation of the digital artery enters a solar foramen and anastomoses with the contralateral artery to form the terminal arch within the solar canal (Figure 1.8). Branches from the terminal arch course through the bone, 4 or 5 of them emerging through foramina on the parietal surface to supply the proximal part of the laminar corium; another 8–10 vessels emerge through foramina near the solar border of the bone and anastomose to form the prominent marginal artery of the sole. This artery supplies the solar and cuneate coria.

The arterial network of the corium can be divided into three regions with independent blood supplies: (1) the dorsal coronary corium, (2) the palmar part of the coronary corium and laminar corium, and (3) the dorsal laminar corium and solar corium.[32] Other regions are supplied by multiple other small arteries. Angiographic studies indicate that blood flow within dermal laminae is from distal to proximal.[10,32]

Branches of the digital arteries in the hindfoot are essentially the same as in the forefoot except for the blood supply to the distal sesamoid bone. In 50% of hindfeet examined in a definitive study, the collateral arch from the plantar branches of the middle phalanx supplied the primary arteries to the proximal navicular network.[18]

VetBooks.ir

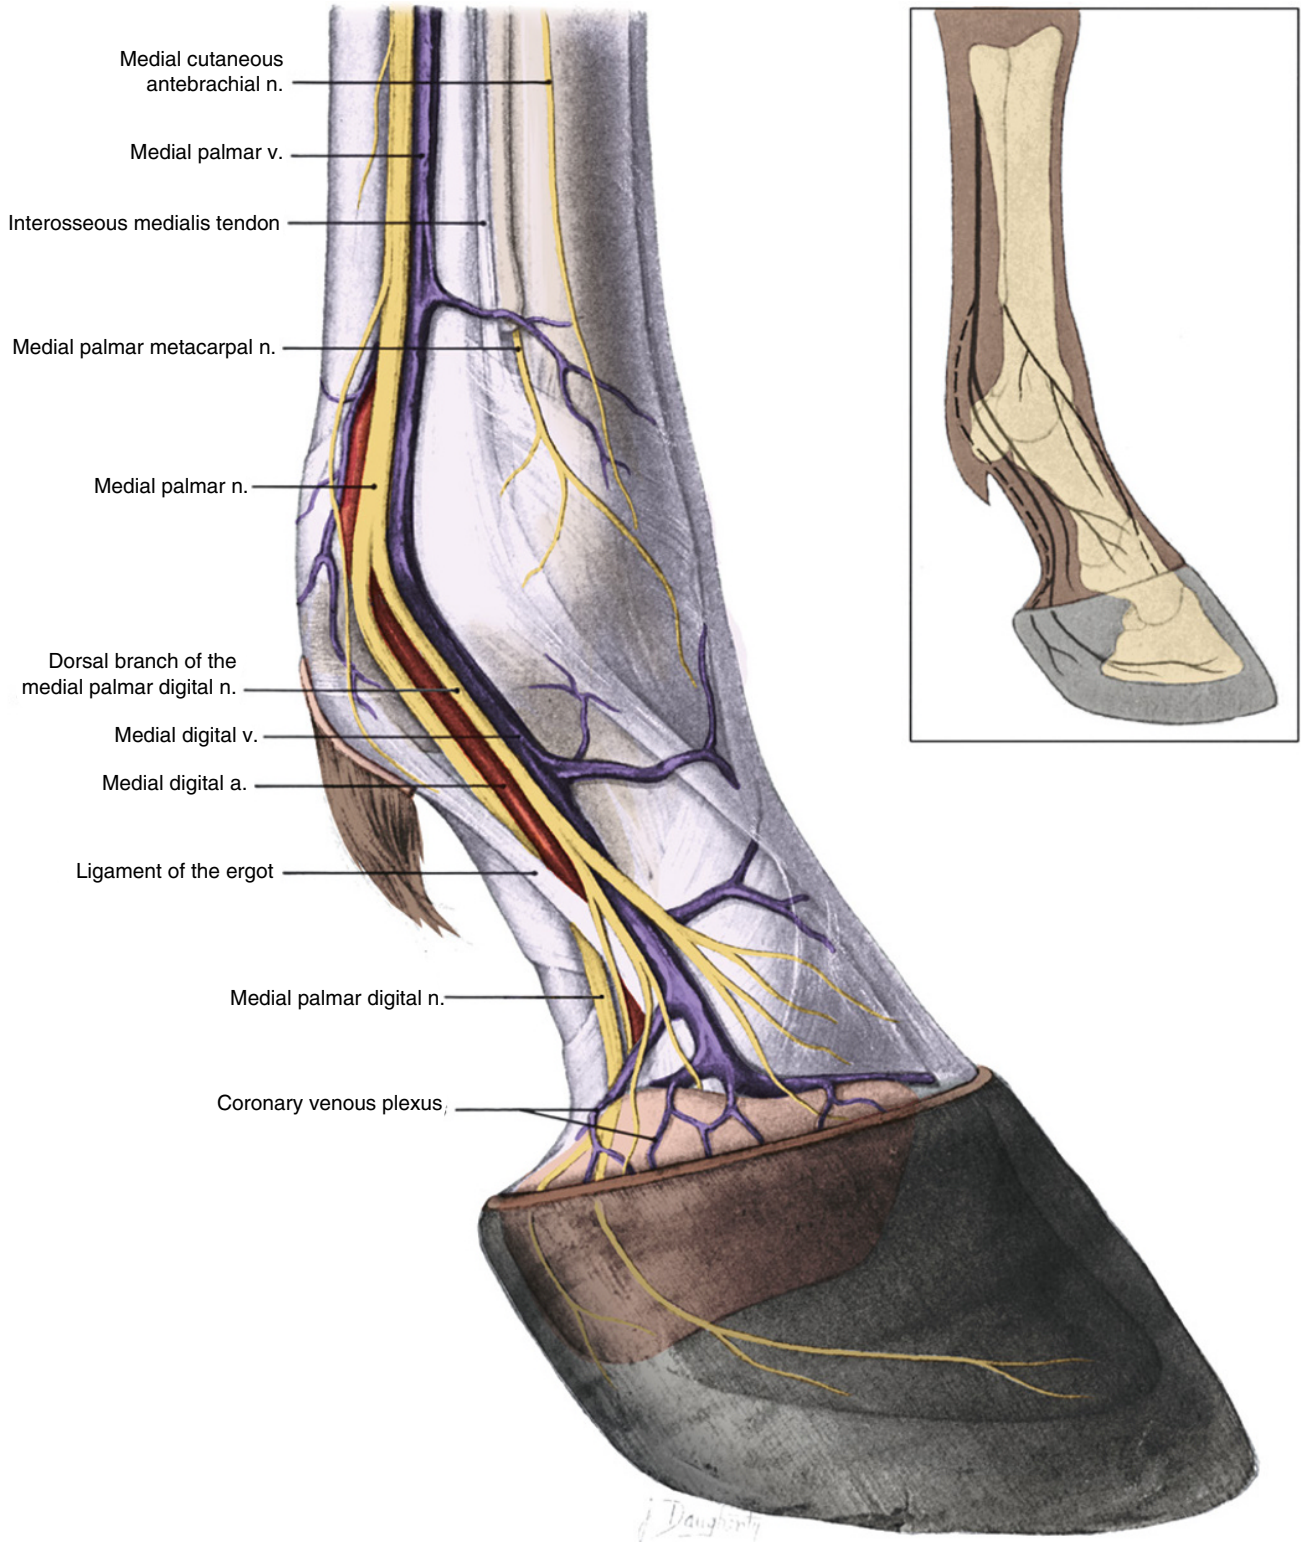

Figure 1.14. Medial aspect of distal metacarpus, fetlock, and digit with skin and superficial fascia removed. Inset: Schematic of the distribution of major nerves; dashed lines indicate variant branches.

Venous Drainage

Venous drainage from the laminar corium begins with veins from the laminar circulation continuing into the parietal (associated with the hoof wall) venous plexus and the coronary venous plexus (Figure 1.16). Veins from the perioplic and coronary coria drain toward the coronary venous plexus, and those from the solar and cuneate coria drain into the solar venous plexus.[26]

Veins in the solar canal come together at the level of the distal sesamoid bone to form the medial and lateral

VetBooks.ir

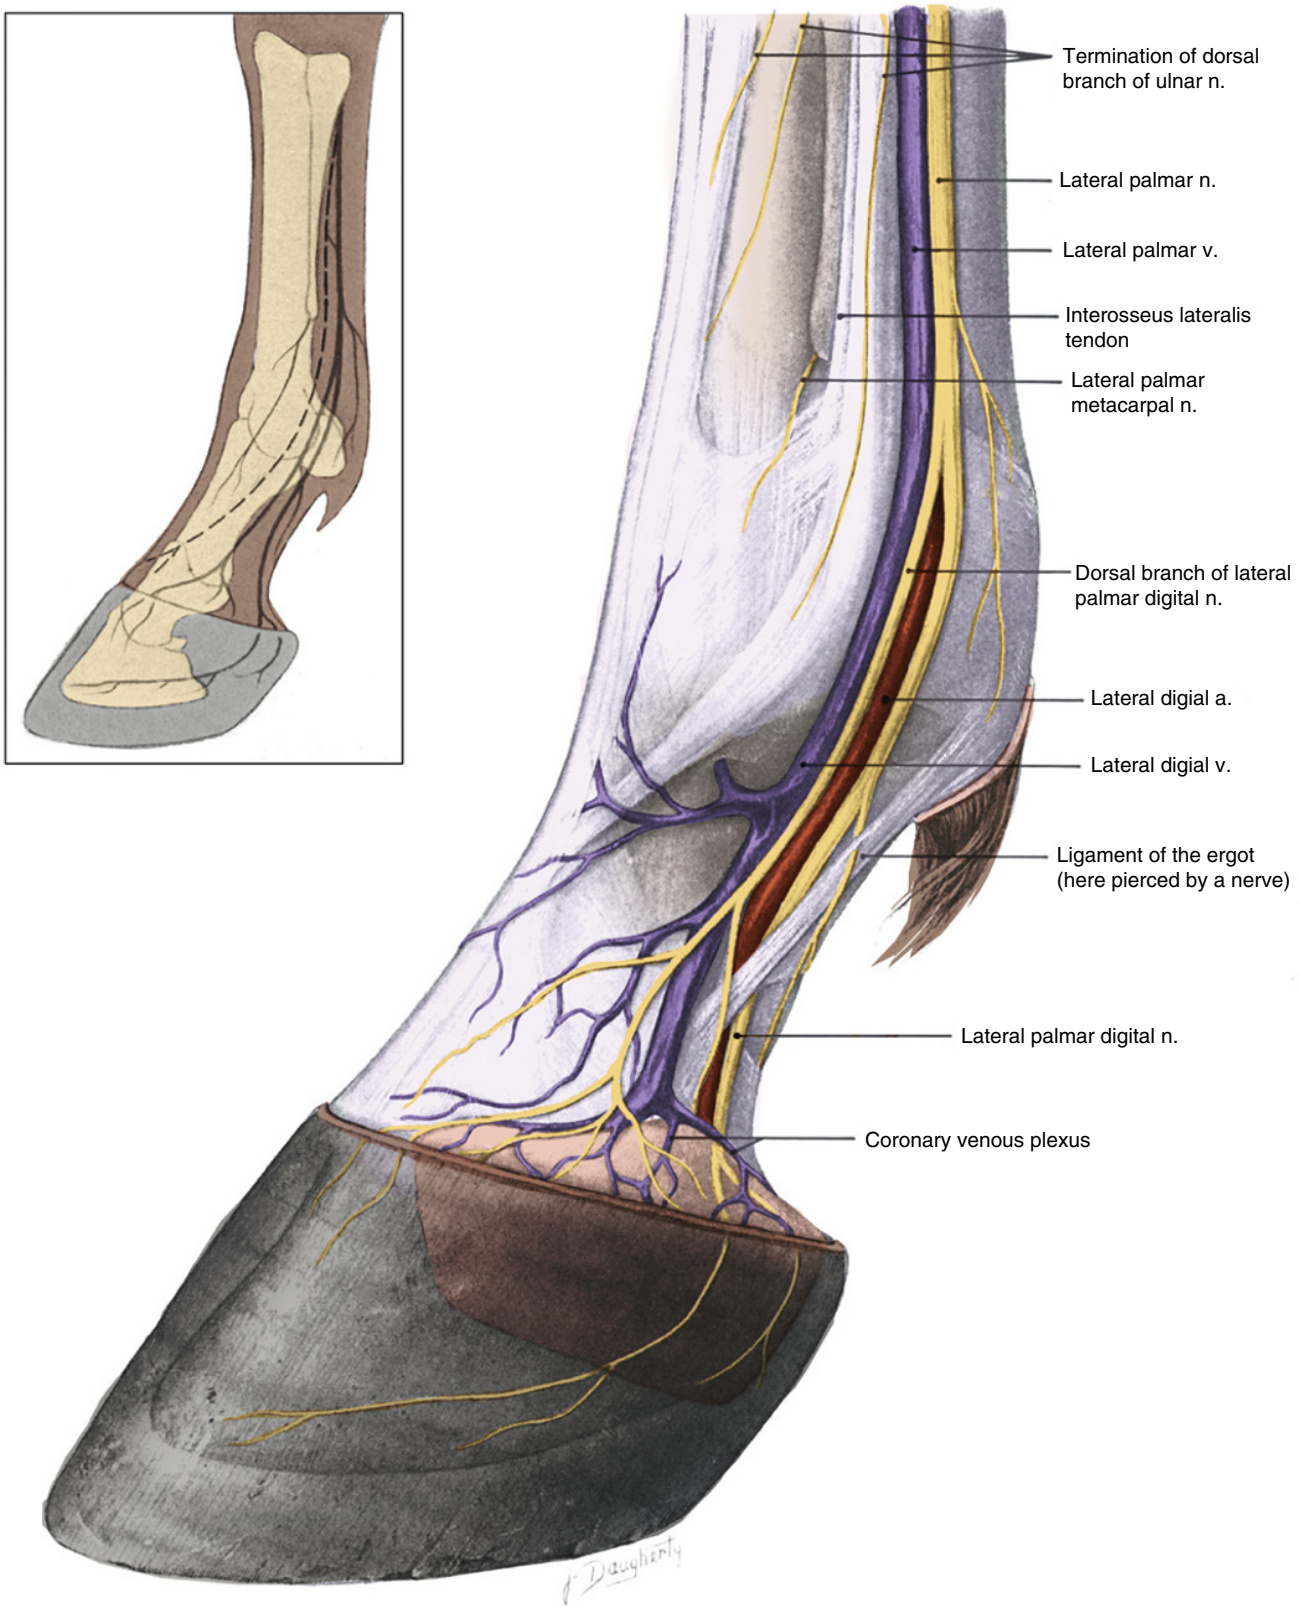

Figure 1.15. Lateral aspect of distal metacarpus, fetlock, and digit with skin and superficial fascia removed. Inset: Schematic of the distribution of major nerves; dashed lines indicate variant branches.

terminal veins. Each terminal vein joins with branches of an inner venous plexus to form a digital vein. The digital vein receives branches from the distal sesamoid bone, coronary vein, inner venous plexus, and large bulbar vein carrying blood from the heel. Most venous blood in the foot is drained by the veins located in the palmar aspect which are largely valveless. Some valves are present in the tributaries of the coronary and subcoronary

veins and in the bulbar veins and their branches. Thus, the flow of blood may take different routes with the weight-bearing force essential to its proximal flow.[26]

Nerves of the Digit and Fetlock

As they descend to the fetlock, the medial and lateral palmar nerves supply small branches to the fetlock and flexor tendons. Each then gives off a dorsal branch at this level, continuing over the widest part of the joint as the medial and lateral palmar digital nerves (Figures 1.14 and 1.15). The corresponding digital artery lies between this dorsal branch and the palmar digital nerve. The dorsal branch courses distad between the digital vein and artery, branching midway down the pastern. In approximately one-third of the cases, an intermediate branch also arises from the dorsal aspect of the palmar digital nerve.[29] The dorsal (and intermediate, when present) branches supply sensory and vasomotor innervation to the dorsal part of the fetlock joint, dorsal parts of the interphalangeal joints, coronary corium and dorsal parts of the laminar and solar coria, and dorsal part of the cartilage of the distal phalanx.[5,12]

The main continuation of the palmar digital nerve descends palmar and parallel to the digital artery. The nerve and artery are deep to the ligament of the ergot as the latter descends obliquely across the lateral aspect of the pastern. A branch may arise from the lateral palmar digital nerve and perforate the lateral ligament of the ergot (Figure 1.15).

The palmar digital nerves supply the palmar parts of the fetlock joint capsule and of the digit: skin, pastern joint capsule, digital synovial sheath and flexor tendons, distal sesamoidean ligaments, coffin joint capsule, navicular bone and its ligaments, navicular bursa, palmar part of the cartilage of the distal phalanx, part of the laminar corium, coria of the sole and frog, and digital cushion.

A fine terminal branch of each palmar digital nerve and an accompanying small artery constitute a neurovascular bundle that descends adjacent to the synovial membrane of the distal interphalangeal joint to enter the distal phalanx.[5]

Additional cutaneous innervation of the fetlock is supplied by terminal branches of the medial cutaneous antebrachial nerve dorsomedially and the dorsal branch of the ulnar nerve dorsolaterally. Medial and lateral palmar metacarpal nerves emerge immediately distal to the distal end of the respective small metacarpal (splint) bone, supplying branches to the fetlock joint capsule and ramifying in the superficial fascia of the pastern. It has been reported that in some instances, a terminal branch from the medial palmar metacarpal nerve descends to the coronary band (Figure 1.14).[19,31] An occasional variant, a palmarly directed branch from the medial palmar nerve in the distal metacarpus, courses palmar to the medial palmar digital nerve, reaching the digital cushion (Figure 1.14). Another variant branch may arise from the lateral palmar nerve in the proximal metacarpus, cross over the fetlock, and extend obliquely to the coronary band (Figure 1.15).

Electrophysiologic studies confirm that stimuli on the medial half of the digit and fetlock of the forelimb are mediated by the median nerve and stimuli on the lateral half are mediated by the median and ulnar nerves.[5]

Although direct communication between the distal interphalangeal joint and the navicular bursa is very rare, indirect communication via diffusion of molecules has been demonstrated.[8] Dye injected experimentally into the distal interphalangeal joint diffused into the navicular bursa and also stained the synovial coverings of the CSLs and the distal sesamoidean impar ligament and the medullary cavity of the navicular bone.

Basic Functions of the Digit and Fetlock

In the standing position, the fetlock and digit are prevented from nonphysiologic hyperextension by the suspensory apparatus of the fetlock (interosseus muscle [suspensory ligament], palmar ligament and proximal sesamoids, and distal sesamoidean ligaments), digital flexor tendons, and collateral ligaments of the joints.

During flexion and extension of the digit, most of the movement comes from the fetlock joint. The least amount of movement is in the pastern joint, and movement in the coffin joint is intermediate. Although the pastern joint is a hinge joint, normally providing only limited flexion and extension, manipulation can produce transverse movement and some rotation when the joint is flexed.

When the unshod hoof contacts the ground, the heels usually strike first, followed in sequence by the ground surfaces of the quarters and toe. Expansion of the heels is facilitated by the elasticity of the hoof wall. Most of the impact is sustained by the hoof wall, and compression of the wall creates tension on the interlocking epidermal and dermal laminae and, hence, to the periosteum of the distal phalanx. The concave sole does not absorb much force although it is depressed somewhat by the downward force of the distal phalanx, causing expansion of the quarters. Descent of the coffin joint occurs as the navicular bone moves in a distopalmar direction,

VetBooks.ir

stretching its collateral (suspensory) and impar ligaments and pushing against the navicular bursa and tendon of the deep digital flexor muscle. Forces acting on the distal phalanx are indicated in Figure 1.17. Magnitude and direction of the forces may change with limb position and loading state.[22] Concussion is further dissipated by pressure from the frog being transmitted to the digital cushion and the cartilages of the distal phalanx.

Lateral expansion of the hoof and cartilages of the distal phalanx compresses the venous plexuses of the foot, forcing blood proximad into the digital veins. The hydraulic shock absorption afforded by the blood within the vessels augments the direct cushioning by the frog and digital cushion and the elasticity of the hoof wall.

During concussion, the palmar ligaments of the pastern joint, the straight sesamoidean ligament, and the tendon of the deep digital flexor provide the tension necessary to prevent overextension of the pastern joint. Contraction of the superficial digital flexor muscle tightens its insertions on the middle phalanx, preventing the pastern joint from buckling.

The suspensory apparatus of the fetlock and the digital flexor tendons ensure that overextension of the fetlock joint is minimized when the hoof strikes the ground. Under extreme loading conditions (e.g. at a gallop or when landing a jump), the palmar aspect of the fetlock comes very close to the ground. During this descent of the fetlock, the coffin joint is flexed by the increased tension on the DDFT.

Metacarpus

The equine metacarpus consists of the large third metacarpal (cannon) bone, the second (medial) and fourth (lateral) metacarpal bones (splint bones), and the structures associated with them. The shaft of each splint bone is united to the cannon bone by an interosseous ligament. Length and curvature of the shafts and the prominence of the free distal ends ("buttons") of the splint bones are variable. The proximal ends of the metacarpal bones articulate with the distal row of carpal bones. The second metacarpal articulates with the second and third carpals; the third metacarpal articulates with the second, third, and fourth carpals; and the fourth metacarpal articulates with the fourth carpal bone.

Dorsal Aspect

The structures of the dorsal aspect of the metacarpus receive their blood supply from small medial and lateral dorsal metacarpal arteries. These originate from the network of small arteries on the dorsum of the carpus (dorsal carpal rete) and descend between the cannon bone and the respective medial or lateral splint bone. The medial cutaneous antebrachial nerve (Figures 1.14 and 1.20) and the dorsal branch of the ulnar nerve (Figures 1.18 and 1.21) provide innervation to this region.

Deep to the skin, the common digital extensor tendon inclines laterad as it ascends from its central position at the fetlock across the dorsum of the cannon bone. Just distal to the carpus, the main tendon and the tendon of the much smaller radial head of the muscle run lateral to the extensor carpi radialis tendon on the prominent metacarpal tuberosity of the third metacarpal bone (Figure 1.20). The tendon of the lateral digital extensor muscle is lateral to the common extensor tendon, and the small radial tendon of the latter usually joins the lateral digital extensor tendon (Figure 1.21). Occasionally the radial tendon pursues an independent course to the fetlock. A strong fibrous band from the accessory carpal bone blends with the lateral digital extensor tendon as it angles dorsad in its descent from the carpus.

Medial and Lateral Aspects

The medial palmar vein is the direct continuation of the medial digital vein at the fetlock. In the distal half of the metacarpus, the vein is related palmarly to the medial

VetBooks.ir

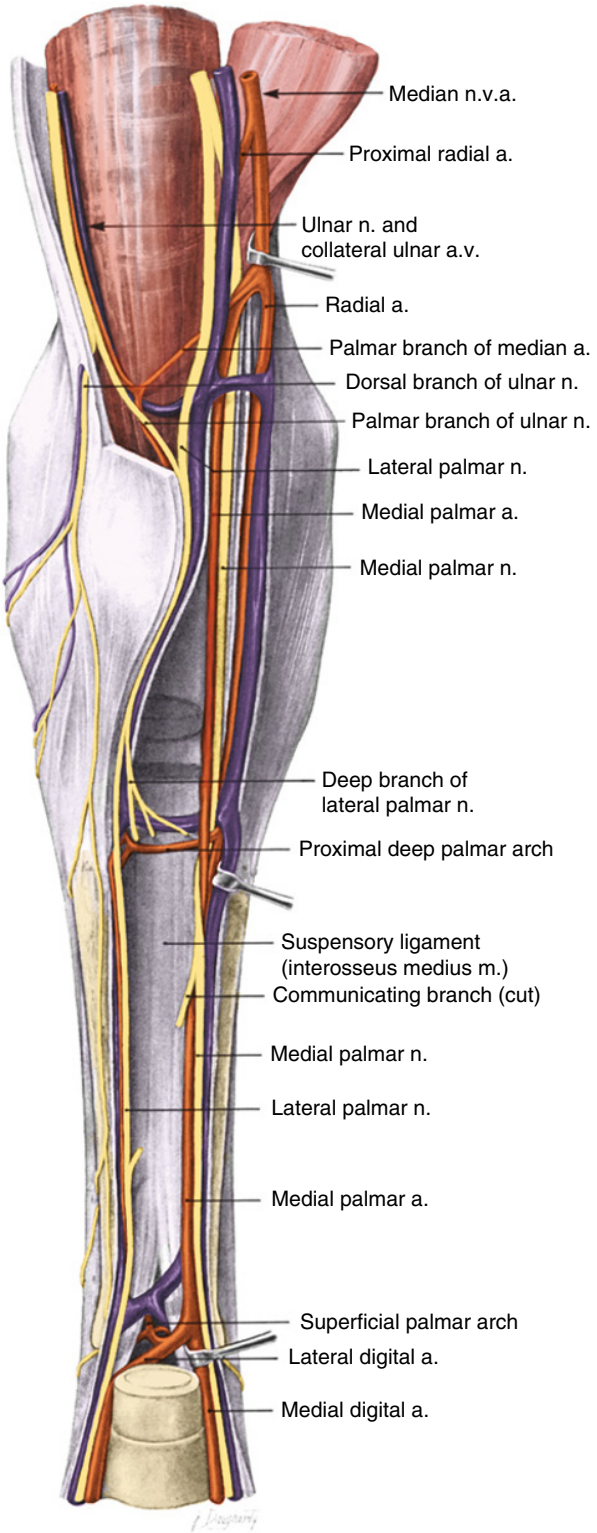

Figure 1.18. Caudal view of left carpus and metacarpus; most of the digital flexor tendons are removed.

palmar nerve (Figure 1.14); in the proximal half, the large medial palmar artery can be seen palmar to the vein (Figure 1.18). A similar relationship exists on the lateral side except that the corresponding lateral palmar artery is generally quite small. The palmar nerves run in the groove between DDFT and suspensory ligament, supplying the digital flexor tendons and the skin superficial to them. At the middle of the metacarpus, the medial palmar nerve detaches a communicating branch that angles distolaterad in the subcutaneous fascia superficial to the flexor tendons to join the lateral palmar nerve. Branches from the dorsal branch of the ulnar nerve ramify in the fascia and skin of the lateral aspect of the metacarpus. Branches from the medial cutaneous antebrachial nerve (itself a branch of the musculocutaneous nerve) supply the medial and dorsal skin of the metacarpus with the large dorsal branch reaching the skin over the dorsomedial aspect of the fetlock.

Palmar Aspect

The SDFT is deep to the skin and subcutaneous fascia throughout the length of the metacarpus. Dorsally, it is intimately related to the DDFT. The latter, in turn, lies against the palmar surface of the suspensory ligament (a.k.a. m. interosseus medius; middle or third interosseous muscle). The carpal synovial sheath, enclosing both digital flexor tendons, extends distad as far as the middle of the metacarpus. At this level, the DDFT is joined by its accessory ligament (carpal check ligament or "inferior" check ligament), a distal continuation of the palmar carpal ligament (Figure 1.32). The medial and lateral lumbricales muscles, fleshy in other species, are reduced in the horse to fibrous slips that originate from either side of the DDFT and insert in the fibrous tissue deep to the ergot. The lumbricales in the pelvic limb tend to be better developed. The digital synovial sheath around the digital flexor tendons is present through the distal fourth of the metacarpus (Figure 1.11).

The metacarpal groove, formed by the palmar surface of the third metacarpal bone and the axial surfaces of the second and fourth metacarpal bones, is occupied by the suspensory ligament. The suspensory ligament arises from the distal row of carpal bones and the proximal end of the third metacarpal bone (Figures 1.18 and 1.19). It is broad, relatively flat, and shorter than the suspensory ligament of the hindlimb. Variable amounts of muscle fibers are seen within the mainly collagenous suspensory ligament primarily in foals, in which these are gradually replaced by collagen with musculoskeletal maturation.[45] In the distal fourth of the metacarpus, the suspensory ligament bifurcates to become associated with the two proximal sesamoid bones. Each branch makes a broad attachment across the abaxial surface of proximal sesamoid bone and blends with the origin of the ipsilateral CSL (Figure 1.12). Two (medial and lateral) vestigial interosseous muscles originate on the heads of the respective splint bones; their slender tendons pass distad alongside the splint bones and end near the buttons by blending into the fascia of the fetlock.

A deep branch of the lateral palmar nerve supplies branches to and then perforates the suspensory ligament, whereupon it divides into the medial and lateral palmar metacarpal nerves. These nerves and their satellite vessels lie in the grooves formed by the cannon bone and the respective splint bones (Figure 1.19). After sending branches to the fetlock joint capsule, each palmar metacarpal nerve emerges distal to the distal extremity

VetBooks.ir

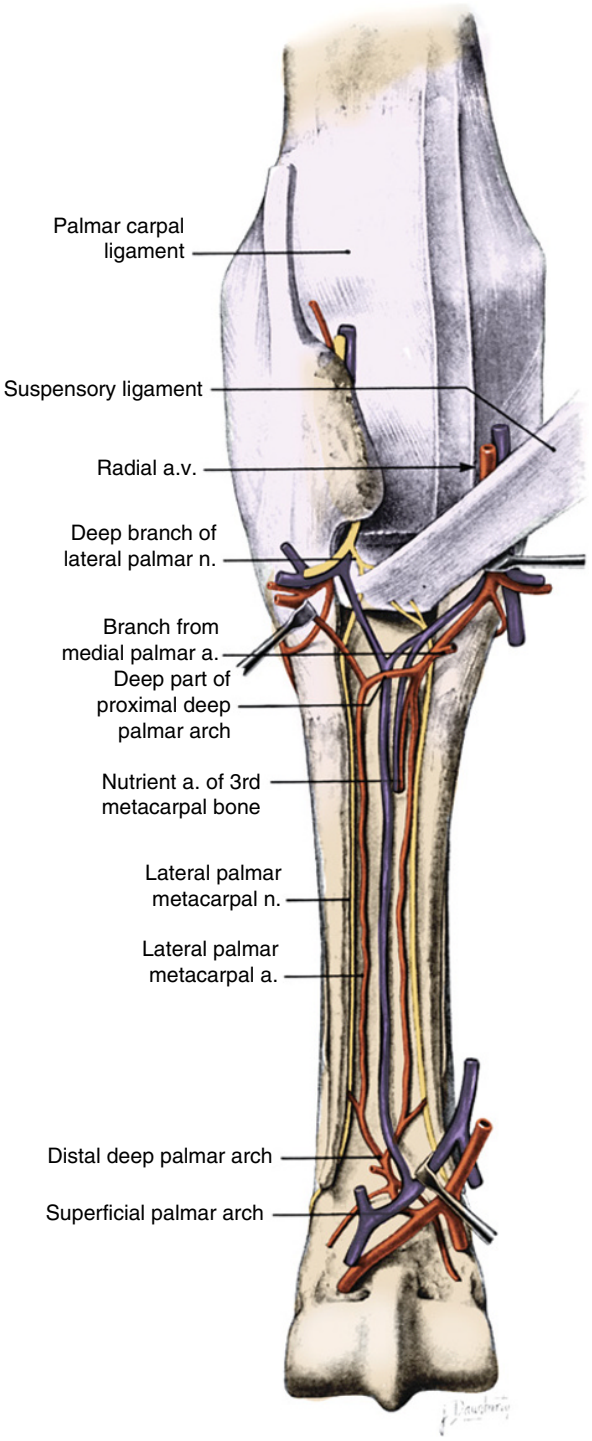

Figure 1.19. Deep dissection of caudal aspects of left carpus and metacarpus with medial palmar artery removed.

(the "button") of the respective splint bone to ramify in skin of the pastern.

The palmar metacarpal arteries originate from the proximal deep palmar arch, an anastomotic complex formed by the termination of the radial artery where it joins the smaller palmar branch of the median artery (Figure 1.19). Part of the arch lies between the carpal check ligament and the suspensory ligament. The medial palmar metacarpal artery supplies a nutrient artery to the third metacarpal bone. Small branches from the palmar metacarpal arteries extend through the interosseous spaces between cannon and splint bones to join the dorsal metacarpal arteries. In the distal fourth of the metacarpus, the palmar metacarpal arteries anastomose to form the distal deep palmar arch. A branch from this arch to the lateral digital artery is termed the superficial palmar arch.

A single, large palmar metacarpal vein courses proximad to join the venous deep palmar arch.

The vascular patterns described above are subject to considerable variations, but the variations are of no clinical significance.

Carpus

The carpal region includes the carpal bones (radial, intermediate, ulnar, and accessory in the proximal row; first, second, third, and fourth in the distal row), the distal end of the radius, the proximal ends of the three metacarpal bones, and the soft tissue structures adjacent to these osseous components.

Dorsal Aspect

A vascular network in the skin on the dorsal carpus, the rete carpi dorsale, is formed by branches from the cranial interosseus, transverse cubital, and proximal radial arteries. Medial and lateral cutaneous antebrachial nerves supply branches to the medial and dorsal aspects of the carpus. The dorsal branch of the ulnar nerve emerges between the tendon of the flexor carpi ulnaris muscle and the short tendon of the extensor carpi ulnaris or between the short and long tendons of the latter muscle (Figure 1.21). The nerve supplies branches to the fascia and skin of the dorsal and lateral aspects of the carpus.

The tendons of each of the antebrachial muscles that cross the carpus are invested with synovial sheaths, excepting the extensor carpi ulnaris (formerly ulnaris lateralis) and flexor carpi ulnaris mm. (Figures 1.20 and 1.21). The tendon sheath of the extensor carpi radialis muscle terminates at the middle of the carpus, and then the tendon becomes adherent to the retinaculum as it reaches its insertion on the metacarpal tuberosity (Figure 1.20). A distal bursa near the insertion often communicates with the carpometacarpal joint.

A subtendinous bursa lies between the tendon of the extensor carpi obliquus and the medial collateral ligament of the carpus (Figure 1.20). In most foals younger than 2 years, the bursa is a separate synovial structure; in older horses it communicates with the adjacent tendon sheath.[36]

The extensor retinaculum serves as the dorsal part of the common fibrous joint capsule of the carpal joints. It attaches to the radius, the dorsal intercarpal and dorsal carpometacarpal ligaments, the carpal bones, and the third metacarpal bone. Laterally and medially it blends with the collateral ligaments of the carpus.

Lateral Aspect

The lateral collateral carpal ligament originates from the styloid process of the radius (Figure 1.22). The

VetBooks.ir

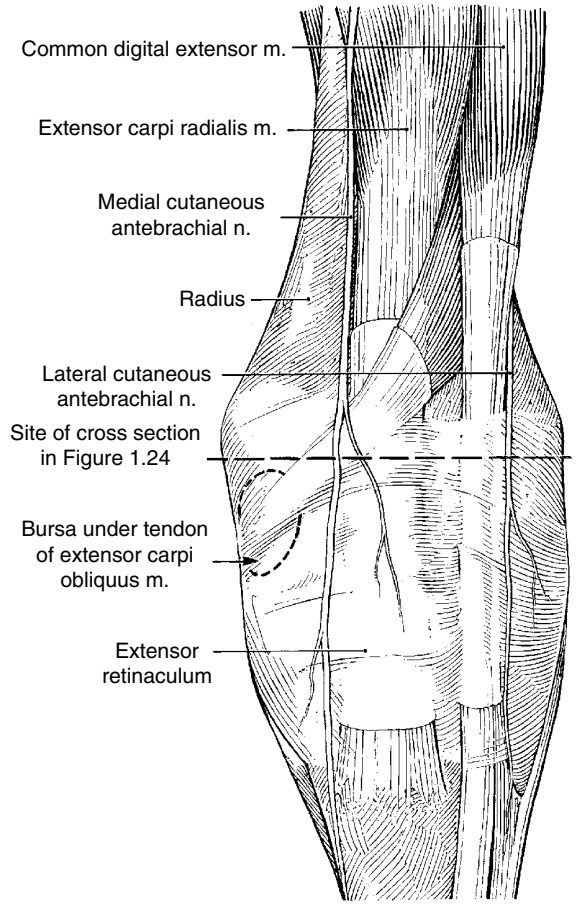

Figure 1.20. Dorsal view of left carpus.

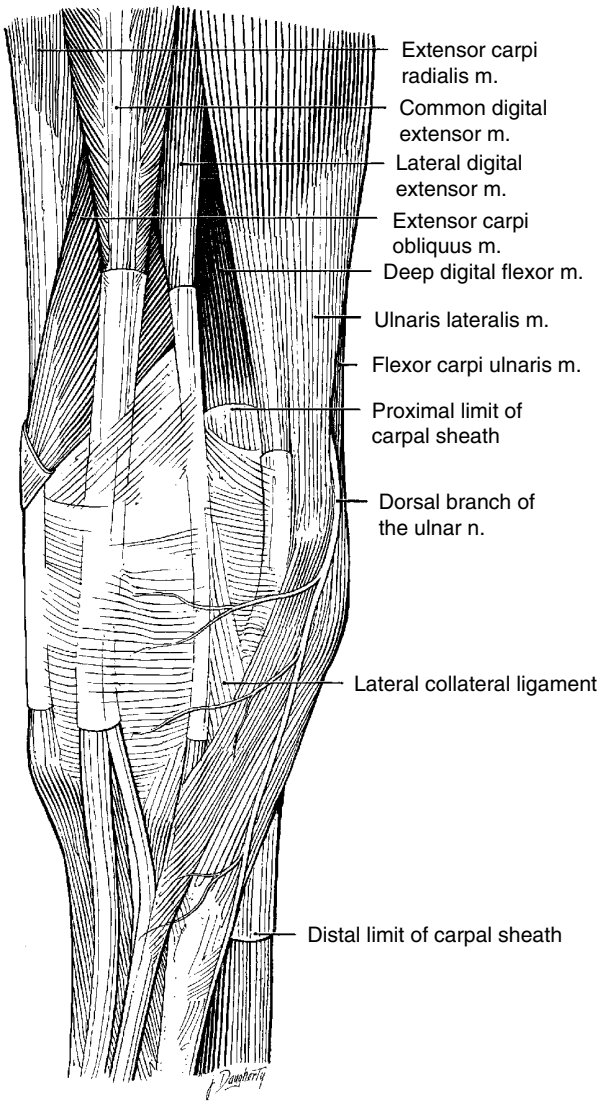

Figure 1.21. Lateral view of left distal forearm, carpus, and proximal metacarpus. Note that the ulnaris lateralis is now called extensor carpi ulnaris.

superficial part of the ligament attaches distally on the fourth metacarpal bone and partly on the third metacarpal bone. A canal between the superficial part and the deep part of the ligament provides passage for the tendon of the lateral digital extensor muscle and its synovial sheath. The deep part of the ligament attaches on the ulnar carpal bone.

Palmar to the lateral collateral carpal ligament, four ligaments attach to the accessory carpal bone, attaching it to adjacent bones (Figure 1.22). Two muscles have insertions on the accessory carpal bone. The short tendon of the extensor carpi ulnaris muscle (formerly ulnaris lateralis m.) attaches to the proximal border and lateral surface of the bone; the muscle's long tendon, enclosed in a synovial sheath, passes through a groove on the bone's lateral surface and then continues distad to insert on base of the lateral splint bone (Figure 1.21). Proximally, a pouch of the antebrachiocarpal joint capsule lies between the long tendon of the extensor carpi ulnaris and the lateral styloid process of the radius. The single tendon of the flexor carpi ulnaris muscle attaches to the proximal border of the accessory carpal bone. A strong fibrous band from the accessory carpal bone attaches to the lateral digital extensor tendon.

Medial Aspect

On the medial side of the carpus, the skin and fascia receive blood from branches of the radial artery. The medial cutaneous antebrachial nerve provides the innervation.

The medial collateral carpal ligament extends from the medial styloid process of the radius and widens distally to attach to the second and third metacarpal bones. Bundles of fibers also attach to the radial, second, and third carpal bones (Figure 1.23). The ligament also joins the flexor retinaculum on the palmar aspect of the joint. At this juncture a canal is formed that accommodates the passage of the tendon of the flexor carpi radialis and its synovial sheath as the tendon descends to the base of the medial splint bone. An inconstant first carpal bone may be embedded in the palmar part of the medial collateral carpal ligament adjacent to the second carpal bone.

Palmar Aspect

The flexor retinaculum is a fibrous band extending from the medial collateral ligament, distal end of the radius, radial and second carpal bones, and proximal

VetBooks.ir

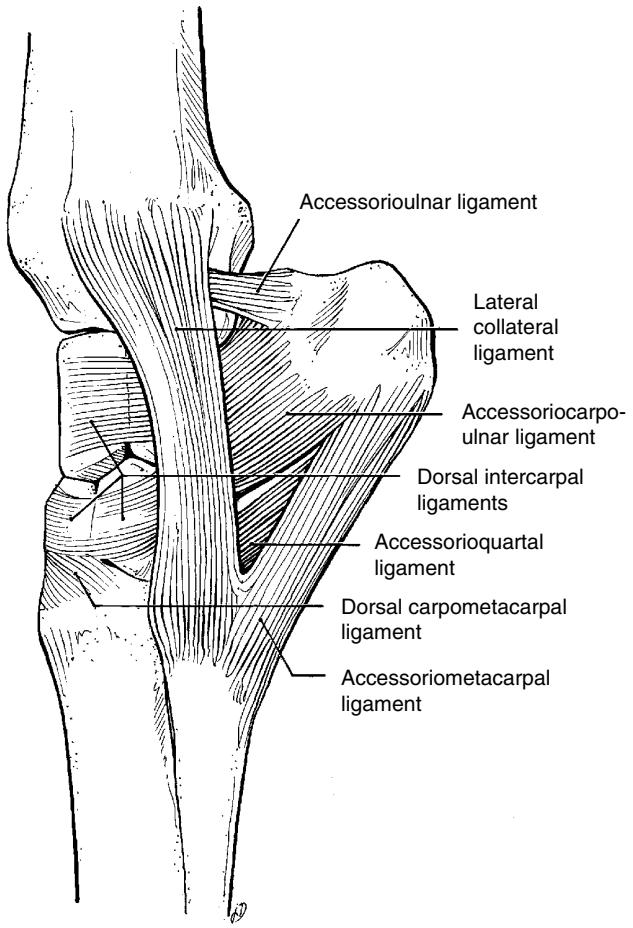

Figure 1.22. Carpal ligaments, lateral view.

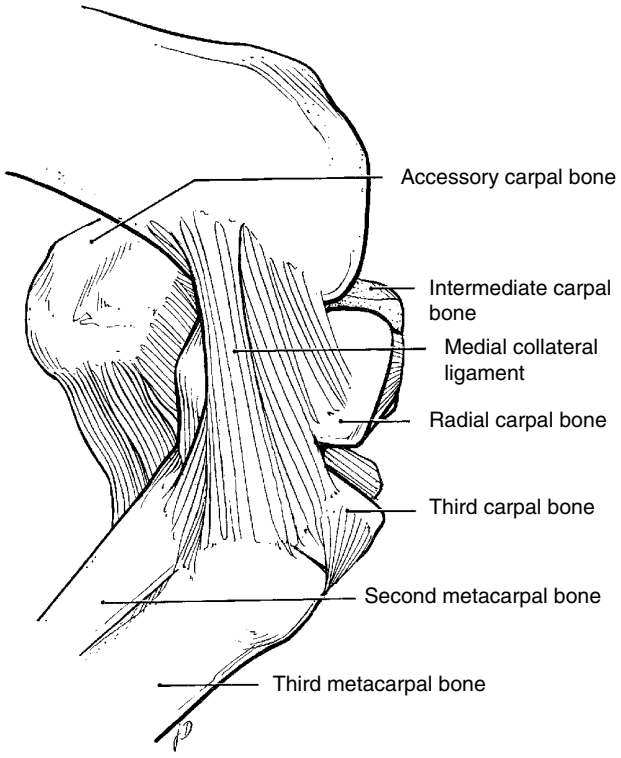

Figure 1.23. Carpal ligaments, medial view.

end of the second metacarpal bone laterad to the accessory carpal bone. By bridging the carpal groove, the flexor retinaculum forms the mediopalmar wall of the carpal canal. It blends both proximally and distally with the fascia of the limb. Proximally, the fan-shaped accessory ligament of the SDFT (radial check ligament) completes the medial wall of the carpal canal. The accessory carpal bone and its two distal ligaments form the lateral wall of the carpal canal. The palmar carpal ligament forms the smooth wall interposed between flexor tendons and the carpal bones; it serves as part of the common fibrous capsule on the palmar side of the carpus. Distally, the palmar carpal ligament gives origin to the carpal check ligament of the DDFT.

The carpal canal (Figures 1.24 and 1.25) contains the following structures: the SDFT and DDFT enclosed in the carpal synovial sheath, the medial palmar nerve and artery, and the lateral palmar nerve, artery, and vein. Medial to the carpal canal, just outside the flexor retinaculum, the tendon of the flexor carpi radialis descends to its attachment on the head of the medial splint bone. The radial artery and vein lie palmar to this tendon embedded in the flexor retinaculum.

The carpal synovial sheath enclosing the digital flexor tendons extends from 8 to 10 cm proximal to the antebrachiocarpal joint to near the middle of the metacarpus (Figure 1.25). Fibers from the carpal check ligament of the SDFT blend into the medial aspect of the proximal end of the sheath. Between the flexor tendons, an intertendinous membrane attaches to the palmaromedial surface of the DDFT and the dorsomedial surface of the SDFT, dividing the carpal synovial sheath into lateral and medial compartments.[40]

In the forearm proximal to the carpus, the palmar branches of the median and collateral ulnar arteries anastomose deep to the flexor carpi ulnaris muscle (Figure 1.18). Small branches from the palmar branch of the median and proximal radial arteries supply the vascular network of the deep palmar carpal region, the rete carpi palmare. The small lateral palmar artery continues distad to near the proximal end of the fourth metacarpal bone where it participates with the radial artery in forming the proximal deep palmar arch. Branches from the radial artery (also a terminal branch of the median artery) extend around the medial aspect of the carpus to contribute to the dorsal carpal rete.

Carpal Joints

The bones of the carpus abut one another at a number of intercarpal joints, but these are capable only of minimal gliding movements. The overall movement of the carpus comes from the horizontally oriented joints: antebrachiocarpal (radiocarpal) between the radius and proximal row of carpal bones, middle carpal between proximal and distal rows of carpal bones, and carpometacarpal between the distal row of carpal bones and the metacarpals. Nearly all of the flexion and extension of the carpus come from the antebrachiocarpal and middle carpal joints; the carpometacarpal joint is a plane joint with minimal movement. The extensive antebrachiocarpal synovial sac extends between the carpal bones of the proximal row, including the accessory carpal bone. It typically does not communicate with the

VetBooks.ir

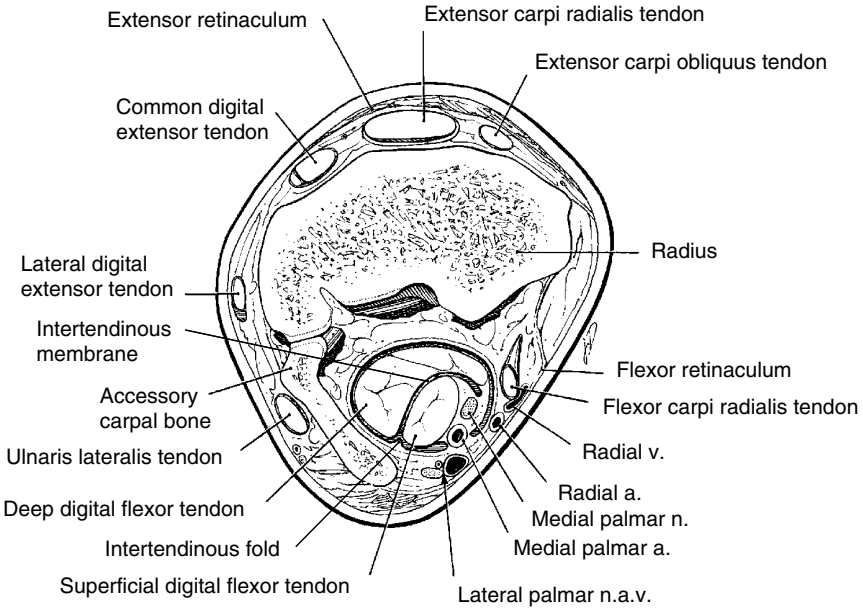

Figure 1.24. Cross section just proximal to the left antebrachiocarpal joint. Note that the ulnaris lateralis (tendon labeled here) is now called extensor carpi ulnaris.

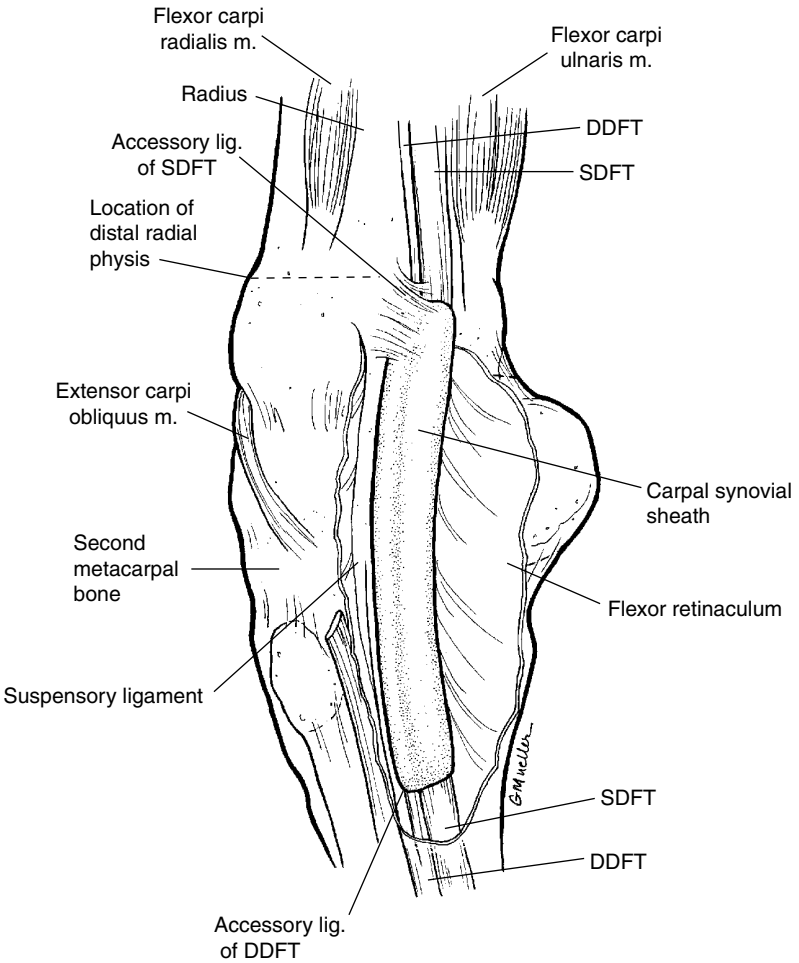

Figure 1.25. Palmaromedial view of carpus with flexor retinaculum cut and reflected. SDFT = superficial digital flexor tendon; DDFT = deep digital flexor tendon.

VetBooks.ir

synovial spaces of the more distal carpal joints. The middle carpal synovial sac communicates with the small carpometacarpal sac between the third and fourth carpal bones.

The carpus is flexed by the combined action of the flexor carpi radialis, flexor carpi ulnaris, and probably the oddly named extensor carpi ulnaris. It is extended by the extensor carpi radialis and extensor carpi obliquus (a.k.a. abductor digiti I longus) muscles and also by the digital extensors. The thick palmar carpal ligament uniting the palmar aspect of the carpal bones serves to prevent overextension of the antebrachiocarpal and middle carpal joints.

Antebrachium

The antebrachium (forearm) includes the radius and ulna and the muscles, vessels, nerves, and skin surrounding the bones. The prominent muscle belly of the extensor carpi radialis muscle creates the distinctive bulging contour on the cranial antebrachium. A horny cutaneous structure, the chestnut, is present on the medial skin of the distal one-third of the forearm. The chestnut is considered to be a vestige of a carpal pad.[28]

There is extensive overlapping among adjacent sensory cutaneous branches of the axillary, radial, musculocutaneous, and ulnar nerves in the forearm.[5] The axillary nerve gives rise to cutaneous branches to the lateral aspect of the brachium and terminates as the cranial cutaneous antebrachial nerve, which courses distad over the extensor carpi radialis muscle (Figure 1.30).

The lateral cutaneous antebrachial nerve arises from the superficial branch of the radial nerve as the latter runs between the extensor carpi radialis and the lateral head of the triceps brachii (Figure 1.30). In its course the lateral cutaneous antebrachial nerve descends to supply the skin on the craniolateral part of the distal forearm. Terminal branches often course as far as the carpus and proximal metacarpus (Figure 1.20).

The medial cutaneous antebrachial nerve continues distad from the musculocutaneous nerve, coursing over the biceps brachii muscle and then along the deep face of the lacertus fibrosus, and continues into the tendon of the extensor carpi radialis muscle. The nerve is readily palpable through the skin as it crosses the cranial edge and then the medial surface of the lacertus fibrosus, dividing here into two main branches (Figure 1.26). The larger branch accompanies the accessory cephalic vein. The nerve continues on the dorsomedial aspect of the carpus and metacarpus to the fetlock. The smaller branch runs briefly with the cephalic vein and then courses obliquely across the medial surface of the radius where the bone is subcutaneous. This branch of the nerve is sensory to the skin as far as the medial carpus.

Ascending over the transverse pectoral muscle, the cephalic vein runs in the groove between the descending pectoral and cleidobrachialis muscles. A small artery accompanies the cephalic vein in the groove. Under cover of the cutaneous colli muscle, the cephalic vein empties into the external jugular vein or occasionally into the subclavian vein. The more cranial accessory cephalic vein joins the cephalic vein close to the point at which the latter gives rise to the median cubital vein (Figure 1.26). The median cubital courses proximocaudad over the insertion of the biceps brachii and then passes over the median nerve and brachial artery to join the brachial vein in the distal part of the brachium. Midway in its course the median cubital vein may receive a large branch emerging from between the radius and the flexor carpi radialis muscle.

The caudal cutaneous antebrachial nerve (from the ulnar nerve) emerges through the pectoralis transversus to innervate the skin on the caudal aspect of the forearm.

Fascia

The deep antebrachial fascia is especially thick. It invests all of the muscles of the forearm and provides for attachment of the tensor fasciae antebrachii muscle medially, the cleidobrachialis muscle laterally, and the biceps brachii muscle cranially (the latter by means of the lacertus fibrosus). The deep fascia blends with the periosteum on the medial radius and with the collateral ligaments and bony prominences at the elbow. Intermuscular septa from the deep fascia extend between the bellies of the antebrachial muscles.

Extensor Muscles

The extensor carpi radialis is the largest of the extensor muscles of the antebrachium. It arises proximally on the lateral epicondyle and radial fossa of the humerus (in common with the tendon of origin of the common digital extensor) and is attached to the elbow joint capsule and the deep fascia in this region. The tendon of the extensor carpi radialis runs nearly the length of the muscle, becoming visible on its cranial surface about halfway on the antebrachium and completely replacing the fleshy muscle bellow at the junction of the middle and distal thirds.

The extensor carpi obliquus muscle originates broadly on the lateral side of the distal radius. Its muscle belly is at first deep to the common digital extensor; then its tendon crosses that of the extensor carpi radialis superficially as it angles distad over the carpus toward its insertion on the base of the medial splint bone. On the medial aspect of the carpus, a bursa underlies the tendon; it usually communicates with the tendon's synovial sheath in older horses (Figure 1.20).[30]

The common digital extensor muscle takes origin along with the extensor carpi radialis on the lateral epicondyle and radial fossa of the humerus, with additional attachments to the ulna, deep fascia, lateral aspect of the radius, and the lateral collateral ligament of the elbow. Its tendon of insertion, enclosed in its tendon sheath, occupies its respective groove on the distal extremity of the radius. A slender tendon from the very small radial head of the muscle accompanies the main tendon as the two tendons enter the synovial sheath proximal to the carpus. Distal to the carpus, it diverges laterad to unite with the tendon of the lateral digital extensor.

The lateral digital extensor originates from the radius, ulna, and lateral collateral ligament of the elbow joint, and the intermuscular septum from the deep fascia. It is a relatively weak muscle whose muscle belly lies adjacent to the radius and ulna between the extensor carpi ulnaris caudally and the larger common digital extensor muscle belly cranially (Figure 1.26). The muscle's tendon crosses

VetBooks.ir

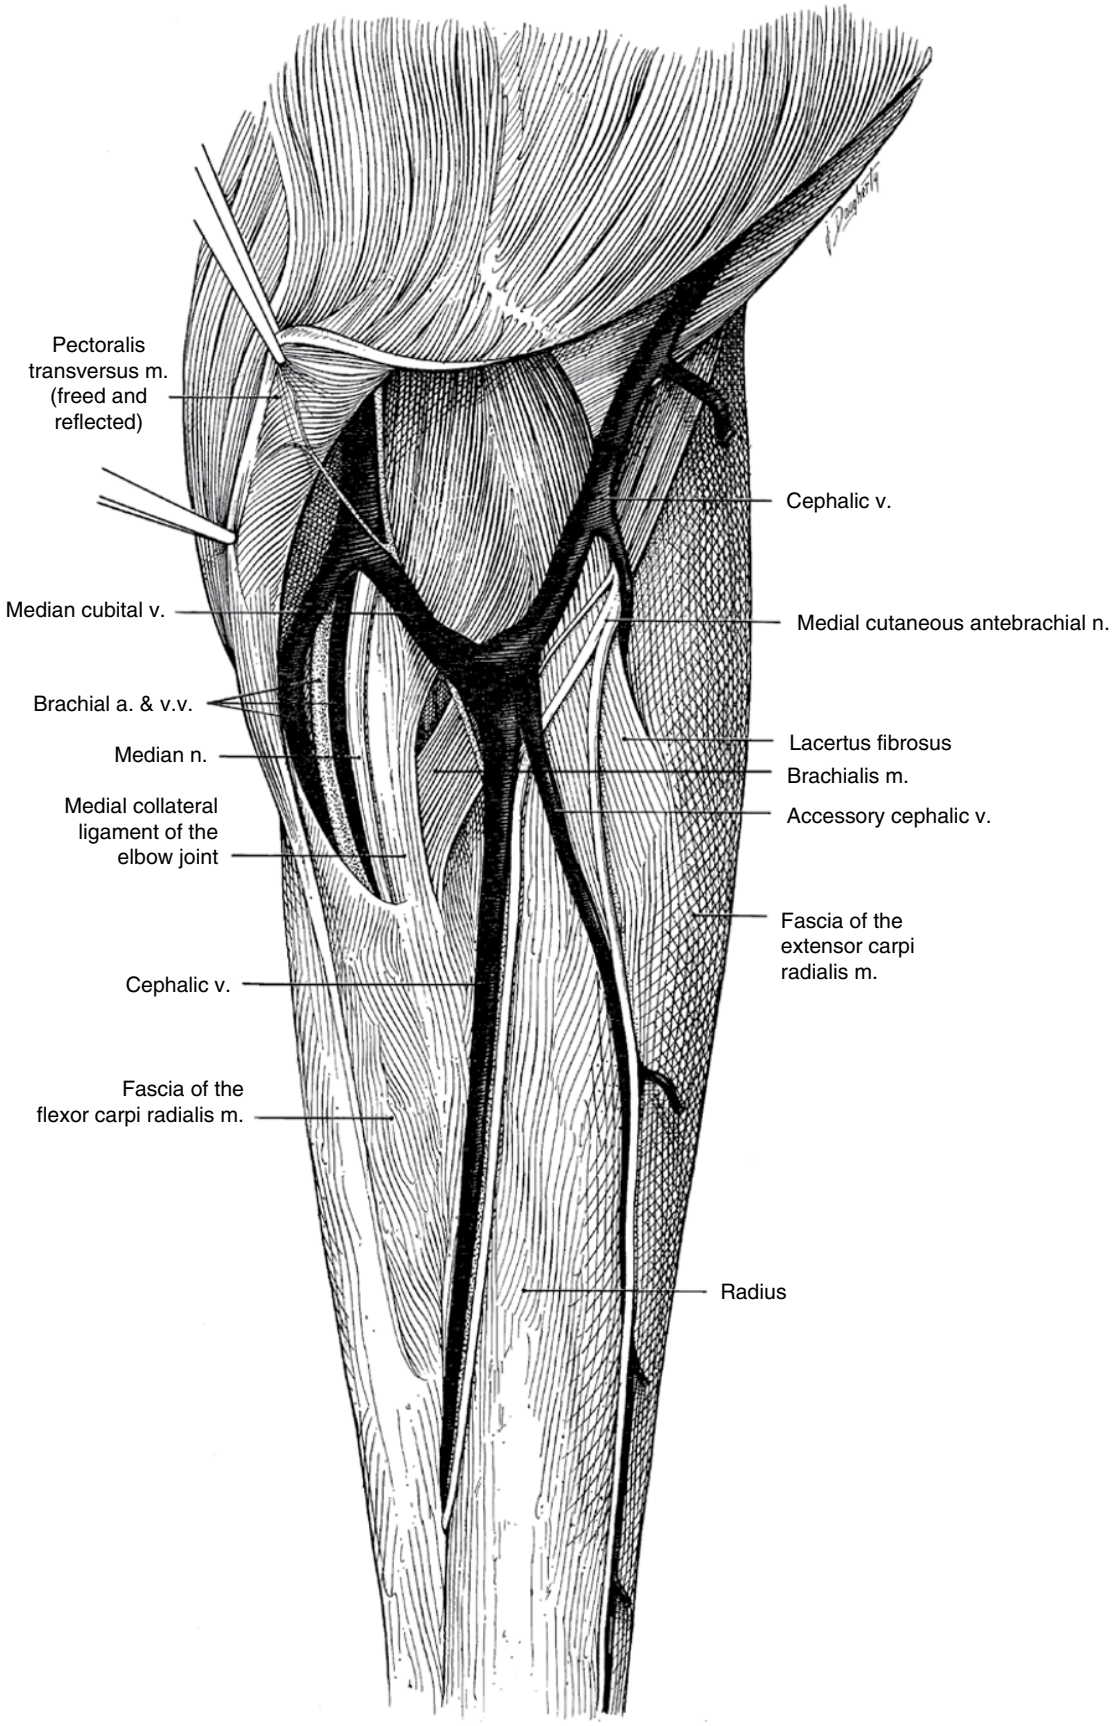

Figure 1.26. Craniomedial view of a superficial dissection of left elbow and forearm.

VetBooks.ir

the carpus surrounded by a tendon sheath within a fascial canal on its way to the proximal phalanx where it inserts.

Flexor Muscles

The flexor carpi radialis muscle is related to the mediocaudal surface of the radius (Figure 1.26), extending from the medial epicondyle of the humerus to the base of the medial splint bone. Caudal to the flexor carpi radialis, the flexor carpi ulnaris muscle consists of an ulnar head from the olecranon and a humeral head from the medial epicondyle; it inserts on to the accessory carpal bone.

Between flexor carpi ulnaris caudally and the lateral digital extensor laterally is the extensor carpi ulnaris muscle (formerly ulnaris lateralis) that originates on the lateral epicondyle of the humerus caudal to the lateral collateral ligament of elbow joint. A bursa lies deep to the muscle at this location; it often communicates with the elbow synovial joint.[30] The muscle extends distad to insert on the accessory carpal bone and, by means of a somewhat longer, sheathed tendon, to the proximal end of the fourth metacarpal bone.

The preceding three muscles flex the carpal joint and, through their humeral origins, extend the elbow joint. Although the extensor carpi ulnaris is morphologically in the extensor group and is supplied by the radial nerve, its attachments make it a flexor of the carpus.

The superficial digital flexor muscle has a single humeral head, which originates from the medial epicondyle of the humerus and then lies deep to the flexor carpi ulnaris and ulnar head of the deep digital flexor (which is quite superficial as it originates from the medial surface of the olecranon). The muscle belly of the superficial digital flexor lies flat against the deep digital flexor muscle. Under the proximal part of the flexor retinaculum, the tendon of the humeral head of the superficial digital flexor is joined by a flat, wide fibrous band, its accessory ligament (really a radial head of the muscle), which arises on a ridge on the mediocaudal surface of the distal half of the radius (Figure 1.32, later in text).

The deep digital flexor muscle has one large humeral head and two small heads originating from the ulna (olecranon) and radius. The long slender tendon of the ulnar head joins the main tendon of the humeral head proximal to the carpus just before the combined tendon becomes enclosed within the carpal synovial sheath alongside the SDFT. The tendon of the radial head also joins the main tendon near this level. The radial head is inconsistently identifiable; when present, it takes origin from the middle third of the caudal radius. A synovial pouch from the elbow joint capsule protrudes distad beneath the humeral head's origin on the medial epicondyle of the humerus.

Nerves and Deep Vessels

The deep branch of the radial nerve descends over the flexor surface of the elbow and supplies motor branches to the extensor muscles of the forearm and the extensor carpi ulnaris.

The ulnar nerve crosses the medial epicondyle of the humerus accompanied by the collateral ulnar artery and vein, descends obliquely across the medial head of the triceps brachii and the elbow, and then runs between the ulnar heads of the flexor carpi ulnaris and deep digital flexor. It supplies these two muscles and the superficial digital flexor. From here the nerve runs under the deep antebrachial fascia, passing between the superficial digital flexor and the extensor carpi ulnaris and finally between the latter and flexor carpi ulnaris muscles as they near their insertions. A few centimeters proximal to the accessory carpal bone, the ulnar nerve divides into palmar and dorsal branches.

Distal to the elbow the median nerve runs along the caudal border of the medial collateral ligament of the elbow joint, cranial to brachial veins and artery (Figure 1.26). In the proximal part of the forearm, the median nerve supplies branches to the flexor carpi radialis muscle, the humeral and radial heads of the deep digital flexor muscle, and the periosteum of the radius and ulna. At about the middle of the forearm, the median nerve divides into the medial and lateral palmar nerves that remain together in a common sheath before separating close to the carpus. The medial palmar nerve descends in the carpal canal; the lateral palmar nerve is joined by the palmar branch of the ulnar nerve and descends within the dense connective tissue of the flexor retinaculum (Figure 1.18).

Just distal to the elbow joint, the common interosseous artery, a branch of the brachial artery, gives off a small caudal interosseous artery and then, continuing as the cranial interosseous, passes through the interosseous space, supplying nutrient arteries to the radius and ulna. Together with the transverse cubital artery (arising proximal to the elbow joint), the cranial interosseous provides branches to the cranial and medial aspects of the forearm.

After giving off the common interosseous artery, the brachial artery continues as the median artery between the flexor carpi radialis and the radius. In the distal part of the forearm, the median artery angles caudad and gives rise to the proximal radial artery, a small vessel that courses to the palmar aspect of the carpus. The median artery terminates at the distal end of the forearm by trifurcating into the large medial palmar artery, the much smaller lateral palmar artery, and, medially, the radial artery (Figure 1.18).

Two median veins accompany the median artery and nerve: a proximal continuation of the lateral palmar vein, which ascends caudal to the artery, and a vein formed by branches from the caudal antebrachial muscles, which ascends cranial to the artery.

Elbow Joint

The two principle flexors of the equine elbow (cubital) joint are the biceps brachii and the brachialis, with lesser contributions made by the extensor carpi radialis and common digital extensor muscles. The principal extensors are the tensor fasciae antebrachii, triceps brachii, and the anconeus; these are assisted by the flexors of the carpus and digit.

The terminal part of the biceps brachii muscle crosses the joint cranially and inserts on the radial tuberosity and medial collateral ligament. This tendon of insertion also gives rise to the lacertus fibrosus, which blends into the deep fascia of the extensor carpi radialis (Figure 1.27).

VetBooks.ir

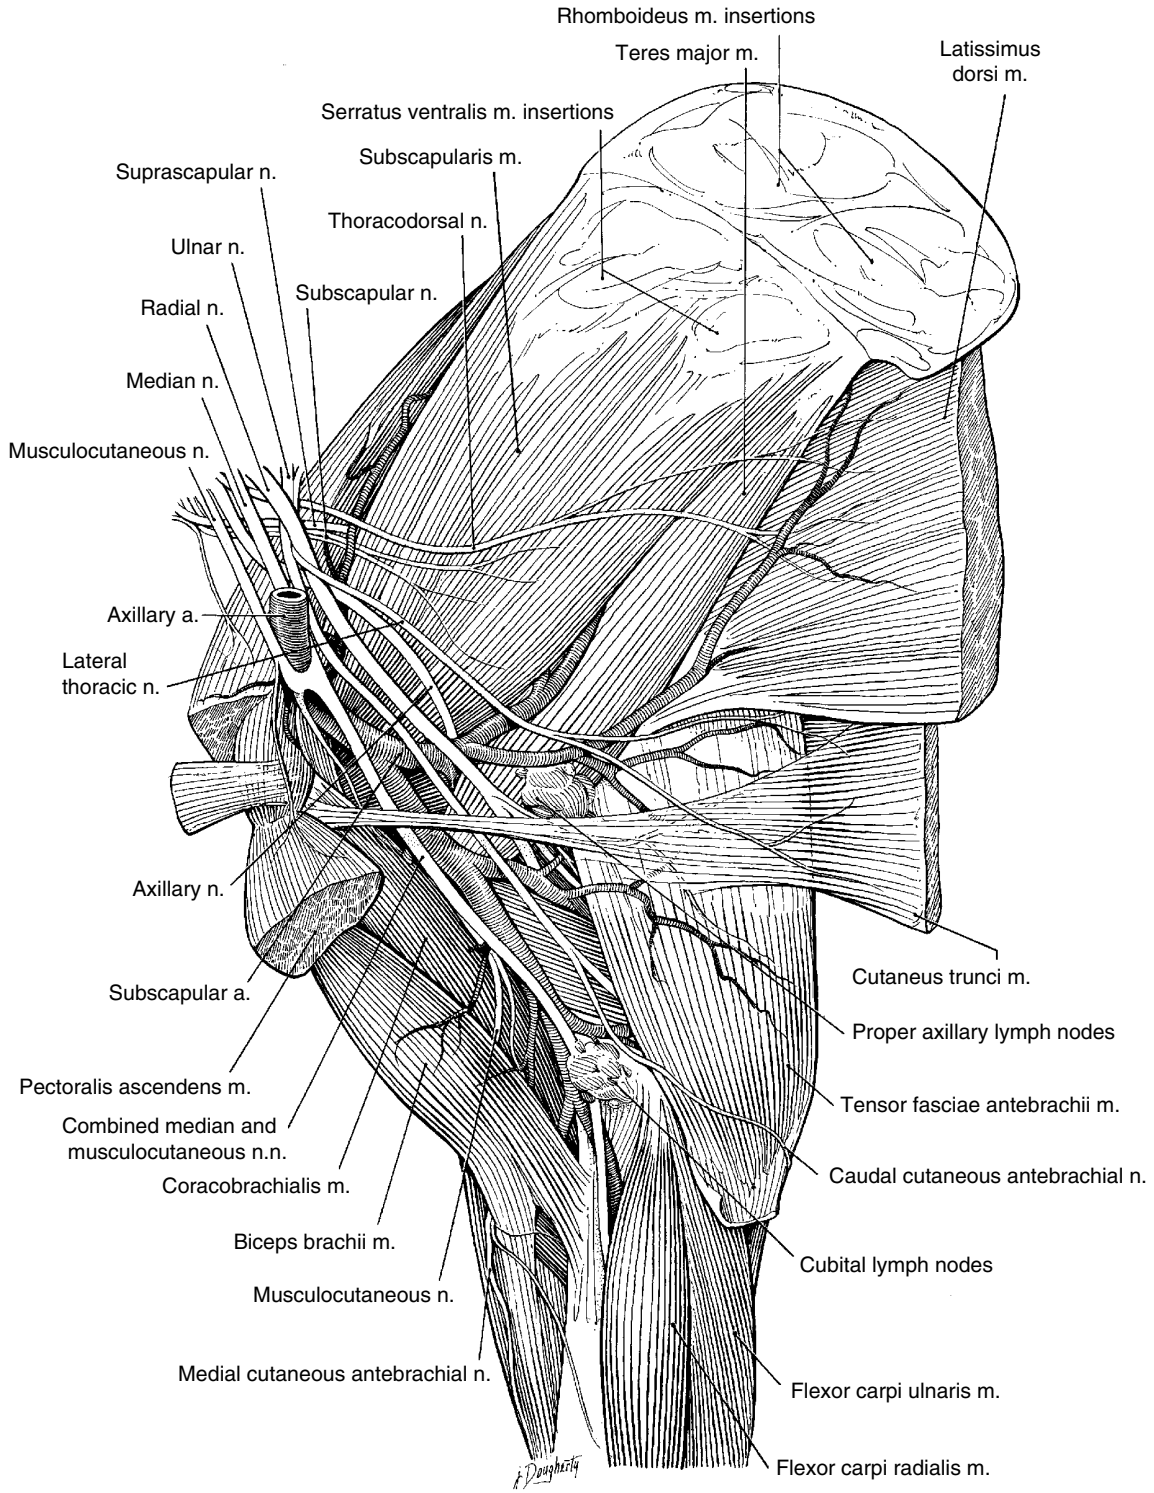

Figure 1.27. Medial view of left shoulder, arm, and proximal forearm. Veins are not depicted.

The terminal part of the brachialis muscle, curving around from its location in the musculospiral groove of the humerus, passes between the biceps brachii and extensor carpi radialis muscles to attach to the medial border of the radius deep to the medial collateral ligament (Figure 1.26). A bursa lies between the tendon and the collateral ligament.[30]

The median nerve, brachial artery, and the two brachial veins lie caudal to the medial collateral ligament of the elbow joint deep to the cranial part of the transverse pectoral muscle (Figure 1.26). Proximocaudal to the joint the collateral ulnar artery and vein and the ulnar nerve with its cutaneous branch (caudal cutaneous antebrachial nerve) cross obliquely between the medial head of the triceps brachii and tensor fasciae antebrachii.

All three principal extensors of the elbow insert on the olecranon tuberosity. A subcutaneous bursa may cover the caudal aspect of the olecranon tuberosity; a

VetBooks.ir

subtendinous bursa lies deep to the tendon of insertion of the long head of the triceps brachii muscle[30] (Figure 1.28). The medially located tensor fasciae antebrachii also inserts on and acts to tense the deep antebrachial fascia. The small anconeus muscle originates from the lateral edge of the olecranon fossa, inserts on the olecranon, and is attached on its deep surface to the elbow joint capsule, acting to elevate it when the joint is extended.

Laterally the elbow is covered by the distal part of the cutaneous omobrachialis muscle. A short, stout lateral collateral ligament extends from the lateral epicondyle of the humerus to the lateral tuberosity of the radius. The cranial part of the joint capsule is robust, but caudally it becomes thinner as it extends into the olecranon fossa deep to the anconeus muscle. The joint capsule is adherent to the anconeus muscle, the collateral ligaments, and tendons of surrounding muscles. Extensions

VetBooks.ir

of the synovial lining of the joint project under the origins of the extensor carpi ulnaris and the digital flexor muscles and into the radioulnar articulation. The elbow joint is supplied by branches from the transverse cubital artery cranially and a branch from the collateral ulnar artery caudally.

The articular surface of the radius features a concave fovea, partially subdivided by two sagittal ridges. This surface plus the trochlear notch of the ulna articulates with the humerus, forming a hinge joint. The articular angle can range from approximately 60° to 150°.[16]

Arm and Shoulder

The "arm" (*L. brachium*) is the region of the limb between the elbow and shoulder (scapulohumeral) joints. Within the superficial fascia over the lateral aspect of the shoulder and arm, the cutaneous omobrachialis muscle arises in the region lateral to the scapula and extends as far distal as the elbow joint (Figure 1.28). The cutaneous muscle is innervated by the intercostobrachial nerve (a branch of the lateral thoracic nerve). The intercostobrachial nerve and branches of the axillary, radial, and spinal nerves provide cutaneous sensation to this region. Superficial blood vessels are branches of the caudal circumflex humeral vessels.

The cleidobrachialis muscle (distal part of the brachiocephalicus) covers the craniolateral aspect of the shoulder joint on the way to its insertion on the deltoid tuberosity, humeral crest, and the fascia of the arm (Figure 1.29). When the head and neck are fixed and the limb is free to swing, this muscle acts as an extensor of the shoulder joint, drawing the forelimb forward. With the limb fixed on the ground, its contraction draws the head and neck into lateral flexion.

Muscles Substituting for Shoulder Joint Ligaments

Cranially, the dense, partly cartilaginous tendon of the biceps brachii muscle originates on the supraglenoid tubercle of the scapula and occupies the intertubercular groove of the humerus. A connective tissue band extends from the lesser tubercle to the greater tubercle, serving as a retinaculum for the biceps tendon. A bursa lies under the tendon, partially extending around its sides. A tendinous band (an "internal tendon") is continuous from the tendon of origin distad through the muscle. In addition to the muscle's primary function of elbow flexion, the internal tendon of the biceps brachii passively fixes the elbow and shoulder in the standing position. The musculocutaneous nerve supplies the biceps brachii.

The supraspinatus muscle arises in the supraspinous fossa, the spine, and cartilage of the scapula. It divides distally to attach to the greater and lesser tubercles of the humerus, serving with the bicipital tendon to stabilize the shoulder joint cranially and to a smaller degree laterally (Figure 1.30). The supraspinatus is a shoulder extensor; it is innervated by the suprascapular nerve, which reaches the supraspinous fossa by coursing between the subscapularis and supraspinatus muscles and then wrapping around the distal fourth of the cranial border of the scapula.

The infraspinatus muscle extends from the scapular cartilage and infraspinous fossa to insert on the caudal and distal parts of the greater tubercle, distal to the insertion of the supraspinatus (Figure 1.30). The partly cartilaginous tendon is protected from the underlying caudal eminence by adipose tissue and a synovial bursa that may communicate with the shoulder joint cavity. The tendon is the main lateral support of the shoulder joint. It is assisted by the teres minor, a smaller muscle deep to the infraspinatus and arising from the infraspinous fossa, the caudal border, and a small tubercle on the distal end of the scapula. It inserts proximal to and on the deltoid tuberosity. The teres minor muscle flexes the joint and, together with the infraspinatus, abducts the arm. The infraspinatus also rotates the arm laterad. The infraspinatus muscle is supplied by the suprascapular nerve, and the teres minor by the axillary nerve.

The subscapularis muscle stabilizes the shoulder joint medially. This adductor of the arm originates in the subscapular fossa of the scapula and inserts on the lesser tubercle of the humerus. Caudal support to the joint is rendered by the long head of the triceps brachii, the only head of this muscle originating from the scapula.

Flexor Muscles of the Shoulder Joint

In addition to the long head of the triceps brachii muscle, four muscles flex the shoulder joint: laterally, the deltoideus and teres minor; medially, the teres major and coracobrachialis; and the latissimus dorsi. The first three muscles are innervated by branches from the axillary nerve; the coracobrachialis, by the musculocutaneous nerve; and the latissimus dorsi, by the thoracodorsal nerve.

The deltoideus lies on the lateral surface of the triceps brachii and partly on the infraspinatus and teres minor muscles. It originates from the caudal border of the scapula and the scapular spine via the aponeurosis covering the infraspinatus and inserts on the deltoid tuberosity of the humerus and the brachial fascia (Figure 1.30).

The teres major muscle extends from the caudal border of the scapula and crosses the medial surface of the triceps brachii to the teres major tuberosity of the humerus, where it inserts in common with the latissimus dorsi muscle (Figure 1.27).

The coracoid process of the scapula gives origin to the coracobrachialis muscle that crosses the medial aspect of the shoulder joint to attach to the humerus just proximal to the teres major tuberosity and on the middle of the cranial surface of the bone. A bursa lies between the tendon of origin of the coracobrachialis and the tendon of insertion of the subscapularis muscle.[30]

Shoulder Joint

The fibrous joint capsule of the shoulder joint attaches up to 2 cm from the margins of the articular surfaces. Two elastic glenohumeral ligaments reinforce the joint capsule on its cranial side as they diverge from the supraglenoid tubercle to the humeral tuberosities. A very small articularis humeri muscle lies on the flexion surface of the joint capsule, extending from the caudal part of the scapula to the caudal surface of the humerus just distal to the head. Innervated by the axillary nerve, the articularis humeri muscle tenses the joint capsule during flexion of the shoulder joint.

VetBooks.ir

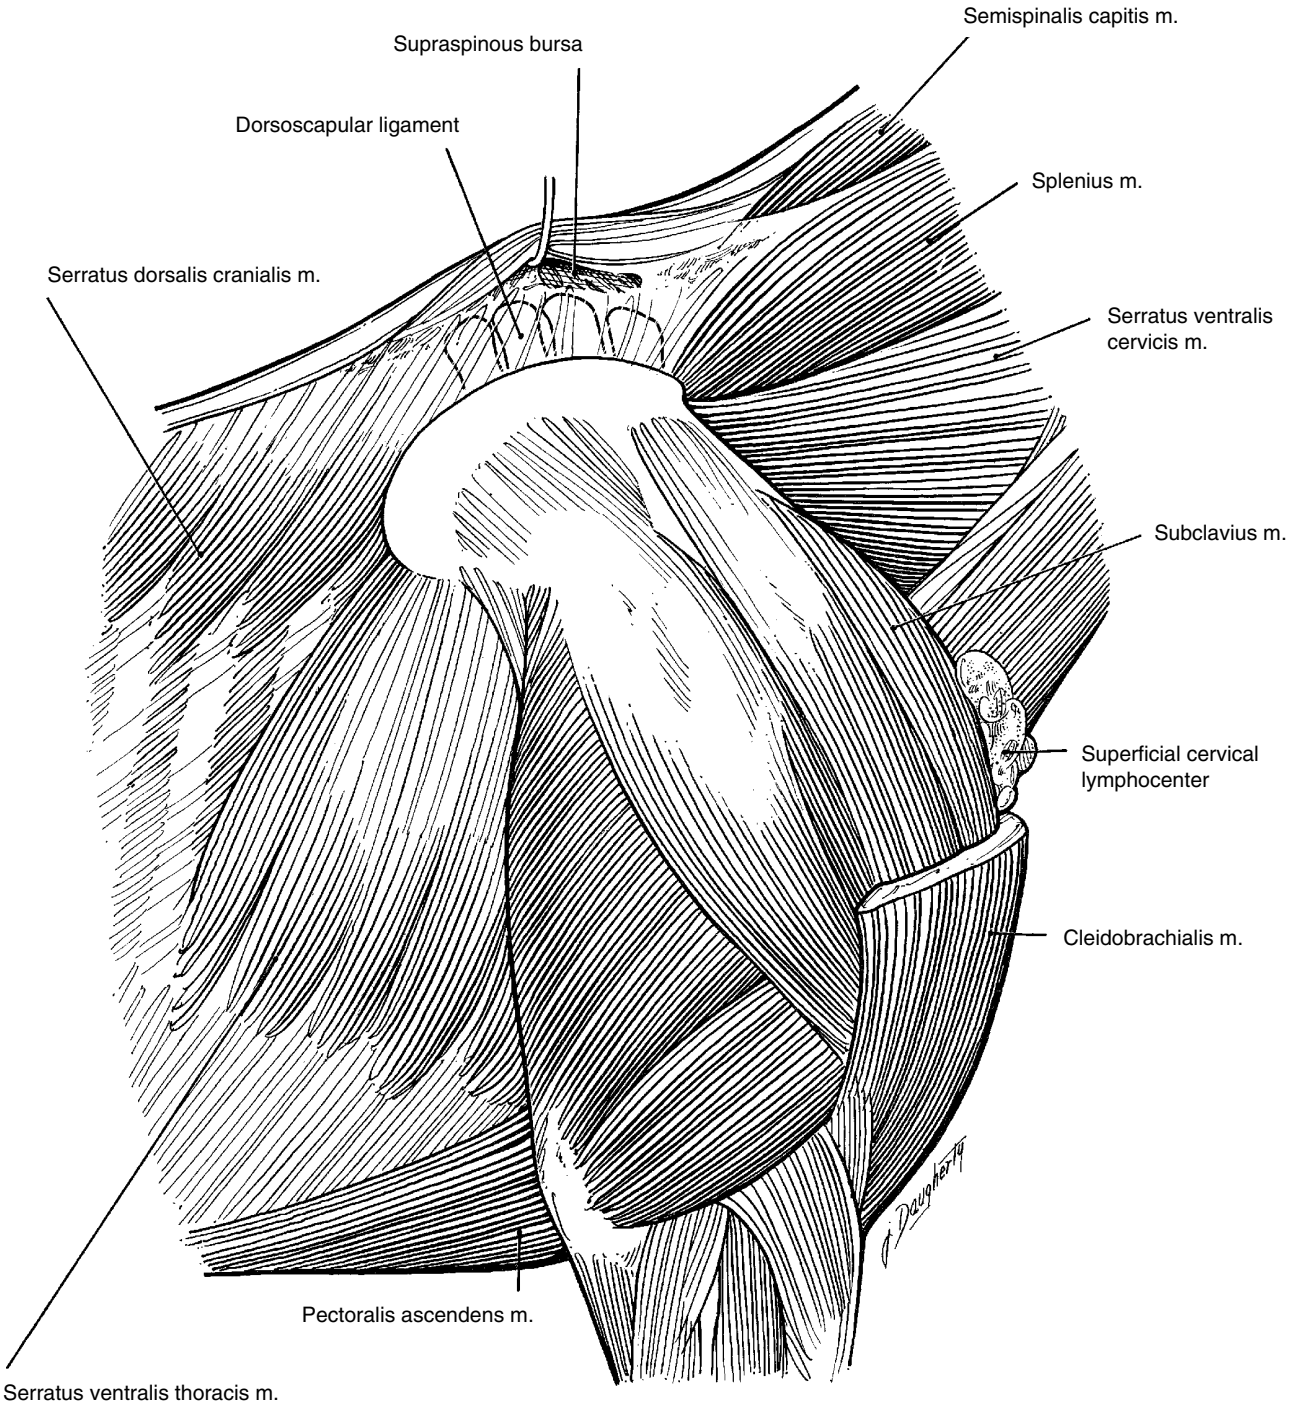

Figure 1.29. Right shoulder and dorsoscapular ligament. Spines of thoracic vertebrae 2–5 are outlined by dashed lines.

Within the shoulder joint the articular surface of the humeral head has approximately twice the area of the glenoid cavity of the scapula even with the small extension afforded by the glenoid lip around the rim. The great stability of this joint is largely owed to the support of the surrounding muscles. In spite of its classification as a ball-and-socket joint, major movements are limited to flexion and extension; muscles around the joint restrict abduction and adduction, and rotation is very limited. While standing, the caudal angle of the shoulder joint is 120°–130°. The angle can increase to approximately 145° in extension and decrease to 80° in flexion.[16]

Muscles of the Scapula

In the scapular region the flat, triangular trapezius muscle covers parts of eight underlying muscles. The cervical part of the trapezius arises by a thin aponeurosis from most of the funicular part of the nuchal ligament and inserts on the scapular spine and fascia of the shoulder and arm. The thoracic part of the trapezius takes an

VetBooks.ir

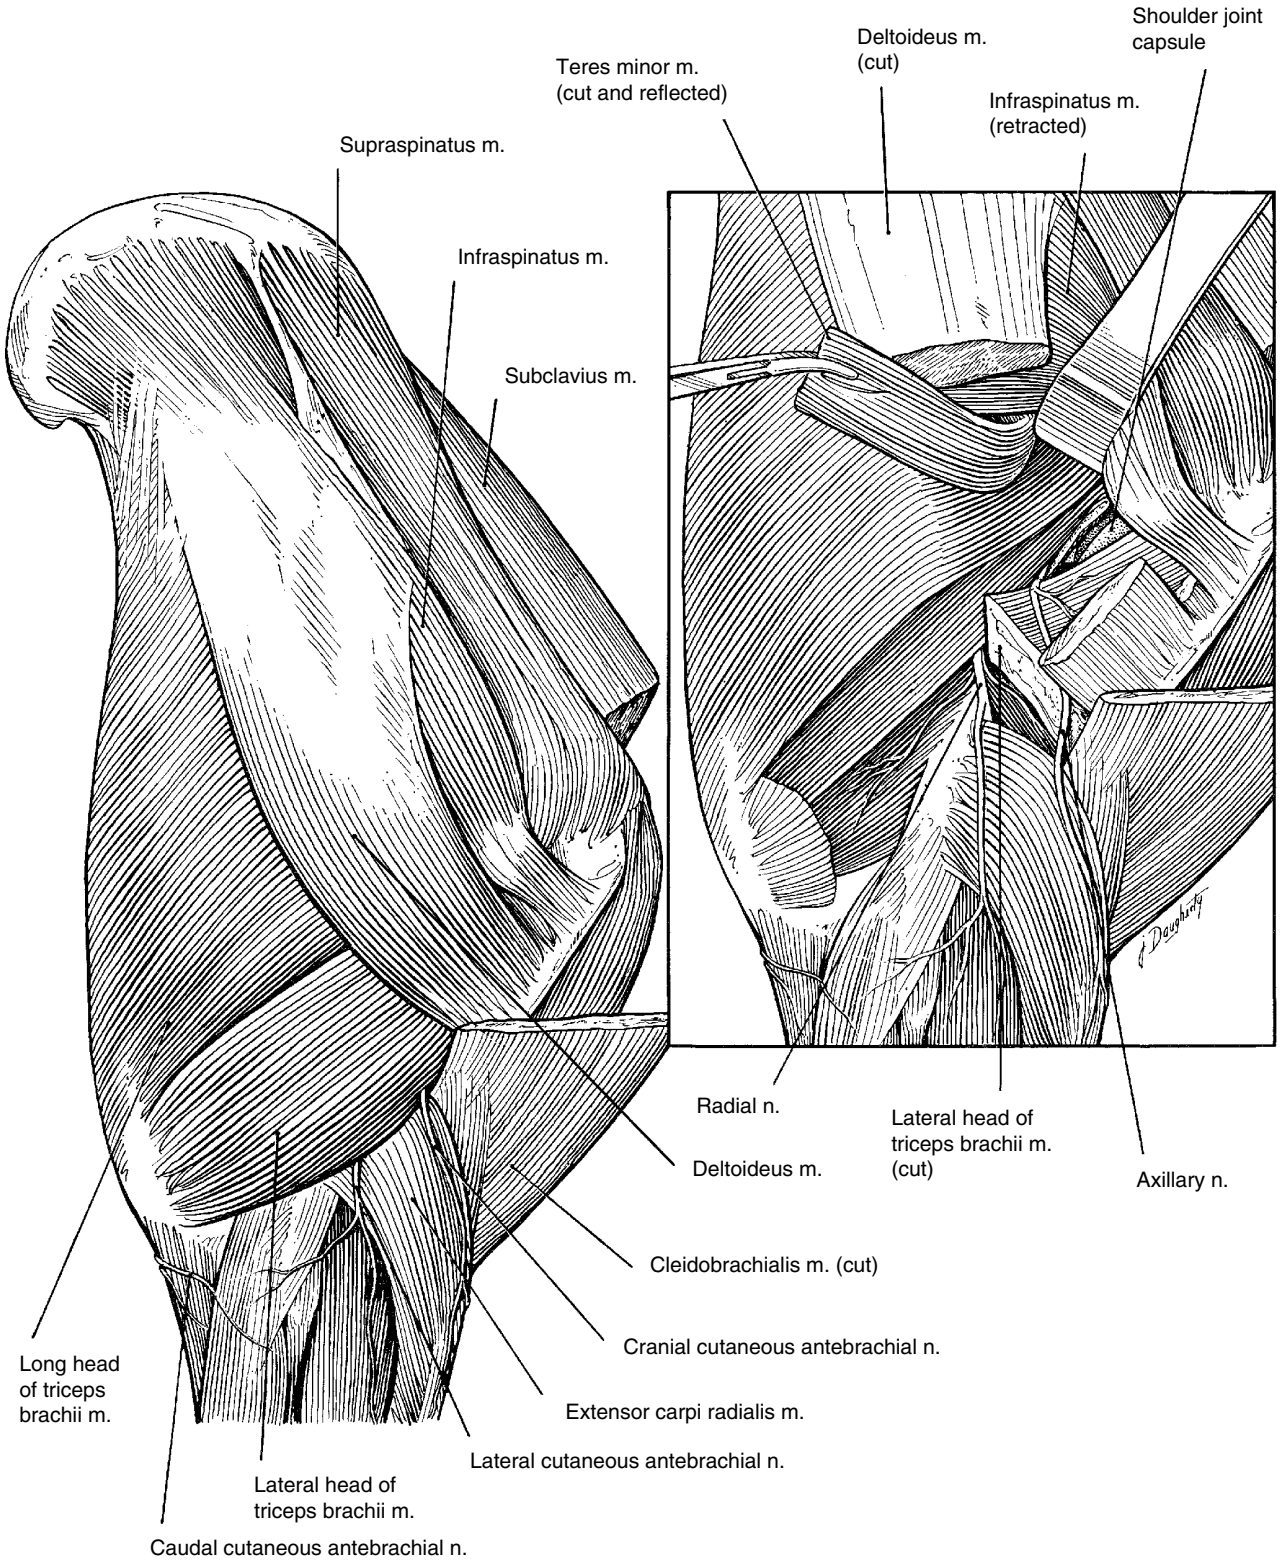

Figure 1.30. Lateral aspect of right shoulder. Inset: Deeper dissection exposing shoulder joint.

aponeurotic origin from the supraspinous ligament from the third to the tenth thoracic vertebrae and inserts on the tuber of the spine of the scapula. An aponeurosis joins the two parts of the trapezius. Innervated by the accessory nerve and dorsal branches of adjacent thoracic nerves, the trapezius muscle elevates the shoulder and draws it either craniad or caudad, depending on the activity of the cervical or thoracic parts, respectively.

Like the trapezius, the rhomboideus possesses cervical and thoracic parts. Lying deep to the trapezius, the rhomboideus cervicis originates from the funicular part of ligamentum nuchae; the rhomboideus thoracis originates

VetBooks.ir

from the superficial surface of the dorsal part of the dorsoscapular ligament. Both parts of the rhomboideus muscle insert on the medial side of the scapular cartilage (Figure 1.27). This muscle is innervated by the sixth and seventh cervical nerves and dorsal branches of nerves adjacent to the rhomboideus thoracis. The rhomboideus draws the scapula dorsocraniad, and, when the limb is stationary, the cervical part helps to raise the neck.

The latissimus dorsi muscle has a triangular shape with the origin arising through a broad aponeurosis from the thoracolumbar fascia. Thin near its aponeurotic origin, the muscle becomes thicker as it approaches its insertion, passing medial to the long head of the triceps brachii to converge on a flat, common tendon of insertion with the teres major muscle on the teres major tuberosity of the humerus (Figure 1.27).

From deep to superficial, the muscles contributing most substantially to the attachment of the thoracic limb to the trunk and neck are the serratus ventralis, pectoral muscles (including subclavius), brachiocephalicus, and omotransversarius. The cervical part of serratus ventralis extends from the transverse processes of the cervical vertebrae C4–C7 to the serrated face of the medial scapula and scapular cartilage; the thoracic part of serratus ventralis converges from the lateral surfaces of the first eight or nine ribs to the serrated face of the scapula and the scapular cartilage. Elastic sheets from the ventral part of the dorsoscapular ligament (Figure 1.31) are interspersed through the attachments of the serratus ventralis on the scapula. The right and left serratus ventralis muscles form a muscular sling suspending the thorax between the thoracic limbs. When both muscles contract, they elevate the thorax; acting independently, each serratus ventralis shifts the trunk's weight to the ipsilateral limb. During locomotion the cervical part of the muscle draws the dorsal border of the scapula craniad; the thoracic part draws the scapula caudad. When the limb is fixed, the cervical portion lifts the neck dorsad and/or pulls it laterad. The long thoracic nerve and branches from the fifth to the eighth cervical nerves supply this muscle.

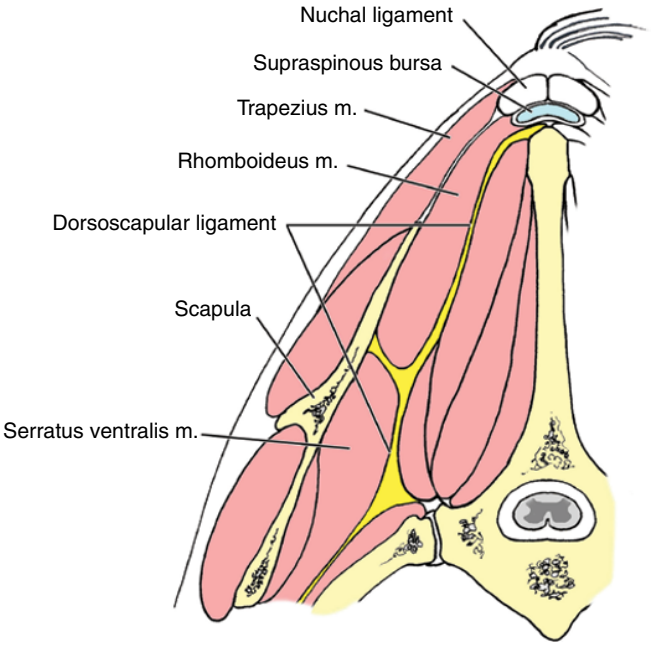

Figure 1.31. Cross section of right dorsoscapular ligament. The ligament covers the medial and ventral aspects of the rhomboideus and gives rise to sheets of elastic tissue that interdigitate with the fascicles of the serratus ventralis.

Pectoral muscles attach to the sternum. There are two superficial pectoral muscles: (1) the descending pectoral muscle passing from the cartilage of the manubrium of the sternum to the deltoid tuberosity and the crest of the humerus and brachial fascia and (2) the transverse pectoral muscle extending from the ventral part of the sternum to the superficial fascia on the medial aspect of the antebrachium and to the humeral crest. The largest pectoral muscle, the deep pectoral (ascending pectoral) muscle (Figure 1.29), passes from its attachments on the xiphoid cartilage, the ventral part of the sternum, the fourth to ninth costal cartilages, and the abdominal tunic to the cranial parts of the lesser and greater humeral tubercles. The subclavius has been traditionally grouped with the pectorals. It arises from the first four costal cartilages and the cranial half of the sternum and ends in an aponeurosis over the dorsal part of the supraspinatus muscle and the scapular fascia (Figure 1.29).

The superficial pectoral muscles adduct the limb. The deep pectoral and subclavius are also adductors, and, if the limb is fixed in the advanced position, they pull the trunk craniad. Cranial and caudal pectoral nerves (with musculocutaneous and intercostal nerves contributing to the cranial pectoral nerves) supply these muscles.

The brachiocephalicus is traditionally divided into two parts based on the embryological location (not apparent in the fully formed muscle) of the clavicular intersection. The cleidobrachialis part of the brachiocephalicus muscle extends from the clavicular intersection to the arm and is innervated by the axillary nerve. The mastoid part of the muscle (a.k.a. cleidomastoideus) lies between the intersection and its attachments to the mastoid process and nuchal crest of the skull, partly overlapping the omotransversarius muscle dorsally. The omotransversarius originates from the wing of the atlas and the transverse processes of the second, third, and fourth cervical vertebrae and inserts on the humeral crest and fascia of the shoulder and arm. The cleidobrachialis is innervated by the accessory nerve (cranial nerve XI), and the omotransversarius is innervated segmentally by cervical spinal nerves.

Dorsoscapular Ligament

Further attachment of the limb to the trunk is afforded by a thickened specialization of the thoracolumbar fascia, the dorsoscapular ligament (Figure 1.31). Its collagenous portion attaches to the third, fourth, and fifth thoracic spines under the nuchal ligament close to the supraspinous bursa.[15] This part of the dorsoscapular ligament passes ventrad, attaching to the medial surface of the rhomboideus thoracis muscle. As it curves ventral to the muscle, the collagenous part transitions to elastic tissue. A horizontal lamina of this elastic part forms the ventral sheath of the rhomboideus thoracis muscle. Vertical laminae project from the ventral aspect of the horizontal lamina, investing bundles of the serratus ventralis muscle that insert on the scapula (Figure 1.31).

VetBooks.ir

Nerves and Vessels

The ventral branches of spinal nerves C6 through T2 create the brachial plexus, which perforates the scalenus muscle and passes into the forelimb craniomedial to the shoulder joint (Figure 1.27). Vessels supplying the thoracic limb accompany the nerves in this location.

Suprascapular vessels accompany the suprascapular nerve, passing laterad between the subscapular and suprascapular muscles. The median nerve descends with the axillary artery, forming a loop medial to the artery by uniting with a large branch from the musculocutaneous nerve. Proximal branches from the musculocutaneous nerve supply the coracobrachialis and biceps brachii muscles. Distal to the axillary loop, the median and musculocutaneous nerves are contained in a common sheath, coursing distad along with the brachial artery. In the middle of the arm, the musculocutaneous nerve terminates by dividing into a distal branch supplying the brachialis muscle and the medial cutaneous antebrachial nerve that spirals around the biceps brachii to the lacertus fibrosus.

The axillary nerve crosses the medial surface of the subscapularis muscle, and, together with the large subscapular vessels (from the axillary vessels), the nerve passes laterad between the subscapularis and teres major muscles. Innervating these muscles and others of the caudal shoulder, the axillary nerve is accompanied by the caudal circumflex humeral artery, a branch of the subscapular artery. It ultimately gives rise to the cranial cutaneous antebrachial nerve.

The large radial nerve and smaller ulnar nerve descend close to each other medial to the subscapular artery and then caudal to the brachial vein. After supplying a branch to the tensor fasciae antebrachii muscle, the radial nerve plunges laterad between the teres major and the triceps to run along the musculospiral groove of the humerus. Here it gives off lateral cutaneous branches to the caudodistal aspect of the arm and supplies branches to the triceps brachii and anconeus muscles. Just proximal to the elbow joint, the radial nerve divides into deep and superficial branches. The deep branch supplies the craniolateral muscles of the antebrachium. The superficial branch winds laterad between the lateral head of the triceps brachii and the extensor carpi radialis muscles accompanied by the transverse cubital artery. It gives rise to the lateral cutaneous antebrachial nerve, which supplies sensory innervation to the fascia and skin of the lateral aspect of the forearm (Figure 1.30).

The ulnar nerve angles caudodistad to the middle of the arm. It gives rise to the caudal cutaneous antebrachial nerve that courses across the medial surface of the tensor fasciae antebrachii (Figure 1.27). The continuation of the ulnar nerve passes between that muscle and the medial head of the triceps brachii, accompanied here by the collateral ulnar vessels as they cross the medial humeral epicondyle.

After giving off the cranial circumflex humeral vessels in the proximal part of the brachium, the axillary vessels continue as the brachial artery and vein. As they descend the arm they give rise to the deep brachial vessels supplying the triceps muscle and then the collateral ulnar vessels caudally and the bicipital vessels cranially. The transverse cubital vessels are given off cranially and pass distolaterad deep to the biceps brachii and brachialis muscles to the cranial aspect of the cubital joint. The nutrient artery of the humerus may come from the first part of the collateral ulnar artery, or it may arise from the brachial artery.

Lymphatic Drainage

Lymphatic vessels from structures distal to the elbow are afferent to the cubital lymph nodes, a group of 5–20 small nodes found just proximal to the medial side of the elbow (Figure 1.27). Efferent vessels from the cubital lymph nodes end in the proper axillary lymph nodes on the medial surface of the teres major muscle (Figure 1.27). These also receive lymph from the muscles of the arm and shoulder and from the adjacent skin and the ventrolateral trunk. Vessels from the proper axillary lymph nodes carry lymph to the caudal deep cervical lymph nodes. Some efferents of the deep cervical nodes drain directly into the venous system; others pass to other regional nodes and therefore drain indirectly through these to the venous system.[28]

Lymphatic vessels from the skin of the entire thoracic limb, neck, and dorsolateral trunk and more proximal parts of the limb are afferent to the superficial cervical lymphocenter on the cranial border of the subclavius muscle, deep to the brachiocephalicus. Efferent lymphatic vessels from the superficial cervical lymph nodes terminate in the caudal deep cervical lymph nodes or by entering the common jugular vein.[16,28]

Stay Apparatus of the Thoracic Limb

Muscles, tendons, and ligaments constituting the stay apparatus of the thoracic limb fix the carpus, elbow, and shoulder joints in the standing position (Figure 1.32). This complex of structures functions almost entirely as a passive, force-resisting system.[35] It permits the horse to stand (and sleep) with a minimum of muscular activity. The elasticity of the tissues in the stay apparatus also stores energy during weight-bearing and redeliver that energy back to the limb during the swing phase of gait, markedly improving the efficiency of movement, especially when working at speed.

In the manus, elements of the stay apparatus resist nonphysiologic hyperextension of the fetlock and interphalangeal joints.

The DDFT forms a continuous ligamentous band from its accessory (carpal check) ligament to the solar surface of the distal phalanx. This is the only element that resists hyperextension of the distal interphalangeal joint; as a consequence, disruption of this part of the suspensory apparatus can produce a characteristic hyperextension of the coffin joint, identifiable as the foot is rotated back onto the heels and the toe lifts from the ground.

The four palmar ligaments stretched tightly across the pastern joint, the straight distal sesamoidean ligament, and the digital flexor tendons (with their accessory ligaments) prevent hyperextension of the pastern joint.

The suspensory apparatus is a ligamentous continuum extending from the proximal end of the third metacarpal bone to the proximal and middle phalanges. It consists of the suspensory ligament, palmar ligament with its embedded proximal sesamoid bones, and the distal sesamoidean ligaments. The SDFTs and DDFTs

VetBooks.ir

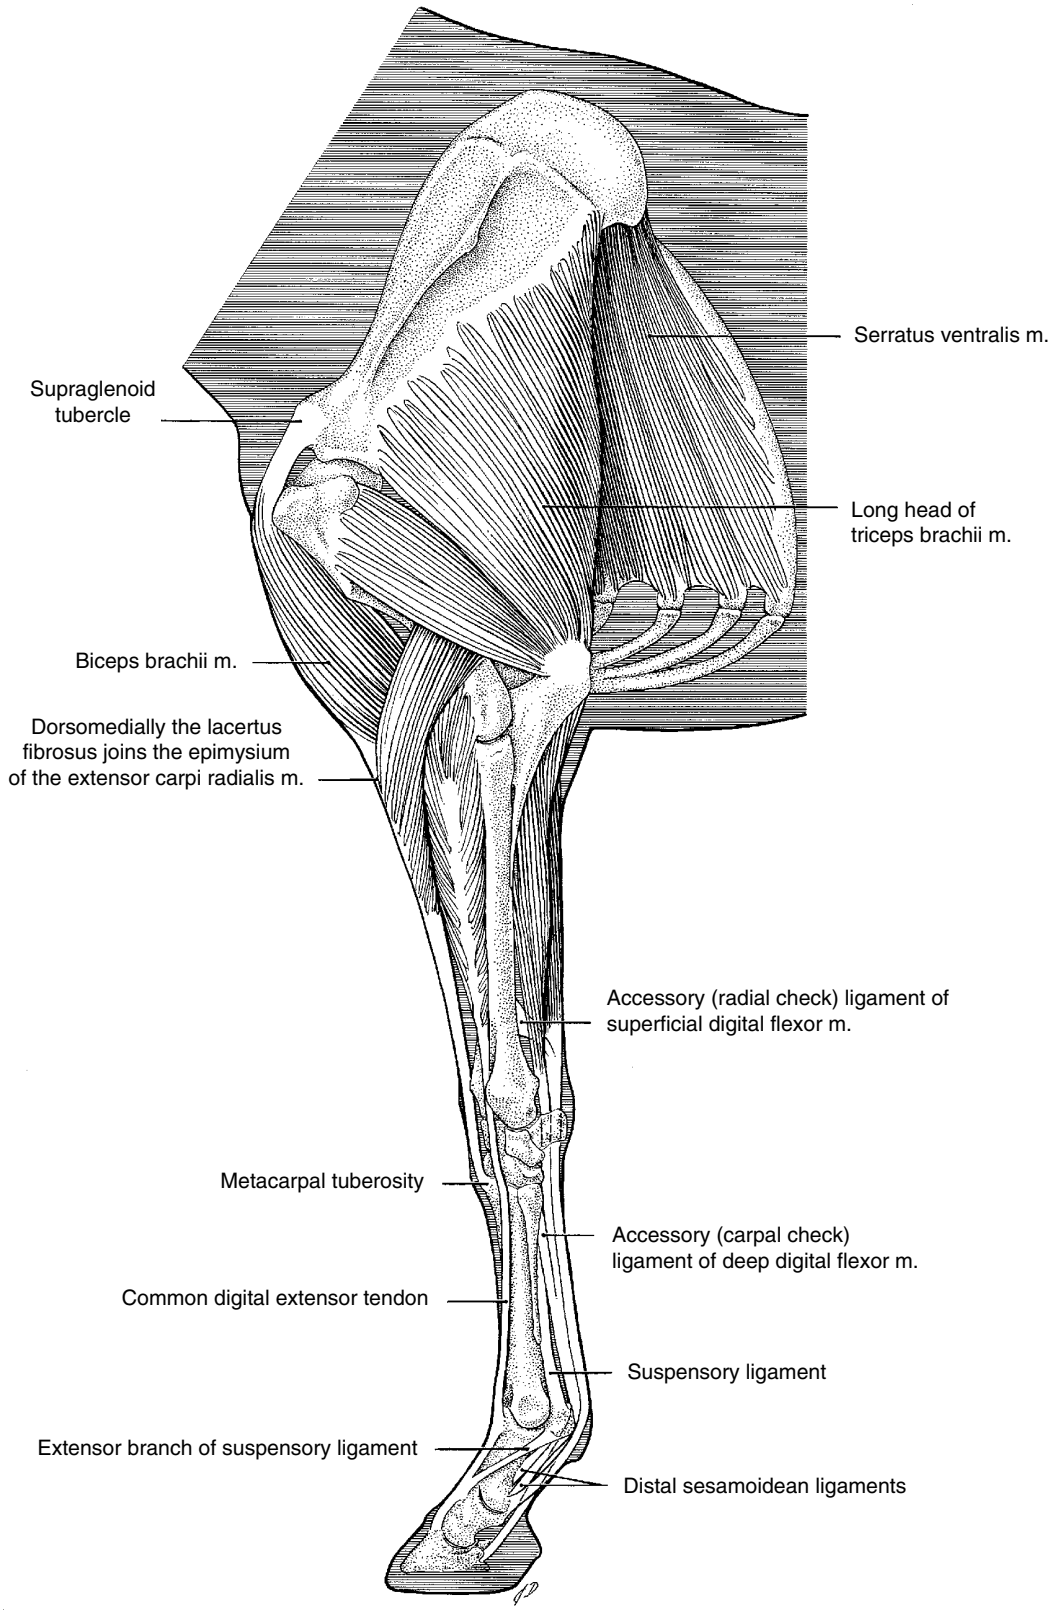

Figure 1.32. The passive stay apparatus of the left thoracic limb with assisting active elements.

and their accessory (check) ligaments assist the suspensory apparatus of the fetlock in suspending the fetlock and preventing excessive overextension of the metacarpophalangeal joint and collapse of the fetlock during loading.[11] Disruption of the suspensory apparatus alters its support of the fetlock, resulting in "sinking" or hyperextension of the fetlock.[35]

The skeletal elements of the carpus exhibit some stability in extension. Soft tissue stabilization is provided by the palmar carpal ligament and the collateral ligaments.

VetBooks.ir

Palmarly, the digital flexor tendons bridging the carpus in the carpal canal between their respective accessory ligaments, and dorsally the extensor tendons, principally the extensor carpi radialis tendon, lend further stability to the carpus.

A certain amount of muscle tone prevails in all "resting" muscles of the limb, even during most stages of sleep. Tension exerted by the long head of the triceps brachii muscle is essential to prevent flexion of the elbow joint.[33] The elbow's eccentrically placed collateral ligaments afford it surprising stability in the extended position, a stability enhanced by the triceps' tone. Flexion of the joint is further limited by the superficial digital flexor muscle descending from its attachment of the medial epicondyle of the humerus.[11]

A tendinous continuum extending from the supraglenoid tubercle of the scapula to the metacarpal tuberosity is formed by the main tendon of the biceps brachii muscle and its fibrous "internal tendon" and superficial connection to the fascia of extensor carpi radialis muscle via the lacertus fibrosis. Through the tendon of insertion of the extensor carpi radialis, a continuous band is therefore created from the scapula to the metacarpus. This complex prevents flexion of the loaded shoulder joint caused by the weight of the trunk being transferred to the appendicular skeleton via the scapular attachments of the serratus ventralis muscle and the dorsoscapular ligament.

HINDLIMB

Digit and Fetlock

The hindfoot is somewhat smaller and more elongate than the forefoot. Compared with the forefoot, the angle of the toe of the hindfoot is slightly greater (i.e. it is steeper).[1] The middle phalanx is narrower and longer, and the proximal phalanx somewhat shorter than their counterparts in the thoracic limb (Figure 1.33).

The long digital extensor muscle's tendon attaches to the dorsal surfaces of the proximal and middle phalanges and the extensor process of the distal phalanx, but the tendon of the lateral digital extensor usually does not reach the digit as it does in the thoracic limb. Digital flexor tendons, tendon sheaths, and bursae of the hind digit are not remarkably different. The suspensory apparatus of the fetlock and the configuration of the fetlock (metatarsophalangeal) joint are much the same as in the thoracic limb except that the dorsal articular angle of the fetlock is approximately 5° greater (i.e. is slightly more "upright").

Blood Vessels and Nerves of the Hind Digit and Fetlock

The principal blood supply to the fetlock and digit of the pelvic limb is derived from the continuation of dorsal metatarsal artery III, the distal perforating branch, which bifurcates into medial and lateral digital arteries in the distoplantar region of the metatarsus. A small secondary supply is contributed by medial and lateral plantar arteries that join the digital arteries to form the superficial plantar arch just proximal to the widening of the fetlock (Figure 1.34). Branches of the digital arteries form a pattern similar to that in the thoracic limb except for the blood supply to the navicular bone. In contrast to all arteries originating from palmar arterial branches of the middle phalanx, in the pelvic limb, half of the primary arteries originate from the plantar arterial branches of the middle phalanx, and half from the collateral arch (cf. Figure 1.8). More significantly, a greater number of vessels enter the distal border of the navicular bone from the distal anastomotic network in the hindfoot than the same region in the forefoot.[18]

Venous drainage of the digit of the pelvic limb is similar to that of the forelimb. The digital veins carry blood to the plantar common digital veins at the level of the fetlock.

The pattern of distribution of the plantar digital and plantar metatarsal nerves in the fetlock and digit of the pelvic limb is similar to the pattern of the counterpart nerves in the thoracic limb. Some differences exist, however. The dorsal branch of each plantar digital nerve is given off more distally than the corresponding branch of the forelimb. Medial and lateral dorsal metatarsal nerves (from the deep fibular—formerly peroneal—nerve) course distad subcutaneously parallel and dorsal to the medial and lateral plantar metatarsal nerves (Figures 1.34 and 1.35). The lateral plantar metatarsal nerve extends distad over the fetlock to the lateral aspect of the pastern, while the medial plantar metatarsal nerve may reach as far as the coronet; both dorsal metatarsal nerves continue into the laminar corium.[20] Terminal branches of the saphenous nerve medially, the superficial fibular nerve dorsally and laterally, and the caudal cutaneous sural nerve dorsolaterally complete the sensory innervation to the skin of the fetlock.

Metatarsus

The equine metatarsus is about 16% longer than the corresponding metacarpus, and the third metatarsal bone is more round in cross section than the third metacarpal bone.[16] The lateral splint bone, particularly its proximal extremity, is much larger than the medial splint bone.

Dorsal Aspect

Three superficial nerves supply sensory innervation to the skin of the dorsal, lateral, and medial aspects of the metatarsus. Dorsally and laterally the two terminal branches of the superficial fibular nerve descend as far as the fetlock. The terminal branch of the caudal cutaneous sural nerve descends obliquely from the lateral aspect of the hock to course over the dorsolateral part of the third metatarsal bone, terminating in the skin of the fetlock, and the terminal branch of the saphenous nerve supplies medial skin of the metatarsus down to the fetlock.

The dorsal common digital vein II (great metatarsal vein) ascends from a venous arch proximal to the proximal sesamoids as the primary continuation of the venous drainage on the medial side of the digit and fetlock. At first, the great metatarsal vein lies along the medial border of the suspensory ligament, and then it angles dorsad in a groove on the third metatarsal bone to the hock where it becomes the cranial branch of the medial saphenous vein (Figure 1.35).

VetBooks.ir

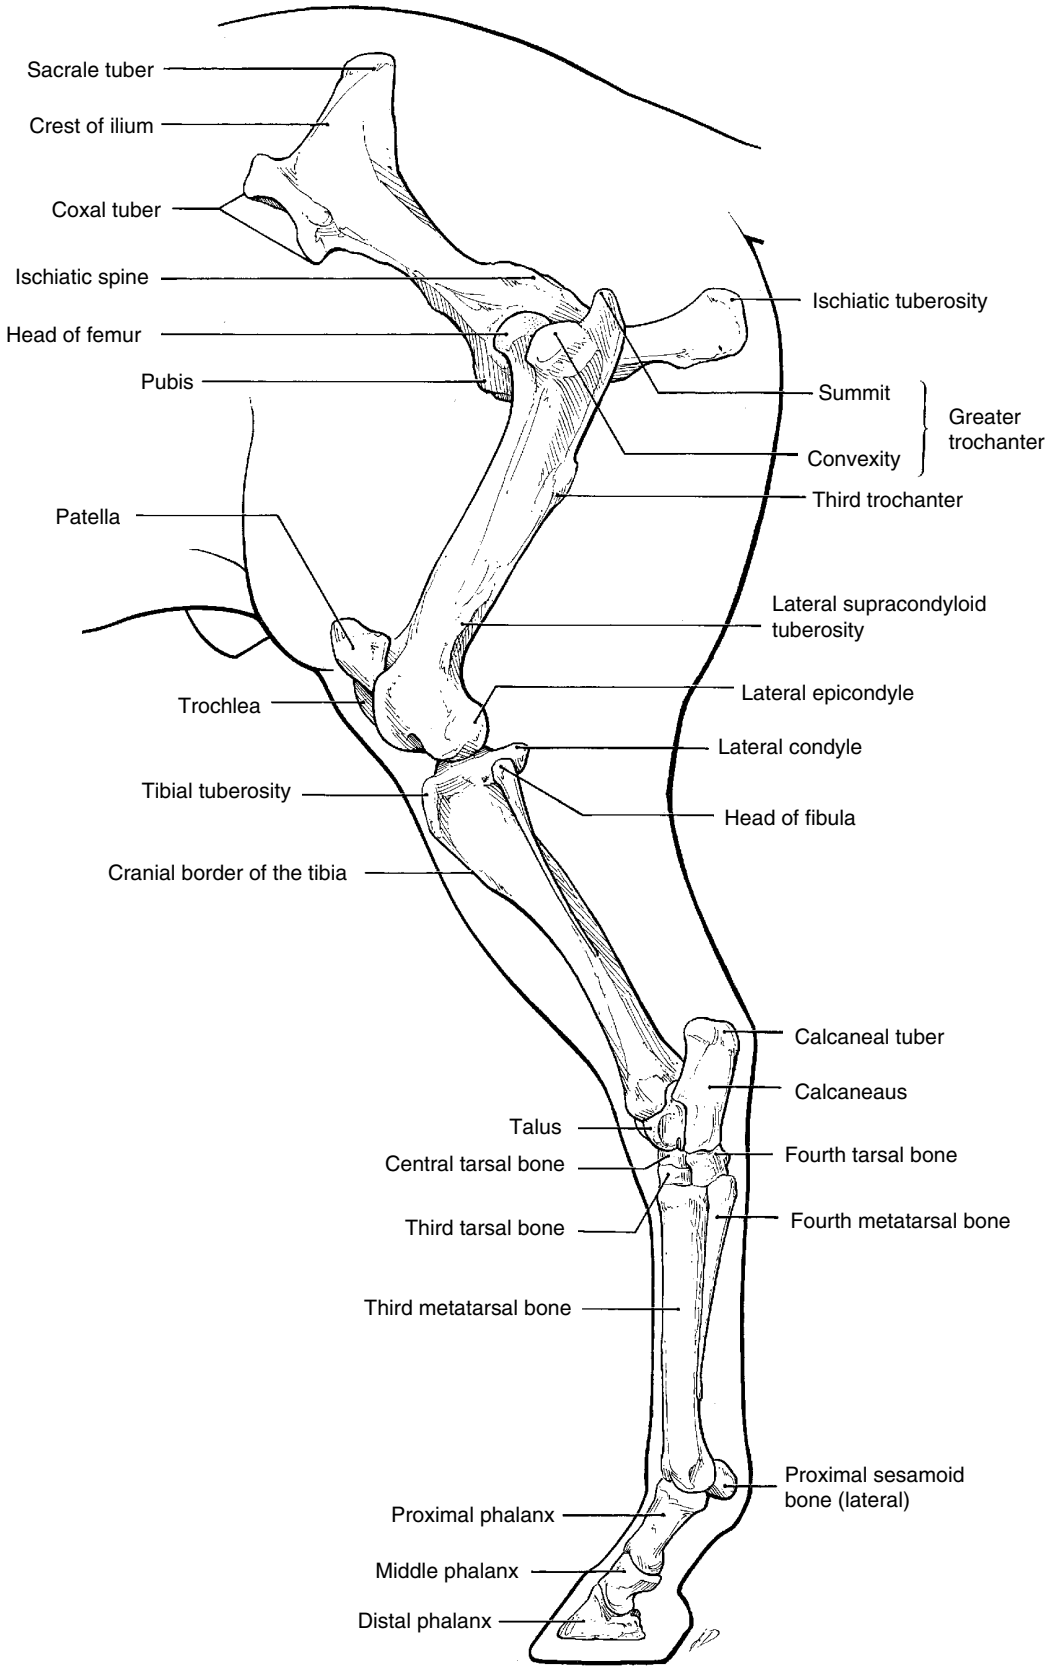

Figure 1.33. Bones of the left pelvic limb. Lateral view.

VetBooks.ir

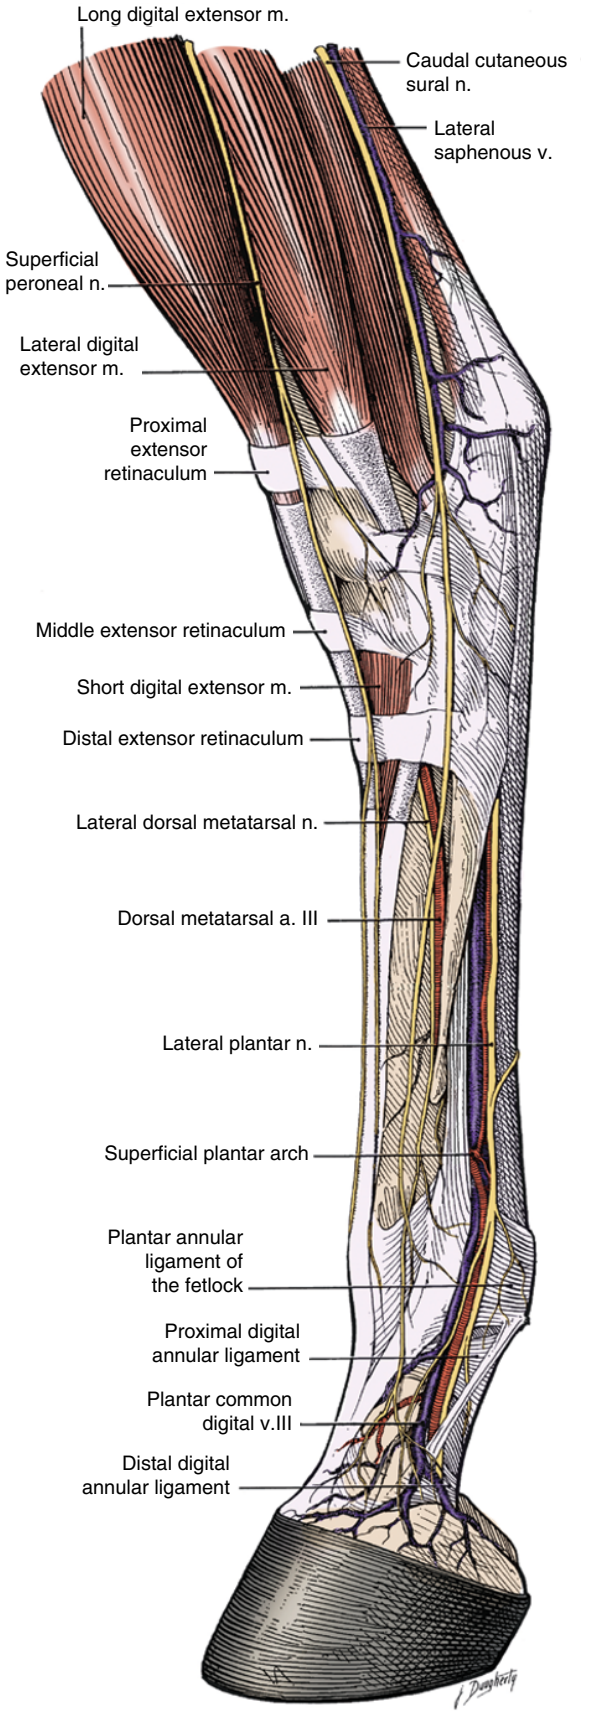

Figure 1.34. Lateral view of left distal crus and pes. Please note that the term "fibularis" has superseded "peroneus" (fibular rather than peroneal) although both are widely used.

The tendon of the long digital extensor muscle extends the length of the metatarsus on the dorsal surface of the cannon bone. At the proximal third of the metatarsus, the tendon of the lateral digital extensor muscle joins the long digital extensor tendon. Rarely, the tendon of the lateral digital extensor courses separately to the proximal phalanx. The angle formed by the conjoined long and lateral digital extensor tendons is occupied by the thin, triangular short digital extensor muscle. This vestigial muscle originates on the lateral collateral ligament of the hock, the lateral tendon of the fibularis tertius, and the middle extensor retinaculum. It inserts on the long digital extensor tendon. All digital extensor muscles are bound down by the distal extensor retinaculum in the proximal third of the metatarsus (Figure 1.34).

Emerging under the distal edge of the distal extensor retinaculum, the large dorsal metatarsal artery III ("great metatarsal artery") runs obliquely to the groove between the third and fourth metatarsal bones. A very small satellite vein and the lateral dorsal metatarsal nerve run with the artery. The terminal branch of the caudal cutaneous sural nerve crosses superficial to the dorsal metatarsal artery III (Figure 1.34). Distally the artery passes between the cannon and lateral splint bones near the button of the splint. Here it continues as the distal perforating branch, sending branches to the distal deep plantar arch and then dividing into medial and lateral digital arteries. These continue along the plantar aspect of the third metatarsal bone in the distal fourth of the metatarsus.

The lateral dorsal metatarsal nerve remains superficial, courses to the fetlock, and descends on the dorsal pastern to terminate in the laminar corium. The medial dorsal metatarsal nerve supplies sensory fibers to the hock joint capsule and a motor branch to the short digital extensor muscle. The nerve courses between the long digital extensor tendon and the second metatarsal bone to be distributed distally to the pastern and laminar corium (Figure 1.35).

Lateral and Medial Aspects

The lateral and medial plantar nerves lie plantar to their satellite vessels along the dorsal borders of the digital flexor tendons (Figures 1.34 and 1.35). These nerves supply the lateral, medial, and plantar structures of the metatarsus. The lateral plantar nerve gives rise to a deep branch close to the tarsus; this is the parent trunk of the deeply located lateral and medial plantar metatarsal nerves that pursue courses homologous to the palmar metacarpal nerves in the forelimb. It likewise gives off a sensory branch to the suspensory ligament at this level.

At about the mid-metatarsus, the medial plantar nerve gives off the communicating branch that angles laterodistad superficial to the digital flexor tendons to join the lateral plantar nerve in the distal fourth of the metatarsus. The communicating branch is generally smaller than its counterpart in the metacarpus, and it may be absent.

On each side the very small medial and lateral plantar arteries arise from the deep plantar arch in the proximal metatarsus, itself supplied mainly by the proximal perforating branch from the dorsal pedal artery. The plantar arteries course down to the distal end of the

VetBooks.ir

VetBooks.ir

metatarsus where they send branches to the respective digital arteries, forming the superficial plantar arch.

Plantar Aspect

The SDFT is similar to the corresponding tendon in the metacarpus.[11] The deep digital flexor muscle's principal tendon is intimately related to the SDFT. In the proximal third of the metatarsus, the tendon of the medial digital flexor muscle (a.k.a. the medial head of the deep digital flexor muscle) joins the main part of the DDFT. A poorly developed, slender accessory ligament (tarsal or "inferior" check ligament) arises from the plantar aspect of the fibrous joint capsule of the hock. Longer and more slender than its counterpart in the forelimb, it joins the DDFT near the middle of the metatarsus. The tarsal check ligament may be absent in some horses, and it is usually absent in mules and ponies.[16]

The suspensory ligament takes origin from a large area on the proximal aspect of the third metatarsal bone, with a smaller attachment on the distal row of tarsal bones. Lying within the plantar groove created by the metatarsal bones, the suspensory ligament of the hindlimb is relatively thinner, more rounded, and longer than the ligament of the forelimb. In some horses (e.g. Standardbreds), the suspensory ligament of the hindlimb contains more muscle than the suspensory ligament of the forelimb.[45] The two extensor branches course in a similar manner to those in the forelimb. Vestigial medial and lateral interossei and lumbricales muscles are present in the metatarsus as in the metacarpus.

Distribution of the medial and lateral plantar metatarsal arteries coursing distad under the suspensory ligament to the distal deep plantar arch is similar to the distribution of the palmar metacarpal arteries. Satellite veins accompany the arteries.

Tarsus (Hock)

The bones of the tarsus include the talus, calcaneus, and central, fused first and second, third, and fourth tarsal bones (Figure 1.33). Proximally, the trochlea of the talus articulates with the tibia in the tarsocrural (a.k.a. tibiotarsal) joint; the distal row of tarsal bones and the three metatarsal bones articulate in the tarsometatarsal joint. Extensive collateral ligaments span these and the intertarsal joints. In the horse, nearly all the movement of the hock arises from the tarsocrural joint.

Dorsal Aspect

The large cranial branch of the medial saphenous vein continues proximad and crosses the mediodorsal aspect of the tarsus, lying upon the dorsomedial pouch of the tarsocrural joint capsule (Figure 1.36). The dorsal pedal vein is continued proximad by the cranial tibial vein, which lies under the cover of the cranial tibial muscle. The superficial fibular (peroneal) nerve lies lateral and parallel to the tendon of the long digital extensor muscle. The middle extensor retinaculum leaves the lateral tendon of insertion of the fibularis (peroneus) tertius muscle, wraps superficial to the long digital extensor tendon and its sheath, and attaches to the calcaneus.

The long digital extensor tendon is located just lateral to the palpable medial ridge of the trochlea of the talus. Its synovial sheath extends from the level of the lateral malleolus distad nearly to the junction of the tendon with the tendon of the lateral digital extensor muscle (Figure 1.34). The short digital extensor muscle covers the tarsal joint capsule, the dorsal pedal artery, and the termination of the deep fibular nerve as it bifurcates into the two dorsal metatarsal nerves (Figure 1.34).

As it crosses the dorsal surface of the tarsocrural joint, the tendon of the fibularis tertius muscle is superficial to the tendon of the cranial tibial muscle (Figures 1.35 and 1.36). After passing deep to the proximal extensor retinaculum, it splits to create a sleevelike cleft through which the tendon of the cranial tibial and its synovial sheath pass. Having allowed passage of the cranial tibial tendon, the fibularis tertius divides into a dorsal and a lateral tendon of insertion. The dorsal tendon inserts on the third tarsal and third metatarsal bone (Figure 1.36). The lateral tendon extends distad deep to the long digital extensor tendon. It then bifurcates and inserts on the calcaneus and the fourth tarsal bone.

The tendon of the cranial tibial muscle, having emerged through the fibularis tertius, itself bifurcates into a dorsal tendon, which inserts on the cannon bone, and a medial ("cunean") tendon, which angles mediad to insert on the first tarsal bone after passing superficial to the medial tendon of insertion of the fibularis tertius. A large bursa (cunean bursa) is interposed between the cunean tendon and the long medial collateral ligament (Figure 1.37).

The cranial tibial artery is the main blood supply to the pes (tarsus, metatarsus, and digit). At the level of the tarsocrural joint, it is continued as the dorsal pedal artery (Figure 1.36). Branches from the dorsal pedal artery form the dorsal tarsal rete in the tarsal fascia. Small medial and lateral tarsal arteries arise from the dorsal pedal artery and supply respective sides of the tarsus. Before continuing as the dorsal metatarsal artery III, the dorsal pedal artery gives off the proximal perforating branch that traverses the vascular canal formed by the central, third, and fourth tarsal bones. This branch joins the proximal deep plantar arch. Satellite veins accompany the arteries.

Lateral Aspect

The caudal cutaneous sural nerve innervates the lateral aspect of the tarsus as it courses superficial to the calcaneus and from the more dorsally located superficial fibular nerve (Figure 1.34).

The tendon of the lateral digital extensor muscle is bound by a fibrous band in a groove in the lateral malleolus of the tibia and then passes through the long lateral collateral ligament of the tarsus as it angles dorsodistad (Figure 1.38). A synovial sheath enfolds the tendon from just proximal to the lateral malleolus to a point just proximal to the tendon's junction with the long digital extensor tendon. Plantar to the lateral extensor tendon, the lateroplantar pouch of the tarsocrural joint capsule protrudes between the lateral malleolus and the calcaneus.

Medial Aspect

The chestnut, the keratinaceous vestige of a tarsal pad, is located in the skin on the distomedial aspect of

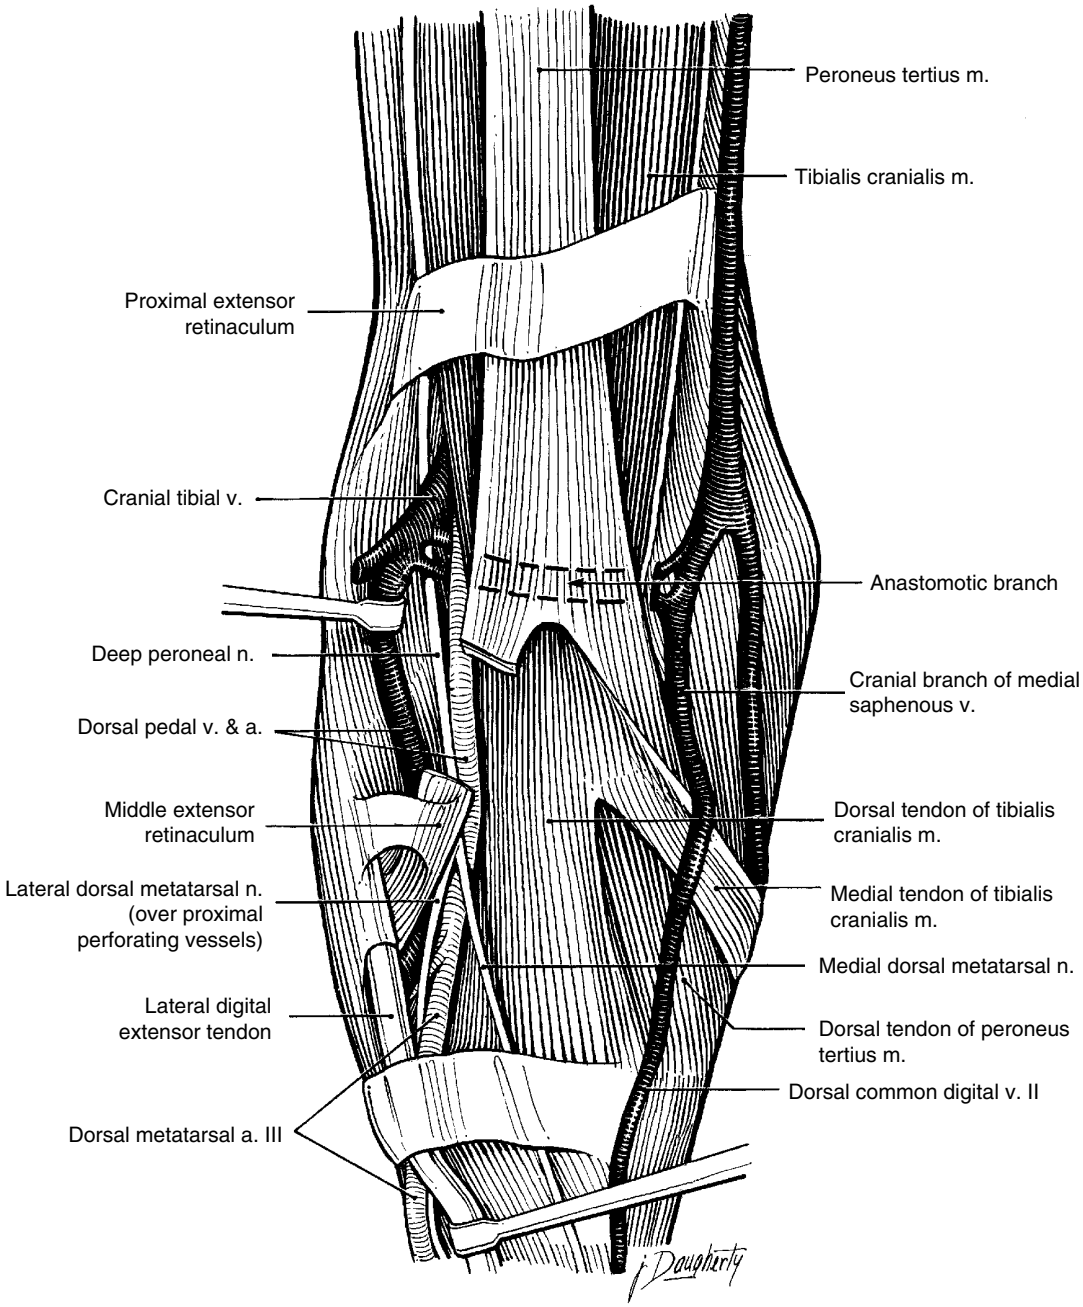

Figure 1.36. Dorsal dissection of right tarsus. The long digital extensor and short digital extensor muscles have been removed. The lateral tendon of the fibularis tertius is sectioned. Please note that the term "fibularis" has superseded "peroneus" (fibular rather than peroneal), although both are widely used.

the tarsus. Branches from the saphenous and tibial nerves supply sensory innervation to the medial aspect of the tarsus. The large cranial branch of the medial saphenous vein courses subcutaneously, superficial to the dorsomedial pouch of the tarsocrural joint capsule. At the level of the medial malleolus of the tibia, it sends a small anastomotic branch to the cranial tibial vein. The caudal branch of the medial saphenous vein receives blood from branches in the medial and plantar regions of the hock.

A palpable feature of the medial aspect of the hock is the medial (cunean) tendon of the cranial tibial muscle as it inserts on the fused first and second tarsal bone. The bursa between the cunean tendon and the distal part of the long medial collateral ligament of the tarsus is not normally palpable (Figure 1.37). The tendon of the medial digital flexor (a.k.a. medial head of the deep digital flexor muscle or long digital flexor muscle) passes through a fascial tunnel plantar to the medial collateral ligament. A synovial sheath surrounds this tendon from the distal fourth of the tibia to the tendon's junction with the main tendon of the deep digital flexor (Figure 1.39). A compartment of the tarsocrural joint capsule, the medioplantar pouch, is located a short distance plantar to the medial digital flexor tendon and proximal to the sustentaculum tali of the calcaneus at the level of the medial malleolus.

VetBooks.ir

VetBooks.ir

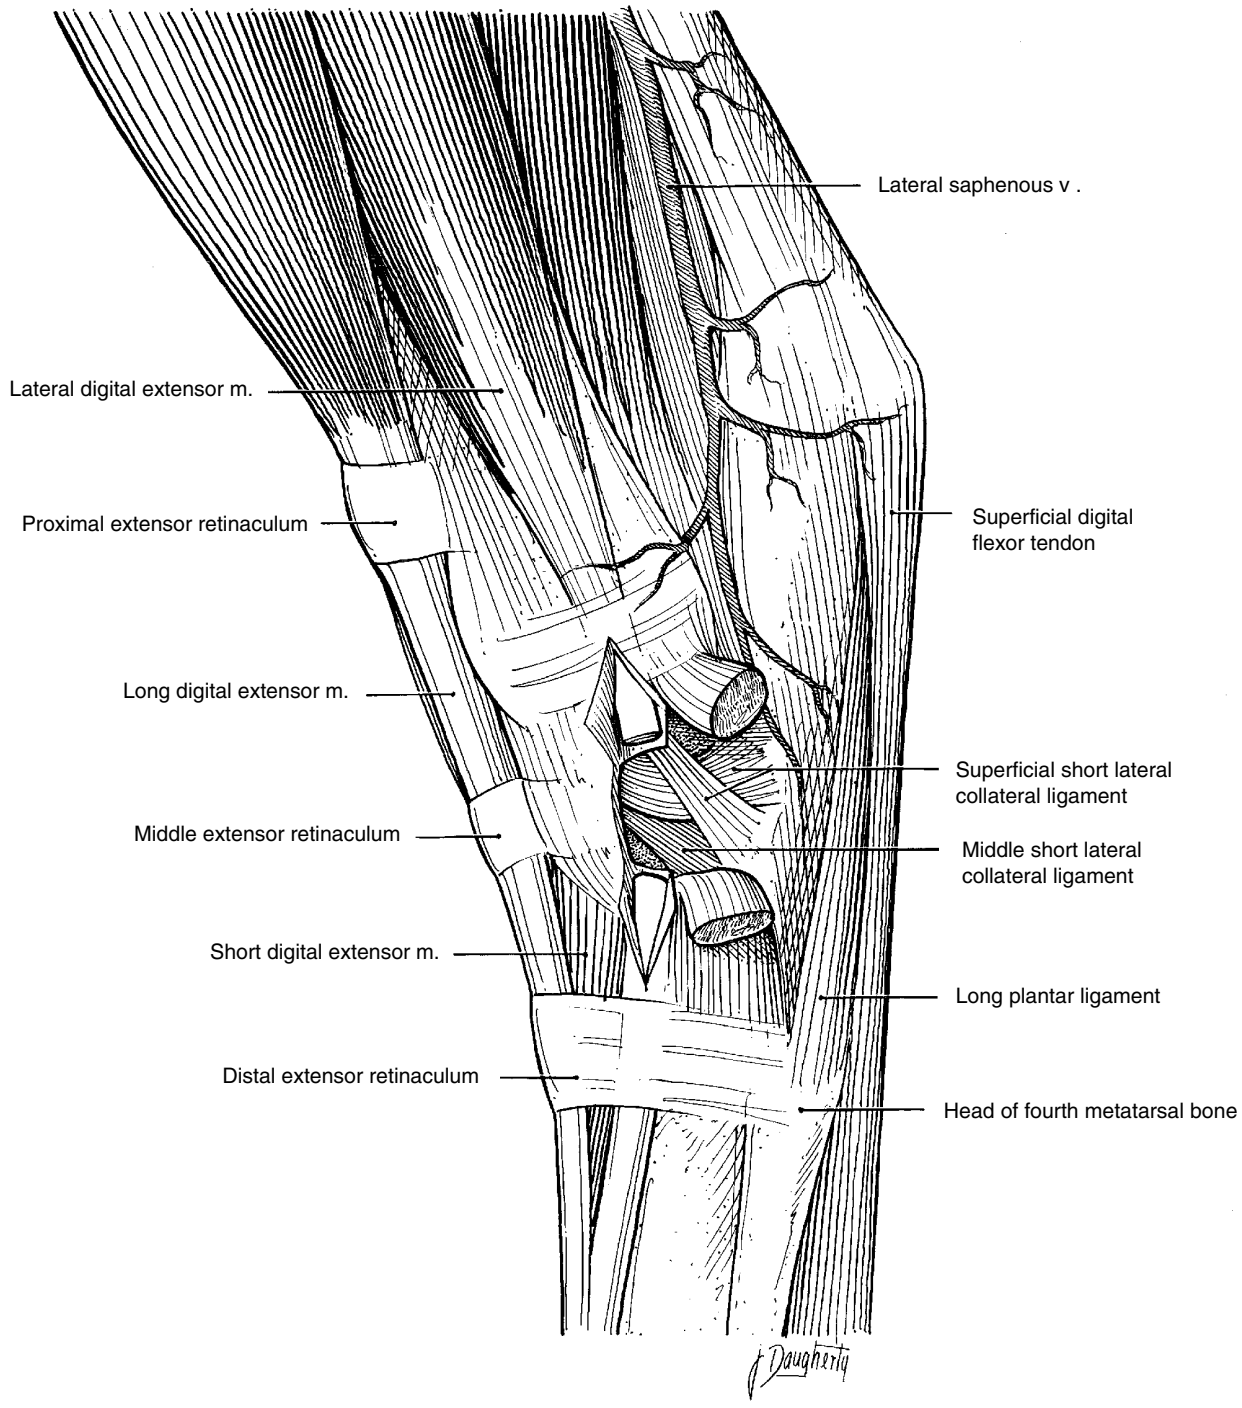

Figure 1.38. Lateral view of left tarsus. The long lateral collateral ligament has been cut and reflected. A section of the lateral digital extensor tendon has been removed.

The tarsal fascia thickens into a flexor retinaculum, bridging the groove on the calcaneus to form the tarsal canal containing the principal tendon of the deep digital flexor muscle. The tendon's synovial sheath, the tarsal sheath, extends from a level proximal to the medial malleolus to the proximal fourth of the metatarsus (Figure 1.35). After joining the anastomotic branch of the caudal tibial artery just proximal to the tarsus, the saphenous artery continues distad with the tendon (Figure 1.37). It bifurcates at the level of the sustentaculum tali of the calcaneus into small medial and lateral plantar arteries. Medial and lateral plantar nerves from the tibial nerve in the distal crural region also accompany the principal DDFT (Figure 1.37). At the level of the tarsometatarsal joint, the medial plantar nerve and artery cross obliquely over the plantar surface of the DDFT to the medial side of the tendon.

Plantar Aspect

In the distal third of the crus, the tendon of the superficial digital flexor muscle arcs around the medial side of

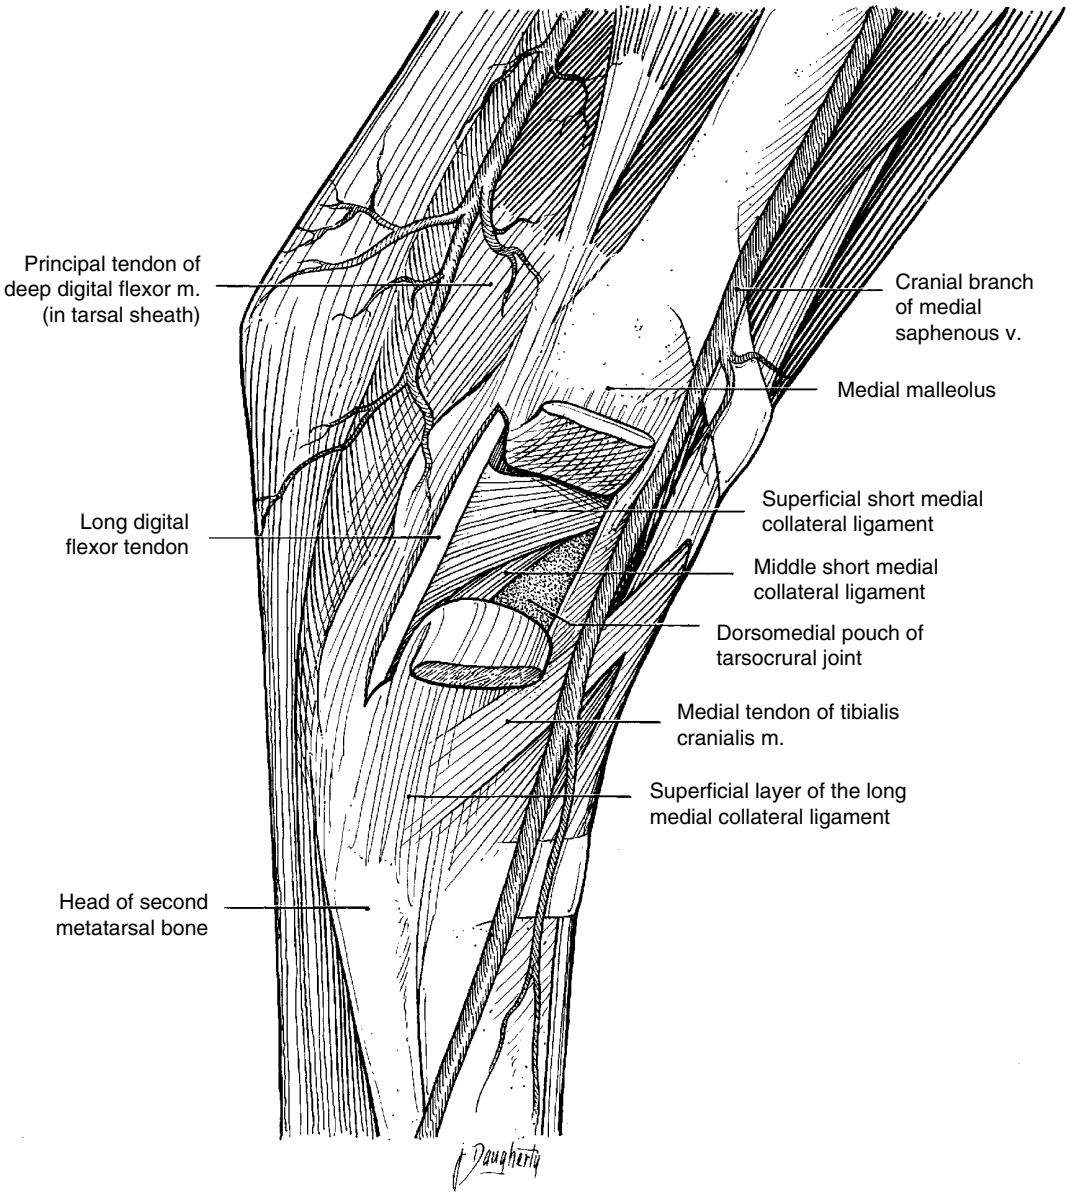

Figure 1.39. Medial view of left tarsus. The long medial collateral ligament has been cut and reflected. The tendon sheath of the long digital flexor tendon has been opened. Please note that "long digital flexor" is an alternative term for the medial head of the deep digital flexor muscle.

the tendon of the gastrocnemius muscle to become superficial as the tendons approach the calcaneal tuber. The SDFT flattens and is joined by aponeurotic connections of the biceps femoris and semitendinosus muscles. This tendinous complex attaches to the point and sides of the calcaneal tuber. The continuation of the tendon then narrows and continues distad superficial to the long plantar ligament. The tendon of the gastrocnemius, deep to the superficial digital flexor at the hock, inserts on the plantar surface of the calcaneal tuber. An elongated bursa is interposed between the two tendons just above the tarsus. A smaller bursa is present between the SDFT and the calcaneal tuber. These two bursae usually communicate across the lateral surface of the gastrocnemius tendon.[30] An inconstant subcutaneous bursa may develop over the superficial digital flexor at the level of the calcaneal tuber.

Deep to the superficial digital flexor, the long plantar ligament is attached to the plantar surface of the calcaneus. It terminates distally on the fourth tarsal bone and the proximal extremity of the fourth metatarsal bone (Figure 1.38).

Tarsal Joint (Hock Joint)

The distal end of the tibia features deep grooves that constitute the cochlear articular surface. In the standing position, the dorsal articular angle of the hock is around 150°.[16] The joint can be flexed to the extent that the metatarsus contacts the cranial crus. During flexion of the tarsocrural joint, the pes is directed slightly laterad due to the configuration of the joint. Joints between the tarsal bones of the same row, the intertarsal joints, and the tarsometatarsal joint are capable of only a small

VetBooks.ir

amount of gliding movement, so that nearly all of the hock's range of motion arises from the tarsocrural joint.

A long collateral ligament and three short collateral ligaments bind each side of the hock (Figures 1.38–1.40).[43] The long lateral collateral ligament extends from the lateral malleolus and attaches distally to the calcaneus, talus, fourth tarsal, lateral splint, and cannon bones. The three short lateral collateral ligaments are fused proximally where they attach to the lateral malleolus. The superficial component attaches distoplantarly to both the talus and calcaneus, whereas the middle and deep short lateral collateral ligaments attach solely on the lateral surface of the talus.

The long medial collateral ligament of the hock has less well-defined borders than its lateral counterpart. From its proximal attachment on the medial malleolus, the long medial collateral ligament extends distad and divides into two layers along its dorsal border. The superficial layer passes over the cunean tendon of the cranial tibial muscle and attaches to the fused first and second tarsal bones and the second and third metatarsal bones just distal to the cunean bursa. The deep layer attaches distally to the talus and the central and third tarsal bones. The plantar edge of the ligament attaches to the deep fascia over the sustentaculum tali and the ligament between the second and third metatarsal bones.

The superficial short medial collateral ligament extends from the medial malleolus to the tuberosities of the talus and the ridge between them (Figure 1.39). The middle short medial collateral ligament extends obliquely from the medial tibial malleolus to the sustentaculum tali and central tarsal bone. It lies on the medial surface of the talus between the two tuberosities, varying in position during movement of the joints. The smallest component, the deep short medial collateral ligament, courses from the distal edge of the medial tibial malleolus obliquely to the ridge between the two tuberosities of the talus.

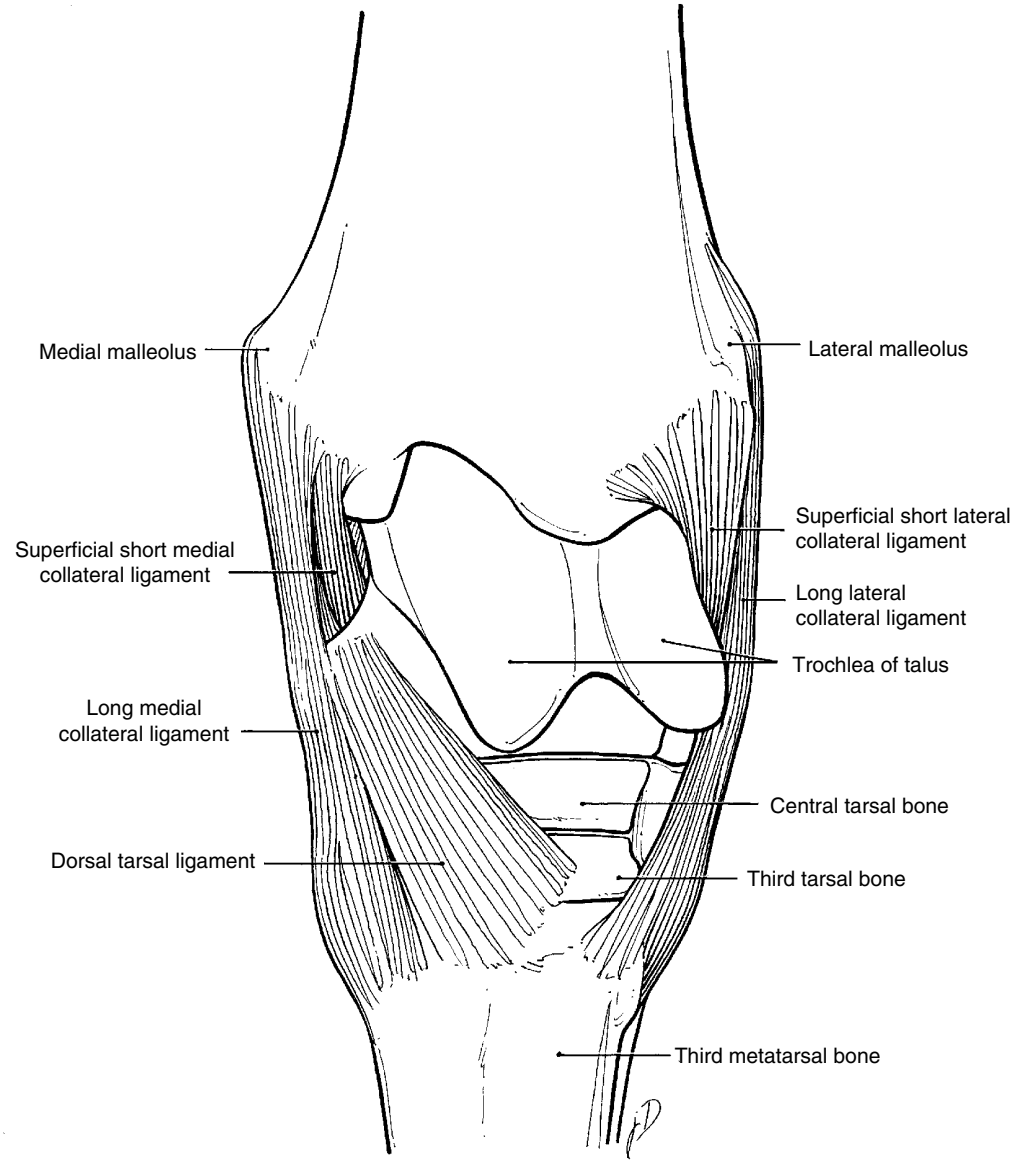

Figure 1.40. Dorsal view of right tarsus.

VetBooks.ir

A dorsal tarsal ligament fans out distad from the distal tuberosity of the talus, attaching to the central and third tarsal bones and the proximal extremities of the second and third metatarsal bones (Figure 1.40). A plantar tarsal ligament attaches to the plantar surface of the calcaneus and fourth tarsal bone and the fourth metatarsal bone. Smaller, less distinct ligaments join contiguous tarsal bones.

The tarsal joint capsule is thinnest dorsally and thickest in its plantar and distal parts. Cartilage in the capsule covering the flexor groove of the sustentaculum tali provides a smooth surface for the DDFT. Distally the tarsal check ligament of the DDFT takes origin from the fibrous joint capsule.

Three pouches can protrude (most notably with joint effusion) from the large tarsocrural synovial sac where it is not bound down by ligaments: the dorsomedial (largest), medioplantar, and lateroplantar pouches. The tarsocrural sac consistently communicates with the synovial sac associated with the proximal intertarsal joint formed by the talus and calcaneus proximally and the central and fourth tarsal bones distally. The distal intertarsal sac, between the central tarsal and contiguous bones and the distal tarsal row, typically does not communicate with the proximal intertarsal sac, but may communicate with the synovial sac of the tarsometatarsal joint. Communications have been demonstrated in 8.3%–23.8% of cases studied.[38]

Movements of the Tarsocrural Joint

The tarsocrural joint is flexed by contraction of the cranial tibial muscle and the passive pull of the tendinous fibularis (peroneus) tertius. Contraction of the gastrocnemius, biceps femoris, and semitendinosus muscles and the passive pull of the tendinous superficial digital flexor muscle extend the joint. By virtue of its attachments in the extensor fossa of the femur proximally, and on the lateral aspect of the tarsus and dorsal surface of the third metatarsal bone distally, the fibularis tertius passively flexes the tarsocrural joint when the stifle joint is flexed. The superficial digital flexor originates in the supracondyloid fossa of the femur and attaches to the calcaneal tuber. This part of the superficial digital flexor serves to passively extend the tarsocrural joint when the femorotibial joint is extended. The two tendinous, passively functioning elements constitute the reciprocal apparatus (Figure 1.41).

Crus (Leg or Gaskin)

The crus is the region of the hindlimb containing the tibia and fibula, extending from the tarsocrural joint to the femorotibial joint. The proximal end of the fibula articulates with the lateral condyle of the tibia. Distally the fibula narrows to a free end, terminating in the distal one-half to two-thirds of the crus as a thin ligament. An interosseous ligament occupies the space between the two bones. The cranial tibial vessels pass through the proximal part of the ligament. The current preference among anatomists is to replace the Greek word "peroneus" with its Latin equivalent "fibularis" in the naming of crural structures.

Beneath the skin and superficial fascia, a dense crural fascia invests the entire region. The deep crural fascia is continuous with the femoral fascia and with tendons descending from the thigh. It blends with the medial and lateral patellar ligaments and attaches to the medial tibia in the middle of the leg. Caudally, the crural fascia forms the combined aponeuroses of the biceps femoris and semitendinosus muscles that attach with the SDFT to the calcaneal tuber. Deeper layers of the crural fascia invest the muscles of the leg.

Cranial Aspect

The belly of the long digital extensor muscle is prominent beneath the skin on the craniolateral aspect of the crus. It originates in common with the fibularis tertius from the extensor fossa of the femur, the common tendon descending through the extensor sulcus of the tibia (Figure 1.42). The long digital extensor muscle is related on its deep side to the tendinous fibularis tertius and the fleshy cranial tibial muscles. Caudally, it contacts the lateral digital extensor muscle from which it is separated by a distinct intermuscular septum. The superficial fibular nerve courses distad in the groove between the digital extensor muscles and angles craniad toward the hock. The deep fibular nerve courses distad between the two muscles on the cranial surface of the intermuscular septum. At its origin this nerve sends branches to the digital extensor muscles, fibularis tertius, and cranial tibial muscles (Figures 1.42 and 1.43).

Deep to and intimately associated with the fibularis tertius, the cranial tibial muscle covers the craniolateral surface of the tibia, originating from the tibial tuberosity, lateral condyle, and lateral border of the bone and from the crural fascia (Figure 1.42). After it passes through the interosseous space (between the tibia and fibula), the cranial tibial artery courses distad on the tibia deep to the cranial tibial muscle, accompanied by two satellite veins.

Lateral Aspect

The caudal cutaneous sural nerve arises from the tibial nerve (Figure 1.43). Along with the lateral saphenous vein, the caudal cutaneous sural nerve courses laterad across the gastrocnemius muscle. The nerve and vein then descend under the crural fascia and tarsal attachment of the biceps femoris muscle to the distal third of the crus where the nerve penetrates the crural fascia and divides into several branches, one of which courses distad over the hock to the metatarsus (Figures 1.34 and 1.43).

The tibial attachment of the biceps femoris muscle is a broad aponeurosis. It sweeps across the proximal third of the lateral crus to attach to the cranial tibial border. Deep to the belly of the biceps femoris, the common fibular nerve crosses the lateral surface of the lateral head of the gastrocnemius muscle and divides into superficial and deep fibular nerves (Figure 1.43). Caudal to these, the lateral digital extensor muscle originates on the fibula, interosseus ligament, lateral surface of the tibia, and the lateral collateral ligament of the femorotibial joint. The lateral head of the deep digital flexor muscle lies caudal to the belly of the lateral digital extensor.

The lateral head of the gastrocnemius originates on the lateral supracondyloid tuberosity of the femur.

VetBooks.ir

Under the crural fascia in the proximal half of the crus, the small soleus muscle extends from its origin on the fibula along the lateral aspect of the gastrocnemius muscle to join the gastrocnemius tendon (Figure 1.43).

Medial Aspect

Throughout most of its length, the medial surface of the tibia is subcutaneous (Figure 1.35). Sensation is provided to the medial and cranial aspects of the crus by branches of the saphenous nerve. The distal continuation of the nerve follows the prominent cranial branch of the medial saphenous vein that angles across the medial surface of the tibia. Accompanied by the saphenous artery, the smaller caudal branch of the medial saphenous vein crosses medial to the medial head of the deep digital flexor muscle and joins the cranial branch of the vein superficial to the tibial attachment of the semitendinosus muscle.

Deep to the crural fascia and caudal to the caudal branch of the medial saphenous vein, the tibial nerve descends along with branches of the caudal femoral vessels. The tibial nerve bifurcates into the medial and lateral plantar nerves about 8–10 cm proximal to the point of the calcaneal tuber. These nerves continue distad to the tarsus where they diverge to pursue their independent courses.

The caudal tibial vessels lie deep to the tendon of the medial head of the deep digital flexor as it passes distad. The anastomosis between the caudal tibial and saphenous vessels is located medial to the main tendon of the deep digital flexor (Figure 1.37).

Caudal Aspect

Descending from their origins on the supracondylar tuberosities of the femur, the two heads of the gastrocnemius surround the round, mostly tendinous superficial digital flexor. The latter wraps medially from deep to superficial around the gastrocnemius tendon in the distal third of the crus.

The deep digital flexor muscle possesses three heads with a bewildering variety of names that appear in anatomical texts (Figure 1.45). In the distal third of the crus, the flat tendon of the caudal tibial (the superficial head) joins the larger tendon of the lateral head, whereas the tendon of the medial head (medial digital flexor, long digital flexor) passes over the medial aspect of the hock to join the principal tendon in the proximal metatarsus.

Stifle (Genu)

The stifle is the region that includes the stifle joint (femorotibial joints and femoropatellar joint) and surrounding structures.

Cranial Aspect

Cutaneous innervation of the cranial aspect of the stifle is provided by terminal branches of the lateral cutaneous femoral nerve and lateral branch of the iliohypogastric nerve.

Three patellar ligaments descend from the patella, converging to their attachments on the tibial tuberosity. Between the ligaments and the joint capsule of the femoropatellar joint is an extensive fat pad that wraps around the sides of the ligaments (Figure 1.42). The space between the medial and middle patellar ligaments is greater than the space between the middle and lateral ligaments, reflecting the more widely spaced origin of the medial patellar ligament as it arises from the parapatellar fibrocartilage. The fibrocartilage extends mediad from the patella, giving attachment to the medial patellar ligament. This arcs and descends medial to the medial ridge of the femoral trochlea, attaching distally on the medial side of the tibial tuberosity.

Two bursae lie under the middle patellar ligament. The proximal infrapatellar bursa lies between the proximal part of the ligament and the pointed distal end (apex) of the patella. The distal infrapatellar bursa lies between the ligament and the groove of the tibial tuberosity. Inclining mediad from the lateral aspect of the patella, the lateral patellar ligament serves as an attachment for the biceps femoris muscle and for the fascia lata just before the ligament attaches to the lateral aspect of the tibial tuberosity. The tendon from the biceps femoris continues on to the cranial surface of the patella.

The base, cranial surface, and medial border of the patella, and the parapatellar fibrocartilage and femoropatellar joint capsule all serve as attachments for the insertions of the quadriceps femoris muscle.

Lateral Aspect

The insertional parts of the biceps femoris and the semitendinosus muscles dominate the lateral aspect of the stifle region. The tendon from the cranial part of the biceps femoris inserts on the lateral patellar ligament and the patella; the tendon from the middle division of the muscle sweeps craniodistad to insert on the cranial border of the tibia.

Cutaneous innervation is supplied to this region by branches from several nerves: lateral branches of the iliohypogastric and ilioinguinal nerves, the lateral cutaneous sural nerve originating from the common fibular nerve and passing out between the middle and caudal divisions of the biceps femoris, the caudal cutaneous sural nerve (from the tibial nerve), and terminal branches of the caudal cutaneous femoral nerve (from the caudal gluteal nerve).

Deep to the distal part of the biceps femoris muscle, the lateral femoropatellar ligament extends obliquely from the lateral epicondyle of the femur to the lateral border of the patella (Figure 1.44). The lateral head of the gastrocnemius muscle is crossed by the common fibular nerve and, further caudal, by the caudal cutaneous sural nerve and the lateral saphenous vein (Figure 1.43). As it extends from the lateral epicondyle of the femur to the head of the fibula, the thick lateral collateral ligament passes superficial to the tendon of origin of the popliteus muscle that originates from the lateral epicondyle cranial to the collateral ligament. A pouch from the lateral femorotibial joint capsule lies deep to the tendon. The common tendon of the long digital extensor and fibularis tertius takes origin from the extensor fossa in the craniodistal surface of the lateral epicondyle of the femur. The tendon is cushioned as it extends distad by an elongated pouch from the lateral femorotibial joint capsule.

VetBooks.ir

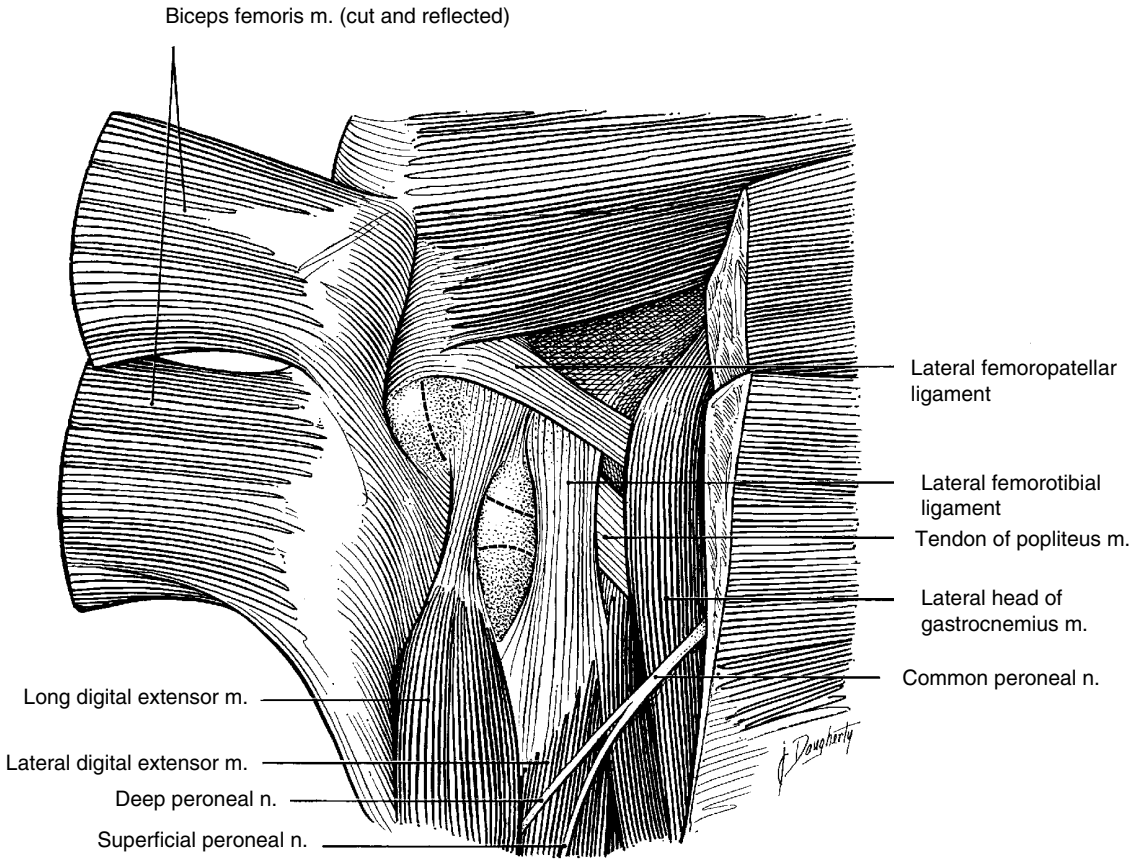

Figure 1.44. Deep dissection of lateral aspect of left stifle with femoral and tibial condylar surfaces indicated by dashed lines. Please note that the term "fibularis" has superseded "peroneus" (fibular rather than peroneal), although both are widely used.

Caudal Aspect

The caudal femoral nerve supplies the skin of the caudal aspect of the stifle. The caudal part of the biceps femoris muscle covers the lateral head of the gastrocnemius; a division of the biceps femoris inserts on the cranial border of the tibia, while another continues distad to attach to crural fascia and the calcaneal tuber. The semitendinosus muscle sweeps to its insertion on the cranial border of the tibia and distad toward its tarsal insertion, covering the medial head of the gastrocnemius. The tendons of the two heads of the gastrocnemius combine, and in the proximal part of the crus, the tendon is superficial to the tendon of the superficial digital flexor muscle. Separation of the two heads of the gastrocnemius muscle reveals the tendinous superficial digital flexor muscle that arises in the supracondylar fossa of the femur between the two heads, its initial part embedded in the lateral head (Figure 1.45).

After giving rise to the caudal cutaneous sural nerve, the tibial nerve descends between the two heads of the gastrocnemius along the medial side of the superficial digital flexor. The tibial nerve supplies the gastrocnemius, soleus, superficial digital flexor, deep digital flexor, and popliteus muscles. The femoral artery gives off the distal caudal femoral vessels and continues as the popliteal artery, descending between the two heads of the gastrocnemius (Figure 1.46). Distal to the stifle joint, the popliteal vessels divide into cranial and caudal tibial vessels. The larger cranial artery, the main blood supply to the pes, deviates laterad into the interosseous space between the tibia and fibula; the smaller caudal tibial artery continues distad between the tibia and the popliteus muscle. Satellite veins of the same name accompany these vessels.

The triangular popliteus muscle extends mediodistad from its origin on the lateral epicondyle of the femur (Figure 1.44). The tendon of origin passes deep to the lateral collateral ligament of the stifle joint, partly enveloped in its course by an extension of the femorotibial joint capsule. The popliteus broadens and inserts on the medial part of the caudal tibia, lying alongside the medial head of the deep digital flexor (Figure 1.45).

Medial Aspect

Skin and fascia on the medial aspect of the stifle are supplied by the saphenous and lateral cutaneous femoral nerves. The region is traversed by the medial saphenous vein and the saphenous artery and nerve. Cranially, the vastus medialis of the quadriceps femoris muscle attaches to the parapatellar fibrocartilage, medial border of the patella, and medial patellar ligament. The strap-like sartorius muscle attaches to the medial patellar ligament and the tibial tuberosity. Caudal to the sartorius, the gracilis muscle also attaches to the medial patellar ligament and to the medial collateral ligament

VetBooks.ir

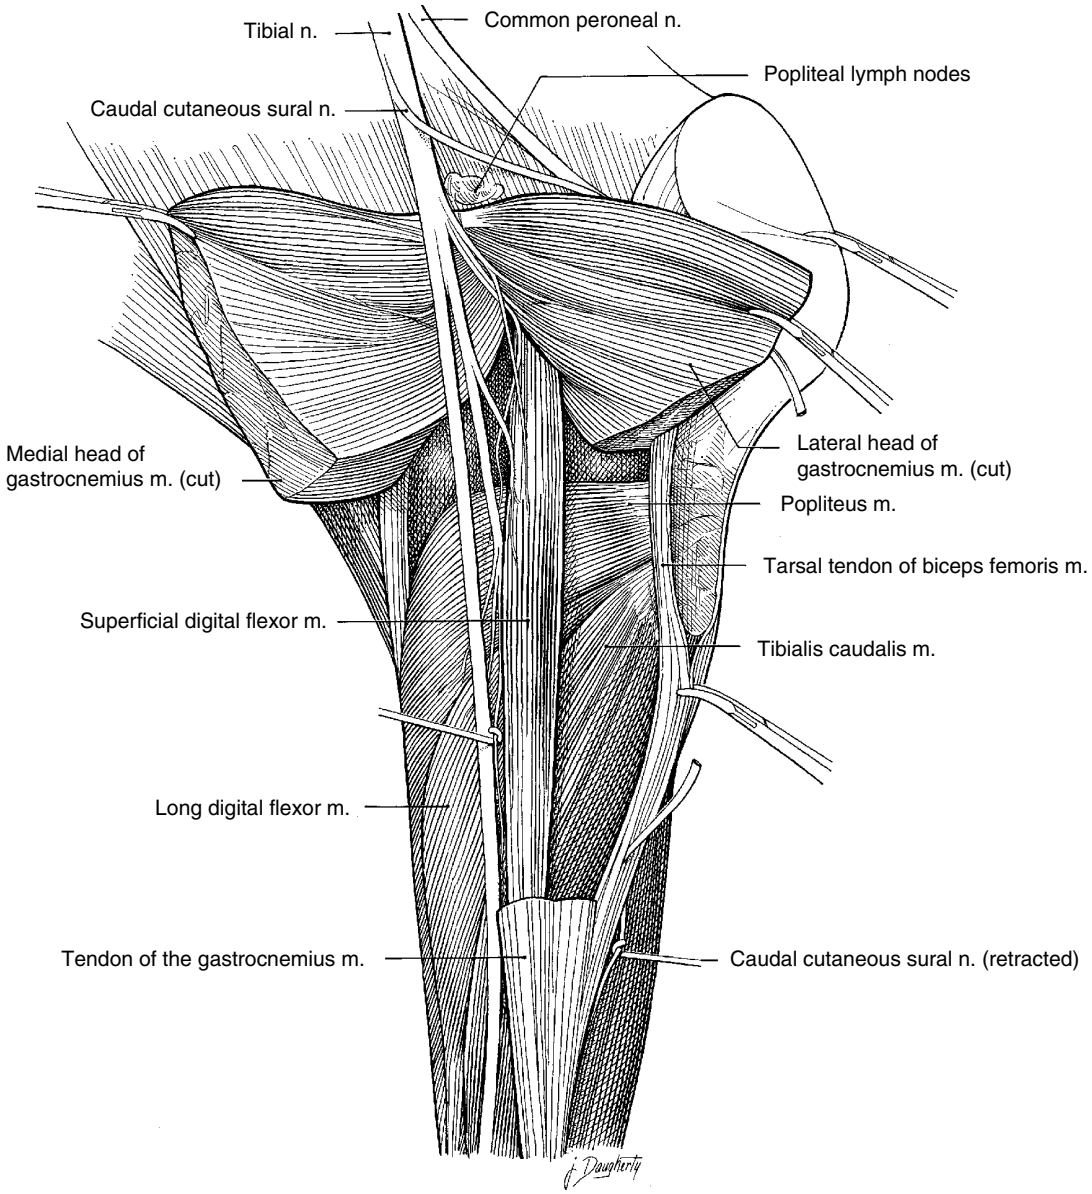

Figure 1.45. Dissection of caudal aspect of right stifle and crus. Please note that the term "fibularis" has superseded "peroneus" (fibular rather than peroneal), although both are widely used.

of the femorotibial joint and the crural fascia (Figure 1.47).

The medial collateral ligament of the femorotibial joint extends from the medial epicondyle of the femur to just distal to the margin of the medial tibial condyle (Figure 1.47). In its course, it detaches fibers to the medial meniscus. The adductor muscle inserts on the ligament and the medial epicondyle. The medial femoropatellar ligament is thinner than its lateral counterpart. It extends from proximal to the medial epicondyle of the femur to the parapatellar fibrocartilage, blending with the femoropatellar joint capsule in its course.

Stifle Joint

The stifle is the "true knee." It comprises two joints, the femoropatellar and femorotibial joints, which together form a hinge joint. The synovial space of the stifle is partitioned into three distinct sacs: the femoropatellar sac and right and left femorotibial joint sacs.[34]

Femoropatellar Joint

The patella is a sesamoid bone between the termination of the quadriceps femoris muscle and the three patellar ligaments constituting the tendon of insertion. The articular surface of the patella is much smaller than the trochlear surface of the femur; the larger gliding surface of the trochlea accommodates the proximal–distal movements of the patella. Contact between the patella and trochlea changes as the patella moves on its gliding surface. During full extension and "locking" of the stifle, the patella is rolled onto to its narrow distal articular surface (resting surface). The narrow craniodorsal surface of the proximal part of the trochlea offers a complimentary resting surface for the patella in this position.[37]

VetBooks.ir

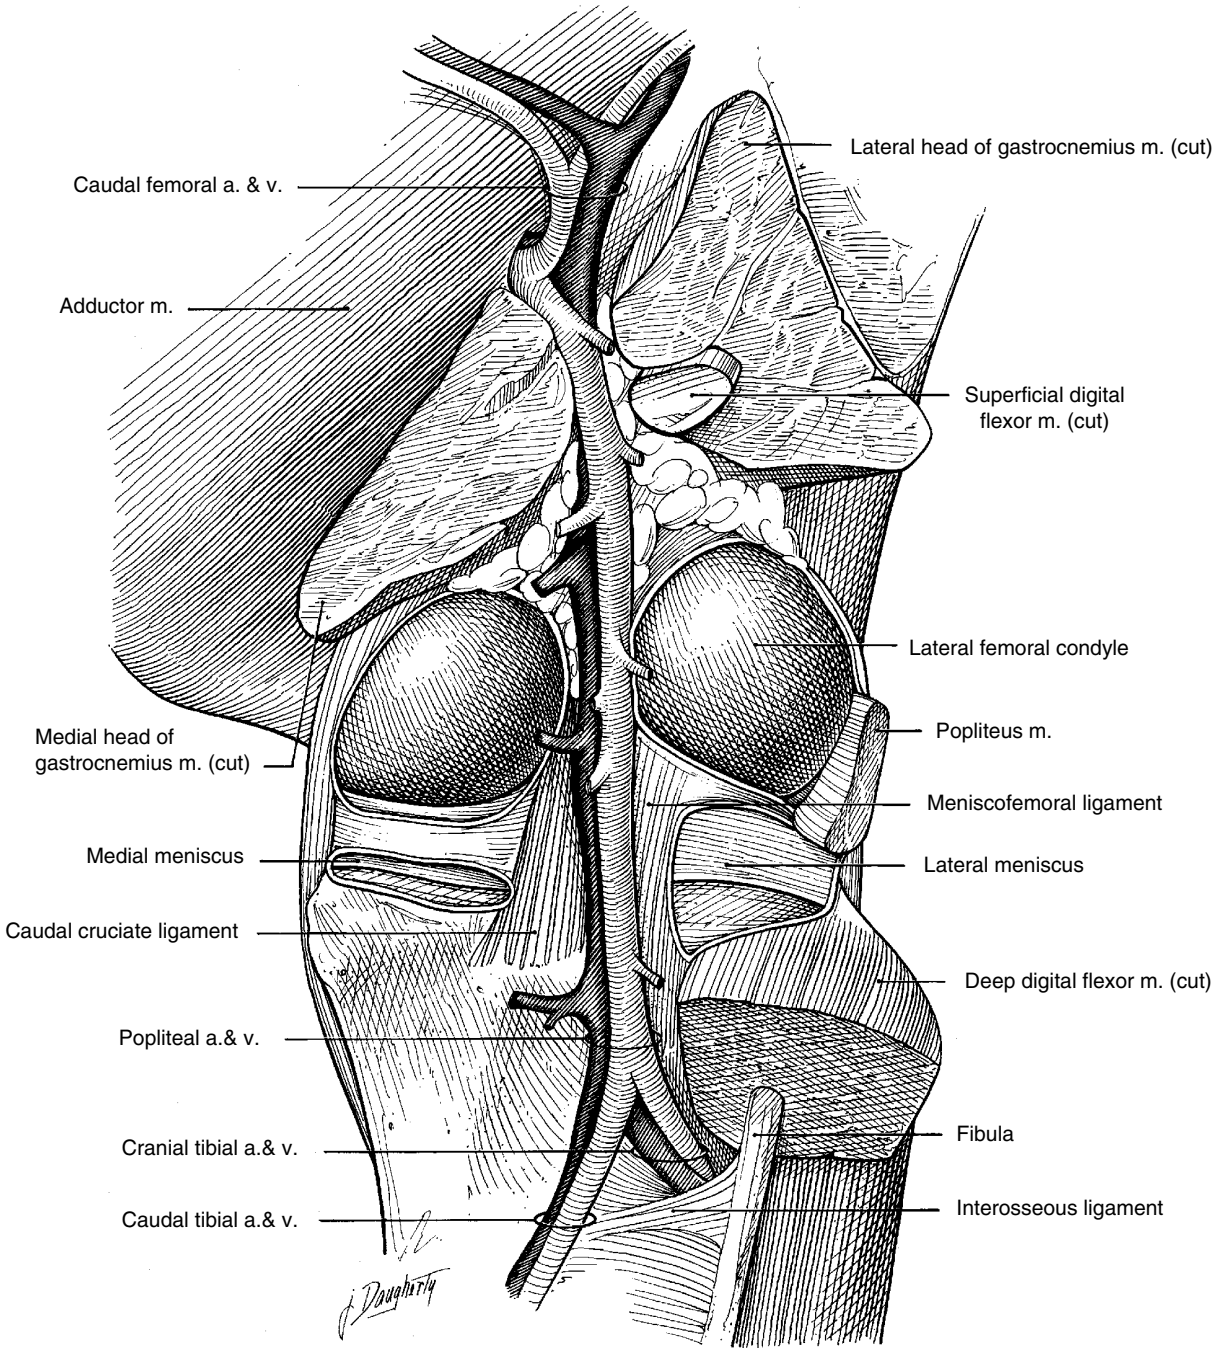

Figure 1.46. Deep dissection of caudal aspect of right stifle. The joint capsule of the femorotibial joint has been opened.

A voluminous joint capsule attaches to the edges of the femoral trochlea, and its patellar attachment lies close to the edge of the patellar articular surface. A large pouch from the joint capsule protrudes proximad under a fat pad and the distal part of the quadriceps femoris muscle. The vastus intermedius of the quadriceps femoris attaches, in part, to the femoropatellar joint capsule, acting to tense the capsule during extension of the femoropatellar joint.

Femorotibial Joint

The fibrous part of the joint capsule is thick caudally, thin cranially. The cruciate ligaments of the femorotibial joint lie between the joint capsule's medial and lateral synovial sacs. These two sacs rarely communicate with one another, although the medial sac communicates with the femoropatellar joint sac in a majority (65%) of horses.[34] Two fibrocartilaginous menisci intervene between the femoral and tibial articular surfaces. An extension of the lateral synovial sac encloses the tendon of origin of the popliteus muscle, and another protrudes distad under the common tendon of origin of the long digital extensor and fibularis tertius muscles.

The two fibrocartilaginous menisci are crescent shaped, thicker peripherally and thinner along the concave edge. Their proximal surfaces are concave to accommodate the convex femoral condyles. Distally they conform to the articular surfaces of the tibial condyles.

VetBooks.ir

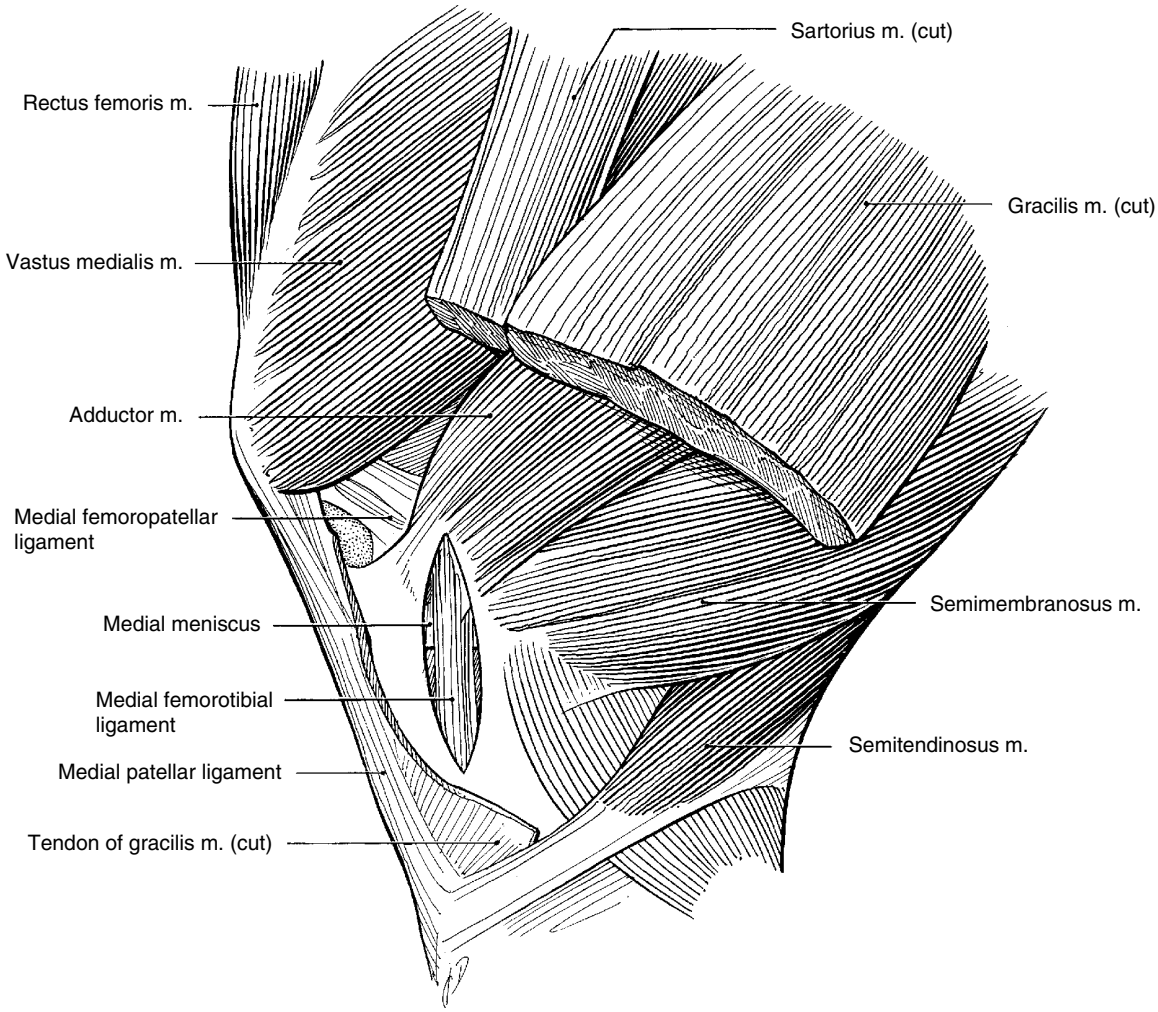

Figure 1.47. Deep dissection of medial aspect of left stifle. Tendon of adductor muscle is incised to reveal medial collateral ligament of the stifle.

Cranial and caudal ligaments anchor each meniscus to the tibia, and a meniscofemoral ligament attaches the caudal aspect of the lateral meniscus to the caudal surface of the intercondyloid fossa of the femur.

In addition to the support rendered by medial and lateral collateral ligaments, the femur and tibia are joined by the two cruciate ligaments that cross one another in the intercondyloid space between the two synovial sacs of the femorotibial joint. The caudal cruciate ligament, the more substantial of the two, extends from the cranial part of the intercondyloid fossa of the femur to the popliteal notch of the tibia, crossing the medial aspect of the cranial cruciate ligament. From its attachment on the caudolateral side of the intercondyloid fossa, the cranial cruciate ligament attaches to a central fossa between the articular surfaces of the condyles.

The stifle is supplied principally by the descending genicular artery that originates from the femoral artery and descends toward the medial aspect of the stifle joint deep to the sartorius and vastus medialis muscles.

Movements of the Stifle Joint

In the standing position, the caudal angle of the stifle joint is around 150°.[16] Extension of the stifle joint through action of the quadriceps femoris, tensor fasciae lata, and cranial division of the biceps femoris muscles is limited by tension from the collateral and cruciate ligaments. Flexion of the joint by the semitendinosus, middle division of the biceps femoris, popliteus, and gastrocnemius muscles is limited only by the caudal muscle masses. During flexion the crus is rotated slightly mediad, and the femoral condyles and menisci move slightly caudad on the tibial condyles.

When a horse shifts its weight to rest on one hindlimb, the supporting limb flexes slightly as the contralateral relaxed limb is brought to rest on the toe. The pelvis is tilted so that the hip of the supporting limb is higher. The stifle on the supporting limb is locked in position as the medial patellar ligament and parapatellar cartilage are pulled proximad and mediad to engage the medial ridge of the femoral trochlea. The locked position achieved by this configuration together with the support rendered by the other components of the stay apparatus minimizes muscular activity in the supporting limb while the relaxed contralateral hindlimb is resting. A very small amount of muscle tone in the vastus medialis is necessary to stabilize the stifle in the locked position.[38]

VetBooks.ir

Thigh and Hip

Lateral Aspect

Cutaneous innervation is supplied to the lateral aspect of the thigh and hip by the lateral branches of the iliohypogastric and ilioinguinal nerves, the caudal cutaneous femoral nerve, and the dorsal branches of the lumbar and sacral nerves.[17]

From caudal to cranial the superficial muscles of the lateral thigh and hip are the semitendinosus, biceps femoris, gluteus superficialis, gluteus medius, and tensor fasciae lata. Both the semitendinosus and biceps femoris have ischiatic (pelvic) and vertebral origins. The semitendinosus attaches to the first and second caudal vertebrae and fascia of the tail, and the biceps femoris attaches to the dorsal sacroiliac ligament and the gluteal and tail fasciae. A prominent longitudinal groove marks the site of the intermuscular septum between the semitendinosus and the biceps femoris muscles.

The strong gluteal fascia gives origin to the long caudal head and the cranial head of the superficial gluteal (gluteus superficialis) muscle. The two heads of the superficial gluteal muscle come together in a flat tendon that attaches to the trochanter tertius of the femur.

The large middle gluteal (gluteus medius) muscle forms most of the mass of the rump. The middle gluteal muscle is massive, giving the rump its rounded shape. It takes origin from the aponeurosis of the longissimus lumborum muscle, the gluteal surface of the ilium, the tuber coxae and tuber sacrale, the sacrotuberal and dorsal sacroiliac ligaments, and the gluteal fascia. Distally the muscle attaches to greater trochanter and the intertrochanteric crest. A smaller deep part of the middle gluteal, the gluteus accessorius, arises entirely from the ilium. Its tendon passes over greater trochanter on its way to attach on the crest distal to the trochanter. The large trochanteric bursa lies between the tendon and the cartilage covering the convexity (Figure 1.48).

The small deep gluteal (gluteus profundus) muscle is deep to the caudal part of the gluteus medius, arising from the ischiatic spine and body of the ilium and attaching on the medial edge of the convexity of the greater trochanter (Figure 1.50). This muscle covers the hip joint and parts of the articularis coxae, a small fusiform muscle that occasionally has two heads. A bursa is commonly present under the tendon of insertion of the deep gluteal.[30]

The tensor fasciae latae muscle arises from the tuber coxae and fans out distally to insert into the fascia lata. An intermuscular septum attaches the caudal part of the muscle to the cranial head of the superficial gluteal. The fascia lata attaches to the patella and the lateral and middle patellar ligaments (Figures 1.48 and 1.49).

On the caudal side of the proximal part of the femur lie three short muscles that arise from their origins on the ischium, pubis, ilium, and wing of the sacrum to insert in the trochanteric fossa. These are the gemelli, external obturator, and internal obturator muscles, which are rotators of the hip joint. The nearby quadratus femoris muscle extends from the ventral aspect of the ischium to a line on the femur near the distal part of the lesser trochanter where it produces hip extension.

A broad sheet of dense white fibrous connective tissue, the sacrotuberous (sacrotuberal) ligament (a.k.a. broad pelvic ligament), forms most of the lateral wall of the pelvic canal, attaching dorsally to the sacrum and first two caudal vertebrae and ventrally to the ischiatic spine and ischiatic tuber (Figure 1.50). The ventral edge of the sacrotuberous ligament creates two openings along the dorsal edge of the ischium: the lesser and greater ischiatic foramina that allow passage of neurovascular bundles to the soft tissues of the rump.

Branches of the cranial gluteal vessels and nerve pass through the greater ischiatic foremen to supply the gluteal muscles, tensor fasciae latae, and articularis coxae. The caudal gluteal vessels and nerve perforate the sacrotuberal ligament dorsal to the sciatic nerve. The caudal gluteal nerve divides into two trunks. The dorsal trunk supplies the biceps femoris, middle gluteal, and long head of the superficial gluteal; after supplying a branch to the semitendinosus, the ventral trunk continues as the caudal cutaneous femoral nerve. The latter passes outward between the biceps femoris and semitendinosus to branch subcutaneously over the lateral and caudal surfaces of the thigh and hip. Muscles in this region are supplied by the caudal gluteal vessels.

In this region the internal pudendal artery courses on the deep face of the sacrotuberous ligament. It will terminate in branches that supply the urogenital organs and the perineal region. Iliolumbar vessels (from the cranial gluteal vessels) course laterad between the iliacus muscle and the ilium, supplying branches to the iliopsoas and longissimus lumborum. The vessels then go around the lateral border of the ilium and supply branches to the middle gluteal and tensor fasciae latae.

The large, flat sciatic nerve passes through the greater ischiatic foramen and courses ventrocaudad on the sacrotuberale ligament (Figure 1.50). Turning distad, the nerve passes over the gemelli, the tendon of the internal obturator, and the quadratus femoris, supplying branches to these muscles. A large branch is detached that supplies the semimembranosus, the biceps femoris and semitendinosus, and adductor medially and the biceps femoris laterally. The sciatic nerve terminates by dividing into common fibular and tibial nerves.

Medial Aspect

The medial aspect of the thigh receives cutaneous innervation from a mosaic of sensory nerves, including lateral cutaneous femoral nerve (craniomedial thigh); medial branches of the iliohypogastric, ilioinguinal, and genitofemoral nerves (medial thigh); and branches from the caudal cutaneous femoral nerve (caudomedial thigh).[17]

Accompanied by the small saphenous artery and the saphenous nerve, the large medial saphenous vein pursues a subcutaneous course proximad on the cranial part of the gracilis muscle and then between the gracilis and sartorius muscles to join the femoral vein. The broad gracilis muscle covers most of the medial aspect of the thigh, attaching proximally to the prepubic tendon, adjacent surface of the pubis, accessory femoral ligament, and middle of the pelvic symphysis. The narrow sartorius muscle takes origin from the tendon of the psoas minor and ilial fascia and descends toward its insertion in the stifle that blends with the aponeurosis of the gracilis.

The pectineus muscle lies deep to the gracilis. It originates on the cranial border of the pubis, the prepubic tendon, and accessory femoral ligament and inserts on

VetBooks.ir

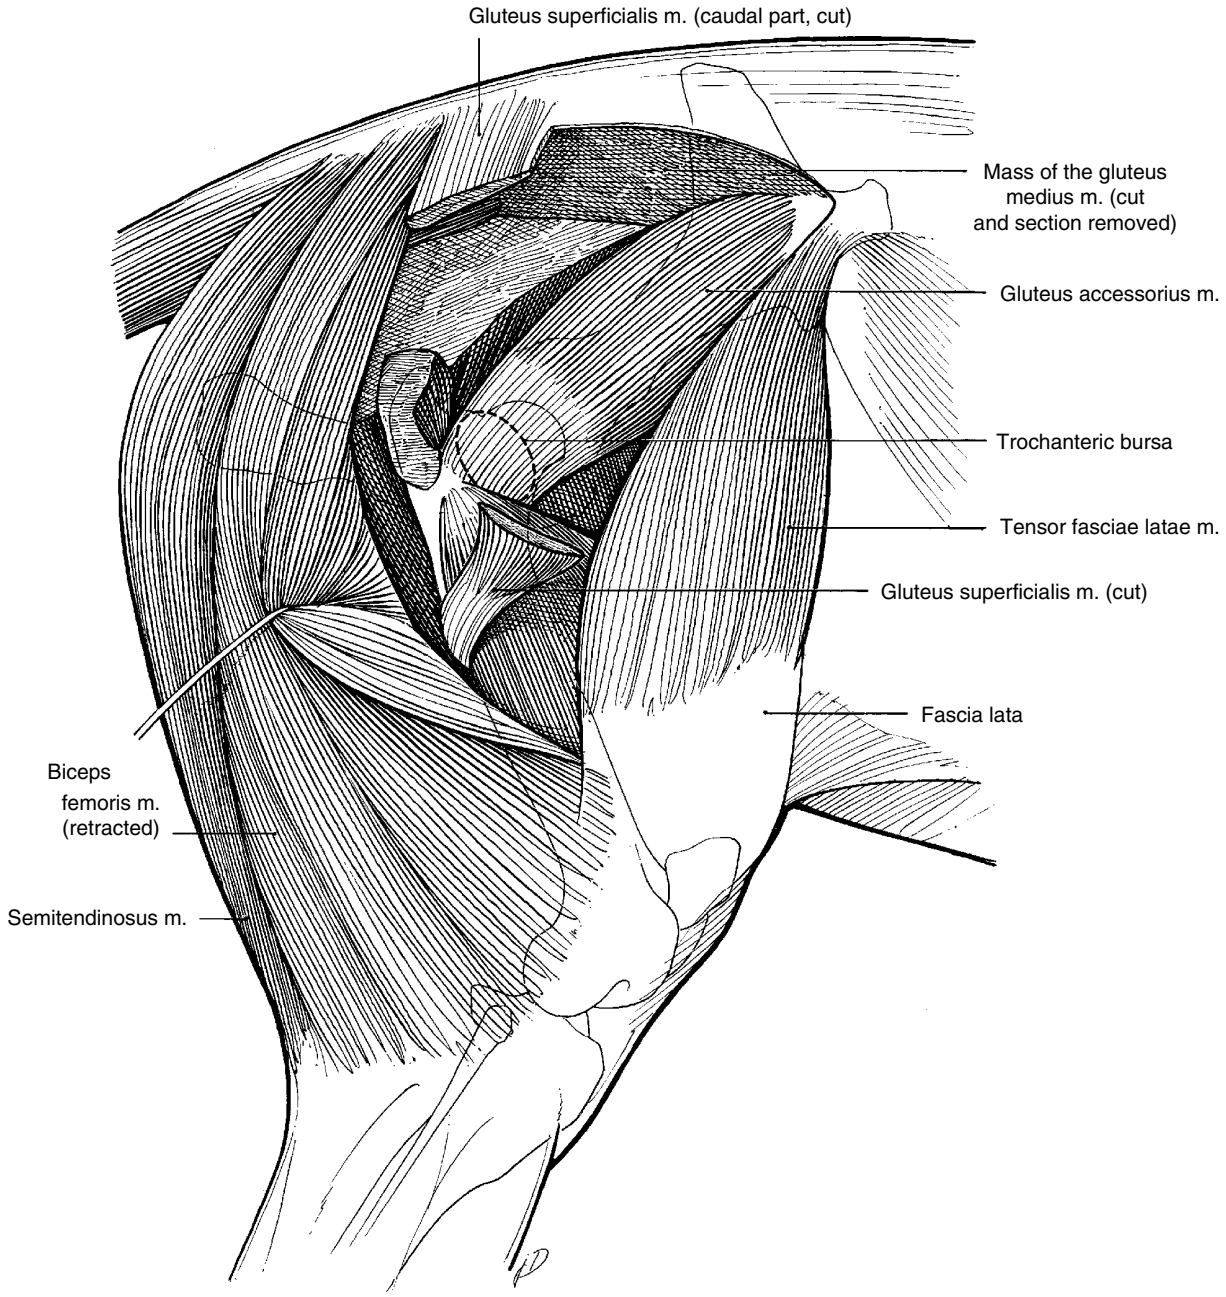

Figure 1.48. Lateral dissection of right thigh and hip. Most of the superficial and middle gluteal muscles have been removed.

the medial femur. The femoral canal, containing the neurovascular bundle supplying the pelvic limb, is bordered caudally by the pectineus, cranially by the sartorius, laterally by the vastus medialis and iliopsoas, and medially by the femoral fascia and cranial edge of the gracilis. The canal contains the femoral artery and vein, the saphenous nerve, and an elongated group of lymph nodes of the deep inguinal lymphocenter. Within the canal the saphenous nerve detaches a motor branch to the sartorius muscle (Figure 1.51).

Caudal to the pectineus and vastus medialis, the thick adductor muscle extends from the ventral surface of the ischium and pubis to the caudal surface of the femur, the medial femoral epicondyle, and the medial collateral ligament of the femorotibial joint. The obturator nerve passes through the cranial part of the obturator foramen and external obturator muscle and branches to supply the external obturator, adductor, pectineus, and gracilis muscles (Figure 1.51). Branches from the obturator artery (from the cranial gluteal artery) supply the muscles in this region.

Cranial Aspect

The quadriceps femoris, articularis coxae, and sartorius muscles lie in the cranial part of the thigh and hip. In addition, the iliacus muscle crosses the cranial aspect of the hip where the muscle is joined by the psoas major, creating the conjoined iliopsoas muscle. Their common tendon inserts on the lesser trochanter. The psoas major

VetBooks.ir

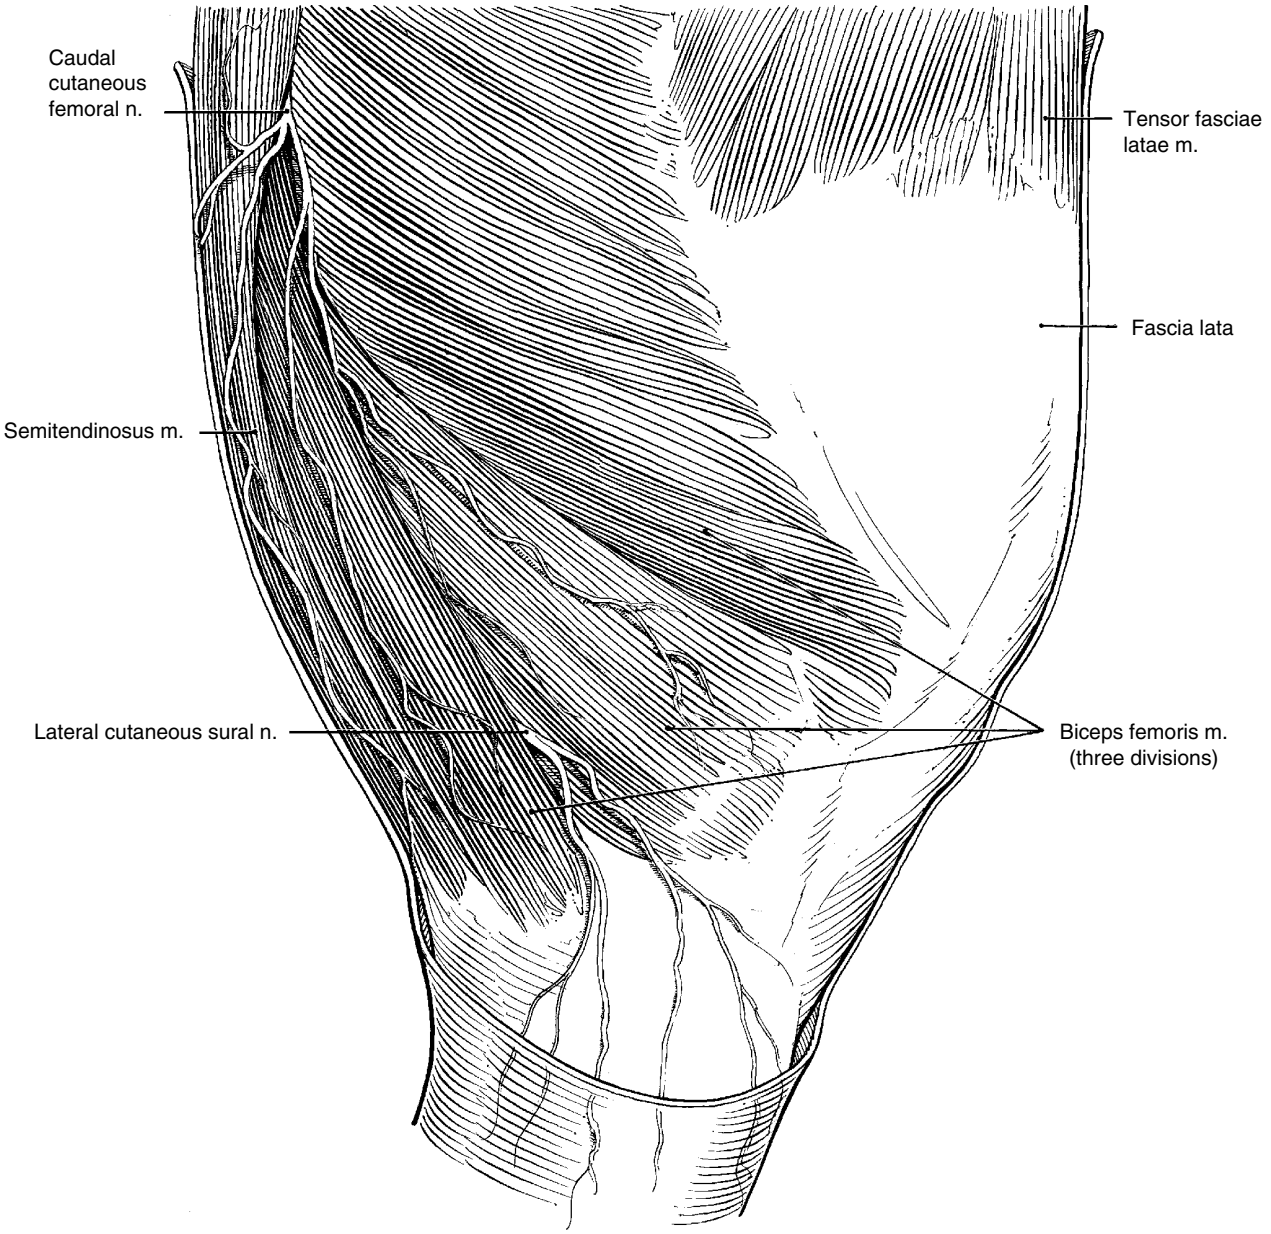

Figure 1.49. Lateral view of right stifle and thigh.

arises from the last two ribs and the lumbar transverse processes; the iliacus comes from the wing of the sacrum, ventral sacroiliac ligaments, ilium, and tendon of the psoas minor muscle.

Three heads of the quadriceps femoris muscles (vastus lateralis, vastus intermedius, and vastus medialis) take origin from the shaft of the femur. The fourth head, the rectus femoris, originates via a pair (medial and lateral) of tendons from the ilium craniodorsal to the acetabulum (Figure 1.50). A bursa is located under the lateral tendon.[30] All four heads of the quadriceps femoris attach to the patella. Bursae occur commonly under the insertions of the rectus femoris, vastus lateralis, and vastus medialis.

The femoral nerve passes distad between the iliopsoas and sartorius muscles. It supplies branches to the iliopsoas (which also receives segmental innervation from lumbar nerves) and to all heads of the quadriceps femoris. Near the insertion of iliopsoas, the femoral nerve gives rise to the saphenous nerve.

Caudal Aspect

Innervation to the caudal skin of the thigh and hip is provided principally by the caudal cutaneous femoral nerve (Figure 1.49). The main muscle mass is that of the semitendinosus and the semimembranosus with the caudal division of the biceps femoris related to these laterally and the gracilis medially. The long head of the semimembranosus attaches to the caudal border of the sacrotuberous ligament. The thicker short head attaches to the ventral part of the ischiatic tuber. The thick, roughly three-sided belly of the semimembranosus ends on a flat tendon that attaches to the medial femoral epicondyle.

VetBooks.ir

Blood Supply to the Thigh

The external iliac artery gives off the deep femoral artery just prior to passing through the femoral ring to continue as the femoral artery. The deep femoral courses between the sartorius and iliopsoas muscles and then between the latter and the pectineus. After supplying branches to the deep inguinal lymphocenter, the deep femoral artery gives off the large pudendoepigastric trunk. This divides into the caudal epigastric artery and the external pudendal artery. The deep femoral artery continues ventral to the pubis as the medial circumflex femoral artery. This supplies the iliopsoas, pectineus, external obturator muscles, adductor, and semimembranosus. Satellite veins accompany the arteries.

The femoral artery continues distad through the femoral canal accompanied on its caudal side by the femoral vein and cranially by the saphenous nerve. Within the canal the femoral artery gives off the lateral circumflex femoral artery that enters the quadriceps femoris, passing between the vastus medialis and rectus femoris.

The femoral artery directly supplies branches to muscles in this region. At the distal end of the femoral canal, the saphenous artery leaves the femoral artery and passes to the subcutaneous tissues between the gracilis and sartorius muscles. It courses caudodistad, related caudally to the much larger medial saphenous vein. The saphenous nerve accompanies the vessels as they course over the tendon of the gracilis. At the level of the proximal crus, the saphenous artery and medial saphenous vein each divide into cranial and caudal branches. In its course, the saphenous artery supplies the sartorius, gracilis, and adductor muscles as well as fascia and skin.

The next branch of the femoral artery is the nutrient artery of the femur, and then the large descending genicular

VetBooks.ir

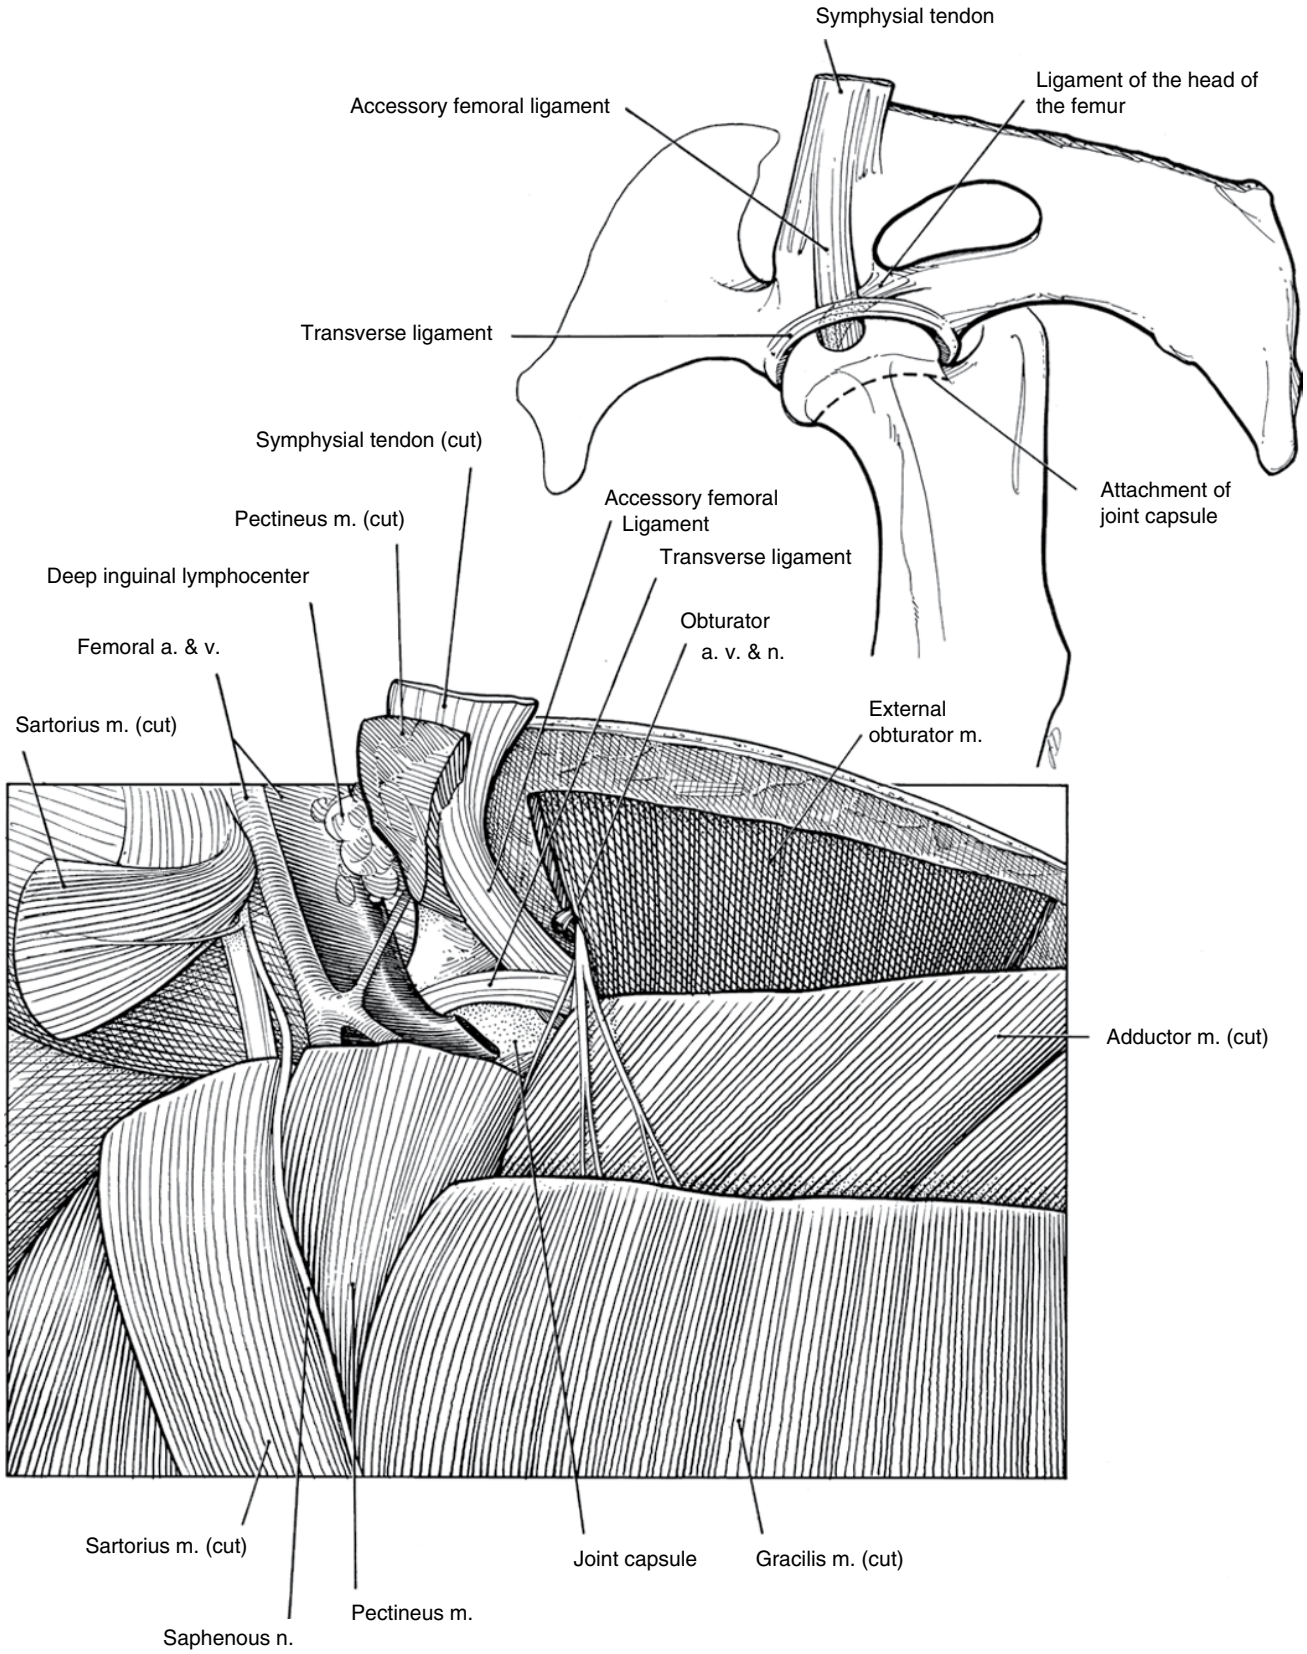

Figure 1.51. Deep dissection of right hip. Ventromedial view.

VetBooks.ir

artery is detached from the cranial wall of the femoral artery. In the distal third of the thigh, the descending genicular artery courses distocraniad between the sartorius and the adductor, supplying these muscles and terminating in branches to the stifle.

The femoral artery gives off its last branch, the (distal) caudal femoral artery, and continues between the medial and lateral heads of the gastrocnemius as the popliteal artery (Figure 1.46). The caudal femoral artery pursues a short course caudad, giving off muscular branches to the superficial digital flexor and gastrocnemius. Ascending branches from this substantial artery supply thigh and calf muscles. A descending branch of the caudal femoral artery runs distocaudad over the lateral head of the gastrocnemius along with the lateral saphenous vein. The many branches of the caudal femoral artery make anastomotic connections between the obturator artery proximally and the saphenous artery distally.

Hip (Coxofemoral) Joint

The acetabulum of the os coxae is formed where the ilium, ischium, and pubis meet. The lunate surface of the acetabulum, a cup-shaped cavity arcing around a deep nonarticular fossa, articulates with the head of the femur. A fibrocartilaginous rim, the acetabular labrum, increases the articular surface of the acetabulum. The transverse acetabular ligament bridges the labrum across the medially located acetabular notch, binding two ligaments as they emerge from the fovea capitis of the femoral head (Figure 1.51). The ligament of the head of the femur comes from the fovea and attaches in the pubic groove on the ventral aspect of the pubis. The thick accessory femoral ligament passes out through the acetabular notch to blend into the prepubic tendon. It provides partial origin to the gracilis and pectineus muscles.

The capacious joint capsule of the hip attaches to the acetabular labrum and on the neck of the femur a few millimeters from the margin of the femoral head (Figure 1.51). The synovial membrane within the joint wraps around the intracapsular ligaments. An outpocketing of the synovium passes out through the acetabular notch to lie between the accessory femoral ligament and the pubic groove. The fibrous joint capsule is intimately attached to the fascia of the external obturator and deep gluteal muscles. Fat covers the capsule dorsally. The articularis coxae muscle is related to the lateral aspect of the hip joint, detaching some fibers to the joint capsule. During flexion of the hip joint, the articularis coxae tense the joint capsule.

Movements of the Hip Joint

While the hip joint is a ball-and-socket joint, it is capable only of very limited movement beyond flexion and extension. Abduction of the thigh is restricted by the ligament of the head of the femur and the accessory femoral ligament. Adduction is checked by the attachments of the gluteal muscles on the femur. In the normal standing position, the caudolateral part of the head of the femur lies outside the acetabulum. The hip joint is slightly flexed in this position. The range of motion between extreme flexion and extension is only 60°.[16]

Flexor muscles of the hip joint are the gluteus superficialis, tensor fasciae latae, rectus femoris, iliopsoas, sartorius, and pectineus. Extensor muscles of the hip joint are the gluteus medius, biceps femoris, semitendinosus, semimembranosus, adductor, and quadratus femoris. Muscles adducting the thigh include the gracilis, sartorius, adductor, pectineus, quadratus femoris, and obturatorius externus. Slight abduction is exerted on the thigh by all three gluteal muscles. The thigh is rotated laterad by the iliopsoas, external and internal obturators, and the gemelli. Medial rotation is accomplished through the combined action of the adductor and gluteus profundus muscles.

Pelvis

The equine pelvis, like that of other animals, comprises ilium, ischium, and pubis; these bones are individually identifiable in the young but have fused by 10–12 months of age.[16] The acetabulum is formed through contributions from all three bones of the pelvis.

The wing-shaped ilium presents two prominences, visible landmarks on the horse. The dorsally directed tuber sacrale inclines mediad toward its fellow, so that the two sacral tubers come within 2–3 cm over the first sacral spinous process. The ilial wing sweeps ventrolaterad as the tuber coxae, creating the point of the hip. Caudally, the ischial tuberosity presents as a laterally directed ridge to which muscles of the thigh attach.

The pubis and ischium from each side meet ventrally at the pelvic symphysis. In the young animal fibrocartilage joins the bones. Later in life, a synostosis is formed as the cartilage ossifies in a cranial to caudal sequence.

Lymphatic Drainage

Two lymphocenters are involved in the lymphatic drainage of the pelvic limb. The popliteal lymphocenter consists of 3–12 small popliteal lymph nodes embedded about 5 cm deep between the biceps femoris and semitendinosus muscles adjacent to the tibial nerve (Figure 1.44). They may be absent in some horses. The popliteal lymph nodes receive afferent lymphatics from the distal pelvic limb. Efferents drain to the deep inguinal lymphocenter.

The deep inguinal lymphocenter is a mass of lymph nodes 8–12 cm long within the femoral canal. It consists of 16–35 individual lymph nodes. In addition to receiving lymphatic vessels from the popliteal lymphocenter, the lymph nodes of the deep inguinal lymphocenter (Figure 1.50) receive vessels from the caudal abdominal wall and superficial inguinal lymph nodes. Efferent vessels from the deep inguinal lymphocenter are afferent to the medial iliac lymph nodes, located retroperitoneally near the origin of the external iliac arteries.[16]

Stay Apparatus of the Pelvic Limb

The quadriceps femoris muscle and the tensor fasciae latae act to pull the patella, parapatellar cartilage, and medial patellar ligament proximad to the locked position over the medial trochlear ridge of the femur when the limb is positioned to bear weight at rest (Figure 1.52). Through the components of the reciprocal apparatus (cranially,

VetBooks.ir

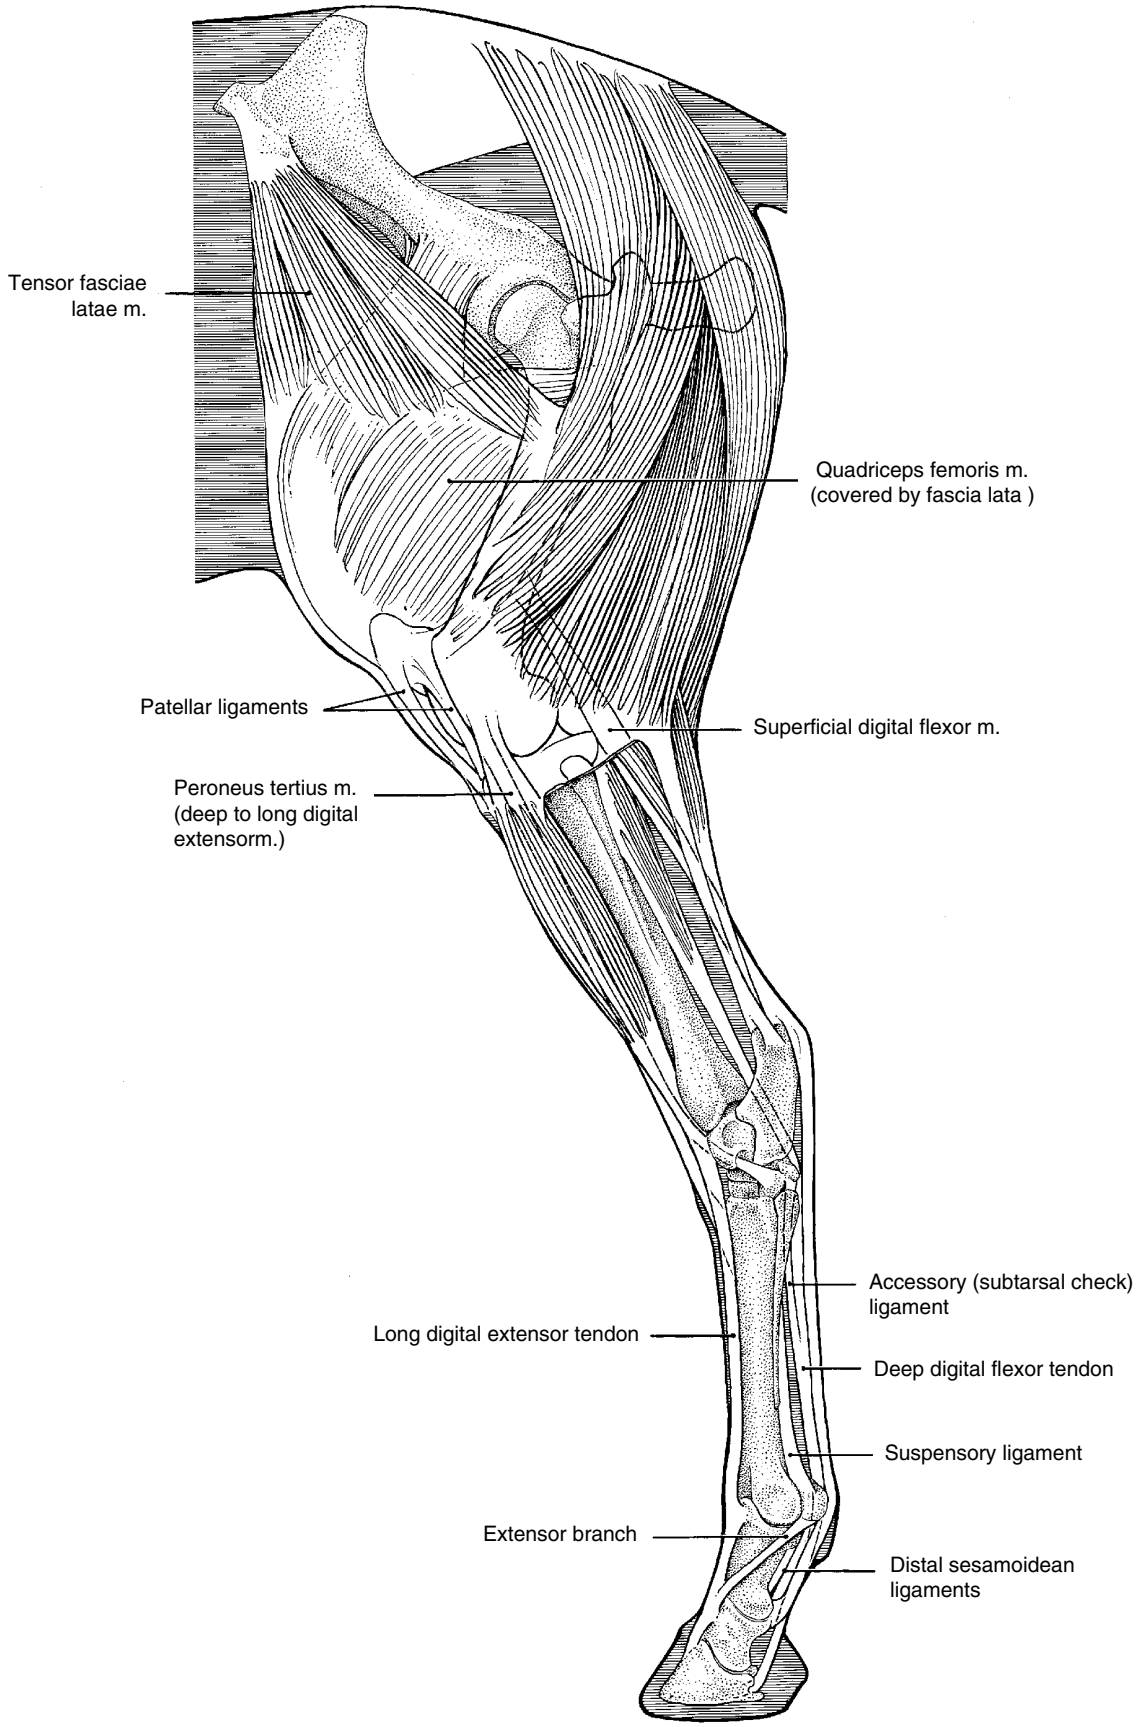

Figure 1.52. Stay apparatus of the pelvic limb.

VetBooks.ir

fibularis tertius and, caudally, superficial digital flexor), the tarsus is correspondingly locked in extension. Even during sleep, small amount of muscular tone in the quadriceps muscle assures stability of this locked configuration, preventing flexion of the stifle and tarsocrural joints.[39]

Distal to the hock the elements of the stay apparatus are analogous to those of the thoracic limb. The superficial digital flexor is connected proximally to the calcaneal tuber (effectively, its "check ligament"), and the deep digital flexor is anchored via its accessory (tarsal check) ligament to the thick plantar part of the tarsal fibrous joint capsule. Prevention of overextension of the fetlock and interphalangeal joints during the fixed, resting position is accomplished through the support rendered by the digital flexor tendons and the suspensory apparatus (suspensory ligament, proximal sesamoid bones, and their ligaments).

AXIAL COMPONENTS

Vertebral Column

The vertebral formula of the horse is 7 cervical, 18 thoracic, 6 lumbar, 5 sacral, and an inconsistent number of caudal vertebrae (ranging from 15 to 21). There is some individual variation in numbers of other vertebrae, most commonly in the number of lumbar vertebrae where five or seven are sometimes seen (there is an increased incidence of five lumbar vertebrae in Arabian horses[41]). The typical vertebra possesses a ventrally placed, roughly cylindrical body whose cranial and caudal ends articulate with adjacent vertebrae at the intervertebral disc (Figure 1.53). A bony vertebral arch attaches to the body and surrounds the spinal cord. The aperture created within a given vertebrae by the dorsal

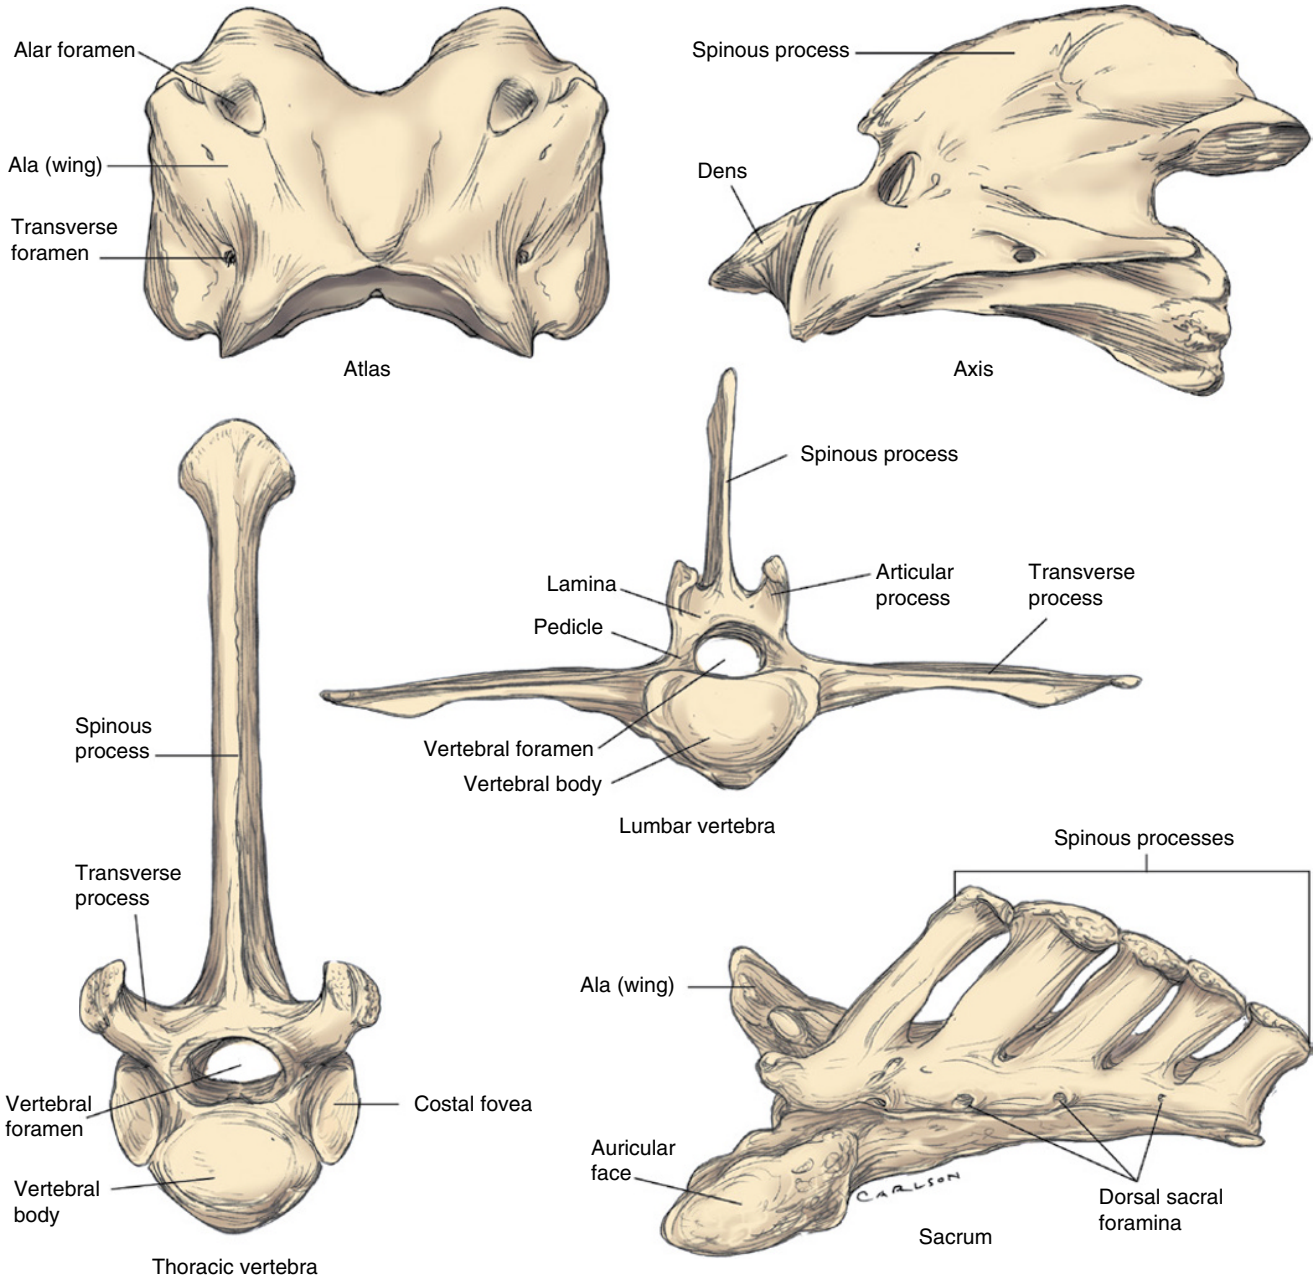

Figure 1.53. Vertebrae.

VetBooks.ir

aspect of the body and the medial and ventral parts of the arch is the vertebral foramen; where vertebral foramina of adjacent vertebrae are aligned to admit the spinal cord, the resulting passageway is called the vertebral canal. The vertebral canal is widest in the caudal cervical–cranial thoracic region, where it accommodates the cervical enlargement of the spinal cord. A second dilation of the canal occurs in the lumbar region where the lumbosacral enlargement of the cord resides.

The vertebral arch comprises the pedicles and laminae, which together create the "roof" over the spinal cord. The pedicles are the vertical attachments to the vertebral body. The dorsal part of the arch is created by the right and left laminae. The arch is characterized by vertebral notches, indentations on the cranial and caudal aspects of the pedicle. When individual vertebrae are articulated, the cranial vertebral notch of one vertebra abuts the caudal vertebral notch of another, creating an intervertebral foramen through which the spinal nerve emerges from the vertebral canal.

The vertebral arch features other bony processes that bear synovial joints between adjacent vertebrae and that serve as sites of attachment for epaxial muscles. Each vertebra has a single dorsal midline spinous process and two transverse processes that arise near the point at which the pedicle attaches to the body. The dorsal contour of the equine thorax and loin is largely determined by the relative size and prominence of the spinous processes of thoracic and lumbar vertebrae. Arising adjacent to the spinous process are a pair of cranial articular processes and a pair of caudal articular processes.

Cervical Vertebrae

The first two cervical vertebrae are highly modified to meet their specialized function in permitting movement of the head. The first vertebra is the atlas. It lacks the cylindrical body characteristic of other vertebrae, instead taking the form of a bony ring comprising dorsal and ventral arches. The spinous process is likewise absent. The transverse processes are modified into the wings of the atlas. These are robust, bent in a ventrolateral direction, and strongly concave ventrally. Their craniolateral edges form a prominent palpable ridge caudal to the ramus of the mandible. The dorsal aspect of the wing of the atlas bears three foramina: the transverse foramen, the alar foramen, and the lateral vertebral foramen. The cranial aspect of the atlas possesses two deeply concave cranial articular foveae, which form a synovial joint (the atlanto-occipital joint) with the occipital condyles. The caudal articular foveae are also concave and participate in the synovial atlantoaxial joint.

The second cervical vertebra is the axis. The body of the axis is long, and its cranial extremity is modified into a scoop-like projection called the dens, which features a rounded ventral articular surface that articulates with the floor of the atlas. The caudal extremity of the axis' body is deeply concave where it articulates with the body of the third cervical vertebra. The spinous process of the axis is tall and long, modified into a thick midline plate. The transverse processes are small and caudally directed.

The third through seventh vertebrae are similar to one another and follow the basic pattern of most vertebrae. They are progressively shorter from cranial to caudal. Cervical vertebrae three, four, and five bear a distinct ventral crest on their bodies. This crest is diminished in size on the sixth and absent from the seventh cervical vertebra. Articular processes on these cervical vertebrae are large, with prominent oval fovea for articulation between vertebral arches. The cranial articular processes present their foveae in the dorsomedial direction; caudal articular processes have complementary foveae directed in the ventrolateral direction. Transverse processes are broad, each with two thick tubercles for muscular attachment. Transverse processes of the sixth cervical vertebra are especially robust, while those of the seventh are somewhat diminished relative to the other cervical vertebrae. The dorsocaudal aspect of the seventh cervical body features a costal fovea that participates in the synovial articulation of the head of the first rib with the seventh cervical and first thoracic vertebrae. The spinous process of the seventh cervical vertebra is tall compared with other cervical vertebrae.

Thoracic Vertebrae

There are usually 18 thoracic vertebrae in the horse, although on occasion there may be one more or one less than typical. The bodies of the thoracic vertebrae tend to be short with a small vertebral arch dorsally. The spinous processes are relatively tall, with the first four or five increasing in height and more caudal spinous processes gradually decreasing in height until at the level of the 12th thoracic vertebra, after which they are the same height as those of the lumbar vertebrae. The tall spinous processes of those first 12 vertebrae constitute the withers. The dorsal apex of the spines is somewhat expanded and in young horses surmounted by cartilage. The cartilage is replaced by bone as the horse ages, with the cartilages associated with the prominence of the withers persisting the longest at 10 years or more. The anticlinal vertebra is defined as the one whose spinous process is perpendicular to the long axis of the vertebral column. The spinous processes of more cranial vertebrae incline caudad, while those of more caudal vertebrae incline craniad. In the horse, the anticlinal vertebra is usually the 16th and occasionally the 14th.

The vertebral bodies possess cranial and caudal costal foveae for articulation with the heads of ribs, excepting the last thoracic vertebra, which features only cranial costal foveae. Transverse processes are irregular, largest in the cranial thoracic vertebrae and gradually decreasing in size toward the lumbar region. Mammillary processes appear in the caudal thoracic region. These are directed craniad and arise primarily from the transverse processes. In the most caudal of the thoracic vertebrae, they arise in common from the transverse and cranial articular processes and may for this reason be called mamilloarticular processes.

Lumbar Vertebrae

There are usually six lumbar vertebrae, although five and seven have also been reported. The cylindrical bodies of the lumbar vertebrae are somewhat flattened dorsoventrally, especially the last three. Except for the seventh and sometimes the sixth lumbar vertebrae, a ventral crest is prominent. The spinous processes project

VetBooks.ir

slightly craniad. The vertebral arches tend to overlap dorsally, except at the L5–L6 and L6–S1 interspaces where the larger interarcuate spaces are much larger and clinically accessible. The cranial and caudal articular processes articulate in an approximation of the sagittal plane, an orientation that allows for a very slight degree of flexion and extension of the vertebral column but prevents lateral flexion. The transverse processes of the lumbar vertebrae are large and blade-like. They project laterad. The caudal aspect of the fifth transverse process articulates with the cranial aspect of the sixth. The caudal aspect of the sixth transverse process features a large concave facet through which it articulates with the sacrum.

Sacrum

The equine sacrum is a single bone formed through fusion of embryologically distinct sacral vertebrae, generally five of these, with four, six, and seven sacral vertebrae also being reported.[41] Fusion is usually complete by 5 years of age. The sacrum is triangular and gently curving so as to present a slightly concave ventral aspect. Intervertebral foramina are transformed by the fusion of adjacent vertebrae into a row of four dorsal sacral foramina and four ventral sacral foramina, through which pass dorsal and ventral branches, respectively, of the sacral spinal nerves. The spinous processes remain individually distinct and incline slightly caudad. The second through fifth spinous processes end in slight enlargements that are not uncommonly bifid.

The first sacral vertebra gives rise to the wings of the sacrum. Their articular surfaces face dorsolateral to articulate with the auricular surface of the ilium. The ventral aspect of the first sacral vertebra is slightly rounded, forming the promontory of the sacrum, the point from which the conjugate diameter (the dorsal–ventral distance) of the pelvic canal is measured.

Caudal Vertebrae

Although there is considerable individual variation, the average horse has 18 caudal vertebrae. Only the first three or so have vertebral arches, the remaining being represented by cylindrical bodies only. The first caudal vertebra is not uncommonly fused with the sacrum, especially in old horses.

Vertebral Articulations

Excluding the atlantoaxial joint (a pivot joint), the joints of the vertebral column all permit small amounts of flexion, extension, lateral flexion, and limited rotation. These movements are especially limited through thoracic and lumbar regions, but the cervical vertebral column is capable of more extensive movement. Intervertebral discs of fibrocartilage are interposed between adjacent vertebral bodies. Further stabilization is provided to the vertebral column by (1) the continuous dorsal and ventral longitudinal ligaments on their respective surfaces of the vertebral bodies; (2) a supraspinous ligament that passes along the dorsal aspect of the spinous processes of thoracic, lumbar, and sacral vertebrae; and (3) interspinal ligaments that pass between adjacent spinous processes. In the thoracic region, intercapital ligaments pass transversely between the heads of contralateral ribs over the dorsal aspects of the intervertebral discs. Articulations between articular processes on vertebral arches are true synovial joints. In the cervical region, these constitute broad plates, oriented in a nearly horizontal plane to permit significant lateral bending. Articular facets on the cranial articular processes face dorsomediad, while the complementary facets on the caudal articular processes face ventrolaterad. Synovial joints also exist between the transverse processes of the fifth and sixth lumbar vertebrae and between the transverse processes of the sixth lumbar vertebra and the wings of the sacrum.

Sacroiliac Region

The axial skeleton and appendicular skeleton of the hindlimb are united at the sacroiliac joint (Figure 1.54). This planar joint is created by the auricular face of the wings of the sacrum, which are oriented dorsolaterad, and the auricular face of the wings of the ilia, which angle ventromediad. This joint is histologically synovial but is capable of only extremely limited gliding movement. Its principle purpose is most likely absorption of some of the concussive forces transmitted through the appendicular skeleton to the vertebral column. The joint capsule is close-fitting and is substantially reinforced by

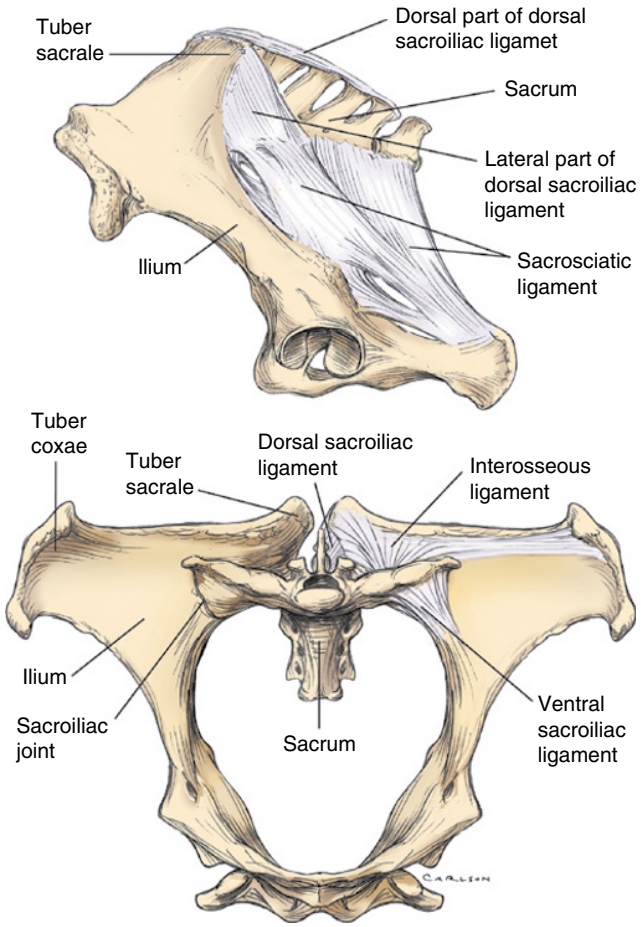

Figure 1.54. Sacroiliac joint. Lateral (top) and cranial (bottom) views.

VetBooks.ir

a series of sacroiliac ligaments that contribute markedly to the overall stability of the joint and probably act to transfer most of the weight of the trunk to the pelvic limbs. These ligaments can be summarized as the ventral sacroiliac ligament, dorsal sacroiliac ligament, and interosseous ligament.

The ventral sacroiliac ligament surrounds the joint and fills the space between the ilium and the ventral aspect of the wing of the sacrum. The dorsal sacroiliac ligament presents two distinct portions. One (dorsal or short part) arises from tuber sacrale and inserts on the spinous processes of the sacral vertebrae. The other (lateral or long part) arises from tuber sacrale and the caudal edge of the ilial wing and inserts along the lateral aspect of the sacrum. From here it blends ventrad into the broad sacrosciatic ligament that fills the space between the pelvis and sacrum. The interosseous ligament (interosseous sacroiliac l.) consists of strong, vertically oriented fibers between the ventral part of the wing of the ilium and the dorsal aspect of the wing of the sacrum.

Ligamentum Nuchae

The topline of the neck is in part determined by the presence of the ligamentum nuchae (nuchal ligament), which in horses extends from its cranial attachments on the external occipital protuberance to the spinous process of the third or fourth thoracic vertebra. Both parts of the nuchal ligament (funicular and laminar) are paired. The rope-like funicular part is connected to sheets that compose the laminar portions. These midline elastic sheets arise from the second through fifth cervical vertebrae and insert on the spines of the second and third thoracic vertebrae.[24] Bursae are consistently found between the funicular part of the nuchal ligament and the atlas and between the nuchal ligament and the second thoracic spine. These are the bursa subligamentosa nuchalis cranialis and the bursa subligamentosa supraspinalis, respectively. A third bursa (bursa subligamentosa nuchalis caudalis) is inconsistently found between the nuchal ligament and the spine of the axis.[13,16]

Muscles of the Trunk and Neck

Muscles of the torso (neck, trunk, and tail) may be roughly divided into those dorsal to the transverse processes (epaxial muscles) and those ventral to the transverse processes (hypaxial muscles). The dorsal branches of the spinal nerves innervate the epaxial muscles while hypaxial muscles receive their innervation from the ventral branches.

The epaxial muscles are extensors of the vertebral column and are themselves divided into three parallel bundles of fascicles: from lateral to medial these are the iliocostalis system, the longissimus system, and the transversospinalis system (Figure 1.55). The iliocostalis system (named for its attachments to the ilium and ribs) does not extend into the neck. The others continue into the cervical region and are associated with additional distinct muscles. Of these, the splenius muscle is most superficial (Figure 1.56). The splenius possesses capital and cervical parts. Both arise from the third, fourth, and fifth thoracic spines and from the funicular part of the nuchal ligament, and they insert on the nuchal crest of the skull, the wing of the atlas, and the transverse processes of the third, fourth, and fifth cervical vertebrae. The splenius extends the neck and elevates the head, and it is largely the rhythmic contraction of this powerful muscle that creates the thrusting movements of the neck during the gallop.[27]

Deep to the splenius are a number of shorter muscles extending from the cervical vertebrae to the skull; these "specific activators of the head" are important in giving the head and neck its considerable range of motion.

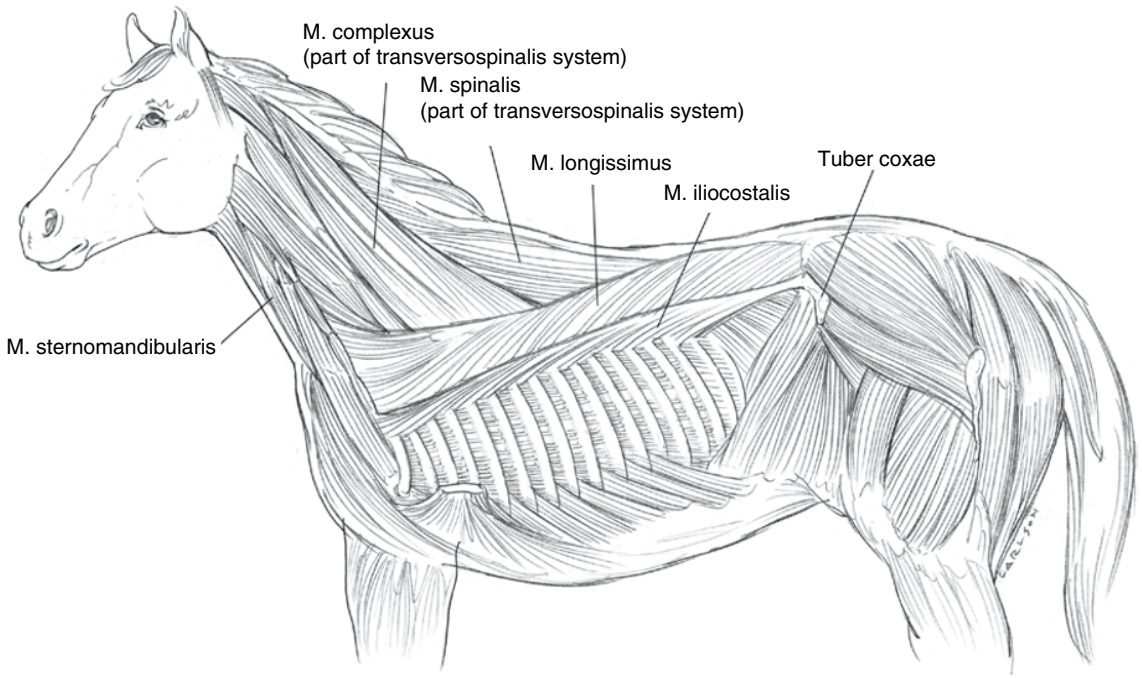

Figure 1.55. Deep muscles of trunk.

VetBooks.ir

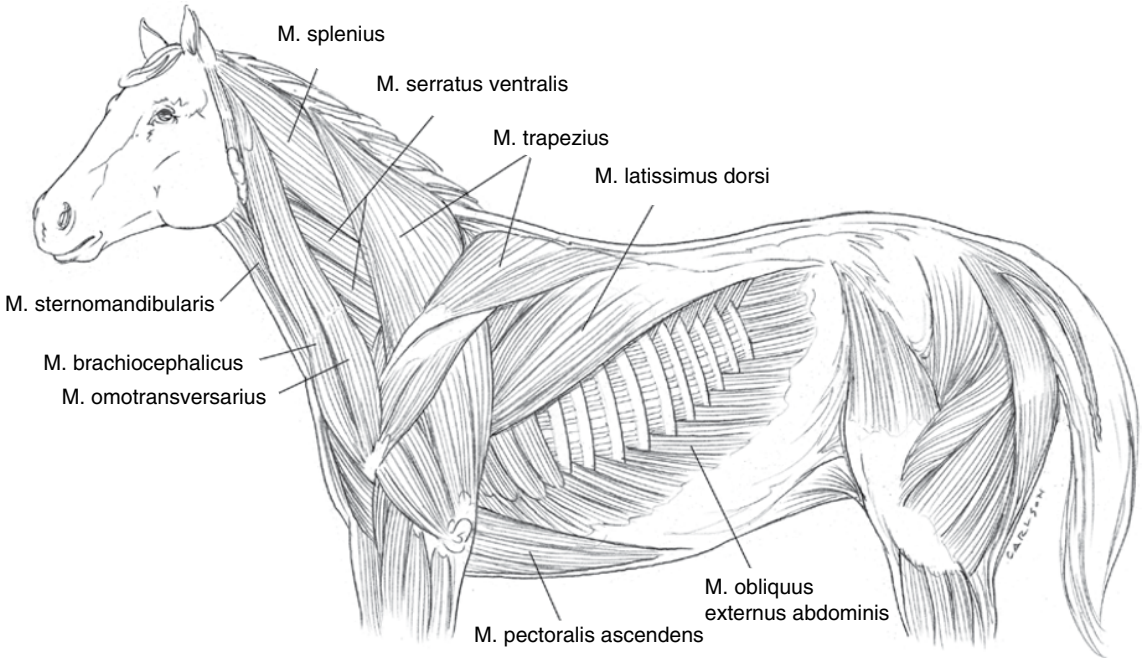

Figure 1.56. Superficial muscles of trunk. Cutaneous muscles have been removed.

Among those dorsal to the transverse processes are the cranial and caudal parts of the obliquus capitis muscle. The cranial part bridges between the nuchal crest and the cranial border of the wing of the atlas. The caudal part is a large, powerful rotator of the atlantoaxial joint. It attaches to the cranial border of the wing of the atlas and the vertebral arch of the axis.

Deep to the oblique muscles are a series of straight muscles that link the skull to the atlas and axis. The major part of rectus capitis dorsalis attaches on the caudal aspect of the occipital bone and the spinous process of the axis; its minor portion lies dorsal to the dorsal atlanto-occipital membrane, bridging between occipital bone and the wing of the atlas. Rectus capitis ventralis runs from the base of the skull to the ventral arch of the atlas. Rectus capitis lateralis attaches from the wing of the atlas to the paracondylar process. These last two muscles are relatively weak in the horse.

The longus capitis muscle bridges between the transverse processes of C2 through C4 or C5 and the ventral skull.

Activators of the head that are above the transverse processes will extend the atlanto-occipital and atlantoaxial joints; those ventral to the transverse processes flex those joints. When acting unilaterally, all of these muscles have the ability to turn the head laterally.

The longissimus group is described as having lumbar, thoracic, cervical, atlantal, and capital portions. It is most robust in the lumbar region, where it gives a well-conditioned horse's back its typical rounded appearance.

Hypaxial muscles of the trunk (the psoas minor, quadratus lumborum, and the four abdominal muscles on each side) act to flex the vertebral column during the gallop. Epaxial muscles extend the vertebral column. When they contract unilaterally, both hypaxial and epaxial muscles create lateral movement of the trunk and neck.

In the ventral neck, the equine m. longus colli is particularly well developed relative to other domestic species. The cervical portion of this muscle arises from the transverse processes and bodies of the third through sixth cervical vertebrae in paired bundles that converge to an insertion on the preceding vertebral bodies, sometimes bridging more than one intervertebral space. The most cranial attachment is on the ventral aspect of the atlas. The thoracic portion of the longus colli arises on the lateral vertebral bodies of thoracic vertebrae one through six, passing craniad to insert on the transverse processes of cervical vertebrae six and seven.

The omohyoideus muscle is well developed in the horse. It arises from an aponeurosis in the fascia near the shoulder joint. Its muscle belly is closely attached to the deep side of the brachiocephalicus until the neck's midpoint, where the omohyoideus becomes evident as a distinct muscle as it passes craniad deep to the sternocephalicus muscle. Near its insertion on the lingual process, it fuses with its partner from the contralateral side and with the sternohyoideus.

The right and left sternomandibularis muscles of the horse are fused on midline near their origin on the manubrium. Near mid-neck, the two halves separate, moving from their position ventral to the trachea to a more lateral location. As the muscle approaches its insertion on the sternomandibular tuberosity on the ramus of the mandible, it narrows to a distinct tendon that is visible in the cranial neck just caudal to the caudal border of the mandible. The tendon of insertion is classically considered one side of Viborg's triangle.

ACKNOWLEDGMENT

The authors thank Dr. Robert A. Kainer for his contributions to this chapter in the previous edition.

CHAPTER

Examination for Lameness

HISTORY, VISUAL EXAM, AND CONFORMATION

Gary M. Baxter and Ted S. Stashak

INTRODUCTION

Lameness is an indication of a structural or functional disorder in one or more limbs or the axial skeleton that is evident while the horse is standing or at movement.[29] Lameness can be caused by trauma (single event or repetitive work), congenital or acquired anomalies, developmental defects, infection, metabolic disturbances, circulatory and nervous disorders, or any combination of these. The diagnosis of lameness requires a detailed knowledge of anatomy, an understanding of kinetics and kinematics, and an appreciation for geometric design and resultant forces. It is important to differentiate between lameness resulting from pain and nonpainful alterations in gait, often referred to as "mechanical lameness," and lameness resulting from neurologic (nervous system) dysfunction.[8,35] Lameness due to pain is most common in the horse.

A complete lameness examination helps to differentiate among the many types of lameness problems in the horse. The objectives of a lameness examination are to determine:

1. Whether the horse is lame
2. Which limb or limbs are involved
3. The site or sites of the problem
4. The specific cause of the problem
5. The appropriate treatment
6. The prognosis for recovery

The steps to perform a routine or traditional lameness examination include:

1. Complete history including signalment and use
2. Visual exam of the horse at rest
3. Palpation of the musculoskeletal system including hoof tester examination of the feet
4. Observation of the horse in motion (usually at a straight walk and trot/lope followed by circling)
5. Observation of the horse under saddle or in work if necessary
6. Manipulative tests such as flexion tests
7. Diagnostic anesthesia if necessary
8. Diagnostic imaging

Palpation of the limbs and axial skeleton and hoof tester examination of the feet are usually performed prior to exercising the horse. However, some clinicians prefer to observe the horse at exercise prior to palpation of the musculoskeletal system. Diagnostic anesthesia and imaging often follow to document the location of the pain, specific cause of the problem, extent of injury, and prognosis for recovery.

ADAPTIVE STRATEGIES OF LAME HORSES

Horses adapt to lameness with compensatory movements of specific body parts.[11,12,39] With most lameness conditions, the horse attempts to "unload" the lame limb during weight-bearing or the stance phase of the stride. In a kinetic study of forelimb lameness, the vertical force peak had the highest sensitivity and specificity for lameness classification.[12,24] Horses accomplish this by abnormal movement of a body part (head nod or pelvic hike), weight shifting (to the contralateral or diagonal limb or torso), change in joint angles (lack of fetlock extension), and alterations in foot flight.[39] For example, hyperextension of the fetlock has been shown to be an indirect

Figure 2.1. Chronic hindlimb lameness that has resulted in a wide flat foot on the sound left hindlimb and a narrow, upright hoof on the lame right hindlimb.

measure for the vertical ground reaction force and is reduced in the lame limb at the stance phase proportionally to the degree of lameness.[12,32,39] In addition, in horses with chronic lameness, the limb with the flatter hoof exhibits higher vertical loads because it is the non-lame limb (Figure 2.1).[39] Detecting these compensatory movements is an integral part of diagnosing lameness in the horse. The most consistent compensatory movements that are observed are the vertical displacement and acceleration of the head in forelimb lameness and of the sacrum and tuber coxae in hindlimb lameness.[11,25,39] Although overlap of these movements can occur (head movement with hindlimb lameness and pelvic movement with forelimb lameness), they tend to occur primarily in moderate to severe lameness. In addition, more subtle lameness causes fewer compensatory changes, making lameness diagnosis more difficult, and problems within the axial skeleton (back) may also alter the movement of the limbs.[19,39] Although some of these gait changes may be difficult to appreciate during visual examination of a lame horse, it should be remembered that the primary adaptive strategy of the horse is to redistribute load to compensate for pain in a limb without causing an overload situation in other limbs.[39]

CLASSIFICATION OF LAMENESS

There are a variety of ways to classify lameness in the horse. In most cases there is a primary or baseline lameness that contributes to the most obvious gait abnormalities. Compensatory, secondary, or complementary lameness results from overloading of the other limbs as a result of the primary lameness.[33] Lameness may also be classified according to when it occurs (or is best observed) within the stride. The different classifications of lameness are defined below:

1. Supporting limb lameness: Apparent when the foot first contacts the ground or when the limb is supporting weight (stance phase). Injury to bones, joints, soft tissue support structures (e.g. ligaments and flexor tendons), and the foot are considered causes of this type of lameness. This is by far the most common type of lameness identified in the horse.
2. Swinging limb lameness: Evident when the limb is in motion. A variety of pathologic changes may be the cause, and the majority of these problems are thought to involve the upper limbs or axial skeleton.[35]
3. Mixed lameness: Evident both when the limb is moving (swing phase) and when it is supporting weight (stance phase). Mixed lameness can involve any combination of structures affected in swinging or supporting limb lameness.
4. Primary or baseline lameness: Most obvious lameness or gait abnormality that is observed before flexion or manipulative tests.[7,33] This can be complicated by lameness in multiple limbs, but in most cases the lameness that is the worst is considered the primary lameness. Evaluation of the primary lameness should be performed initially before scrutinizing complementary lameness problems.
5. Compensatory or complementary lameness: Pain in a limb can cause uneven distribution of weight on another limb or limbs, which can produce lameness in a previously sound limb. It is common to have complementary lameness produced in a forelimb as a result of lameness in the opposite forelimb.[35] Also, a lameness in a hindlimb can mimic a forelimb lameness on the ipsilateral side (right hind and right fore). Quantitative lameness evaluations suggest that an apparent lameness in the forelimb and hindlimb on the same side often suggests a primary hindlimb lameness and a false compensatory forelimb lameness.[25] Additionally, lameness in one hindlimb may contribute to lameness in the opposite hind.

Even minor changes in weight-bearing can produce complementary lameness at high speeds, especially over long distances. The feet, suspensory ligament, sesamoid bones, hocks, and flexor tendons seem to be affected most commonly.[35] Complementary lameness in the same limb usually results when excess stress occurs to an otherwise healthy structure in an attempt to protect a painful region in that limb. For example, a horse with navicular syndrome often lands toe first, potentially contributing to toe bruising and/or osteitis.

By observing the gait from a distance, one can usually determine whether the lameness is supporting limb, swinging limb, or mixed. Some conditions that cause supporting limb lameness may cause the horse to alter the movement of the limb to protect the foot when it lands. This can be mistaken for swinging limb lameness. Because of this and other adaptive strategies that occur in lame horses, some clinicians feel that mixed lameness occurs most commonly in horses.[33]

Character of the Stride

The character of the stride of a limb is important to the diagnosis of lameness. When observing the stride, the following characteristics should be observed:

The phases of the stride: The stride consists of a cranial phase and a caudal phase. The cranial phase of the stride is in front of the footprint of the opposite limb, and the caudal phase is behind it (Figure 2.2). With lameness, the cranial or caudal phases may be shortened. If the cranial phase is shortened, there may be a compensatory lengthening of the caudal phase, and vice versa.

VetBooks.ir

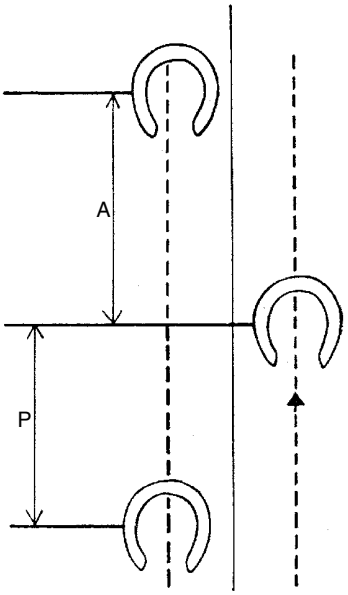

Figure 2.2. Phases of the stride. (A) The cranial phase of the stride is the half of the stride in front of the print of the opposite foot. (P) The caudal phase of the stride is the half of the stride in back of the print of the opposite foot.

Alterations in phase of the stride are best viewed from the side of the horse. Potential causes for a shortened cranial phase of the stride include navicular syndrome, joint problems such as osteoarthritis (OA), shoulder problems, and bone spavin. Causes of shortened caudal phase of the stride may include digital annular ligament desmitis and tendonitis or tenosynovitis involving the flexor tendons.[35]

The arc of foot flight: The arc of foot flight is usually changed when there is pain anywhere in the limb. The arc of one foot should be compared with that of the opposite member when viewed from the side. In some cases, the arc is changed in both forefeet (bilateral navicular syndrome, laminitis, etc.) or in both hindfeet (bilateral bone spavin). In the hindlimb, the arc may be changed enough to cause the toe to drag when the limb is advanced because of reduced flexion of the hock or stifle joints. Most horses exhibiting a decrease in height of the foot flight arc also show alteration in their phase of stride. For subtle alterations in the hoof flight arc of the hindlimb, it is sometimes helpful to observe the horse from the rear to compare the extent and duration that the horse presents the solar surfaces of both feet to the observer. In general, the less sole that can be seen, the lower the arc of foot flight in the limb.[35]

How the foot lands: When a painful condition is present in the foot, the horse usually indicates the pain by placing its weight opposite to the pain. For example, with pain in the heel region, the horse may only toe-touch. If the lesion is in the lateral portion of the sole, the weight is carried on the medial side of the foot, and vice versa.

Joint extension: The degree of extension of the fetlock (how close the back of the fetlock approaches the ground) during weight-bearing is a sensitive indicator of how much weight the horse is willing to bear on that limb. Reduction in fetlock extension during weight-bearing usually indicates the lame limb (Figure 2.1). This sign can be observed at a walk and/or a trot.

Joint flexion angles: Joint flexion angles are best viewed from the side and may or may not be associated with alterations in the hoof flight arc and phase of stride. One limb is compared with the other and the degree of flexion is assessed. In some cases, horses compensate with an increased flexion of the unaffected limb.

Head and pelvic movement: Horses use their pelvis or hemipelvis with hindlimb lameness similar to how they use their head and neck with forelimb lameness. Both are used as a method to "unweight" the lame limb, and the amount of movement of each is often proportional to the degree of lameness. Movement of the head and pelvis (or hemipelvis) is best observed from the side and should be correlated with gait changes.[7]

Other Lameness Factors

It is generally considered that the majority of lameness problems in horses occur in the forelimb due to the increased weight-bearing on the forelimbs (60%–65%) and the shock of landing that the forelimbs absorb during movement.[7,35] The hindlimbs propel the horse during movement and carry less of the overall weight. This results in greater concussion to the structures of the forelimbs. However, breed and use can alter this typical relationship. For instance, horses that pull carts or perform events such as dressage, cutting, and reining, which place greater stress on the hindquarters, often have a higher percentage of hindlimb lameness. Many hindlimb lameness problems involve the hock and/or stifle. Horses within a discipline that do different activities may also have different limbs that are affected most commonly. For instance, horses used for heading in team roping have more problems in the right forelimb, and horses used for heeling have more bilateral hindlimb lameness problems.[13] Although there is considerable overlap, common lameness conditions that are associated with the specific type of work should be suspected first (Table 2.1). See Chapter 9 for further information on occupation-related lameness conditions.

It is also believed that approximately 95% of lameness in the forelimb occurs distal to the carpus.[35] Close evaluation of the distal limb should be performed in any horse with forelimb lameness before considering an upper limb problem, unless a more proximal condition is obvious. In the hindlimb, approximately 80% of lameness problems are thought to involve the hock or stifle.[35] Therefore, after preliminary examination of the foot and distal limb, the hock and stifle should be closely evaluated until conditions of those two regions can be eliminated.

Multiple other factors that may contribute to lameness should also be considered. Horses that are improperly or irregularly shod may become lame. Surfaces that are too soft, too hard, slippery, or rocky may aggravate conformational imperfections or may be the outright cause of lameness. Improper conditioning resulting in muscle fatigue is considered to be a common cause of performance-related injuries. Young horses in work may develop lameness problems more easily than older horses due to the immaturity of their musculoskeletal system. With the emphasis on racing and showing young

Table 2.1. Occupation-related lameness problems (See Chapter 9 for further information.)

Occupation	Lameness Conditions
TB and QH racehorse (Fatigue-associated repetitive overuse)	Foot bruising, quarter cracks, heel pain Forelimb fetlock synovitis and fractures Carpal synovitis and fractures Bucked shins in young horses Fatigue/stress fractures—MC/MT, P1, humerus, tibia, pelvis SDFT tendonitis Suspensory injuries Coffin joint synovitis/OA—QH Proximal suspensory desmitis—QH Catastrophic fractures—sesamoids, P1, MC/MT, and humerus Palmar/plantar osteochondral disease (POD)
STD racehorse (hindlimb > forelimb)	Front feet bruising and corns Hindlimb fetlock synovitis and fractures Carpal synovitis and fractures (C3) Fatigue/stress fractures—similar to TB and QH but tibia most common Suspensory injuries especially PSD, SDFT tendonitis Hock, stifle, and sacroiliac problems

VetBooks.ir

horses, many lameness problems may be produced that would not occur in older, more mature horses.

SIGNALMENT AND USE

Patient age and use are important considerations when determining potential lameness conditions. For example, an aged crossbred horse used for ranch work, occasional rodeo performance, and trail riding will have a higher incidence of problems associated with the forefeet, low-motion joints (e.g. pastern and distal tarsal joints), and ligaments. In contrast, a young racehorse will often have lameness problems associated with high-motion joints (e.g. carpus and fetlock), sprain/strain of flexor support structures, and stress-related fractures. Horses used for competitive trail or endurance riding often sustain a higher incidence of sprain/strain injuries, tendonitis, and stress-related fractures to the phalanges. Young cutting horses appear to be prone to stifle issues, and any young horse just beginning training may become lame from developmental orthopedic-related problems.

HISTORY (ANAMNESIS)

A detailed medical history should be obtained on every horse. Records should include specific information regarding the duration and intensity of the lameness, specific symptoms, the activity immediately preceding the lameness, and any previous treatments or therapies employed. The following questions should be asked:

1. What activity does the horse perform and did the lameness occur during this activity?
2. How long has the horse been lame? (Acute vs. chronic injury.)
3. Has the horse been rested or exercised during the lameness period? (The horse may not exhibit the same lameness if it has been rested.)
4. Has the lameness worsened, stayed the same, or improved? (May indicate severity of the problem.)
5. Was the cause of the lameness observed? (This should include the character of the lameness at the onset.)
6. Does the horse warm out of the lameness?
7. When do you notice the lameness most consistently?
8. What treatments have been given, and have they helped? (Response to treatment may help predict the prognosis of the case but may also mask the severity of lameness and give a false impression of recovery.)
9. When was the horse last shod or trimmed? (Lameness directly after shoeing may suggest that the feet were trimmed too short or a nail was driven into or near sensitive tissue.)
10. What are the abnormalities that the owner or trainer observe or feel when they ride the horse or watch the horse go?

VISUAL EXAMINATION AT REST

A careful visual examination is made with the horse standing squarely on a flat surface at rest.[8,35] This should be done at a distance and then up close, viewing the horse from all directions. From a distance, the body type is characterized (stocky vs. slender); conformation is noted; and body condition and alterations in posture, weight shifting, and pointing are also noted. It is important to look for changes in contour of the limbs and asymmetry between limbs.

Under normal circumstances, the forelimbs bear equal weight and are opposite each other. With bilateral forelimb involvement, the weight may be shifted from one foot to the other, or both limbs may be placed too far out in front of the horse. In the hindlimbs, it is normal for the horse to shift its weight from one limb to the other. If the horse consistently rests one hindlimb and refuses to bear weight on it for a length of time or cannot be forced to bear weight on it at all, lameness in that hindlimb should be considered. Even small alterations in limb positioning and posturing may suggest a potential problem and should be investigated during the lameness examination.

At close observation, each limb and muscle group should be observed and compared to its opposing member for symmetry. Feet are observed for abnormal wear, hoof cracks, imbalance, size, and heel bulb contraction (Figure 2.3). All joints and tendons and their sheaths are visually inspected for swelling, and the muscles of the limbs, back, and rump are observed for swelling and atrophy. Comparing one side to the other is most important. Each abnormal finding should be ruled out as a cause of lameness during exercise and palpation examination. For the forelimbs, the limb with the narrowest (smallest) foot and highest heel with varying degrees of extensor muscle atrophy is usually the lame or lamest (if the problem is bilateral) limb.[7] The foot is smaller due to chronic alteration in weight-bearing, and the muscle atrophy results from a reluctance to extend that limb. For the hindlimb, atrophy of the middle gluteal and/or gracilis muscles usually indicates the lame limb (Figures 2.4 and 2.5). Generally, if one tuber sacrale is higher than the other and/or the pelvis appears tilted, the horse will usually have an asymmetrical gait (Figure 2.6).

Figure 2.3. Horse with two different front feet: low heel and long toe on the left fore and a more upright hoof conformation on the right front. Unlike many horses with this hoof conformation, this horse was lame on the left forelimb.

Figure 2.6. Rear view of the pelvis of a horse with a history of an acute onset of right hind lameness. There is asymmetry to the sacroiliac region visible and pain on firm palpation of the right tuber sacrale.

CONFORMATION

Simultaneously while performing a visual examination on any horse presented for lameness, the conformation of the horse, especially the limbs, should be assessed. It is important to have a basic understanding of conformation and how abnormalities in conformation may contribute to alterations in limb movement and lameness. Conformation refers to the physical appearance and outline of a horse as dictated primarily by bone and muscle structures.[22,29] It is often a subjective assessment based on what a particular breed may consider to be "ideal."[10] However, it can be difficult to specifically define *ideal* or *normal* conformation because the guidelines depend on the classification, type, breed, and intended use of the horse.[29,30] Despite these difficulties, it is well recognized that certain conformation traits may predispose to lameness and these should be observed during the initial visual exam of any lame horse. For instance, poor forelimb conformation was found to be a predisposing factor for young Standardbred racehorses that developed lameness in the middle carpal joint.[37] The trick becomes determining which abnormal conformational traits are contributing to lameness in any given horse because many conformational traits are not always related to performance and unsoundness.[21,30] One study that evaluated conformational traits of Thoroughbred yearlings found only weak associations between performance and conformation that could not be accounted for by the very strong relationship between pedigree and conformation.[28] More such studies that attempt to evaluate the association between limb conformation and specific lameness conditions are needed to truly determine the effect of conformation on lameness in performance horses.

Ideally, conformation assessment of a lame horse should relate to function,[9] but objective studies relating specific conformational traits to performance or lameness problems can be difficult to perform.[10,21,23] To complicate things more, while many lameness problems occur in the lower limbs, the causative factors may be located in the upper limbs or body; therefore, overall conformation must be considered together with limb conformation. Objective techniques to assess conformation as it relates to movement and lameness in horses are needed to truly quantify its contribution to lameness. Furthermore, conformation is often a subjective assessment, and improved techniques to quantify conformation as it relates to lameness are needed.

Types and Breeds

Horses are broadly classified as draft horses, light horses, or ponies. Classifications are further divided by type according to overall body style and conformation

VetBooks.ir

and the work for which the horse is best suited. Light (riding and driving) horses are by far the most common and can be described as one of several types: pleasure horse, hunter, stock horse, sport horse, animated (show) horse, and racehorse.

A "breed" is a group of horses with common ancestry and usually strong conformational similarities. In most cases, a horse must come from approved breeding stock to be registered with a particular breed. If a horse is not eligible for registration, it is considered to be a "grade" or "crossbred" horse. Several breeds can have similar makeup and be of the same type. For example, most Quarter horses, Paint horses, and Appaloosas are considered to be stock horse types. In addition, racing Quarter horses often have considerable Thoroughbred background. Some breeds contain individuals of different types within the breed; Thoroughbreds can be of the race, hunter, or sport horse type. In addition, crossbreeding horses of different breeds to attain characteristics for a specific sport is not uncommon.

Systematic Evaluation of Conformation

Although breed characteristics may vary, the process of evaluating any horse should be similar. A general systematic assessment of the horse's four functional sections is made (head and neck, forelimbs, trunk, and hindlimbs), giving each area approximately equal importance (Figure 2.7).[36] The horse's specific conformational components or traits are then evaluated in more detail.

The evaluation begins by viewing the horse from the near (left) side in profile and assessing balance by comparing the forehand (head, neck, and forelimbs) to the hindquarters (hindlimbs and croup). Attention should be paid to the curvature and proportions of the top

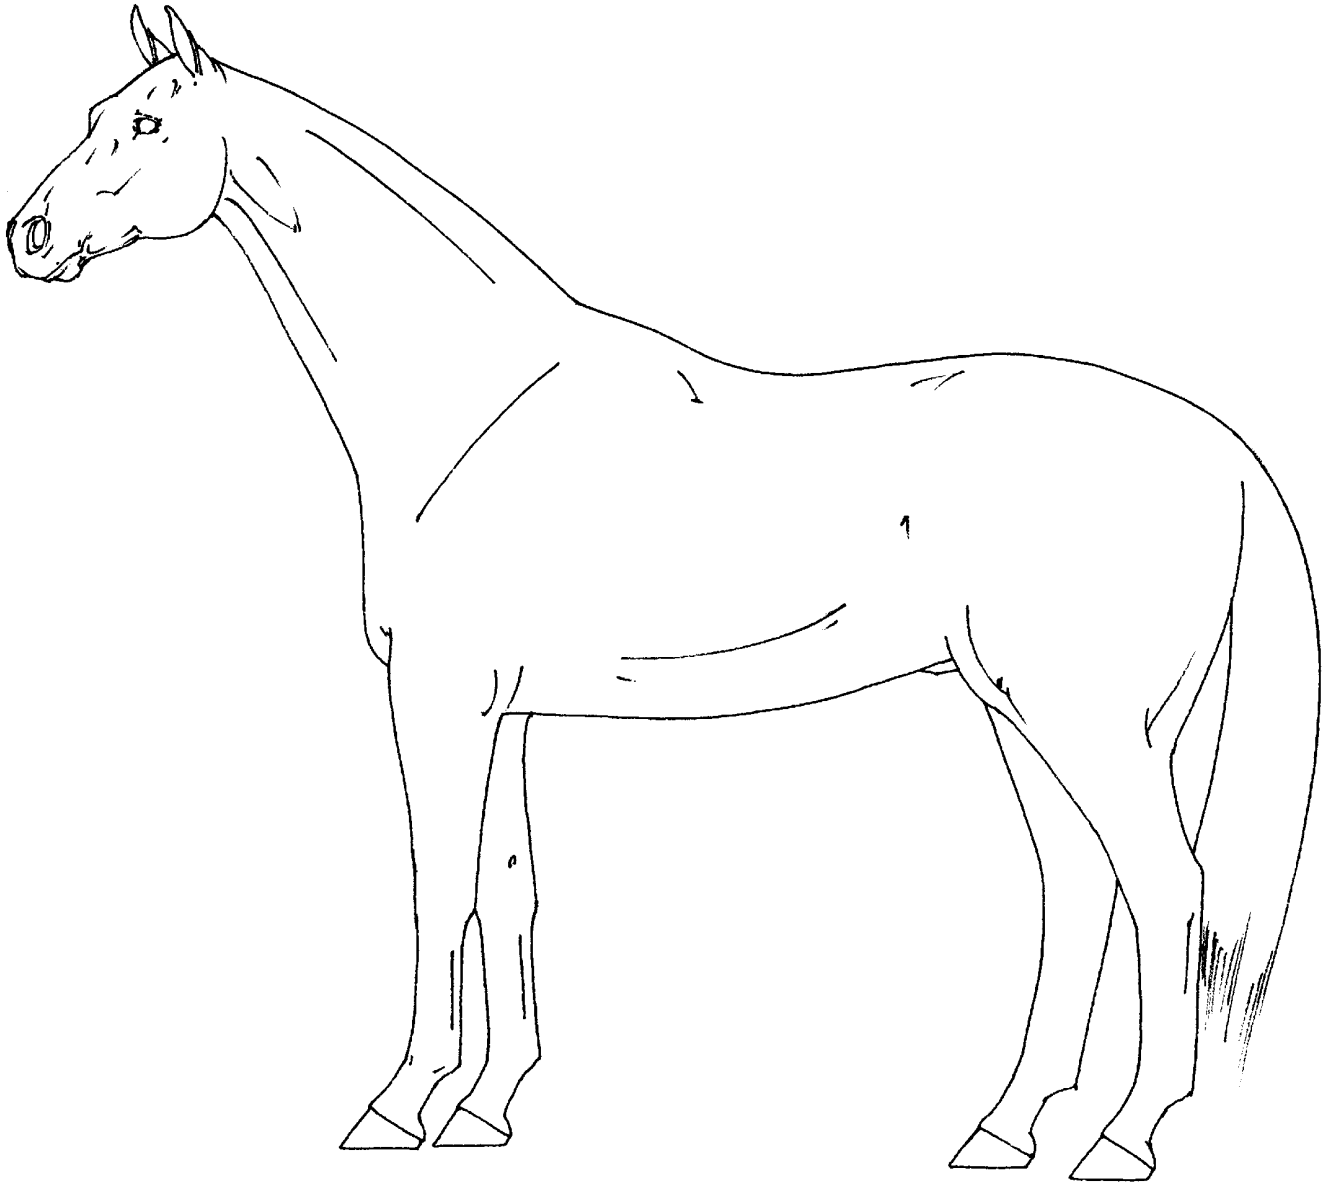

Figure 2.7. Normal horse. The body and limbs should be well proportioned.

VetBooks.ir

line, and observations made from poll to tail and down to the gaskin. The attachment of the appendicular skeleton (limbs) to the axial skeleton (head and trunk) should be observed with emphasis placed on limb angles. There is a strong relationship between long bone lengths and wither heights at differing ages, suggesting that horses should be proportional regardless of their size.[1]

From the front of the horse, the limbs and hooves are evaluated for straightness and symmetry. The depth and length of the muscles in the forearm and chest are observed. Evaluation of balance, top line, and limb angles is confirmed by viewing the off (right) side of the horse.

From directly behind the tail, the straightness and symmetry of the back, croup, point of the hip, and buttock are evaluated along with the hindquarters and the hindlimbs. This is also the best vantage point for evaluating back muscling, alignment of the vertebral column, and (provided the horse is standing square) left-to-right symmetry.

The observer should then make another entire circle around the horse, this time stopping at each quadrant to look diagonally across the center of the horse. From the rear of the horse, the observer should look from the left hindlimb toward the right forelimb and from the right hindlimb toward the left forelimb. This angle will often reveal abnormalities in the limbs and hooves that were missed during the side, front, and rear examinations. The horse is then viewed from the front in a similar diagonal approach. While observing the horse, it is helpful to obtain an overall sense of correctness of each of the four functional sections: head/neck, forelimbs, trunk (barrel), and hindlimbs.

Head and Neck

The size or shape of the head is often breed specific, but does not appear to influence performance or lameness. The neck acts as a lever to help regulate the horse's balance while moving; therefore, it should be long and flexible with a slight convex curve to its top line.[9,21] Jumping horses have been found to benefit from longer necks, probably because they make it easier to maintain balance over the fence.[21]

Forelimbs

Kinematic/kinetic studies have confirmed that at the beginning of the stance phase, the distal portion of the forelimb is subjected to more stress from weight-bearing forces than the distal portion of the hindlimb.[5,6] The forelimbs tend to "bounce," whereas the hindlimbs "slide."[21] The forelimbs are considered to support approximately 60%–65% of the horse's body weight, so they should be well muscled and conformed normally.[9,36]

Trunk (Barrel)

The horse should have adequate heart girth and width (spring) to the ribs to house the vital organs. The back should be well muscled and strong so that the horse is able to carry the weight of its internal organs and the rider and saddle.

Hindlimbs

The hindlimbs are the source of power for propulsion and stopping.[36] The hindlimb muscling should be appropriate for the type, breed, and use of the horse. The croup and points of the hip and buttock should be symmetrical, and the limbs should be straight and angled correctly.

CONFORMATION COMPONENTS AND TRAITS

Balance

Balance refers to the relationship between the forehand and hindquarters, between the limbs and the body, and between the right and the left sides of the body (Figures 2.7–2.9). It is a subjective assessment based on the overall conformation of the horse. A well-balanced horse is thought to move more efficiently, thereby experiencing less stress on the musculoskeletal system. However, one study that measured multiple conformational traits in racehorses found that 25% of all parameters showed a significant difference between the left- and right-sided measurements.[40]

The center of gravity is a theoretical point in the horse's body around which the mass of the horse is equally distributed. It is located at a point of intersection of a vertical line dropped from the highest point of the withers and a line from the point of the shoulder to the point of the buttock. The center of gravity is usually just behind the xyphoid and two-thirds the distance down from the top line of the back[36] (Figure 2.9).

Although the center of gravity remains relatively constant when a well-balanced horse moves, most horses must learn to rebalance their weight (and that of the rider and tack) when ridden. To pick up a front foot to step forward, the horse must shift its weight toward the rear. The amount of this weight shift depends on the horse's conformation, the position of the rider, the gait, the degree of collection, and the style of the performance. The higher the degree of collection, the more the horse must step under the center of gravity with the hindlimbs.

If the forehand is proportionately larger than the hindquarters, particularly if it is associated with a downhill top line, the center of gravity tends to shift forward. This causes the horse to travel heavy on his front end, setting the stage for increased concussion, stress, and lameness. When the forehand and hindquarters are balanced and the withers are level with or higher than the level of the croup, the horse's center of gravity is located more toward the rear. Such a horse can carry more weight with his hindquarters, thus moving in balance and exhibiting a lighter, freer motion with the forehand than the horse with withers lower than the croup. However, hip height was consistently 2–3 cm greater than wither height in young growing Thoroughbreds, suggesting that level top lines may only develop with maturity, if at all.[38] Even with a level top line, if the forehand is heavily muscled in comparison to the hindquarters, the horse may travel heavy on the forehand.

A balanced horse has approximately equal lower limb length and depth of body. The lower limb length (chest floor to the ground) should be equal to the distance from the chest floor to the top of the withers

VetBooks.ir

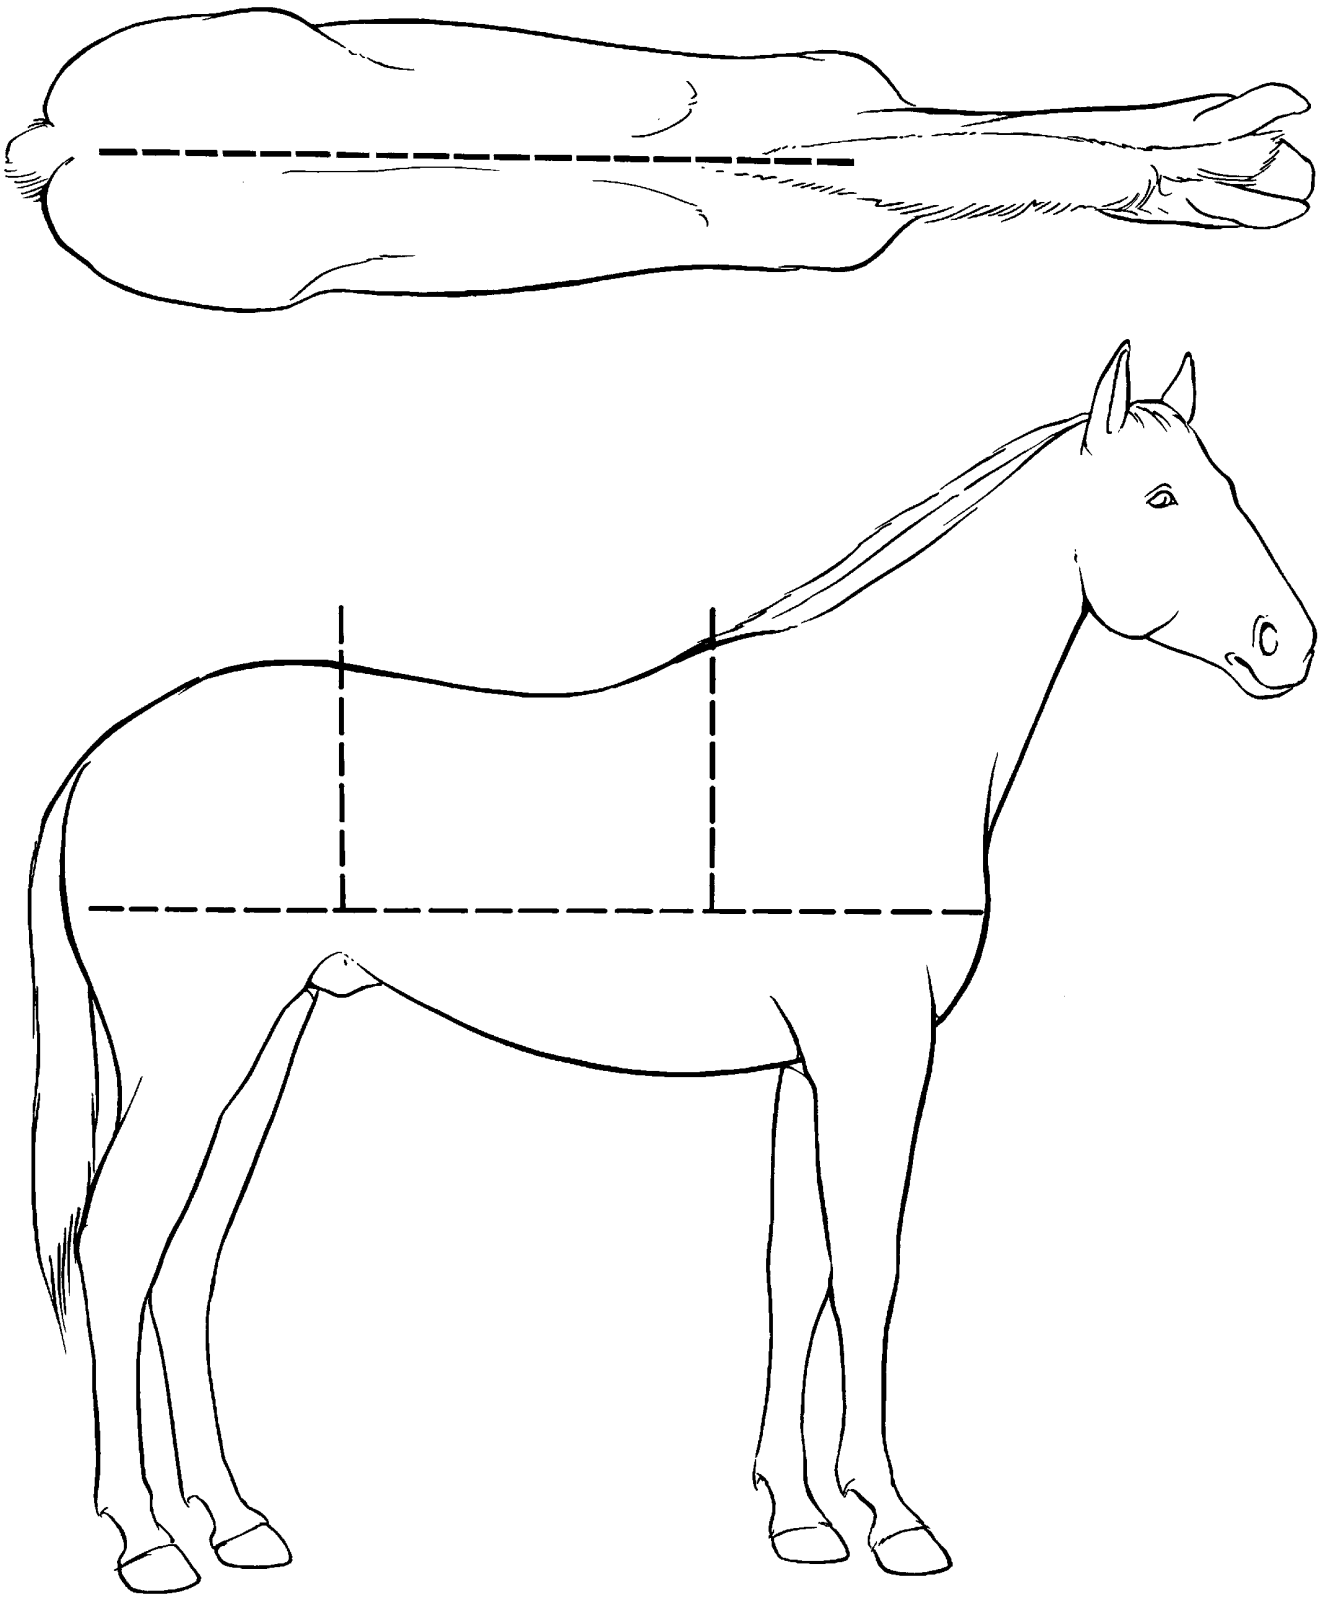

Figure 2.8. Axial alignment. A line drawn from the center of the withers through the center of the back should roughly divide the body into two equal halves. Bottom: Balance is evaluated by dividing the body into three equal parts.

(Figure 2.9). Proportionately shorter lower limbs are associated with a choppy stride. The horse's height or overall limb length (point of the withers to the ground) should approximate the length of the horse's body (the point of the shoulder to the point of the buttock) (Figure 2.9). A horse with a longer body than its height often experiences difficulty in synchronization and coordination of movement. A horse with limbs proportionately longer than the body may be predisposed to forging, overreaching, and other gait defects. Overall, the right side of the horse should be symmetrical with the left side.

Proportions and Curvature of the Top Line

The ratio of the top line's components, curvature of the top line, strength of loin (longissimus dorsi muscles in the lumbar region), sharpness of withers, slope to the croup, and length of the underline in relation to the length of back all affect a horse's movement (Figures 2.8 and 2.9).[36]

The neck is measured from the poll to the highest point of the withers (Figure 2.9). The back measurement is taken from the withers to the caudal extent of the loin located in front of the pelvis. The hip length is measured from the caudal loin to the point of the buttock (Figure 2.9).

A neck that is shorter than the back tends to decrease a horse's overall flexibility and balance. A back that is much longer than the neck tends to hollow (flex down or is more concave). A very short hip, in relation to the neck or back, is associated with lack of propulsion and often a downhill configuration. A general rule of thumb is that the neck length should be greater than or equal to

VetBooks.ir

the back length and that the hip should be at least two-thirds the length of the back (Figure 2.9).

The shape of the neck is determined by the "S" shape formed by the seven cervical vertebrae. The neck should have a graceful shape that rises up out of the withers, not dipping ventral (downward) in front of the withers. The thickest point in the neck should be at the ventral limits. Ewe-necked horses often have a long, ventral curve to the neck that appears to attach low on the chest. The attachment of the neck muscles to the shoulders should be smooth. The dorsal (upper) neck length (poll to withers) should be twice the ventral (lower) neck length (throat latch to chest). This is dictated to a large degree by the slope of the shoulder. A horse with a steep shoulder has an undesirable ratio (approaching 1:1) between the dorsal and ventral neck lengths.[36]

The withers should blend gradually into the back, ending ideally at about the midpoint of the back. In one study all circumference measurements and the majority of the length measurements in a group of National Hunt racehorses were significantly correlated with the height of the horse at the withers.[40] The back behind the withers should resemble a natural place for a saddle, beginning with prominent withers located above or behind the heart girth. The neck and forearm muscles and the ligamentum nuchae should attach at the highest point of the withers. There should not be a prominent dip in the muscles in front of or behind the withers (Figure 2.10). Low (mutton) withers limit a horse's ability to raise its back as it lowers and extends its neck. A horse with a well-sloped shoulder usually has correctly placed withers.

The longissimus muscles that run along the spine should be flat and appear strong rather than sloped and weak. The back muscles aid to counteract the gravitational pull from the weight of the horse's internal organs and to support the rider's weight.

The loin is located along the lumbar vertebrae from the last thoracic vertebrae to the lumbosacral junction (Figure 2.9). The loin should be well muscled and relatively short. Horses termed "long-backed" often have an acceptable back length but a long, weak loin. A horse with a weak and/or long loin and loose coupling (flanks) tends to have a hollow back. (The coupling is the area behind the ribs and in front of a vertical line dropped from the point of the hip). A horse that has a chronic hollow back may be predisposed to focal lumbar pain, pinched nerves, or vertebral damage.[36] In addition, kinematic studies have documented that even subtle hindlimb lameness can alter movement of the thoracolumbar region, potentially contributing to secondary musculoskeletal pain in the region.[19]

The loin and coupling transfer the motion of the hindquarters up through the back and forward to the forehand; therefore, they should be strong and well connected. A short, heavily muscled loin may have great strength, power, and durability but may lack the flexibility of a more moderately muscled loin. A lumpy appearance in the loin may indicate abnormal alignment (subluxations) of the vertebrae or damage to the supraspinous ligament.[36]

The croup is measured from the lumbosacral junction to the tail head. The croup should be fairly long, because this is associated with a good length to the hip and a desirable forward placement of the lumbosacral articulation. The top line (the back) should be short in relation to the underline. Such a combination indicates strength plus desirable length of stride.

Substance

Thickness, depth, and breadth of bone, muscle, and other tissues are described as "substance." Muscle

Figure 2.10. Marked ventral curvature or lordosis of the back is considered to be undesirable because it may predispose to back problems.

VetBooks.ir

substance is described by the type, thickness, and length of the muscle and the position of attachment. Other substance factors include weight of the horse, height of the horse, size of the hoofs, depth of the heart girth and flank, and spring of rib.

"Spring of rib," which is best viewed from the rear, refers to the curvature of the ribs. In addition to providing room for the heart, lungs, and digestive tract, a well-sprung rib cage provides a natural, comfortable place for a rider's legs. A slab-sided horse with a shallow heart girth is difficult to sit upon properly; an extremely wide-barreled horse can be stressful to the rider's legs.

"Substance of bone" refers to adequacy of the bone to the horse's weight ratio. Traditionally, the circumference around the cannon bone just below the carpus serves as the measurement for substance of bone. For riding horses, an adequate ratio is approximately 0.7 inches of bone for every 100 lbs of body weight.[36] Using this rule, a 1,200-lb. horse should have an 8.4-inch cannon bone circumference.

Correctness of Angles and Structures

The correct alignment of the skeletal components provides the framework for muscular attachments. The length and slope to the shoulder, arm, forearm, croup, hip, stifle, and pasterns should be appropriate and work well together. There should be a straight alignment of bones when viewed from the front and rear, large clean joints, high-quality hoof horn, adequate height and width of heel, concave sole, and adequate hoof size.

Forelimbs

Cranial View

Both forelimbs should be of equal length and size and should appear to bear equal weight when the horse is standing squarely. A line dropped from the point of the shoulder (middle of the scapulohumeral joint) to the ground should bisect the limb. The manner in which the shoulder blade and arm (humerus) are conformed and attach to the chest often dictates the alignment of the lower limb. Whether the toes point in or out is often related to upper limb structures, which is why it may be counterproductive to alter a limb's alignment through radical hoof adjustments. The toes should point forward, and the width of the feet on the ground should be the same as the width at the origin of the limbs in the chest (Figure 2.11).

The medial/lateral (ML) slope of the humerus is evaluated by finding the point of the shoulder and a spot in front of the point of the elbow on each side. The four points are then connected visually. If the resulting box is square, the humerus lies in an ideal position for straight lower limbs. If the bottom of the box is wider, the horse may toe in and travel with loose elbows and paddle. If the bottom of the box is narrower, the horse will probably toe out, have tight elbows, and wing in.

The muscles of the forearm (antebrachium) should extend to the knee, tapering gradually rather than ending abruptly a few inches above the knee. This is believed to allow the horse to use its front limbs in a smooth, sweeping, forward motion. The pectoral muscles should also extend far down onto the limb. The pectoral and

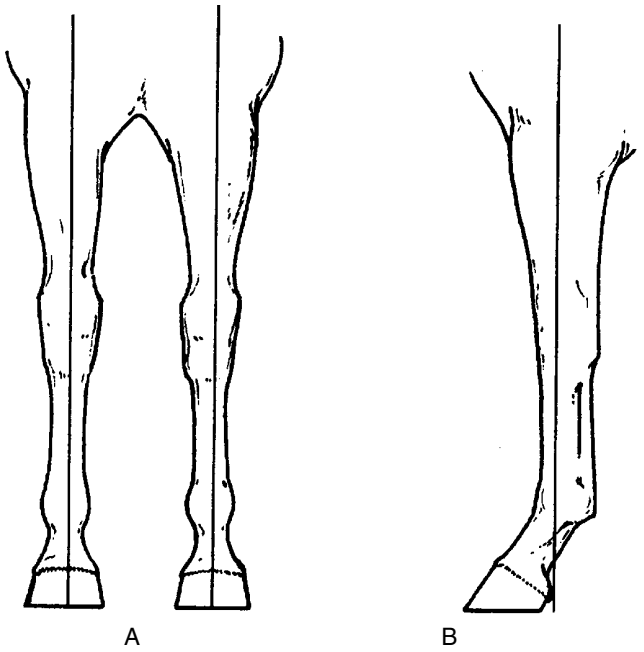

Figure 2.11. Cranial and lateral views of normal forelimbs. (A) A line dropped from the point of the shoulder joint should bisect the limb. (B) A line dropped from the tuber spinae of the scapula should bisect the limb down to the fetlock and end at the heel bulbs.

the forearm muscles help a horse to move its limbs laterally and medially and to elevate the forelimb. It is believed by some horseman that long forearms and short cannon bones are conducive to speed,[26] but this has not been documented.[29]

The carpal joints should be balanced and should not deviate toward, or away from, one another. The cannon bone should be centered under the carpus and not to the lateral side (bench knees). Deviations from a straight limb may cause strain on the collateral support structures and asymmetrical loading (compression) of the hinge joints in the forelimb.

Lateral View

When viewed from the side, limbs should exhibit a composite of moderate angles so that shock absorption is efficient (Figure 2.12). The shoulder angle is measured along the spine of the scapula, from the point of the shoulder to the point of the withers. The angle of the scapula and shoulder tend to increase (become more upright) as horses mature from foals to adults.[1] The shorter and straighter the shoulder, the shorter and quicker the stride, and the more stress and concussion that is transmitted to the limb.[21] Studies in dressage horses and show jumpers have found that a more horizontal scapula was related to a higher level of performance.[22,27] Also important is the angle the shoulder makes with the arm, which should be at least 90°. Horses with a more horizontally positioned scapula or a more flexed shoulder joint show more maximal extension of the elbow joint relative to the angle at initial ground contact.[5] This prolongs the stance phase. A long sloping scapula is ergonomically efficient and is thought to place the rider more to the rear of the horse, resulting

VetBooks.ir

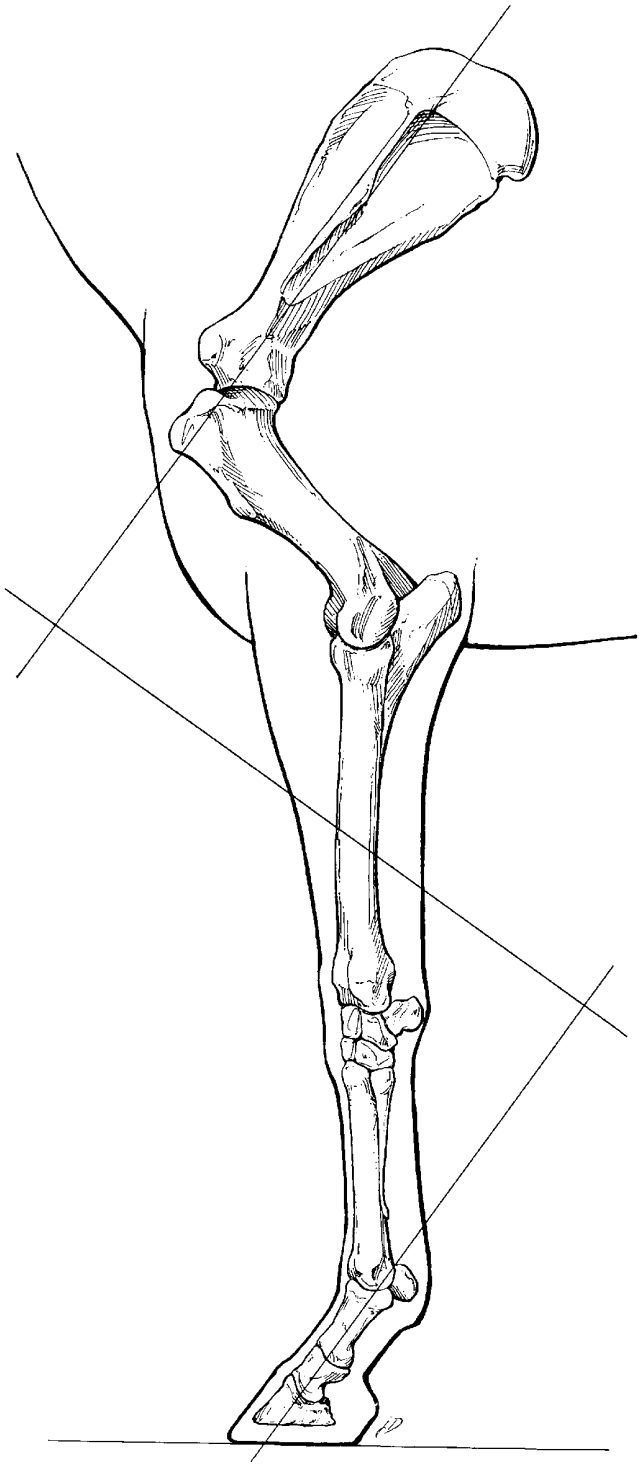

Figure 2.12. The angle of the shoulder usually influences the angle of the pastern.

in improved balance.[21] The scapulohumeral (shoulder) joint is supported entirely by the muscles and tendons surrounding it. Because this muscle support is so important to proper movement, a horse should have well-developed muscles in this region.

The length of the humerus (from the point of the shoulder to the point of the elbow) can affect stride length (Figure 2.12). A long humerus is associated with a long, reaching stride and good lateral ability; a short humerus is related to a short, choppy stride and poor lateral ability. A long humerus corresponds to a long triceps muscle that facilitates a larger range of elbow movements.[21] In general, the steeper the angle of the humerus, the higher the action; the closer the angle is to horizontal, the lower the action.

The angle formed by the humerus and radius and ulna at the elbow joint should be between 120° and 150°.[36] A more flexed elbow together with a horizontal scapula results in a longer stance duration, which is thought to improve gait quality with more collection in the forelimbs.[21,23] Straighter conformation (lesser angulation) at this joint may result in a short, choppy gait and increased concussion on the distal limb.

Ideally the limb should form a straight column from the elbow joint to the fetlock. This conformation will disseminate the axial compression forces to all bony surfaces equally. With malalignment, axial compressive forces become focused on one side, and tensional forces are created opposite to it, increasing the stress and strain on musculoskeletal structures.[36]

The carpus (knee) is a complex joint and functions in flexion, absorption of concussion, and extension. Flexion primarily occurs at the radiocarpal and middle carpal joints, and extension occurs by a locking mechanism while the horse is weight bearing during the extension phase of the stride. The carpal bones should be in good axial alignment with the radius and third metacarpal bone and of sufficient size to support downward concussive forces. The carpus should appear straight and not deviate forward or backward (Figure 2.13).

Fetlock joints should be large enough and angled to permit free movement. A more extended fetlock joint resulted in more maximal extension, which correlated with a good gait in the forelimbs in one study.[6] It has also been found that a straighter hindlimb fetlock joint angle results in a longer stride and swing duration.[6] A study on Swedish Warmblood horses found the mean front fetlock angle to between 146° and 155° and the mean hind fetlock angle between 153° and 161°.[22]

This is considerable variation in the literature regarding what the "normal" hoof-pastern axis of the forefoot should be. Previous reports of angles less than 50° are currently considered to be too low, and normal angles are thought to be approximately 54°.[4,29,36] Although these angles may vary considerably, the angle of the dorsal hoof wall should be similar to the angle of the pastern.[9] Exceptionally long, sloping pasterns or a broken-back hoof-pastern axis are thought to increase strain to flexor support structures of the fetlock and phalanges (Figure 2.14). Short, upright pasterns or a broken-forward hoof-pastern axis are thought to cause greater concussive stresses to the fetlock, phalangeal joints, and foot.[4,9,29]

The hoof should be appropriately sized for the size for the horse, well shaped (more round than egg shaped), and symmetric. It should have high-quality hoof horn, adequate height and width of heel, a concave sole, and a robust frog. The bulbs of the heel should lie vertically below the central axis of the cannon bone in the sagittal plane (Figure 2.11B). Normally trimmed hooves usually impact the ground heel first or flat-footed.[4,36] Studies have documented that lower hoof angles predispose

VetBooks.ir

racehorses to musculoskeletal injuries and contribute to a multitude of lameness problems in the palmar aspect of the foot.[26,29,31]

Faults in Conformation of the Forelimbs

Base-Narrow

In base-narrow conformation, the distance between the center of the feet on the ground is less than the distance between the center of the limbs at their origin in the chest when viewed from the front (Figure 2.15). This is often seen in horses with large chests and well-developed pectoral muscles, such as the Quarter horse. This conformation may be accompanied by a toe-in (pigeon-toed) or toe-out (splay-footed) conformation. Base-narrow conformation inherently causes the horse to bear more weight on the outside of the foot than on the inside.

Base-Wide

In base-wide conformation, the distance between the center of the feet on the ground is greater than the distance between the center of the limbs at their origin in the chest when viewed from the front (Figure 2.16). This condition is found most commonly in narrow-chested horses and may be accompanied by toe-out (splay-footed) position of the feet. Base-wide, toe-out conformation usually causes winging of the limb to the inside (Figure 2.17). Base-wide conformation may force the horse to land on the inside of the foot, increasing weight-bearing forces on the inside of the foot and entire limb.

Toe-In or Pigeon-Toed

Toe-in is the position of the feet in which the toes point toward one another when viewed from the front (Figures 2.18 and 2.19). Its point of origin can be as high as the chest or as low as the fetlock down. It is often accompanied by a base-narrow conformation but rarely is present when the horse is base-wide. In the

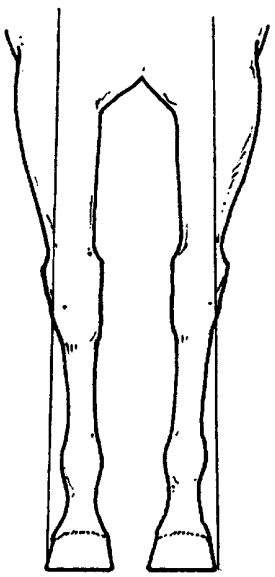

Figure 2.15. Base-narrow conformation. The distance between the center lines of the limbs is greater than the distance between the center lines of the feet on the ground.

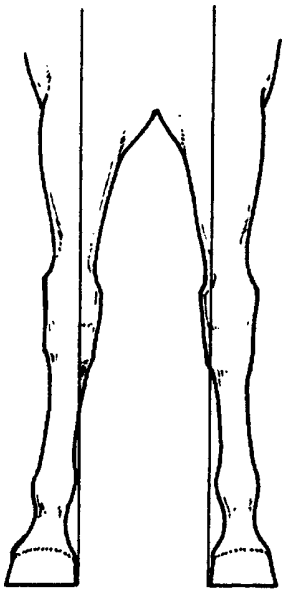

Figure 2.16. Base-wide conformation. The distance between the center lines of the feet is greater than the distance between the center lines of the limbs at the chest.

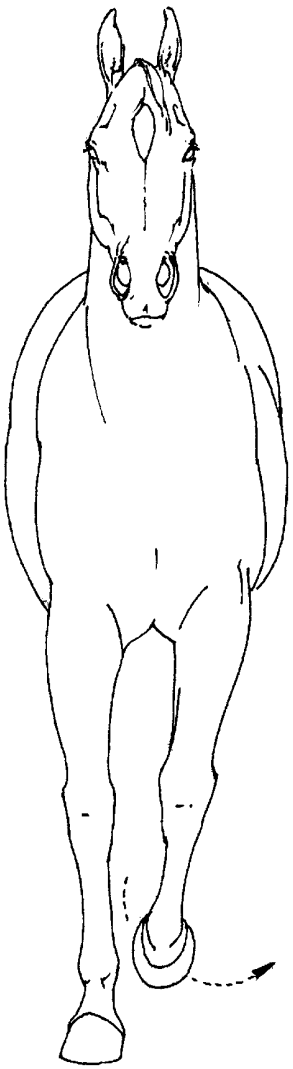

Figure 2.17. Winging, which may cause interference, is caused by a toe-out position of the foot.

VetBooks.ir

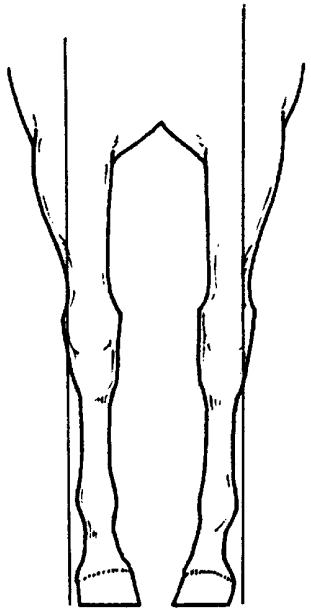

Figure 2.18. Base-narrow, toe-in conformation.

Figure 2.19. Horse with a slight varus deviation of the distal limb. Slight toe-in or pigeon-toed conformation is relatively common and does not appear to contribute to lameness in many cases.

young foal, the condition may be seen as the result of an angular limb deformity. Proper trimming and corrective shoeing of the feet may prevent worsening of the condition, especially in growing horses. One study documenting variations in conformation in Swedish Warmblood horses found a 50% frequency of mild toe-in conformation in elite sport horses, suggesting that minor deviations do not impair soundness or performance.[22]

Toe-Out or Splay-Footed

In a toe-out or splay-footed conformation, the toes point away from one another when viewed from the front (Figure 2.20). The point of origin is usually at the

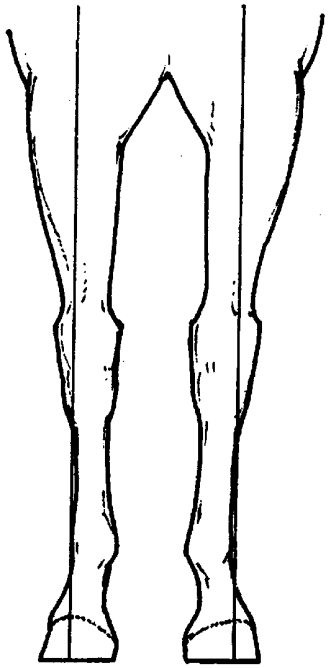

Figure 2.20. Base-narrow, toe-out conformation.

chest, but the condition can be associated with outward rotation of the fetlock. It may be accompanied by either base-wide or base-narrow conformation. As with a toe-in conformation, it may be controlled or partially corrected by corrective trimming or shoeing. The flight of the foot goes through an inner arc when advancing, contributing to interference with the opposite forelimb (Figure 2.17).

Base-Narrow, Toe-In Conformation

Base-narrow, toe-in conformation causes excessive strain on the lateral collateral support structures of carpus, fetlock, and phalangeal joints (Figure 2.18). It often causes paddling and appears to be a common conformational abnormality.

Base-Narrow, Toe-Out Conformation

Base-narrow, toe-out conformation is one of the worst types of conformation in the forelimb (Figure 2.20). The closely placed feet, combined with a tendency to wing inwardly from the toe-out position, commonly cause limb interference or plaiting. The hoof breaks over the inside toe, swings inward, and lands on the outside wall, contributing to increased strain on the limb below the fetlock. The base-narrow limb position places the weight on the outside wall, as with base-narrow, toe-in conformation.

Base-Wide, Toe-Out Conformation

When a horse is base-wide, the feet usually toe out. The base-wide conformation places the greatest stress on the inside of the limb (Figure 2.21). The foot usually breaks over the inside toe, wings to the inside, and lands on the inside hoof wall. Interference is common, similar to any type of toe-out conformation. Some horses, especially those with base-narrow, toe-out conformation, tend to place one foot directly in front of the other.

VetBooks.ir

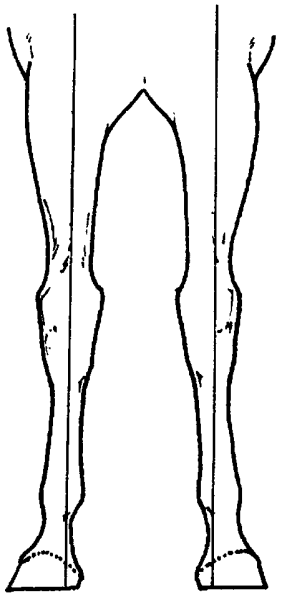

Figure 2.21. Base-wide, toe-out conformation.

This is an undesirable characteristic referred to as "plaiting," because it can produce interference and stumbling when the advancing limb contacts the one placed in front of it. Plaiting tends to be seen more commonly in the hindlimbs than the forelimbs.

Palmar (Backward) Deviation of the Carpus (Hyperextended Knees, Calf Knees)

Backward deviation of the carpus (back at the knee) is thought to place increased stress on the palmar soft tissue structures and increase compression on the dorsal aspect of the carpus (Figure 2.13). Backward knee conformation is thought to make horses working at speed more susceptible to carpal injuries, but this is not widely accepted. Hyperextension of the carpus is not the only reason for carpal injuries; long toes were associated with carpal problems in Thoroughbred racehorses in one study.[31] Additionally, injury to the palmar soft tissue structures of the carpus may contribute to this conformation, suggesting that it may not be a strictly genetic influence.

Dorsal (Forward) Deviation of the Carpus (Bucked Knees or Knee Sprung)

This condition may also be called "goat knees" or "over in the knees" (Figure 2.13). It is generally believed that "bucked knees" is a less serious problem than the calf-knee condition and may protect against carpal disease in racehorses.[29] However, severe dorsal deviation may be more dangerous for the rider because the horse's knees are on the verge of buckling forward. Forward deviation of the carpus may be caused by contraction of the carpal flexors (i.e. ulnaris lateralis, flexor carpi ulnaris, and flexor carpi radialis) in young horses and may place increased strain on the extensor carpi radialis and the suspensory ligament.[36] Congenital forms are nearly always bilateral and may be accompanied by a forward knuckling of the fetlocks. The condition is often present at birth and usually disappears by 3 months of age if it is not severe. One study documenting the variations in conformation in Swedish Warmblood horses found that considerably more elite sport horses were "buck kneed" than "calf kneed," while the reverse was true in riding school horses.[22]

Lateral Deviation of the Carpus (Bowlegs, Carpal Varus, or Bandy-Legged Conformation)

Carpal varus is an outward deviation of the carpus (or inward deviation of the distal limb) when viewed from the front of the horse (Figure 2.22A). It may be accompanied by a base-narrow, toe-in conformation. This condition increases tension on the lateral surface of the carpus and compression on the medial surface of the carpus and carpal bones (Figure 2.18). This deviation may be correctable in young horses, but growth of the knee is thought to reach a plateau at approximately

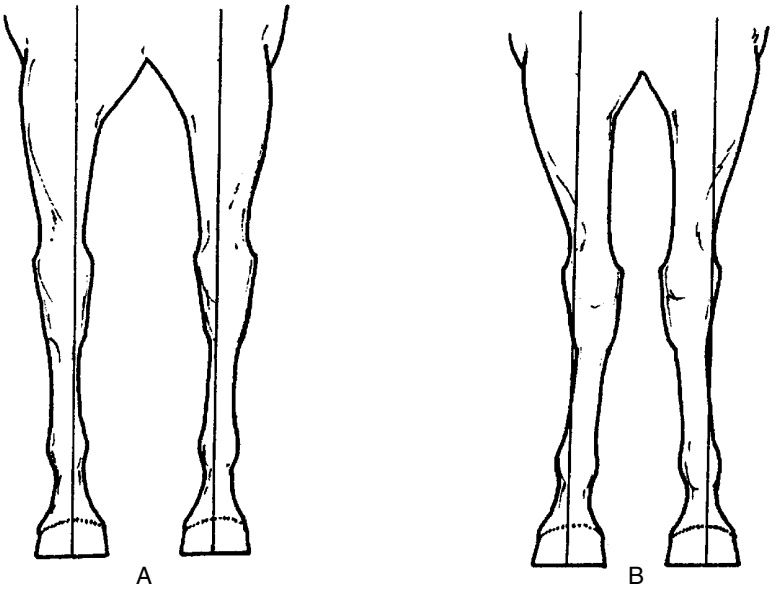

Figure 2.22. Examples of abnormal carpal conformation as compared to Figure 2.11. (A) Carpal varus or bowlegs. (B) Carpal valgus or knock knees. Some degree (<5°–7°) of carpal valgus is considered to be within normal limits in most horses.

VetBooks.ir

140 days of age in Thoroughbreds, suggesting that most carpal deviations (lateral or medial) should be corrected before this age.[38] However, carpal and fetlock conformation changed greatly in Thoroughbred foals up to 18 months of age in one study suggesting that the window of growth may be longer than previously thought.[34]

Medial Deviation of the Carpus (Knock Knees, Carpus Valgus)

Medial angular deviation of the carpus (or lateral deviation of the distal limb) can result from abnormalities of the distal metaphysis, physis, and epiphysis of the radius; from abnormal development and alignment of the carpal bones; or from carpal joint laxity (Figure 2.22B). This deviation contributes to increased tensional strain on the medial collateral ligaments of the carpus and compression forces on the lateral (concave) surface of the carpus. Varying degrees of stresses are also transmitted to the joints proximal and distal to the carpus. Varying degrees of outward rotation of the cannon bone, fetlock, and foot may accompany this entity. Mild carpal valgus (5°–7°) may have a protective mechanism against carpal injuries, as the odds for carpal fracture and effusion decreased with an increase in carpal angle in Thoroughbred racehorses.[2] However, in a study of National Hunt racehorses, carpal valgus conformation was associated with an increased risk for SDF tendon injury.[41] In the same study, valgus deformations of the carpus, fetlock, and tarsus were all associated with an increased risk of injury and considered to be detrimental to performance.[41]

Bench Knees (Offset Knees)

Bench knee is a conformation in which the cannon bone is offset to the lateral side and does not follow a straight line down from the radius when viewed from the front (Figure 2.23). Increased weight-bearing on the medial splint bone is thought to occur in bench-kneed horses. This is thought to contribute to increased stress on the interosseous ligament predisposing to "splints." In a study documenting the conformational abnormalities in 356 Warmblood horses, more than 50% were bench kneed.[22] The combination of bench knees and carpal valgus is common, and offset knees has been associated with fetlock problems in racing Thoroughbreds.[2]

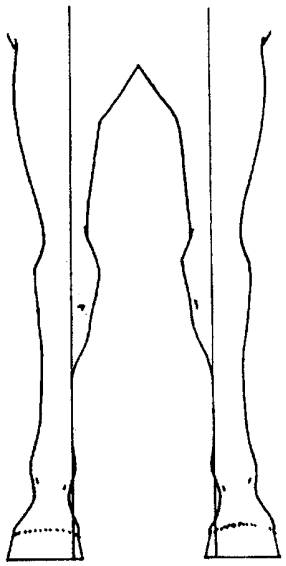

Figure 2.23. Offset knees (bench knees), which are characterized by the cannon bones being set too far laterally.

Short Upright Pastern

A short upright pastern is believed to increase concussion and injuries to the fetlock and phalangeal joints, the navicular bone region, and soft tissue structures within the metacarpus (Figure 2.24).[29,36] If the angle of the hoof is more upright than that of the pastern, it is referred to as a broken-forward hoof-pastern axis.[21] This type of conformation is often associated with a base-narrow, toe-in conformation and is often seen in horses with short limbs and a powerful body and limb musculature. Additionally, a straight shoulder (more vertical) usually accompanies a short upright pastern.

Long Sloping Pastern

A long sloping pastern is characterized by a normal or subnormal angulation of the forefoot (less than 50°–54°) with a pastern that is too long for the length of the limb (Figure 2.25). If the angle of the hoof is more acute (lower) than that of the pastern, it is referred to as a broken-backward hoof-pastern axis.[21] It is often seen in horses with long toes and/or low heels and may

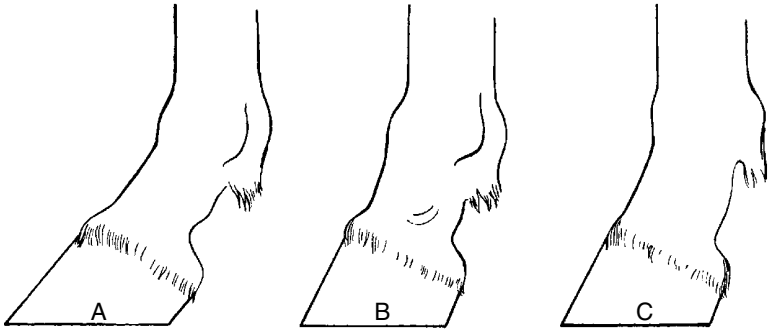

Figure 2.24. Examples of pastern conformation. (A) A normal angulation of hoof wall and pastern. (B) A short upright pastern. (C) A long upright pastern.

VetBooks.ir

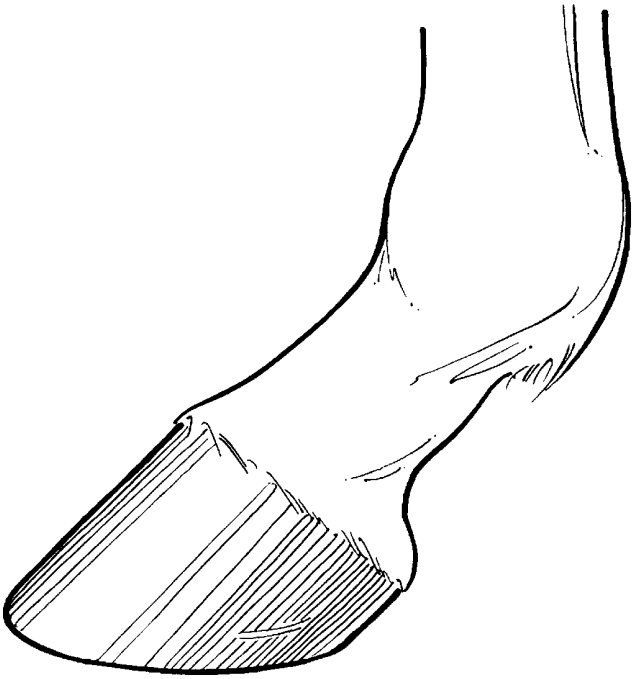

Figure 2.25. Example of a long sloping pastern that is often associated with a broken-back hoof-pastern axis. A long toe and a low heel often contribute to this conformation. The weight-bearing surface of the foot is well forward of the metacarpus/metatarsus.

predispose a horse to injury of the navicular region, flexor tendons, sesamoid bones, and suspensory ligament (Figure 2.25).[36] Long pasterns were also found to increase the odds of Thoroughbred racehorses fracturing a front limb,[2] and the risk of SDF tendon injury increased with an increase in fetlock joint angle in a study of National Hunt racehorses.[41]

The Hindlimbs

The hindlimbs constitute the "engine" of the horse regardless of its intended use. Endurance horses typically have longer, flatter muscles, stock horses have shorter, thicker muscles, and all-around horses have moderate muscling. Lack of hindlimb musculature or a disparity between the forelimb vs. hindlimb muscle mass may suggest chronic hindlimb lameness problems.

Lateral View

When viewed from the side, the hindlimbs should exhibit a composite of moderate angles so that shock absorption will be efficient (Figure 2.26). A line from the point of buttock to the ground should touch the hock and end slightly behind the bulbs of the heels. A hindlimb in front of this line is often standing under (Figure 2.27) or sickle hocked (Figure 2.28); a hindlimb behind this line is often post-legged (Figure 2.29) or camped out (Figure 2.30). The hindquarter should be symmetric and well connected to the barrel and the lower limb. The gluteal muscles should tie well forward into the back, and the hamstrings should extend down low into the Achilles tendon of the hock.

Figure 2.26. Normal hindlimb conformation as viewed from the side. A line dropped from the point of the buttock (tuber ischii) should follow the cannon bone.

The relationship of the length of the bones, the angles of the joints, and the overall height of the hindlimb often dictate the type of action and amount of power produced. The length and slope to the pelvis (croup) are measured from the point of the hip to the point of the buttock. A flat, level croup is associated with hindlimb action that occurs behind the hindquarters rather than underneath it. A "goose rump" is a very steep croup that places the hindlimbs so far under the horse's belly that structural problems may occur due to the overangulation. Somewhere between these two extremes is ideal. In general, a more flexed hip causes a more protracted position of the hindlimb at the stance phase and a more horizontal femur during the swing phase. The coxal angle (angle between the ilium and ischium) was recently shown to have a positive effect on performance in National Hunt racehorses, and the risk of pelvic fractures decreased with an increasing coxal angle.[3,41]

Probably the most important individual conformational detail in sport horses is the femur. A long and forwardly sloping femur places the hindlimbs more under the horse, which allows the horse to keep its balance more easily because the limb is closer to the center of gravity.[21,22] A forwardly sloping femur has also been shown to have a positive effect on soundness. A long femur is thought to result in a longer stride with more reach. A short femur is associated with the short, rapid

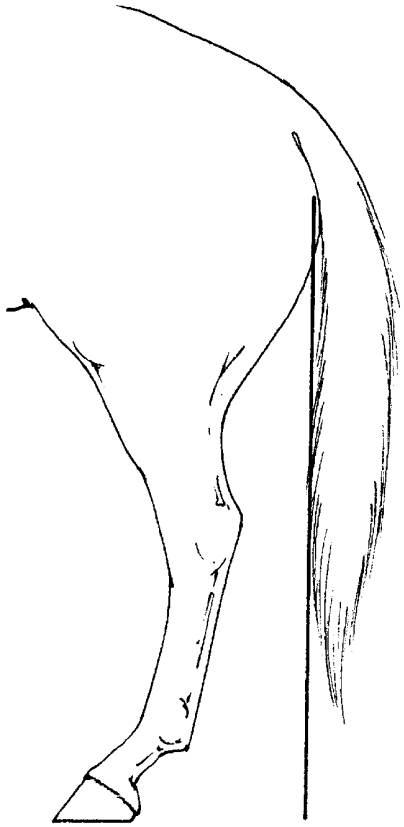

Figure 2.27. Standing under behind (compare with Figure 2.26).

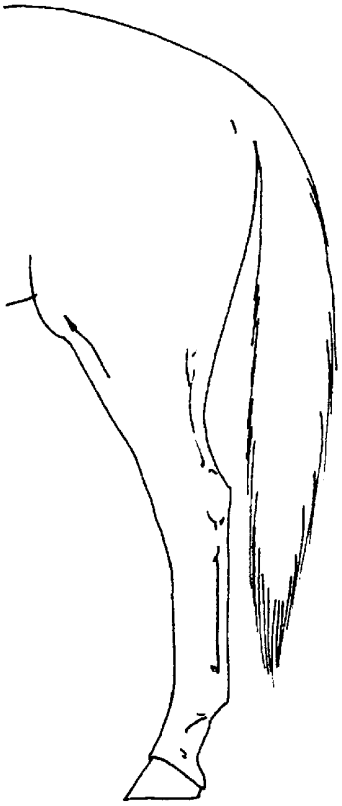

Figure 2.29. Post-legged refers to too little angulation of the hock and stifle joints. The hock is very straight and angles of more than 165°–170° are considered to be abnormal.

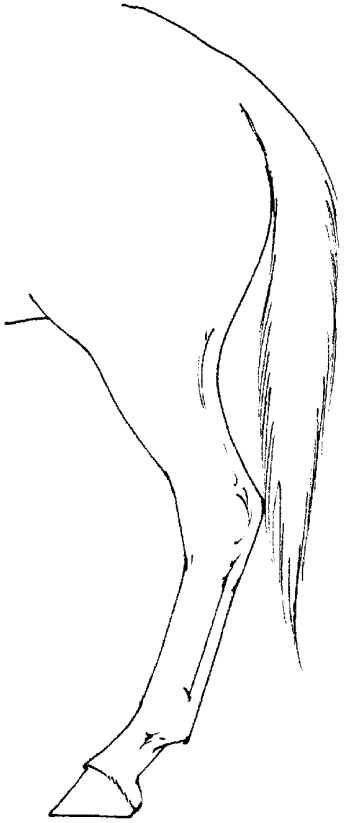

Figure 2.28. Sickle hocks. The angle of the hock looks excessive but is actually less than normal. Hocks with an angle of less than 150°–153° are considered to be sickle.

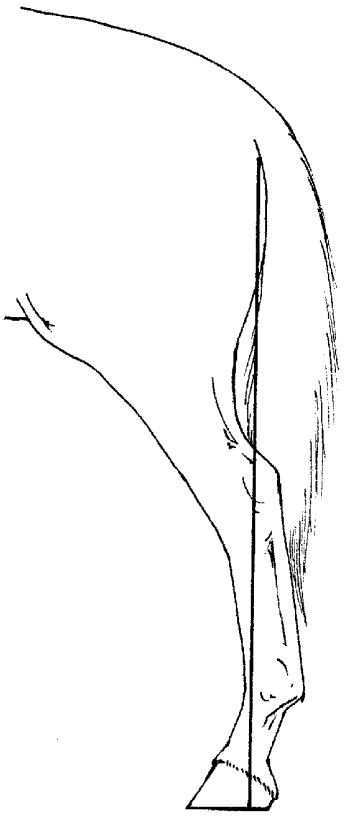

Figure 2.30. Camped out behind (compare with Figure 2.26).

VetBooks.ir

stride characteristic of a sprinter. The gaskin length (stifle to hock) should be shorter than the femur length (buttock to stifle). A gaskin length longer than the femur length tends to be associated with cow hocks and sickle hocks.

Hindlimbs with less angulation (open angles, straighter hindlimbs when viewed from the side) usually have a shorter overall limb length and produce efficient movement suitable for hunters or racehorses. Generally, hindlimbs with more angulation (closed joints) have a longer overall limb length and produce a more vertical, folding action necessary for collection characteristic of dressage horses.[36] An overall limb length that is too long may contribute to either a camped-out or sickle-hocked conformation. Elite Warmblood horses were found to have larger hock angles (straighter) than other groups of horses.[22] Horses with lameness and back problems usually have significantly smaller hock angles than sound horses.[21]

Caudal View

From the rear, both hindlimbs should be symmetrical, have the same length, and bear equal weight (Figure 2.31). A left-to-right symmetry should be evident between the peaks of the croup (tuber sacrale), the points of the hip, the points of the buttock, and the midline position of the tail. A study in Standardbred trotters found that hindquarter asymmetry (tuber sacrale at unequal heights) and associated factors had a negative effect on performance (Figure 2.32).[14] In addition, poor development of the epaxial muscles in the thoracolumbar region and asymmetry of the hindquarter musculature but not asymmetry of the tuber sacrale were common findings in sport horses with documented sacroiliac disease.[16] The widest point of the hindquarters should be the width between the stifles. A line dropped from the point of the buttock to the ground should essentially bisect the limb; however, the

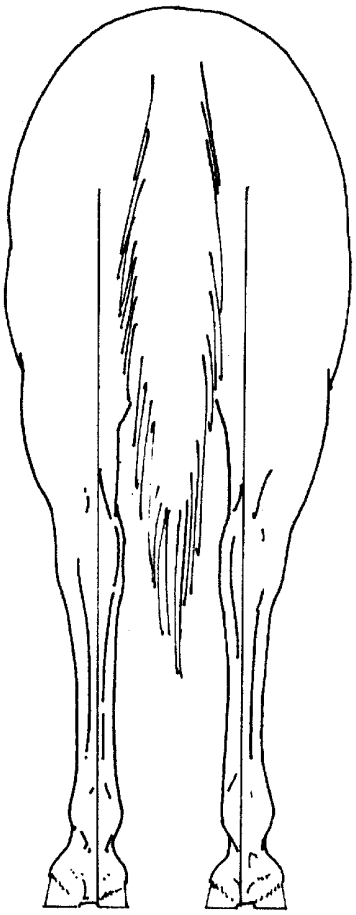

Figure 2.31. Normal hindlimbs as viewed from the rear. A line dropped from the point of the buttock (tuber ischii) should bisect the limb.

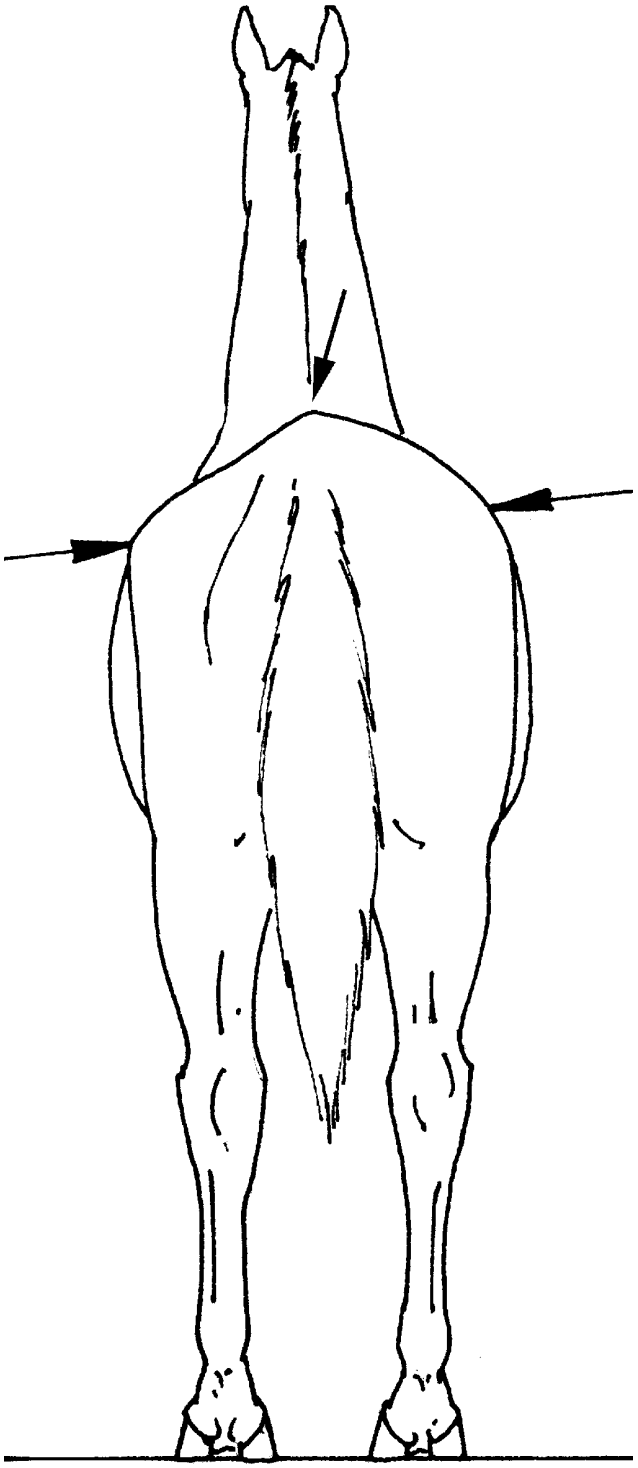

Figure 2.32. Asymmetry between the peaks of the croup, points of the hip, and points of the buttock (arrows).

VetBooks.ir

hindlimbs are not designed to point absolutely straight forward.[29] About 80% of all Warmblood riding horses and Standardbred trotters have outwardly rotated hindlimbs.[21] It is also normal for the stifles to point slightly outward, which in turn causes the points of the hocks to face slightly inward and the toes to point slightly outward. When the cannon bone faces outward, the horse is considered to be cow-hocked (Figure 2.33); when the cannon bones face inward, the horse is bowlegged (Figure 2.34).

Faults in Conformation of the Hindlimbs

Excessive Angulation of the Hock (Sickle Hocks, Small Hock Angles)

Mean hock angles in normal horses are thought to be approximately 155°–165°.[18,21] Hock angles less than 150°–153° are considered sickle (Figure 2.28).[21,29] When viewed from the side, the angle of the hock is decreased so that the horse is standing under from the hock down. This places the hock under greater stress and may predispose to synovial distension in the stifle and hock joints and bone spavin.[21,29] A small tarsal angle was significantly associated with radiographic signs of OA in the distal tarsus in a large number of Icelandic horses.[3] Small hock angles may also impair a horse's ability to attain the level of collection required for good performance in advanced classes. One study on elite Swedish Warmblood sport horses found that none of the show jumpers and only one of the dressage horses were "sickle hocked."[22]

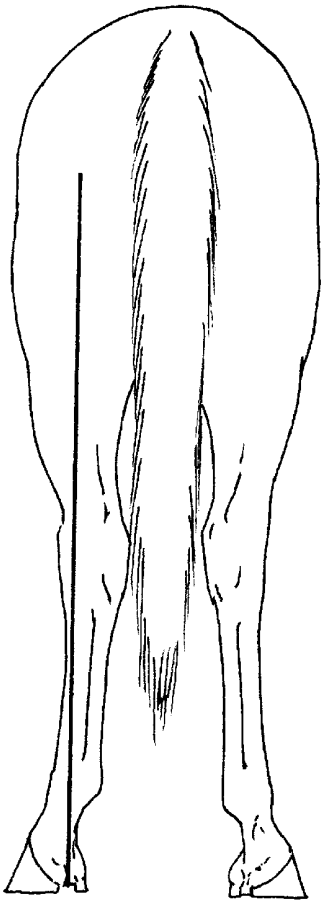

Figure 2.33. Cow hocks accompanied by base-wide conformation (compare with Figure 2.26). Such horses are often base-narrow at the hocks and base-wide from the hocks down.

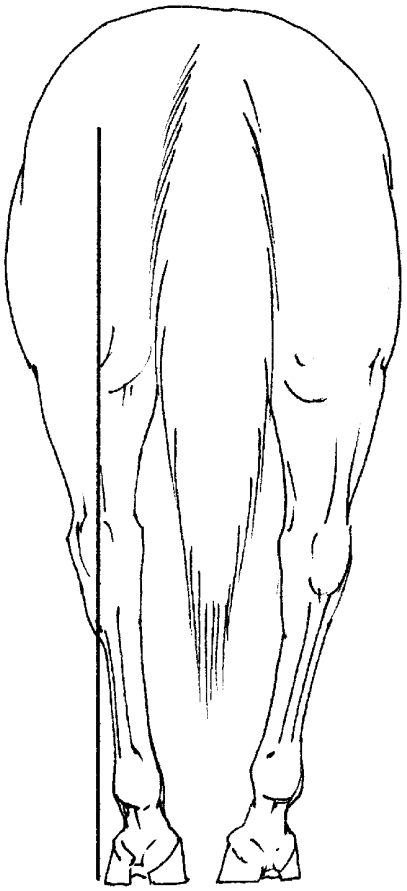

Figure 2.34. Base-narrow behind (compare with Figure 2.32). This is often accompanied by "bowlegs," as shown.

Excessively Straight Limbs, "Straight Behind"

When viewed from the side, there is very little angle between the tibia and femur, and the hock is excessively straight (large hock joint angle of more than 165°–170°) (Figure 2.29).[18,29] This is believed to predispose the horse to bog spavin, thoroughpin, upward fixation of the patella, and hindlimb proximal suspensory disease (PSD).[17,29,36] Older horses with straight angles are also prone to degenerative suspensory disease, and the prognosis of horses treated surgically for hindlimb PSD is negatively associated with straight hock conformation.[17] Horses with large tarsal angles showed less tarsal flexion and less energy absorption at the tarsus during the impact phase, potentially contributing to the development of OA.[18] Generally, the pastern conformation is usually too straight when the tarsus is too straight.

Medial Deviation of the Hock (Cow Hocks or Tarsal Valgus)

"Cow-hocked" means that the limbs are base-narrow down to the hock and then base-wide from the hock to the feet (Figure 2.33). The hocks are too close together and

VetBooks.ir

point toward one another, and the feet are widely separated. Cow-hocked conformation is a common defect, and some believe that it is a serious hindlimb conformation flaw.[36] However, others feels that a slight valgus deformity of the hindlimbs, provided that the metatarsal bones remain vertical, is not a cause for concern.[29] Sickle hocks and cow hocks can occur concurrently and may have a compounding effect on hindlimb lameness problems.

Base-Narrow

Base-narrow conformation of the hindlimbs means that the distance between the center of the feet is less than the distance between the center of the limbs in the thigh region, when viewed from behind (Figure 2.34). This is observed most commonly in heavily muscled horses. It causes excessive strain on the lateral aspect of the limb, and most of the horse's weight is placed on the outside of the hooves. Base-narrow conformation is often accompanied by "bowlegs" or a condition in which the hocks are too far apart. The limbs may appear fairly straight to the hock and then deviate inward, and the hocks may bow outward during movement.

Conformation of the Foot

Hoof anatomy and conformation are also discussed in Chapters 1 and 11.

The Forefoot

Ideally, the forefoot should be round and wide in the heels, and the size and shape of the heels should correspond to the size and shape of the toe. The bars should be well developed (Figure 2.35). The wall should be thickest at the toe and should thin gradually toward the heels; the inside wall should be slightly straighter than the outside wall. The sole should be slightly concave medial to lateral and front to back, but excessive concavity may suggest a chronic foot problem. There should be minimal contact between the ground and the sole, and toe lengths of greater than 1 1/2 inches cranial to the apex of the frog when viewed from the bottom of the foot may suggest excessive toe length.

The mean hoof angle of the forefoot is usually 50°–55°, and the angle of the heel should be approximately the same as the angle of the toe.[4,9] However, the angle of the hoof is less important than the hoof-pastern axis when evaluating foot conformation. Toe wall length relative to heel wall length should be approximately 2 : 1 in the forefoot and 2 : 1.5 in the hindfoot.[4] Break-over should occur squarely over the center of the toe and not over the medial or lateral portions of the toe. The frog should be large and well developed with a good cleft, have normal consistency and elasticity, and be dry and soft. It should divide the sole into two nearly equal halves, and the apex should point to the center of the toe. In most horses, the apex of the frog should end approximately 1–1 1/2 inches behind the toe.[7]

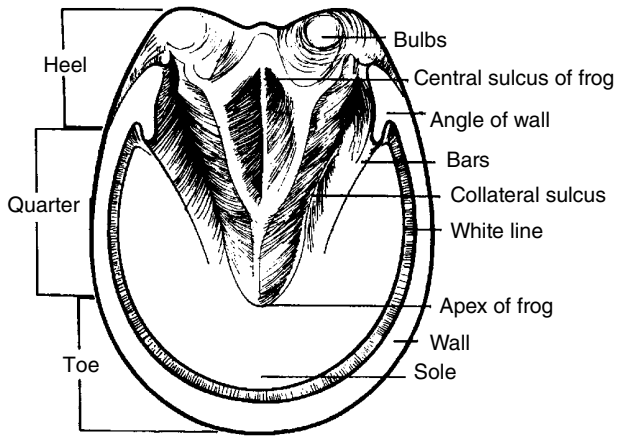

Figure 2.35. Normal forefoot with structures labeled.

The Hindfoot

The hindfoot is usually narrower, has a larger hoof angle, and has a more pointed appearance at the toe than the forefoot (Figure 2.35).[4,5] Break-over should be evident straight over the toe, and the frog should divide the sole into equal halves. The mean hoof angle in the hindfoot is usually 55° or greater, and there should be no defects in the wall.[4,36] The sole of the hindfoot is normally more concave than that of the forefoot.

Medial–Lateral Hoof Balance

ML hoof balance is often used to describe the relationship between the two halves of a hoof when viewed from the front and the levelness of the coronary band compared to the ground surface (Figure 2.37). It is used to assess the symmetry (or asymmetry in many cases) and can suggest the type of concussive forces on the hoof wall. In general, the coronary band should be level medial to lateral and parallel to the ground. In addition the lateral and medial aspects of the hoof wall should be approximately the same length and angle.

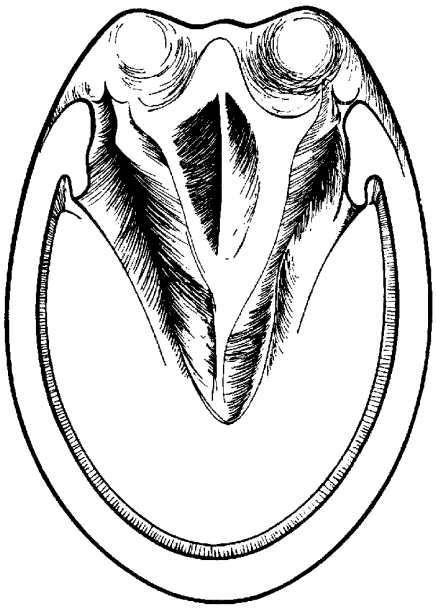

Figure 2.36. Normal hindfoot (compare with Figure 2.35). The toe of the hindfoot is more pointed than that of the forefoot.

VetBooks.ir

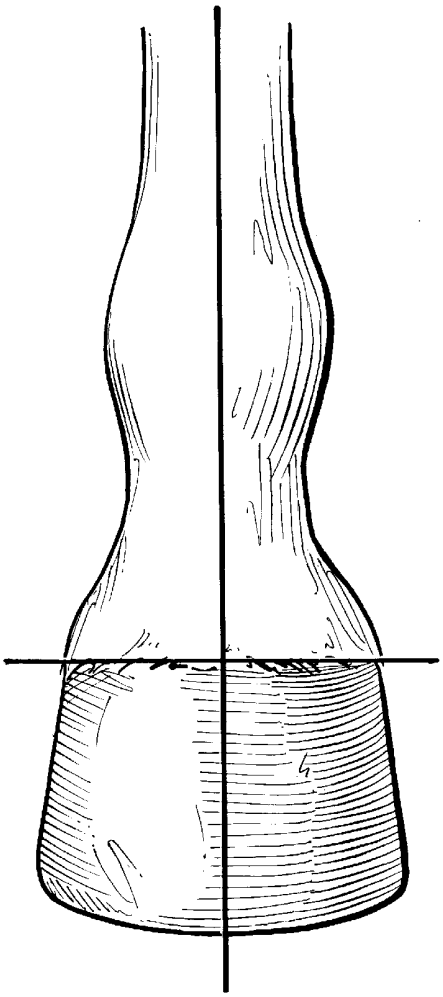

Figure 2.37. A hoof is considered to be in ML balance when an imaginary line through the coronet is parallel to the ground surface and perpendicular to a line that bisects the limb axis when viewed from the front.

Abnormal Conformation of the Foot

Flat Feet

A flat foot lacks the natural concavity in the sole; it is not a normal condition in light horses but is present in some draft breeds. Flat feet may be heritable and are observed more commonly in the forefeet than in the hind. The horse may land on the heels to avoid sole pressure with this condition. Sole bruising is a common sequela of flat feet. There is no known cure for flat foot, but corrective shoeing may help prevent resultant lameness.

Contracted Foot or Contracted Heels

A contracted foot is a condition in which the foot is narrower than normal, especially the back half of the foot (Figure 2.38). This condition is much more common in the front feet than in the hindfeet, and it may be unilateral or bilateral. Hoof contraction can occur rapidly in the heels with a long-toe, low-heel conformation, resulting in a low hoof angle.[7] Heel contraction also occurs with disuse of the foot as is seen with chronic lameness conditions. Heel contraction can be quantified using several techniques (Figure 2.39).

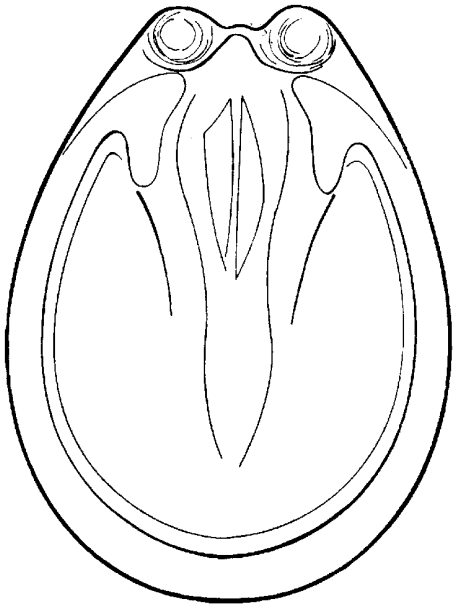

Figure 2.38. Contracted foot illustrating narrowing of the heels and quarters (compare with Figure 2.35).

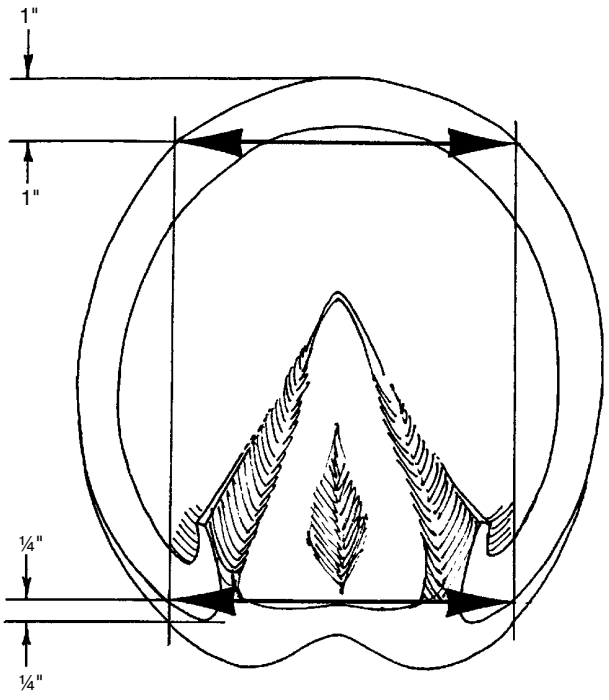

Figure 2.39. One method to quantify heel contraction. The width of the heels 1/4 inch from the heel buttresses should equal or exceed the width of the trimmed foot 1 inch behind the toe.

Certain breeds of horses normally have a foot that more closely approaches an oval than a circle in shape. A narrow foot is not necessarily a contracted foot; donkeys and mules normally have a foot shape that would be called contracted in a horse. Foot contraction may be present in the Tennessee Walking Horse and American

VetBooks.ir

Saddlebred when these horses are used for show because the hoof wall is allowed to grow excessively long.

A unilateral contraction of one forefoot may be present in some horses. This may be congenital or developmental, but it is not known whether it is a heritable abnormality. The contracted foot may or may not eventually show lameness, but it should be regarded as an undesirable feature. A small foot on one side with a normal opposite foot may be normal for certain horses, but it may also indicate a subclinical lameness in the foot with the steeper hoof angle.[42] This is often referred to as "mismatched" or "uneven" feet. In a recent study of Dutch Warmblood horses, the prevalence of "uneven" front feet was 53% with weak genetic correlations. However, the study concluded that reducing the occurrence of uneven feet by selection was possible without limiting progress in sport horse performance.[15]

Buttress Foot

"Buttress foot" is a swelling above the dorsal surface of the hoof wall at the coronary band (Figure 2.40). This swelling may be from low ringbone or a fracture of the extensor process of the distal phalanx (coffin bone). A conical deformity of the toe from the coronary band to the ground surface occurs due to the deformed hoof growth associated with chronic swelling at the coronary band. This often results in a triangular or pyramidal shape to the foot (Figure 2.41).

Club Foot

A "club foot" usually refers to a foot with a foot axis greater than or equal to 60° (Figure 2.42). A unilateral club foot may be due to an injury that has prevented proper use of the foot (disuse due to chronic lameness) or from a flexural deformity involving the deep digital flexor tendon, seen primarily in foals. It may be developmental or acquired and may or may not contribute to a lameness problem.[7,29]

PALPATION AND MANIPULATION

Gary M. Baxter and Ted S. Stashak

Palpation of the musculoskeletal system is a very important aspect of any lameness evaluation.[2] With practice and experience, subtle abnormalities can be detected that are often indicative of the site of the problem. Thorough palpation of the patient is often performed prior to observing it at exercise, but this is often patient and clinician dependent. Most manipulative tests are performed after exercise. A systematic approach of palpation is recommended to avoid missing abnormalities. One approach is to palpate the forelimb proximally to distally in a weight-bearing position and then distally to proximally with the limb picked up or unweighted (Video 2.1).[2] Palpation of the hindlimbs can be performed in the same manner, paying close attention to the medial aspects of the stifle and tarsus (Video 2.2). The back and axial skeleton are usually palpated last because some horses become agitated with manipulation of the back (Video 2.3). Hoof tester examination of the feet is usually performed after the entire musculoskeletal system has been palpated. The following discussion briefly describes techniques to visually examine, palpate, and manipulate the different anatomic regions of the equine musculoskeletal system to ensure a complete examination.

FOOT

The size and shape of the foot on the lame limb should be compared to its opposite member. The examiner is looking for asymmetry in foot size, abnormal hoof wear, ring formation and heel bulb contraction, shearing of the heels and quarters, hoof wall cracks, swellings that are primarily associated with the coronet, and foot imbalances.[15,17] Asymmetry in foot size may be a result of trauma, lack of weight-bearing leading to contraction, and congenital or developmental defects. In general, the limb with the smallest foot is usually the lame limb. Hoof wall ring formation can be unilateral (trauma) or bilateral and is not always associated with lameness (Figure 2.43). Heel contraction often results from decreased weight-bearing of the affected limb and is usually a symptom rather than the cause of the lameness (Figures 2.44 and 2.45). Visual examination of heel bulb contraction is best performed with the examiner standing or squatting near the flank and looking at both right and left heel bulbs at once (Figure 2.44). Asymmetry in heel bulb height (sheared heels) is most frequently associated with improper trimming and shoeing. Foot imbalances can either be dorsopalmar/plantar (DP), lateral/medial (LM), or a combination of the two (Figures 2.44 and 2.45). These imbalances often alter the shape of the hoof wall and can result in abnormal stresses applied to the foot and other support structures.

After superficial cleaning of the sole, abnormal wear on the shoe and/or sole, collapsed heels, heel bulb contraction, and frog atrophy should be noted (Figure 2.46). Secondary frog atrophy may accompany heel contraction

Figure 2.43. Bilaterally symmetrical hoof wall rings that were not associated with lameness or any other known problem within the hoof wall.

Figure 2.44. View of both front feet in a horse with forelimb lameness. The front feet of the same horse as viewed from the side are illustrated in Figure 2.45. The medial wall of the right foot is concave with the coronary band pushed proximally suggesting excessive concussion. In addition the heels are contracted and overgrown.

in chronic cases. The sole should be slightly concave. Some horses are flat-footed and therefore predisposed to sole bruising. Convexity of the sole dorsal to the apex of the frog ("dropped soles" in front of the frog) is considered abnormal and is often associated with rotation of the distal phalanx. In some cases, the offending cause of lameness may be identified immediately, such as a nail wedged in the frog (Figure 2.47). However, the clefts of the frog may need to be opened with a knife to properly evaluate the depths of the sulci for evidence of thrush or canker.

The hoof wall should be checked for cracks that may extend into the sensitive laminae (they are most common in the toe and quarter), uneven wear, and excessive

VetBooks.ir

Figure 2.45. Front feet of the horse in Figure 2.44 as viewed from the side. The front feet have markedly different hoof angles. The right foot has contracted heels resulting in a very upright conformation compared to a low underrun heel with a long toe on the left foot, resulting in a low hoof conformation. In addition, the coronary band on the right has an abnormal contour suggesting foot imbalance.

Figure 2.46. A front foot with severely overgrown heels that have resulted in atrophy of the frog. The frog should be prominent and approximately level with the widest part of the heels.

dryness (Figure 2.48). Dishing (concavity) of the dorsal aspect of the hoof wall is often indicative of chronic rotation of the distal phalanx, excessive toe length, or a flexural deformity involving the deep digital flexor tendon (DDFT) (Figure 2.49).

A hoof tester is an instrument that permits deep palpation of the sole, frog, and wall of the hoof (Figure 2.50). When applied properly, the examiner tries to identify and localize hoof sensitivity (Video 2.4). Most normal horses should be able to withstand a fair bit of hoof tester pressure without showing signs of discomfort. The arm of the hoof tester that is applied to the hoof wall is continually checked so pressure is not being applied to the coronary band.

Figure 2.47. This horse presented for an acute onset hindlimb lameness. A nail was found protruding from the apex of the frog. Based on the location, entry into the navicular bursa would be unlikely.

Figure 2.48. Partial-thickness dorsal hoof crack associated with a long toe and a concavity of the dorsal hoof wall. Both factors most likely contributed to the development of the crack in this horse.

The order of hoof tester application is less important than being systematic and complete (Video 2.4). One method is to begin at the lateral or medial angle of the sole and continue hoof tester pressure at 2- to 3-cm intervals until the entire surface of the sole is checked. This is followed by pressure applied to the frog (caudal, central, and cranial) from both the medial and lateral heel. Lastly,

VetBooks.ir

Figure 2.49. Concavity of the left front foot in a horse with chronic laminitis. This horse was most lame in the left forelimb.

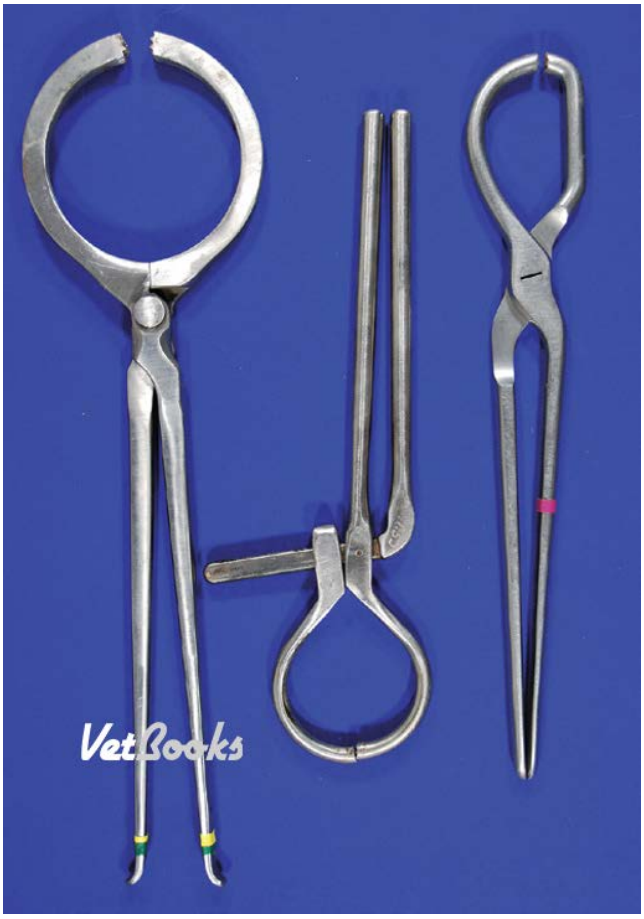

Figure 2.50. Examples of several types of hoof testers. Left: GE Forge and Tool Works, 959 Highland Way, Grover Beach, CA, 93433. Middle, Ryding Hoof Tester, Jorgenson Labs, 2198 W 15th St., Loveland, CO, 80537. Right: Kane Enterprises, AG-TEK Division, P.O. Box 1043, Sioux Falls, SD, 57101.

the hoof tester is applied to the hoof wall across the heels, and then it can be applied diagonally from the medial heel to the dorsolateral hoof and then from the lateral heel to the dorsolateral hoof. If sensitivity is encountered, it is necessary to confirm whether the response is from pain and not just a whimsical reaction by the horse. Repeatability is the key to being confident with your findings. True sensitivity is identified by repeated intermittent hoof tester pressure that results in persistent reflexive withdrawal (flexing the shoulder and trying to take the foot away) with hoof tester pressure. Obviously varying amounts of hoof tester pressure are applied to elicit a response, and this is dependent on sole thickness and the painfulness of the condition. Hoof tester responses should be compared with those obtained from the opposite foot.

In general, diffuse sole sensitivity may suggest a sagittal fracture of the distal phalanx, extensive sole bruising, and in some cases laminitis. More localized hoof tester sensitivity is usually obtained with sole bruising, puncture wounds, close or hot nail, and localized subsolar abscesses. Hoof tester sensitivity over the central third of the frog is usually consistent with pain in the region of the navicular bone (Figure 2.51). A hoof tester or a hammer can also be used to strike (percuss) the hoof wall. A painful response may be suggestive of laminitis or a defect along the hoof wall. A hollow sound over the dorsal hoof wall may suggest separation between the sensitive and insensitive laminae (e.g. white line disease, chronic laminitis, etc.).

The coronary band should be palpated for heat, swelling, and pain on deep pressure. Effusion of the distal interphalangeal (DIP) joint is usually palpable just dorsal and proximal to the coronary band (Figure 2.52).[2,5] Using both hands can facilitate determining if the swelling is fluid or thickened tissue. Firm, often nonpainful swelling in this region may also be evidence of low ringbone. Heat, pain, and swelling with or without drainage of one of the heel bulbs are often found in horses with subsolar abscesses (Figure 2.53) as many of these abscesses tend to break out in the heel bulb region.

Figure 2.51. A Ryding Hoof Tester being applied over the central third of the frog of the forefoot to produce direct pressure over the navicular region.

VetBooks.ir

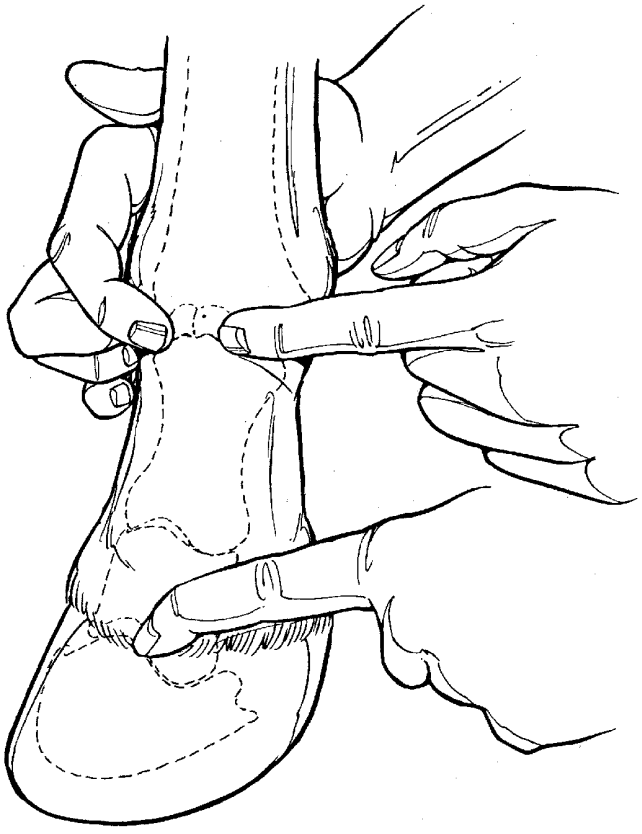

Figure 2.52. Lower finger marks the site of swelling and pain associated with fracture of the extensor process. Upper fingers are applied over the dorsal aspect of the fetlock to identify synovial distension and thickening of the joint capsule.

PASTERN

The dorsal, medial, and lateral surfaces of the proximal interphalangeal (PIP) joint should be palpated for enlargement and heat, which may be suggestive of high ringbone (Figure 2.54). Comparison to the opposite pastern is always recommended. However, it is not uncommon to have the lateral to medial dimensions of one pastern to be slightly larger than its opposite member. With the limb off the ground, the distal sesamoidean ligaments and flexor tendons (superficial and deep digital flexors) are palpated deeply for pain, heat, and swelling (Figure 2.55). Particular attention is paid to the lateral and medial branches of the superficial digital flexor tendon (SDFT) as they attach to the middle phalanx. Tendonitis of the DDFT and/or tenosynovitis of digital flexor tendon sheath (DFTS) are often identified by swelling, effusion, and sometimes pain in this region. Pain on deep palpation of the DDFT just above the heel bulbs using your thumb may be suggestive of injuries to the tendon further distally in the hoof capsule. Deep palpation of the lateral and medial eminences (wings) of the middle phalanx may elicit pain if a fracture is present. With the hands placed on the hoof wall, the phalangeal joints should be rotated medially and laterally. The collateral ligaments can be stressed, laterally and medially, by placing one hand lateral or medial over the pastern joint, while the other hand is used to pull the foot toward that side (Figure 2.56). This bending force creates increased tension on the collateral ligaments of the phalangeal joints.

Figure 2.53. Palpation of the heel bulbs to identify heat, pain, and swelling that may be associated with subsolar abscesses.

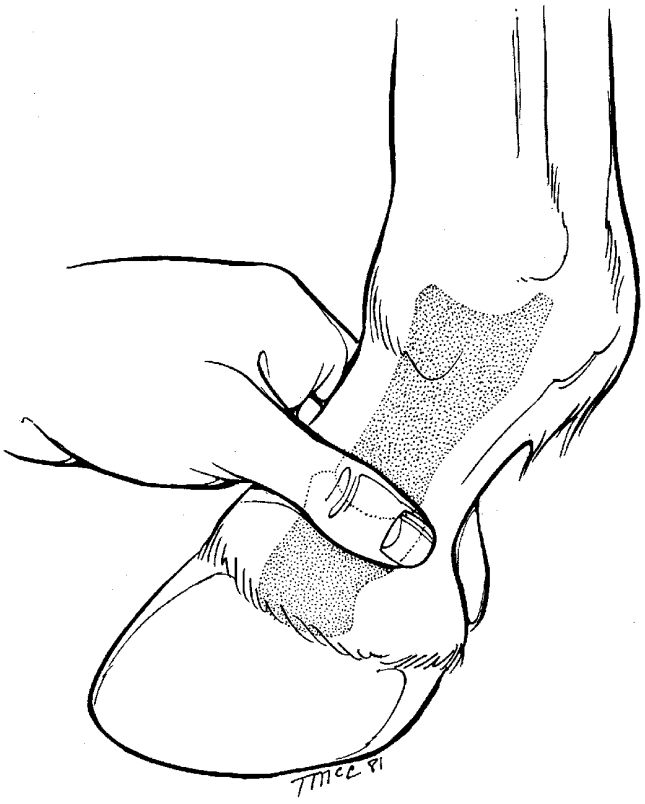

Figure 2.54. Palpation of the pastern. Thickening in this region may suggest the presence of ringbone.

VetBooks.ir

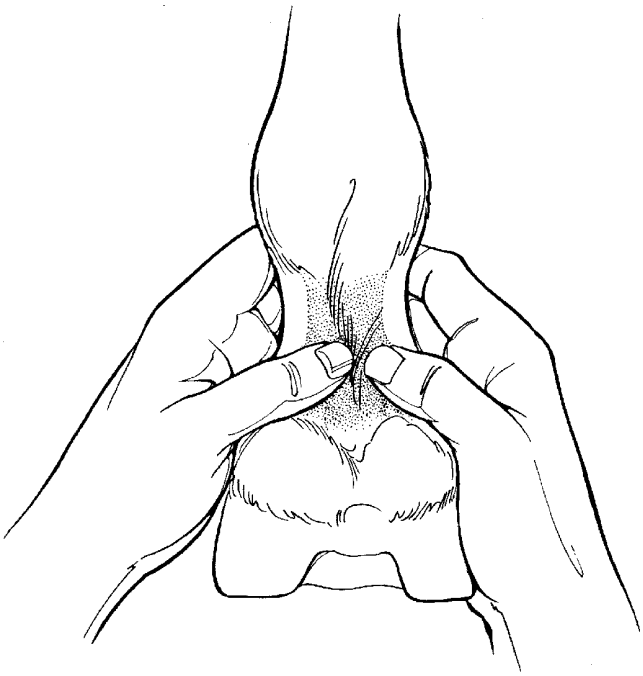

Figure 2.55. Palpation of the distal sesamoidean ligaments, branches of the superficial digital flexor tendon (SDFT), and the deep digital flexor tendon (DDFT) in the palmar/plantar aspect of the pastern. The DDFT should be palpated with digital pressure using your thumb as far distally as possible between the heel bulbs.

FETLOCK

The dorsal and palmar/plantar pouches of the metacarpophalangeal/metatarsophalangeal (MCP/MTP) joint should be palpated for swelling, effusion, or thickening of the joint capsule (Figures 2.52 and 2.57). Using both hands to help palpate the multiple joint pouches is very helpful.[2] Pressure should be applied to the lateral and medial branches of the suspensory ligament just above their attachments to the proximal sesamoid bones. Pain and/or swelling at this location may suggest desmitis of the suspensory branch, sesamoiditis, or apical/abaxial fractures of the sesamoid bone. The SDFT and DDFT and digital sheath should also be palpated for heat, pain, swelling, or effusion. Some distension of the DFTS of all four limbs is not uncommon in performance horses. This often is referred to as "wind puffs."

With the limb off the ground, thumb or finger pressure should be applied to the basilar, body, and apical portions of the proximal sesamoid bones (Figure 2.58). Sensitivity and pain may indicate a sesamoid fracture or desmitis of the suspensory ligament. The fetlock should be rotated and the collateral ligaments checked in a similar manner to that of the pastern joint (Figure 2.56). Additionally, the fetlock joint should be passively flexed to identify pain and assess the range of motion. This is accomplished by extending the carpus as much as possible and flexing the fetlock by placing one hand on the pastern (Figure 2.59). This technique flexes the fetlock joint separate from the phalangeal joints in contrast to all of the joints of the distal limb (Figure 2.60).

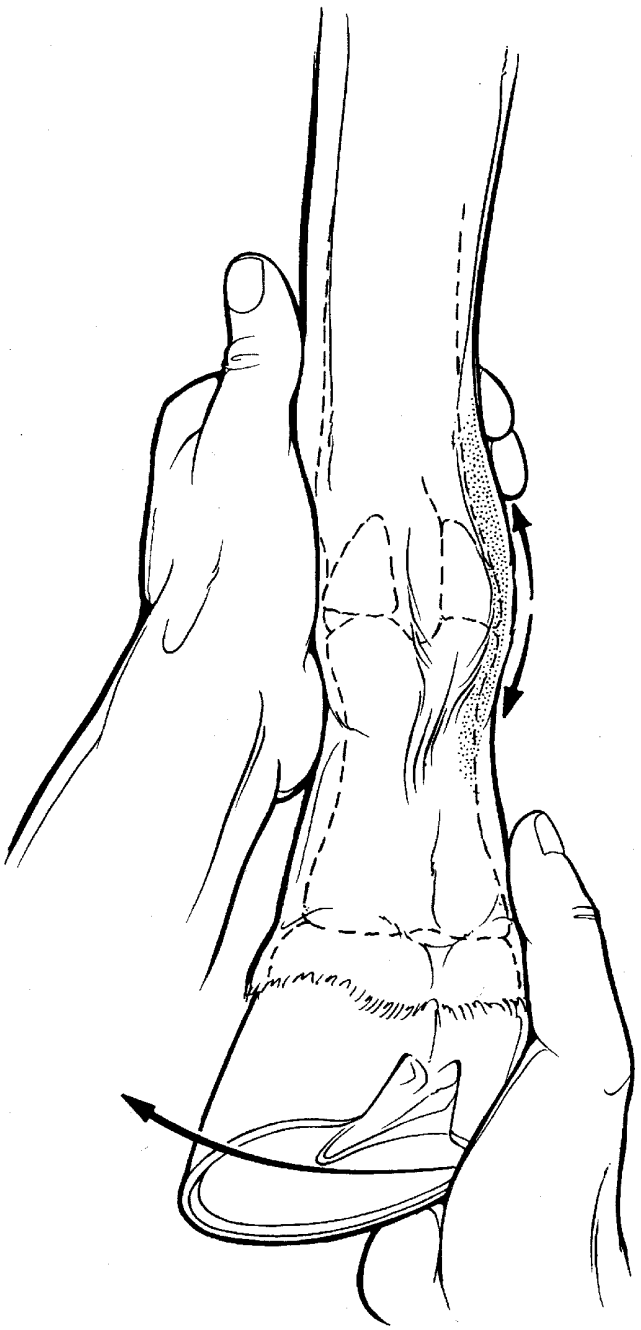

Figure 2.56. Tension is applied to the collateral ligaments supporting the fetlock and interphalangeal joints (pastern and coffin) to identify pain.

METACARPUS/METATARSUS (MC/MT)

Palpation of the dorsal aspect of the metacarpus should be performed, especially in young racehorses. Firm pressure applied with the fingertips often elicits a painful response in horses with dorsal metacarpal disease (buck shins). Heat and swelling over the dorsal middle third of the metacarpus may also be present (Figure 2.61). The extensor tendons on the dorsal surface of the MC/MT should be palpated for swelling, thickness, and pain, especially in horses with a history of trauma/laceration to this region.

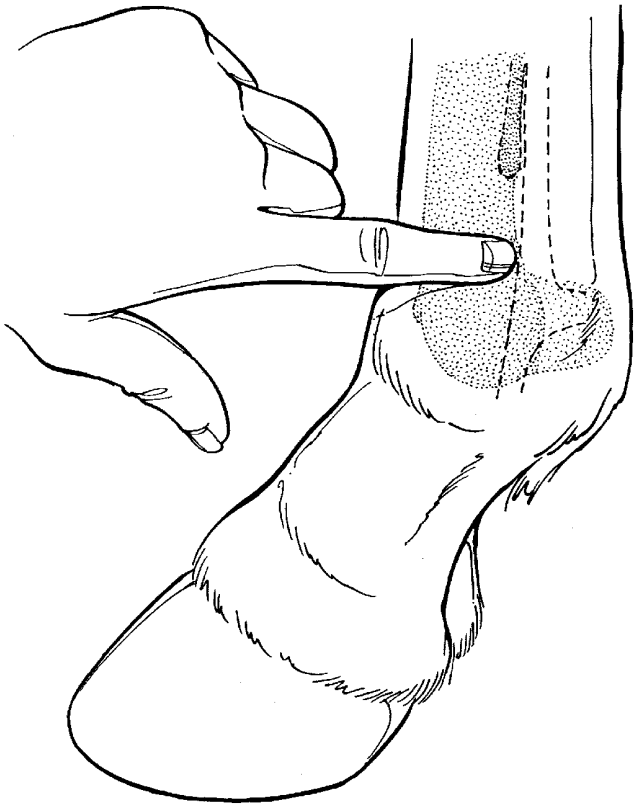

Figure 2.57. Finger marks the palmar recesses of the fetlock joint capsule. Distention at the site results from synovial effusion.

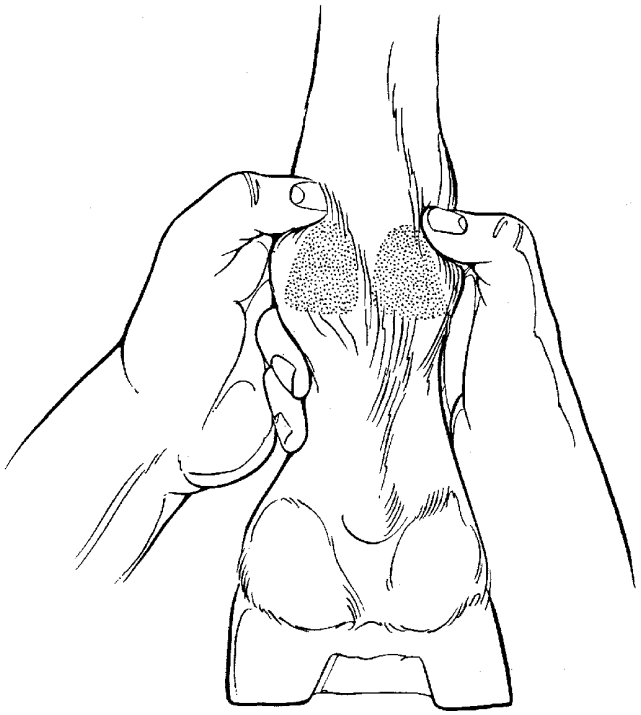

Figure 2.58. Digital pressure applied to the apical sesamoid region to detect pain, heat, and asymmetry. Palpation of the midbody and basilar aspects of the bones should also be performed.

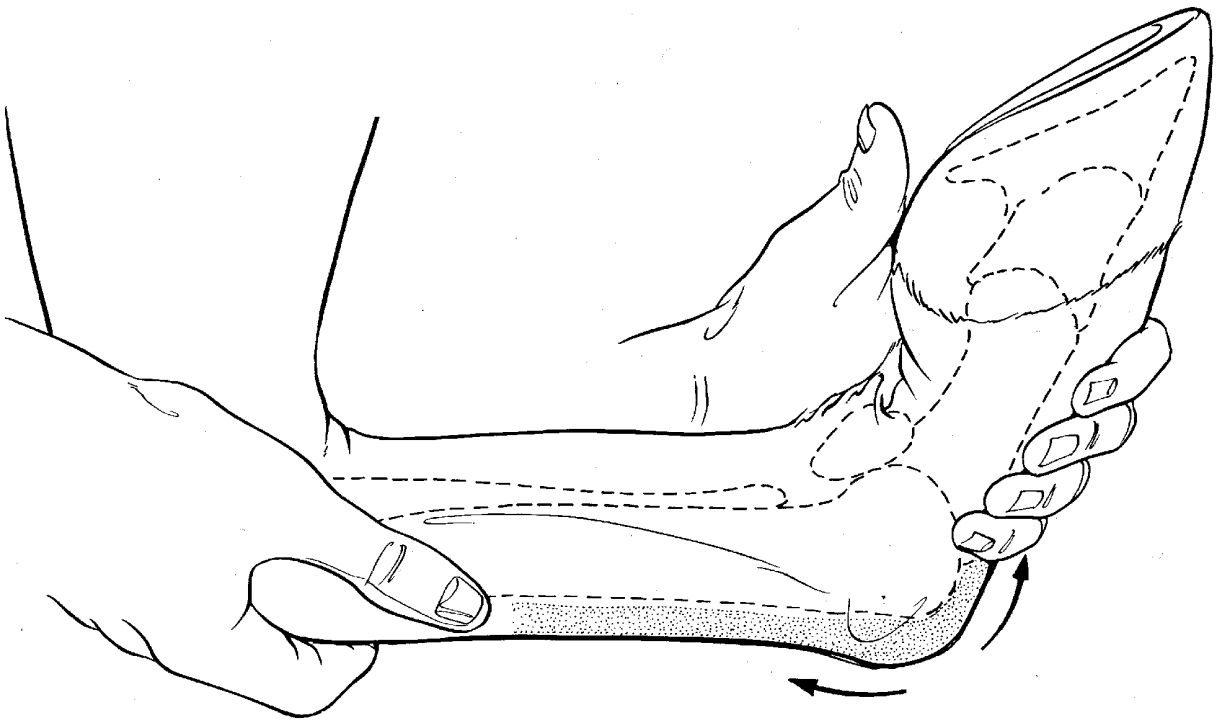

Figure 2.59. Fetlock flexion test is performed by extending the carpus and flexing the fetlock joint. One hand is placed on the dorsal aspect of the pastern to create fetlock flexion without flexion of the interphalangeal joints.

VetBooks.ir

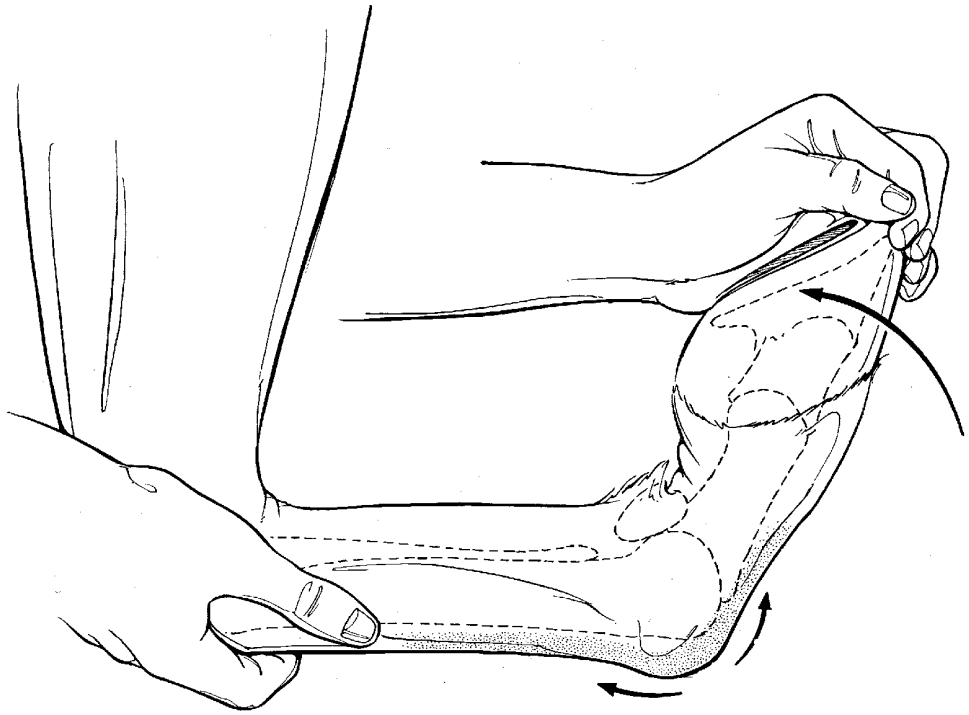

Figure 2.60. Distal limb flexion test in which the interphalangeal (pastern and coffin) and fetlock joints are flexed simultaneously.

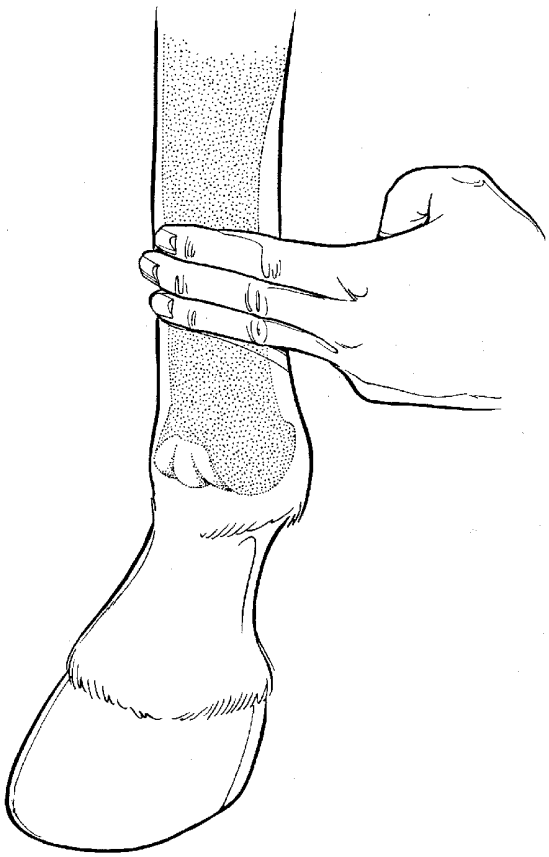

Figure 2.61. Palpation over the dorsal middle third of the metacarpus to identify heat, pain, and swelling associated with dorsal metacarpal disease.

The entire length of each small metacarpal/metatarsal bone (splint bone) should be palpated for heat, pain, and swelling with the limb weighted and unweighted. With the limb elevated, the palmar/plantar and axial surfaces of the splint bones can be palpated by pushing the suspensory ligament and tendons toward the opposite side (Figure 2.62). The splint bone can be palpated with the thumb applying pressure as needed. Heat, pain, and swelling may indicate a fracture or a condition referred to as "splints" if located in the proximal aspect of MCII. Splint fractures most commonly involve the medial splint bone in the forelimb and the lateral splint bone of the hindlimb. It is not uncommon to palpate nonpainful enlargements of the splint bone, which are often incidental findings. However, some middle and proximal splint bone fractures heal with excessive callus that may contribute to lameness.

SUSPENSORY LIGAMENT

The suspensory ligament (interosseous medius muscle) lies just palmar/plantar to the splint bones in the metacarpal/metatarsal groove. It should be palpated with the limb weight-bearing and with the limb flexed. Deep palpation is often needed to identify swelling and pain, and comparison between the lateral and medial branches may be helpful.[2,6] Damage to the suspensory tends to occur distally within the branches of the suspensory ligament or at its proximal attachment to the MC/MT. However, secondary suspensory desmitis may be associated with a healing splint fracture anywhere along its length. The proximal attachment of the suspensory ligament to the MC/MT can be palpated by pushing the flexor tendons to the side and applying pressure

VetBooks.ir

Figure 2.62. Palpation of the medial (axial) surfaces of the small metacarpal bones. The fetlock can be flexed to relax the suspensory ligament to permit easier palpation.

with the thumb with the limb held in a flexed position (Figure 2.63). Alternatively, pressure can be applied to this region by placing the palm of the hand on the dorsal MC and wrapping the fingers around the medial side of the MC. The fingertips are used to "squeeze" the limb and apply pressure to the proximal palmar MC region (Figure 2.64). Many horses may react initially by withdrawing (flexing) the limb. However, with constant pressure, this response often fatigues. A painful withdrawal that persists (does not fatigue) often suggests a problem in the proximal suspensory region.[10,15] Palpation of the proximal suspensory region is more difficult in the hindlimbs than the forelimbs because it is closely surrounded by the small metatarsal bones and the SDFT is less easily pushed to the side (Figure 2.65).

FLEXOR TENDONS

The SDFT and DDFT are located palmar to the suspensory ligament and are intimately associated with each other. The proximal one-third of the flexors (associated with the carpus) and distal one-third (associated with the fetlock) are encased in tendon sheaths, whereas the central one-third is covered by a paratendon only. Each region should be palpated carefully for heat, pain, and swelling with the tendons weighted and then again with the limb unweighted and the tendons relaxed. With the limb held in one hand, an attempt should be made to roll or separate the SDFT from the DDFT with the thumb and forefinger (Figure 2.66). If normal, they can be easily separated and differentiated. With pathology such as tendonitis, varying degrees of adhesions between the two as well as thickening will result in an inability to separate them. Most horses respond slightly to "pinching" the SDFT between the thumb and index finger. Pain will be elicited easily with palpation in most horses with tendonitis. The inferior check ligament (accessory ligament of the DDFT) lies directly palmar to the suspensory ligament and can be palpated by holding the ligament between the index finger and the thumb or by applying pressure from the palmar aspect with the thumb.

CARPUS

The carpus should be visually examined for swelling/effusion on the dorsal and palmar surfaces. Point swelling associated with the radiocarpal and middle carpal joints that occurs medial to the extensor carpi radialis tendon is often present in horses with osteochondral chip fractures and/or OA (Figure 2.67). More diffuse swelling of these joints may indicate more severe articular pathology. Distention of the tendon sheaths of the extensor tendons overlying the carpus (common digital and extensor carpi radialis) is uncommon but may indicate tenosynovitis and/or rupture, particularly of the common digital extensor tendon in foals (Figure 2.68). A diffuse fluctuant, subcutaneous swelling over the dorsal surface of the carpus is consistent with acute hematoma/seroma or chronic hygroma (Figure 2.69). Swelling/effusion of the palmar carpal canal may be found with accessory carpal bone fractures, tenosynovitis (carpal tunnel syndrome), or osteochondroma formation of the caudal distal aspect of the radius (Figure 2.70).[15]

Palpation of the carpal joints and bones including the accessory carpal bone is best done with the carpus flexed. The degree of carpal flexion or range of motion should also be evaluated. In the normal horse the flexor surface of

VetBooks.ir

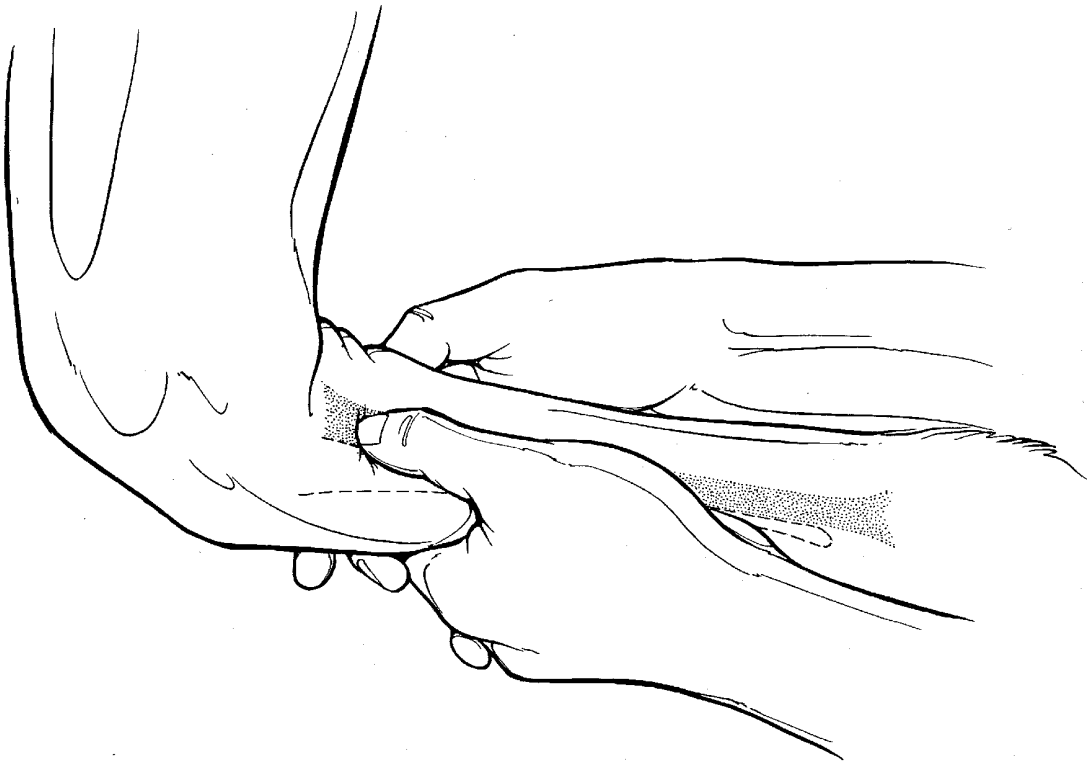

Figure 2.63. Palpation of the origin of the suspensory ligament in the proximal aspect of the metacarpal region. A repeatable painful response may suggest proximal suspensory desmitis.

Figure 2.64. Method used to apply digital pressure to the suspensory ligament in the proximal palmar metacarpal region.

Figure 2.65. Method used to apply digital pressure to the suspensory ligament in the proximal plantar metatarsal region.

the metacarpal region can approximate that of the forearm when the carpus is flexed (Figure 2.71). With the carpus held in flexion, the individual carpal bones are evaluated by deep digital pressure along the dorsal articular surfaces (Figure 2.72). With the carpus flexed and the tension of the ulnaris lateralis and flexor carpi ulnaris reduced, the accessory carpal bone can be manipulated, potentially identifying a fracture (Figure 2.73). In some cases, an osteochondroma on the caudodistal aspect of the radius may be palpable if effusion of the carpal canal is present.

FOREARM (ANTEBRACHIUM) AND ELBOW

The distal aspect of the radius, soft tissues of the forearm, and the elbow joint (cubital joint) should be palpated for swelling, heat, and pain. A firm, usually nonpainful but fluctuant swelling at the point of the elbow is consistent with an elbow hygroma, also known as olecranon bursitis (Figure 2.74). Severe swelling and an inability to extend the limb (dropped

VetBooks.ir

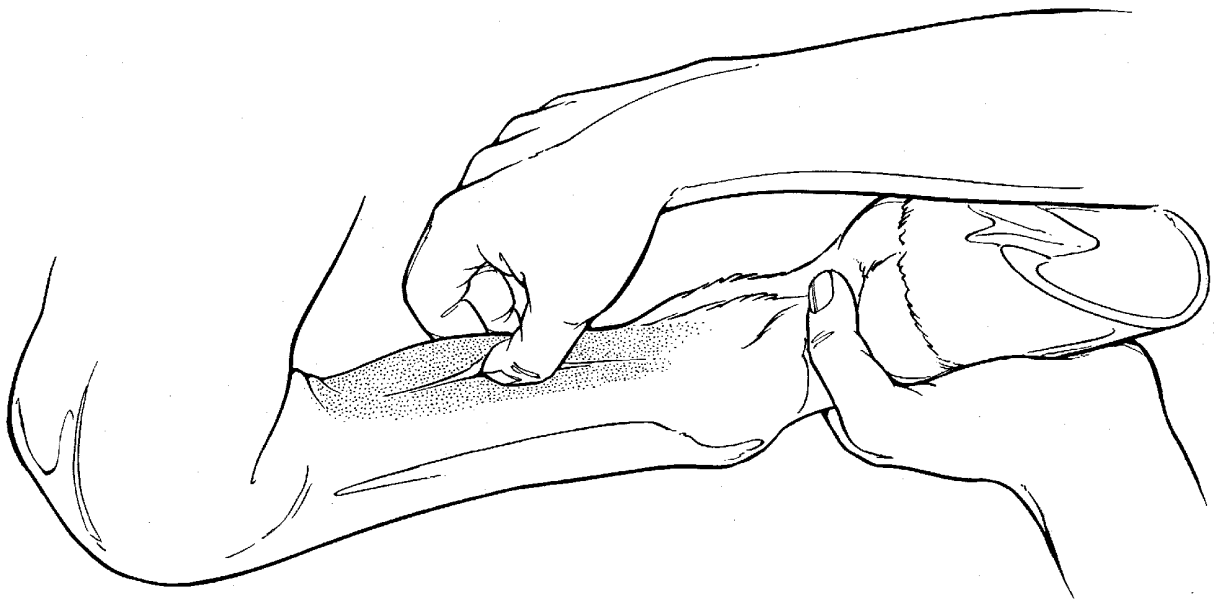

Figure 2.66. Palpation of the flexor tendons with the fetlock flexed to permit separation of the superficial and deep digital flexor tendons. Inability to separate the tendons usually suggests tendonitis.

Figure 2.67. Effusion of the radiocarpal joint was visible and easily palpable in both the dorsomedial and palmarolateral joint pouches in this horse.

Figure 2.68. Effusion of the extensor carpi radialis tendon sheath is usually characterized by swelling that courses up and down the cranial aspect of the carpus.

elbow) are consistent with a fracture of the olecranon. In cases of non-displaced or chronic olecranon fractures, palpation of the caudal aspect of the olecranon may reveal variable degrees of swelling and pain with digital pressure. Elevation of the limb into extension may elicit a painful response (Figure 2.75). Severe swelling, crepitation, and pain may be observed in horses with humeral fractures and can be confused with fractures of the olecranon.

SHOULDER AND SCAPULA

The soft tissues around the shoulder joint (scapulohumeral joint) should be observed for muscle atrophy and palpated for swelling, pain, and/or crepitus. Infraspinatus

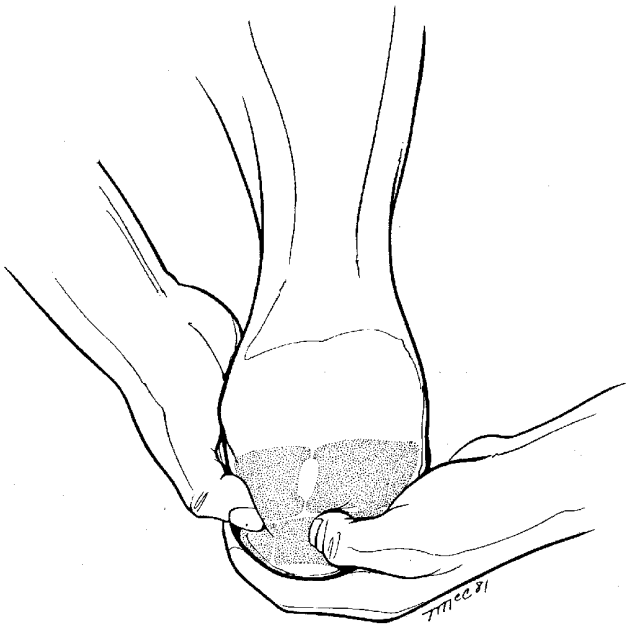

Figure 2.72. The dorsal articular margins of the carpal bones can be palpated after the carpus is flexed to identify pain within the individual carpal bones and/or capsulitis.

Figure 2.74. A small fluid-filled swelling was present on the point of the elbow in this horse, consistent with olecranon bursitis. The skin was also thickened in the region, but no lameness was present.

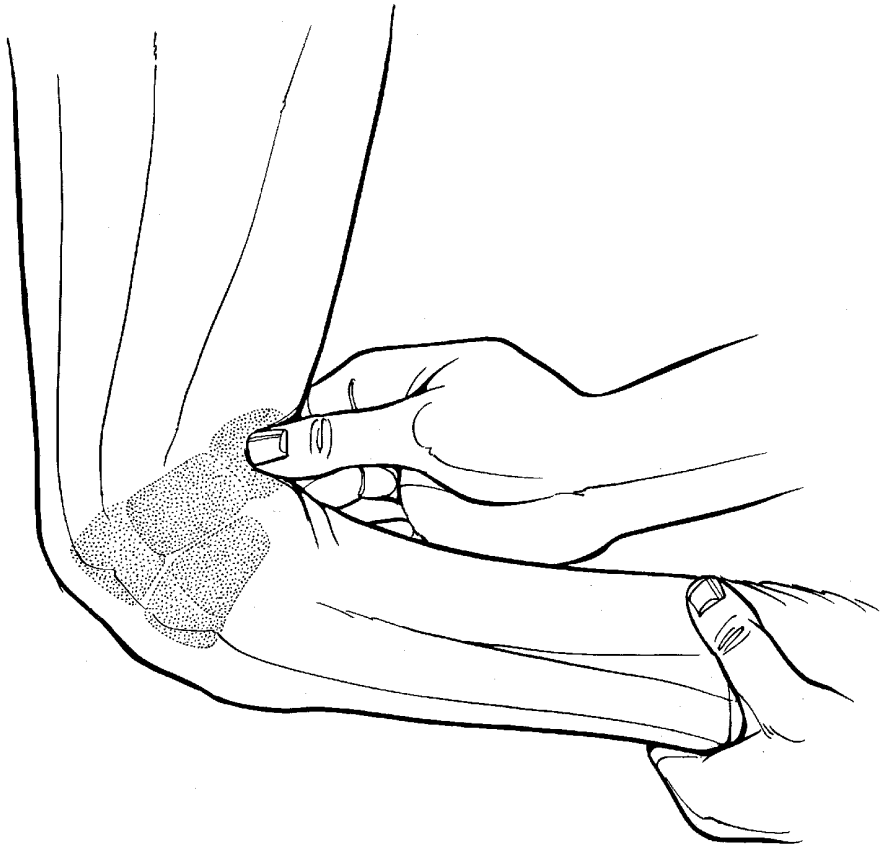

Figure 2.73. Palpation of the accessory carpal bone to identify a possible fracture. This is best done with the carpus flexed to decrease the tensional influence of the tendinous insertions of the ulnaris lateralis and flexor carpi ulnaris muscles.

VetBooks.ir

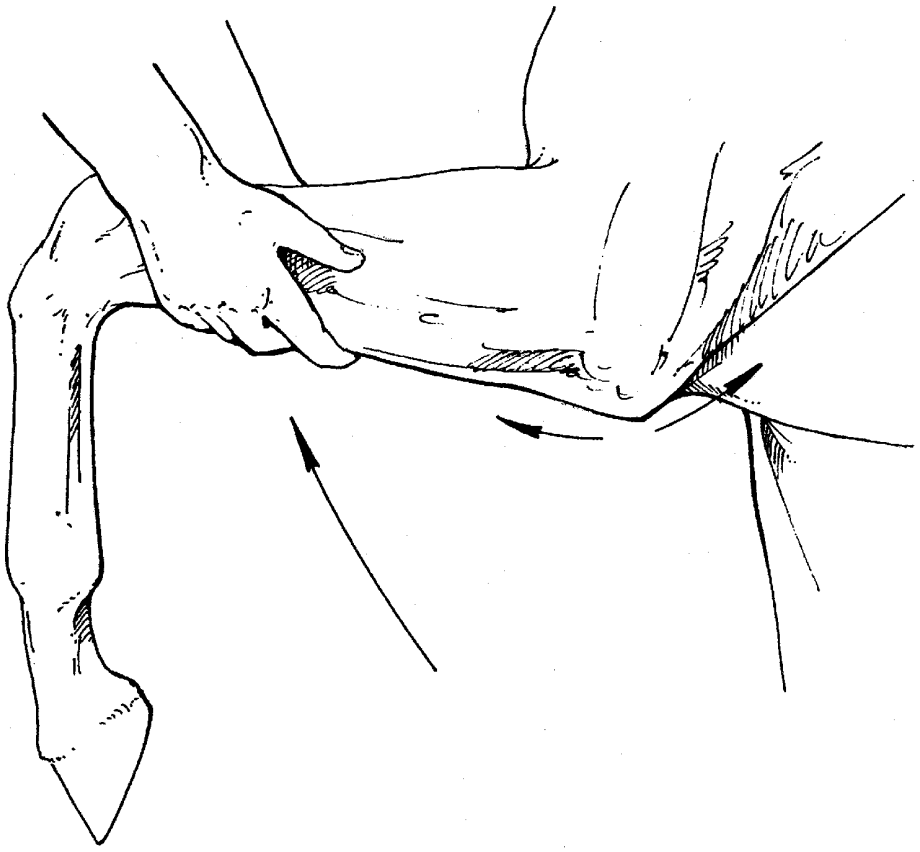

Figure 2.75. Elevating the limb into extension to flex the elbow joint extends the shoulder and increases the tension on the triceps brachii tendon at its insertion on the olecranon process.

and supraspinatus muscle atrophy is commonly seen in horses with suprascapular nerve paralysis or osteochondrosis (Figure 2.76). Particular attention should also be paid to the bicipital bursa region (cranial aspect of shoulder), and deep digital palpation is recommended in this region. The muscle and tendon should be grasped with the fingers and thumb and pulled laterally. The shoulder joint can be palpated deeply by applying thumb pressure cranial to the infraspinatus tendon at the location for intra-articular injection. A consistent painful response is suggestive of intra-articular pathology. Fractures of the scapula and proximal humerus may also elicit a painful response with this manipulation. Elevation of the limb as described for the elbow joint may also result in a painful response, particularly if a fracture or a lesion within the joint is present (Figure 2.75). Horses with midbody scapular fractures often have an external swelling located above the shoulder joint directly over the scapula. These, often young horses, will carry their distal limbs toward midline.

TARSUS (HOCK)

The tarsus is a common site contributing to hindlimb lameness and is complicated anatomically. Understanding the anatomy is critical to be able to accurately diagnose problems in this area. Synovial structures located in the tarsus include the tarsocrural joint, tarsal sheath, and calcaneal bursa. The tarsocrural joint has multiple outpouches that can result in tarsal swelling, and this soft, fluctuant swelling is often referred to as "bog spavin." The synovial effusion can be easily compressed from the dorsal pouches to distend the plantar pouches of the joint capsule and vice versa (Figure 2.77). Firm, diffuse swelling of the tarsus can occur due to trauma and inflammation of the fibrous joint capsule (capsulitis) and surrounding ligamentous support structures. This firm swelling may or may not be associated with synovial effusion of the joint (Figure 2.78). Effusion/swelling of the tarsal sheath is often referred to as "thoroughpin" and can usually be observed and palpated on the medial aspect of the tarsus. Unlike effusion of the tarsocrural joint, tarsal sheath effusion is asymmetrical on the limb (medially) and runs in a distal to proximal direction (Figure 2.79). Tarsocrural joint effusion is symmetrical and courses circumferentially around the tarsus. Tarsal sheath effusion may be a cosmetic blemish but can be indicative of problems of the DDFT or the sustentaculum tali of the talus (Figure 2.79). Effusion of the calcaneal bursa is often characterized by small pockets of fluid on each side of the SDFT above and below the point of the hock (Figure 2.80). Swelling associated with a capped hock is subcutaneous, whereas effusion within the calcaneal bursa is beneath the SDFT.

The medial aspect of the distal tarsal joint region (distal intertarsal and tarsometatarsal joints) should be closely examined visually and with palpation to detect bone

VetBooks.ir

Figure 2.76. Atrophy of the shoulder muscles in young horses is often seen with osteochondrosis of the shoulder joint.

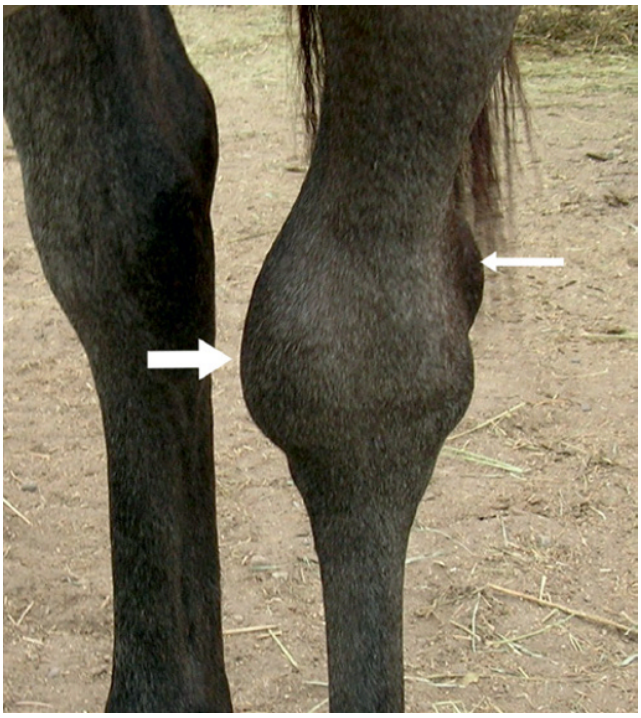

Figure 2.77. Young horse with effusion of the tarsocrural joint that is easily compressible and nonpainful (white arrows).

Figure 2.78. This young horse had a history of previous trauma to the tarsus. Part of the swelling was firm and painful to palpation, but there was also effusion within the tarsocrural joint.

Figure 2.79. Effusion of the tarsal sheath on the medial aspect of the tarsus that was associated with fragmentation of the sustentaculum tali.

proliferation associated with the distal tarsal joints (bone spavin) (Figure 2.81). In the normal horse there is a smooth contour that tapers to the distal tarsal bones as they join the proximal metatarsus. This is easily visualized from the rear and palpated from the side. If this region appears boxy with obvious enlargement, OA of the distal intertarsal and/or the tarsometatarsal joints should be suspected. These medial enlargements have also been referred to as "tarsal shelves" (Figure 2.82). Applying pressure over the medial aspect of the distal tarsus has been referred to as the Churchill pressure test. Using the index and middle fingers, firm pressure is applied to the plantar aspect of the proximal end (head) of the second

VetBooks.ir

Figure 2.80. Effusion within the calcaneal bursa can often be palpated as fluid outpouchings above and below the retinaculum of the superficial digital flexor tendon (arrows).

metatarsal (splint) bone (Figure 2.83). The test is considered positive if the horse flexes and abducts the limb away from the pressure especially if there is a marked difference in the response between the two tarsi.[2,4]

Enlargement of the long plantar ligament or SDFT (curb), luxation of the SDFT over the calcaneus, and subcutaneous swelling over the calcaneus (capped hock) are closely associated with the plantar aspect of the tuber calcis. This area should be palpated for enlargement of the plantar ligament (Figure 2.84), swelling and pain associated with the superficial flexor tendon (Figure 2.85), displacement of the SDFT (Figure 2.86), and a fluid swelling at the point of the hock referred to as "capped" hock (Figure 2.87). Swelling associated with a capped hock is always subcutaneous and does not involve the calcaneal bursa.

TIBIA

The tibial region can be a difficult region to detect abnormalities both visually and with palpation. Swelling and pain in the caudal tibial region may suggest myositis of the semimembranosus and semitendinosus muscles or gastrocnemius tendonitis. Focal swelling of the distal medial epicondyle of the tibia can be associated with a fracture or medial collateral ligament injury. Severe pain with deep digital palpation of the distal third of the tibia, together with a severe lameness and a positive flexion test, may suggest the possibility of an incomplete tibial fracture. A complete fracture of the tibia is associated with non-weight-bearing lameness, severe swelling, limb deviation, and crepitation on palpation and manipulation.

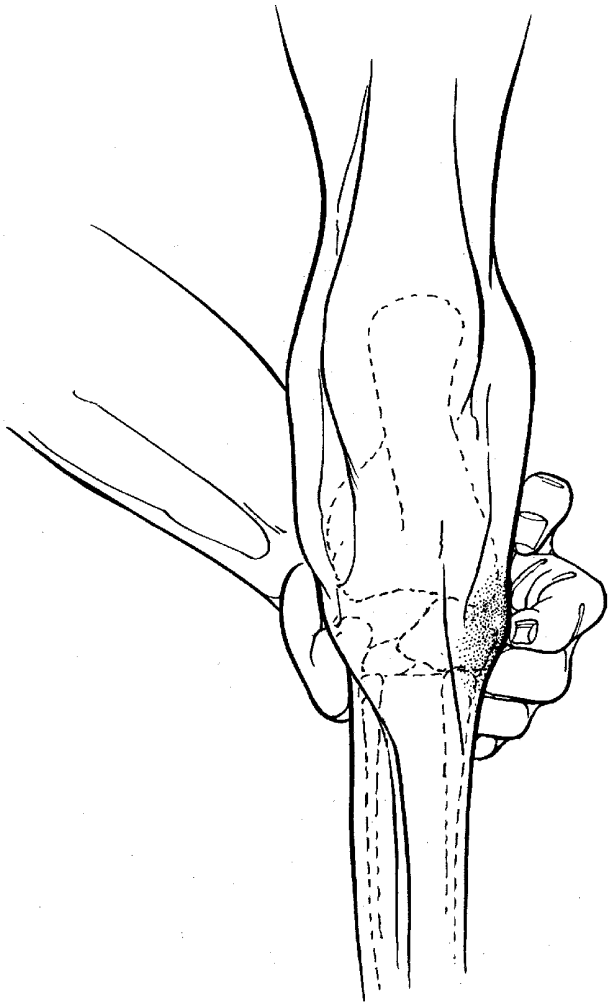

Figure 2.81. Palpation over the distal tarsal joints on the medial aspect of the tarsus, often referred to as the "Churchill test."

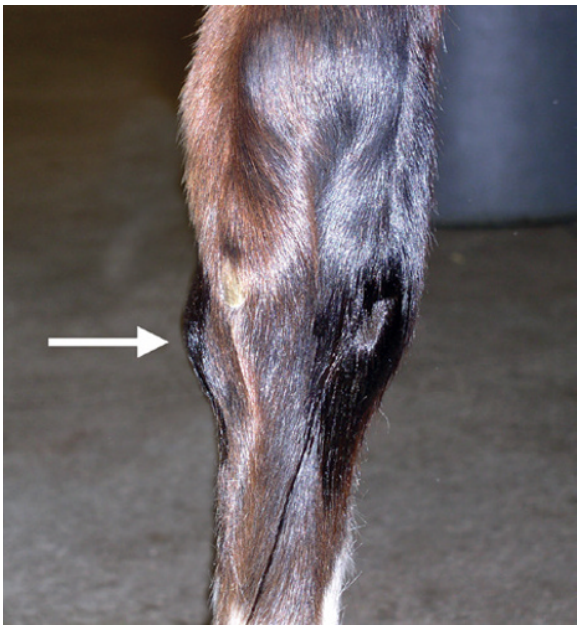

Figure 2.82. Enlargement of the medial aspect of the distal tarsus (arrow) consistent with distal tarsal OA (bone spavin).

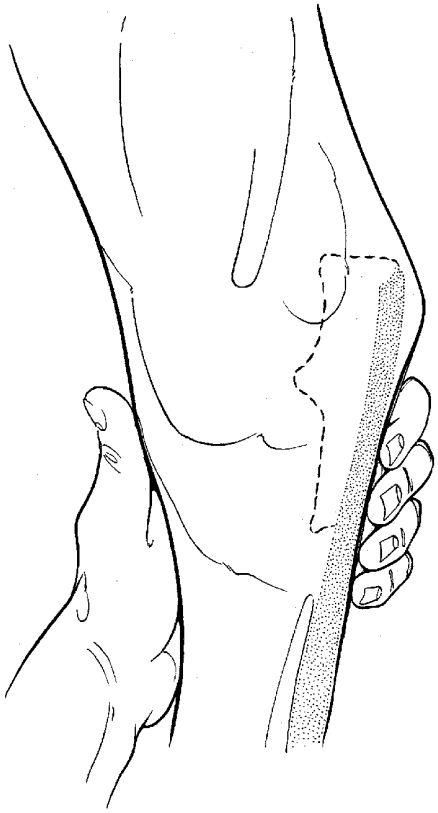

Figure 2.84. Palpation of the long plantar ligament over the plantar aspect of the calcaneus. Swelling in this region is often referred to as a curb but may represent tendonitis of the superficial digital flexor tendon instead. Foals with a "curby" appearance may also have incomplete ossification of the tarsal bones.

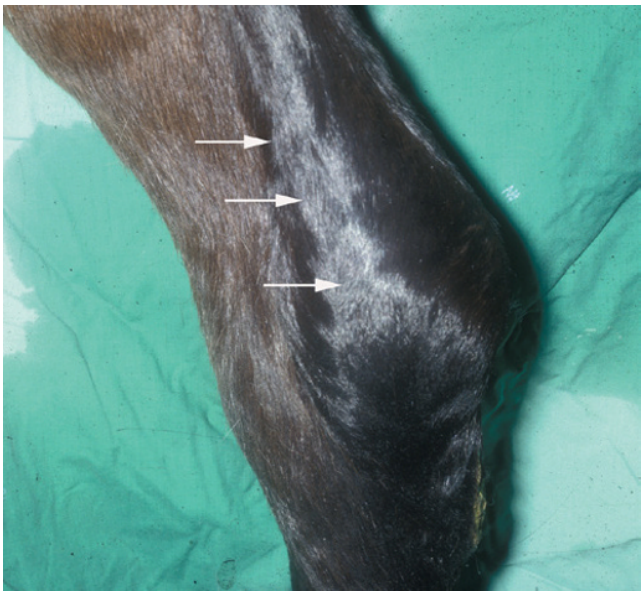

Figure 2.86. Lateral displacement of the superficial digital flexor tendon from the point of the calcaneus (arrows). Effusion of the calcaneal bursa is also usually present in these horses.

VetBooks.ir

The semimembranosus and semitendinosus muscles should be palpated for any evidence of pain and swelling suggestive of myositis (hamstring pull) and for firm scarring/fibrosis that is often present with fibrotic myopathy (Figure 2.88). Although an uncommon site for problems, the gastrocnemius tendon should be palpated for swelling and pain. An attempt should also be made to extend the hock joint if clinical signs consistent with rupture of the peroneus tertius muscle are present during exercise. With the stifle flexed, the hock can be extended, and a characteristic dimpling of the gastrocnemius tendon occurs (Figure 2.89).

Figure 2.87. Swelling of the subcutaneous bursa at the point of calcaneus, often referred to as a "capped hock."

STIFLE

The stifle should be observed and palpated for swelling and/or atrophy of the associated muscle groups and for fluid distension of the joints. Distension of the femoropatellar joint is best seen from the lateral view (Figure 2.90), and distension of the medial femorotibial (MFT) is best observed from the cranial aspect (Figure 2.91). However, palpation is the preferred method to detect effusion within the stifle joints. The femoropatellar joint pouch is located on the cranial aspect of the stifle beneath the patella ligaments. In general, effusion of the femoropatellar joint makes palpation of the three distal patellar ligaments

Figure 2.88. Horse with fibrotic myopathy of the left hindlimb. There is atrophy of the semitendinosus muscle and firm scar tissue palpable in the caudal tibial region (arrow).

Figure 2.90. Effusion can be seen and palpated within the femoropatellar joint cranial to the patella ligaments (arrow).

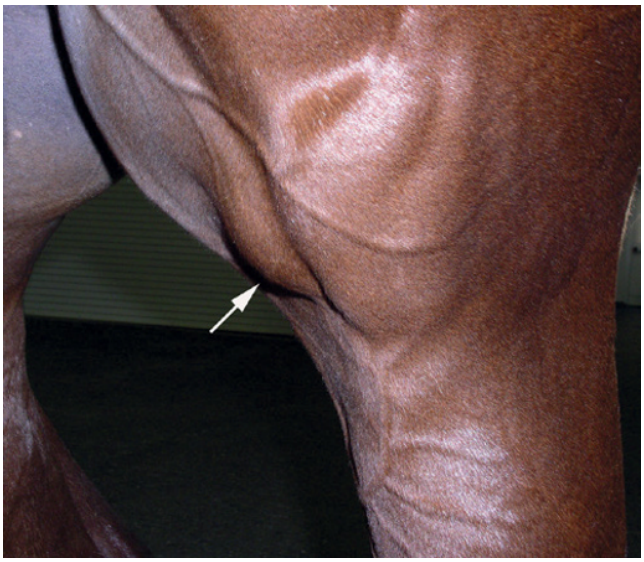

Figure 2.91. Visible and palpable effusion within the medial femorotibial joint is present just behind the medial patella ligament (arrow).

more difficult. These ligaments should be easily palpable across the dorsal aspect of the stifle and are the landmarks to locate the three synovial pouches of the stifle. The patella ligaments should be palpated for evidence of thickening and pain suggestive of desmitis. Fluid distension of the femoropatellar pouch may indicate pathology within the femoropatellar joint or within the MFT joint because they communicate with each other. The MFT joint pouch is located medial to the medial patella ligament directly above the tibial plateau. The lateral femorotibial joint is located lateral to the lateral patella ligament, and effusion within this joint is rarely detected. Palpation of the stifle joints for effusion should always be compared to the opposite limb. In general, abnormalities within the stifle joint are usually accompanied with synovial effusion. Effusion of the femoropatellar and MFT joints can be associated with a variety of clinical problems (see the stifle section in Chapter 5 for details).

The patella and patellar ligaments should be palpated for parapatellar inflammation and pain, crepitation, and displacement. The patellar displacement test involves pushing the patella proximally (upward) and laterally (outward) in an attempt to engage the medial patellar ligament over the medial trochlea. Most horses object to this manipulation, but if the patella is easily displaced upward with apparent locking, it may suggest intermittent upward fixation of the patella. With complete upward fixation, the horse will be unable to flex its stifle or hock and may drag its limb behind in extension (Figure 2.92).

Manipulative tests may also be performed on the stifle to assess the cruciate ligaments and medial collateral ligament.[15] These tests are very subjective and only used in those horses when other clinical signs suggest injury to these structures. The cruciate test can be performed from either the caudal or cranial aspect of the limb. With the caudal approach, the examiner stands behind the horse with his/her arms brought around the limb and the hands clasped together at the proximal end of the tibia (Figure 2.93). The examiner's knees or knee should be in close contact with the plantar aspect of the calcaneus, and the examiner's toe is placed between the bulbs of the heels. This positioning helps to stabilize the limb. In this position the examiner pulls the tibia sharply caudally and releases it to go cranially, feeling for looseness and crepitation that may suggest cruciate ligament damage. With a cranial cruciate ligament rupture, the looseness is felt as a sliding movement in a cranial direction (cranial drawer sign). However, a generalized looseness within the stifle is often the only definitive finding because it is difficult to identify the phase (caudal or cranial) in which the movement occurs.

With the cranial approach, the examiner stands in front of the affected limb with one hand placed on the proximal tibial tuberosity. The other hand is used to pull the tail to that side to force the horse into weight-bearing. The tibia is pushed caudally as quickly and forcibly as possible, which is thought to stress the cranial and caudal cruciate ligaments (Figure 2.94). This may be repeated multiple times, after which the horse may be trotted off and the degree of lameness observed. An increase in lameness may indicate a sprained or ruptured cruciate ligament, but is not specific for this injury.[15]

The medial collateral ligament test is performed by placing the shoulder or outside hand over the lateral aspect of the stifle and abducting the distal limb with the other hand (Figure 2.95). Increased lateral movement of the distal limb indicates complete rupture of the medial collateral ligament. The opposite approach may be performed to test the integrity of the lateral collateral ligament, but injuries to this ligament are uncommon. If a sprain to the ligament is suspected, the limb may be repeatedly abducted several times, after which the horse is trotted off and the degree of lameness assessed.

VetBooks.ir

Figure 2.92. This young horse had a completely locked patella that caused it to drag its left hindlimb.

Figure 2.93. The caudal cruciate test is performed by grasping the tibia from behind and quickly pulling the tibia caudally. Increased movement of the tibia or a painful response may suggest damage to one of the cruciate ligaments.

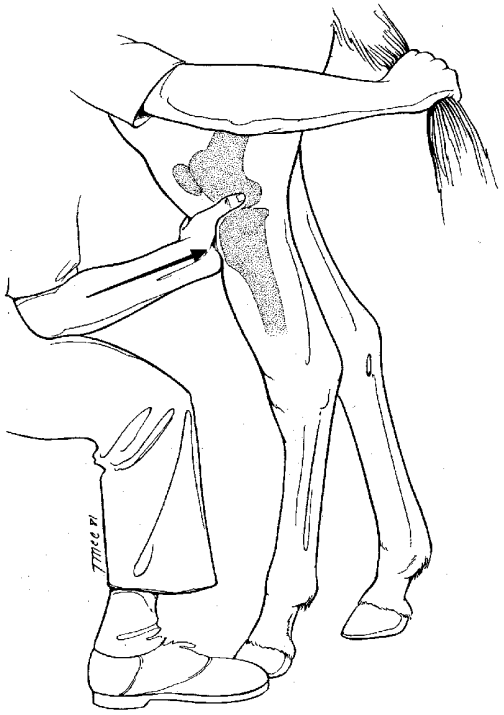

Figure 2.94. Positioning to evaluate for potential problems associated with the cranial cruciate ligament. The examiner places one hand on the proximal tibia and forces it caudally (arrow) to check for increased movement (cranial drawer) of the tibia in relation to the femur. The examiner may also repeatedly push the tibia caudally several times and then trot the horse off to see if this manipulation worsens the lameness.

VetBooks.ir

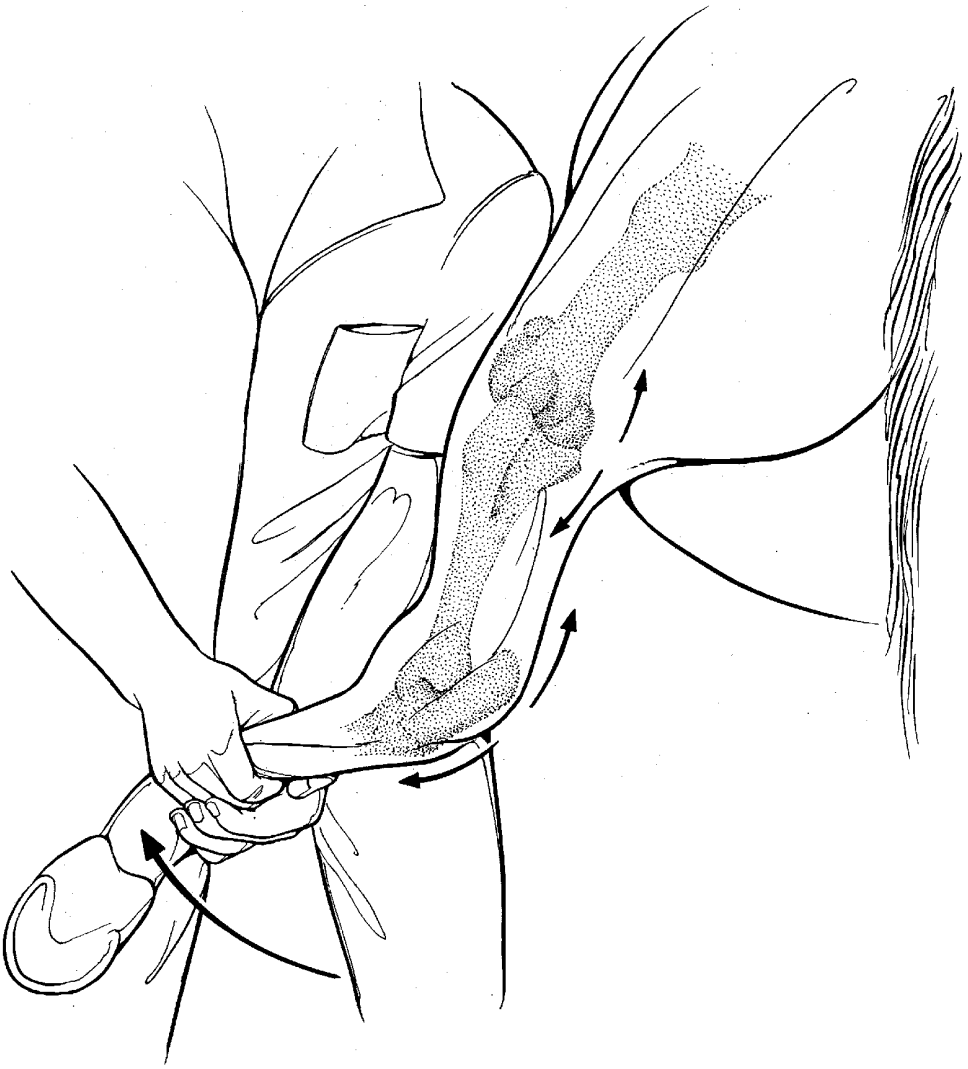

Figure 2.95. Test to stress the medial collateral ligaments of the hock and stifle. Alternatively, one hand can be placed on the medial aspect of the distal tibia to selectively stress the medial collateral ligament of the femorotibial joint. The examiner's shoulder can be placed over the middle of the tibia and both hands on the distal metatarsus to selectively stress the medial aspect of the hock.

FEMUR

The muscles surrounding the femur are primarily examined for swelling and/or atrophy. The femoral artery should be palpated for the quality of pulsations on the medial side of the thigh in the groove between the sartorius muscle cranially and the pectineus muscle caudally. If the pulse is weak or nonexistent, thrombosis of the iliac artery may be contributing to the lameness. Pressure can be applied to the greater trochanter, and if painful, middle gluteal muscle strain or trochanteric bursitis (whirlbone disease) should be suspected[4]. Complete fractures of the femur usually result in non-weight-bearing lameness with severe swelling and limb shortening due to overriding of the fracture (Figure 2.96). Femoral neck fractures are more difficult to diagnose because they typically cause less swelling and lameness than diaphyseal femoral fractures. With time the swelling may migrate distally on the medial side of the thigh, giving the impression that the distal femoral region is involved.

HIP

The hip should be examined for asymmetry, swelling, and atrophy of associated muscle groups. With hip problems, swelling over the coxofemoral joint may be visually apparent, and pain can often be elicited with deep palpation directly over the joint using the palm of the hand. At a walk, a stifle-out, hock-in, toe-out gait (external rotation) is frequently observed, with an apparent shortening of the limb length (Figure 2.97). From the side, the affected limb may appear to be straighter than the contralateral limb. With the metatarsus held in hand, the coxofemoral joint can be manipulated into extension, flexion, and abduction to check for evidence of pain and crepitation. Additionally, the hip can be intermittently flexed and auscultated with a stethoscope at the same time to identify crepitation. Limb abduction is often painful to horses with hip conditions, and repeated limb abduction will often exacerbate the lameness.

VetBooks.ir

Figure 2.97. Typical toe-out, hock-in stance that often accompanies problems within the hip and pelvic region.

PELVIS

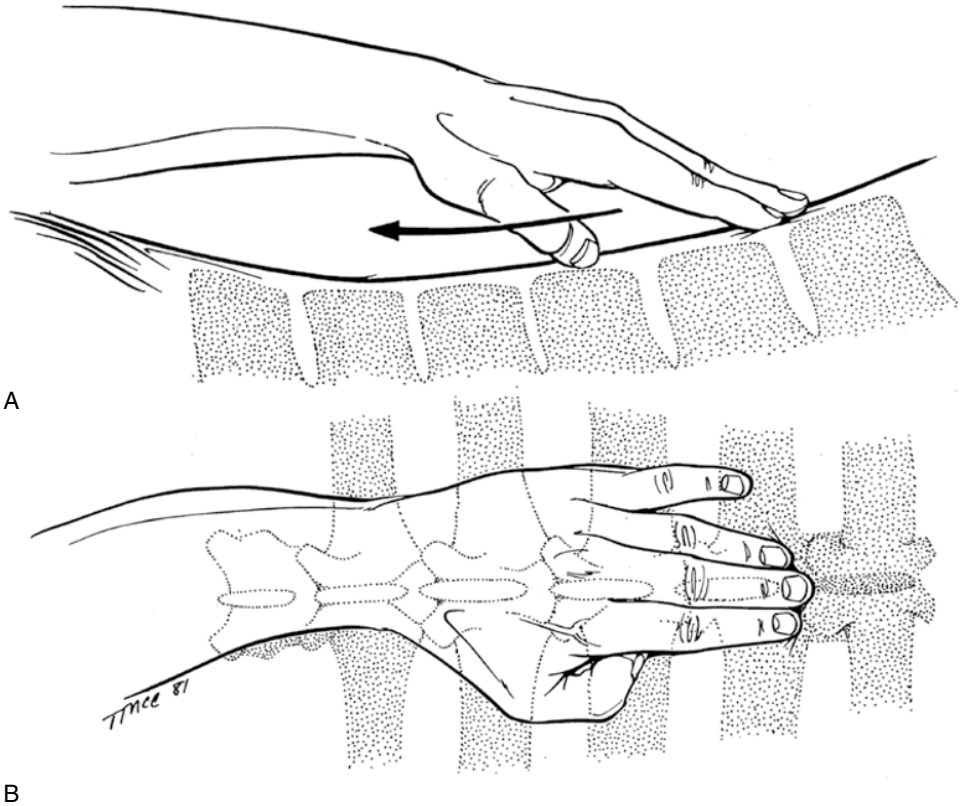
Visual identification of asymmetry of the bones and musculature of the pelvis is an important aspect of examination of the pelvis. This includes the tuber coxae, the tuber ischium, the tuber sacrale, and the gluteal muscles on each side. Asymmetry of the bony pelvis often suggests a pelvic fracture, subluxation of the sacroiliac region, or fracture of the specific bony prominence. Gluteal muscle atrophy often accompanies chronic pelvic fractures but can be seen with any chronic hindlimb lameness (Figure 2.98). Crepitus associated with pelvic fractures can usually be elicited by swaying the horse from side to side or can sometimes be detected on rectal examination.

BACK

Visual assessment of the horse's back includes observing the muscle contour from the side and axial alignment from the rear (Figure 2.99). The dorsal spinous processes should be palpated for axial alignment, protrusion or depression, swelling, and interspinous distance (Figure 2.100). Any muscle swelling, atrophy, or asymmetry in the epaxial musculature should also be noted.

Palpation is usually best performed with firm fingertip pressure using both hands simultaneously (Figure 2.101). Alternatively, the palm of the hand can be used to apply downward pressure to the epaxial muscles (Video 2.3).[2] Palpation of the epaxial muscles lateral to the dorsal spinous processes along the entire length of the back should be performed. Many horses may respond to downward pressure in the lumbar region by ventroflexing their backs, but this response often fatigues and withdrawal is less prominent. In horses that have clinically significant back pain, ventroflexion of the back is often severe, and any increase in finger- or palm-applied pressure greatly increases this response. The horse attempts to "drop down" to get away from hand pressure. Palpation may also cause the horse to vocalize, swish its tail, or actually kick out behind. Back palpation is somewhat subjective, and, therefore, the assessment requires clinical experience. In some cases, tightening of the longissimus dorsi muscle may be felt with palpation rather than a painful withdrawal response. This usually signifies that the horse is attempting to fix the vertebral column because ventroflexion is painful.[15]

VetBooks.ir



The examiner may also wish to assess the horse's willingness to ventroflex, dorsiflex, and lateroflex its thoracic and lumbar vertebrae.[15] Assessment of the horse's ability to ventroflex the back is obtained by exerting downward pressure to the muscles in the thoracolumbar region. A blunted instrument (needle cap) run over the croup usually causes dorsiflexion or arching of the back. Lateral flexion can usually be assessed by firmly stroking either side of the thoracolumbar region with a blunted instrument. Reluctance to flex the back in any of these directions may suggest muscle tightening and back rigidity within the thoracolumbar region (see Chapter 6 for further information on examination of the back and axial skeleton).

NECK

The neck should be examined for contour from the side and axial alignment from the front and rear. Excessive ventral arching of the neck in the mid-cervical region may be seen in some cases of cervical vertebral malformation. A straight (extended) poll can be seen with atlanto-occipital and atlanto-axial malformations. Splinting and spastic contraction of the neck muscles with or without signs of spinal ataxia is often consistent with vertebral fracture. Generally these horses are very painful.

The transverse processes should be palpated for alignment and symmetry and to detect evidence of atrophy. Muscle atrophy is most often observed in the caudal neck region dorsal to the cervical vertebrae and may be symmetric or asymmetric. Swelling of the neck either lateral or ventral is generally a sign of trauma or infection.

The neck should be flexed laterally and ventrally and extended to assess flexibility, range of motion, and pain. Lateral flexing can be done by pulling the horse's head by the halter to one side and then to the other. Alternatively, lateral neck flexion can be encouraged by holding a "treat" at the horse's shoulder. Most horses should be able to flex their neck laterally enough that the muzzle almost contacts the craniolateral shoulder region. Ventroflexion is assessed by feeding the horse from the ground level, and extension is evaluated by elevating the head and neck. Resistance to neck movement in any direction is usually due to pain and can be from many potential causes.

FLEXION TESTS/MANIPULATION

Most flexion tests, regardless of the location, are usually performed for 30–60 seconds and are a subjective method to further isolate the site of the lameness (Videos 2.5 and 2.6). In one recent study, flexion duration for 5 seconds had similar responses to tests performed for 60-second questioning whether the duration of flexion is that important.[1] In addition, the response to flexion tests must be interpreted in light of clinical findings because many otherwise normal horses may demonstrate positive responses.[11,18] These false-positive responses are thought to be directly related to the force applied to the limb. In one study only 20 of 50 horses responded to a "normal" distal limb flexion, while 49 of 50 horses responded to a "firm" distal limb flexion.[11] Another study revealed that more than 60% of 100 sound horses had a positive response to distal limb flexion and that the positive outcome increased significantly with age.[3] Both of these studies question the validity of distal limb flexion tests to predict future joint-related problems.[3,11] In addition, false-positive responses to flexion seem to occur more commonly in horses in active work than in horses that have been rested or turned out to pasture.[12] In general, there are more false-positive results to flexion at any location than false-negative results, but both can occur. False-positive responses are most common in front fetlock flexion tests.

Because both the amount of force and the duration for which it is applied may affect the response to flexion, the procedure should be standardized as much as possible to minimize variability.[7,8,18] For instance, the same person should flex the right and left limbs at any location for the same period of time so they can be accurately compared. Different people may have slight differences in the way they hold the limb or apply pressure to the limb, which can alter the responses. Despite this potential for variability, the flexion techniques performed by experienced veterinarians are usually sufficient to objectively assess responses to flexion.[7] Two relatively recent studies using inertial sensor-based systems have documented that a positive response to flexion results in significant changes to the objective measurements of pelvic movement.[9,14] However, the variation in measured symmetry following flexion within and between horses showed that the individual response to flexion may be highly variable.[14]

Passive flexion usually refers to manipulation of a joint during routine palpation of the horse, and pain detected with passive flexion often predicts a significant response to a subsequent flexion test. However, flexion tests can also be used to subjectively assess the severity of damage within an affected joint(s). In general, the severity of damage is often proportional to the severity of the response to the flexion test. For instance, horses with severe responses to carpal, fetlock, or stifle flexion typically have significant intra-articular or extra-articular pathology. However, flexion tests are not specific for the joint because it is nearly impossible to flex a single joint without affecting other nearby joints and soft tissues. Flexion of a joint not only increases the intra-articular and subchondral bone intraosseous pressures within the joint but also compresses and stretches the joint capsule and surrounding soft tissues.[12,16] The numerous other "structures" that are being manipulated with any flexion test should always be considered when interpreting the clinical significance of flexion tests.

The responses to flexion should be graded in some manner and included in the records. This is most important when reevaluating the lameness to more accurately determine whether improvement is being made. The author uses a grading scale of negative, mild response, moderate response, and severe response to assess the flexion tests. Alternatively, a plus-minus system may be used with "–" being no response and 1+ equating to mild, 2+ to moderate, and 3+ to severe. Regardless of the system used, the responses to flexion are a very important aspect of the lameness examination and should be recorded (Video 2.5). Additionally, changes in lameness in the limb not being flexed (weight-bearing limb) should also be recorded because this is often an important clinical finding. This contralateral response to flexion tends to occur most commonly in horses with bilateral hock and carpal problems.[12]

DISTAL LIMB/PHALANGEAL/FETLOCK FLEXION

Attempts can be made to isolate the fetlock joint from the pastern and coffin joints during flexion of the distal limb (Video 2.5). However, it is nearly impossible to only flex the fetlock or only flex the pastern or coffin joints. Flexion of the fetlock joint can be performed by placing one hand on the dorsal MC/MT and pulling up on the pastern with the opposite hand (Figure 2.59). Flexion of just the phalangeal joints is performed by maintaining fetlock extension by placing one hand on

VetBooks.ir

the fetlock while flexing the phalanges by pulling up on the toe with the opposite hand (Figure 2.102). All three joints can be flexed together (distal limb flexion) by pulling up on the toe and phalanges with both hands while facing toward the back of the horse (Figure 2.103). In general, it is nearly impossible to isolate the phalanges from the fetlock region in the hindlimb; therefore, most distal limb flexion tests performed in the hindlimb include all three joints (distal limb flexion test; Figure 2.103).

Regardless of how the flexion test is performed, the fetlock/phalanges are held in position for 30 seconds, after which the horse is trotted off and lameness is observed. Differences in the severity of the responses may be used to suggest whether there may be a problem in the fetlock vs. the pastern or coffin joints. A painful response to phalangeal flexion and a negative response to fetlock flexion may suggest a problem in the coffin or pastern joint or any soft tissue structure in the area. A negative response to phalangeal flexion together with positive responses to both the fetlock and distal limb flexion suggests a fetlock problem. Any positive signs should be checked with the opposite limb because a marked asymmetry in responses to distal limb flexion tests is an important clinical finding and further indicates

Figure 2.102. Hand and limb positioning to perform flexion of the phalangeal joints without flexing the fetlock.

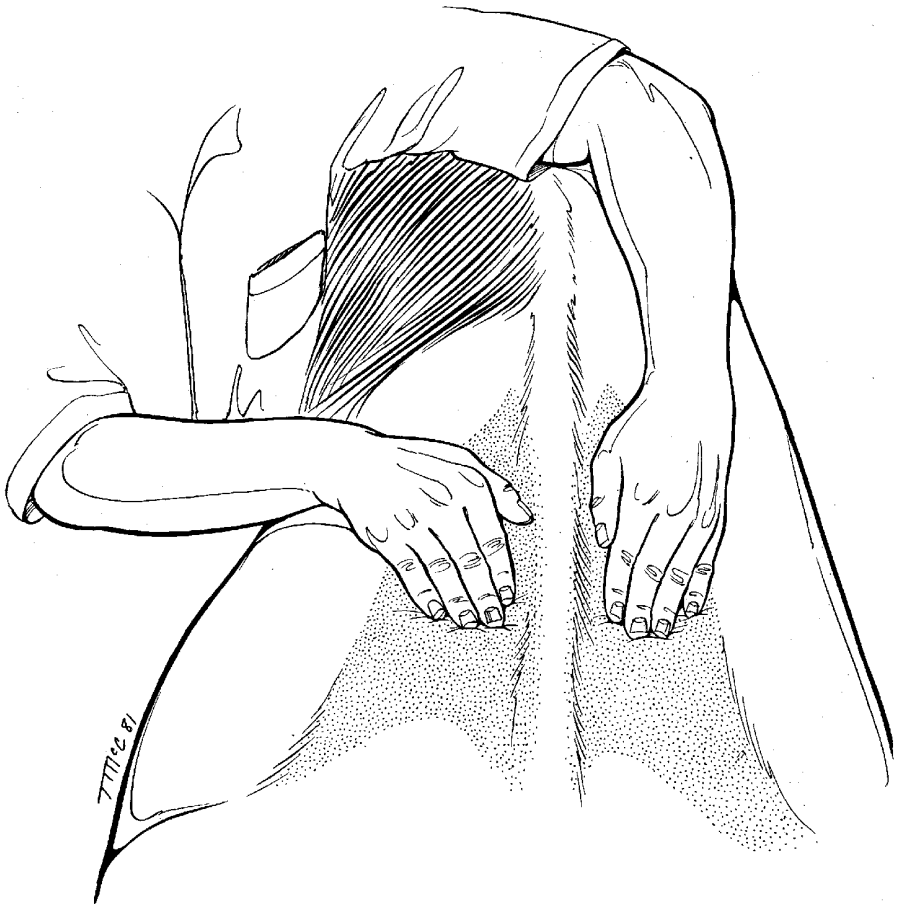

Figure 2.101. Firm pressure applied to the back musculature from the withers to the tuber sacrale to identify a painful response. The fingers should be held flat to prevent "digging in" with the fingertips. Firm pressure can also be applied using the palms of your hands.

VetBooks.ir

Figure 2.103. Hand and limb positioning to perform distal limb flexion (phalangeal and fetlock joints) of the hindlimb.

a potential problem in the area. However, false-positive fetlock flexion tests do occur, especially in horses in work, and many horses may show a positive response if a large amount of force is applied to the fetlock/distal limb. One study in normal horses evaluating the force applied for the fetlock and phalangeal flexion test by different examiners found that the force varied considerably and was frequently too high.[18]

CARPAL FLEXION

The carpal flexion test is very useful to help isolate a problem to the carpus. A negative response does not rule out a problem in the carpus (many horses with osteochondral fragmentation are not positive to carpal flexion), but a positive response is highly suggestive of a carpal problem (few false-positive responses). This is in contrast to the fetlock, where false-positive responses are much more common. Carpal flexion is performed by grasping the metacarpus with the outside hand while facing the horse, pulling up on the distal limb (Figure 2.71). The foot should be able to contact the caudal aspect of the olecranon in normal horses. The carpus is held in this position for 30–60 seconds, after which the horse is jogged away and observed for increased lameness.

ELBOW FLEXION

It is difficult to completely separate the elbow from the shoulder when performing upper limb flexion tests in the forelimb. This is analogous to the tarsus and stifle in the hindlimb because flexion of one area often affects the other. However, flexion of the elbow can be performed by lifting the antebrachium (forearm) so that it is parallel to the ground but not pulled forward (Figure 2.75). This flexes the elbow and causes the carpus and distal limb to hang freely. The limb is held in this position for 30–60 seconds and the horse is jogged off. Elbow flexion is usually not part of a routine lameness evaluation and is performed when an abnormality in the elbow region is found on physical examination.

SHOULDER/UPPER FORELIMB FLEXION

Manipulation of the upper forelimb can be performed either by pulling the limb cranially and upward or by pulling the limb caudally. The cranial approach is similar to flexing the elbow; only the limb is pulled forward and will flex the elbow and extend the shoulder. This is usually performed by standing in front of the limb, grasping the antebrachium, and lifting the limb up and forward (Figure 2.104). This exacerbates lameness problems in the caudal aspect of the elbow and the cranial aspect of the shoulder. The more the limb is elevated, the more pressure is applied to the cranial aspect of the shoulder. The position is maintained for 30–60 seconds (or as long as the horse tolerates it), and the horse is jogged off. Horses with supraglenoid tubercle fractures of the scapula, and horses with bicipital bursitis often respond to this type of shoulder manipulation.

The caudal approach to flex the shoulder joint can be performed by placing one hand on the olecranon process and pulling the limb caudally. Alternatively, the cranial antebrachium may be grasped and pulled caudally together with the distal limb instead of applying pressure to the olecranon (Figure 2.105). The position is maintained for 30–60 seconds (or as long as the horse tolerates it), after which the horse is jogged off.

TARSAL/HOCK FLEXION

The tarsal flexion test or spavin test is somewhat of a misnomer because it flexes the fetlock, stifle, and hip in addition to the hock (Video 2.6). A positive response to hock flexion is not synonymous with a tarsal problem but can be used together with other physical examination findings to suggest a problem in the tarsus. Hock flexion is performed by placing the outside hand when facing the rear of the horse on the plantar surface of the distal third of the metatarsus and elevating the limb to flex the hock (Figure 2.106). The opposite hand is then placed around the metatarsus, and the limb is held with both hands while facing the back of the horse. The grip

Figure 2.104. Upper limb flexion test in which the limb is pulled cranially and upward to "stress" the shoulder region.

VetBooks.ir

Figure 2.105. Flexion of the upper forelimb can be performed by grasping the antebrachium and foot and pulling the limb caudally.

should avoid the sesamoid bones and be loose enough to avoid excessive pressure to the flexor tendons and suspensory ligament. The fetlock and phalanges should not be forcibly flexed.

Alternatively, the tip of the toe can be held so the pastern and fetlock joints are extended and the hock is flexed (Figure 2.107). It may also be beneficial to gradually flex the tarsus to its fullest extent over a 15-second period to avoid resentment by the horse. In some cases in which the horse tends to lean away from the examiner, it may be helpful to place the horse adjacent to a solid support (i.e. wall or fence) or have an assistant provide counterbalance to the tuber coxae of the opposite hip. Once the tarsus is in full flexion, it is held in this position for 30–60 seconds, the limb is released gradually, and the horse is trotted off.

A positive hock flexion test is indicated by an increase in lameness of the flexed limb. However, increased lameness of the opposite limb (standing limb) is thought to occur with some upper limb lameness problems (sacroiliac problems). The first few steps the horse takes after this test are often the most important. If there is any question regarding the validity of the flexion test, it should be repeated. Two of the most common errors in performing this test are not obtaining full tarsal flexion and spooking the horse so that it balks at the onset of

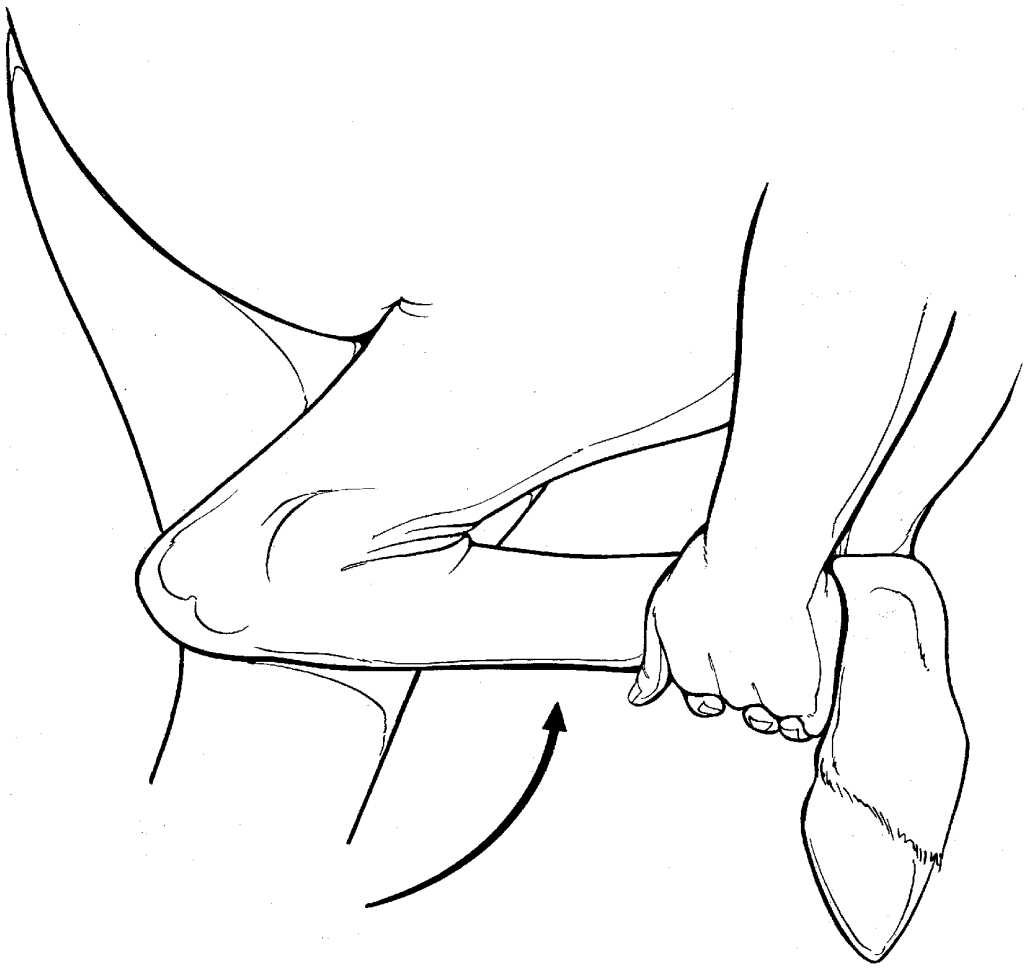

Figure 2.106. Hock or tarsal flexion (spavin) test. The hindlimb is flexed so that the metatarsus is approximately parallel to the ground. This test is not specific for the tarsus because it flexes both the stifle and the fetlock to some degree.

VetBooks.ir

Figure 2.107. Positioning to perform hock or tarsal flexion of the hindlimb where the limb is held by the hoof.

Figure 2.108. Flexion of the stifle is performed by pulling the hindlimb caudally and lifting up on the distal tibia.

the test rather than jogging off at a smooth pace. The response to tarsal flexion should nearly always be compared to the opposite limb because an asymmetrical response is often an important clinical finding.

STIFLE FLEXION

The stifle flexion test is often used in an attempt to separate stifle pain from tarsal pain in horses that respond to a tarsal flexion test. In most cases the stifle flexion test will flex the hock less than the tarsal flexion test will flex the stifle. In many cases it can be more specific for stifle problems, but this is debatable. It is performed by grasping the distal tibia and pulling the limb backward and upward until maximal stifle flexion is achieved (Figure 2.108). It is best to face toward the back of the horse with the limb in front of you when performing this test (Video 2.6). The limb is held in this position for 60 seconds and the horse is trotted off. Some clinicians prefer to perform the stifle flexion test before the hock flexion test, while others do the opposite. A positive tarsal flexion together with a more positive stifle flexion may suggest that the lameness is due to a stifle problem and vice versa.

FULL-LIMB FORELIMB AND HINDLIMB FLEXION

Full-limb forelimb and hindlimb flexion tests can be used as quick screening tests to determine whether more isolated flexion tests may be necessary. If there is no response to flexing all of the joints at one time, the potential for getting positive responses to individual flexion tests is thought to be unlikely. Full-limb forelimb flexion is performed by grasping the foot and lifting the leg to flex the fetlock, carpus, and elbow. The opposite hand is placed on the metacarpus, and the limb elevated and pulled forward to extend the shoulder (Figure 2.109). Full-limb hindlimb flexion is performed by grasping the foot and flexing the fetlock, hock, and stifle simultaneously. The hindlimb is pulled out behind the horse to help flex the stifle (Figure 2.110). The limb is usually held in position for 30–60 seconds. A negative response is thought to suggest that individual flexion responses will also be negative, but this has not been determined definitively for either the forelimb or hindlimb.

NAVICULAR WEDGE TEST

The navicular wedge test can be performed in two different ways.[2] A wedge (usually a block of wood) may be placed beneath the frog of the affected foot while the opposite limb is held up. It is thought to apply direct pressure to the frog region, similar to hoof testers, and is usually performed for 30–60 seconds, after which the horse is trotted off.[2] Alternatively, the toe is forced into an

VetBooks.ir

Figure 2.109. Positioning to perform a full-limb flexion of the forelimb. All of the joints in the limb are flexed simultaneously.

Figure 2.110. Positioning to perform a full-limb flexion of the hindlimb.

elevated position in relation to the heel by placing a wooden wedge under the toe (Figure 2.111). This serves to increase the tension on the DDFT and increase pressure over the navicular bone. The wedge may also be applied to the medial or lateral aspects of the foot to manipulate the soft tissues of the digit.[12] The opposite limb is elevated for 30–60 seconds, and the horse is trotted off. Although these tests are often used for horses with suspected navicular syndrome, one clinical study found that they were not helpful in differentiating navicular region pain from other causes of palmar heel pain.[13] Any cause of heel/foot pain may be exacerbated with these tests.

DIRECT OR LOCAL PRESSURE PLUS MOVEMENT

The premise for applying direct pressure to a specific site and watching the horse trot is to confirm the significance of palpation findings. A positive response to static palpation does not necessarily indicate the site of the problem. However, increasing the baseline lameness by deep palpation of a suspicious area or anatomic structure will often confirm the potential of a problem in the area. Direct pressure is usually applied manually, but hoof testers can be used to apply pressure to the sole of the foot. The limb is usually elevated, the site is compressed for 15–30 seconds, and the horse is trotted off. Exacerbation of the lameness by one or more grades is considered a positive response.[2] The direct pressure test is most commonly performed over swellings of the splint bones, dorsal metacarpus, flexor tendons, suspensory body and branches, and medial aspect of the tarsus. It also may be used to assess pain in the proximal suspensory region of both the forelimb and hindlimb and several areas of the axial skeleton.

Rectal Examination

A rectal examination may be indicated in some horses with upper hindlimb lameness. It is most commonly performed in horses with suspected pelvic fractures or problems in the sacral region. Information also may be obtained rectally in horses with iliopsoas myositis, fractured vertebrae, or thrombosis of the iliac arteries.[15] Rectal examination is usually performed with the horse standing still, but it may be beneficial to walk the horse while performing the rectal exam (so-called walking rectal). The examination is often performed in a cranial-to-caudal direction. Pressure should be applied to the iliopsoas muscle located cranial to the pelvic brim. The aorta and iliac arteries should be checked for normal pulsation. The symmetry of the pelvis is palpated by comparing one side to the other (Figure 2.112). With displaced ilial fractures, an obvious asymmetry may be present, and rocking the horse from side to side may reveal crepitus or movement of the bones. The ventral aspect of the sacral vertebral bodies should be checked for alignment and any depression or protrusion into the pelvic canal, which may indicate fracture or subluxation. Rectal ultrasound of the pelvis may be performed at the same time as palpation to further document abnormalities.

Neurological Examination

Any horse with a suspected neurological problem should have a complete neurological examination performed (see Chapter 12 for this description). However, determining the presence of hindlimb weakness and correct limb placement can be performed quickly and may

VetBooks.ir

A B C D

Figure 2.111. A (10″ × 10″) 15° wooden wedge block with a nonslip surface can be used for distal limb manipulation during lameness evaluation. The foot is typically placed in four different orientations; toe wedge (A), heel wedge (B), lateral wedge (C), and medial wedge (D). Depending on the orientation of the block, different tissues within the hoof are placed under compression or tension. Source: Courtesy of Dr. Randy Eggleston.

help suggest neurological problems. Hindlimb weakness can be assessed by either pushing the horse from one side to the other or more commonly be pulling its tail to each side. This has been referred to as the sway test or tail pull test.[15] Normal horses resist pulling the tail, while many ataxic horses appear relatively weak and do very little to resist being pulled from one side to the other. However, this test is very subjective, and many young Warmblood horses with underdeveloped hindlimb musculature often appear to be very weak but are not neurological.

Limb placement can be assessed by walking the horse over a curb, circling, positioning the limb across midline while standing, and trotting in a serpentine pattern. Repeated stumbling, hitting the curb, circumduction of the hindlimbs, and a general sense of not knowing where the hindfeet are suggest a neurologic problem. Some horses that have bilateral hindlimb ataxia may also appear very "bouncy" when trotted and when stopped suddenly from a trot may stumble in the hindlimbs. A variety of neurologic conditions may be confused with lameness

VetBooks.ir

problems and at times differentiating between lameness and neurologic disease can be very difficult (see Chapter 12 for more information on neurologic examination).

SUBJECTIVE ASSESSMENT OF LAMENESS

Kevin G. Keegan

The word "lame" stems from the Proto-Indo-European language root *lem*, meaning literally "broken," with comparative usage in Old English (*lame*), Old Norse (*lami*), and Proto-Germanic (*lahm*).[31] The word *lame* is an adjective, as in a *lame* limb. In modern veterinary usage, we use a derivative of the word as the noun *lameness*, the state of being *lame*. *Lameness* is a clinical sign not a disease.[32,48] A synonym is *limp*, also used as a verb, as in "the horse *limps*." A horse with lameness is a limping horse.

Most lameness is caused by pain during weight-bearing, with shifting of load away from the source limb onto the other three, non- or less afflicted, limbs. In human medicine lameness due to pain on weight-bearing is called *antalgic* ("against pain") gait and is considered the medical term for "limping." In the bipedal human the main feature of antalgic gait is decreased duration of stance time of the affected versus unaffected limb.[36] But this is frequently not true in the quadruped equine unless the lameness is severe, and, instead, it is a decrease in peak vertical ground reaction force on the affected limb that is the primary effect of weight-bearing pain.[10,54,55] But also decreased vertical ground reaction force can be a sign of a comparative unilateral weakness, neurologic dysfunction, anatomical asymmetry, and, to a limited degree and uncommonly, even primary functional asymmetry (handedness, laterality), a dominance of one side of the brain in controlling particular activities. Horses without pain, neurologic abnormality, or weakness in the limbs or torso usually move symmetrically and are not lame.

Detection of the clinical sign of lameness by observing the horse move in most situations is a simple concept. It is the recognition of asymmetric gait. However, it is more difficult in practice because of inherent limitations in spatial and temporal resolution of unaided human eyesight. In contrast, determination of the cause and importance of lameness is frequently both difficult and complex, requiring detailed knowledge of anatomy; understanding of how movement of the head, torso, and limbs are affected by limb loading and unloading; a complete and systematic palpation and manipulation of the entire limb and torso; knowledge of breed- and use-specific diseases that cause lameness; localization of the focus of pain with local anesthesia; and quality imaging. Obtaining relevant history, visual examination of the horse at rest, and palpation and manipulation of the limbs and torso are covered in earlier chapters. Subjective evaluation of the horse during movement to detect and assess lameness is the purpose of this chapter.

A horse without lameness moves symmetrically, with equal amplitude of movement in the head, torso, and limbs during the right and left halves of the stride. A horse with lameness due to pain in a limb moves asymmetrically. This does not mean that all horses with musculoskeletal or neuromuscular abnormality move asymmetrically or show lameness. It is possible for horses with bilateral pain or disease to move symmetrically, at least in some strides, especially when moving in a straight line. But one limb is usually slightly worse, and an average asymmetry of movement, or lameness, over all strides is retained. Axial skeletal disease in particular may cause relatively equal amounts of pain during both steps in a stride so that lameness may not be displayed. However, most horses with musculoskeletal disease will display lameness, and many horses that display lameness have musculoskeletal disease.

The asymmetric movement in horses with musculoskeletal or neurologic abnormality causes a decrease in resultant ground reaction forces, because most pain or dysfunction occurs during weight-bearing. Some abnormalities may also cause pain in the swing (non-weight-bearing) phase of the stride, but there is objective evidence that the abnormal movement due to pain or dysfunction in the swing phase of the stride affects kinematics (and likely ground reaction forces) also in the stance phase of the stride.[27] In other words, pure swinging limb lameness conditions without weight-bearing signs have not been shown to exist and if they do exist are not common.[9] In addition, asymmetric limb movement without asymmetry in weight-bearing, though technically defined as lameness, is more likely simply a sign of conformational difference or handedness and not clinically significant as a sign of disease.

Movement of the midline of the horse's body, more precisely movement of the head and pelvis, in the same sagittal plane of the body's center of mass, is directly related to vertical ground reaction forces on the limbs during weight-bearing.[13] Movements of the abaxial appendages are more naturally variable (right vs. left and stride by stride) and more affected by idiosyncratic factors, like conformation and handedness (predominance or preference of one side of the body over the other). Higher variability and more complex association to multiple causative factors decrease the usefulness of specific limb movements to reliably signal painful weight-bearing lameness.[1,44,45] For these reasons, observation of how the midline (head and torso) moves is more sensitive and specific for weight-bearing lameness detection than evaluation of limb movement. Exceptions to this generalization include dorsiflexion of the fetlock during weight-bearing and amplitude of hindlimb protraction, both of which, when decreased, have been shown to be reliable indicators of abnormality.[12,19,30] These are discussed later in this section.

However, there are a few musculoskeletal/neurological abnormalities that are most easily recognized as specific "odd" limb movements and, if seen unilaterally, satisfy the definition of lameness. Fibrotic myopathy of the stifle flexor muscles, stringhalt, momentary or intermittent upward fixation of the patella, gastrocnemius muscle injury, peroneus tertius rupture, and "shivers" can be recognized merely by observing limb movement

VetBooks.ir

during the swing phase of the stride or when not weight bearing. Although these are thought to be pure "swinging limb" lameness conditions, with pain or dysfunction isolated to the swing phase of the stride, and therefore exceptional to biomechanical descriptions of weight-bearing lameness, the author has measured horses with these conditions and found that decreases in vertical movement of the torso are likewise seen. Thus, in these few exceptional conditions, the descriptions of asymmetric vertical movement of the head and pelvis may not adequately explain the quantity of dysfunction, but they remain valid for describing side of lameness. Detection of these lameness conditions by observing characteristic abnormal limb movement is discussed later.

EVALUATION OF THE HORSE FOR LAMENESS AT THE WALK

Because limb and torso movements are slower when walking, it is the easiest gait in which to observe lameness. However, for disease of mild severity, vertical ground reaction force may not reach a minimum threshold for pain, but the horse walks without visible asymmetric movement and is not subjectively lame. It is thought that sometimes, and for some conditions, lameness is more visible at the walk than at other gaits, but for weight-bearing lameness, this is most likely because movement speed is within the temporal resolution of unaided human sight. Weight-bearing lameness at the trot measures greater than lameness at the walk.[4]

The trajectory of vertical head movement during the walk of a horse with unilateral forelimb lameness is asymmetric (Figure 2.113). At the walk, as in other gaits at slow speeds, the front limbs acts almost exclusively like a strut or crutch, so head movement trajectory in a horse with forelimb lameness is usually shaped like depicted below, being highest from the ground right before or during the first part of stance of the lame or lamer forelimb and lowest during stance of the not lame or less lame forelimb. This corresponds only vaguely to the concept of "head nod" understood by many veterinarians and taught to veterinary students of the horse's head moving "down on the sound" limb and "up on the lame" limb. This explanation of "head nod," however, is actually not precisely true, and a more accurate description of "head nod" during the trot will be developed later in this section.

Vertical movement of the pelvis at the walk does not follow this downward and then upward trajectory. Instead it is upward and then downward with the low positions at the beginning of, and the high positions, during stance. Also with two and three limbs alternately bearing weight at the same time, vertical pelvic movement (VPM) at the walk may not be a simple biphasic pattern. Total vertical pelvis movement is also less than that of the head, and the amount of asymmetry between right and left hindlimb strides is more difficult to see. These characteristics make detecting hindlimb lameness using VPM at the walk more difficult than using head movement to detect forelimb lameness at the walk. Alterations in hindlimb movement like decreased hindlimb protraction, prominent circumduction, or excessive rotation are more obvious than asymmetry of VPM.

Other forelimb and hindlimb movement parameters, besides vertical head and pelvic movement, which indicate lameness, may also be seen at the walk, but these will also be seen at the trot.

Evaluation for lameness at the walk can be enhanced by turning the horse in a tight circle, especially on hard surfaces or on surfaces with high frictional forces between the bottom of the foot and the ground. If weight-bearing or torque of the inside limb elicits pain, then the outside limb will display accelerated protraction and earlier-than-expected initiation of weight-bearing. This abnormal movement is more prominent

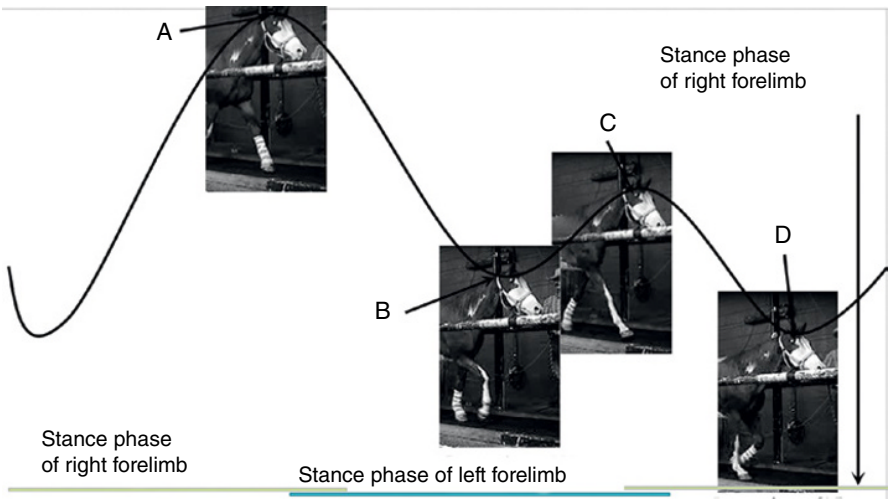

Figure 2.113. Typical vertical head trajectory of a briskly walking horse with a forelimb lameness (in this specific case a left forelimb lameness). (A) Highest head height immediately before impact of the lame or more lame (left) forelimb (note bandage: inferior check ligament previously injected with collagenase to induce lameness). (B) Local minimum head position during stance phase of lame or more lame forelimb that is higher than that during stance phase of the non-lame or less lame forelimb (D). (C) Local maximum head position right before impact of the non-lame or less lame forelimb that is lower than before impact of the lame or more lame forelimb (A). (D) Lowest head position during stance phase of the non-lame or less lame forelimb.

VetBooks.ir

for forelimb compared with hindlimb lameness, most likely because of higher percent of total body weight borne by the forelimbs compared with the hindlimbs at the walk. Limb position and foot placement under the body, as well as head height from the ground (in forelimb lameness), can also be assessed during turning. The outside limb swings forward and lands quickly, crossing over the lame inside limb. Head movement trajectory during turning with forelimb lameness is typical of an impact-type forelimb lameness seen at the walk and the trot, with the head moving upward greatly during impact of the lame, inside, forelimb.

Lameness conditions that can usually be recognized and diagnosed almost solely by evaluation of gait at the walk include:

1. Fibrotic myopathy: Injury to the stifle flexor muscles (biceps femoris, semimembranosus, semitendinosus) most likely occurs with stifle hyperextension when the hindlimbs are protracted forward and the horse either falls or the hind torso lowers as in a sliding stop. Injury to the stifle flexors can result in pain soon after injury, but fibrosis or ossification at the musculotendinous junction, which can be palpated, is a common, more chronic result. This injury leads to a characteristic hindlimb swing trajectory beginning with increased retraction, followed by the limb swinging forward with low flight arc and slightly shortened length of protraction, and ending with an elevation of the hoof, which precedes an unusual, goose-stepping-like retraction of the hoof backward immediately before impact (Figure 2.114). In contrast the normal hoof flight trajectory has shorter retraction, higher swing trajectory, and greater protraction, with the hoof ending its flight moving forward and downward. It was previously believed that this condition was an isolated swinging limb lameness seen especially and primarily at the walk, with a decrease or elimination of signs at higher speed gaits, and rarely causing clinically significant restricted use or decrease in function. However, recent kinematic studies prove that the condition also causes decreased hindlimb propulsion with characteristic decreased rise of the pelvis after affected hindlimb stance, i.e. a lack of hindlimb vertical propulsion. Moreover, when the restriction in movement is eliminated by transection of the fibrosis, the abnormal swing movement and decreased hindlimb propulsion are both eliminated.
2. Stringhalt: Stringhalt causes lameness of presumed neurologic origin characterized as a sudden hyperflexion of the hindlimb. Known causes are chronic toxicity from ingestion of certain species of weeds (dandelion family) in times of drought and prior trauma to the dorsal surface of the hindlimb metatarsus and tarsus. The hindlimb hyperflexion can be slight or dramatic and may vary in amplitude from stride to stride. When severe, it appears to disturb the horse, but in many cases the horse seems indifferent when it occurs. It is generally thought only to cause dysfunction during the hindlimb hyperflexion, but this author has also measured decreased weight-bearing in the affected limb, and treatment by surgical removal of a length of long digital extensor tendon/muscle can eliminate the hyperflexion and decrease both lameness and apparent discomfort in severe cases.
3. Upward fixation of the patella: Momentary or intermittent upward fixation of the patella is dysfunction in the normally smooth locking and then unlocking of the patella over the top of the medial condyle of the femur during an otherwise normal hindlimb movement. At the end of limb extension, before lift-off of the hindlimb foot, to prepare for initiation of swinging the limb forward, quadriceps muscle activity elevates the patella, unlocking it from the femur and allowing stifle flexion. Delayed or incomplete

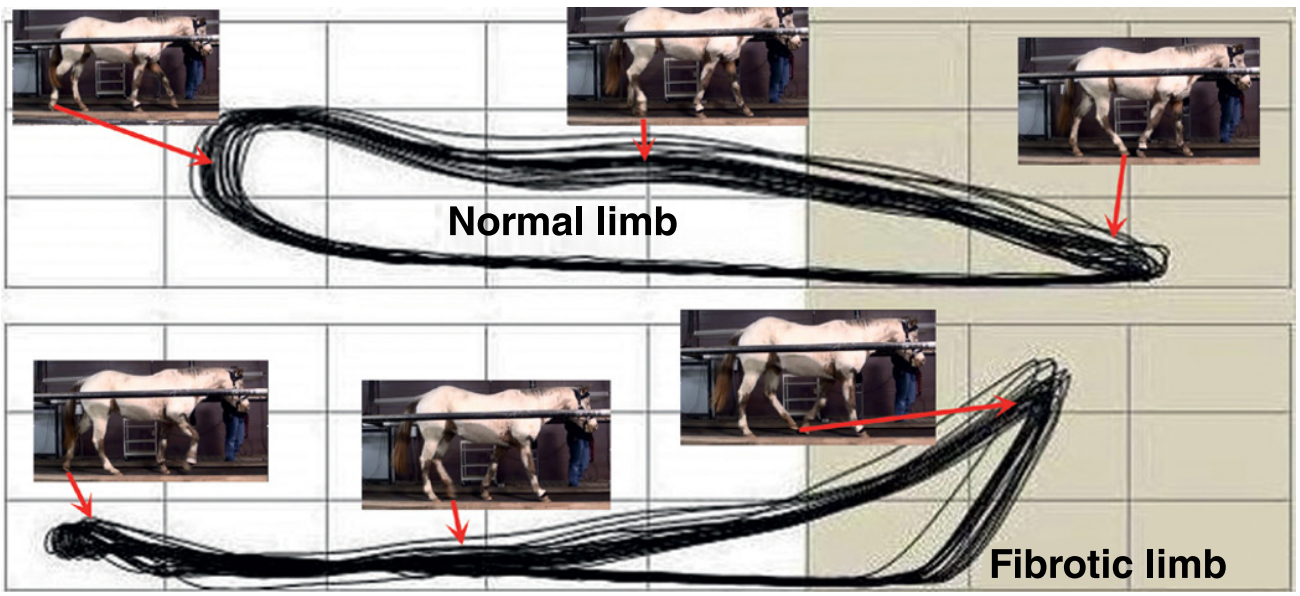

Figure 2.114. Hoof flight trajectories during fibrotic myopathy of the stifle flexor muscles (biceps femoris, semitendinosus, semimembranosus) with associated still video frames indicating limb positions. Upper trajectory is that of the contralateral normal hindlimb foot. Lower trajectory is that of the affected hindlimb foot.

VetBooks.ir

unlocking results in increased tension in the patellar ligaments at the end of limb extension, followed by a forced unlocking, and then an abnormal release of stored energy, as limb hyperflexion, when finally released. The resulting hyperflexion of the hindlimb is not unlike that of stringhalt (see previous paragraph), but is different in that it is preceded by delayed stifle extension with prolonged weight-bearing and increased hindlimb retraction. Also, momentary or incomplete upward fixation of the patella, compared with stringhalt, is more intermittent (thus the alternative name of the condition, *intermittent* upward fixation of the patella), from stride to stride. In addition to these swinging limb abnormalities, momentary/incomplete/intermittent upward fixation of the patella causes hindlimb weight-bearing lameness, primarily decreased propulsion of the pelvis upward after hindlimb pushoff.

4. Gastrocnemius muscle injury: Injury to the gastrocnemius muscle insertion causes characteristic internal rotation (calcaneus moves abaxially) of the hindlimb at the end of weight-bearing. Only a few cases with definitive diagnosis have been described.[52]
5. Peroneus tertius rupture: Rupture of the peroneus tertius is usually caused by the horse falling with the hindlimbs retracted, falling in a full hindlimb cast, or struggling to free an entrapped or restrained hindlimb. Rupture of this dense fibrous ligament that spans two highly mobile joints (stifle and hock) disrupts the normal function of the hindlimb of coupled stifle and hock flexion and extension. With this injury, at the termination of hindlimb stance, stifle flexion initiates swing of the hindlimb forward, but the hock does not actively flex. Hock flexion is thus delayed, weight-bearing and retraction of the affected hindlimb is prolonged, and the hock flexes only with distal limb momentum as it swings forward. Although at rest the horse can seemingly bear full weight when standing, decreased weight-bearing during movement occurs in the affected limb.
6. Shivers: Shivers is a presumed degenerative neurologic abnormality that causes a hyperflexion or lifting of the hindlimbs, which is more like a spasm than a gait abnormality.

EVALUATION OF THE HORSE AT THE TROT

In many disciplines and breeds of horses, the trot is the most common gait used for observing lameness. In principle the other symmetrical gaits are similar to the trot with the head and pelvis falling and rising during the first and second halves of stance, but with greater (less commonly) or lesser (more commonly) amplitude. So, the basic biomechanical principles describing alteration of head and pelvic height with lameness are the same, but the amplitudes of asymmetries are different. Additional information on lameness in "gaited" horses is explained in Chapter 9.

Detection of lameness in quadrupeds is easiest during the symmetrical gaits, like the trot. A normal expected symmetry provides a standard against which amplitudes of asymmetry between right and left halves of a stride can be compared within the individual horse. However the limbs experience greater vertical force and faster rates of force application at the trot compared to the asymmetric gait of the canter at equivalent speeds, despite the presence of a single-limb weight-bearing portion of the stride.[5,49,56] Decreased loading and weight shifting off a painful limb is more easily accomplished in the symmetrically moving horse. All of these factors contribute to understanding and appreciating why lameness is not only easiest but also more accurately and more precisely evaluated at the symmetric gaits. It has been shown that lameness even at a slow trot will be detected earlier and more consistently than lameness at the asymmetric gait of the gallop.[34]

Speed of movement at the trot has been shown to affect amplitude of lameness, especially when using limb movement as the indicator of lameness. It is reasonable to think that the amplitude of lameness displayed by the horse will increase with speed of movement, but this is not the case. When relying on subjective evaluation, it frequently appears that lameness is greater at slower trotting speeds,[36] but this is most likely because it is easier to see. When measuring lameness, it seems that, instead, there is an optimum speed of movement when lameness amplitude is greatest and stride-by-stride variation is least.[37] Finding this optimal speed is most likely to be successful by allowing the horse to move naturally. This can be confusing when blocking horses, since horses, feeling better, may want to move faster after a successful block. To prevent changes in amplitude of lameness due to speed of movement, one should attempt to keep speed of movement the same before and after block.

The most sensitive body-movement indicators of lameness in quadrupeds is the pattern of vertical movement of the midline of the horse or vertical movement of the head for forelimb lameness and vertical movement of the entire pelvis for hindlimb lameness. Limb movement parameters are useful in some cases, but in general they are too variable and inconsistent to be considered more sensitive and specific indicators of lameness than vertical movement of the head and pelvis.

EVALUATION OF VERTICAL MOVEMENT OF THE HEAD FOR FORELIMB LAMENESS

In order to understand the biomechanics of vertical head movement as it relates to forelimb lameness, some simple principles must be understood. When a horse is trotting, the body moves down and then up in one half of the stride and then down and then up again in the other half of the stride, and the head normally follows this movement pattern. A stride begins when a limb strikes the ground and ends when that same limb strikes the ground again at the start of the next stride. In the non-lame horse, the downward movement in the first half of the stance of one forelimb is equivalent to that in the first half of stance in the other forelimb. Likewise, in the non-lame horse, the upward movement in the second half of stance in one forelimb is equivalent to that in the second half of stance in the other forelimb. Therefore, horses without lameness will have no difference in the lowest positions of the head during stance or in the highest positions of the head before and after stance.

VetBooks.ir

Therefore, vertical head movement in the perfectly "not lame" horse can be modeled as if there is only one predictable periodic signal at twice the stride rate when the horse is trotting, which is that following the vertical movement of the center of mass of the body (Figure 2.115).[13]

Alternatively, when a horse is lame or more lame in one forelimb, then another periodic factor, at the stride rate, or ½ the frequency of the normal expected vertical movement, additionally influences vertical head height from the ground. The horse will always try to move the head upward during pain with maximum effect at the moment of peak pain. Overall head trajectory is the simple summation of these two components in the horse with lameness. The phase or timing relationship between these two components determines the overall shape of vertical head trajectory. This phase relationship between vertical movement components has been described previously.[2,29,38]

When pain (or other dysfunction) is greatest during the first half of stance, component summation results in an augmentation (a raising) both of the maximum head position before lame (or more lame) stance and of minimum head position during stance of the lame (or more lame) forelimb. Overall vertical head trajectory (a combination of the two components) features differences in maximum and minimum head positions between right and left sides of the stride that are of the same sign, meaning that the highest maximum head height occurs before and the highest minimum head height occurs during lame or more lame forelimb stance (Figure 2.116).

Conversely, when the pain is greatest during the second half of stance, there is augmentation of the minimum head position during stance of the lame or more lame forelimb, as in an impact lameness, but, instead, there is also augmentation in the maximum position of the head after pushoff of the lame or more lame forelimb, which is unlike an impact lameness. Overall vertical head trajectory features differences in maximum and minimum head positions that are of opposite sign, with highest minimum position during and highest maximum position following lame or more lame forelimb stance (Figure 2.117).

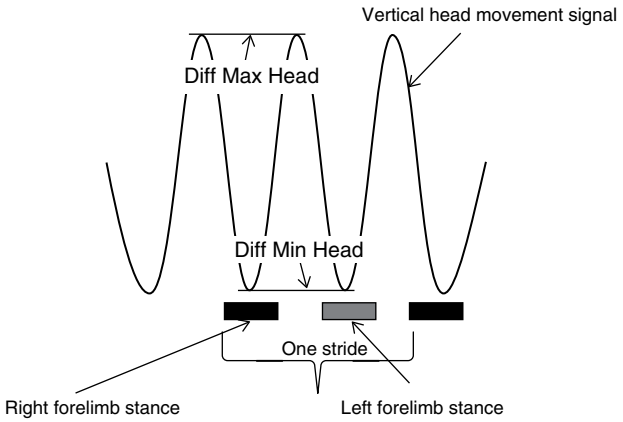

Figure 2.115. Head movement trajectory in non-lame trotting horse following trajectory of center of mass of the body. Trajectory is similar to a sine wave at frequency of twice stride rate because movement is down and then up twice per single stride. In a horse without lameness, downward movement in first half of stance of one forelimb is equivalent to that in the opposite forelimb, and upward movement in second half of stance of one forelimb is equivalent to that in the opposite forelimb. Therefore, the differences in positions of the head from the ground at local minimums (during stance) or, Diff Min Head, is equal to 0. Likewise, difference in positions of head from the ground at local maximums (between the stance phases of each forelimb), or Diff Max Head, is equal to 0.

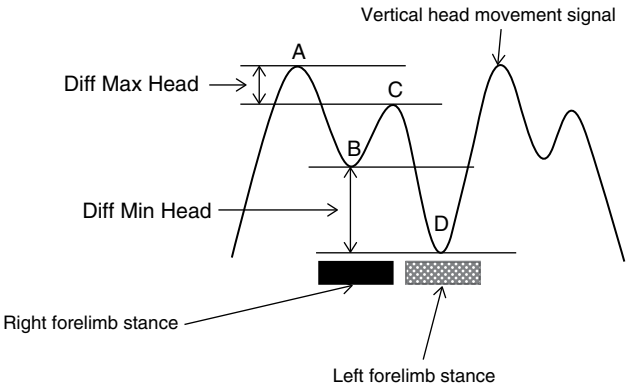

Figure 2.116. Overall vertical head trajectory pattern for horse with impact-type right forelimb lameness or lameness with pain greatest in the first half of, in this case, right forelimb stance. Peak (highest maximum) head vertical position occurs near beginning of stance of the lame or more lame forelimb. Diff Max Head or first maximum head height (A: near beginning of stance of the right forelimb) minus second maximum head height (C: near beginning of stance of the left forelimb) is a positive value. Lowest head position occurs during stance of the not or less lame forelimb. Diff Min Head or first minimum head height (B: during stance of the right forelimb) minus second minimum head height (D: during stance of the left forelimb) is a positive value. Diff Max Head and Diff Min Head are the same sign. For right forelimb lameness, both Diff Max Head and Diff Min Head are positive.

In both of the above types of lameness, the entire amplitude of forelimb lameness is reflected in a combination of the difference in low and high heights of the head. The classic description of "head nod" as only "down on sound" or only as "up on bad" neglects consideration of differences in both the minimum and maximum head positions and will therefore underestimate amplitude of forelimb lameness.

When pain is greatest near the middle of stance, the effect of the head moving upward during peak pain will augment only the minimum head position during stance of the lame or more lame forelimb so that there is a difference in the minimum head positions between right and left stance but no difference in maximum positions of the head (Figure 2.118; Diff Max Head = 0). In this case the amplitude of "head nod," usually described as "down on sound" or "low on sound," captures the entire amplitude and will not underestimate forelimb lameness. This is probably why midstance forelimb lameness is easiest to detect subjectively and veterinarians infrequently disagree on limb involved or amplitude with this type of forelimb lameness.

The classic "head nod" as "down on sound" implies that in a forelimb lame horse, the head moves down when the non-lame or less lame forelimb is weight bearing, and then up when the lame or more lame forelimb is weight bearing. This is a deficient simplification that

VetBooks.ir

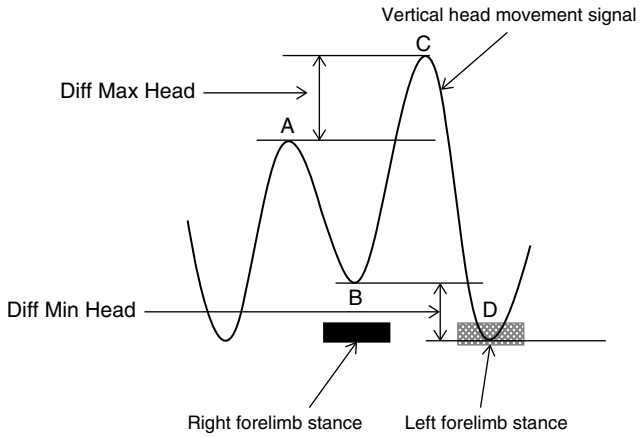

Figure 2.117. Overall vertical head trajectory pattern for horse with pushoff type, in this case right forelimb lameness, or lameness with pain greatest in the second half of right forelimb stance. Peak (highest maximum) head vertical position occurs near beginning of stance of the not or less lame forelimb. Diff Max Head or first maximum head height (A: near beginning of stance of the right forelimb) minus second maximum head height (C: near beginning of stance of the left forelimb) is a negative value. Lowest head position occurs during stance of the not or less lame forelimb. Diff Min Head or first minimum head height (B: during stance of the right forelimb) minus second minimum head height (D: during stance of the left forelimb) is a positive value. Diff Max Head and Diff Min Head are of opposite signs. For a right forelimb pushoff lameness Diff Min Head is positive (+) and Diff Max Head is negative (–).

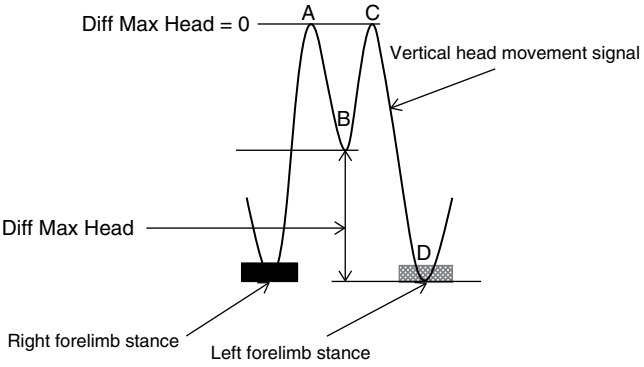

Figure 2.118. Overall vertical head trajectory pattern for horse with midstance right forelimb lameness or lameness with pain greatest in the middle of right forelimb stance. Peak (maximum) head vertical position before right and left forelimb stance is equivalent. Diff Max Head or first maximum head height (A: near beginning of stance of the right forelimb) minus second maximum head height (C: near beginning of stance of the left forelimb) = 0. Lowest head position occurs during stance of the not or less lame forelimb. Diff Min Head or first minimum head height (B: during stance of the right forelimb) minus second minimum head height (D: during stance of the left forelimb) is a positive value.

is really only true in horses with severe lameness. But, in horses that are trotting, the head follows the center of mass of the body, moving down when the horse is landing on a forelimb and then up when the horse pushes off that forelimb, even with moderate to severe lameness. The head does not just move up during the stance phase of the lame limb and down during the stance phase of the sound limb. So why is this incorrect maxim "down on sound" propagated in our veterinary lexicon and still taught to veterinary students?

Examining the different shapes of the trajectories of vertical head movement as one (the most simple) type of forelimb lameness is gradually increased suggests the origin and context of this false maxim (Figure 2.119). Considering a very mild lameness, the asymmetry of the down and then up movement, twice per stride, is small, so there is just a little less downward motion of the head (upper left quadrant, Figure 2.119) during lame limb stance. The head halts its fall at a slightly higher vertical position during lame or more lame forelimb stance compared with not lame or less lame forelimb stance. As the lameness increases, this asymmetry is increased, but the overall shape of the vertical head movement trajectory (upper right and lower left quadrants, Figure 2.119) is retained. Ultimately, as the amplitude of lameness is further increased, an inflection point in the trajectory is reached, and the downward and then upward movement of the head is now upward in the first and then downward in the second half of stance. This can appear as primarily upward movement with subjective evaluation. This deficient version of "down on sound" seems correct only when the lameness is severe, so, in the practical sense, it is not a useful explanation.

With pain in the forelimbs that is maximum during the first half of weight-bearing, the horse will move its head upward so that it is decelerating upward at the beginning of stance and then accelerating downward during the remaining first half of stance. Thus the head will fall from a relatively higher position but then halt its descent prematurely so that it ends up at a local minimum position higher compared with its position during the contralateral (less lame side) stance. The common description of this "head nod" phenomenon as "down on sound," meaning moving down more on the sound limb, is therefore also not always true, and the actual length of downward descent may be greater than during the same period of contralateral (not lame or less lame) forelimb stance. The more accurate descriptive maxim in this type of forelimb lameness would therefore be "lowest on sound."

Alternatively, if the pain is present during the second half of stance when the head is normally moving upward with the center of mass of the body, the head will move up more, decelerating at the end of stance. The head will then reach its highest vertical position preceding the beginning of stance in the contralateral, non-lame or less lame, forelimb. There will be a difference in the maximum heights of the head with the head highest before the stance phase of the not lame or less lame forelimb. This is opposite that of lameness that occurs during the first half of stance, where the head will move up more after pushoff of the non-lame or less lame forelimb. However, side of lameness remains determined correctly by the maxim "lowest on sound." "Lowest on sound" is a correct description of side of lameness, regardless of timing of lameness within stance.

Thus the side of forelimb lameness is identified by the difference in the low or minimum positions of the head during stance, and timing of lameness is determined by the difference in the high or maximum positions of the head occurring after pushoff of each forelimb.

VetBooks.ir

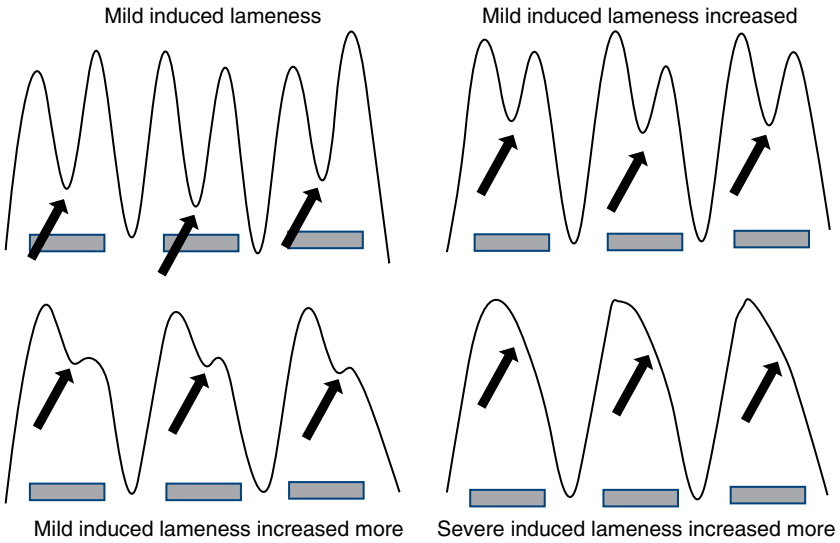

Figure 2.119. Overall vertical head trajectory patterns for a horse with gradually increasing forelimb lameness from sole pressure. Least amount of induced lameness shown in upper left plot and most amount of induced lameness shown in lower right plot. Gray bars indicate stance phase of one forelimb. As amplitude of lameness increases, characteristic downward and then upward head movement changes (reverses) to upward and then downward head movement until lameness amplitude increases to the point that greatest observed movement direction is upward during lame or more lame forelimb stance and downward during not or less lame forelimb stance.

The amplitude of lameness, which affects both the difference in the low and high positions of the limb, is proportional to some combination of these differences. The better maxim, or definition of "head nod," to determine side of lameness, is "lowest on sound." However, the amplitude of this explanation of "head nod" will not always be proportional to the true amplitude of forelimb lameness, because a difference in low positions of the head, depending on the timing of lameness, may represent only a portion of the head movement asymmetry. The side of lameness can be determined by the difference in the low positions of the limb, but the amplitude of lameness must take into consideration both the differences in the high and low positions of the head.

When horses are trotted in a straight line while restrained by a handler or during lunging, both which are common activities used by practitioners to evaluate horses for lameness, the speed of movement is such that most forelimb lameness is measured as greatest during the first half of stance (impact to midstance). This is most likely because at slow speeds the front limb acts mostly as a strut or crutch with little contribution to active propulsion of the body forward, most of which is provided by pushoff of the hindlimbs. At higher speeds pushoff-type forelimb lameness is measured with greater frequency. Although timing of forelimb lameness is most likely dependent upon speed of movement and ground surface qualities,[3] knowledge of whether the lameness is manifested primarily during the first or second half of stance may be valuable to the practitioner in helping to localize the cause of lameness within the affected forelimb.

Other random causes of vertical head movement, which will interfere with subjective evaluation of head nod, must somehow be extracted and ignored by the examiner when detecting forelimb lameness. This can be difficult with misbehaving horses when they are randomly shaking or jerking the head in the vertical plane.

WITHERS MOVEMENT

Vertical movement of the withers may also be used to detect and measure amplitude of forelimb lameness, and there is evidence that the character of withers vertical movement may help to differentiate compensatory from primary lameness in the multiple limb lameness situation.[42] When the asymmetry of withers movement is opposite in sign to that of the asymmetry of head movement, for example, if lowest head position is during the stance phase of the left forelimb (a sign of right forelimb lameness) but lowest withers position is during the stance phase of right forelimb, a primary hindlimb lameness (right) should be suspected. Whereas when the asymmetry of withers movement is the same sign as that of asymmetry of head movement, a primary forelimb lameness should be suspected.

However, in general asymmetric withers movement is less sensitive than asymmetric head movement at detecting amplitude of forelimb lameness. Because the forelimb is attached to and supports the axial skeleton by a soft tissue sling mechanism, ground reaction force and body center of mass effects on each other are damped, and the amplitude of asymmetric movement is suppressed.

EVALUATION OF VERTICAL MOVEMENT OF THE PELVIS FOR HINDLIMB LAMENESS (THE *V*ERTICAL *P*ELVIC *M*OVEMENT [VPM] METHOD)

Evaluation of hindlimb lameness is easier conceptually, but more difficult practically, than evaluation of forelimb lameness. It is easier conceptually because movement of the posterior half of the horse's torso can be modeled as a simple single free body moving down and up in response to resultant and applied ground reaction forces.[7] It is more difficult practically because the amplitude of vertical movement is small and more difficult to see.

VetBooks.ir

The most direct observational sign of hindlimb lameness is asymmetric vertical movement of the entire posterior end (pelvis) of the horse. The horse has no large mass on a long lever arm projecting out of the hindquarters, so the simple mechanism achieved by altering head movement to adjust forelimb weight-bearing is not available to the horse with hindlimb lameness. Other adjustments must be performed. To decrease force on the hindlimbs, the pelvis either falls less (like dropping a ball from a lower height), if the pain is greatest in the first half of stance, or rises less, from decreased hindlimb vertical propulsion, if pain is greatest during the second half of stance. As the severity of hindlimb abnormality increases, both decreased fall and decreased rise (impact and pushoff lameness) are seen. The adjustments made by the horse to decrease fall and to decrease rise of the pelvis are different.

Decreased fall of the pelvis results in a difference in low positions of the pelvis near midstance, lower (i.e. closer to the ground) on the not lame or less lame hindlimb, if the pain is primarily in the first half of hindlimb stance (Figure 2.120). For purposes of classification, this can be called an "impact"-type hindlimb lameness.

When pain is greatest in the second half of stance, the horse pushes off less, causing the pelvis to rise less, resulting in a difference in the high positions of the pelvis (Figure 2.121). It is lower after lame limb pushoff. For purposes of classification, this can be referred to as a "pushoff"-type hindlimb lameness.

Hindlimb lameness can be both impact and pushoff, which becomes more common as hindlimb lameness increases in severity. Hindlimb lameness can also be impact on one side and pushoff on the other, a bilateral lameness, but this is not common. Unlike forelimb lameness, where at moderate speeds most lameness is of the impact type, for hindlimb lameness a predominant impact- or pushoff-type lameness occur with approximate equal frequency. This is probably because the hindlimb acts as both a propulsive force during pushoff and a braking force during impact even at moderate speed of movement. There is objective evidence that impact and pushoff hindlimb lameness have different vertical and horizontal ground reaction force profiles.[6]

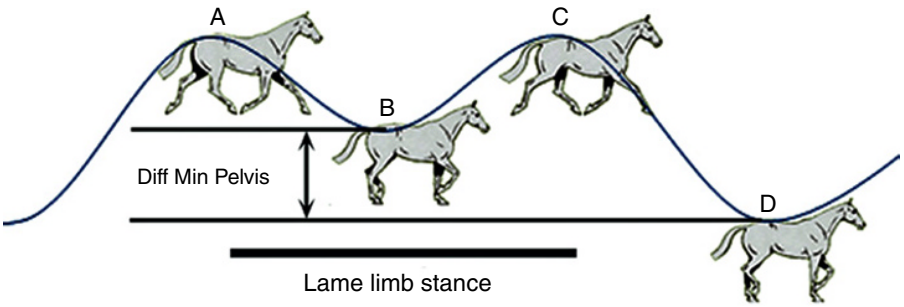

Figure 2.120. Overall vertical pelvis trajectory pattern for horse with impact-type hindlimb lameness or lameness with pain greatest in the first half of hindlimb stance. Peak (maximum) vertical pelvic position before right and left hindlimb stance is the same. Diff Max Pelvis or first maximum pelvis height (A: near beginning of stance of the right hindlimb) minus second maximum pelvic height (C: near beginning of stance of the left hindlimb) is zero. Lowest pelvic position occurs during stance of the not or less lame hindlimb. Diff Min Pelvis or first minimum pelvic height (B: during stance of the right hindlimb) minus second minimum pelvis height (D: during stance of the left hindlimb) is a *positive value for right hindlimb lameness (and a negative value for left hindlimb lameness)*.

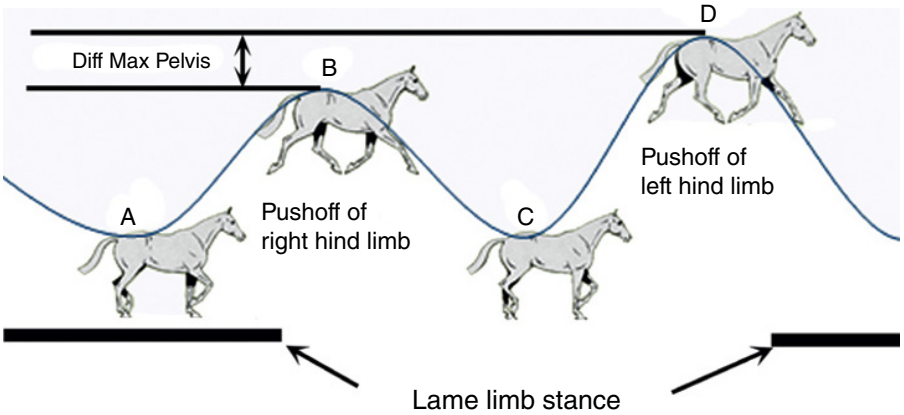

Figure 2.121. Overall vertical pelvis trajectory pattern for horse with pushoff-type right hindlimb lameness or lameness with pain greatest in the second half of right hindlimb stance. Peak (maximum) vertical pelvic position after pushoff of left hindlimb (D: before impact of right hindlimb) is greater than vertical pelvic position after pushoff of right hindlimb (B: before impact of left hindlimb). Diff Max Pelvis or first maximum pelvis (near beginning of stance of the right hindlimb, D) minus second maximum pelvic height (B: near beginning of stance of the left hindlimb) is positive. Lowest pelvic position occurs during stance of right and left hindlimbs. Diff Min Pelvis or first minimum pelvic height (A: during stance of the right hindlimb) minus second minimum pelvis height (C: during stance of the left hindlimb) is zero.

VetBooks.ir

Knowledge of and ability to detect the different types of pelvic asymmetry may be helpful to veterinary practitioners isolating lameness within the affected limb.

Decreased pelvic fall during hindlimb lameness is accomplished by complex muscular activity in the proximal hindlimb, by shifting weight to the contralateral forelimb, and by "hip hiking" as the horse attempts to use the lame-side hemipelvis in a similar (but not so successful) manner as it uses its head in forelimb lameness, elevating the lame-side hemipelvis immediately before weight-bearing. Alternatively, decrease pelvic rise during pushoff-type hindlimb lameness is primarily caused by reduced extensor muscle activity, resulting in decreased propulsion of the body mass upward and forward. Because the pelvis rises to a lower height relative to the ground after deficient pushoff, swinging the limb forward subsequently requires more limb flexion to prevent toe dragging. This increase limb flexion during swing creates the "hip dip" that occurs after stance of the lame-side hindlimb. Insufficient limb flexion and "hip dip" result in toe dragging, an additional sign of a hindlimb lameness characterized by decreased pushoff. Because the causes of decreased hindlimb impact and decreased hindlimb pushoff are different, impact- and pushoff-type hindlimb lameness should be considered separate entities, and total amount of hindlimb lameness is the sum of both.

EVALUATION OF PELVIC ROTATION FOR HINDLIMB LAMENESS (THE *P*ELVIC *R*OTATION *M*ETHOD [PRM])

Some veterinarians observe for hindlimb lameness at the trot by assessing amount of "hip hike" and "hip dip," which are manifestations of asymmetric pelvic rotation in the frontal plane, instead of observing whole pelvis rise and fall as described above.[35,39,40] However, reference to the "hip" (coxofemoral joint) in this observation method is actually a misnomer as the hip joint is not visible under the gluteal muscle masses. The evaluator is actually observing vertical movement of the tubera coxae.

When a horse is trotting, the vertical movement trajectory of each tuber coxae is normally asymmetric in time (i.e. it is not similar to a perfect sine wave). It moves downward during the first half of stance to reach a local minimum at midstance and then upward as the horse straightens and pushes off the hindlimb. The tuber coxae then moves down a greater amount as the limb flexes and swings forward, reaching its lowest position from the ground after that hindlimb pushoff. Finally, during hindlimb protraction, the tuber coxae moves upward, back to its original height, in preparation for hindlimb hoof contact and the beginning of the next stride's stance (Figure 2.122).

The pelvis is minimally rotated, and the right and left tuber coxae are at equivalent heights when the normal (i.e. not lame) horse is not weight bearing with one hindlimb in retraction just after pushoff and one in protraction, just before impact. The pelvis is maximally rotated when one hindlimb is weight bearing and the other is swinging forward, with the tuber coxae on the weight-bearing side higher than the tuber coxae on the non-weight-bearing side. The pelvis is rotated toward the hindlimb swinging forward.

With most hindlimb lameness, total vertical movement of the tuber coxae is greatest on the lame or more lame side. This may be because of both a "hip dip" (a low position of the tuber coxae) right after pushoff of the lame hindlimb and a "hip hike" (a high position of the tuber coxae) right before impact of the lame limb. A "hip dip" occurs because the lame hindlimb, after weak pushoff and small amplitude of pelvic rise, must have increased flexion (and dipping of the tuber coxae

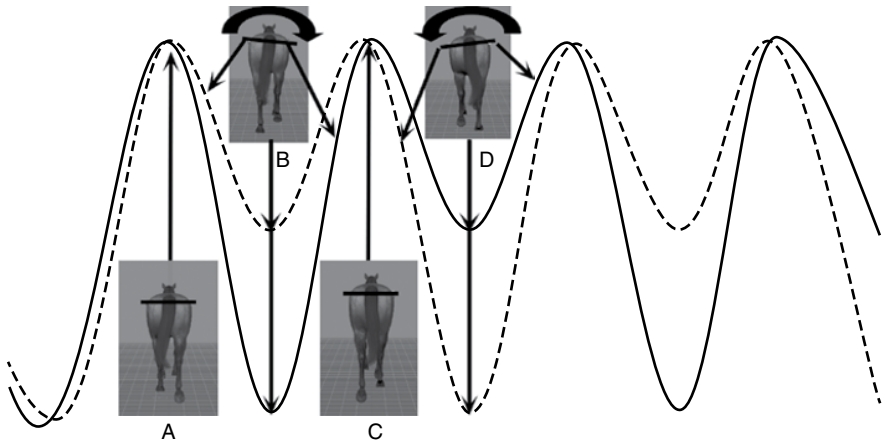

Figure 2.122. Vertical trajectories of right (solid line) and left (dashed line) tuber coxae in horse without hindlimb lameness. (A) Just before impact of left hindlimb and after pushoff of right hindlimb, both tuber coxae at same vertical heights from the ground and the pelvis are not rotated relative to the ground. (B) During left hindlimb stance, left tuber coxae at local minimum that is higher than right tuber coxae local minimum when right hindlimb at midswing. The pelvis is rotated to the right with the right hindlimb flexed. (C) Just before impact of right hindlimb and after pushoff of left hindlimb, both tuber coxae at same vertical heights from the ground and the pelvis, once again, are not rotated relative to the ground. (D) During right hindlimb stance, right tuber coxae at local minimum, which is higher than left tuber coxae local minimum when left hindlimb at midswing. The pelvis is rotated to the left with the left hindlimb flexed. *Source*: Screenshots of horse animations taken (with permission) from LamenessTrainer.com (authors/developers S.D. Starke, G.C. VetBooks.ir

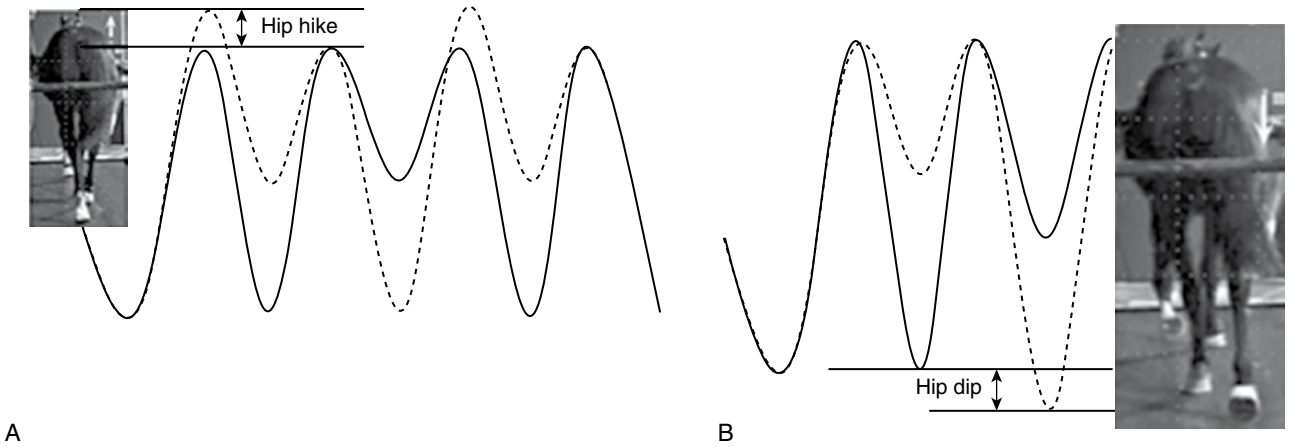

Figure 2.123. (A) Description of "hip hike" as a modification of lame-side tuber coxae trajectory. Upward movement of tuber coxae reaching highest vertical position before impact of lame hindlimb, such that vertical position of tuber coxae before lame (or more lame) side hindlimb impact is higher than that of the opposite side vertical tuber coxae position before the normal (or less lame) side hindlimb impact. (B) Description of "hip dip" as a modification of lame-side tuber coxae trajectory. Downward movement of tuber coxae reaching lowest vertical position after pushoff of lame hindlimb, such that vertical position of tuber coxae after pushoff of lame (or more lame) side hindlimb is lower than that of opposite side vertical tuber coxae position after pushoff of normal (or less lame) hindlimb.

to that side) to prevent toe dragging (Figure 2.123). Sometimes this flexion is insufficient to prevent toe dragging, and toe dragging is also considered a sign of hindlimb lameness. A "hip hike" occurs in an attempt to prevent or dampen pelvic fall before lame hindlimb impact. As such, the "hip hike" signifies an impact-type hindlimb lameness (which, for the VPM, would create a difference in low pelvic positions), and "hip dip" signifies a pushoff hindlimb lameness (which, for the VPM, would create a difference in high pelvic positions). An alternative description of "hip hike" that does not account for type of hindlimb lameness (impact or pushoff) defines it as the total movement upward of the tuber coxae on the lame side instead of the relative differences in tuber coxae height from the ground between right and left stances.[40] This definition suggests that "hip dip" and "hip hike" are not separate phenomena describing different timing of hindlimb lameness.

Both VPM and pelvic rotation, compared to most hindlimb movement parameters, are more sensitive and specific indicators of hindlimb lameness. When veterinary trainees were tested for determining hindlimb lameness, those that concentrated observation on evaluating pelvic movement scored better than those that spent time observing limb movement.[50] The pelvis rotation method, which is easiest to see because the motion is greater, relies on pelvic anatomy symmetry and pelvic rotation around the lumbosacral joint. However, preexisting asymmetry of pelvic anatomy may cause asymmetry of pelvic rotation, or the appearance of asymmetric pelvic rotation, when VPM is symmetric between right and left hindlimbs. The VPM, which is more difficult to see in some horses because the amplitude of vertical displacement can be small, depends directly on the force of impact and pushoff of the hindlimbs. An easily visible marker fixed to the most dorsal aspect of the pelvis between the tuber sacrale may help to detect this asymmetric movement.

There is some evidence that pelvic rotation, or the range of motion of the vertical movement of the tuber coxae, is not proportional to severity of lameness above mild hindlimb lameness.[51] It is clear that pattern of vertical movement of the tubera coxae (pelvic rotation method [PRM] of hindlimb lameness detection) does not accurately quantify the true state of vertical tubera sacral movement (VPM method) and vice versa; in other words, they do not exactly evaluate the same thing.[51] In one study "hip hike" was the most sensitive indicator of mild hindlimb lameness.[40] In one study vertical movement of the tuber sacrale had the highest discriminating power for determination of hindlimb lameness.[15]

The best position for the evaluator using the PRM is behind the horse with the horse moving away from the evaluator with spatial resolution of the observer degrading with each stride. The VPM method is more versatile because it can be observed equally well from all perspectives. Nevertheless, most practitioners today use the PRM in some form for detection and evaluation of hindlimb lameness. Table 2.2 and Figure 2.124 compare and contrast the observations for hindlimb lameness using the VPM and PRM.

An excellent online training site, www.lamenesstrainer.com, lets one practice both methods of hindlimb lameness detection (VPM and PRM).

BILATERAL LAMENESS

In theory asymmetric head and pelvic vertical movement will not be observed with a bilateral lameness of equal intensity in both limbs.[11] However, horses with bilateral lameness most often have one side slightly worse than the other, and an asymmetry representative of this difference will be observed. Occasionally the lameness will be shifting from one side to the other between strides or between trials of trotting away and then toward the observer. When a bilateral lameness is suspected, attempts to "lateralize" the lameness assist in the evaluation. Turning the horse in a circle, lunging in both directions, flexing or stressing one limb, and blocking and then observing the horse in motion are methods that "lateralize" a bilateral lameness.

VetBooks.ir

Table 2.2. Methods of lameness evaluation using pelvic movement.

	Method of Lameness Evaluation Using Pelvic Movement	
Type of Hind Limb Lameness	Vertical Pelvic Movement(VPM)	Pelvic Rotation (PRM)
Impact Hind Limb Lameness	Diff Min Pelvis Positive for right, negative for left	Hip Hike Greater on lame side
Pushoff Hind Limb Lameness	Diff Max Pelvis Positive for right, negative for left	Hip Dip Greater on lame side

Compares and contrasts the pelvic movement parameters for both the vertical pelvic movement method (VPM) of hind limb lameness detection as well as that of the pelvic rotation method (PRM). Diff Min Pelvis is the difference in whole pelvis minimum position between left and right hind limb stance. Diff Max Pelvis is the difference in whole pelvis maximum position before right hind impact minus whole pelvic position before left hind limb impact. "Hip Hike" is the greater elevation of the tuber coxae before lame (or more lame) hind limb impact compared to before not lame (or less lame) hind limb impact. "Hip Dip" is the more lower position of the tuber coxae when the lame (or more lame) limb is swinging forward compared to the low position of the tuber coxae when the not lame (or less lame) hind limb is swinging forward.

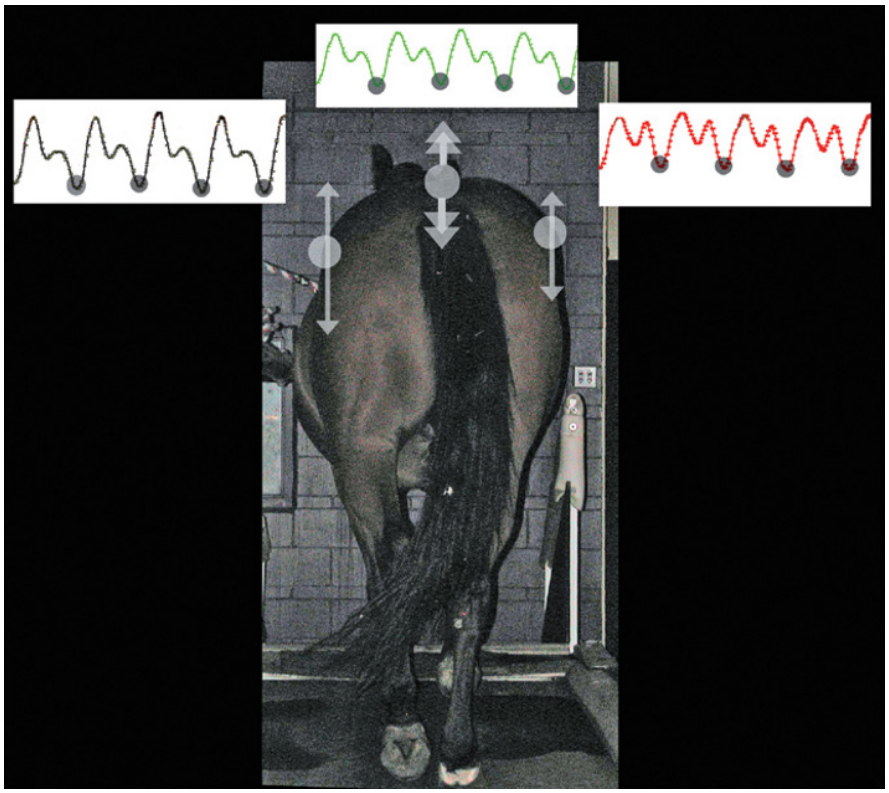

Figure 2.124. Two methods of hindlimb lameness detection and evaluation. Vertical pelvic movement method evaluates imaginary "ball" on midline of pelvis between the tuber sacrale. Pelvic rotation method evaluates imaginary "balls" located at left and right tuber coxae. Vertical pelvic movement method relies on temporal asymmetry of movement of entire pelvis, with less downward movement of the pelvis (pelvis stops downward movement at higher height) during stance phase of lame limb and/or less upward movement of the pelvis (pelvis stops upward movement at lower height) after pushoff of the lame limb, depending on whether the lameness is impact or pushoff or both. Top curve (green) indicates dorsal pelvic movement through four strides of horse with left hindlimb lameness with black circle at time of sound (right) hindlimb stance (synchronous with picture). Pelvic rotation method relies on greater total vertical movement of the tuber coxae on the lame hindlimb side. Curve on left (black) indicates left tuber coxae vertical movement through four strides in horse with left hindlimb lameness with black circles at time of sound (right) hindlimb stance (synchronous with picture). Curve on right (red) indicates right tuber coxae vertical movement through four strides in horse with left hindlimb lameness with black circles at time of sound (right) hindlimb stance (synchronous with picture).

VetBooks.ir

If attempts to lateralize the lameness do not successfully produce observable asymmetric movement, the evaluator must rely on absolute movement parameters, differentiating these from his/her memory bank of how a normal horse moves. For bilateral forelimb lameness, a diagonal advanced placement of the forelimb, with the forelimb hoof hitting the ground before the contralateral hindlimb (but this is normal in some breeds), and an overall suppression of vertical head movement (compared with vertical movement of the torso) are sometimes appreciated. For both bilateral forelimb and hindlimb lameness, a stiff, shuffling, and short appearing stride may be seen.[43] However, unless the norm of the horse before the onset of lameness is known, this can be difficult to differentiate from individual, idiosyncratic locomotion patterns.

OBSERVING MOVEMENT OF THE LIMBS

Many motion parameters have been measured and studied as lameness indicators in horses, and there are many limb movement parameters that have been associated with lameness. It is not unusual to find in the literature reports of kinematic studies in which many different limb motion parameters were measured but few were found to be significantly associated with lameness. Although there is considerable overlap, there is also considerable contradiction between studies as to which motion parameters are sensitive indicators of lameness in horses. Some difference can be explained by differences in the models of lameness being studied. Despite these qualifications, there are some limb movement parameters that can be used as indicators of lameness in horses. However, high variability and low consistency, with some exceptions, make observing limb movement changes less critical for detecting and evaluating for lameness.

JOINT ANGLE MEASUREMENTS ASSOCIATED WITH LAMENESS

Decreased weight-bearing due to lameness in the forelimbs or hindlimbs will decrease maximum fetlock extension and maximum coffin joint flexion during the stance phase of the lame limb compared with the stance phase of the contralateral sound limb (Figure 2.125).[12,19] Maximum fetlock extension and coffin joint flexion during stance are sensitive indicators of both forelimb and hindlimb lameness in the horse. Fetlock extension during lame limb stance was 8° less than sound limb stance in a sole pressure-induced lameness model of a grade 2 (out of 5) lameness.[12] If fetlock joint angle could be detected sensitively and accurately, it would be an excellent visual clue for the detection and evaluation of forelimb and hindlimb lameness.[12] Carpal extension during stance is reduced but only with moderate to severe lameness.[28]

STRIDE TIMING AND LENGTH VARIABLES ASSOCIATED WITH LAMENESS

Stride timing variables (stance duration, swing duration, etc.) are relatively insensitive and inconsistent indicators of lameness. Unless the lameness is severe, when stance time is shortened, stance time can be relatively

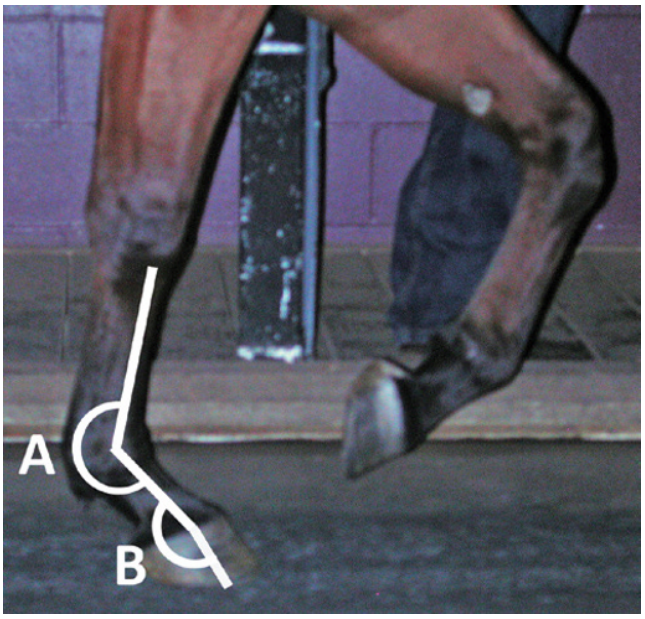

Figure 2.125. (A) Fetlock extension and (B) coffin flexion angles during full weight-bearing. With lameness (A) decreases and (B) decreases.

increased in either the lame or more lame hindlimb or in the non-lame or less lame contralateral hindlimb,[53,55] whereas relative stance duration as a percentage of total stride time and total stride time consistently decreases in the lame or more lame limb. Diagonal advanced placement, or initiating stance sooner in the limb diagonal to the lame limb (or ipsilateral limb for the rack and pace), may also be shortened. Step duration, or the time between pushoff of one limb and impact on the contralateral limb, on the other hand, is shorter between pushoff of the lame and impact of the sound limb than between pushoff of the sound limb and impact of the lame limb.[10] However, stride timing variables are strongly dependent on speed of forward movement and training, which makes them less useful for detecting lameness before and after blocking or treatment.[20]

Stride length is shortened significantly only in moderate to severe lameness.[4] Step length, or the distance between placements of opposite limbs, is less between placements of the lame and then sound limbs than between placement of the sound and then lame limb.[10] Height of foot flight arc may be increased or decreased in the lame forelimb compared to the sound forelimb, and the shape may be different, depending on the cause of lameness.[12] Dragging the hindlimb toe is commonly thought to be a sign of subtle hindlimb lameness, but this may not always be true. In the hindlimb, the height of hoof flight arc is determined by two competing factors with the strongest determining the overall effect. Decreased propulsion during pushoff of the lame hindlimb causes the rear torso to rise less. In order to bring the affected limb forward during the swing phase of the stride without dragging it on the ground, the proximal limb joints will flex more. The comparative extents of the decreased torso rise and increased limb flexion determine the height of the hoof flight arc. Amplitude of limb retraction is variable depending on type of lameness and conditions of evaluation.[12]

VetBooks.ir

Although amount of limb abduction or adduction during the swing phase of the limb has been thought to be indicative of certain lameness conditions, this has not been objectively studied. Placement of the hoof during weight-bearing either directly under (less lame limb) or abaxial (more lame limb) is, ostensibly, a sensitive indicator of lameness. However, this author has measured this in many horses with induced lameness and found this to be inconsistent and contradictory.

HOOF TRAJECTORY ASSOCIATED WITH LAMENESS

The length and shape of forelimb and hindlimb hoof trajectory during the swing phase of the stride are commonly perceived to be associated with lameness. However, objective measurements of these changes have not been confirmed, and in a few cases have contradicted, these perceptions. Forelimb protraction, the cranial phase of the hoof flight arc, will either decrease or increase with lameness, depending upon type of lameness.[28] For example, in the foot, heel lameness (e.g. navicular disease) generally decreases, but toe (e.g. laminitis) lameness generally increases forelimb retraction. However, hindlimb protraction is usually decreased in most cases of hindlimb lameness.[30] Unilateral decreased hindlimb protraction is easy to recognize in the lame limb at the trot by visualizing the distance between the affected hindlimb at full protraction and the ipsilateral forelimb at full retraction (Figure 2.126). This distance is longer on the lame side. However, a simultaneous increase in retraction of the forelimb, which occurs in some forelimb lameness conditions, will interfere with the proper interpretation of this sign.[12]

There are numerous other subjective observations thought to indicate lameness in the horse, including amount of head flexion when ridden, overall straightness of movement, sequence and timing of foot fall cadence, being "on the bit," amount of "engagement" of the hindlimbs, "ease" of transition from one gait to another, overall willingness to move, and many others. When lameness is difficult to detect because asymmetric vertical movement of the head and pelvis is less than what can be seen by the naked eye, the veterinarian is forced perhaps to then attempt to observe many different things. In general, limb movement, pelvic rotation, and other highly subjective observations may be used to help confirm the existence and extent of lameness and in some cases may even hint at the location of abnormality within a lame limb, but they should not contradict vertical head and pelvic parameters that are directly related to altered vertical ground reaction forces, and if they do, they should be considered idiosyncratic and not indicative of abnormality. Some clinicians have claimed even that lameness can be observed by detecting expressions on the horse's face during riding or lunging, an equine "pain face."[18] However "painful" facial expressions may signify discomfort in any body system or because of a variety of causes including those that cause lameness.

LAMENESS EVALUATION DURING IPSILATERAL GAITS

The vertical movement trajectories of the head and pelvis during the rack and pace are identical in concept but smaller in amplitude compared to that found at the trot. The body still moves down during the first half and up during the second half of stance. Therefore the same principles of altered movement with lameness can be

Figure 2.126. Hindlimb protraction is easily seen when viewing from the side of the horse. The hoof of the retracted ipsilateral forelimb acts as a point of reference. Hindlimb protraction is reduced in most hindlimb lameness; thus, the space between the retracted forelimb and protracted hindlimb is greater (arrows) on the lame hindlimb side.

VetBooks.ir

considered, with "lowest on sound" for both head and pelvic movement for fore- and hindlimb lameness, as an accurate indicator of side of lameness. However, the total vertical movement with these ipsilateral gaits tends to be less than the trot, with more rolling from side to side than vertical movement up and down. So, although, in principle, vertical movement of the head and pelvis should be good indicators of lameness, they may be more difficult to observe. Certainly, also, the compensatory lameness patterns for ipsilateral gaits will be different than that for the contralateral trot. More information of lameness in gaited breeds can be found in Chapter 9.

EVALUATION OF LAMENESS AT THE LUNGE

Evaluation for lameness during the lunge, on either soft or hard ground, is thought to exacerbate and bring out lameness that may not be seen when the horse is moving in a straight line. Moving in a circle, because the torso and limbs are tilted relative to ground surface, alters the distribution of ground reaction forces both within a single limb and between right and left limbs. However, because the torso is tilted relative to the ground,[24,25] there is normal asymmetrical peak vertical forces between the inside and outside limb[14,17] and normal vertical movement of both the head and pelvis.[41,46] These asymmetries must be appreciated and understood as normal. Large horses, small diameter circles, and high speed of movement will exacerbate these asymmetries. It has also been determined that the amplitude and characteristics of vertical head and pelvic asymmetries are dependent on type of ground surface on which the horse is lunged, and because of high normal horse-to-horse variability, an asymmetry observed in one direction should not be identified as abnormal until lunging in the other direction is also observed. However, deviations from these known asymmetric patterns can be used and analyzed to help locate or confirm lameness to a particular limb.

On soft surfaces the outside limbs are less efficient at turning and propulsion because the foot digs into the soft surface as the limb is pushing off the ground. When the outside forelimb is pushing off, the horse is essentially changing direction. On soft ground that "gives way," changing direction is less efficient. Therefore, on soft ground, the head is thrown upward during pushoff of the outside forelimb, assisting the horse in changing direction toward the inside of the circle. This might appear as an outside forelimb pushoff-type lameness to some observers. Similarly, pushoff of the outside hindlimb is less efficient, but this causes the pelvis to rise less, making the horse appear to have an outside hindlimb lack of vertical propulsion. Also, the pelvis, tilted toward the middle of the circle of movement, falls less during weight-bearing of the inside hindlimb, mimicking an impact-type hindlimb lameness. If using pelvic rotation instead of VPM to detect hindlimb lameness, these characteristics would appear as "hip hike" on the inside hindlimb and "hip dip" (if this can indeed be seen) on the outside hindlimb. The veterinarian must then determine if the inside hindlimb "hip hike" and the outside hindlimb "hip dip" are the same lunging in the other direction.

On hard surfaces, asymmetries of vertical head and pelvic movement are primarily related to rotation of the torso with decreased downward movement of the head and pelvis and decreased upward movement of the pelvis during and after inside forelimb and hindlimb stance (or "hip hike" and "hip dip" on the inside hindlimb). This might appear as inside forelimb and hindlimb lameness to an observer evaluating vertical movement of the head for forelimb lameness and vertical movement of the pelvis or rotation of the pelvis for hindlimb lameness.[41,46,47]

These characteristics of asymmetry should be considered when evaluating horses for lameness at the lunge. Also, it has been shown that even normal horses trained to lunge will frequently move in one direction differently than in the other direction.[8,46] This increased variability makes detecting lameness at the lunge more complicated compared to straight-line evaluation. Disagreement between veterinarians of the existence, side, and amplitude of lameness observed during the lunge is higher than that for evaluation of lameness in the straight line.[26] However, if horses show consistent lameness during a straight-line trot, they will most commonly show lameness in the same limb during the lunge on the same surface and rarely only in the opposite side limb.

EVALUATION OF LAMENESS UNDER SADDLE

Some veterinarians believe that a lameness evaluation that does not include evaluation under saddle is incomplete. Certainly, evaluation for lameness under circumstances and in surroundings that are far removed or different from the usual and expected activity of the horse may fail to expose the true abnormality, adversely affecting performance of the horse. In some environments, for example, in a large arena with an appropriate surface, evaluation for lameness under saddle is easier and in many cases preferred. This is especially true for some breeds that do not trot regularly unless under saddle. However, evaluation for lameness under saddle is not always practically available to the veterinarian, and it should not be expected that lameness under saddle would always be worse or more visible than lameness without a rider. Although the extra weight and back extension may induce more pain,[16] the influence of the rider and excitement of the horse may serve to mask lameness.[33] Rider position and activity can also create artifactual (i.e. "false") lameness that will interfere or confuse veterinary examination for clinical abnormality.

A rider properly sitting the trot, in synchrony with the horse's vertical torso movement, will create the least artifacts on the observed lameness. A rider posting (performing a rising trot) moves forward and upward when one forelimb (usually the inside limb if riding in circle) is weight bearing and then backward and downward when the same-side hindlimb is pushing off. The effect of the upward and forward movement is increased weight-bearing on one forelimb, which, if that limb is painful, could worsen the perceived lameness in that limb. However, the backward and downward movement during pushoff of the same-side hindlimb (the inside hindlimb when riding in a circle) will frequently blunt or reduce the expected pelvic rise. This effect will tend to create what appears to be a lack of opposite hindlimb propulsion, a false lameness in a normal horse.[47] Effects of posting and moving in a circle are frequently additive and, depending on the

VetBooks.ir

surface characteristics, may either exacerbate or mask existing lameness when the rider posts while riding in small circles. Thus a rider posting on the right forelimb riding to the left may have what appears to be a left hindlimb lack of pushoff lameness (or "hip dip"). If the horse has preexisting left hindlimb pushoff lameness, this lameness will be exacerbated. If the horse has a preexisting right hindlimb pushoff lameness, this lameness will be reduced or masked. All these findings should be considered when evaluating horses for lameness under saddle. As with lunging, if a horse displays lameness consistently without a rider, it will usually display lameness in the same limb with the rider, and it is uncommon for lameness to be displayed in only a different limb.

Hindlimb and concurrent hindlimb and forelimb lameness has also been shown to be associated with saddle slip, slightly more frequently toward the lame than the non-lame or less lame side. Saddle slip increased when lame horses were ridden in circles and when the rider was posting.[21–23]

SUBJECTIVE SCORING METHODS

The AAEP Lameness Scale

The American Association of Equine Practitioners (AAEP) lameness scale is a subjective scoring method used to describe lameness (Table 2.3). Consistency, and to some extent, severity, of lameness is assessed by the ability to observe lameness under different conditions. It is an accurate but imprecise (there are only five grades) method to assess severity of lameness. Lameness amplitude can significantly change but remain within a single grade. Practitioners use the AAEP scale primarily as a communication tool that estimates overall lameness severity and consistency.

In the United Kingdom a scale from 1 to 10, which is basically the same at the above AAEP scale, but splitting each grade into two separate categories, is used (Table 2.4).

Table 2.3. American Association of Equine Practitioners Lameness Scale.

Grade	Description
0	Lameness not perceptible under any circumstances.
1	Lameness is difficult to observe and is not consistently apparent, regardless of circumstances (e.g. under saddle, circling, inclines, hard surface, etc.).
2	Lameness is difficult to observe at a walk or when trotting in a straight line but consistently apparent under certain circumstances (e.g. weight-carrying, circling, inclines, hard surface, etc.).
3	Lameness is consistently observable at a trot under all circumstances.
4	Lameness is obvious at a walk.
5	Lameness produces minimal weight bearing in motion and/or at rest or a complete inability to move.

Table 2.4. United Kingdom Lameness Scale

Grade	Description
0	Not lame
1–2	Lameness hard to detect at walk or trot
3–4	Lameness barely detectable at walk, easy to see at the trot
5–6	Lameness easily detectable at the walk
7–8	Hobbling at the walk, unwilling to trot
9–10	Non-weight bearing

OBJECTIVE ASSESSMENT OF LAMENESS

Kevin G. Keegan

VetBooks.ir

The standard of practice to detect and assess severity of lameness in horses is observing the horse in motion with the naked eye and then scoring using a discrete scale, for example, the AAEP or UK lameness scales/grades. This is sufficient for some cases. However, clinical studies strongly suggest that detection and evaluation of lameness in horses using the naked eye is insufficient in many cases, especially when the severity of lameness is mild.[22,25,30,33,45] Multiple limb involvement and compensatory movement in the opposite half of the body, and observation of different movement parameters, contribute to variability in assessment. Agreement, even between experts, for the detection of mild lameness between AAEP grades 1 and 2 or for picking the most affected limb is only slightly above chance.[30] The most likely explanation for this is limited temporal resolution of the human eye to detect fast events and small amounts of asymmetry in the movement of the horse.[51] Furthermore, unblinded subjective assessment is predisposed to bias.[1] Objective assessments of lameness by precise and accurate measurement of ground reaction force or asymmetry of movement at high sampling rates can be used to mitigate these limitations.

MEASUREMENT OF GROUND REACTION FORCES (KINETICS)

Most diseases that cause lameness do so because of pain during weight-bearing. A horse will bear less weight on an affected limb to decrease pain, resulting in decreased ground reaction force, which can be objectively measured. The stationary force plate, force-measuring treadmill, force-measuring devices attached to the bottom of the hoof, and pressure-sensitive mats have been used to measure ground reaction forces in moving horses.[4,5,8,9,17,18,20,23,26–29,35,46,47,49,50,53,68,71,73–75] The stationary force plate is the most commonly used and cited method.

During an evaluation for lameness with the stationary force plate, the horse is moved over the force plate so that at least one, and preferably just one, hoof strikes the force plate completely within the confines of the surface of the force plate (Figure 2.127). Ground reaction forces can be measured in all three directions—vertical, horizontal, and transverse (Figure 2.128). Decreased vertical ground reaction force and, to some extent, altered horizontal ground reaction forces are most often associated with lameness in the horse. Lower peak forces and impulse (area under the force vs. time curve) are associated with increasing severity of lameness. It is also likely that the shape of the vertical and horizontal ground reaction force curves contains information relevant to determining timing of lameness and differentiating whether pain is maximum during limb impact, in the first half of stance or during pushoff, in the second half of stance.[5,20,75] It has been shown that horses with an impact hindlimb lameness, or less movement of the pelvis downward, have decreased peak vertical ground reaction force, decreased deceleratory horizontal ground reaction force, and decreased vertical ground reaction impulse in the first half of stance.[8] Horses with reduced hindlimb propulsion, or decreased pelvic rise after hindlimb pushoff, have decreased vertical ground reaction impulse in the second half of stance and a conversion of vertical force to acceleratory horizontal ground reaction force. In other

Figure 2.127. Stationary force plate set for evaluation of lameness in horses. White line outlines approximate area of top of force plate, which is embedded into the ground and covered with a rubber mat to prevent shying. *Source*: Courtesy of Dr. Michael Schoonover at Oklahoma State University.

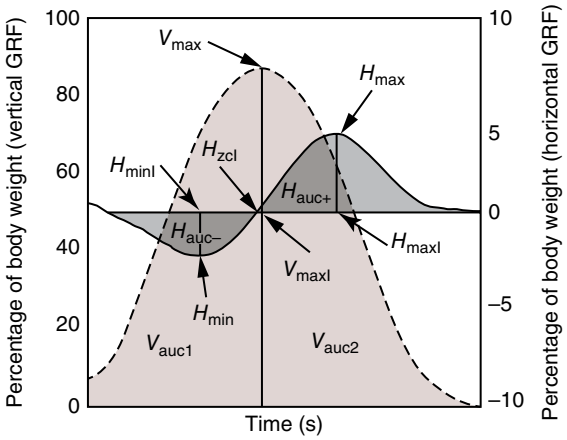

Figure 2.128. Stationary force plate data (from a single hoof strike) of relevance for determination of lameness. V_{max} = peak vertical ground reaction force. V_{auc1} = vertical impulse (force × time) in first half of stance. V_{auc2} = vertical impulse (force × time) in second half of stance. H_{min} = peak negative (deceleratory) horizontal ground reaction force in first half of stance. H_{max} = peak positive (acceleratory) horizontal ground reaction force in second half of stance. H_{auc-} = deceleratory horizontal impulse. H_{auc+} = acceleratory horizontal impulse. V_{maxl} = time index of V_{max}. H_{minl} = time index of H_{min}. H_{maxl} = time index of H_{max}. H_{zcl} = time index of horizontal ground reaction force cross over from deceleratory to acceleratory force. No transverse forces are shown.

VetBooks.ir

words, the horse pushes off with less vertical force but with more horizontal ground reaction force in the second half of stance.

The stationary force plate is a precise and accurate instrument. Variability between trials in controlled conditions is low (coefficients of variation below 10%), and sensitivity is high enough to detect subclinical lameness.[27] However, acquiring data requires controlled conditions. The hoof must strike completely within a relatively small area, often requiring multiple attempts. Speed of movement is controlled, both to increase the chance of successful hoof strike and to decrease variability between hoof strikes. The stationary force plate is considered by some to be a gold standard for objective lameness evaluation in horses, but the controlled conditions required for acquiring consistent results make it unlikely to be adopted for routine use in clinical practice. Although it varies with breed, the forelimb of horses that are not lame trotting across the force plate at moderate speed will strike the force plate with vertical force approximately equal in magnitude to 100% of its body weight.[4] The hindlimb of normal horses trotting across the force plate at slow to moderate speed will strike with vertical force equivalent to about 90% of body weight.[8] Induction of "subtle," mild, and moderate lameness decreased vertical ground reaction force in horses trotting on a treadmill by 4%, 9%, and 24%, respectively.[72] Horses with AAEP grade 4 lameness will strike the forelimb with a force as low as 50% of body weight.

MEASUREMENT OF MOVEMENT (KINEMATICS)

Kinematics is the measurement and study of movement. Limb and torso pain alters the normal movement of the horse. If pain predominates in one side of the body, the normal symmetric movement between right and left parts of the stride will become asymmetric. Kinematics, like kinetics, can be used to quantify absolute movement measures that may correlate well with lameness. However, most applications quantify lameness by measuring the asymmetry of movement between left and right sides of the body. Many different motion parameters have been studied and used to detect and evaluate forelimb and hindlimb lameness in horses, including vertical movement of the torso (head bob, pelvic fall and rise),[14] stride and step length and timing,[13] pelvic rotation (hip hike and dip),[44,56] limb and hoof flight pattern,[13] and joint angle extremes and range of motion.[13] Asymmetric vertical movement of the torso, because it is more directly associated with vertical ground reaction force, is the most sensitive kinematic indicator of lameness.[14,16,31]

The body motion changes of lameness are more variable stride by stride than changes in ground reaction force. High stride-by-stride variability of lameness lowers the signal (lameness) to noise ratio, rendering it more difficult to detect small amplitudes of lameness or small changes in amplitude of lameness. Variability can be decreased by strictly controlling conditions of evaluation. Alternatively, or in addition, the adverse effect of stride-by-stride variation can be minimized by collecting data from a high number of contiguous (one after the other) strides. Despite the higher variability compared to the force plate, results of kinematic evaluation of lameness are generally more intuitive and easy to understand for the veterinary practitioner. The practicing veterinarian can more easily apply significant findings in kinematic studies of lameness in their standard lameness evaluation techniques.

The original kinematic technique was camera based. The horse is filmed while moving and body motion is quantified by analyzing trajectories of markers attached to the body of the horse (Figure 2.129). Computer

Figure 2.129. Marking of the horse with reflective spheres (head, right hoof walls, pelvis) for camera-based kinematic evaluation of lameness.

VetBooks.ir

assistance is used to track, record, segment (into strides), and extract relevant (to lameness) features from the trajectories of the marked body parts. Analysis of the trajectories, most likely the asymmetry of trajectory motion between right and left parts of the stride, can then be used to detect and measure lameness. Although there are many different commercially available camera-based systems, they all depend on unobstructed line-of-site light transmission. The camera-based kinematic technique is more sensitive than subjective evaluation for detecting asymmetry of motion because the sampling rate of the camera can exceed the temporal resolution of the unaided human eye by several orders of magnitude. In order to collect multiple contiguous strides at maximum spatial resolution, kinematic evaluation of lameness in horses is usually performed on the equine treadmill with the horse remaining within the cameras' field of view. Movement of the horse on a treadmill is different than overground with longer stance times, earlier placement of the forelimb, increased retraction of both fore- and hindlimbs, and decreased vertical movement of the hooves and withers.[11] Some lameness that is visible (or measurable) overground may not be seen (or measured) on the treadmill, and vice versa. Horizontal ground reaction forces on the limbs of horses, which are different when trotting on the treadmill, with increased braking (negative horizontal in the first half of stance) and decreased propulsive (positive horizontal in the second half of stance), may be the cause of this discrepancy. Newer kinematic systems with automatic calibration and tracking of markers and user-friendly software to collect and display results greatly simplify use of this technique, but the requirement for dedicated space and multiple cameras to collect multiple strides with adequate spatial resolution limits this practice to research centers and technologically advanced clinics. Most of the early investigations searching for the most sensitive and accurate indicators of pain-induced lameness were carried out using these systems, and it is expected that most of the research into development of models to study equine motion for many different reasons will continue with this type of technology.

Asymmetry of motion can be more readily measured using inertial sensors attached to the horse's body.[6–8,18,21,32,34–36,42,48,54,55,57,58,60,61,64–66,69] Sensor data is wirelessly transmitted to the evaluator, so spatial resolution does not decrease with distance of subject from the evaluator, and line-of-site requirements are relaxed. Motion data from multiple contiguous strides in an overground setting can be collected and evaluated. Wireless transmission of body-mounted inertial sensor data allows clinicians to objectively evaluate lameness in horses in a natural clinical environment. For these reasons, using body-mounted inertial sensors to measure lameness is more intuitive and practical than other methods. In one study inertial sensor-derived lameness measures agreed more closely with blinded subjective evaluation of experts than results from a stationary force plate.[18] In another study, body-mounted inertial sensors identified an induced lameness in horses trotting in a straight line before a consensus of expert evaluators performing full lameness evaluations.[45] The remainder of this section describes one system in use today.

The Q® with Lameness Locator®

The Q® (hardware) and Lameness Locator® (software) was specifically designed as an aid to the practicing equine veterinarian for detection and evaluation of lameness in horses. Equine veterinarians and engineers at the University of Missouri in collaboration with the Hiroshima Institute of Technology in Japan developed the technology.

The Q consists of three inertial sensors, a tablet PC for data collection, analysis, and archiving, a sensor battery charger, and accessories for attaching the sensors to the horse's body (Figure 2.130). The inertial sensors are attached to the head, right forelimb pastern, and dorsum of the pelvis between the tuber sacrale. Each sensor is 1.5 inches by 1.25 inches by 0.75 inches and weighs 28 g. Vertical accelerations of the head and pelvis and angular velocity of the right distal forelimb are measured and wirelessly transmitted (Bluetooth Class 1) in real time to a handheld tablet computer. Range of transmission is up to 100 m, although larger transmission distances can be attained with additional Bluetooth repeater technology or with more sensitive or directional antennas. Sensor data (acceleration) is algorithmically converted to vertical position relative to the ground, which is the data of interest to the evaluator. Additional custom-designed algorithms are used to detect and quantify forelimb and hindlimb lameness when the horse is moving in a symmetrical gait, which is usually the trot. Proper trotting strides are automatically detected by the software when the horse is moving. Non-trotting strides are automatically extracted and discarded before analysis. An additional sensor can be attached to the lower waist of the rider to evaluate rider activity, to determine if the rider is sitting or posting correctly, and to assess how rider activity affects the measurement of lameness. A new research version that tracks movement with 9 degrees of freedom and allows determination of acceleration in the global reference frame is available, allowing flexibility in placement of sensors (number and location) for further kinematic research. Automatic Interpretation and Degree of Evidence (AIDE) algorithms, developed from studies of induced lameness and from contemporary clinical cases, for straight-line evaluation, lunging, flexions, effect of blocking and treatment, under-saddle evaluation, and compensatory lameness, simplify interpretation of kinematic values related to lameness for the practitioner. Mobile Q, with collection of data on smartphone devices and analysis in the cloud, is currently in development.

Lameness Locator® algorithms were developed from previous kinematic research and clinical testing. Best sensor type and locations were determined by data mining of accumulated motion data from groups of sound horses, horses with naturally occurring lameness, and horses with various models of induced lameness. Vertical head and pelvic acceleration are converted to vertical position in space and separated into components by custom error-correction algorithms. Random and nonperiodic movement is discarded, minimizing the negative effect of asymmetry due to nonclinical reasons. Remaining periodic movement is separated into movement due to lameness at stride frequency (the lameness component) and natural vertical motion at twice stride

VetBooks.ir

Figure 2.130. The Q™ (hardware) with Lameness Locator® (software) on standing horse. (A) Head accelerometer attached to head bumper. (B) Right forelimb gyroscope attached to dorsal pastern in pouch. (C) Pelvic accelerometer attached with foam pad and rubberized grip device. (D) Instrumented horse in motion.

frequency (the expected vertical movement).[2,52] Outlier data is detected and discarded. Simple, experimentally determined reference range estimates between likelihood of "lameness" and "not lameness," and the strength ("weak," "moderate," and "strong") of this evidence, are presented to the veterinary user. Results are standardized to normal expected vertical movement (the periodic component of vertical movement at twice stride frequency) to accommodate for large differences in body size or natural "boundingness" in trot. Lameness is detected and quantified by reporting means and standard deviations of maximum and minimum height differences of the head (for forelimb lameness evaluation) and pelvis (for hindlimb lameness evaluation) position. Location of lameness to limb (or limbs) and timing of peak lameness within the stride phase of a limb are determined by the association of head and pelvic movement to movement (angular velocity) of the right forelimb. All assessment of amplitude of lameness is generated by data from the head and pelvis sensors, and the right forelimb sensor is simply a stride event marker.

Lameness evaluation results are reported in a graphical display that depicts amplitude of impact and propulsion asymmetry in each stride. Lameness can be evaluated with the horse trotting in a straight line, while lunging (at the trot), and trotting under saddle. Response

VetBooks.ir

to flexion tests and blocking (or other treatment) can be quantified. Compensatory or multiple limb lameness patterns can be determined by studying the distribution of impact and pushoff asymmetry in all four limbs. At the time of this writing, Lameness Locator® is being used in >300 private practice and university veterinary teaching hospital sites around the world. The Q® and Lameness Locator® are sold only to licensed veterinarians. Using data mining techniques on inertial sensor data from large numbers of cases with definitive diagnoses opens the possibility of determining likelihood of site of lameness within the limb derived from inertial sensor results.

Measuring Forelimb Lameness

Forelimb lameness is reported in a graphical display and by calculating lameness values (Figure 2.131). The forelimb lameness display provides a qualitative description of the forelimb lameness by representing each analyzed stride as a single ray directed outward from the plot origin. Each ray on the plot is a stride. The length of the ray is representative of the amplitude of asymmetric head motion for that stride. The direction of the ray on the plot represents the side and timing of lameness for that stride. Using polar coordinate terminology, rays in quadrant 1 (upper right) represent lameness in the right forelimb during the first half of stance, from impact to midstance; rays in quadrant 2 (upper left) represent lameness in the right forelimb during second half of stance, midstance to pushoff; rays in quadrant 3 (lower left) represent lameness in the left forelimb during the first half of stance; and rays in quadrant 4 (lower right) represent lameness in the left forelimb during the second half of stance.

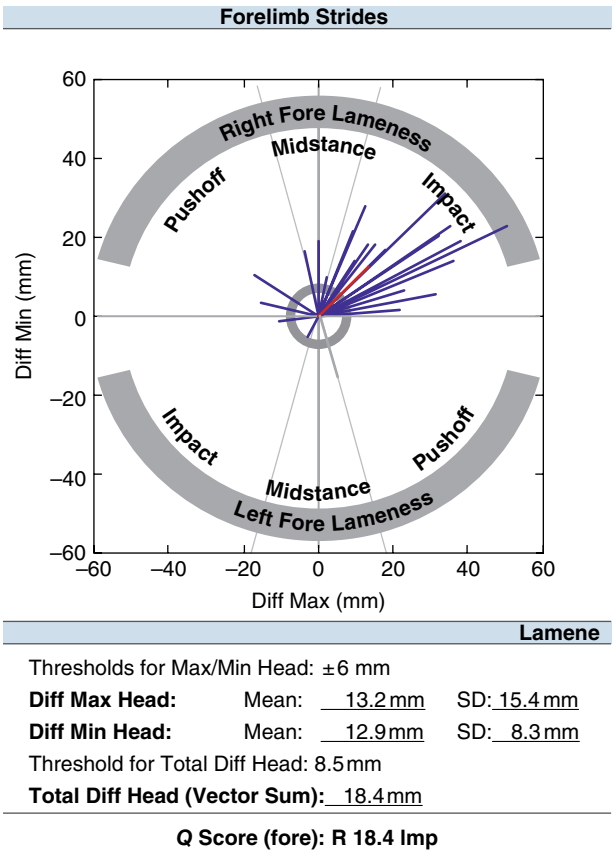

Figure 2.131. Output of Lameness Locator® indicating right forelimb impact lameness. Predominance of rays pointing in quadrant 1 (upper right) have Diff Max Head and Diff Min Head > reference range of ±6 mm and Vector Sum or Total Diff Head > 8.5 mm. Standard deviations of Diff Min Head less than mean Diff Min Head indicating consistent right-sided lameness.

The lameness values provide a more quantitative description of the forelimb lameness. Forelimb lameness is quantified by calculation of the difference in maximum head position between left and right forelimb strides (Diff Max Head) and the difference in minimum head position between left and right forelimb strides (Diff Min Head). Diff Max Head and Diff Min Head are calculated for every stride selected for analysis, and the mean and standard deviation over all strides are reported. The signs of Diff Max Head and Diff Min Head determine side and timing of lameness. The approximate reference range for consideration of "lameness" for these values is ±6 mm. Because forelimb lameness results in a combination of both differences in maximum and minimum heights of the head, the total overall forelimb lameness is a calculated sum called Total Diff Head or Vector Sum (VS). Because Diff Max Head and Diff Min Head take on both positive and negative values depending on side and timing of lameness, the total amplitude of lameness is a vector sum of both measures. Thus, $VS = \sqrt{(\text{Diff min Head})^2 + (\text{Diff max Head})^2}$. Since the approximate reference ranges of Diff Max Head and Diff Min Head are ±6 mm, the approximate reference range of $VS = \sqrt{(6)^2 + (6)^2}$, or 8.5 mm. These reference ranges are actually confidence intervals of the inertial sensor measures that were determined experimentally in a group of >125 horses evaluated for lameness subjectively by at least three experienced veterinarians when the average AAEP score was 0. Variation of lameness side and amplitude, which is related to strength of evidence, is assessed along with amplitude of lameness. The AIDEs used in this system remind the user of the statistical nature of these reference ranges with language indicating weak or strong evidence and reminders to repeat trials when measures are within reference range. Some horses with measures below these reference ranges, but highly consistent, may still have clinical disease. Clinically relevant reference ranges may be higher or lower depending on intended use and specific clinical situation.

When the lameness evaluation is restricted to relatively slow speeds with the horse being led by a handler restrained by a lead rope, the majority of forelimb lameness is measured during the first half of stance (impact to midstance). This is likely because at slow speeds the horse primarily uses the forelimb as a strut with little active forelimb pushoff.

Measuring Hindlimb Lameness

Hindlimb lameness is reported in a graphical display that depicts deficiency of right and left hindlimb impact (first half of stance) or pushoff (second half of stance; Figure 2.132).

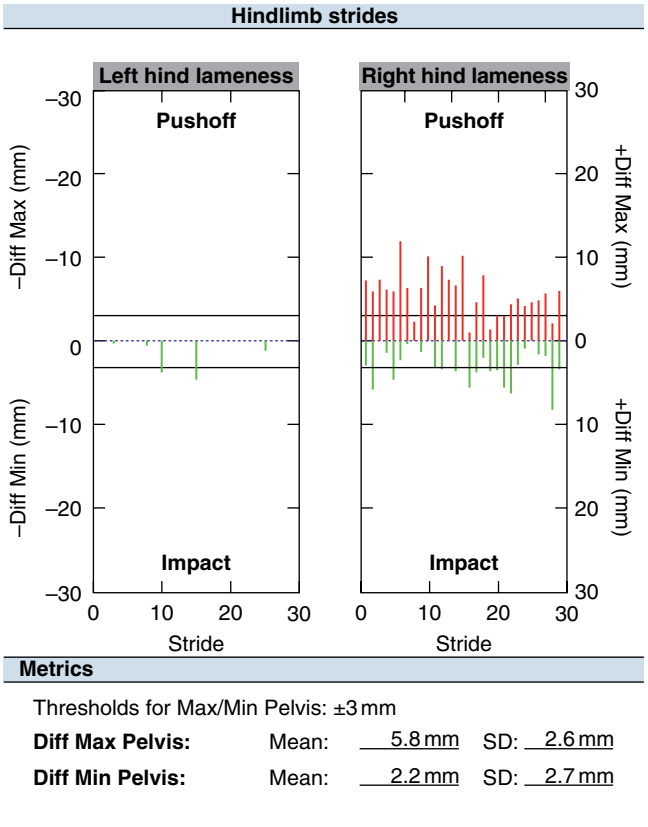

Figure 2.132. Output of Lameness Locator® indicating right hindlimb pushoff lameness. Most red rays (Diff Max Pelvis) are on right side. This indicates most Diff Max Pelvis are + in sign, i.e. the pelvis is thrust up less after pushoff of right hindlimb compared with left hindlimb. Diff Max Pelvis > reference range of ±3 mm. Standard deviation of Diff Max Pelvis less than mean of Diff Max Pelvis, indicating consistent lameness.

The hindlimb lameness display is a qualitative description of the hindlimb lameness. The left side of the display represents qualities of the left hindlimb function. The right side of the display represents qualities of the right hindlimb function. Each vertical line on the display moving from left to right is a measure of either the deficiency of impact (pelvic fall) or the deficiency of pushoff (pelvic rise) for that stride. The length of the line is representative of the amplitude of lameness.

Display of hindlimb lameness, with two subplots, one representing function of the left and the other representing function of the right hindlimb, is different from display of forelimb lameness, as one plot combining Diff Max Head and Diff Min Head. Why? The displays are different because the biomechanical model of VPM with hindlimb pain is different from that of vertical head movement for forelimb pain. VPM is modeled as a single free body falling less due to factors occurring in the first half of stance, which are different from factors causing less pelvic rise during pushoff of a hindlimb in the second half of stance. Diff Max Head and Diff Min Head are dependent quantities caused by the same thing (head moving upward at moment of peak pain), whereas Diff Max Pelvis and Diff Min Pelvis are independent quantities caused by different things.

The lameness values give a more quantitative description of the hindlimb lameness. Hindlimb lameness is quantified by calculation of the difference in maximum pelvic position between left and right hindlimb strides (Diff Max Pelvis) and the difference in minimum pelvic position between left and right hindlimb strides (Diff Min Pelvis). Diff Max Pelvis and Diff Min Pelvis are calculated for every stride collected, and the mean and standard deviation over all strides are reported. The signs of Diff Max Pelvis and Diff Min Pelvis determine side and timing of lameness. Positive values indicate right hindlimb lameness, and negative values indicate left hindlimb lameness. High Diff Max Pelvis absolute values indicate pushoff-type hindlimb lameness. High Diff Min Pelvis absolute values indicate impact-type hindlimb lameness. The approximate reference range for lameness for both measures is ±3 mm, which are confidence intervals of the measure when hindlimb mean subjective AAEP score = 0. These confidence intervals were determined and should be interpreted like the reference ranges of Diff Max Head and Diff Min Head for forelimb lameness.

Detecting Compensatory Lameness

In trotting quadrupeds a primary lameness in the front half of the body will sometimes cause compensatory movements in the back half of the body and vice versa, such that an apparent multiple limb lameness is present. Interpretation of these compensatory movements is sometimes referred to as the "law of sides." The first principle of the "law of sides" states that an apparent ipsilateral lameness, i.e. forelimb and hindlimb lameness on the same side of the body, is likely primary hindlimb lameness and a compensatory but false forelimb lameness. The second principle of the "law of sides" states that an apparent contralateral lameness, i.e. forelimb and hindlimb lameness on opposite sides of the body, is likely primary forelimb lameness and a compensatory but false hindlimb lameness.

Experimental studies have determined that the first principle of the law of sides is, for the most part, true.[38,40,41,70,72] Pain during stance in the hindlimb will cause the horse to shift weight forward onto the simultaneously weight-bearing contralateral forelimb, and the head will fall more than normal. Normal falling of the head during weight-bearing of the opposite forelimb will be less, giving the appearance of an ipsilateral forelimb lameness ("low on sound"). Although there is significant variability from horse to horse, which is likely dependent on the type of primary hindlimb lameness, even slight primary hindlimb lameness may cause compensatory movement in the head that mimics significant forelimb lameness. This suggests the possibility, depending on the sensitivity of detection, of missing the identification of the primary hindlimb lameness because of the more apparent compensatory but false forelimb lameness. The increased sampling frequency of the inertial sensors compared to the unaided human eye decreases the chance of this confusion.

The second principle of the "law of sides" is less true and less straightforwardly explained.[23,38,73,74] Primary forelimb lameness can cause compensatory movements in the vertical movement of the pelvis attributable to

VetBooks.ir

both hindlimbs such that false hindlimb lameness could be measured in both sides. Primary forelimb lameness causes the horse to shift its center of gravity slightly toward the back half of the body during the stance phase of the affected forelimb. This causes the pelvis to fall more in the contralateral hindlimb compared with the ipsilateral hindlimb, mimicking impact-type lameness in the opposite hindlimb, ipsilateral to the primarily lame forelimb. However, the horse moving forward will push off less from the opposite/diagonal hindlimb (contralateral to the forelimb with primary lameness) to lessen shifting of weight forward onto the primarily lame forelimb, causing the pelvis to rise less and giving the appearance of a contralateral pushoff-type hindlimb lameness. Thus, primary forelimb lameness may cause compensatory movements that mimic ipsilateral hindlimb impact-type lameness but contralateral pushoff-type hindlimb lameness. Generally the ipsilateral impact-type "false" hindlimb lameness is small and less common than the contralateral pushoff-type "false" hindlimb lameness. Compensatory pelvic movement patterns with primary forelimb lameness are regularly measured with the increased sensitivity of the inertial sensors, and these patterns are useful for helping to detect and evaluate forelimb and multiple limb lameness (Figure 2.133). Compensatory pelvic movements with primary forelimb lameness are not commonly observed subjectively.

Compensatory lameness should reduce when the primarily lameness is reduced with blocking. Compensatory lameness patterns are seen when the horse is trotting in a straight line and while lunging. During lunging, compensatory patterns are additive to directional patterns, sometimes exacerbating and sometimes masking multiple limb effects.

Known compensatory lameness patterns were described in the previous section. However, there may be other reasons for an apparent multiple limb lameness. Secondary lameness arises when a primary lameness causes weight shifting away from the primary limb to other limbs. If this weight shifting compensation overloads the other limb(s), supraphysiologic strain may occur, which could damage tissue or cause pain, or both. Although less is known about secondary lameness patterns (because it is difficult to study experimentally), certain patterns in trotting horses have been suggested based on clinical impression. In horses that trot, primary forelimb lameness will most likely overload the opposite forelimb or the opposite hindlimb, but it will unlikely overload the ipsilateral hindlimb. Primary hindlimb lameness will equally likely overload the contralateral fore- or hindlimb, but will unlikely overload the ipsilateral forelimb (Figure 2.134). Secondary lameness should not reduce immediately when the primary lameness is reduced with blocking. Secondary lameness, because it is caused by physiologic overload that may damage anatomic structures that span a length of the limb, for example, the suspensory apparatus or flexor tendons, is also more difficult to block completely with lower limb blocks, and frequently small or partial improvements are seen with successively higher blocks.

Following the logic of Occam's razor (the principle of parsimony), which states that the simplest explanation of competing explanations for a series of observations is usually the most correct, and our knowledge of compensatory (previous section) and secondary lameness patterns, one can make a reasonable and evidence-based guess as to which limb in a multiple limb lameness is the primary source of lameness. In a study of over 1200 horses evaluated for lameness, multiple limb lameness was measured in just over half (57%) of horses with lameness when trotting in a straight line. Therefore, when measuring lameness in horses actually presented for lameness, multiple limb lameness is the norm rather than the exception.

Considering both impact- and pushoff-type forelimb lameness together, but hindlimb impact and pushoff lameness as separate quantities, there are only eight possible "types" of multiple limb lameness:

1. Forelimb lameness with ipsilateral hindlimb lameness that is both decreased impact and decreased pushoff (Figure 2.135).

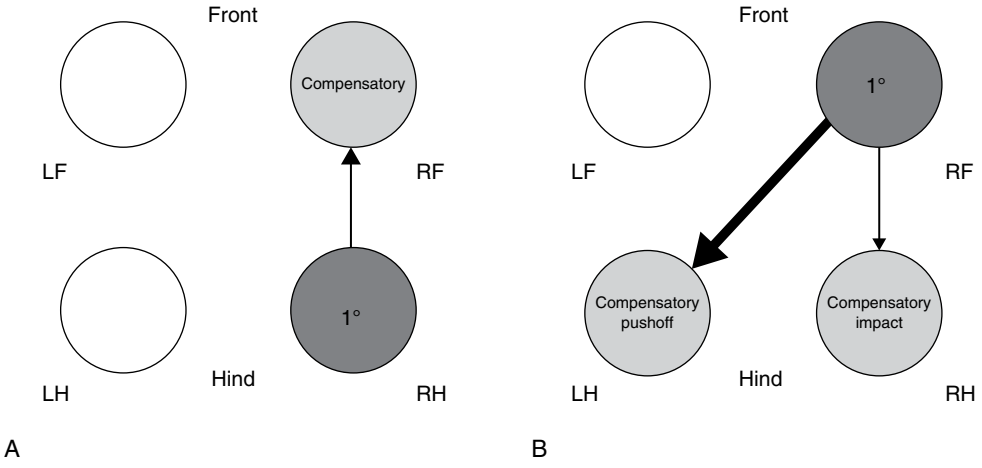

Figure 2.133. Known compensatory lameness patterns. (A) First part of the law of sides. Concurrent apparent ipsilateral forelimb and hindlimb lameness is usually a primary hindlimb lameness and an ipsilateral compensatory (false) forelimb lameness. (B) Second part of the law of sides. Concurrent forelimb and either compensatory contralateral hindlimb pushoff or ipsilateral hindlimb impact (or both) lameness. Compensatory contralateral compensatory hindlimb pushoff lameness is more common and usually more prominent.

VetBooks.ir

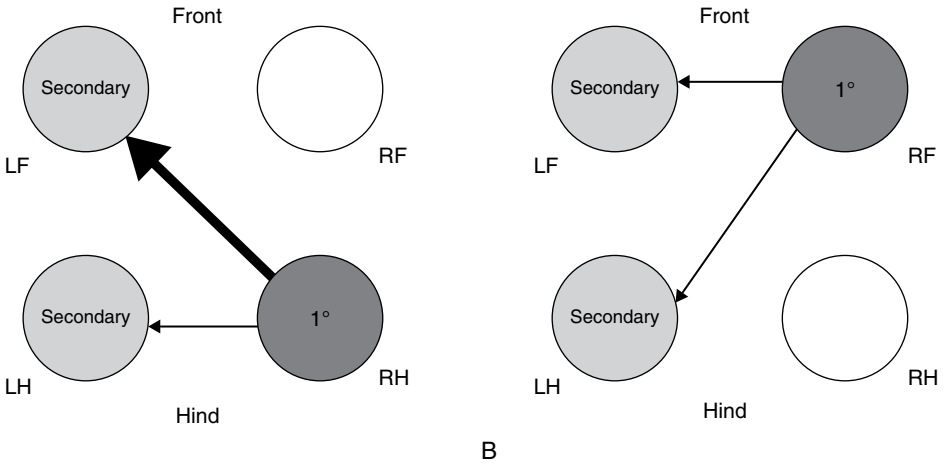

Figure 2.134. Suspected secondary lameness patterns. (A) Primary hindlimb lameness will most frequently overload opposite forelimb, less frequently overload the opposite hindlimb, and infrequently overload the ipsilateral forelimb. (B) Primary forelimb lameness will equally frequently overload the opposite forelimb and/or the opposite hindlimb, but infrequently overload the opposite forelimb.

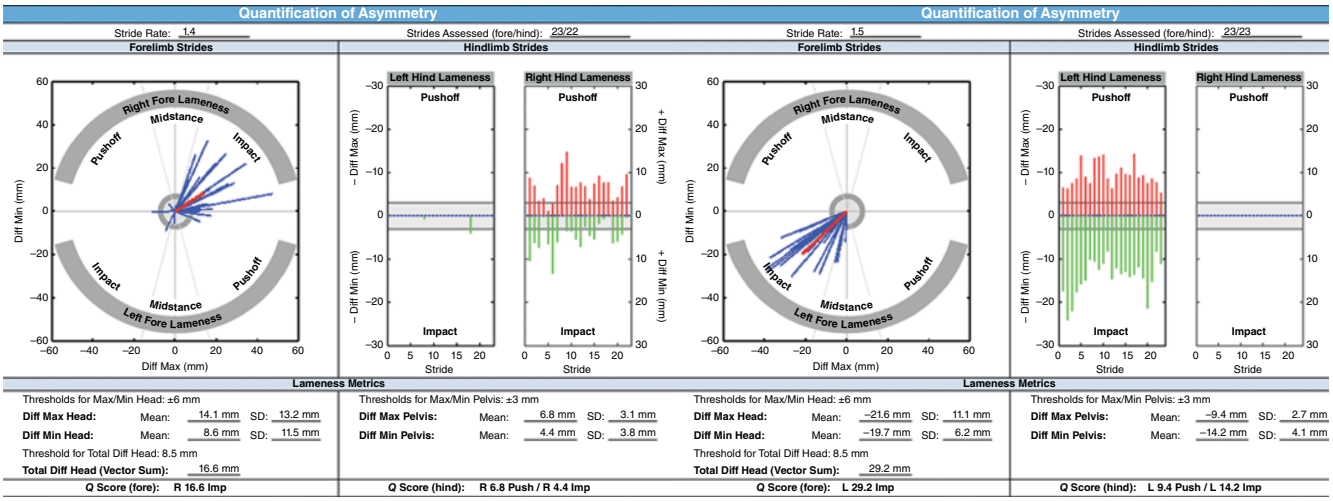

Figure 2.135. Lameness Locator® reports of multiple limb lameness. Left report: Right hindlimb pushoff and impact lameness and ipsilateral (right) forelimb lameness. Right report: Left hindlimb pushoff and impact lameness and ipsilateral (left) forelimb lameness. Both are examples of first part of the law of sides, which is primary hindlimb lameness with compensatory (false) ipsilateral forelimb lameness.

In about 700 horses measured with multiple limb lameness, this was the second most common type, occurring in about 19% of all initial evaluations of multiple limb cases. The simplest explanation of this type of multiple limb lameness is primary hindlimb lameness with compensatory forelimb lameness (the first principle in the "law of sides"). Horses with this type of multiple limb lameness had a high definitive diagnostic rate (82%) with 73% ultimately determined to have only a hindlimb diagnosis and another 14% having diagnoses in both hindlimb and front limb. Less than 11% ultimately were diagnosed with primary forelimb disease/abnormality.

2. Forelimb lameness with ipsilateral hindlimb lameness that is only decreased pushoff (Figure 2.136).

This type was seen in about 10% of all cases of multiple limb lameness. The simplest explanation of this type of multiple limb lameness is primary hindlimb lameness and compensatory forelimb lameness (the first principle in the "law of sides"). Horses with this type of multiple limb lameness had a (62%) definitive diagnostic rate, but with 66% ultimately determined to have only a hindlimb diagnosis and another 20% having both a hindlimb and a forelimb diagnosis. Only 11% ultimately were diagnosed with a primary forelimb lameness.

3. Forelimb lameness with ipsilateral hindlimb lameness that is only decreased impact (Figure 2.137).

This type was uncommon, occurring in less than 10% of all multiple limb lameness cases. Equally legitimate explanations for this type of multiple limb lameness are primary hindlimb lameness with compensatory forelimb lameness, and vice versa, or primary forelimb lameness with compensatory hindlimb lameness. This type of multiple limb lameness had a 78% definitive diagnosis rate, but 4% had only a

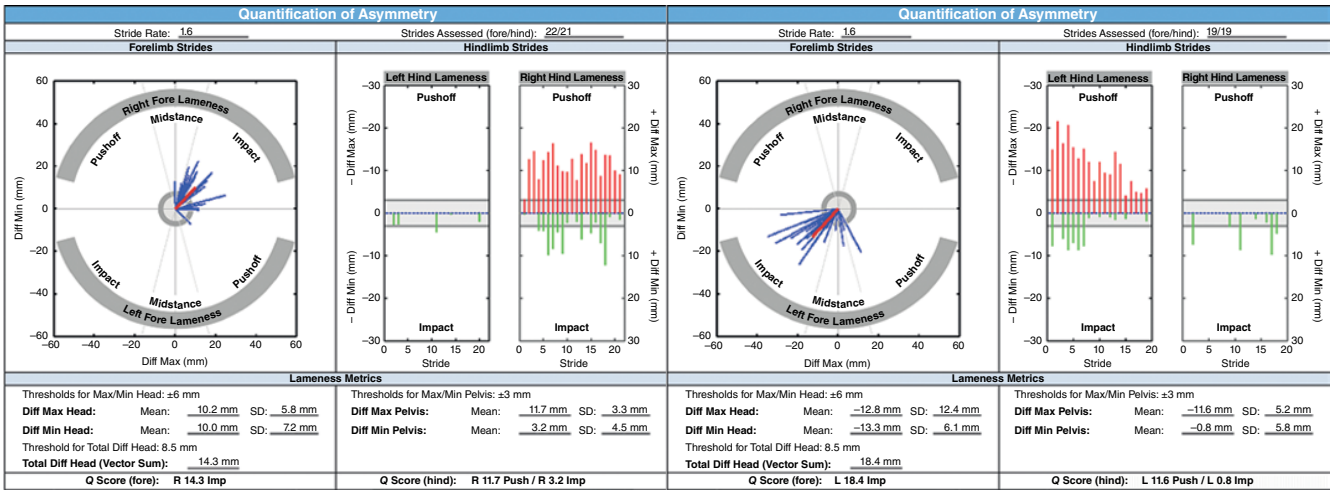

Figure 2.136. Lameness Locator® reports of multiple limb lameness. Left report: Right hindlimb pushoff only, no impact lameness, and ipsilateral (right) forelimb lameness. Right report: Left hindlimb pushoff only, no impact lameness, and ipsilateral (left) forelimb lameness. These are examples of the first part of the law of sides: primary hindlimb lameness with compensatory (false) ipsilateral forelimb lameness.

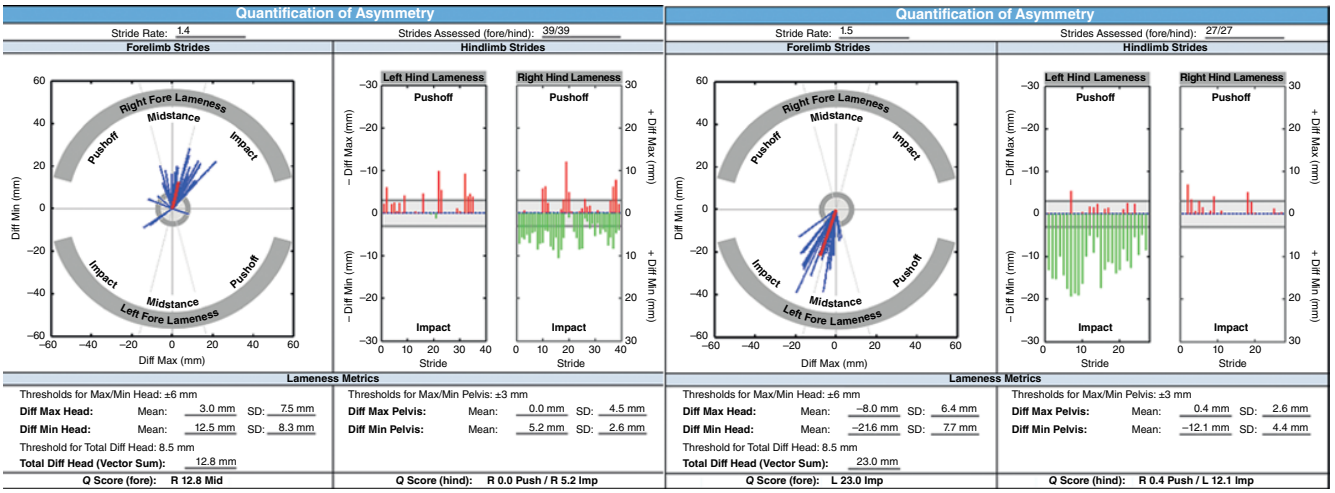

Figure 2.137. Lameness Locator® reports of multiple limb lameness. Left report: Right hindlimb impact only, no pushoff lameness, and ipsilateral (right) forelimb lameness. Right report: Left hindlimb impact only, no pushoff lameness, and ipsilateral (left) forelimb lameness. This multiple limb pattern can be equally explained by either the first or second part of the law of sides, either a primary hindlimb lameness with compensatory ipsilateral forelimb lameness or primary forelimb lameness with compensatory ipsilateral hindlimb impact lameness.

hindlimb diagnosis, 11% had both a forelimb and a hindlimb diagnosis, and 45% had only a forelimb diagnosis, about 1/3 being a bilateral forelimb lameness condition. Also, a relatively high percentage (9%) of these cases had diagnosis of abnormality not located within the limbs. When seeing this type of multiple limb lameness, it was equally likely for the primarily lameness to be in the forelimb or in the hindlimb.

4. Forelimb lameness with ipsilateral hindlimb lameness that is decreased pushoff and contralateral hindlimb lameness that is decreased impact (Figure 2.138).

   This type occurred rarely. It was seen in only 4% of all multiple limb cases. There is no easy, compensatory- or secondary-only explanation of this pattern. A complicated explanation of primary hindlimb lameness, with compensatory ipsilateral forelimb lameness, and secondary contralateral hindlimb lack of impact lameness is required to fully explain this pattern. However, this type of multiple limb lameness had a relatively high rate (71%) of definitive diagnosis, with 35% ultimately diagnosed with only a hindlimb problem, 25% with both a hindlimb and forelimb problem, 20% with only a forelimb problem (but bilateral in 100%), and 20% with a non-limb diagnosis. This type of multiple limb lameness pattern had the highest percentage of "other" diagnosis (problem found but not in the limbs).

5. Forelimb lameness with contralateral hindlimb lameness that is decreased pushoff and decreased impact (Figure 2.139).

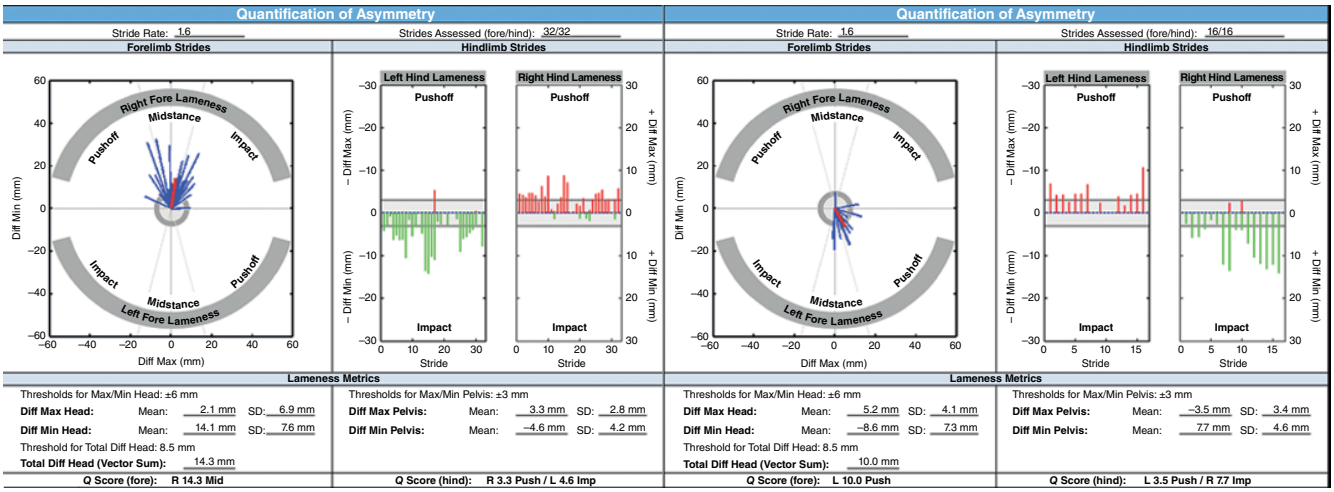

Figure 2.138. Lameness Locator® reports of multiple limb lameness. Left report: Right hindlimb pushoff, left hindlimb impact, and right forelimb lameness. Right report: Left hindlimb pushoff, right hindlimb impact, and left forelimb lameness. No simple single compensatory or secondary multiple limb lameness pattern completely explains this pattern. The best explanation is primary hindlimb lameness, with compensatory ipsilateral forelimb, and secondary contralateral hindlimb lameness exists.

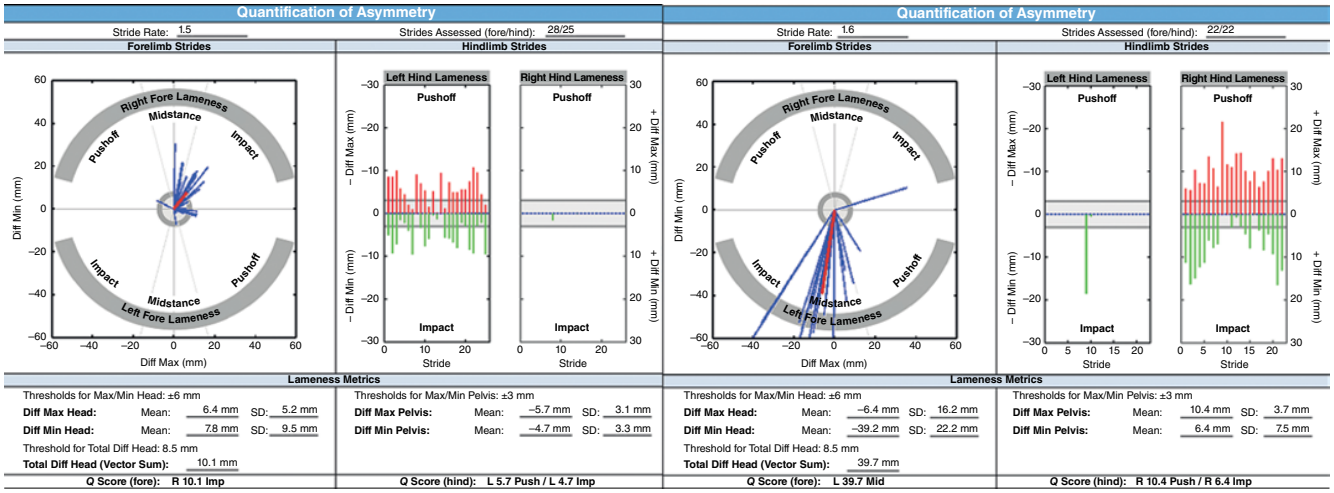

Figure 2.139. Lameness Locator® reports of multiple limb lameness. Left report: Left hindlimb pushoff and impact lameness and contralateral right forelimb lameness. Right report: Right hindlimb pushoff and impact lameness and contralateral left forelimb lameness. The best explanation for this type is primary forelimb with compensatory contralateral hindlimb pushoff lameness and secondary contralateral hindlimb impact lameness.

This type occurred in 17% of multiple limb cases. A possible explanation of this type of multiple limb lameness is primary forelimb lameness with compensatory (or secondary) contralateral hindlimb lack of pushoff and secondary (to the contralateral lack of hindlimb pushoff) ipsilateral hindlimb impact lameness. This type of multiple limb lameness had a high (71%) definitive diagnostic rate, with 66% having a diagnosis only in the forelimbs, with about ¼ (27%) being bilateral, 19% having a diagnosis only in the hindlimbs, and 13% having a diagnosis in both a hindlimb and a forelimb. Only about 2% had diagnosis in an area of the body other than in the limbs.

6. Forelimb lameness with contralateral hindlimb lameness that is only decreased pushoff (Figure 2.140).

This type occurred in 23% of all multiple limb cases, which is the most common multiple limb lameness type. The simplest explanation for this type of multiple limb lameness is primary forelimb with compensatory contralateral lack of hindlimb pushoff. This type of multiple limb lameness had a 70% definitive diagnosis rate, with 78% ultimately having only a forelimb lameness, with about 1 in 5 (22%) being bilateral, 13% having an ultimate diagnosis in both a forelimb and a hindlimb, and only 4% having a diagnosis only in the hindlimb. A diagnosis of "other," or an abnormality localized but not in the limbs, was present in only 4% of cases.

7. Forelimb lameness with contralateral hindlimb lameness that is only decreased impact (Figure 2.141).

This type occurred in less than 10% of cases. No compensatory-only pattern can explain this type of multiple limb lameness. Equally legitimate explanations are primary forelimb lameness and secondary

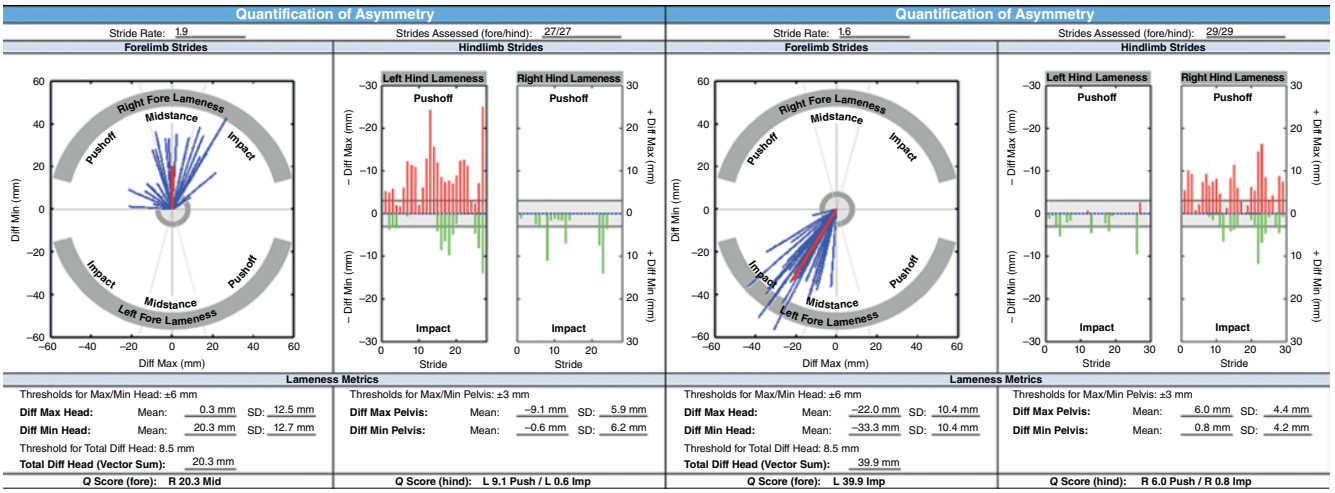

Figure 2.140. Lameness Locator® reports of multiple limb lameness. Left report: Left hindlimb pushoff only, no impact lameness, and contralateral right forelimb lameness. Right report: Right hindlimb pushoff only, no impact lameness, and contralateral left forelimb lameness. Best explanation is second part of the law of sides, or primary forelimb lameness with compensatory contralateral hindlimb pushoff lameness.

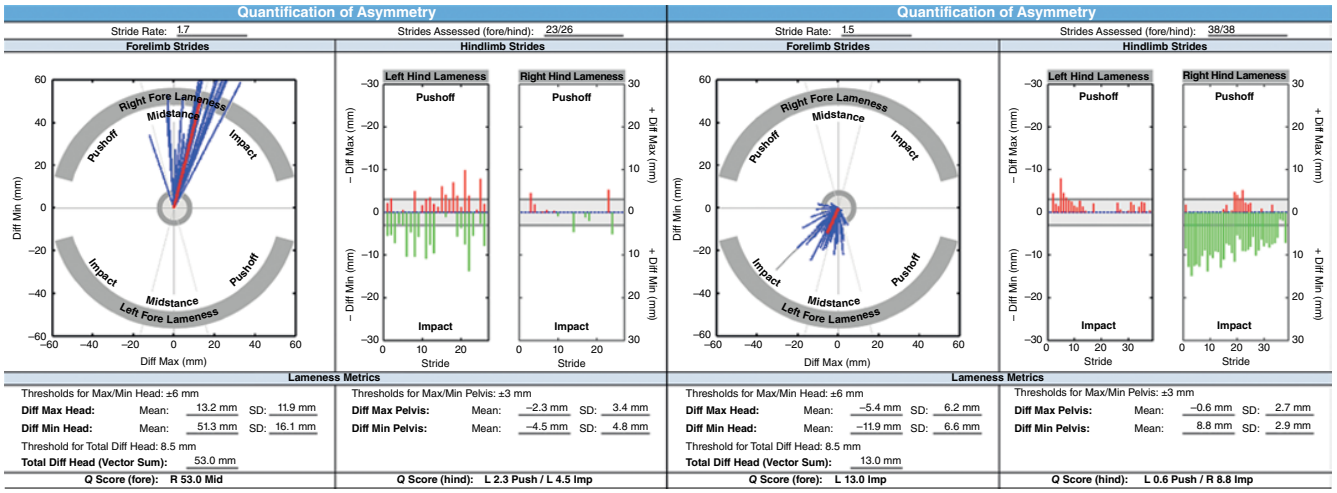

Figure 2.141. Lameness Locator® reports of multiple limb lameness. Left report: Left hindlimb impact only, no pushoff lameness, and contralateral right forelimb lameness. Right report: Right hindlimb impact only, no pushoff lameness, and contralateral left forelimb lameness. No compensatory lameness pattern explains this pattern. The best explanation of this type of multiple limb lameness is primary forelimb lameness and secondary hindlimb lameness or primary hindlimb lameness and secondary forelimb lameness.

hindlimb lameness and primary hindlimb lameness and secondary forelimb lameness. This type of multiple limb lameness had the lowest (54%) definitive diagnostic rate, with 75% ultimately having a diagnosis of only forelimb abnormality, with about 1 in 3 (31%) being bilateral, 11% that ultimately had a diagnosis in both a forelimb and a hindlimb, only 6% with an ultimate diagnosis in only a hindlimb, and an (8%) "other" (diagnosis not in the limbs) diagnostic rate.

8. Forelimb lameness with contralateral hindlimb lameness that is decreased pushoff and ipsilateral hindlimb lameness that is decreased impact (Figure 2.142).

This type occurred in about 7% of all multiple limb cases. It is easily explained by the second principle in the "law of sides," with contralateral hindlimb lack of pushoff and ipsilateral hindlimb lack of impact. This type of multiple limb lameness had a 71% definitive diagnostic rate. Ultimately 61% of cases had only a forelimb diagnosis, with 27% being bilateral forelimb lameness, only 3% with both a forelimb and a hindlimb diagnosis, 28% with a hindlimb only diagnosis, and less than 8% with a diagnosis of "other" (abnormality found but not in the limbs).

Flexion Tests

Lameness Locator® can be used to objectively quantify the effect of flexion tests. Reference ranges and confidence intervals established for trotting in a straight line and collecting at least 25 contiguous strides, however, are not applicable. The effect of flexion tests is usually dissipated after fewer (>25) numbers of strides, and the veterinarian usually evaluates the effects of flexion

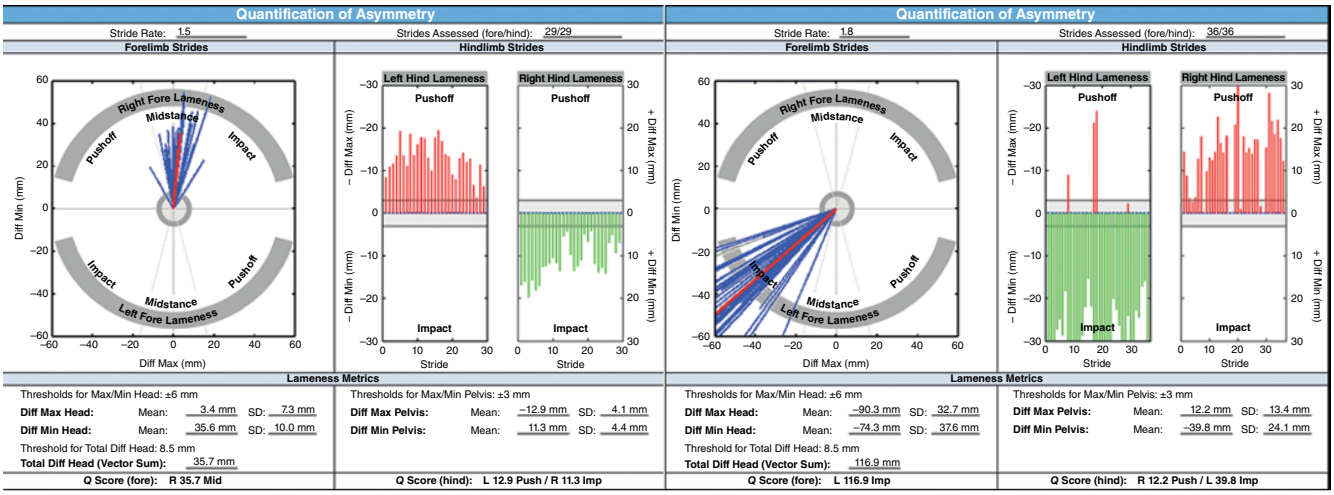

Figure 2.142. Lameness Locator® reports of multiple limb lameness. Left report: Left hindlimb pushoff, right hindlimb impact, and right forelimb lameness. Right report: Right hindlimb pushoff, left hindlimb impact, and left forelimb lameness. The best explanation of this type of multiple limb lameness is the second part of the law of sides, or primary forelimb lameness with compensatory contralateral hindlimb pushoff lameness and ipsilateral hindlimb impact lameness.

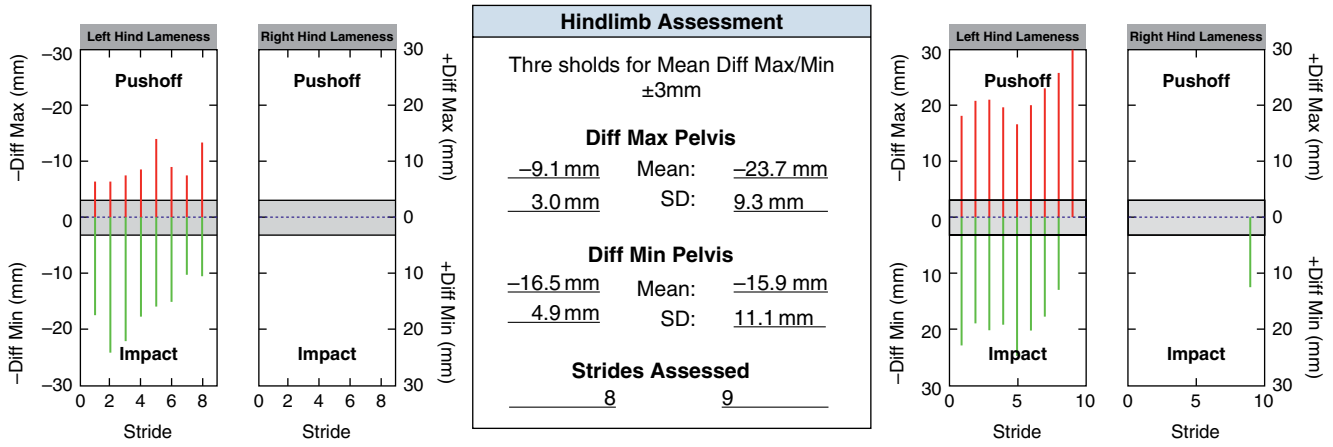

Figure 2.143. Lameness Locator® reports of before (left) and after (right) left hindlimb flexion. Absolute value of Diff Max Pelvis increases from |–9.1| to |–23.7| mm. This is a strong positive left hindlimb flexion test. Eight strides were collected as baseline before flexion and nine strides were collected after flexion.

tests by trotting the horse off in one direction only. Therefore, a baseline trot off in one direction without flexion should be collected as baseline before flexion. A positive response to flexion is then ascertained by simply comparing the amplitude of the lameness values for that limb before and after flexion (Figure 2.143). It is interesting that most hindlimb flexion tests are associated with an increase in Diff Max Pelvis, but not Diff Min Pelvis, or a decrease in hindlimb propulsion and not in a decrease in hindlimb impact.[43,67] In one study a minimum increase in Diff Max Pelvis of about 4.5 mm indicated a positive flexion test.[43]

Evaluation of Lameness Before and After Blocking

One of the most useful applications of using body-mounted inertial sensors is to more precisely and accurately evaluate the effect of blocking for reducing lameness.[56,64–66,69] This protects against the bias inherent in unblinded subjective evaluation. Bias can be positive, believing the lameness to be improved but in reality not, or negative, believing the lameness to be unchanged when in fact it is greater or lesser than before block. A desire for observing improvement in lameness after blocking is made stronger late in the day, after several blocks have been applied with no improvement, and especially in horses that are difficult or dangerous to block. On the other hand, partial improvements in lameness, or a change in the timing of lameness, may be mistaken for no effect. Objective measurements reduce these potential mistakes. Also, intraindividual (between horse) variation in lameness has been shown to be less than interindividual (within horse) variation of lameness; therefore smaller changes in amplitude of lameness and a quantitative percent improvement can be confirmed.

Lameness Locator® calculates percent improvement in lameness in two ways: (1) returning the amplitude of asymmetry (i.e. lameness) down to perfect mean symmetric movement and (2) returning the amplitude of lameness to within the reference range of asymmetry where even experts, performing full lameness evaluations, do not conclude that the horse is "lame." The first

VetBooks.ir

method is a very conservative assessment where 100% improvement is rare but small changes in amplitude of lameness are unlikely to be misinterpreted. The second method is a more liberal assessment with 100% improvement more common, but where small changes of amplitude of mild lameness may be seem exaggerated.

The first method is calculated as follows:

$$\frac{IS_{\text{before block}} - IS_{\text{after block}}}{IS_{\text{before block}}}$$

where IS *is inertial sensor measure*.

The second method is calculated as follows:

$$\frac{IS_{\text{before block}} - IS_{\text{after block}}}{IS_{\text{before block}} - IS_{\text{threshold}}}$$

where *threshold* is an experimentally determined value of the confidence interval of the inertial sensor measure in a group of horses thought not to be lame by experts during full lameness evaluations.

For example, a horse with a Diff Max Pelvis before block of +12 mm and a Diff Max Pelvis of +6 mm after block would have a 33.3% improvement in lameness ((12 – 8)/12 = 0.33…) using the first method and a 66.7% improvement in lameness ((12 – 8)/(12 – 6) = 0.66…) using the second method. Preference for method will depend on characteristics of the individual case, including beginning amplitude of lameness, stride-by-stride and (if known) trial-by-trial variation of lameness, and whether the lameness is a single or multiple limb lameness. It should be noted that any percent improvement above 100%, or that switches to the other limb, is interpreted as an elimination of lameness, when in reality some pain on weight-bearing may still be present. Also, at the time of this writing, this software considers any improvement below 25% improvement as no improvement.

There is some evidence that regional nerve blocks in non-lame horses do not appreciably change gait, do not make the horse appear subjectively to be lame, and do not significantly alter vertical ground reaction forces.[71] However, regional limb blocks in the front limb have been shown to prolong stance and the transition from braking to propulsion, supportive evidence that some proprioceptive deficit or loss is induced.[19,37] When using inertial sensors to evaluate blocking, users may measure subtle changes in lameness that are less or not apparent when relying on subjective evaluation.[45] For example, it is not uncommon, in fact it is usual, for lameness to get worse (increase in amplitude) when a limb is blocked in an area that is below or does not include the anatomic structure or area with pain. In other words, blocking a normal part of a painful limb will increase lameness. This effect is increased with successive blocks that do not include the focus of pain. Although blocking a normal limb in a horse without lameness has not been shown to significantly affect force plate results,[71] kinematic evidence suggests lower limb loading. If lameness increases with the blocking of normal limbs or with the blocking of normal parts of limbs displaying lameness, then one cannot expect a total removal of lameness when the causative focus is finally found. Having lameness increase after a block is a good sign that the evaluator has picked the correct limb as the primarily lame limb, but has yet to have localized the origin of lameness within the limb. In many studies blocking of the definitive primary source of lameness significantly decreased but did not eliminate the lameness, and the locomotion of the horse after diagnostic analgesia is not always identical to that of a non-lame horse. This suggests that it is more appropriate than to compare the after block evaluation to the evaluation done immediately before the block evaluated, instead of comparing to the trial before any blocks were applied.

When using inertial sensors to evaluate lameness, one will soon realize that the level of lameness, especially in the beginning of the evaluation, may not be stable. Lameness can increase, decrease, switch limbs, or change in timing at the beginning of a lameness evaluation. Beginning a series of blocking procedures before the lameness is stabilized risks misinterpretation and misdiagnosis. When using inertial sensors to evaluate response to blocking, it is recommended to first stabilize the lameness by some movement (walking) or exercise (light lunging on soft surface) and to avoid strong joint flexions or deep palpations of limb structures before assessing for lameness. Lameness can be considered stabilized when the amplitude (±8.5 mm for head and ±3 mm for pelvic movement asymmetry), limb(s) involved, and timing of lameness are consistent in back-to-back trials conducted within a few minutes of one another.

Evaluation of Lameness During the Lunge

Lameness Locator® can be used to objectively quantify lameness while the horse is trotting in a circle. Some lameness conditions in horses are more apparent when the horse is moving in a circle. Reference ranges and confidence intervals established for trotting in a straight line and collecting at least 25 contiguous strides, however, are not applicable. When the horse is trotting in a circle, the torso and limbs are tilted toward the center of the circle.[10] Depending on the horse, its speed of movement, the radius of the circle it is moving in, and the characteristic of the surface, this tilt can be significant. Also, on soft surfaces, the circular movement, centripetal forces, angle, and inclination of the limbs relative to the ground cause less efficient outside limb pushoff, and this creates normal asymmetric movement. However, the effects of tilt and surface characteristics can be individually predicted and accounted for.[59]

On soft surfaces, because the outside forelimb is less efficient during pushoff (the surface gives way to the forelimb pushing off), the horse will throw its head upward and inward to assist in turning. Likewise the outside hindlimb is less efficient at pushoff with the outside hindfoot digging into the surface. Subsequent pelvic rise from this less efficient pushoff is less than after pushoff of the inside limb. Also, the torso tilting toward the inside of the circle results in less downward fall of the head during inside forelimb stance and of the pelvis during inside hindlimb stance (decreased downward movement of the inside head and pelvis is independent of type of surface). So, on soft surfaces, there is an appearance of an outside forelimb pushoff-type lameness (right going to left and left going to right), an outside hindlimb pushoff-type lameness, and an inside hindlimb impact-type lameness. These patterns of asymmetry should be expected when lunging on soft surfaces (Figure 2.144).

VetBooks.ir

In contrast, on hard surfaces, torso tilt is the primary and most significant factor creating asymmetric head and pelvic vertical movement, so an inside forelimb impact-type forelimb (less head fall on the inside forelimb) and an inside hindlimb impact (less pelvic fall) and pushoff (less pelvic rise) lameness are frequently seen and should not be unexpected (Figure 2.145).

Surfaces with characteristics that are intermediate between hard and soft may have hybrid vertical head and pelvic height asymmetries. However, certain asymmetric movements are abnormal regardless of direction or surface characteristics. Impact-type lameness on the outside forelimb or pushoff-type forelimb lameness on the inside forelimb should not be expected on any surface. Impact-type lameness on the outside hindlimb should also not be seen in any direction or on any type of surface.

Evaluation of Lameness with Sedation

Examination of the horse in motion for lameness is more complicated in anxious and misbehaving horses. Random movement of the head, frequent and abortive gait transitions from trot to canter, rearing, jumping, attempting to bite the handler, all of these behaviors make it more difficult to detect small asymmetries (mild lameness) in vertical head and pelvic movement. Also, anxiety of the horse may mask the display of lameness. Lameness amplitude will vary more from stride to stride and confidence in results is sacrificed. This is a problem with both subjective and objective lameness evaluation. Some of the variable movement can be removed when using objective measurement methods with algorithms that extract and discard random movement, and presumably this is done also subjectively, and collecting data on higher numbers of multiple contiguous strides can mitigate some of the negative consequences of high stride-by-stride variability. However, stride-by-stride variability can be noticeably reduced with mild sedation, increasing the consistency of measurement and confidence in interpretation. Also, most studies have shown that mild sedation, although it may significantly affect limb movement parameters (e.g. stride length) sometimes used to assess lameness, does not as a rule artificially lower amplitude of head vertical movement asymmetry, and does not artificially lower amplitude of VPM asymmetry, as might be expected if sedation caused significant orthopedic analgesia.[3,15,61] Some protocols tested include 0.1–0.3 mg/kg xylazine and 0.025 mg/kg acepromazine. The author also believes that mild sedation in anxious or misbehaving horses allows are more thorough and particular limb and torso palpation. Of course, mild sedation may also facilitate blocking procedures in some horses. There are some circumstances of lameness evaluation (prepurchase examination, substance use before competition, owner preference) that do not allow the use of mild sedation, but if possible the clinician can mildly sedate without adversely affecting blocking results.

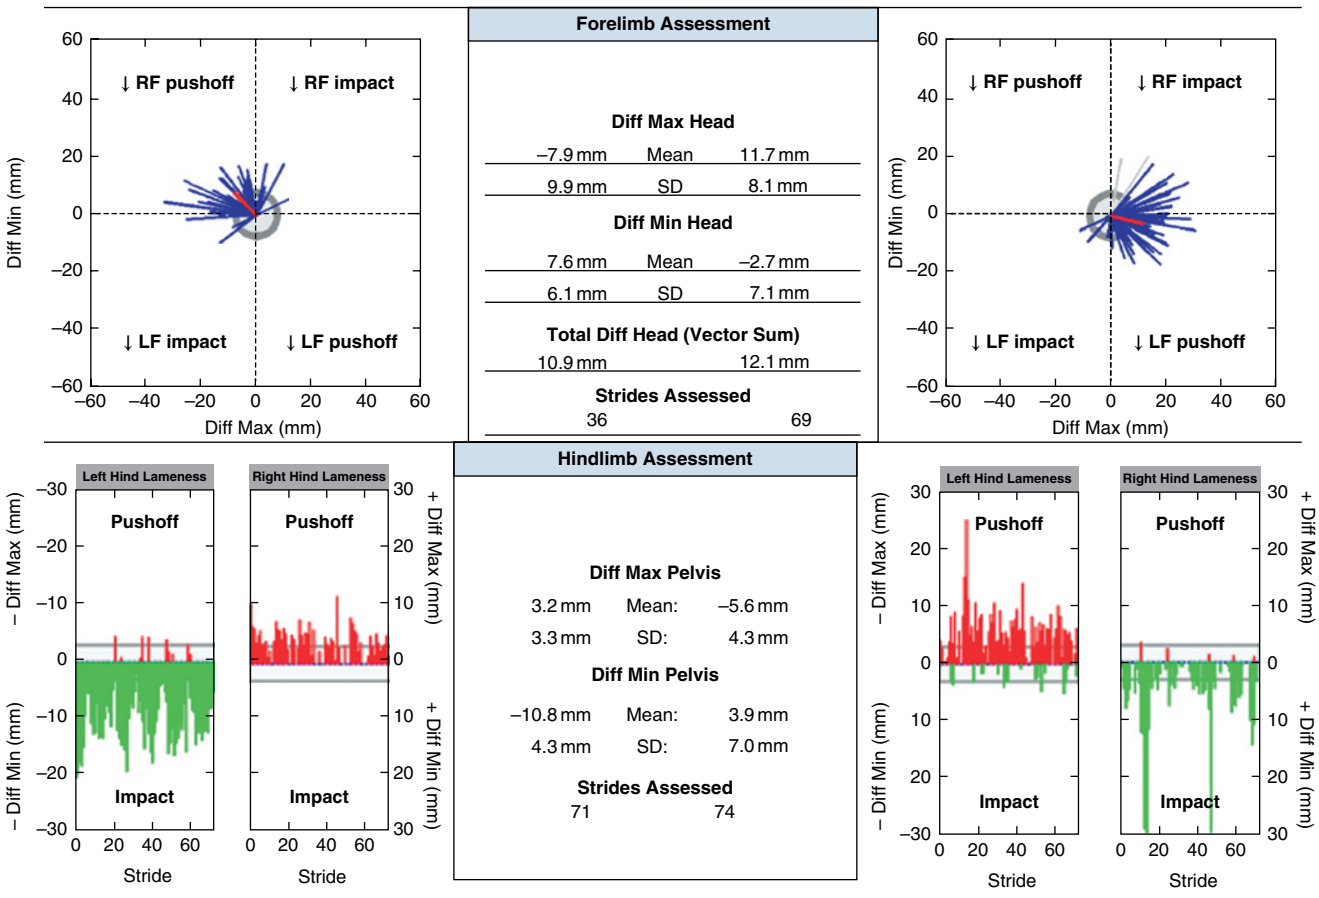

Figure 2.144. Lameness Locator® report of a non-lame horse lunging on a soft sand surface. Outside forelimb pushoff lameness, outside hindlimb pushoff lameness, and inside hindlimb impact lameness are measured.

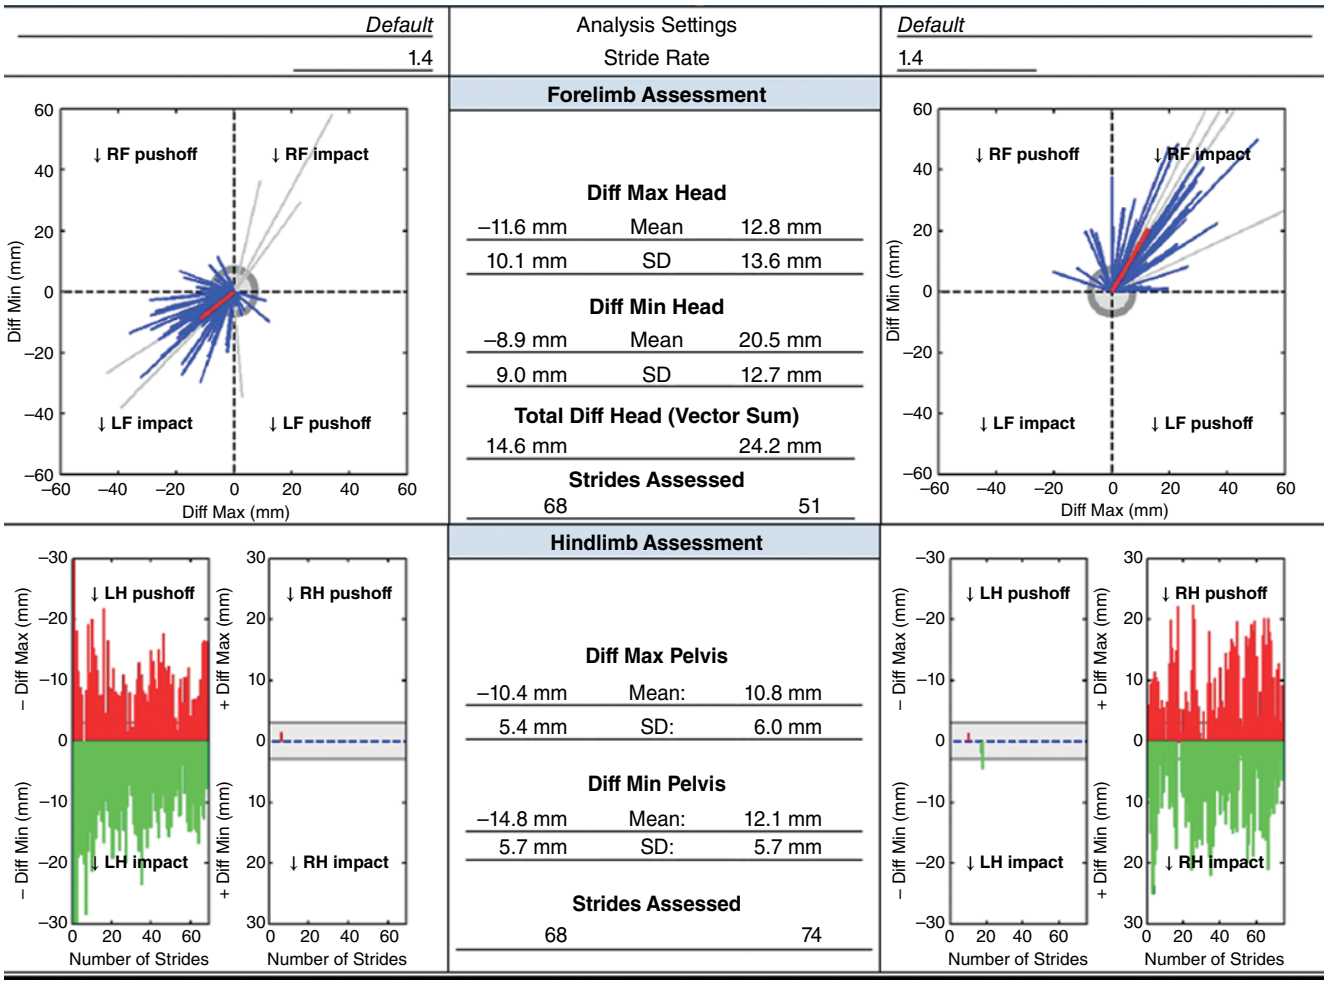

Figure 2.145. Lameness Locator® report of a normal horse lunging on a hard (asphalt) surface. Inside forelimb impact and inside hindlimb impact and pushoff lameness are measured.

Measuring Bilateral Lameness

No method that uses asymmetry as the measure of lameness can detect a perfectly bilateral lameness, and no measurement method that does not have a reasonable absolute known normal for the particular measurement for the individual horse can detect the existence of a perfectly bilateral pathological condition.[12] However, most bilateral conditions that cause lameness will have one side that is more affected than the other so that some lameness can be measured. Therefore, a bilateral lameness measured in a horse traveling in straight line will be an underestimation of the amplitude of true lameness. "Lateralization" of the lameness by measuring while lunging in both directions and then comparing both directional trial results can assist in estimating the true amplitude of lameness in both limbs, but until the pain in one limb is totally eliminated with blocking can the total lameness in one limb be determined. This fact should be realized when assessing treatments in studies using subjects with bilateral pathological conditions. In quadrupeds, the state of the two limbs in the other half of the body must also be determined.

Evaluation of Lameness Under Saddle

The Q® can be used to evaluate lameness under saddle with or without instrumentation of the rider with a separate inertial sensor. If used with the rider sensor, rider activity is detected, monitored, and assessed, and lameness is interpreted in light of this activity. If used under saddle without the rider sensor, rider activity should be known and noted by the evaluator so that any expected effects on lameness measurement can be properly interpreted. Rider activity affects lameness measurement under saddle.[39,62,63] Because there is no need for a handler to run back and forth multiple times leading the horse overground, assessment under saddle facilitates collection of data from multiple contiguous strides over longer periods of time (several minutes) compared to in-hand straight-line evaluation. Also, many horses behave better with less variable movement when under saddle. The collection of larger numbers of contiguous strides with lower stride-by-stride variability aids in detecting mild lameness or finding small changes in lameness severity. In most assessment, environments (arena and round pens) collecting unbroken under-saddle data for several minutes assumes that the horse will be ridden in a circular path.

VetBooks.ir

The Q® includes an optional Lameness Locator® module that collects and evaluates data from an inertial sensor attached to the rider at waist level in a belt with a pouch. Additional stabilization of the sensor to prevent independent wiggling, which creates motion noise, may be necessary. The rider inertial sensor measures and assesses vertical and horizontal (backward and forward) acceleration of the rider when the horse is trotting. The data is used in conjunction with that from the horse-mounted sensors to determine if the rider is sitting the trot, sitting the trot correctly, performing the rising trot (posting), and posting on the correct limb given the direction of motion selected for collection. The rider posting on the incorrect limb given the direction of movement may exacerbate lameness, but this is not currently evaluated.

Turning the rider sensor on initiates Lameness Locator®'s software for under saddle collection and analysis. Four synchronous channels of data (horse head, horse right forelimb, horse pelvis, and rider) are collected. Because it is assumed that the horse will be ridden in a circular path, and direction of movement affects vertical head and pelvic movement asymmetry, the user must assign direction of movement as either "ride to left" or "ride to right." Riding in one direction, the rider is asked to either sit the trot or post on the correct (outside) limb, or both, each for the desired duration. The desired trial length most conveniently includes one full rotation around a large arena or multiple rotations for riding in smaller circles. Strides collected with the rider sitting the trot and strides collected with the rider posting on the correct limb are automatically detected and separated. Improper technique when sitting the trot with either asymmetrical (right vs. left strides) or asynchronous (to the horse's vertical movement) vertical rider movement is flagged and will not be analyzed. Proper riding technique is verified, and the number of strides collected during each activity in one direction is displayed for analysis. Data collection for under-saddle evaluation while riding in the other direction is collected and analyzed in a separate trial. Riding to the left and riding to the right are then compared for each rider activity collected in a dual trial report similar to that for evaluating lunging in either direction (Figure 2.146).

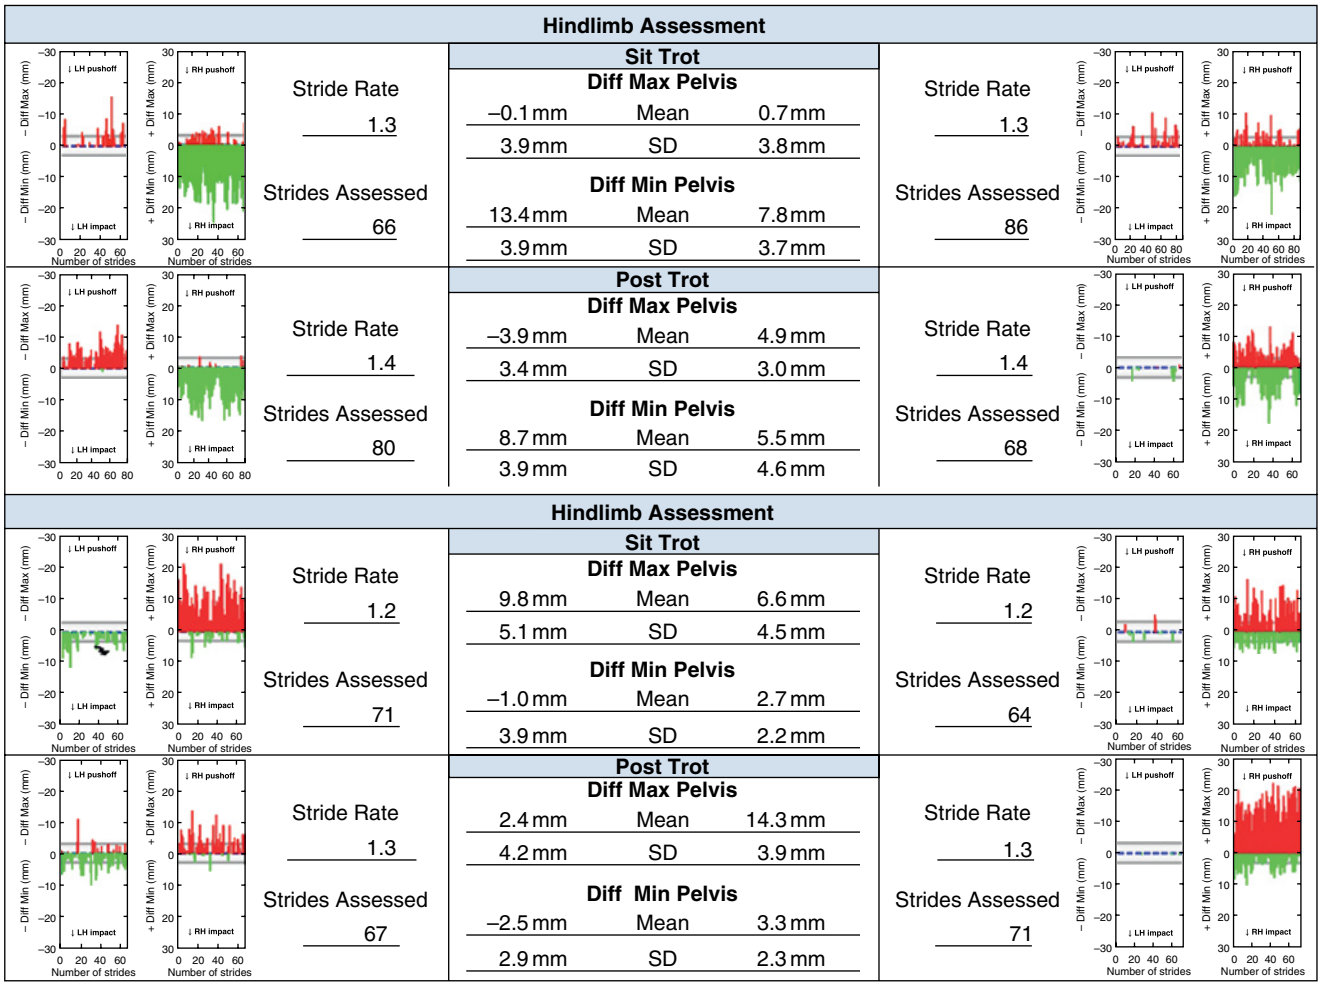

Figure 2.146. Lameness Locator® hindlimb lameness dual reports for ride to left versus ride to right. Results of sit trot are at top of report and results of posting are at bottom of report. Top report: This horse has a right hindlimb impact lameness riding in both directions under both activities that is unaffected by activity. However, note the artifactual production of a left hindlimb pushoff lameness when riding to the left and posting on the right forelimb. Bottom report: This horse has a right hindlimb pushoff lameness riding in both directions under both activities that is strongly affected by posting. Note the decrease in right hindlimb pushoff lameness when riding to the left (posting on the right forelimb) and the increase in right hindlimb pushoff when riding to the right (posting on the left forelimb).

VetBooks.ir

Sitting the trot, when performed correctly, has the least artifactual effect on assessment of lameness. A rider riding to the left and posting on the right forelimb moves up and forward when the inside (left) forelimb is weight bearing. This movement can exacerbate an existing painful focus in the inside forelimb, making lameness more visible and easily measured. Subsequently, the rider falls downward and backward during pushoff of the inside hindlimb. This rider movement opposes the upward thrust of the horse's inside hindlimb, preventing or lessening pelvic rise. Less pelvic rise after pushoff on the inside hindlimb will be measured as a hindlimb pushoff-type lameness. This later effect of posting is highly predictable and definitive. Horses without hindlimb pain during pushoff will frequently measure with inside hindlimb pushoff-type (lack of impulsion) lameness. Horses with existing pushoff lameness in the inside hindlimb will measure with greater lameness. Horses with existing pushoff lameness on the outside hindlimb (ipsilateral to the posting forelimb) will measure with lesser lameness or the existing pushoff lameness will be completely masked. The effect of posting on lameness will be additive to the effect of direction of movement and to surfaces characteristics, which can be significant when riding in small circles. Lameness Locator® AIDES, taking into consideration both direction of movement, surface characteristics, and rider activity, remind the user about these artifactual effects. Amount of artifactual effect will depend on amplitude of rider posting, which, depending on the individual rider, may differ when riding in opposite directions. The combination of artifactual effects from direction of movement, surface characteristics, and rider activity complicates lameness evaluation under saddle. However, similar to evaluation of lameness while lunging, when lameness is consistently measured during in-hand straight-line evaluation, under-saddle evaluation with the rider sitting the trot uncommonly brings out a lameness in a different limb entirely, and for lameness measured with the rider sitting the trot, evaluation for lameness with the rider posting uncommonly brings out non-artifactual lameness in a different limb. Nevertheless, especially when lameness is not consistently measurable in hand, evaluation of lameness under saddle is a valuable technique to assess some lameness conditions in certain situations.

PERINEURAL AND INTRASYNOVIAL ANESTHESIA

Gary M. Baxter

VetBooks.ir

Local anesthesia is commonly used during a lameness examination to confirm or identify the site or sites of pain where obvious pathology may not exist.[9,17,63,66] It can also be useful to prove the location of a lameness to a client who may be suspicious of another site. Local anesthesia may be accomplished by perineural infiltration (local nerve block), ring block, direct infiltration of a painful region, or intrasynovial injection (joints, tendon sheaths, and bursae). The reader is referred to the accompanying website for individual video clips that demonstrate many of the various techniques.

Perineural infiltration and ring blocks are used to localize the source of pain to a specific region and, therefore, should be performed in a systematic manner starting with the distal extremity and progressing proximally. Direct infiltration and intrasynovial anesthesia are used to identify the involvement of a specific structure or synovial cavity and do not necessarily have to be performed in a systematic manner.[9] It is not uncommon to perform several different types of local anesthesia in the same horse (perineural together with intrasynovial), depending on the specific clinical signs and problem. With lameness, local anesthesia is important to document the specific site of the problem so that diagnostic imaging (radiography, ultrasonography, or magnetic resonance imaging) can be used to determine the cause of the problem. Other uses of local anesthesia include providing analgesia during and after surgery and pain control for other painful conditions.

TYPES OF LOCAL ANESTHETICS

The local anesthetics most frequently used are 2% lidocaine hydrochloride (Xylocaine hydrochloride) and 2% mepivacaine hydrochloride (Carbocaine). These solutions are potent and rapidly effective, but can be locally irritating. Because mepivacaine is longer lasting, less irritating, and more reliable than lidocaine, it is used most frequently.[5,33,48,66] Lidocaine is thought to last only 60 minutes with the maximum effect at 15 minutes.[73] It was also recently reported to not resolve lameness despite the loss of skin sensation.[33] One study using force plate evaluations indicated that mepivacaine was also only fully effective for 15–60 minutes after a palmar digital (PD) nerve block was performed.[5] The effect of the block began to subside between 1 and 2 hours, but gait characteristics persisted beyond 2 hours. A more recent crossover study indicated that the mean duration of action was 366 minutes with skin sensation returning before the return of lameness.[33] These variables in skin desensitization and duration of action are very important to remember when performing multiple nerve blocks on any given horse over a prolonged period of time. Bupivacaine hydrochloride (Marcaine) may be used if the goal is to provide a longer duration of analgesia (4–6 hours), such as following surgery.[48]

SKIN PREPARATION AND RESTRAINT

The only skin preparation necessary for most sites of regional anesthesia is scrubbing/wiping the area with gauze soaked in alcohol until clean. However, there are a few sites for perineural anesthesia that are adjacent to synovial structures where during injection the needle may inadvertently enter a synovial cavity or the solution may diffuse into these structures. These exceptions include the low four-point block (digital tendon sheath or fetlock joint), the high palmar/plantar blocks (carpometacarpal or tarsometatarsal [TMT] joints, carpal or tarsal sheaths), and the lateral palmar block (middle carpal joint or carpal sheath). A more thorough skin preparation of these sites is recommended to avoid potential complications. A minimum 5-minute scrubbing of the skin and hair with an antiseptic and alcohol is recommended for intrasynovial injections.[29] The horse may be clipped if the hair is unusually long or soiled, but this is not necessary unless utilizing spinal needles with stylets.[1] In all cases, the least amount of local anesthetic possible should be used to reduce tissue irritation and to prevent local diffusion of anesthetic that may complicate the interpretation of the block.

When performing local anesthesia, the horse should be haltered and restrained by an attendant who is standing on the same side of the horse. For intrasynovial anesthesia, a twitch is usually applied so that there is minimal limb movement during the insertion of the needle and injection of the anesthetic. When using local anesthesia in the hindlimb, the practitioner should always be in a position so that minimal bodily harm will result if rapid movement occurs. In most cases the needle is inserted rapidly, and the syringe applied just tight enough to prevent loss of local anesthetic solution during injection.

PERINEURAL ANESTHESIA

Perineural anesthesia is used when the lame limb has been identified, but the exact region affected cannot be determined by other methods. Even if a suspicious region is identified, it is often useful to anesthetize the region to confirm that the lameness is emanating from a single location. It is not uncommon to find several regions on one limb or find that other limbs may be contributing to the overall lameness problem. In these cases local anesthesia allows one to interpret the percentage that each region is contributing to the lameness. In addition, the degree of improvement with perineural blocks may aid in the interpretation of the findings on imaging.

Perineural anesthesia is typically performed in a stepwise manner starting from the distal limb and progressing proximally. In general, the accuracy of desensitizing a nerve is greater in the distal limb (distal to the carpus and tarsus) than more proximally where the nerves are deeper and covered with soft tissue. Also, the more distal

VetBooks.ir

the nerve, the more specific or smaller the region is that is anesthetized. In most cases perineural anesthesia is thought to desensitize the skin and all deep structures distal to the site of injection. However, aberrant nerves exist and should be remembered when interpreting the response to a block. Some feel that ring blocks are more reliable to completely desensitize the skin than local perineural blocks.[75] However, ring blocks are not commonly performed when attempting to accurately locate the site of lameness. Guidelines for performing perineural anesthesia are given in Table 2.5.

A thorough knowledge of the neuroanatomy of the involved region and a good understanding of the limitations of perineural anesthesia are necessary to properly apply and interpret perineural anesthesia. Accurately determining whether the nerve has been completely desensitized by the block is often the first step in interpreting the result. Complete desensitization of the nerve is often evaluated by checking the skin sensation distal to the point of injection. This can be performed with a blunt object such as a pen, hemostat, or needle cap. These objects should not be jabbed into the skin, but applied gently at first with a gradual increase in pressure. Most horses are receptive to this technique and will quietly respond if the nerves are not totally desensitized. However, some horses are difficult to read, and skin sensation may persist even with an effective block. In contrast, one recent study indicated that lidocaine blocked skin sensation without resolving an experimentally induced lameness in 3/8 horses.[33] This difficulty of using skin sensation to indicate the success of a block is especially amplified for those performed more proximally in the limb (above the fetlock). Other manipulative tests that previously caused pain (such as hoof tester examination, deep palpation, and flexion) may need to be repeated to accurately determine if the block worked. The ultimate test is whether lameness is no longer present, but for those horses that have not improved,

Table 2.5. Guidelines for perineural local anesthesia.

Specific block	Needle size	Volume of anesthetic	Sterile skin prep recommended (Yes or No)	Location
Palmar/plantar digital (PD)	25 g, 5/8″	1–1.5 mL	No	Just above collateral cartilages
Basisesamoid (high PD)	25 g, 5/8″	1.5–2 mL	No	At the base of the proximal sesamoid bone
Pastern ring block	22 g, 1–1.5″	2–3 mL	No	Above collateral cartilages and directed dorsally
Abaxial sesamoid	25 g, 5/8″	1.5–2 mL	No	Abaxial surface of proximal sesamoid bone
Low palmar or 4-point	22–25 g, 5/8–1″	2–3 mL/site	Yes	Distal metacarpus (above buttons of splint bones)
High palmar or 4-point	25 g 5/8″ and 20–22 g 1.5″	3–4 mL/site	Yes	Proximal metacarpus
Lateral palmar (lateral approach)	20–22 g 1″	4–6 mL	Yes	Distal to accessory carpal bone
Lateral palmar (medial approach)	25 g, 5/8″ or 22 g 1″	3–4 mL	No	Medial aspect of accessory carpal bone
Ulnar	20 g 1.5″	10 mL	No	4″ above accessory carpal bone
Median	20–22 g 1.5–2.5″	10 mL	No	Caudal to radius below pectoralis muscle
Medial cutaneous antebrachial	22–25 g 1–1.5″	5–10 mL	No	Mid-radius near cephalic and accessory cephalic veins
Low plantar or 6-point	25 g, 5/8″ or 22 g 1″	2–3 mL/site	Yes	Distal metatarsus and each side of long digital extensor tendon
High plantar, high 4-point or subtarsal	25 g 5/8″ and 20–22 g 1.0″	3–4 mL/site	Yes	Proximal metatarsus
Deep branch of lateral plantar	20–22 g 1.0″	3–5 mL	Yes	Lateral aspect of proximal metatarsus
Tibial/peroneal	20–22 g 1.5″	10–20 mL/site	No	4″ above point of hock on lateral and medial aspects of limb

VetBooks.ir

accurate interpretation of complete nerve desensitization is important. Therefore, it is recommended that multiple approaches be used before deciding whether perineural anesthesia was or was not successful.

The Forelimb

Palmar Digital (PD) Block

The medial and lateral PD nerves are located just palmar to their respective artery and vein and lie along the dorsal border of the SDFT proximal to the pastern joint and along the DDFT distal to the pastern joint. The injection is done with the foot elevated in most cases. Some prefer to stand with their backs toward the animal's rear end while holding the hoof between their knees. Others prefer holding the pastern with one hand while injecting with the other and assume either a lateral or frontal position in relation to the limb (Figure 2.147; Video 2.7). The PD nerves should be anesthetized just distal to or at the proximal border of the collateral cartilages (Figures 2.147 and 2.148). Blocking the nerves at this location reduces the risk of anesthetizing the dorsal branches of the PD nerve.[64,66] If the PD block is performed 2–3 cm above the collateral cartilages, the proximal interphalangeal (PIP) joint is often desensitized in addition to the foot.[65] The PD nerve and neurovascular bundle are easily palpable at the level of the collateral cartilage just behind the DDFT. A 25-gauge, 5/8-inch (1.5-cm) needle is inserted into the subcutaneous tissue in a proximal to distal direction over the nerve, and 1–1.5 mL of local anesthetic solution is injected perineurally.[66,75] The needle is retracted slightly and redirected if excessive pressure is needed to inject. Since there are several tissue planes, it is advisable to inject a small amount of local anesthetic as the needle is being withdrawn. Each nerve can be injected individually (preferred by the author) or the needle can be directed across midline under the skin to inject the contralateral nerve (Figure 2.148).

Figure 2.147. This image illustrates the positioning to perform a PD nerve block when facing the back of the horse and holding the limb with one hand. The needle is directed toward the hoof and is inserted at or below the level of the collateral cartilages.

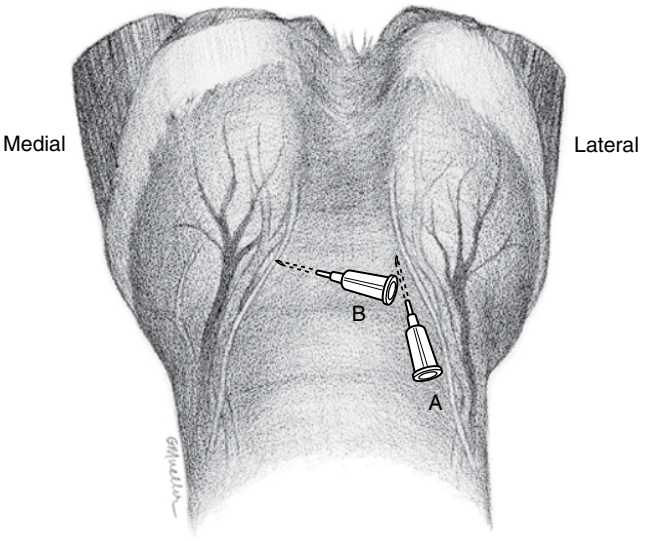

Figure 2.148. Injection sites for a PD nerve block. In (A), the needle is inserted parallel to the lateral PD nerve, while in (B), the needle enters just off midline and is inserted in the subcutaneous tissues to approximate the medial PD nerve.

Loss of skin sensation at the coronary band in the heel region and loss of deep sensation between the heel bulbs after 5–10 minutes are a reliable indication that the block was successful.[48] Previous hoof tester pain should also be eliminated following the block. Lameness assessment of the horse following the block should be performed in a similar manner as was done prior to the block. In cases of many foot-related lameness conditions, the lameness will often shift to the opposite forelimb. Structures that are desensitized with a biaxial PD nerve block include the entire sole, the navicular apparatus and soft tissues of the heel, the entire DIP joint of the forelimb, the distal portion of the DDFT, and some of the distal sesamoidean ligaments.[21,48,63,66] Partial desensitization of the PIP joint is also thought to occur in some horses.[75]

Pastern Ring or Semi-ring Block

A pastern ring block is performed just above the collateral cartilages of the distal phalanx at the same site as the PD block (Figure 2.149A). A 20- to 22-gauge needle is used to inject 3–4 mL of anesthetic subcutaneously laterally and medially from the site of the respective PD block. The needle is directed dorsally perpendicular to the long axis of the pastern to about the level of the medial and lateral collateral ligaments. This will anesthetize the dorsal branches of the PD nerve and will desensitize all the deep structures distal to the block. However, because the dorsal branches of the digital nerves are thought to contribute little to sensation within the foot, the pastern ring block is unlikely to improve lameness that has not been eliminated with a PD nerve block.[21,48] The pastern ring block can be performed with the limb in a full weight-bearing position but is easier to perform with the foot off the ground. Horses tend to resent this block more than the PD or basisesamoid nerve blocks.

VetBooks.ir

Figure 2.150. Needle location to perform an abaxial sesamoid nerve block in the forelimb.

Basisesamoid or High PD Block

An alternative to the pastern ring block is the basisesamoid block. This block is performed similarly to the PD block, only it is more proximal on the limb at the base of the proximal sesamoid bones (often referred to as a high PD block). The PD nerves can be palpated at this location, and 1.5–2 mL of anesthetic is deposited directly over the nerves using a 25-gauge, 5/8-inch (1.5-cm) needle (Figure 2.149; Video 2.8). The basisesamoid block will desensitize the dorsal branch and the PD nerve at a more proximal location in the pastern. This block desensitizes the palmar/plantar soft tissue structures of the pastern, PIP joint, and all structures of the foot. Because it is performed at the base of the sesamoid bones, it is unlikely to desensitize any of the fetlock joint.

Abaxial Sesamoid Block

The neurovascular bundle is easily palpable along the abaxial surface of the proximal sesamoid bone. With the limb elevated and holding the fetlock in the palm of the hand, isolate the palmar nerve by rolling it away from the artery and vein with the thumb or forefinger. A 5/8-inch (1.5-cm), 25-gauge needle is used to inject 1.5–2 mL of anesthetic perineurally (Figure 2.150; Video 2.9). Alternatively, the block can be performed with the horse standing (Video 2.10). It is best to use a small volume of anesthetic and direct the needle distally to avoid partial desensitization of the fetlock joint.[66] The biaxial block desensitizes the foot, middle phalanx, PIP joint, distopalmar aspects of proximal phalanx, distal portions of the SDFT and DDFT, distal sesamoidean ligaments, and digital annular ligament.[48,66] Loss of skin sensation at the coronary band in the toe region together with loss of skin sensation on the palmar pastern is used to determine the success of the block.[48] While it is common to find that skin sensation still exists over the dorsal surface of the phalanges, this does not mean that the phalanges and all the deep structures are not desensitized.

Low Palmar Block (Low 4-Point Block)

The low palmar block is often referred to as the low 4-point block because both palmar and palmar metacarpal nerves are anesthetized at the distal aspect of the metacarpus/metatarsus (Figure 2.151; Video 2.11). The lateral and medial palmar nerves lie between the suspensory ligament and the DDFT. Since they assume a vein–artery–nerve relationship, these nerves are located closer to the DDFT and lie on its dorsal edge.[47] These nerves are relatively deep but can be reached in most cases with a 5/8-inch (1.5-cm), 25-gauge needle (a 1-inch, 22-gauge needle may also be used), after which 2–3 mL of local anesthetic is deposited. It is best to perform these blocks 1 cm proximal to the distal ends of the splint bones to avoid injection into the digital flexor tendon sheath.[34,48,68]

Blocking the palmar nerves alone will not completely desensitize the fetlock joint. Two additional nerves, the medial and lateral palmar metacarpal nerves, innervate the deep structures of the fetlock.[56,75] These nerves course parallel and axial to the second and fourth metacarpal bones. A 5/8-inch (1.5-cm), 25-gauge needle or a 1-inch (2.5-cm), 22-gauge needle is used to inject 2–3 mL of anesthetic around these nerves as they emerge from the distal edges of the second and fourth metacarpal bones (Figure 2.151b). However, because the palmar pouches of the fetlock joint can be inadvertently entered at this location, these nerves can also be anesthetized more proximally.[48,68]

Both the palmar and palmar metacarpal nerve blocks can be performed while the horse is bearing full weight or the limb can be held with the opposite hand. It is usually easier to perform in the standing position. Anesthesia of these four nerves effectively desensitizes the deep structures of the fetlock region and all structures

VetBooks.ir

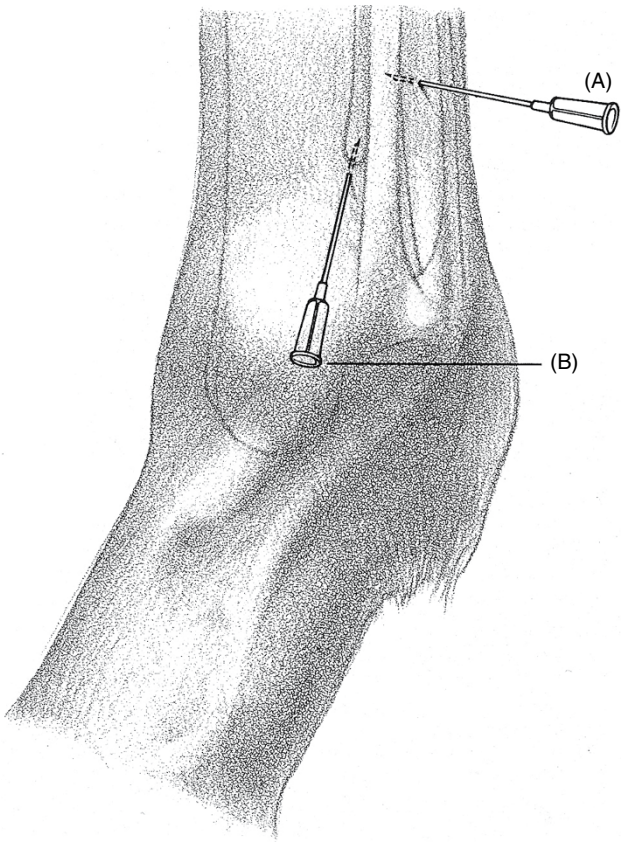

Figure 2.151. Low palmar or 4-point block. (A) Site for palmar nerve block, but it is recommended to go 1 cm proximal to the distal end of the small metacarpal bones. (B) Site for palmar metacarpal nerve block at the distal end of the splint bones.

distally.[48] Anesthesia of the skin over the dorsal aspect of the pastern and fetlock indicates that the block was successful. Some skin sensation may be present over the dorsal surface of the fetlock joint as a result of the sensory supply from the medial cutaneous antebrachial distribution.[56]

High Palmar (High 4-Point Block)

The high 4-point or high palmar block is analogous to the low 4-point block because the same four nerves are anesthetized in the proximal aspect of the metacarpus just below the carpometacarpal joint. However, the high palmar block is more difficult to perform because the soft tissue structures are more closely confined to the metacarpus and the palmar metacarpal nerves are located deeper within the axial borders of the second and fourth metacarpal bones. In addition, the distal outpouchings of the carpometacarpal joint extend approximately 2.5 cm distal to the joint in close proximity to the nerves and can be entered when blocking the palmar metacarpal nerves.[23,34] Therefore, aseptic preparation of the injection sites is recommended when blocking the palmar metacarpal nerves.

The proximal palmar nerves are anesthetized in the groove between the suspensory ligament and the DDFT. The nerves lie under heavy fascia, palmar to the vein and artery, and rest against the dorsal, lateral, and medial

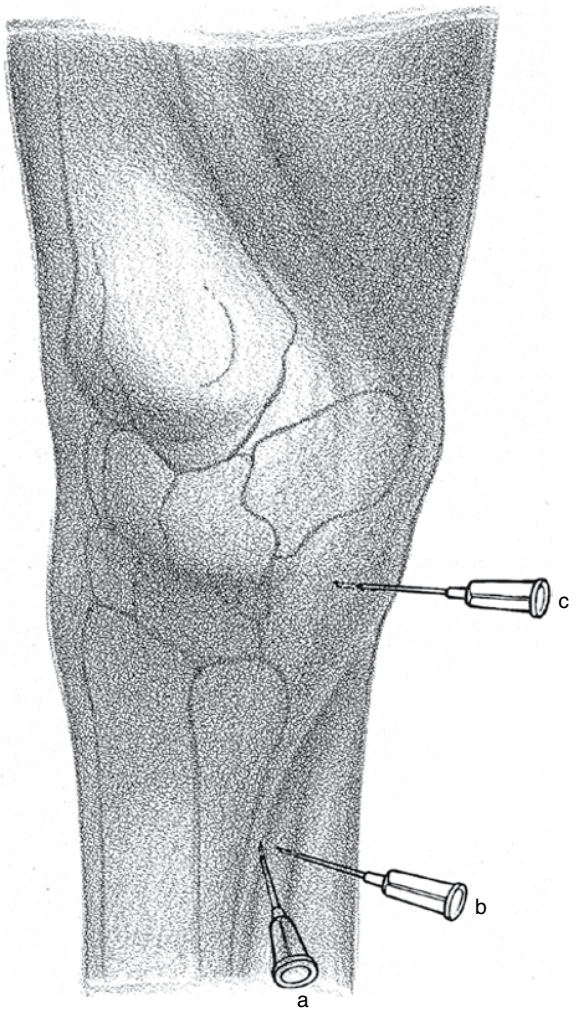

Figure 2.152. High 4-point block. (a and b) Needle positioned lateral and medial to block the palmar nerves. (c) Needle positioning to perform the lateral approach to block the lateral palmar nerve. Needle positioning to block the palmar metacarpal nerves is not shown but is located axial to the heads of the splint bones.

aspects of the deep digital flexor tendon (DDFT). A 5/8-inch (1.5 cm), 25-gauge needle is inserted through the heavy fascia, and 3–4 mL of anesthetic is deposited (Figure 2.152a and b).[48] Blocking just the palmar nerves will not completely desensitize the deep structures of the metacarpus.[75] The palmar metacarpal nerves run parallel and axial to the second and fourth metacarpal bones, and each can be desensitized by infiltration of 3–4 mL of local anesthetic along the axial surfaces of the metacarpal bones (Figure 2.153b_1 and b_2). A 20- to 22-gauge, 1.5-inch needle is directed toward the palmar metacarpus along the axial borders of the splint bones until bone is contacted. The needle is withdrawn slightly and aspirated to be certain that the needle is not within the carpometacarpal joint before the anesthetic is deposited. Blocking the palmar metacarpal nerves is usually performed with the limb held, whereas anesthesia of the palmar nerves is often easier with the limb weight-bearing.[48]

These four nerve blocks will effectively desensitize the deep structures of the metacarpus with the exception of the origin of the suspensory ligament.[34] The medial

and lateral palmar metacarpal nerves innervate the interosseous ligaments of the second and fourth metacarpal bones, the interosseous lateralis and medialis muscles, and the suspensory ligament (interosseous muscle).[56] The palmar nerves innervate the flexor tendons and the inferior check ligament.[48] Horses that become sound after this block warrant diagnostic imaging of the metacarpal region. Lack of improvement with a high palmar block does not necessarily rule out a problem at the origin of the suspensory. Because of the difficulty of performing this block and its lack of specificity, use of the high palmar block has fallen out of favor with many clinicians. The lateral or medial approach to the lateral palmar nerve is usually performed instead especially if a proximal suspensory problem is suspected. Alternatively, a high 2-point block can be performed to desensitize the metacarpal region.

Lateral Palmar Block (Lateral Approach)

The lateral palmar nerve originates at a variable distance proximal to the carpus and represents a continuation of the median nerve plus the palmar branch of the ulnar nerve. The lateral palmar nerve courses in a dorsolateral direction distal to the accessory carpal bone and runs along the palmar distal aspect of the accessoriometacarpal ligament (Figure 2.153d). At the proximal end of the fourth metacarpal bone, the lateral palmar nerve gives off its deep branch that detaches branches to the origin of the suspensory ligament and divides into the lateral and medial palmar metacarpal nerves (Figure 2.153b_1 and b_2).[75] The lateral palmar nerve can be anesthetized just below the accessory carpal bone (lateral approach) or axial to the accessory carpal bone in a more proximal location (medial approach). This block desensitizes the origin of the suspensory ligament and other deep structures of the palmar metacarpus. Performing this block avoids the necessity of direct infiltration of the suspensory ligament and anesthesia of the palmar and palmar metacarpal nerves independently.[24,34]

The lateral palmar nerve is anesthetized with 4–6 mL of anesthetic administered through a 1-inch (2.5-cm), 20-gauge needle midway between the distal border of the accessory carpal bone and the proximal end of the fourth metacarpal bone on the palmar border of the accessoriometacarpal ligament (Figures 2.152c and 2.153d).[3,75] The needle is directed in a palmarolateral-to-dorsomedial direction and must penetrate the 2- to 3-mm thickness of the flexor retinaculum of the carpus (Video 2.12).[3,34] This block may be performed with the horse standing or with the carpus slightly flexed.[3,34] Skin sensation is not useful to evaluate the effect of the block. Instead, lack of any response to deep palpation of the proximal suspensory ligament often suggests an effective block.

Lateral Palmar Block (Medial Approach)

The lateral palmar nerve may also be blocked medial to the accessory carpal bone.[10] This medial technique is thought to reduce the risk of inadvertent injection into the carpal canal, which may occur with the lateral approach to the lateral palmar nerve.[24,48,49] The site of injection is a longitudinal groove in the fascia palpable over the medial aspect of the accessory carpal bone, palmar to the insertion of the flexor retinaculum that forms the palmaromedial aspect of the carpal canal.[10,48] With the limb weight-bearing, a 25-gauge, 5/8-inch needle is inserted into the distal third of the groove in a mediolateral direction perpendicular to the limb. The needle should contact the bone and 3–4 mL of anesthetic is injected (Figure 2.154). In some cases the injection may be difficult until the needle is withdrawn slightly or redirected. The author uses a 22-gauge, 1-inch (2.5 cm) needle and 3–4 mL of anesthetic for this technique (Video 2.13). A recent contrast study indicated that anesthetic may be distributed proximally to the distal third of the antebrachium following this block.[49] Skin sensation is not useful to evaluate the effect of the block, and lack of pain on palpation of the suspensory ligament is often the best indicator of success.

High 2-Point Block

The high 2-point block is a combination of the lateral palmar block and the high medial palmar block (1 nerve

VetBooks.ir

Figure 2.154. The medial approach to desensitize the lateral palmar nerve is located on the axial border of the accessory carpal bone.

(b) Site for medial cutaneous antebrachial nerve block as nerve crosses the lacertus fibrosus, which blocks both the cranial (b1) and the caudal (b2) branches.

of the high 4-point block). When performed, all deep and superficial structures on the palmar aspect of the metacarpus distal to the block will be desensitized. This includes the proximal aspects of the second and fourth metacarpal bones and the origin of the suspensory ligament.

This block can be used instead of the high 4-point and is easier to perform with less risk of complications. However, some clinicians have found it unnecessary to block the medial palmar nerve in conjunction with blocking the lateral palmar nerve.[75]

Ulnar, Median, and Medial Cutaneous Antebrachial Blocks

Perineural anesthesia is used most frequently up to the level of the carpus because the nerves lie superficial and the injection techniques are relatively easy to perform. Above this region intrasynovial anesthesia is often used to identify the site of lameness. However, the carpus and distal aspect of the limb can be desensitized by blocking the ulnar, median, and medial cutaneous antebrachial nerves. The medial cutaneous antebrachial nerve innervates only the skin, so it is primarily used to anesthetize the limb for a surgical procedure.[48] The median and ulnar nerve blocks may be used to locate a painful condition in the distal limb during a lameness examination. For instance, this procedure could be used to rule out lameness of the distal limb if lameness in the proximal forelimb was suspected.

The ulnar nerve is anesthetized approximately 4 inches (10 cm) proximal to the accessory carpal bone on the caudal aspect of the forearm (Figure 2.155C). Careful palpation reveals a groove between the flexor carpi ulnaris and ulnaris lateralis muscles. A 20-gauge, 1.5-inch (3.8-cm) needle is inserted through the skin and fascia perpendicular to the limb. Although the depth of this nerve varies, it is usually about 0.25–0.5 inches (1–1.5 cm) below the skin surface. The local anesthetic (10 mL) is infused both superficially and deeply in this region. Because the palmar branch of the ulnar nerve gives rise to the lateral palmar and palmar metacarpal nerves, anesthesia desensitizes the lateral skin of the forelimb distal to the injection site down to the fetlock.[48] Also, the accessory carpal bone and surrounding structures, palmar carpal region, carpal canal, proximal metacarpus, SDFT, and suspensory ligament are partially blocked by this technique. Lame horses with lesions in the very proximal aspect of the SDFT may only improve after an ulnar block.[11]

The median nerve is anesthetized on the caudomedial aspect of the radius, cranial to the origin of the flexor carpi radialis muscle (Figure 2.155A). The injection site is located just below the elbow joint where the ventral edge of the posterior superficial pectoral muscle inserts in the radius.[48] At this point the nerve is superficial and lies directly on the caudal surface of the radius. A 2- to 2.5-inch (5- to 6.2-cm), 20-gauge needle is inserted obliquely through the skin and fascia to a depth of 1–2

VetBooks.ir

inches (2.5–5 cm). The needle should be kept as close to the radius as possible to avoid the median artery and vein which lie caudal to the nerve, and approximately 10 mL of anesthetic is usually injected.[75] Blocking this nerve alone accomplishes little more than a medial and lateral palmar nerve block. However, blocking the median nerve in conjunction with the ulnar nerve effectively anesthetizes most of the important areas of lameness distal to the blocks.

The two branches of the medial cutaneous antebrachial nerve are blocked on the medial aspect of the forearm halfway between the elbow and the carpus, just cranial to the cephalic vein and just cranial to the accessory cephalic vein (Figure 2.155b_1 and b_2).[75] The nerve is usually just below the skin; however, its location can vary. It is best to block the subcutaneous tissues both cranial and caudal to the cephalic vein. A 22-gauge, 1-inch (2.5-cm) needle is used to deposit 5 mL of anesthetic solution. Alternatively, the medial cutaneous antebrachial nerve may be blocked as it crosses the lacertus fibrosus before it branches (Figure 2.155b).[48,75]

The Hindlimb

The neuroanatomy of the distal hindlimb below the tarsus is somewhat similar to that of the forelimb below the carpus. The majority of perineural techniques described previously for the forelimb are similar in the hindlimb. However, limb positioning, restraint, and the technique may vary slightly. One difference in the neuroanatomy is that lateral and medial dorsal metatarsal nerves from the deep peroneal (fibular) nerve course over the dorsolateral and dorsomedial surfaces of the third metatarsal bone and digits.[75] Therefore, it is recommended to anesthetize the dorsal metatarsal nerves dorsally when performing plantar digital nerve blocks at the pastern and proximal (abaxial) sesamoid bones and low and high 4-point plantar nerve blocks. This is accomplished by injecting 2–3 mL of anesthetic subcutaneously, lateral and medial to the long digital extensor tendon using a 5/8-inch (1.5-cm), 25-gauge needle.

Intrasynovial anesthesia is performed most frequently proximal to (above) the metatarsus in the hindlimb. However, perineural anesthesia of the tibial and peroneal nerves can be used to desensitize the tarsal region. The tibial and peroneal nerve blocks can also be used to determine whether the pain from a severe lameness without clinical findings is located proximal or distal to the hock region. Horses exhibiting subtle lameness are generally not good candidates for tibial and peroneal anesthesia because blocking the peroneal nerve may affect the horse's ability to extend the digit, thus making interpretation of the results difficult.[9]

When dealing with the hindlimb, proper restraint and body positioning are important to prevent bodily harm. In most cases a twitch is applied, and the handler should stand on the same side as the veterinarian. All blocks should be performed with the veterinarian facing toward the back of the horse. The authors routinely begin diagnostic nerve blocks at the level of the proximal sesamoid bones unless there is uncertainty regarding foot involvement. If the foot is suspected, a high PD nerve block in the pastern is usually performed because often there is less concern about anesthetizing more proximal structures. In addition, a low PD block is difficult to perform in the hindfeet because the fetlock flexes when the limb is picked up.

The PD and abaxial sesamoid blocks are best performed with the limb extended behind the horse in a position similar to that when performing a fetlock flexion test or applying a horseshoe. The point of the hock is held fast by cradling it with the inside of the arm and axilla. This position reduces the ability of the horse to withdraw the limb to kick. Perineural blocks performed proximal to the abaxial sesamoid block are usually performed while standing close to the horse and with the limb on the ground. If the horse is prone to kicking, the limb can be held fast by grasping the foot, after which the limb is brought forward (similar to that done with a spavin test) to perform the block.[9]

High Plantar Block

The high plantar block anesthetizes the medial and lateral plantar and plantar metatarsal nerves just below the tarsus analogous to the high palmar block of the forelimb. Anesthesia of the dorsal metatarsal nerves just below the TMT joint may be included in this block to provide complete analgesia to structures in the metatarsal region and below.[48] The plantar metatarsal nerves can be blocked using a 1.5-inch (3.8-cm), 20-gauge needle inserted axial to the second and fourth metatarsal bones and directed dorsally toward the plantar aspect of the metatarsus. Three to four mL of local anesthetic is injected into the region of the origin of the suspensory ligament. Inadvertent administration of anesthetic into the tarsal sheath or the TMT joint can occur when performing anesthesia of the plantar metatarsal nerve.[20,34,48] Because of the potential for intrasynovial injection, careful skin preparation prior to performing this block is recommended.[20,34]

The medial and lateral plantar nerves can be anesthetized by placing 3–4 mL of anesthetic through the heavy fascia adjacent to the dorsal surface of the DDFT in the proximal metatarsal region using a 25-gauge, 5/8-inch needle. If a large volume of anesthetic is used at the site of the lateral plantar nerve block, the deep branch of the lateral plantar nerve (DBLPN) can also be anesthetized.[48] This will block both the medial and lateral plantar metatarsal nerves, negating the need to block these nerves individually. The high plantar block effectively desensitizes the second and fourth metatarsal bones, the suspensory ligament and its origin, and the flexor tendons in the metatarsal region. One study concluded that the high plantar nerve block cannot be used to differentiate between flexor tendon and suspensory ligament lesions because horses with both conditions improved after the block.[40] Because the high plantar block is difficult to perform and interpret and can inadvertently block the tarsal sheath or TMT joint, it is not commonly performed. Most clinicians will perform the DBLPN block instead.

Deep Branch of the Lateral Plantar Nerve (DBLPN) Block

The DBLPN innervates the proximal suspensory in the hindlimb and is removed to treat some horses with hindlimb proximal suspensory desmitis. This nerve can

VetBooks.ir

be selectively desensitized to aid more accurate diagnosis of this condition (Figure 2.156). Two different techniques have been described (Figure 2.157). With the first approach, a 20–22-gauge, 1-inch (2.5-cm) needle is inserted 15 mm distal to the head of the fourth metatarsus and directed perpendicular to skin between the axial border of the fourth metatarsus and the SDFT to a depth of approximately 25 mm (Figure 2.156–2.158).[12,35] This single-injection technique was considered to be 95% accurate to block the DBLPN in a cadaver and live horse study. Alternatively, a 20–22-gauge, 1.5-inch (3.8-cm) needle can be inserted 20 mm distal and plantar to the head of the fourth metatarsus and directed proximodorsally and axial to the bone (Figure 2.157).[25] The needle is advanced to a depth of 1–2 cm and anesthetic is deposited.[25] It is usually best to hold the limb to perform either of these techniques, and it is the author's opinion that the perpendicular approach is easier to perform (Figures 2.156 and 2.157). The single-injection technique for the DBLPN is thought to provide a reliable method for perineural analgesia of the DBLPN for diagnosis of proximal suspensory desmitis of the pelvic limb with a minimal risk of inadvertently desensitizing structures within the tarsal sheath and the TMT joint.[25,35] However, two different *in vivo* studies have shown that

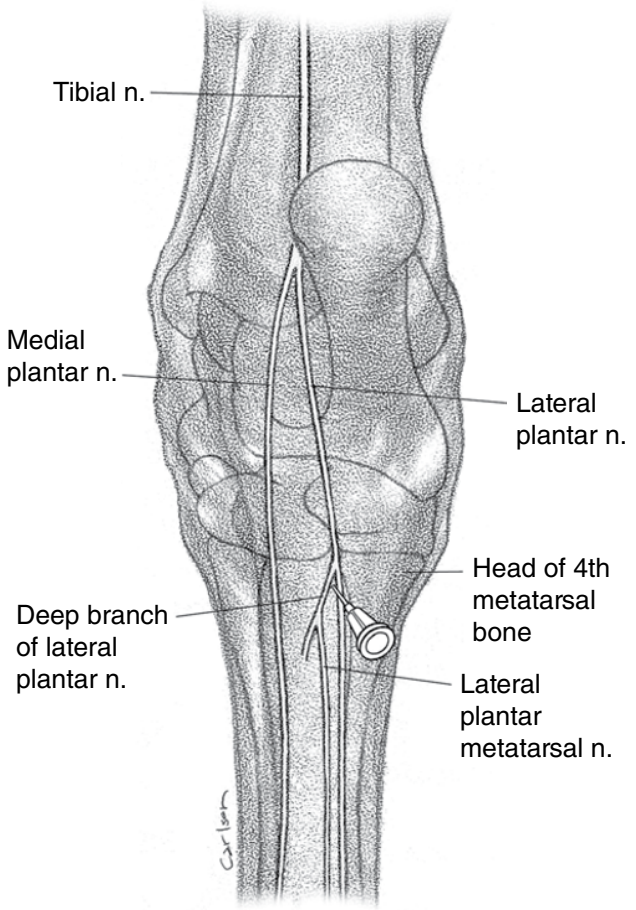

Figure 2.156. Innervation of the proximal suspensory ligament in the hindlimb and the location and positioning of the needle following the perpendicular approach to block the DBLPN just below the tarsus.

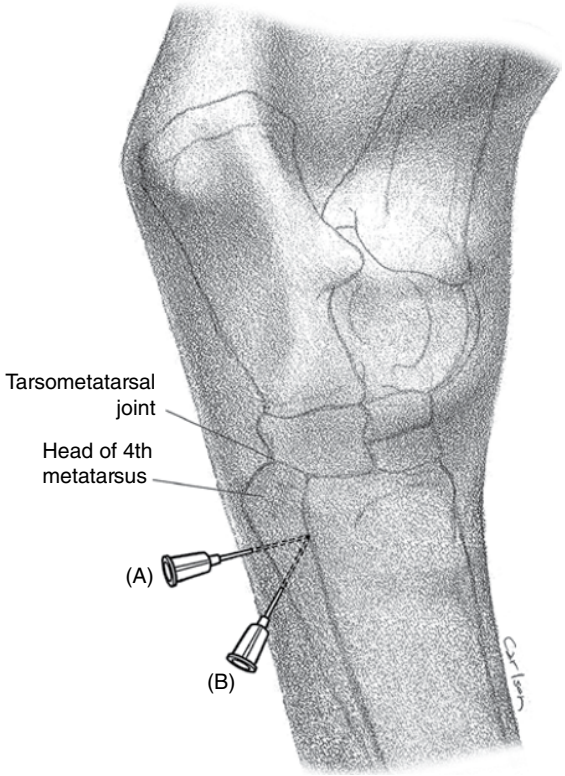

Figure 2.157. The deep branch of the lateral plantar nerve (DBLPN) can be desensitized by inserting a needle 15 mm below the head of the lateral splint bone directed perpendicular to the limb (A) or 20 mm below the head of the lateral splint and directing the needle proximodorsally and axial to the bone (B).

anesthetic can enter the TMT joint and the tarsal sheath following this block regardless of the technique used.[12,13] Diffusion of anesthetic both proximally and distally in the limb can also occur following injection, and the amount of diffusion is volume dependent. Therefore, a small volume of anesthetic (no more than 5 mL) is recommended when performing the DBLPN block to prevent inadvertent desensitization of other structures.[2,12]

Tibial and Peroneal Block

Anesthetizing the tibial and deep and superficial peroneal nerves above the point of the hock desensitizes the entire distal limb.[48] These blocks can be helpful to diagnose some horses with hock lameness, or they can be used to rule out whether the pain causing the lameness is located within the hock or distal limb. However, blocking the peroneal nerve, particularly the common trunk, can affect the ability of the horse to extend the limb and may cause dragging of the toe or knuckling of the fetlock.[9,75] This may complicate the ability to assess improvement in the lameness and injure the horse during the lameness evaluation.

The site for injection of the tibial nerve is approximately 4 inches (10 cm) above the point of the hock on the medial aspect of the limb between the Achilles tendon and the deep digital flexor muscle (Figure 2.159). When the horse is weight bearing, the nerve lies close to the caudal edge of the deep digital flexor muscle.

VetBooks.ir

Figure 2.158. (a) Blocking the DBLPN by inserting the needle 15 mm distal to the head of the lateral splint bone perpendicular to the limb. Some clinicians cradle the limb and pull the tendons medially (b) to facilitate the injection (see Figure 2.156 for needle location).

The nerve (6 mm in diameter) can be palpated caudal to the deep flexor muscle by unweighting the limb and grasping firmly cranial to the Achilles tendon with the thumb and forefinger.[3,75] The block may be performed

Figure 2.159. Image illustrating the locations to block the tibial and peroneal nerves. The site for injection of the tibial nerve is approximately 4 inches (10 cm) above the point of the hock on the medial aspect of the limb between the Achilles tendon and the deep digital flexor muscle. The location to block the peroneal nerves is approximately 4 inches (10 cm) above the point of the hock on the lateral aspect of the limb in the groove formed by the muscle bellies of the lateral and long digital extensor muscles.

by either standing on the lateral side of the limb to be blocked or by reaching across from the opposite limb to access the medial aspect of the limb. A small amount of anesthetic placed in the skin and subcutaneous tissues may minimize the horse's reaction to the block. A 20- to 22-gauge, 1.5-inch (3.8-cm) needle is used to deposit 15–20 mL of anesthetic in several tissue planes in the fascia that overlies the deep digital flexor muscle. Blocking the tibial nerve provides anesthesia to the plantar tarsus, metatarsus, distal Achilles tendon, calcaneus, suspensory ligament, and most of the foot.[9,75]

To completely desensitize the hock and limb distal to the hock, the deep and superficial peroneal (fibular) nerves must be anesthetized.[48,75] The deep peroneal nerve lies near the lateral edge of the cranial tibial muscle close to the tibia. The superficial peroneal nerve lies slightly caudal to the septum of the two extensor muscles and more superficial. The location of injection is approximately 4 inches (10 cm) above the point of the hock on the lateral aspect of the limb in the groove formed by the muscle bellies of the lateral and long digital extensor muscle (Figure 2.159). To block the deep peroneal nerve, a 1.5- to 2-inch (3.8- to 5-cm), 20-gauge needle is inserted in a slightly caudal direction until the needle contacts the caudal edge of the tibia. Ten to 15 mL of anesthetic is injected on the lateral border of the cranial tibial muscle close to the tibia. The needle is then retracted and another 10–15 mL of local anesthetic is injected more superficially in several planes to be sure

VetBooks.ir

that the superficial peroneal nerve is blocked. The depth of the superficial peroneal nerve can vary, so the more superficial injection should include a region from 0.6 to 2.5 cm deep.[75]

An alternative to blocking the superficial and deep peroneal nerves individually is to block the common peroneal nerve proximal to its division.[9] This can be accomplished by blocking the nerve near the origin of the long digital extensor tendon. The nerve can be palpated at this point, and it is anesthetized using a 1.5-inch (3.8-cm), 20-gauge needle to inject 15–20 mL of anesthetic.

Direct Infiltration of Anesthetic

Direct infiltration of anesthesia can be used anywhere a sensitive area is identified. However, it is used most often at sites of insertions of ligaments and tendons (e.g. the proximal interosseous muscle) or at bony prominences (i.e. splints or swellings). The region is infused directly with local anesthetic instead of performing perineural anesthesia. This approach often permits the clinician to be more definitive regarding whether a painful region is contributing to the lameness. The amount of local anesthetic administered depends on the location and dimensions of the area involved.

The origin of the suspensory ligament can be desensitized by direct infiltration (Figure 2.153c_1 and c_2), but perineural anesthesia using the lateral palmar nerve block in the forelimb and the DBLPN block in the hindlimb is preferred. Direct infiltration of the proximal suspensory is best performed with the limb held with the opposite hand. A 1-inch (2.5-cm), 20- to 22-gauge needle is inserted between the attachments of the suspensory ligament and the inferior check ligament in the forelimb or between the fourth metatarsus and the SDFT in the hindlimb.[75] The needle is directed toward the origin of the suspensory ligament and 4–6 mL of anesthetic is injected. Both the lateral and medial sides can be blocked in the same manner, but this is usually unnecessary. Inadvertent injection into the carpometacarpal joint in the forelimb and the TMT and tarsal sheath in the hindlimb can occur with these techniques.[2,3,75]

INTRASYNOVIAL ANESTHESIA

The use of intrasynovial anesthesia plays an important role in the diagnosis of equine lameness.[28,34,43,47,79] In most cases, it is more specific and efficient to anesthetize the specific synovial structure (joint capsule, tendon sheath, or bursa) that is thought to be the cause of the lameness than performing local perineural anesthesia. This is especially true in horses that tend to have joint problems (racehorses) or if the clinical findings suggest involvement of a synovial structure. In addition, intrasynovial anesthesia is commonly performed above the carpus and tarsus where perineural anesthesia becomes more difficult. If intrasynovial anesthesia needs to be performed after perineural anesthesia, it is best to wait at least 3–4 hours for sensation to return.[5,33,75] There is also evidence to suggest that the return of skin sensation does not coincide with the actual return of lameness in some horses.[33] In addition, gait changes may persist beyond 3–4 hours, and it is probably safest to perform intrasynovial anesthesia on a different day.[5,33]

Intrasynovial anesthesia is thought to be more specific than perineural anesthesia because if the lameness improves, the synovial cavity is considered the site of the problem. The three major exceptions to the specificity of intrasynovial blocks are the distal interphalangeal (DIP) joint, middle carpal joint, and the TMT joint. These exceptions are usually related to regional nerves being close to synovial outpouchings of the synovial cavities or passive diffusion of local anesthetic from the synovial cavity.[25,61,63,64,66,67] Intrasynovial anesthesia of the DIP joint can anesthetize the nerves innervating the foot,[6–8,17,18] and intrasynovial anesthesia of the middle carpal joint or TMT joint can provide analgesia of the proximal palmar metacarpal/plantar metatarsal regions, respectively.[14,23,24] In general, the more anesthetic that is used, the greater the likelihood of inadvertent analgesia of surrounding structures.[62,66] Less commonly, nerves that lie close to the site of intrasynovial injection also may be inadvertently desensitized. For example, the lateral plantar nerve may be desensitized when injecting local anesthetic into the TMT joint,[20] and the lateral palmar/plantar nerve above the fetlock may be desensitized when injecting anesthesia into the digital tendon sheath using the proximal approach.[37]

General Technique: Site Preparation, Restraint, and Interpretation

There are several different anatomic approaches that can be used for intrasynovial injections in most synovial cavities. Knowledge of the anatomic landmarks for intrasynovial injections is imperative to be able to competently perform these injections. Practice on cadaver limbs can be very beneficial to improve the proficiency in performing the injection techniques because repeated attempts to locate the synovial cavity are not well tolerated by most horses.

Proper preparation of the site for injection is necessary to prevent subsequent infection within the synovial cavity. Iatrogenic infection appears very rare following anesthesia of a synovial cavity but is more likely to occur when synovial cavities are treated with medications, especially corticosteroids. However, this risk is still quite low with a reported occurrence of 1/1,279 injections (0.08%).[76] Clipping the hair is usually unnecessary because there is no appreciable difference in bacteria-forming units in clipped and haired skin after 5 minutes of preparation with povidone iodine scrub followed by an alcohol rinse.[29] However, if the hair is very long and soiled, it is best to clip the hair overlying the injection site, and clipping is recommended when using spinal needles with stylets.[1] In general, the authors tend to clip a very small area (1–2 cm square) over the site unless the owners/trainers request otherwise. Clipping the hair also has the advantage of marking the site of injection so that a helper knows exactly where to prep the skin. A 5-minute sterile skin preparation is recommended using either povidone iodine or chlorhexidine and alcohol.

An experienced helper makes performing intrasynovial injections much easier and safer. Proper restraint of the horse is also required to prevent injury to personnel and damage to the articular cartilage and to reduce the risk of needle breakage. Be sure to always keep in mind that the handler and any person observing becomes your assumed responsibility.[47] Twitch

VetBooks.ir

restraint is recommended by the authors for all intrasynovial injections unless it is not tolerated by the horse. Horses being treated by intrasynovial injections are often routinely tranquilized, but this is not usually possible for injections used for diagnostic purposes. Local anesthetic (1–2 mL) at the site of injection also may aid in the injection process, especially for synovial cavities in the proximal aspect of the limbs. In addition, the smallest possible gauge needle (usually 20 gauge or smaller) should be used to minimize objection by the horse.

Sterile gloves are recommended to permit careful palpation of the anatomic landmarks and to be able to handle the shaft of the needle without contamination. The injection should be done carefully but also as rapidly as possible. Once the needle has penetrated the synovial space, synovial fluid may be observed draining from the needle hub. The synovial fluid is allowed to run freely until its ejection pressure is reduced to a slow drip. The syringe is then inserted on the finger-stabilized needle hub, and the anesthetic is injected as rapidly as possible. If synovial fluid is not observed, a small syringe can be attached to the needle to withdraw fluid. However, lack of synovial fluid does not necessarily mean that the needle is not within the synovial cavity. To confirm correct needle placement, one can inject a small amount of sterile solution; if there is little or no plunger pressure, it is reasonable to assume that the needle is within the synovial space. However, the only definitive method to confirm that the needle is in the correct location is to obtain synovial fluid. Mepivacaine is the anesthetic of choice for intrasynovial anesthesia because there is some evidence that it is less irritating than lidocaine after intra-articular injection.[8,48] Guidelines for performing diagnostic intrasynovial anesthesia, including suggested volumes of anesthetic to use, are given in Table 2.6.

Assessment of intrasynovial blocks is usually performed 5–30 minutes after completion of the injection. If there is no improvement after 30 minutes, it is unlikely that waiting longer will change the response. In one study, lameness was not apparent after 5 minutes, and the improvement lasted for 55 minutes.[3] In addition, improvement in lameness within 5–8 minutes of injection is often seen after intra-articular injection of the DIP joint in horses with navicular disease or experimentally induced navicular bursal pain.[18,52,63] Evaluation of the effectiveness of the block should include repeating the exercise that resulted in the most significant signs of lameness and possibly re-performing the manipulative/flexion test that made the examiner suspicious that this region was involved. It is important to remember that structures superficial to the synovial cavity may retain their sensitivity.[75] In addition, false-negative intrasynovial blocks have been reported but tend to be uncommon. One report identified a failure of intra-articular anesthesia of the radiocarpal joint to abolish lameness associated with chip fracture of the distal radius.[71] Diffusion of anesthetic to local structures, inadvertent anesthesia of peripheral nerves closely associated with the synovial cavity outpouchings, and the possibility that the injection was not in the synovial cavity should all be considered when assessing the response to intrasynovial anesthesia.

Distal Interphalangeal (DIP) Joint

The DIP joint can be entered using three dorsal approaches (perpendicular, parallel, or dorsolateral) and one lateral approach. These approaches are usually best performed in the standing patient, and a maximum of 4–6 mL of anesthesia is recommended.[66] The dorsolateral and dorsal parallel approaches are used most commonly by the author. The site of injection for the dorsolateral approach is 0.5 inch (1 cm) above the coronary band and 0.75–1 inch (2–3 cm) lateral (or medial) to midline. A 1.5-inch (3.8-cm), 20-gauge needle is inserted from a vertical position and directed distally and medially toward the center of the foot at approximately a 45° angle (Figure 2.160; Video 2.14). The needle should enter the DIP joint capsule at the edge of the extensor process. If entry into the joint is uncertain, the needle can be directed at a more acute angle (more horizontal) to the skin and inserted until the needle contacts the distal end of P2.[26,79] It then is "walked" distally until the joint is penetrated.

Some prefer to enter the joint on the dorsal midline using the proximal outpouching of the DIP joint above the extensor process.[48,63,66] The injection site is just above the coronary band 0.25–0.5 inches (8–12 mm) above the edge of the hoof wall on the dorsal midline of the foot. With the dorsal perpendicular approach, the needle is directed downward perpendicular to the bearing surface of the foot (Figure 2.161; Video 2.15).[48] With the dorsal parallel approach, the needle is directed parallel or slightly downward (hub of the needle is moved proximally) to the ground to a depth of approximately 0.5 inches (12–15 mm) (Figure 2.162; Video 2.16). The dorsal parallel approach is usually easier to perform and is recommended by many clinicians.[48,63,66]

The site for injection for the lateral approach is bounded distally by a depression along the proximal border of the collateral cartilage approximately midway between the dorsal and palmar/plantar border of P2 (Figure 2.163; Video 2.17). A 1-inch (2.5-cm), 20-gauge needle is directed downward at a 45° angle toward the medial weight-bearing hoof surface.[81] Most horses appear to tolerate this technique very well. However, the specificity of the lateral approach is thought to be less than the dorsolateral approach. In one study using cadavers and live horses, contrast material entered the DIP joint in 100% of the cases injected using the dorsolateral approach and 85% of the cases in which the palmar/plantar lateral approach was used.[81] Importantly, with the lateral approach, only 65% of the limbs had contrast exclusively in the DIP joint, 20% had contrast in the digital sheath, and 5% had contrast in the subcutaneous tissues.[81] Because of this and the ease of performing any of the dorsal approaches to the DIP joint, the lateral approach is rarely used.

Several studies have documented that injection of the DIP joint with a local anesthetic is not selective for the joint and it will cause analgesia of the podotrochlear apparatus, navicular bone, and navicular bursa.[7,8,17,39,52,61,64] In addition, injection of the DIP joint may cause partial, and often complete, analgesia of the sole, toe, and heel regions of the foot.[61,62] The analgesic effect increased with time, and 10 mL of anesthetic was more effective than 6 mL in alleviating pain in the foot.[62]

VetBooks.ir

Table 2.6. Guidelines for intrasynovial anesthesia.

Synovial cavity	Needle size	Volume of anesthetic	Approaches and limb position (standing or held)
Coffin joint	20–22 g, 1–1.5″	4–5 mL	Dorsal approaches: standing Lateral approach: standing or held
Pastern joint	20–22 g, 1.5″	4–5 mL	Dorsal and dorsolateral approaches: standing Palmar/plantar approach: held
Fetlock joint	20–22 g, 1–1.5″	8–12 mL	Proximal palmar/plantar approaches: standing or held Collateral sesamoidean approach: held Distal palmar/plantar approach: standing Dorsal approach: standing
Carpal joints	20–22 g, 1–1.5″	8–10 mL	Doral approaches: held Palmar approaches: standing
Elbow	20 g, 1.5″ or 20 g, 3.5″	20–30 mL	All approaches: standing
Shoulder	18–20 g, 3.5″	20–40 mL	All approaches: standing
Tarsometatarsal joint	20 g, 1–1.5″	4–6 mL	All approaches: standing
Distal intertarsal joint	25 g, 5/8″ or 22 g, 1″	3–5 mL	All approaches: standing
Tarsocrural joint	20–22 g, 1.5″	15–20 mL	All approaches: standing
Femoropatellar joint	20 g, 1.5–3.5″	30–40 mL	All approaches: standing
Medial femorotibial joint	20 g, 1.5″	20–30 mL	All approaches: standing
Lateral femorotibial joint	20 g, 1.5″	20–30 mL	All approaches: standing
Coxofemoral joint	16–18 g, 6–8″ spinal	30–60 mL	All approaches: standing
Sacroiliac joint	15–16 g, 10″ spinal	7–10 mL	All approaches: standing
Digital flexor tendon sheath	20–22 g, 1–1.5″	8–15 mL	Proximal approach: standing All other approaches: held
Carpal sheath	20 g, 1.5–3.5″	15–30 mL	Medial approach: standing Lateral approach: held
Tarsal sheath	20 g, 1.5″	15–20 mL	Medial approach: standing
Extensor carpi radialis sheath	20 g, 1.5″	10–20 mL	All approaches: standing or held
Calcaneal bursa	20 g, 1.5″	10–15 mL	Distal approach: standing Proximal approach: standing or held
Bicipital bursa	18–20 g, 3.5–5″ or 20 g, 1.5″	20–30 mL	All approaches: standing
Trochanteric bursa	18–20 g, 1.5–3.5″	7–10 mL	All approaches: standing
Cunean bursa	20–22 g, 1″	2–3 mL	Medial approach: standing

To improve the selectivity of DIP joint anesthesia, a maximum of 5–6 mL of anesthesia is recommended, and assessment of the block should be performed within 10 minutes of injection.[63,66]

Podotrochlear (Navicular) Bursa

The traditional approach to access the navicular bursa is through the heel bulbs.[51,60,62,66] With this approach, a 18-20-gauge, 3.5-inch (8.9-cm) spinal needle is inserted between the heel bulbs just above the coronary band (Figure 2.164; Video 2.18). Local anesthesia at the site of the injection or perineural anesthesia above the heel bulbs may be used to provide skin analgesia prior to the injection. The needle is advanced along a sagittal plane aiming for a point 1 cm below the coronary band, midway between the toe and the heel.[60] The needle is advanced until bone is contacted. Only 2–4 mL or anesthetic or medication can usually be injected, and flexing the lower limb will usually decrease the resistance to injection. Some clinicians prefer to use a special wooden block that unweights the heel and flexes the distal limb to

VetBooks.ir

perform this block (Figure 2.164). Alternatively, the forelimb can be suspended with the metacarpus placed within a padded hoof stand to help facilitate the injection. Radiographic or fluoroscopic documentation of the needle's location is recommended in most cases because it is easy to pass the needle over to the proximal border of the navicular bone into the DIP joint.[28,48] Including radiographic contrast medium into the injection solution and taking a radiograph immediately after the injection can also be used to document a successful injection. The disadvantage of this technique is that the needle passes through the DDFT to gain access to the bursa and is difficult to perform in the standing horse.

The navicular bursa can also be entered from the lateral or medial sides (abaxial or lateral position) just proximal to the collateral cartilage of the distal phalanx. Two lateral techniques that do not penetrate the DDFT have recently been described.[14,50] One technique was performed in the standing horse using radiographic guidance, and the other used ultrasound to help guide the needle into the bursa with the foot placed in a navicular block. Needle entry was along the proximal and dorsoproximal margin of the collateral cartilage, and an 18- to 20-gauge, 3.5-inch (8.9-cm) needle was angled approximately 45° to the horizontal plane toward the 10 o'clock (right front) or 2 o'clock (left front) position (Figure 2.165).[14] The needle was directed beneath the DDFT and digital tendon sheath to enter the bursa. This technique can also be performed with the limb unweighted (Video 2.19). In one study needle placement was confirmed with radiography,[14] while ultrasound was used in the other study.[50] The primary advantage of these techniques is that the needle does not penetrate the DDFT, which may decrease the morbidity associated with the injection. The disadvantages include possible entry into the tendon sheath and DIP joint and the difficulty of placing the needle at the correct angulation. As with all navicular bursal injections, confirmation of correct needle placement is recommended with some type of imaging either before or after the injection.

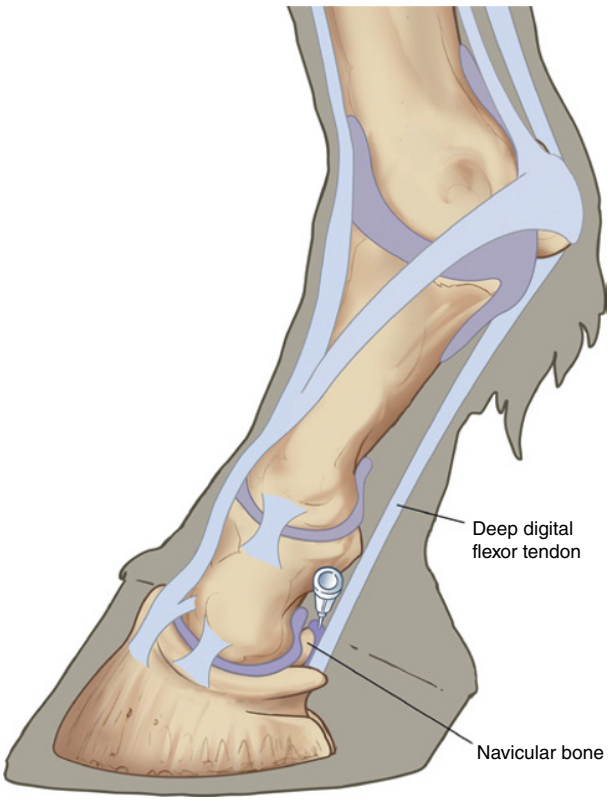

Figure 2.165. Lateral approach to the navicular bursa that avoids penetrating the DDFT. The spinal needle is inserted just above the collateral cartilage and angled at approximately 45° to the horizontal plane to enter the bursa.

A positive response to administration of local anesthesia into the navicular bursa may indicate problems of the navicular bursa, navicular bone and/or its supporting ligaments, sole and/or toe, or distal aspect of the DDFT.[17,48,63,66] Even though diffusion of local anesthetic into the navicular bursa occurs following DIP joint injection,[6–8,39,52] the converse does not occur, and analgesia of the navicular bursa does not result in analgesia of the DIP joint.[66] Pain from the DIP joint can likely be excluded as a cause of lameness if analgesia of the navicular bursa improves the lameness within 10 minutes.[66] In addition, a positive response to intra-articular analgesia of the DIP joint together with a negative response to navicular bursa analgesia incriminates pain within the DIP joint as the cause of lameness.[18,66]

Proximal Interphalangeal (PIP) Joint

There are primarily two approaches (dorsolateral and palmar/plantar) for arthrocentesis of the PIP joint. A dorsal approach has been described but is more difficult to perform[53] and is not recommended by the author. The dorsolateral approach is usually performed with the horse standing but can be done with the limb extended and the sole supported on the knee. The condylar eminences of the distolateral aspect of P1 are identified, and a 1.5-inch (3.8-cm), 20-gauge needle is inserted parallel to the ground surface 0.5 inches (1.2 cm) distal to the palpable eminence.[48,75] The needle is directed beneath the edge of the extensor tendon to enter the joint at a depth of 0.5 inches (Figure 2.166; Video 2.20).

The palmaro/plantaroproximal approach is best performed with the distal limb in a flexed position. A 1.5-inch (3.8cm), 20-gauge needle is inserted perpendicular to the limb into the palpable V-depression formed by the palmar aspect of P1 dorsally, the distal eminence of P1 distally, and the lateral branch of the SDFT as it inserts on the eminence of P2 palmarodistally (Figure 2.167; Video 2.21).[45] This corresponds to the transverse bony prominence on the proximopalmar/plantar border of P2 that is usually easily palpable. The author prefers to angle the needle slightly dorsally to contact P1, and then direct the needle along the palmar/plantar aspect of the bone. This ensures that the needle is just behind P1 where it will enter the PIP joint capsule at a depth of approximately 1 inch (2.5 cm). The main disadvantage of this approach is the inadvertent injection of the digital flexor tendon sheath (DFTS).[53]

Metacarpophalangeal/Metatarsophalangeal (Fetlock) Joints

Three palmar/plantar approaches and one dorsal approach can be used for arthrocentesis of the fetlock joint. The proximal palmar/plantar approach can be

VetBooks.ir

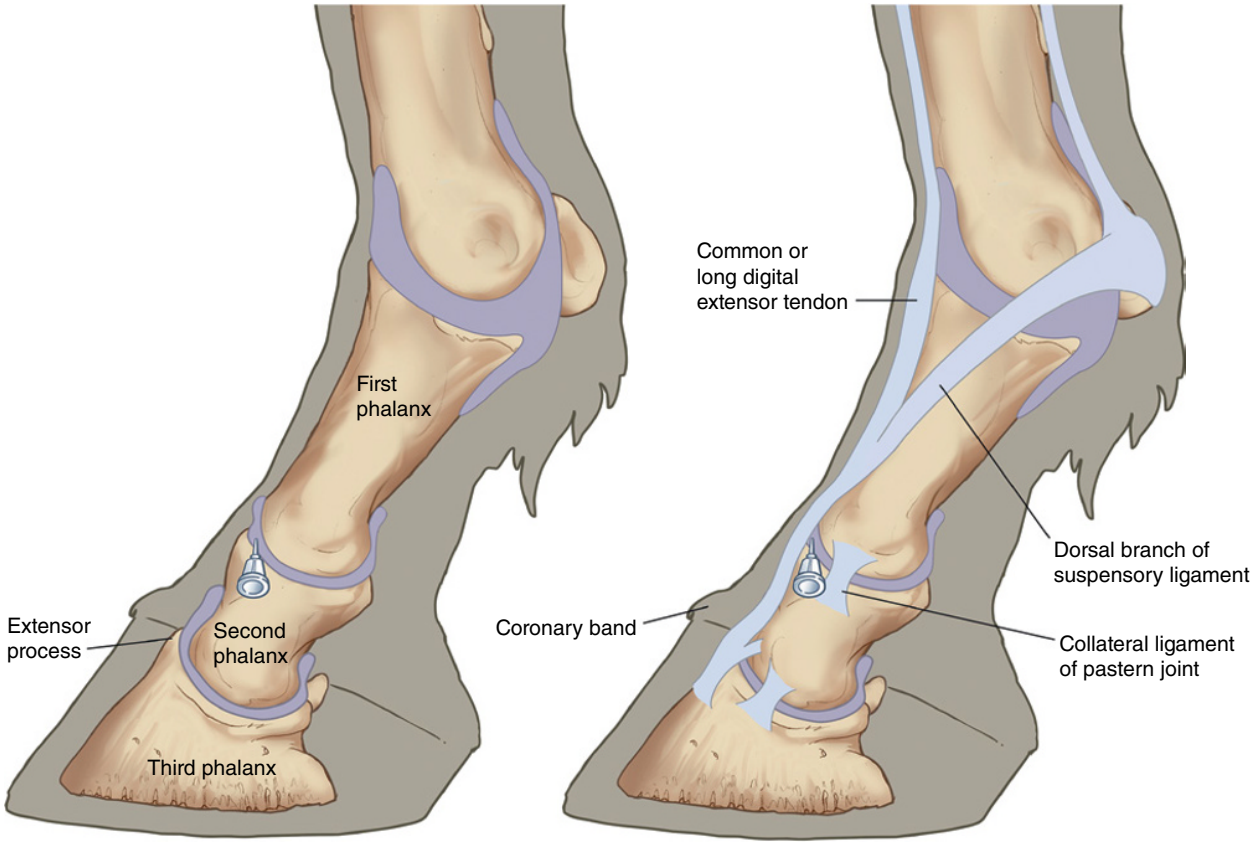

Figure 2.166. Dorsolateral approach to the PIP joint. The needle is inserted at distal border of the P1 condyle beneath the extensor tendon.

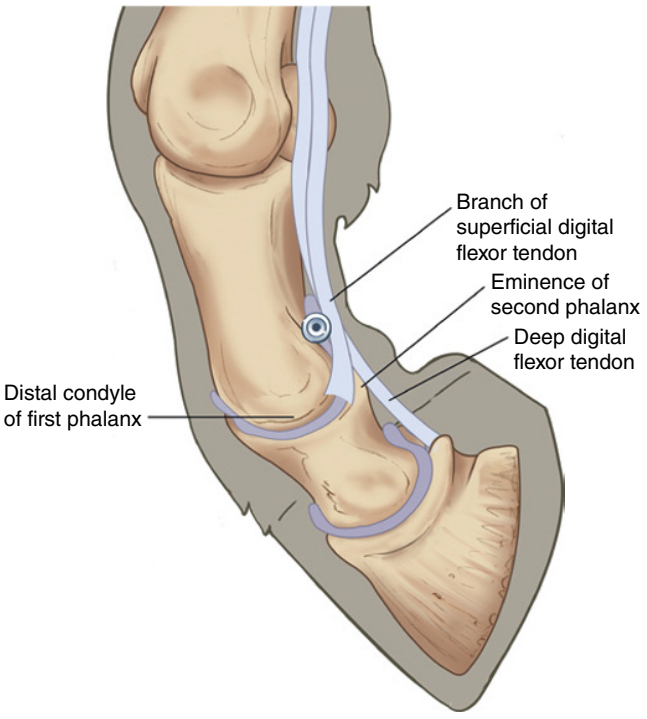

Figure 2.167. Palmar/plantar approach to the PIP joint. The limb is held to relax the palmar structures, and the needle is inserted in a V-shaped depression formed by the palmar aspect of P1 dorsally, the distal eminence of P1 distally, and the lateral branch of the SDFT as it inserts on the eminence of P2 palmarodistally.

performed with the limb weight-bearing or held, the approach through the collateral sesamoidean ligament must be performed with the fetlock joint flexed, and the distal palmar/plantar and dorsal approaches are usually performed in the standing limb. The dorsal and proximal palmar/plantar approaches are usually reserved for horses with significant effusion to avoid damage to the articular cartilage and inadvertent hemorrhage, respectively. Which technique to use is often based on personal preference, although some are easier to perform in the forelimb than the hindlimb.

Proximal Palmar/Plantar Pouch

The boundaries of the palmar/plantar pouches of the fetlock joint are the apical border of the proximal sesamoid bones distally, the distal ends of the splint bones proximally, the third metacarpal/metatarsal bone dorsally, and the branch of the suspensory ligament palmar/plantarly (Figure 2.168). In the normal horse, these pouches appear as a depression, and attempts to retrieve synovial fluid may be difficult. However, they are usually easily identified in horses with fetlock effusion. When performing this approach in the standing patient, a 1-inch (2.5-cm), 20-gauge needle is inserted from lateral to medial and directed distally at a 45° angle to the long axis of the limb (Video 2.22). The disadvantages of this approach are the possibility of contaminating the synovial fluid sample with blood because of the highly vascular synovial membrane and the inability to aspirate

VetBooks.ir

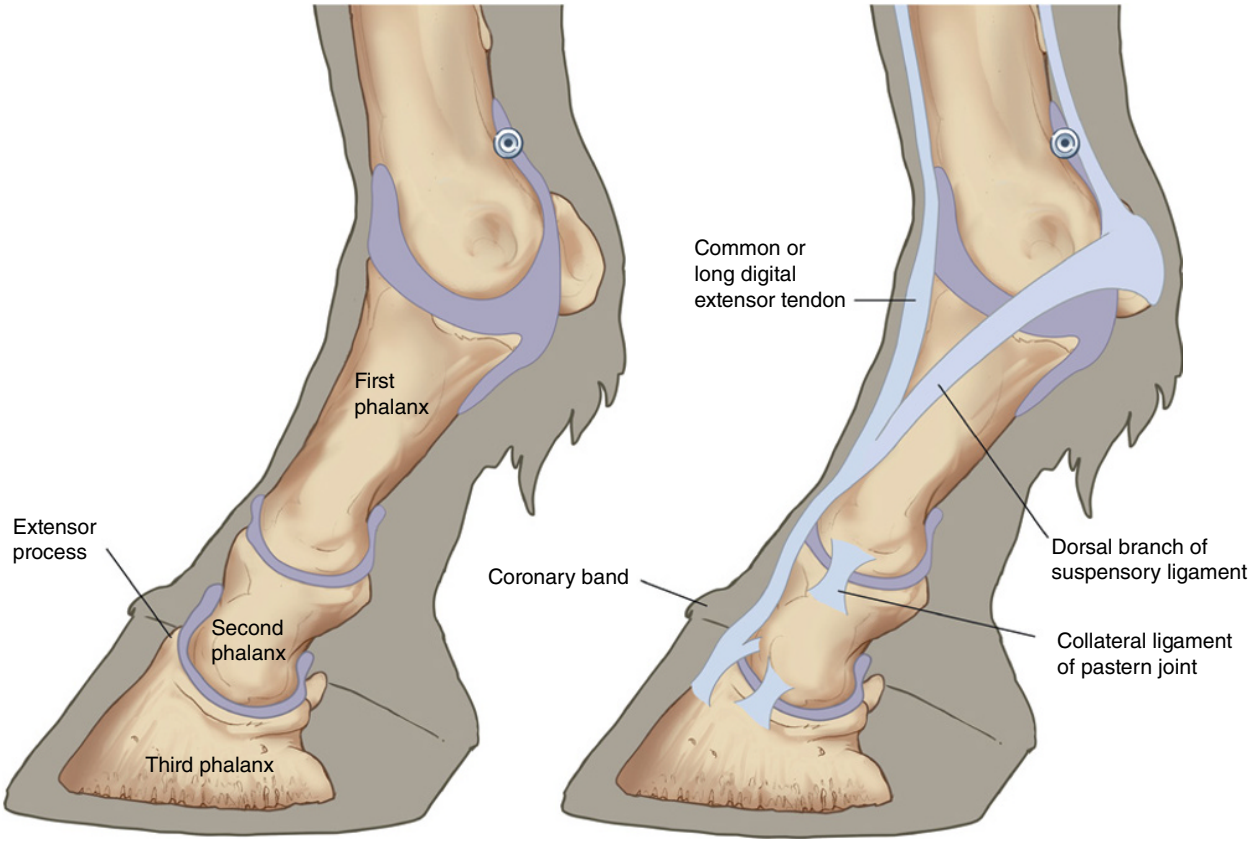

Figure 2.168. Location for injecting the proximal palmar/plantar pouch of the fetlock joint in the standing horse.

synovial fluid because the synovial villi plug the needle.[34,46]

Performing the palmar/plantar approach with the fetlock flexed can potentially minimize these complications (Figure 2.169; Video 2.23). With the fetlock flexed, there is a very palpable depression at the very distal aspect of the pouch just above the branch of the suspensory ligament. A 1-inch (2.5-cm), 20-gauge needle is inserted at this location and directed distally at a 45° angle. The more distal location in the palmar/plantar pouch reduces the risk of iatrogenic hemorrhage.

Collateral Sesamoidean Approach

Arthrocentesis of the fetlock through the lateral collateral sesamoidean ligament is probably the best approach to obtain a hemorrhage-free synovial fluid sample. The fetlock is flexed to increase the space between the articular surfaces of the proximal sesamoid bones and the metacarpus/metatarsus. The depression between the bones is palpated, and a 1-inch, 20-gauge needle inserted through the collateral sesamoidean ligament perpendicular to the limb (Figure 2.170; Video 2.24).[46] If the needle fails to advance, it is most likely contacting bone and will need to be redirected to enter the joint space.

Distal Palmar/Plantar Approach

The distal palmar/plantar approach is performed in the palpable depression formed by the distal aspect of the proximal sesamoid bone and the proximopalmar/plantar eminence of P1. The landmarks are the distal aspect of the proximal sesamoid bone and collateral sesamoidean ligament proximally, the proximal palmar/plantar eminence of P1 distally, and the digital vein, artery, and nerve palmar/plantarly.[72] A 1.5-inch (3.8-cm), 20-gauge needle is inserted in the depression and directed slightly dorsally (10°–20°) and proximally (10°) until the joint is entered (Figure 2.171; Video 2.25). To avoid penetration of the digital sheath, it is important that the needle be inserted dorsal to the PD artery, vein, and nerve. The advantages to this approach are that the landmarks are easily palpable, synovial fluid is often obtained, it can be performed in the standing horse, and horses tolerate the procedure well.[72]

Dorsal Approach

The dorsal approach is usually performed with the limb weight-bearing. The needle is inserted proximal to the proximodorsal limits of P1 in the palpable joint space in a slightly oblique manner, either lateral or medial to the extensor tendon (Figure 2.172; Video 2.26). The fetlock joint capsule is thicker in this location than in the palmar/plantar pouch and appears to cause greater discomfort to the horse than the other techniques.

Digital Flexor Tendon Sheath (DFTS)

There are several outpouchings of the DFTS that may be used for synoviocentesis. In general, the proximal pouch palmar/plantar to the suspensory and the distal

VetBooks.ir

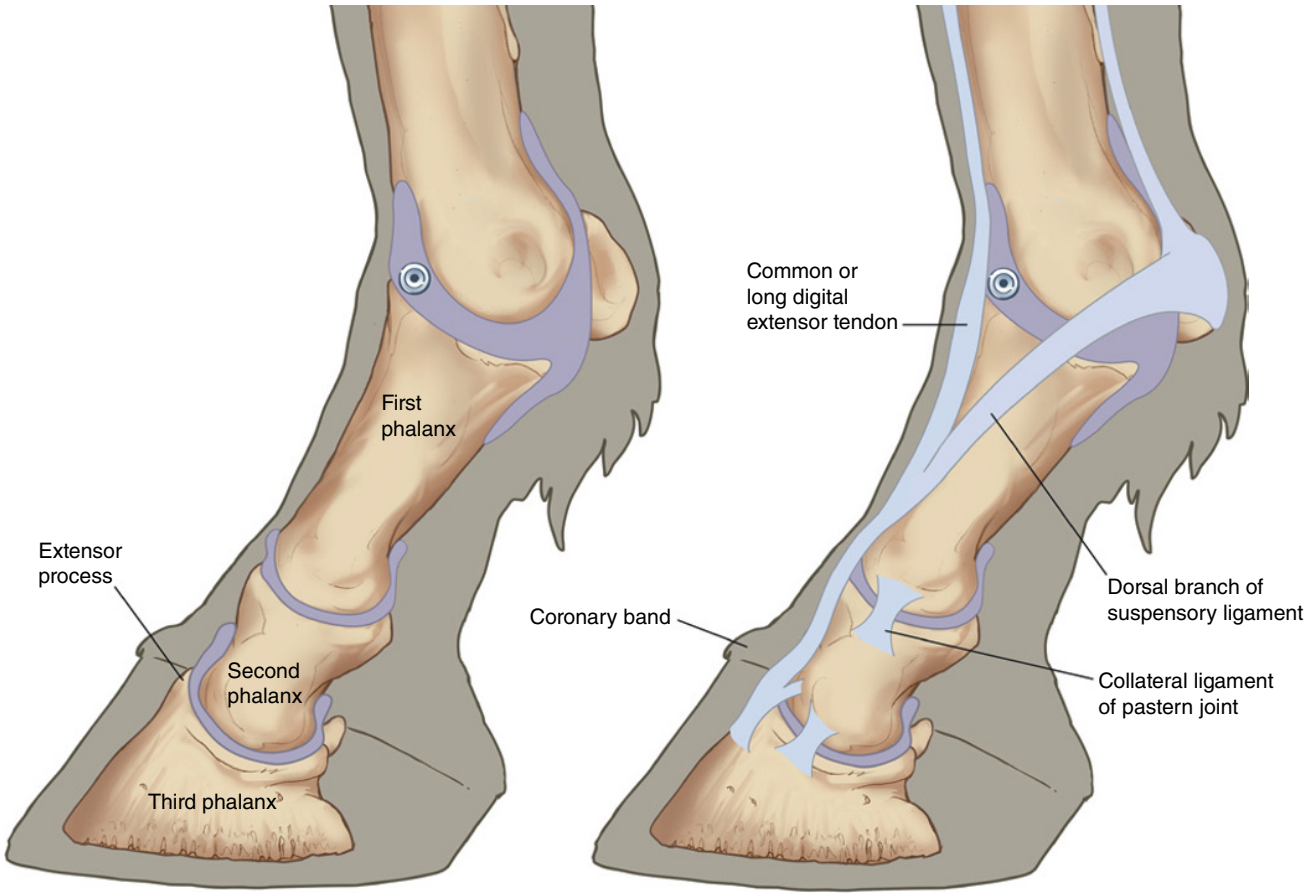

Figure 2.172. Dorsal view of the injection site for the dorsal approach to the fetlock joint in the standing horse.

recess in the pastern superficial to the DDFT are difficult to penetrate without sheath effusion. However, they can often be the easiest approaches to perform if effusion is present. The site for injection of the proximal pouch of the DFTS is 1 cm proximal to the palmar/plantar annular ligament and 1 cm palmar/plantar to the lateral branch of the suspensory ligament (Figure 2.173; Video 2.27). A 1- to 1.5-inch, 20-gauge needle is directed slightly distally until the sheath is penetrated.

The distal outpouching of the DFTS in the pastern region is often palpable as a distinct "bubble" when effusion is present. It is located between the proximal and distal digital annular ligaments and between the diverging branches of the SDFT where the DDFT lies close to the skin.[48] A 20-gauge, 1-inch needle is directed in a lateral to medial direction just beneath the skin so as not to penetrate the DDFT (Figure 2.174; distal needle; Video 28). Alternatively, the needle can be inserted into the outpouching of the DFTS abaxial and distal to the sesamoid bones between the annular and proximal digital annular ligaments. The needle is inserted in a distal to proximal direction at approximately a 45° angle to the sagittal plane (Figure 2.174; proximal needle). This approach is referred to as the basilar sesamoidean approach and can be performed in the standing horse. It has been reported to be more reliable to obtain synovial fluid than the axial sesamoidean approach.[55]

The axial sesamoidean approach at the level of the fetlock and the medial or lateral approach between the annular ligament and proximal digital annular ligament can be performed in the distended and non-distended DFTS. Both approaches are best performed with the limb held with the fetlock slightly flexed. The axial sesamoidean approach is performed 3 mm axial to the palpable border of the midbody of the lateral proximal sesamoid bone using a 1–1.5-inch (2.5–3.8-cm), 20-gauge needle (Figure 2.175; Video 2.29).[31] The needle is directed at a 45° angle to the sagittal plane to a depth of approximately 1.5–2 cm. Ten to 15 mL of anesthetic is recommended for diagnostic purposes for the DFTS. Improvement of lameness in horses after intrasynovial analgesia of the DFTS is usually due to attenuation of pain within the structures contained in the DFTS. Analgesia of the DFTS has little effect on lameness caused by pain originating in the sole, DIP joint, or the navicular bone.[30]

Carpal Joints

Arthrocentesis of the radiocarpal and middle carpal joints can be performed using either a dorsal or palmar approach. The dorsal approach is performed with the carpus flexed, and the palmar approach is performed in the weight-bearing limb and can be somewhat difficult in the non-distended joint. Approximately 10 mL of anesthetic is recommended. Because the carpometacarpal joint and the middle carpal joint communicate, anesthetics injected into the middle carpal joint also desensitize the carpometacarpal joint. Additionally, the carpometacarpal joint has palmar pouches that extend

palmarodistally adjacent to the origin of the suspensory ligament. Anesthetic injected into the middle carpal joint may also desensitize the proximal suspensory ligament and proximal palmar metacarpal region.[23,24]

The sites of injection for the radiocarpal and middle carpal joints are located in palpable depressions lateral or medial to the extensor carpi radialis tendon on the dorsal aspect of each joint (Figures 2.176 and 2.177). The injection is made with a 1-inch (2.5-cm), 20-gauge needle midway between the distal radius and proximal row of carpal bones for the radiocarpal joint (Figure 2.177; Video 2.30) or between the proximal and distal rows of carpal bones for the middle carpal joint (Figure 2.176; Video 2.31). Because the surfaces of the carpal bones are at an angle, the needle should be directed slightly proximally to avoid hitting the articular cartilage.[3,75]

The landmarks for the palmarolateral approach to the radiocarpal joint are the palmarolateral aspect of the radius, proximolateral aspect of the accessory carpal bone, and palmarolateral aspect of the ulnar carpal bone (Figure 2.178).[47,79] A 1-inch (2.5-cm), 20-gauge needle is inserted in this palpable depression at 90° to the long axis of the limb, and the needle is directed dorsomedially (Video 2.32). Another palmarolateral approach is at the midaccessory carpal bone level in a palpable "V" between the tendons of the ulnaris lateralis and the lateral digital extensor.[41,48] The needle is inserted perpendicular to the skin in a small depression 0.5–1 inch (8–12 mm) distal to the "V" in the space between the distal lateral aspect of the radius (vestigial ulna) and the proximal lateral aspect of the ulnar carpal bone.[47,48]

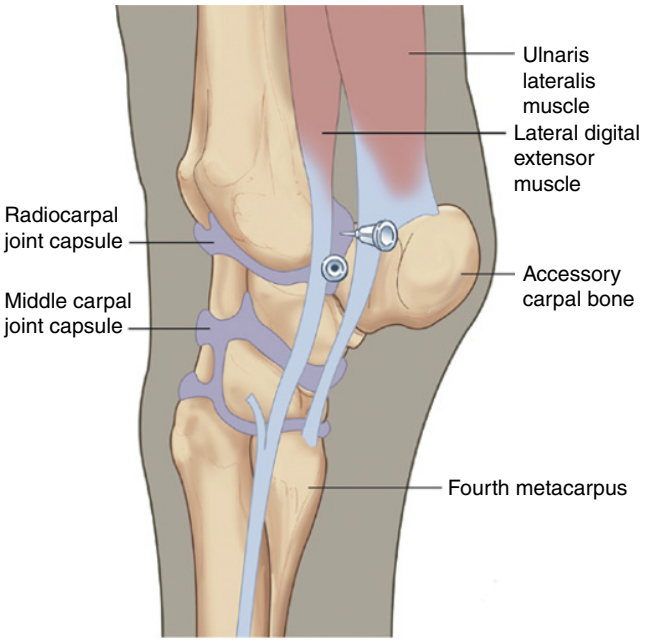

Figure 2.178. Lateral view of the palmarolateral injection sites for the radiocarpal joint in the standing horse.

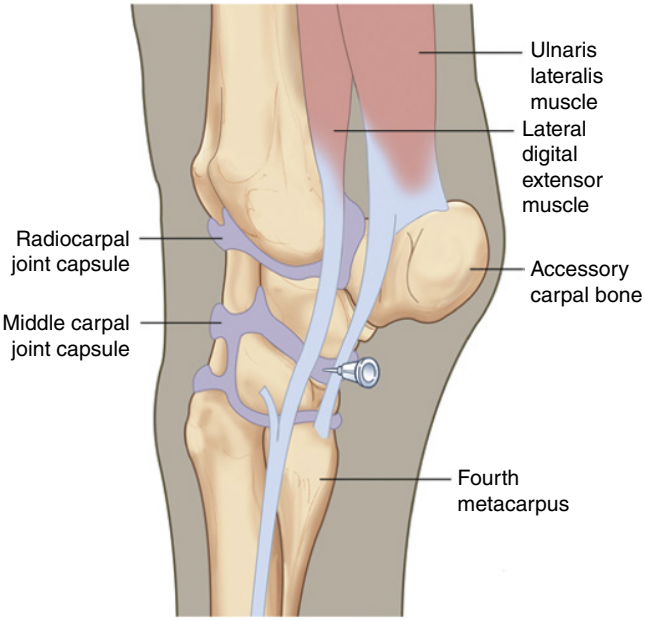

Figure 2.179. Lateral view of the palmarolateral injection site for the middle carpal joint in the standing horse. The palmar joint pouch can be difficult to palpate without the presence of synovial effusion.

The palmarolateral approach to the middle carpal joint is best used if the joint is distended (Figure 2.179; Video 2.33). With distension the joint capsule is superficial and protrudes palmar and lateral to the ulnar and fourth carpal bones distal to the accessory carpal bone. The injection site is approximately 1 inch (2.5 cm) distal to the site of injection of the radiocarpal joint.[2,75] A 1-inch, 20-gauge needle is inserted perpendicular to the skin to a depth of about 0.5 inches (1.2 cm).

Elbow Joint

There are three major approaches to the elbow joint: lateral, caudolateral, and caudal. The lateral approach is within the radiohumeral articulation, whereas the caudolateral and caudal approaches are within the humeroulnar articulation. All three techniques are best performed

VetBooks.ir

while the horse is standing, but can be done with the limb flexed.[75] Injection of the elbow is more difficult than many other joints in the horse, and approximately 20–30 mL of anesthetic is needed for diagnostic purposes.[48]

Lateral Approach

The landmark for the lateral approach is the lateral collateral ligament that extends across the joint from the lateral epicondyle of the humerus to the lateral tuberosity of the radius. Both of these bony landmarks are easily palpated. The elbow joint can be entered either cranial or caudal to the collateral ligament. The site for injection is two-thirds the distance distally measured from the lateral epicondyle of the humerus to the lateral tuberosity of the radius (Figure 2.180).[34,75] A 1.5-inch (3.8-cm), 20-gauge needle is inserted at a 90° angle to the skin just cranial or caudal to the lateral collateral ligament to a depth of 1 inch.[34,48] If injected cranially, it is important to verify that the needle is within the joint because periarticular anesthetic may desensitize the distal branches of the radial nerve, causing temporary paralysis of the extensor carpi radialis and common digital extensor muscles. This will cause the horse to be unable to lock its carpus in extension. If injected caudally, the needle may enter the bursa of the ulnaris lateralis muscle, which is thought to communicate with the elbow joint.[58] However, communication between the bursa and the elbow joint occurred in only 9 of 24 (37.5%) of the joints examined.[58] To avoid the ulnaris lateralis bursa, the needle may be inserted more caudally in the elbow in a palpable depression formed by the caudal epicondyle of the humerus, the caudal proximal tuberosity of the radius, and the anconeal process (Figure 2.181).[75]

Caudolateral Approach

The caudolateral approach is an alternative to placing the needle directly caudal to the collateral ligament using the lateral approach. The injection site is caudal to the palpable humeral epicondyle in the anconeal notch within the humeroulnar joint. This palpable V-shaped depression is usually just below the triceps muscles and 6–8 cm cranio-distal from the point of the olecranon process.[2,3,75] A 1.5- to 3.5-inch (3.8- to 8.8-cm), 20-gauge needle is inserted at a 45° angle to the skin and directed craniomedially (Figure 2.181).

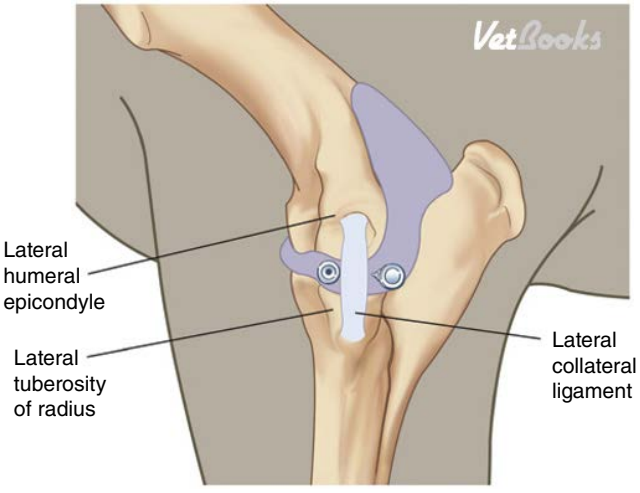

Figure 2.180. The lateral approach to the elbow joint can be made either cranial or caudal to the collateral ligament.

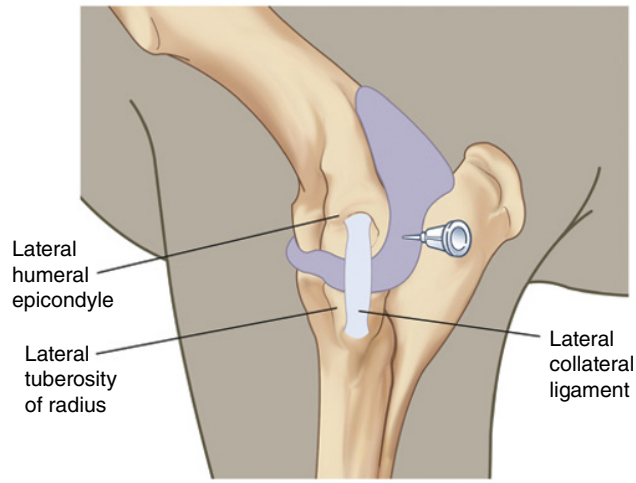

Figure 2.181. Caudolateral approach to the elbow joint just is caudal to the palpable humeral epicondyle in the anconeal notch within the humeroulnar joint.

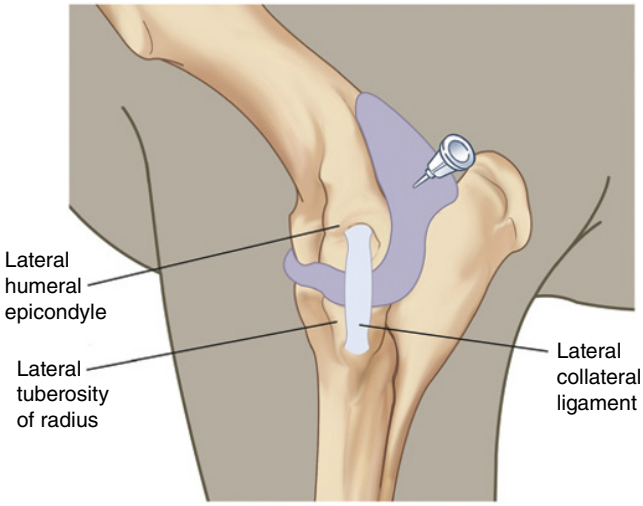

Figure 2.182. The approach to the large caudal outpouching of the elbow joint is 0.5 inches (1 cm) proximal to and one-third of the distance measured caudally from the supracondylar eminence to the point of the olecranon. A 3.5-inch (8.9-cm), 18- to 20-gauge spinal needle is directed distomedially through the triceps musculature at a 45° angle to the long axis of the limb into the olecranon fossa.

Caudal Approach

The large caudal joint pouch of the elbow can be entered from a more proximal location (Figure 2.182). The landmarks are the lateral supracondylar crest of the distal humerus and the most proximal point of the olecranon process.[34,48,58] The injection site is 0.5 inches (1 cm) proximal to and one-third of the distance measured caudally from the supracondylar eminence to the

VetBooks.ir

point of the olecranon. A 3.5-inch (8.9-cm), 18- to 20-gauge spinal needle is directed distomedially through the triceps musculature at a 45° angle to the long axis of the limb into the olecranon fossa (Figure 2.182). Alternatively, the spinal needle may be directed downward along the lateral shaft of the olecranon process to enter the joint.[75] The injection site is 3 cm distal and 2 cm cranial to the point of the olecranon, and the needle is directed distally and cranially to enter the caudal joint pouch just proximal to the anconeal process.

Scapulohumeral (Shoulder) Joint

Arthrocentesis of the shoulder can be difficult due to the depth of the joint. It is a large joint, and 20–40 mL of anesthetic is usually used for diagnostic purposes. It is always performed with the horse standing, and many clinicians now utilize ultrasound to guide the injection. Ultrasound-guided injections of the scapulohumeral joint and bicipital and infraspinatus bursae have been reported to be highly reliable and more accurate than conventional blind techniques.[59] The shoulder joint may communicate with the bicipital bursa in a small percentage of horses, and temporary anesthesia of the suprascapular nerve and paralysis of the infraspinatus and supraspinatus muscles may occur with periarticular injection of anesthetic.[48,75]

Craniolateral Approach

The site for the craniolateral approach to the shoulder joint is located in the notch formed between the cranial and caudal prominences of the lateral tuberosity of the humerus. The caudal prominence (point of the shoulder) is easiest to palpate, and by exerting deep finger pressure, the depression for needle insertion can be palpated 3.5–4 cm cranial to the caudal prominence. This notch is not as readily palpable in heavily muscled horses. A 3.5-inch (8.8-cm), 18- to 20-gauge spinal needle is inserted into this notch and directed parallel to the ground in a caudomedial direction toward the opposite elbow.[48,75] The depth of penetration depends on the size of the horse, but the joint capsule is usually entered at a depth of 2–3 inches (5–7 cm). Synovial fluid can usually be aspirated and is the only definitive method to document correct needle placement. Alternatively, the spinal needle may be inserted slightly more proximal on the limb in a distinct depression located 1–1.5 cm cranial to the infraspinatus tendon and slightly proximal and cranial to the point of the shoulder. The needle is placed parallel to the ground or slightly downward and directed caudomedially at a 45° angle until bone is contacted (Figure 2.183).

Lateral Approach

The landmarks for the lateral approach to the shoulder are the lateral humeral tuberosity and the infraspinatus tendon. A 3.5-inch (8.9-cm), 18- to 20-gauge spinal needle is inserted 1–2 cm caudal and distal to the infraspinatus tendon in line with the lateral humeral tuberosity (Figure 2.183).[3,75] The needle is directed slightly caudally and upward toward the lateral aspect of the humeral head. In general, this approach is more difficult than the craniolateral approach.

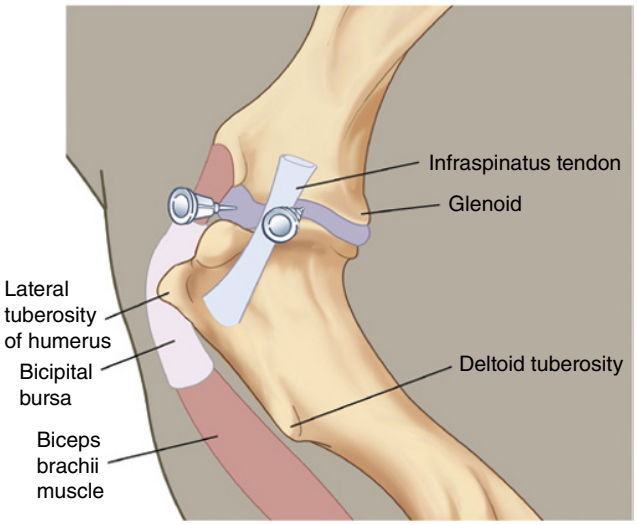

Figure 2.183. Lateral view of the shoulder demonstrating the injection sites for the craniolateral (cranial to the infraspinatus tendon) and lateral (caudal to the infraspinatus tendon) approaches. Ultrasound guidance of the needles can be advantageous with these approaches.

Bicipital Bursa

The bicipital bursa lies cranial to the shoulder and humerus under the biceps brachii muscle. It is a relatively large synovial structure (20–30 mL of anesthetic) but can be difficult to enter because of its depth and the landmarks for injection are not easily palpable. In a recent study that compared two different injection techniques (distal and proximal) to enter the bicipital bursa, the accuracy of injecting the bursa was only 28% and 39%, respectively.[67] The authors concluded that clinicians without previous experience of injecting the bicipital bursa were unlikely to be successful with either approach. This study confirmed the difficulty of injecting the bicipital bursa and is why ultrasound guidance is recommended to improve the accuracy of injections.[59] Alternatively, radiographic examination after injecting radiopaque contrast medium may be used to assess the success of centesis if synovial fluid is not obtained. The proximal and distal approaches to the bursa are usually performed with the limb weight-bearing, but the proximal approach may be done with the limb held.

Distal Approach

The cranial prominence of the lateral tuberosity of the humerus is used as the landmark, as was done for the shoulder joint. The site of injection is 2.5 inches (5–6 cm) distal and 3 inches (7–8 cm) caudal to this prominence. A 3.5-inch (8.9-cm), 18- to 20-gauge spinal needle is directed proximomedially toward the intertubercular groove until it contacts the humerus (Figure 2.184). The depth of the needle depends on the size of the horse, but a 3.5-inch (8.9-cm) spinal needle is usually inserted to the hub in most mature horses.[48] Alternatively, the deltoid tuberosity of the humerus can be palpated and used as a landmark. A 3.5-inch (8.9-cm), 18- to 20-gauge spinal needle is inserted 1.5 inches (3–4 cm) proximal to the distal aspect of the deltoid

VetBooks.ir

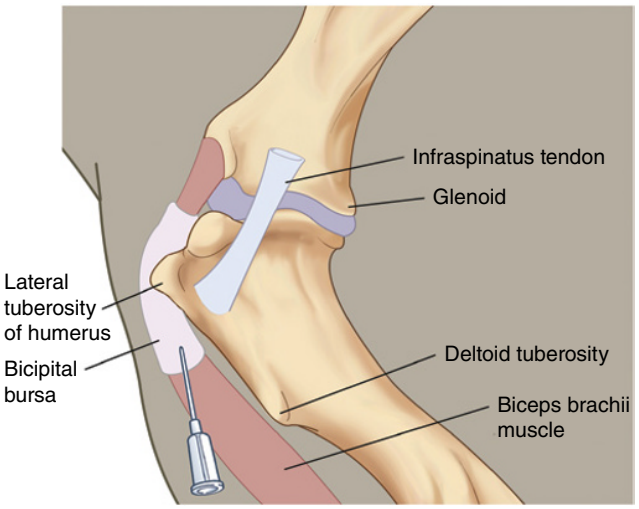

Figure 2.184. Site for the distal approach to the bicipital bursa is located is 2.5 inches (5–6 cm) distal to lateral tuberosity of the humerus.

tuberosity and directed proximomedially (toward to opposite ear) to a depth of 2–3 inches (5–7 cm).[48,75]

Proximal Approach

The proximal approach is performed in the intertubercular groove, which can be palpated medial to the edge of the cranial prominence of the lateral tuberosity of the humerus.[48,67] A 1.5-inch (3.8-cm), 20-gauge needle is inserted into the intertubercular groove in a plane parallel to the bearing surface of the foot at about a 45° angle to the sagittal axis of the horse until the needle strikes cartilage (Figure 2.185). The primary advantages of the proximal approach compared to the distal approach are a slightly improved accuracy of entering the bursa and not needing a 3.5-inch (8.9-cm) spinal needle.

Tarsal (Hock) Joints

There are four joint spaces associated with the tarsus: tarsocrural (TC), proximal intertarsal (PIT), distal intertarsal (DIT), and TMT. The TC joint is considered a high-motion joint, whereas the PIT, DIT, and TMT joints are low-motion joints. Numerous studies have been done to determine the consistency of communication between these joints. The TC and PIT joints communicate consistently and are usually considered as one joint as far as intra-articular injection. Reports of communication between the DIT and TMT joints vary from 8% to 38%.[4,20,42] To complicate things further, the PIT and DIT and the PIT and the TMT joints may also communicate occasionally.[42] Because of these findings, the interpretation of intra-articular anesthesia in the tarsus is not always straightforward. In addition, the communication patterns may differ in the diseased tarsus compared with a normal tarsus, and diffusion of medication may occur between the TMT and DIT joints regardless of the communication pattern. Corticosteroids injected into the TMT joint were consistently found within the DIT joint in all horses sampled.[70]

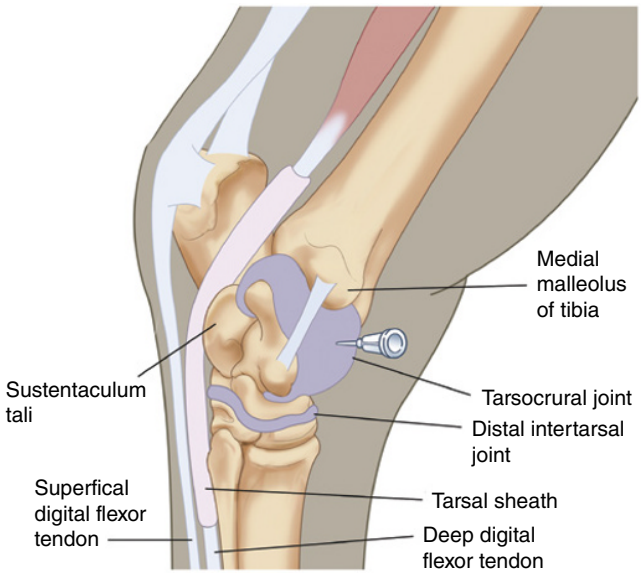

Figure 2.186. Medial view of the injection site for the dorsomedial pouch of the tarsocrural joint.

Tarsocrural Joint

The TC joint is the largest joint pouch in the tarsus and is easy to enter, especially if synovial effusion is present. The joint may be entered dorsally (dorsomedial) or plantarly depending on the clinical situation. For the dorsomedial approach, a 1-inch (2.5-cm), 20-gauge needle is inserted 1–1.5 inches (2–3 cm) distal to the medial malleolus of the tibia, medial, or lateral to the cranial branch of the medial saphenous vein (Figure 2.186; Video 2.34). The needle is advanced in a plantarolateral direction at approximately a 45° until synovial fluid flows from the needle. The dorsomedial approach is usually performed in the weight-bearing limb from the opposite side of the horse, but can be performed from

VetBooks.ir

the same side of the horse. Fifteen to 20 mL of local anesthetic is recommended.

The medial or lateral plantar outpouchings of the TC joint may be used for arthrocentesis, especially if significant synovial effusion is present (Figures 2.186 and 2.187). The palpable landmarks of the lateral plantar pouch are bordered by the tuber calcis caudally, the caudal aspect of the distal tibia cranially, and the proximal aspect of the lateral trochlear ridge of the talus distally (Figure 2.187; Video 2.35).[34] Confirmation that fluid swellings in this location are part of the TC joint can be determined by applying finger pressure to the swellings and feeling the dorsal pouches of the TC joint distend. A 1-inch (2.5-cm), 20-gauge needle is inserted perpendicular to the skin at the site of the effusion with the limb weight-bearing.

Tarsometatarsal (TMT) Joint

The TMT joint is best approached from the plantarolateral aspect of the tarsus with the limb weight-bearing. It is an easy joint to inject with an accuracy rate of 96% in a recent report.[69] The landmarks for injection are the proximal head of the fourth metatarsal (MT IV) bone and the lateral edge of the SDFT. A 1- to 1.5 inch (2.5- to 3.8-cm), 20- to 22-gauge needle is inserted in the small palpable depression 0.25 inch (0.5–1 cm) proximal to the head of MT IV (Figure 2.188; Video 2.36). The needle is directed toward the dorsomedial aspect of the tarsus in a slightly downward direction to a depth of 0.5–1 inch (1–3 cm).[47,48] Synovial fluid is often observed in the needle hub, and 3–5 mL of anesthetic is used for diagnostic purposes. Injecting the anesthetic under pressure was thought to force anesthetic into the DIT joint, but instead it just causes it to accumulate in the subcutaneous tissues.[48] In addition, the anesthetic may enter the tarsal sheath and extend around the tendons of the tibialis cranialis and fibularis tertius when using this approach.[20] A more difficult alternative approach to the TMT joint is from the distomedial aspect of the tarsus. The site for injection is approximately 0.5 inches (1–2 cm) distal to the site used for the medial approach to the DIT joint.[75]

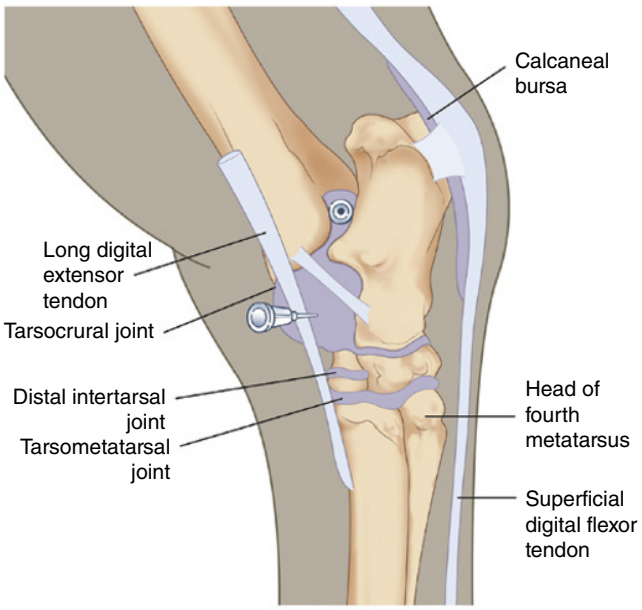

Figure 2.187. Injections sites for the dorsolateral (distal needle) and the lateral plantar (proximal needle) approaches to the tarsocrural joint.

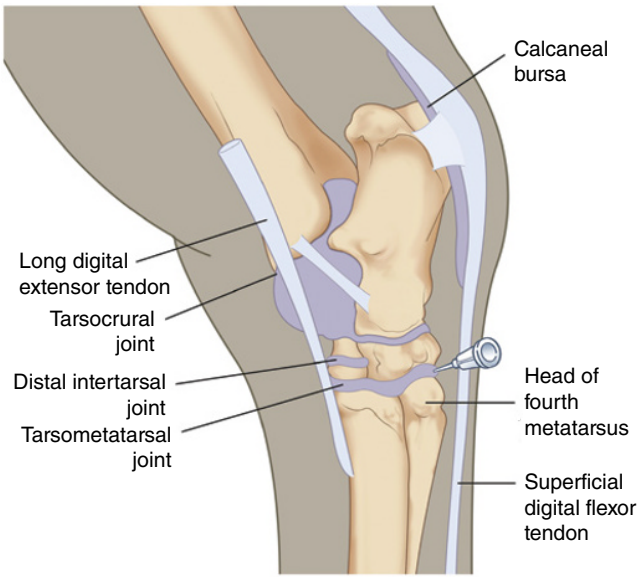

Figure 2.188. Injection site for the TMT joint proximal to the head of the lateral splint bone.

Distal Intertarsal (DIT) or Centrodistal Joint

The site for injection of the DIT joint is on the distomedial surface of the tarsus. The injection is performed from the opposite side of the horse with the limb weight-bearing. It is a difficult joint to inject with an accuracy rate of only 42% in a recent report.[69] One technique is to draw an imaginary line between the palpable distal tubercle of the talus and the space between the second and third metatarsal bones (MT II and III) at their proximal limits.[57,75] A small depression can often be felt with a fingernail just distal to the cunean tendon along this imaginary line. Another approach is to identify the medial eminence of the talus and medial eminence of the central tarsal bone. The site for injection is halfway between these landmarks and 0.5 inch (1 cm) distal to the eminence of the central tarsal bone.[48] A 1-inch (2.5-cm), 22- to 25-gauge needle is directed perpendicular to the long axis of the limb (or slightly caudally) to enter the joint space between the combined first and second tarsal bones, the third, and the central tarsal bones. The needle is advanced to about 0.5 inches (1 cm) and 3–4 mL of local anesthetic is injected (Figure 2.189; Video 2.37). The needle is determined to be within the DIT joint by low resistance to injection without developing a subcutaneous swelling and the ability to aspirate the injected contents of the syringe.[48] The DIT joint is thought to communicate frequently with the cunean bursa.[27]

The DIT or centrodistal joint can also be entered using a dorsolateral approach.[38] The injection site is 2–3 mm lateral to the long digital extensor tendon and

VetBooks.ir

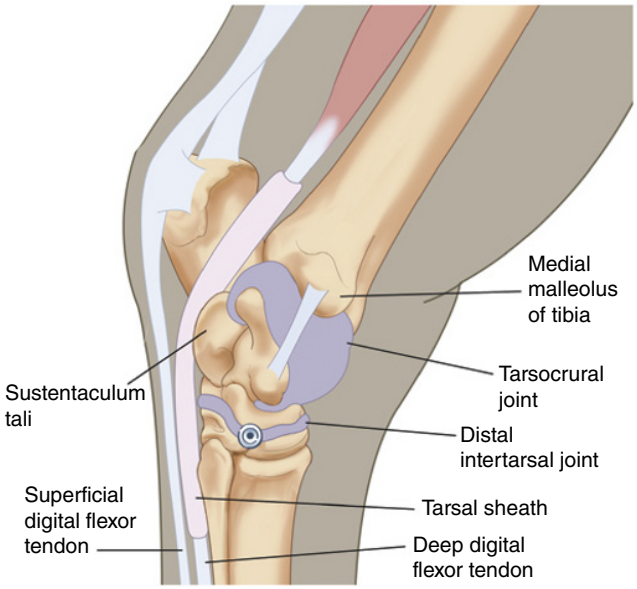

Figure 2.189. Injection site for the medial approach to the DIT joint.

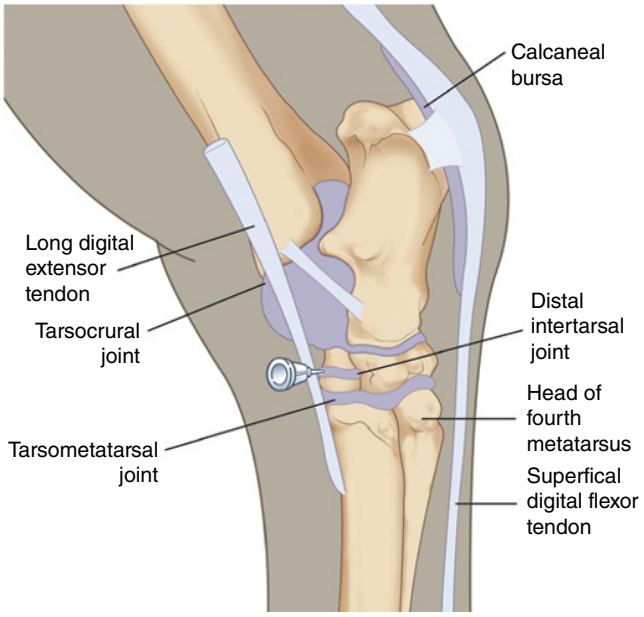

Figure 2.190. The dorsolateral approach to the DIT joint is 2–3 mm lateral to the long digital extensor tendon and approximately 6–8 mm proximal to a line drawn perpendicular to the axis of the third metatarsal bone through the head of the fourth metatarsal bone. This is usually distal to the palpable lateral trochlear ridge of the talus. The needle is directed plantaromedially at an angle of approximately 70° from the sagittal plane until bone is contacted.

6–8 mm proximal to a line drawn perpendicular to the axis of the third metatarsal bone through the head of the fourth metatarsal bone. This is usually distal to the palpable lateral trochlear ridge of the talus. The needle is directed plantaromedially at an angle of approximately 70° from the sagittal plane until bone is contacted (Figure 2.190; Video 2.38). This approach is safer for the clinician because it is performed on the lateral aspect of the tarsus but may be even more technically difficult than the medial approach.

Cunean Bursa

The cunean bursa is located on the medial surface of the distal tarsus between the medial collateral ligament of the tarsus and the medial branch of the tibialis cranialis (cunean) tendon. The bursa is relatively small and is not routinely anesthetized or treated alone because it often communicates with the DIT joint.[27] A 1-inch (2.54-cm), 22-gauge needle is inserted under the distal border of the cunean tendon and directed proximally to enter the bursa. Some clinicians treat the cunean bursa concurrently when medicating the DIT joint in horses with distal tarsal OA.

Calcaneal Bursa

The calcaneal bursa is located between the SDFT and the caudal aspect of the calcaneus. When distended, the bursa has synovial outpouchings medial and lateral to the tendon both proximal and distal to the SDFT retinaculum. These can often be seen as four distinct pockets of fluid surrounding the point of the hock-in horses with bursal distension. Synovial aspiration is best performed using the lateral synovial outpouchings either above or below the SDFT retinaculum with the horse weight-bearing. A 1-inch (2.5-cm), 20-gauge needle is angled proximally within these outpouchings to avoid the SDFT. The sites for needle placement are the same as those described for insertion of the arthroscope into the calcaneal bursa: 1 cm dorsal to the SDFT and 1 cm distal to the medial or lateral aspect of the SDFT retinaculum (Figure 2.191).[36] Approximately 8–12 mL of anesthetic is used to block the bursa.

Stifle Joint

The stifle joint is composed of three synovial compartments: the femoropatellar and the lateral femorotibial (LFT) and medial femorotibial (MFT) joints. Contrast studies have shown that the frequency of communication between the femoropatellar and the MFT joint is approximately 60%–65%.[54,80] The communication, however, is variable and appears to depend on the direction of flow of the injectable agent, the amount of joint inflammation, and anatomic variation. Communication between the femoropatellar and the MFT joint is observed more frequently when the MFT joint is injected than when the femoropatellar joint is injected. Communication between the femoropatellar joint and the LFT joint occurs rarely, and communication between the MFT and LFT joints does not occur under normal situations. Some clinicians feel that each synovial compartment of the stifle should be injected separately to ensure accurate distribution of local anesthetic.[75] However, greater diffusion of local anesthetic between compartments of the stifle probably occurs than what has previously been assumed based on anatomic, latex injection, and contrast arthrography studies.[27,48] The majority of the injection approaches to all compartments of the stifle are performed in the weight-bearing limb, and approximately 20–30 mL of anesthetic is usually recommended in each joint.

VetBooks.ir

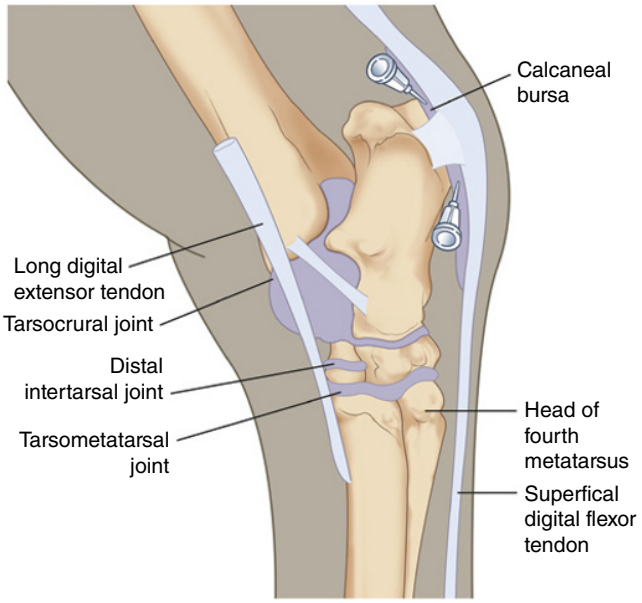

Figure 2.191. Injection sites for the calcaneal bursa are located either above or below the retinaculum of the superficial digital flexor tendon. These injection sites can be difficult to find without effusion.

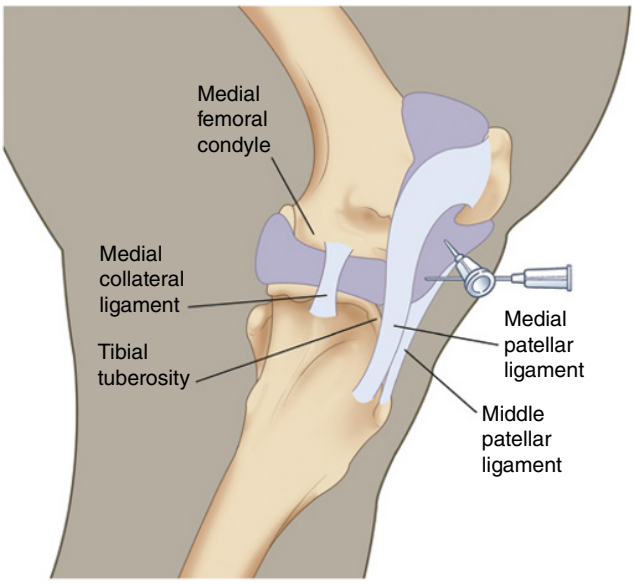

Figure 2.192. Lateral view of the injection sites for the femoropatellar joint. With one approach the needle is inserted perpendicular to the limb, and with the other approach it is angled from distally to proximally under the patella.

Femoropatellar Joint

The femoropatellar joint is the largest of the compartments, and it can be entered from the cranial (on either side of the middle patella ligament) or lateral (caudal to the lateral patella ligament) aspects. In one cranial approach, a 3.5-inch (3.8- or 8.9-cm), 18- to 20-gauge needle is inserted approximately 1–1.5 inches (3–4 cm) proximal to the tibial crest between the middle and medial patella ligaments and is directed proximally under the patella (Figure 2.192). This approach is best performed with the limb in a partial weight-bearing (slightly flexed) position.[2,75] Alternatively, the needle can be directed parallel to the ground with the limb fully weight-bearing.[48] The femoropatellar joint can also be entered just distal to the apex of the patella on either side of the middle patellar ligament with the limb weight-bearing.[79] The joint capsule is superficial at this location, and a 1.5-inch (3.8-cm), 18- to 20-gauge needle is directed at right angles to the skin.

The lateral approach to the femoropatellar joint is performed with the horse weight-bearing (Figure 2.193).[32] The lateral cul-de-sac of the joint is located caudal to the lateral patellar ligament and approximately 2 inches (5–6 cm) proximal to the lateral tibial condyle. A 1.5-inch (3.8-cm), 18- to 20-gauge needle is inserted into the recess perpendicular to the long axis of the femur until the nonarticular portion of the lateral trochlea is contacted. Synovial fluid can be retrieved in most cases, and this approach is usually well tolerated by the horse.

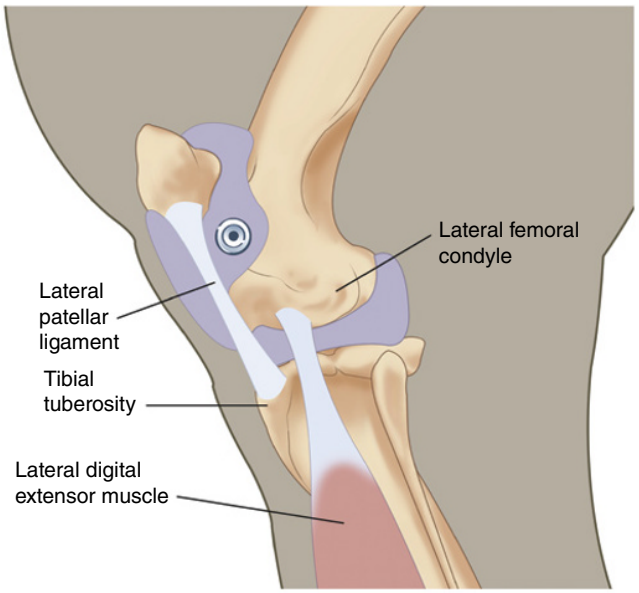

Figure 2.193. Lateral approach to the femoropatellar joint in the lateral cul-de-sac of the joint located caudal to the lateral patellar ligament and approximately 2 inches (5–6 cm) proximal to the lateral tibial condyle.

Medial Femorotibial (MFT) Joint

The site for injection of the MFT joint is located in the space between the medial patellar and medial collateral ligaments just above the palpable proximomedial edge of the tibia in the weight-bearing limb (Figure 2.194).[48] A 1.5-inch (3.8-cm), 18- to 20-gauge needle is inserted just caudal to the medial patellar ligament, 1 cm proximal to the tibia, and directed perpendicular to the long axis of the limb. The needle may need to be repositioned slightly cranially or caudally to help obtain synovial fluid. The medial meniscus will be contacted (penetrated) if the needle is inserted too far caudally or too close to the proximal tibia.[34,79] This approach may be performed from the same side (facing the stifle) or from the opposite side, reaching under the horse's belly.

VetBooks.ir

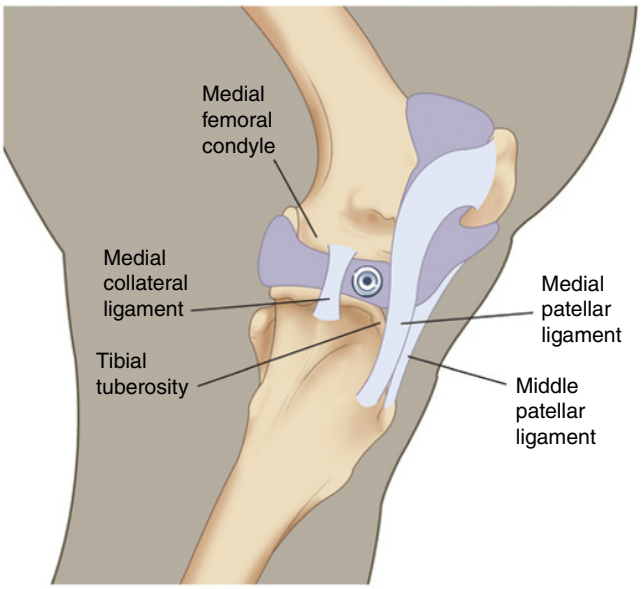

Figure 2.194. Medial approach to the medial femorotibial joint just caudal to the medial patellar ligament and proximal to the tibial crest.

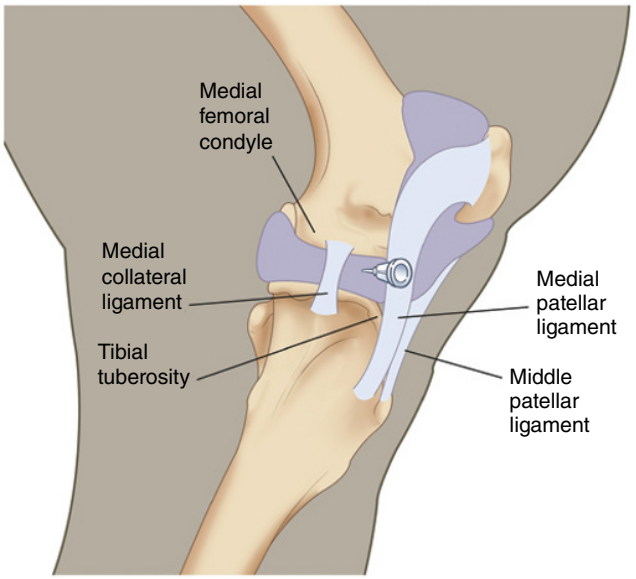

Figure 2.195. With the cranial approach to the MFT joint, the needle is directed in a cranial-to-caudal direction in the depression between the medial patella ligament and the tendon of insertion of the sartorius muscle to enter the proximal outpouching of the joint.

Another approach to the MFT joint is located 0.5–1 inch (1–2 cm) proximal to the medial tibial plateau in the depression between the medial patella ligament and the tendon of insertion of the sartorius muscle.[77] A 1.5-inch (3.8-cm), 20-gauge needle is directed in a cranial-to-caudal direction parallel to the ground and parallel to a plane that bisects the limb (Figure 2.195). The needle enters a medial outpouching of the MFT joint and avoids inadvertent penetration of the medial meniscus and the medial femoral condyle. In addition, synovial fluid is more easily obtained with this approach compared with the medial approach to the MFT joint.

Lateral Femorotibial (LFT) Joint

The site for injection of the LFT joint is slightly caudal to the palpable edge of the lateral patellar ligament just above the proximolateral edge of the tibia with the limb weight-bearing (Figure 2.196; cranial needle). A 1.5-inch (3.8-cm), 18- to 20-gauge needle is inserted at right angles to the long axis of the femur and directed from lateral to medial to a depth of 1 inch (2–3 cm). An alternative approach is to insert the needle just proximal to the tibia in the space between the lateral collateral ligament of the LFT joint and the tendon of origin of the long digital extensor tendon (Figure 2.196; caudal needle).[34,48] The palpable head of the fibula helps to identify these structures. The needle is inserted slowly to a depth of approximately 1 inch (2–3 cm) until the joint capsule is entered.[48]

Single Approach for All Three Joints

All three joints in the stifle can be injected from one cranial site 1.5 cm proximal to the tibia between the lateral and middle patellar ligaments with the stifle slightly flexed.[75] Local skin and subcutaneous anesthesia at the injection site is helpful for this technique. A 3.5-inch (8.9-cm), 18- to 20-gauge spinal needle is inserted and directed caudomedially parallel to the tibial crest toward the MFT joint. The needle is then withdrawn to the subcutaneous tissue and redirected caudolaterally parallel to the tibial crest toward the LFT joint and anesthetic is deposited. The needle is again withdrawn to the subcutaneous tissue and redirected proximally under the patella into the femoropatellar joint.

Trochanteric Bursa

The trochanteric bursa is located beneath the tendon of insertion of the middle gluteal muscle on the cranial

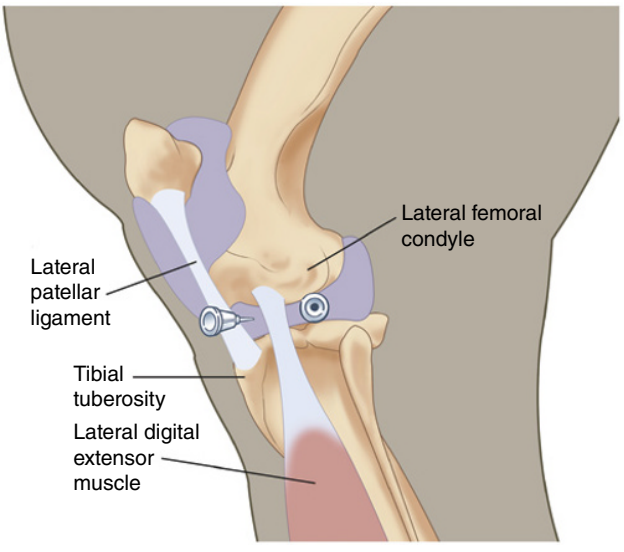

Figure 2.196. Injection sites for the lateral femorotibial joint. One is just proximal to the tibia in the space between the lateral patellar ligament and the tendon of origin of the long digital extensor tendon, and the alternative is caudal to the long digital extensor tendon and cranial to the lateral collateral ligament.

VetBooks.ir

aspect of the greater trochanter of the femur (Figure 1.48 in Chapter 1). The site for injection is between the tendon and the lateral surface of the greater trochanter at the most cranial aspect of the palpable greater trochanter. A 1.5-inch (3.8-cm), 18-gauge needle is usually all that is needed, although larger Warmblood horses may require a longer needle in some cases.[28] The needle is inserted and directed horizontally at right angles to the sagittal plane until bone is encountered. Seven to 10 mL of anesthetic is injected. An alternate method is to direct the needle medially through the middle gluteal muscle directly over the bursa toward the trochanter.[75] A recent study concluded that positioning the limb caudally with the foot non-weight-bearing and on a Hickman block facilitated centesis of the trochanteric bursa.[78] The author has also recommended using ultrasound guidance to improve the success of the injection.[78]

Figure 2.197. Craniolateral view of the injection site for the coxofemoral joint. The needle is inserted in the trochanteric notch and directed at a 45° angle with the long axis until the joint is entered. Ultrasound guidance is recommended to enter the coxofemoral joint regardless of the approach used.

Coxofemoral (Hip) Joint

The coxofemoral joint is one of the most difficult joints to enter.[34,48] This is particularly true in mature, heavily muscled horses. The joint is well away from the proximal end of the femur, and the landmarks for injection are often difficult to palpate. For these reasons, ultrasound guidance of the needle is recommended.[15,82] The procedure is best performed with the horse standing squarely and restrained within stocks. Mild sedation is often advised because movement during the injection procedure may cause the needle to bend or break.

Both craniodorsal and cranioventral approaches have been described. The cranioventral approach requires ultrasound guidance,[82] while the craniodorsal approach may be performed blindly or more optimally with ultrasound guidance.[15] The most important landmarks for the craniodorsal approach are the paired summits of the greater trochanter of the femur. The trochanter is located about two-thirds of the distance between the tuber coxae and the tuber ischii.[48] The greater trochanter is approximately 4 inches (10 cm) wide with a notch between the cranial and caudal protuberances that can be difficult to palpate. The site for injection is about 0.5 inches (1–2 cm) above the middle of the proximal summit of the trochanter (Figure 2.197).[48] A small bleb of local anesthetic is injected subcutaneously over the injection site, and a small stab incision may aid needle insertion.[2,3] A 6- to 8-inch (15- to 20-cm), 16- to 18-gauge spinal needle is directed in a horizontal plane perpendicular to the vertebral column (Figure 2.197). The needle should be directed slightly downward to stay close to the femoral neck so that it is approximately 0.5 inches (1–2 cm) lower than the insertion site after it has been advanced 3–4 inches (8–10 cm). Firm fibrous tissue is often felt just before the needle penetrates the joint capsule at approximately 4–6 inches (10–15 cm). Synovial fluid is often aspirated and 30–60 mL of anesthetic is recommended.[34,48]

Sacroiliac (SI) Joint

The SI joint is not a true synovial joint, but treatment of this region is common in horses with sacroiliac problems. There are several different approaches that can be used to access the sacroiliac region with most resulting in periarticular deposition of medication (not intra-articular). A cadaver study of two different ultrasound-guided injection techniques (cranial parasagittal and caudomedial) concluded that accuracy was poor for intra-articular injection.[74] The described technique by Engeli and Haussler is used by the author and is described here.[22] The horse is usually sedated, restrained in stocks, and the injection site is anesthetized with local anesthesia. The landmark for injection is the cranial aspect of the tuber sacrale. A 10-inch (25-cm), 15- to 16-gauge spinal needle is bent to an angle of about 40° in the direction of the needle's bevel. The needle is inserted through a stab incision in the skin 1 inch (2 cm) cranial to the contralateral tuber sacrale and directed at a 60° angle to the vertical plane. The needle is advanced across midline aiming for a point midway between the ipsilateral tuber coxae and the greater trochanter of the femur until it contacts the medial aspect of the tuber sacrale (Figure 2.198). The needle hub is lifted, and the needle is advanced at a steeper angle along the medial aspect of the ilial wing until it contacts the dorsal surface of the sacrum at a depth of approximately 6–8 inches (15–20 cm).[48] An alternative technique is to insert a 6-inch (15-cm), 18-gauge needle near the cranial aspect of the tuber sacrale. The needle is directed ventrocaudolateral toward the SI joint of the opposite side at a 20°–40° angle to the vertical plane.[19] Ultrasound guidance of SI injections is commonly performed, and both cranial and caudal approaches have been described.[16,74] The reader is referred to Chapter 6 for additional information on SI injection techniques.

Cervical Facets

Centesis of a cervical facet joint is usually performed to administer medication into the joint of a horse that has clinical signs suggestive of disease within the cervical articulation. Lesions of the cervical facets tend to occur most commonly in vertebrae C5 to C6 and C6 to C7.[44] The procedure is performed in the standing sedated horse with the help of ultrasound and is usually performed bilaterally unless a specific side of the lesion has been documented. The approximate location of the

VetBooks.ir

Figure 2.198. Needle location and angulation of the spinal needle used to inject the contralateral sacroiliac joint from the cranial aspect of the tuber sacrale. A 10-inch (25-cm), 15- to 16-gauge spinal needle is bent to an angle of about 40° in the direction of the needle's bevel. The needle is inserted through a stab incision in the skin 1 inch (2 cm) cranial to the contralateral tuber sacrale and directed at a 60° angle to the vertical plane.

injection can be made by using one width of the hand to represent the length of one cervical vertebra.[48] The facet joint is imaged with the ultrasound probe, and a 3.5-inch (8.9-cm), 18- to 20-gauge spinal needle is advanced toward the joint at an angle so the tip of the needle can be seen. The cervical articular processes and joint form an easily identifiable sonographic landmark, a steplike echogenic surface described as having the appearance of a "chair."[44] Ultrasound is used to direct the needle into the joint and the solution is deposited.

ACKNOWLEDGMENT

The authors thank Dr. Ted S. Stashak for his contributions to this chapter in the previous edition.

CHAPTER

Diagnostic Imaging

RADIOGRAPHY

Myra Barrett and Elizabeth Acutt

Radiography is the most frequently used imaging modality in the equine patient, and even with the growth of advanced imaging technologies, radiography remains a first-line screening tool for equine musculoskeletal disease.

Advances in technology have made digital radiography mainstream and accessible to most practitioners. While the many developments in technology have resulted in more accessible and easily shared, high-quality images, the fundamental principles of radiology remain the same as the days of screen-film radiography. The veterinarian must be familiar with the basic instrumentation of an X-ray machine and the radiation safety techniques commonly practiced in radiography. An understanding of the normal equine radiographic anatomy, basic radiographic interpretation principles, examination techniques, and post-capture image processing is essential to perform diagnostic radiographic studies. Too often, knowledge of these basic concepts is overlooked, resulting in inferior radiographic examinations. Poor-quality radiographs may result in erroneous diagnoses and conclusions.

This section is not intended to comprehensively cover the physics behind the different radiographic systems; however, a review of the various technologies available in veterinary medicine including types of digital imaging systems and image display and storage is included. More detailed information is available elsewhere.[22,29,31,49,50,56,63] The normal equine radiographic anatomy with standard projections used in the diagnosis of lameness in addition to the common radiographic signs of bone and soft tissue response to different pathologic processes are also discussed.

EQUIPMENT

Knowledge of radiography equipment including X-ray machines, detector systems, film processing equipment, image viewing devices, and accessory equipment is necessary for obtaining good-quality diagnostic radiographs safely. The reader should also be aware of the advantages and disadvantages of the different equipment options that are available for veterinary practice.

X-ray Machines

The basic control settings of an X-ray machine, the milliamperage (mA), exposure time, and kilovoltage potential (kVp) are located on the control panel and may be changed to vary the exposure (Figure 3.1). Milliamperage is the tube current and refers to the quantity of electrons flowing per second in the X-ray tube. Ultimately, it determines the quantity of X-rays emitted from the X-ray tube.

Exposure time is an important variable in equine radiology. Because of problems related to patient and detector movement, exposure time should be 0.1 second or less, if possible, for equine limb examinations. The use of electronic timers is recommended for accurate timing when the exposure is less than 0.1 second. For equine radiology, an electronic timer with two-step exposure button is desirable.[48] The first step warms the X-ray tube filament; the exposure is made in the second step. The two-step exposure button prolongs the X-ray tube life. Because exposure time (in seconds) multiplied by the milliamperage equals milliamperage-seconds (mAs), radiation exposure is directly related to milliamperage-seconds.

VetBooks.ir

Kilovoltage determines the energy of X-rays being produced. Kilovoltage potential should range from 70 to 90 for equine limb radiographs on mature horses when a portable X-ray machine is used. A 10% increase or decrease in kilovoltage potential effectively doubles or halves the radiation exposure.

The focal spot-film distance (FFD) is the distance from the X-ray tube focal spot to the detector. The focal spot location is usually marked on the outside tube housing; if it is not, the approximate center of the tube housing can be used for its location. A constant FFD is necessary to minimize improper exposures because the intensity of X-rays that expose the film is inversely proportional to the square of the FFD. Therefore, a small difference in the FFD can dramatically change the exposure on the X-ray film.

Some method of measuring the FFD before each exposure should be employed. Measuring devices with converging light beams at the correctly set FFD are easy to use and less cumbersome than a measuring tape or string. The FFD for equine limb radiography should be between 36 and 40 inches (85 and 100 cm) and no less than 24 inches (60 cm). When the FFD is less than 24 inches, the object is magnified, and spatial resolution is reduced. FFDs greater than 40 inches can be used if exposure times are not excessively long. When making radiographs of larger body parts such as necks, it is important to remember that the distance needs to be set from the X-ray tube to the detector, not to the skin surface, a concept that is more easily forgotten when the plate is not well seen by the person holding the X-ray generator.

Collimation is the process of limiting or restricting the primary X-ray beam to the appropriate size to cover the anatomical region of interest within the X-ray detector being used. Collimating the primary beam is a safety practice that must be monitored for each exposure and must be reset if the cassette size changes. Limiting the size of the primary X-ray beam is a major factor in reducing scatter radiation, which keeps radiation exposure to personnel as low as possible. Collimation also improves image quality, particularly in large body parts such as the caudal cervical spine. Fixed cylinders or cones and adjustable light-beam collimators are available (Figure 3.2). The disadvantage of fixed primary beam restrictors is that they do not conform to different cassette sizes. Adjustable light-beam collimation is recommended for equine radiography and is standard to many X-ray machines. They come with an internal light source, preferably 40 W or greater,[48] so the limits of the primary X-ray beam are projected on the X-ray cassette/detector as visible light.

The type of X-ray machines best suited for equine practice depends on the type of practice: out of hospital versus in hospital. The features of the X-ray machines must be matched to fit different practice situations. Some compromises or trade-offs must be made, e.g. less milliamperage or kilovoltage potential for more portability. An ideal X-ray machine for equine radiography has the following features:

1. Easily and quietly movable, with a tube head that can extend to the floor or ground surface
2. Adjustable milliamperage and kilovoltage potential setting
3. Electronic, two-step timer capable of accurate exposure times of 0.1 second or faster
4. Line voltage compensator and compensation meter

Figure 3.1. Control panel for a 30-mA portable X-ray machine.

Figure 3.2. Adjustable light-beam collimator. The primary beam is limited by adjustable leaves in the collimator. A light source within the collimator defines the limits of the primary beam (white arrows).

VetBooks.ir

5. Primary X-ray beam restrictor (the preferred system is an adjustable light-beam collimator)
6. Absence of radiation or electrical hazards

Portable, mobile, and fixed (ceiling-suspended) X-ray machines are available for equine radiography. These differ in size and capacity, from small, portable 15-mA machines to large, fixed 800-mA machines. Portable X-ray machines are best suited for out-of-hospital locations. They are lightweight (30–55 lbs) and can be easily stored for transport. Options for portable X-ray machines include both corded and battery-operated wireless and range in size and weight. Most manufacturers also provide a variety of types of stands on which the portable X-ray machine can be suspended. This helps reduce dose to personnel and minimize motion artifact and fatigue.

High-frequency transformers that reduce the exposure time are available for portable X-ray machines. They are equivalent to a 3-phase, 12-pulse X-ray generator and provide a 40%–50% increase in exposure compared with a full-wave rectified machine. The practical application is to reduce the exposure time and still obtain an adequate exposure for a diagnostic radiograph. A line voltage compensator is also desirable for portable X-ray machines. It is especially important in field situations, where the line voltage may fluctuate with the simultaneous use of the electrical equipment, and it can compensate for a line voltage drop when a long electrical extension cord is used.

Fixed X-ray machines are usually suspended from the ceiling. They are limited to use within a single room. These machines can be coupled with large transformer systems that are capable of providing high milliamperage (800–1,000 mA). Ceiling-suspended tubes are easily movable and can be locked into position by magnetic locks while the X-ray exposure is made. The tube should be capable of extending to the floor. X-ray machines with high milliamperage capability have fast exposure times, eliminating most motion artifacts when radiographing equine limbs.

Types of Digital Radiography

Digital radiography can be divided into computed radiography (CR) or direct digital radiography (DDR).

CR uses a detector panel that stores the image and then uses a separate image readout unit. In DDR, the detector panel converts the X-rays into electrical charges by means of a direct readout process. DDR systems can be further divided into direct or indirect conversion technologies depending on the type of X-ray conversion used. Both CR and DDR systems convert the electronic signal to digital data and send it to an acquisition device. At this point, the digital data is considered "raw," and it can be further processed.

The term picture archiving and communication system (PACS) is used to describe a system that allows for image retrieval, review, processing, interpretation, and storage. The term "image processing" incorporates multiple steps in the acquisition of a digital image before the study is completed. During the image processing, the raw image can be manipulated with the purpose of having the best image possibly available for interpretation at the viewing station. Key factors that can be manipulated include the lookup table (LUT), which allows the operator to change the grayscale of the image by altering the actual pixel values, region of interest, and contrast, as well as other options. Once the study is completed, the images are sent to the viewing station where Digital Imaging and Communication in Medicine (DICOM) viewing software is used for image display on a computer monitor. A complete discussion of image processing is beyond the scope of this chapter. More in-depth information is available in textbooks of diagnostic radiology physics and radiology journal articles.[9,29,31,41]

DIGITAL RADIOGRAPHY SYSTEMS

Computed Radiography

CR systems are similar to screen-film systems, in which a cassette stores the latent image until processing. In CR, the cassette contains an imaging plate possessing photostimulable phosphors (PSP). After the imaging plate is exposed to X-ray photons, the PSP change to a higher energy state and store the latent image until processing.

When the cassette is placed in the reader unit, the imaging plate is automatically removed from the cassette and scanned by a laser beam. The laser light stimulates the energy trapped in the PSP, and visible light is released from the plate. The released light strikes a photomultiplier tube and is converted into an electronic signal. The magnitude of the electronic signal represents the degree of X-ray attenuation of the structure that was imaged and is also assigned a corresponding shade of gray after conversion from analog-to-digital format.[62] The data is then stored temporarily in a local hard disk. Subsequently, the imaging plate is exposed to bright white light to erase any residual trapped energy before it is returned to the cassette for reuse.[9] The whole readout process for a 14 × 17-in. image plate takes approximately 30–40 seconds.[29] The resultant image is sent to an acquisition computer, where post-processing manipulations can be performed.

The separation of the readout unit in CR systems means that in a multi-veterinarian practice, cassettes can be divided between practitioners, both in the field and in the clinic to allow for simultaneous performance of multiple radiographic examinations. It also enables a degree of wireless imaging not always afforded by digital systems since the cassettes themselves do not require wires. The initial costs of a CR system are less than those of a DDR system, which may also make the system a more attractive prospect for purchase.[2] CR units can also be appealing in mixed animal practice because of the flexibility in the use of plates. However, the resolution achieved by these systems is often inferior to DR systems, which have several other advantages, outlined below.

Direct Digital Radiography

DDR systems have a direct readout, meaning that the detector sends the signal straight to the computer instead of using a reading unit such as the CR system. The time

VetBooks.ir

lapse between exposure to image display takes less than 10 seconds, which increases the patient throughput.[29] The ability to rapidly take multiple sequential views can facilitate greatly the workflow in a busy practice and is more likely to result in the acquisition of high-quality, diagnostic images, since immediate assessment of patient positioning and generator settings is possible. Two different DDR conversion systems exist: direct and indirect conversion.

Direct conversion systems feature a flat panel detector containing photoconductors such as selenium (most commonly used), lead iodide, lead oxide, thallium bromide, or gadolinium compounds.[29] The photoconductors are the first layer in contact with the X-ray photons that exit the patient and are responsible for converting them into electrical charges. The electrical charges are stored in capacitors and then read row by row, and the information is sent to the computer after analog-to-digital conversion. More detailed information is available in radiology journal articles.[29,62]

Indirect conversion can be done with two technologies: charged coupled device (CCD) or indirect flat panel detector. In a CCD, the X-ray photons from the patient are converted to light after striking a scintillator layer. The light is then usually minified with a lens to fit in the small CCD where it is recorded and converted into electrical charges. In the process of light minification, some of the light photons are lost and do not reach the CCD unit. This results in increased image noise compared with flat panel detectors in which minification is not applied.[62] The noise, edge distortion, and artifacts that are frequently seen in CCD systems mean that this technology has largely fallen out of favor. As a result, servicing and repairing such systems has become complex and costly.

An indirect flat panel detector also contains a scintillator layer, or intensifying screen, made of cesium iodide crystals. Other materials used in the scintillator layer include gadolinium-based crystals. The advantage of cesium iodide scintillators is that the crystals can be structured into 5–10-μm-wide parallel needles, which reduce the spreading of light within the scintillator. Hence, the spatial resolution is increased. The high resolution of these systems means that they are the gold standard of medical imaging.

While initial DDR systems required wired connections between the plate and the reader, many fully wireless systems are now on the market. Comparison charts are available for the commercially available DDR systems and are a good reference source when selecting a system for purchase. Other considerations besides cost when selecting a system include the logistics of maintenance, service and repair, warranty duration, and the availability of technical help in the case of software/hardware malfunction.[2]

Digital Image Display

A computer used in a digital image viewing station consists of two basic parts: one or more monitors (hardware) and a DICOM viewer (software). A monitor used for digital radiography should have excellent resolution, high brightness (luminance), and wide dynamic range. The resolution of a monitor is dictated by the pixel and matrix size. As the pixel size decreases and the matrix size increases, the monitor's resolution improves. The dynamic range of a monitor is the luminance ratio between the darkest (black) shade and the brightest (white) shade that the monitor can display. The dynamic range of a monitor is usually correlated to the luminance; thus, the higher the monitor brightness, the higher the dynamic range.

A wide variety of Windows- or Apple-based DICOM software programs are available and include free Internet-downloadable versions to more sophisticated software that requires purchase or leasing contracts. Free versions typically are less robust and may limit the size of study that can be downloaded. The different DICOM viewing software provides the user with the ability to further manipulate and improve the image displayed on the monitor. Features such as modifying contrast (window and level), image sharpening, edge enhancement, zoom, measurement tools, multiplanar reconstruction, etc. are included in most DICOM viewers but differ among vendors depending on the quality of the software (Figure 3.3).

Digital Image Storage and Transmission

The technology for digital imaging storage and transmission is rapidly evolving, making storage and sharing relatively simple. Images can be stored on an on-site server, and many vendors offer cloud-based storage as well. While convenient, reliance solely on cloud-based storage requires a fast and reliable Internet connection. The growth of the practice of teleradiology—the electronic transmission of images for interpretation and consultation—has been enhanced via downloadable DICOM images or web-based viewing of images. These options for image transmission are preferable to emailing jpeg images, which have lower resolution and have to be converted back to DICOM images in order to be manipulated.

Accessory X-ray Equipment

Accessory X-ray equipment for equine musculoskeletal examinations has special requirements. Good-quality, well-maintained accessory equipment is necessary to ensure that quality radiographic examinations are performed safely. Accessory equipment consists of grids, markers, and film-marking systems, detector holders, padded tables for radiographic projections under general anesthesia, and positioning aids. These pieces of equipment are used with conventional or digital radiography. Most accessory equipment is available commercially, but because of the unique requirement of equine radiology, some equipment, such as cassette holders, padded tables, and positioning aids, may have to be custom built locally.

Grids

Radiographic grids are used to decrease the amount of scattered radiation that exposes the X-ray film. Because scattered radiation exposes film from several directions, it has the effect of decreasing image detail and contrast. Radiographs of thicker body parts, such as

VetBooks.ir

Figure 3.3. Foot radiographs displayed on Horos, an example of free-downloadable image viewing software developed for Apple computer products. *Source*: Courtesy of Dr. Kathryn Wulster.

the caudocranial view of the stifle or cervical spine, are more affected by scatter radiation and can most benefit from the use of a grid. Phosphor is very sensitive to scatter radiation, and grids remain of importance even when using CR and DDR systems.

The advantages of using a grid are increased film detail and contrast, which improve the diagnostic quality of the film. The main disadvantage of a grid is increased radiation exposure to personnel. Increased radiation exposure is particularly important in equine radiography, for which low-output X-ray machines are extensively used.

Current recommendations are to consult with the system vendor regarding the requirement for and specifications of a grid.[22]

Film Markers and Marking Systems

Adequate, legible film marking is necessary but often overlooked in equine radiography. Proper identification procedures are necessary for follow-up comparative examinations and for accurately documenting when, where, what, and by whom the examination was performed. Such documentation on the film in a proper permanent fashion may also be needed for medical-legal purposes. Although most digital systems provide electronic markers, they don't always transfer with the metadata, and if the plate is held incorrectly, the laterality marker may not be on the correct side. Therefore, it is optimal to use a lead marker that indicates the limb being imaged and laterality in conjunction with the digital marker. The lead marker should be placed on the lateral aspect of the limb.

Positioning Aids

Positioning blocks are necessary for radiation safety purposes and to facilitate consistent views or projections of an examined part. Detector holders and blocks enable personnel who hold the cassette to position their hands away from the primary X-ray beam, even though they are wearing lead-impregnated gloves. For equine limb examinations, a detector holder (tunnel) for weight-bearing foot studies and a positioning block are necessary.

A plain wooden or Perspex block can be used to elevate the foot and enable acquisition of the entire foot and enable proper alignment of the X-ray beam for lateromedial and dorsopalmar/plantar views. The foot should be positioned on the block in such a way as to enable its close proximity to the cassette or plate and minimize magnification. Blocks should be used bilaterally to allow even weight bearing. A detector holder (tunnel) is necessary for the proximopalmaroproximodistal oblique (skyline) view of the navicular bone and can also be used for the dorsal 60° palmar oblique view. The detector holder protects the detector from damage caused by direct weight bearing by the horse. An alternative technique for acquiring the dorsal 60° palmar oblique view is to place the foot resting on its toe on a Redden navicular block using a horizontal beam alignment (Figure 3.4). These positioning aids allow routine examinations of the limb to be performed in a safe, consistent manner.

VetBooks.ir

Figure 3.4. Acquisition of 60° dorsoproximal to palmarodistal oblique using a Redden navicular block.

RADIATION SAFETY

The general principles of radiation safety are as follows:

1. Keeping personnel as far away from the radiation source (X-ray tube) as possible
2. Using protective barriers
3. Reducing X-ray exposure factors
4. Using a radiation-monitoring system

Keeping personnel as far away from the X-ray source as possible can be accomplished by having nonessential personnel leave the immediate area, using cassette holders and positioning blocks, providing tranquilization or general anesthesia when needed,[1] using an X-ray tube stand or support, and having a 1- to 2-meter-long cord connected to the exposure button. No part of the body should be exposed to the primary X-ray beam.

The personnel subject to the greatest exposure when performing equine examinations are those holding the horse's limb, the detector holder, and those holding the halter.[1] Therefore, if personnel must be near the animal when the X-ray examination is performed, they should wear lead personal protective equipment (PPE).

A radiation-monitoring system should be used by all radiology personnel. These systems not only provide safety guidance but also protect against possible legal implications. Film-badge monitoring systems and service can be purchased from commercial sources.

Equipment necessary for safely operating an X-ray machine includes detector holders, lead PPE, aluminum filters, and an adjustable light-beam collimator. Detector holders eliminate the need to handhold detectors, increasing the distance between hands and the X-ray beam.

Lead aprons, thyroid shields, and gloves should be worn by everyone assisting with the X-ray examination. Protective gear should have at least 0.5-mm lead equivalent. Lead PPE provides adequate protection from secondary and scattered radiation but not from primary radiation. The life of lead PPE can be prolonged by hanging them when they are not in use. This prevents cracks or holes forming in the lead-impregnated lining as a result of improper care. All lead PPE should be radiographed periodically to check for damage (Figure 3.5).

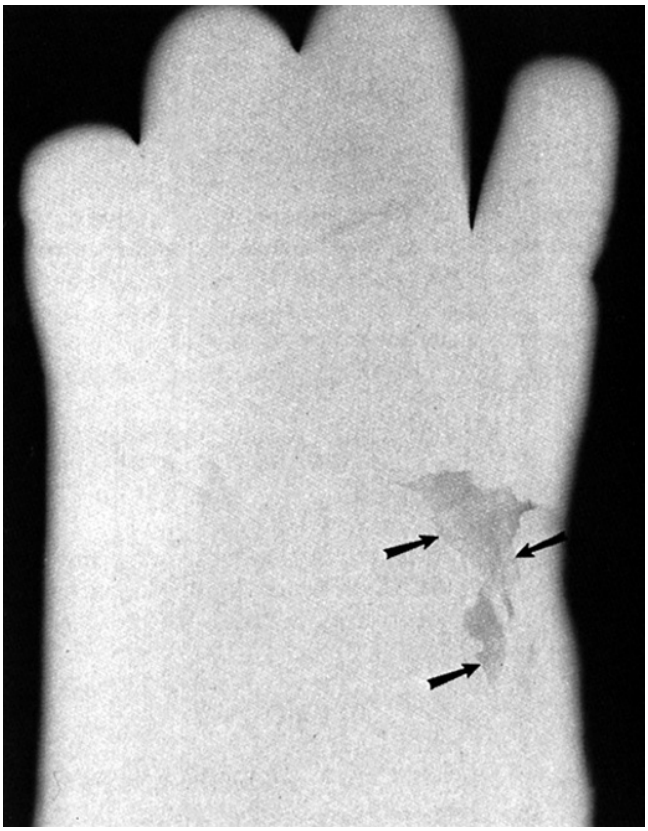

Figure 3.5. Radiograph of a lead glove, showing a lucent area (arrows) that represents a defect or hole in the lead lining.

An X-ray beam-limiting device or collimator (Figure 3.2) is an important, yet overlooked, piece of radiation safety equipment. The size of the primary X-ray beam is a major factor in determining radiation dose to the hands. Adjustable light-beam collimators have the advantage of limiting the primary X-ray beam to the exact cassette size, regardless of the FFD. The light also assists alignment of the primary X-ray beam with the cassette. Every X-ray machine should have an adjustable beam-limiting device.

In summary, the following safety measures should be observed:

- Never handhold the X-ray detector during an exposure. Detector holders or handles should be used.
- All personnel not needed for assistance with the X-ray examination should leave the immediate area.
- Lead gloves, thyroid shields, and aprons should be worn by all individuals assisting with the X-ray examination.
- A primary X-ray beam-restricting device should be used, preferably an adjustable light-beam collimator.
- If possible, rotate personnel responsible for holding the detector; avoid routinely using the same person for this job.
- Do not allow anyone under 18 years of age to assist with an X-ray examination.

VetBooks.ir

- Pregnant personnel should have limited role in X-ray examination and use additional monitoring (waist badge under lead gown).
- Chemical restraint and positioning devices should be used to minimize motion and personnel exposure and limit retake examinations
- Use a radiation-monitoring system

The veterinarian in charge is responsible for the radiation safety practices used by his/her employees. Providing necessary radiation safety equipment and following these rules should keep exposure levels below the limits recommended by the National Council on Radiation Protection and Measurements.[40]

CONTRAST EXAMINATIONS

A contrast radiographic examination consists of using a radiocontrast agent to better define suspicious lesions detected clinically or radiographically but not distinctly seen on survey radiographs. Nonionic, iodinated contrast material is most useful for contrast examinations in lame horses. While previously cost prohibitive, nonionic formulas are now more affordable and readily available and are safer than ionic contrast material. Positive-contrast agents are commercially available in an injectable form and include iohexol (Omnipaque [Nycomed Inc, 90 Park Avenue, New York, NY]) and iopamidol (Isovue [Bracco Diagnostics, Princeton, NJ]). The use of negative-contrast agents (gas) has been reported but has not found widespread, routine acceptance.[3] Procedures most commonly performed are injection of a draining tract (sinography or fistulography) and myelography. Other contrast examinations such as arthrography and tendonography have become less popular and in the majority of cases have been replaced by ultrasound, computed tomography, magnetic resonance imaging, or arthroscopy.

Fistulography or Sinography

Fistulograms provide valuable diagnostic information when chronic draining tracts or recent traumatic puncture wounds are present. Survey radiographs of the area should be made first. If the source or cause of the draining tract or puncture wound is not clearly identified on the survey radiographs, a fistulogram can be performed to obtain additional diagnostic data.[13,15,33,36]

The technique consists of injecting undiluted water-soluble triiodinated contrast material into the draining tract as aseptically as possible. Water-soluble contrast material is used because it is less viscous and penetrates chronic draining tracts more easily than oil-based contrast material. To avoid contrast material draining from the tract after injection, an inflatable, cuffed (Foley) catheter or a small polyethylene tube inserted some distance into the tract can be used before injecting the material. Filling is best accomplished if the contrast material is injected under pressure; thus, some form of occlusion of the tract opening is necessary.

When the distal extremity is being examined, it is important to flex and extend the region slowly. This allows a tract that may be closed while the horse is standing to open up, permitting the contrast to enter the tract. The volume needed for injection is not consistent, and when fistulograms are performed, the injection of an insufficient volume is a common error.[32] Contrast material should be injected until back pressure is felt on the syringe plunger or external leakage is observed. A single radiograph can also be made to determine if an adequate volume of contrast material was injected. After contrast material has been injected to delineate the entire tract, orthogonal radiographic views should be made for complete evaluation. Any contrast material that leaks onto the skin surface should be removed before radiographs are made.

A fistulogram may demonstrate (1) the extent and direction of the tract to aid in surgical exploration, (2) communication with underlying soft tissue structures (e.g. tendon sheaths or synovial joints) (Figure 3.6a), (3) osseous involvement (e.g. sequestra or osteomyelitis associated with surgical implants), and (4) filling defects (which appear radiolucent because of displacement of contrast material) (Figure 3.6b).[15] Filling defects may be caused by fibrous reaction within the tract or by foreign bodies. Fibrous tissues generally have irregular borders, whereas foreign bodies such as wood splinters have sharp, straight borders. Small foreign bodies may not be identifiable on a fistulogram because of the overlying opacity of the contrast material. In such cases, ultrasound imaging may provide additional diagnostic information.[13]

Myelography

Myelography in the horse is used to substantiate cervical spinal cord compression suspected from a neurologic and/or radiographic examination. It also serves to identify the location, extent, and type of compressive lesion present, which is necessary for determining the prognosis and indication for surgical intervention.

Prior to myelography, survey radiographic examination of the entire cervical spine is necessary. Survey radiographs should include neutral lateral images as well as right 45–55° dorsal-left ventral and left 45–55° dorsal-right ventral oblique images. The radiographs should be assessed for malalignment, cervical vertebral malformation and stenosis, articular facet pathology, fractures and osteochondrosis, disk space or endplate changes, and any other potentially relevant lesions (Figure 3.7). The accuracy of the subjective evaluation of survey radiographs for predicting a compressive lesion has been reported to be 70% at C3–C4 and only 40% in all other levels of the cervical spine.[37]

There are different methods for quantitatively assessing cervical spine survey radiographs to try to predict a possible compressive spinal cord lesion. Moore et al., in 1994, suggested the intravertebral sagittal ratio that represents the ratio of the minimum sagittal diameter of the vertebral canal to the maximum sagittal diameter of the corresponding vertebral body, obtained at the cranial aspect of the vertebra and perpendicular to the vertebral canal.[38] A sagittal ratio of less than or equal to 50% from C4 to C6 or less than or equal to 52% at C7 is a strong predictor (26.1–41.5 likelihood ratio) of vertebral canal narrowing. The sensitivity and specificity of this method for detecting cervical stenotic myelopathy is greater than or equal to 89% at each vertebral site from C4 through C7.[38] Mayhew and Green, in 2000, reported

VetBooks.ir

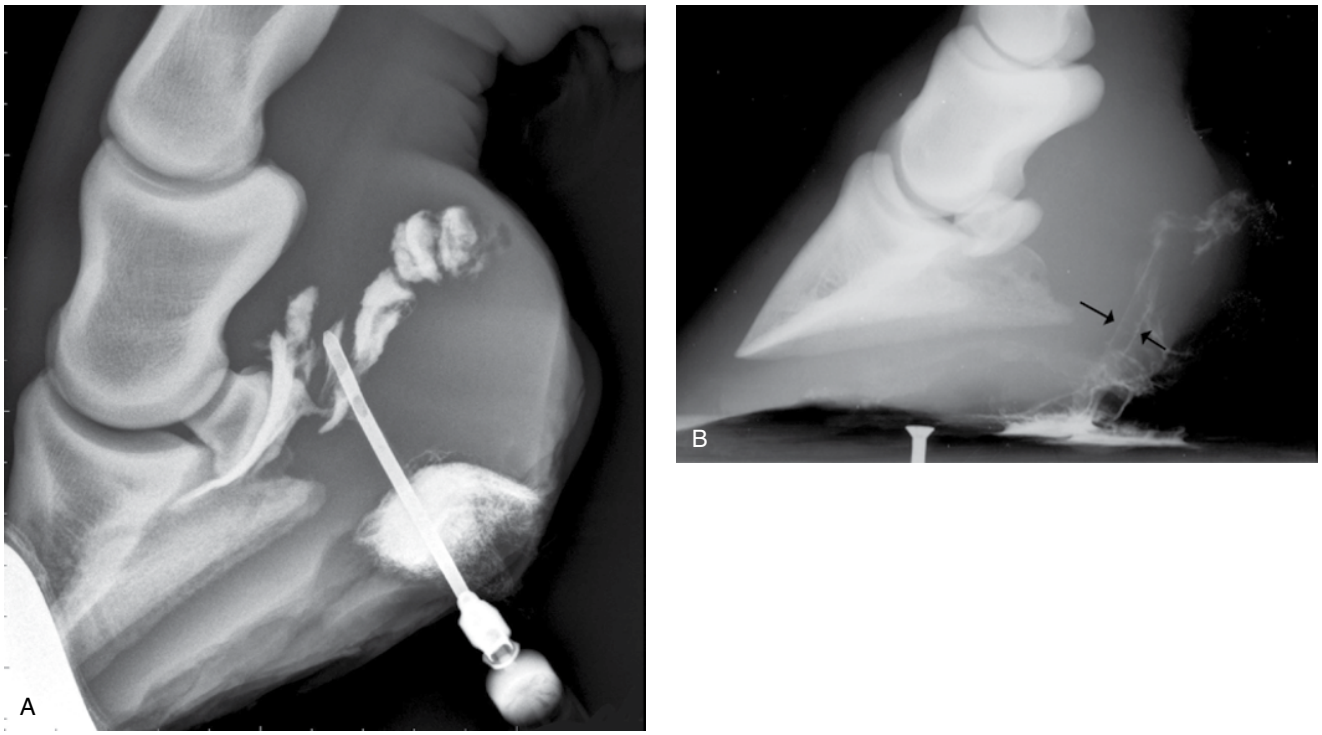

Figure 3.6. (A and B) Lateromedial (LM) projections of the distal limb after injection of iodinated contrast material into an externally draining tract. Image (A) shows filling of the navicular bursa with contrast material consistent with a communication between the draining tract and the bursa. Image (B) shows a well-defined filling defect outlined by contrast material representing a wood foreign body (black arrows).

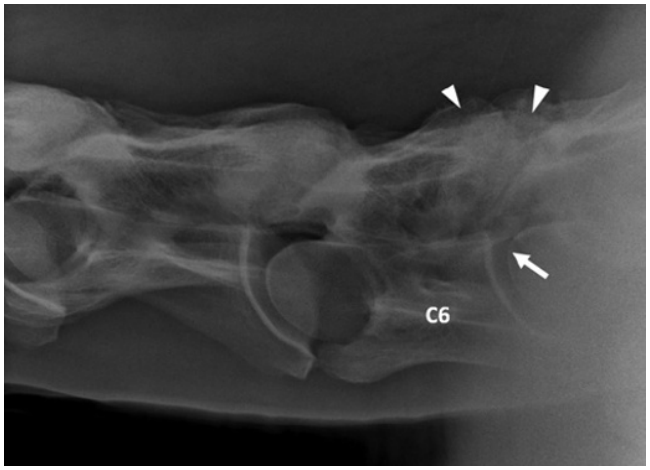

Figure 3.7. Lateral survey radiograph of the caudal cervical spine, showing moderate enlargement and irregular bony proliferation (arrow heads) around the articular facets of C6–C7, with narrowing of the intervertebral foramen (arrow). There is also mild enlargement of the articular facets at C5–C6.

the intervertebral sagittal ratio as a way to evaluate survey radiographs for cervical vertebral malformation. This technique represents the ratio of the minimal distance taken from the most cranial aspect of the vertebral body to the most caudal aspect of the vertebral arch of the vertebra located cranially and the maximal sagittal diameter of the vertebral body.[37] A study by Hahn et al. in 2008 compared the utility of the intra- and intervertebral sagittal ratio methods for diagnosing cervical vertebral malformations. It was concluded that a sagittal diameter ratio of less than or equal to 48% at any intra- or intervertebral site from C2 to C7 represents cervical vertebral malformation.[21] Hughes et al. examined intra- and inter-observer agreement of cervical vertebral sagittal diameter ratios and found that intra-observer repeatability was moderate and that significant inter-observer variation was seen, as such acceptable agreement was rarely achieved for any observer pair.[26] Considering the above discussion, the practitioner should be aware of the inevitable false-positive results because some horses may have a narrow vertebral site and not necessarily represent a spinal cord compressive lesion, as well as being cognizant of the subjective nature of such measurements and their interpretation.

Myelography with nonionic, water-soluble contrast material has proven to be an acceptable and safe diagnostic procedure in the horse.[8,33,36,44] Iohexol and iopamidol are nonionic contrast agents that have relatively few side effects.[33,37,61] With the horse under general anesthesia and in the lateral recumbent position, its head is elevated, and approximately 40–50 mL iopamidol 300, or 370 mg iodine/mL or iohexol 300, or 350 mg iodine/mL is injected into the subarachnoid space at the cisterna magna.[8,36] Iohexol may produce slightly less of an inflammatory reaction than iopamidol, but both contrast agents are relatively safe for myelography in the horse.[8] The higher concentration contrast material provides better contrast in large horses.

Lateral cervical radiographs centered over the cranial, mid-cervical, and caudal cervical regions are made with the spine in a neutral position. A flexed lateral

VetBooks.ir

projection is made in the mid-cervical region, and an extended lateral one is made in the caudal cervical region. Additional flexed and extended projections at different sites may be necessary. The contrast material can be visualized via ventrodorsal radiographs over the cranial and mid-cervical regions, but because of the thickness of the body area, it is usually not possible to visualize the contrast material in the caudal cervical region of the adult horse.

On a normal myelogram study, several variations need to be noted and not confused with false-positive lesions. On neutral lateral radiographs, there are areas of some degree of elevation of the ventral contrast column at each intervertebral disk. On flexed lateral radiographs, there is also narrowing of the dorsal subarachnoid space, most frequently at C3–C4 and C4–C5, and the ventral column at these locations appears as a thin line. On extended lateral views, the dorsal column does not narrow, and the ventral column is increased in width.

Most lesions detected via cervical myelograms in the horse are compressive lesions from cervical stenosis, either bony or ligamentous, or the result of vertebral instability (Figure 3.8). These lesions may cause substantial narrowing, obliteration, or displacement of the contrast column. The most common sites of compression, in order of decreasing frequency, are C3–C4, C6–C7, C5–C6, and C4–C5.[47] Suggested methods for assessment of a spinal cord compressive lesions include the reduction of 50% or more of the dorsal contrast column compared with the thickness of the subarachnoid space cranial to the narrowing,[44] narrowing of the dorsal and ventral contrast columns by more than 50% in

Figure 3.8. (A) Normal flexed lateral myelogram of the cranial cervical region, showing contrast material in the subarachnoid space and narrowing of the ventral column at C3–C4 (arrow). No narrowing of the dorsal column or significant spinal cord compression is present. (B) Flexed lateral myelogram of the cranial cervical region, showing ventral and dorsal (arrows) contrast columns narrowed by more than 50% and a narrowed spinal cord, suggesting dynamic cervical stenosis. (C) Extended lateral myelogram of the mid-cervical region at the level of C4–C5, showing stenosis of the spinal canal on the cranial aspect of C5 with narrowing of the dorsal contrast column by at least 50% (arrow).

VetBooks.ir

diametrically opposed sites,[47] and 40% reduction of the entire dural diameter.[58]

The results obtained from these methods should be interpreted with caution due to the risk of false-positive results. It has been suggested that a reduction of 70% of the dorsal contrast column is needed to avoid false-positive diagnosis.[6] A study by van Biervliet et al. in 2004 showed a high sensitivity and specificity of the reduction of 20% of the entire dural diameter at C6–C7 in neutral or flexed myelographic projections for diagnosing cervical stenotic myelopathy. Using this parameter at any other site, the test had only low sensitivity and high specificity.[5] One should be aware that besides obtaining false-positive results, misinterpretation of myelograms can occur with suboptimal technique or when the lesion is lateralized, and only lateral radiographic views are made. Increasing use and availability of CT myelography of the cervical spine has also revealed lateralized compressive lesions from enlarged articular process joints that may be occult on standard radiographic myelograms.[30]

Arthrography

For diagnosis of articular cartilage and subchondral bone injury, arthrography in most cases has been replaced by more advanced imaging modalities and arthroscopy. However, positive and double contrast examinations may provide diagnostic information when evaluating cartilage and subchondral bone damage in joints that are not accessible for advanced imaging such as the shoulder.[42] Arthrography continues to prove useful in assessment of traumatic joint injuries for joint capsular disruption or synovial defects (fistulae or hernias). In cases of trauma, care must be exercised to not enter the joint through damaged or contaminated tissues to minimize the risk of joint infection or inflammatory reaction.

Tendonography

Although the use of ultrasound has rendered contrast studies of tendon sheaths almost obsolete, there remain cases in which contrast studies can be useful and can be more readily interpreted than an ultrasound evaluation. In particular, the use of contrast studies when trying determining the presence of synovial herniation or intrasynovial communication is generally rewarding.[14] For example, distension of an extensor tendon sheath on the dorsal aspect of the carpus is easily evaluated with a contrast study and can determine if communication with the carpal joint exists. In addition, the use of intrathecal contrast radiography alongside intrathecal analgesia for detection of digital flexor tendon sheath pathology has been shown to provide high sensitivity (96%) and specificity (80%) for detection of manica flexoria tears.[16] Reported detection of these tears on ultrasonographic evaluation alone is as low as 52%.[53]

Other modalities such as computed tomography and magnetic resonance imaging have proved to add substantial diagnostic information in the diagnosis of soft tissue and bone injuries and will be discussed further in this chapter.

PRINCIPLES OF RADIOGRAPHIC INTERPRETATION

There are three basic steps to radiographic interpretation: (1) evaluating the quality of the examination, (2) listing radiographic findings, and (3) synthesizing a radiographic impression, diagnosis, and/or prognosis. Checking film exposure, labeling, collimation, and positioning are performed to evaluate image quality. This is an important step because poor-quality radiographs result in missed or improperly diagnosed conditions. A properly exposed radiograph should allow observation of bone and soft tissue outlines, and the film detail should be sufficient to demonstrate bone trabeculae.

Positioning should be evaluated by inspecting joint space and bone alignment. Poorly positioned studies may result from the horse not standing squarely and/or improper alignment of the X-ray tube and detector.

Complete radiographic studies with orthogonal and oblique images are required for thorough evaluation of the region of interest. Limiting studies for the sake of saving time or money risks lesions going undetected. In addition to standard studies, special projections are sometimes needed to better define and demonstrate suspected lesions.

When reading the radiograph, a systematic thorough inspection of the entire image should be done so that nothing is missed. Identifying radiographic abnormalities requires knowledge of both normal radiographic anatomy and radiographic signs of disease. Without knowledge of either, a correct radiographic interpretation is usually not made and risks both false-negative and false-positive diagnoses. One of the most common errors in assessment is termed "satisfaction of search" and refers to the tendency to incompletely examine the study for other abnormalities once one lesion is identified. This is particularly common when other abnormalities are on the periphery of the image.

The third step is formulating a radiographic impression, diagnosis, or differential diagnosis. Knowledge of disease pathophysiology and its relationship to radiographic signs is necessary for this step. The radiographic diagnosis cannot be made in a vacuum, and the radiographic findings and their significance must be correlated with other diagnostic information, such as history, signalment, physical examinations, and perineural anesthesia results, to arrive at a final diagnosis.

Radiology of Soft Tissue Structures

Soft tissue changes may be primary pathologic changes, secondary to more serious bone changes, or incidental findings of no clinical significance. Fascial planes, tendons, ligaments, and some portion of joint capsules may be seen because of adipose tissue (fat) within and around these structures. Fat is less opaque and appears slightly darker than muscle, skin, tendons, or ligaments on a radiograph (Figure 3.9). Soft tissue structures should be evaluated for thickening, mineralization, and free gas (radiolucencies).

VetBooks.ir

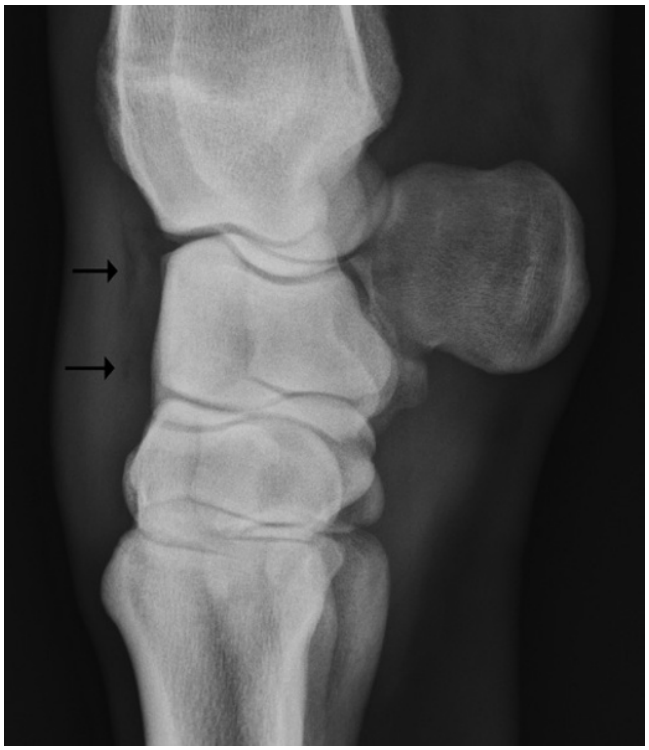

Figure 3.9. Lateromedial (LM) projection of a normal carpus showing the fat pads (adipose tissue bodies) as lucent structures within the dorsal soft tissues (arrows).

Figure 3.10. Lateromedial (LM) projection of carpal effusion. Note the soft tissue thickening on the dorsal aspect of the carpus obliterating the normal fat pads (see Figure 3.9). There are multiple, small, and irregular osseous bodies on the palmar and dorsal aspects of the carpus consistent with osteochondral fragments.

Soft Tissue Thickening

Soft tissue thickening in the equine extremity can be localized or diffuse. Diffuse swelling is often associated with edema or cellulites. Localized thickening may be identified radiographically within or around joints, tendons, or muscles (Figure 3.10). Differentials include synovial effusion, direct soft tissue injury such as tendinous lesions, and masses such as granulomas and abscesses, among other differentials. Though neoplasia of the equine limb is rare, it should still be considered as a differential when warranted. Radiographic signs of soft tissue thickening include an increased soft tissue prominence, displacement of fat bodies (adipose tissue) around the joint capsule or tendon sheaths, and mottling or obliteration of adipose tissue in fascial planes around muscles, joint capsules, or tendons.

Mineralization

Dystrophic mineralization of soft tissue in equine limbs is most frequently secondary to trauma or degenerative injury. Mineralization within ligamentous and tendinous structures usually indicates chronic or more advanced degenerative disease and is most commonly seen in the suspensory ligament branches and distal deep digital flexor tendon (DDFT; Figure 3.11).[45] Synovial mineralization and articular chondral fragment mineralization indicate chronic joint disease. Hematomas, granulomas, and areas of necrosis can mineralize as can certain types of neoplasia such as mast cell tumor.[34] Calcinosis circumscripta is a form of dystrophic mineralization most frequently seen periarticular in the horse. A round

Figure 3.11. Lateromedial (LM) projection of the distal extremity. Linear soft tissue mineralization is present just palmar to the flexor cortex of the navicular bone consistent with dystrophic mineralization of the deep digital flexor tendon in this region.

"cauliflower-shaped" appearance is usually present with calcinosis circumscripta.

Gas

Gas may be present in the soft tissue structures of equine limbs as a result of traumatic lacerations, puncture

VetBooks.ir

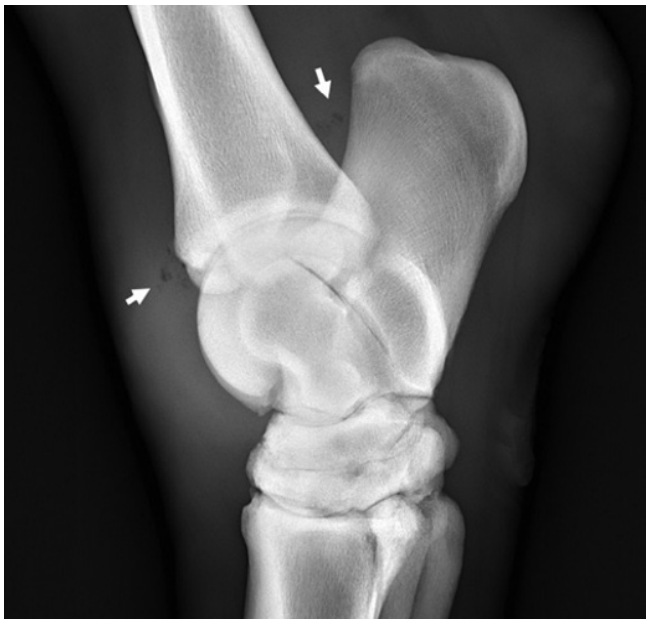

Figure 3.12. Lateromedial projection of the tarsus. Multiple, small gas opacities are visible within the proximal aspect of the tarsocrural joint (arrows). This horse was subsequently diagnosed with septic arthritis of the joint, and the presence of intra-articular gas was likely a result of anaerobic bacterial infection. Degenerative changes within the distal tarsal joints were an incidental finding.

wounds, needle centesis, or gas-producing bacterial organisms. Radiographic signs of soft tissue emphysema include radiolucent regions within soft tissue structures (the radiolucencies should be differentiated from fat) and a focal accumulation of gas with an air–fluid level that occurs with abscesses.

Localization of intra-articular gas is important diagnostically and prognostically. When gas is identified in a joint (Figure 3.12), there are three primary causes: (1) iatrogenic, incidental gas due to synovial centesis, (2) septic arthritis, and (3) "vacuum phenomenon" (nonclinically significant) gas that occurs when a joint is flexed.[20,54] In rare cases, idiopathic gas is found in markedly osteoarthritic joints; in the authors' experience, this primarily occurs in the carpus and is of uncertain origin. Because of the high clinical importance of diagnosing septic arthritis, it is preferable to obtain radiographs of a joint suspected of being septic prior to synovial centesis to reduce confounding factors for interpreting sources of intra-articular gas.

Entheses

An enthesis is a point in the bone at which a soft tissue structure attaches. The soft tissues involved can include tendons, ligaments, or joint capsule. A pathologic change at these sites is known as enthesopathy and can be secondary to many disorders, but most commonly includes trauma or degenerative or inflammatory conditions and may be intra- or extra-articular (Figure 3.13). In cases of an acute traumatic event, an avulsion fracture at the enthesis may occur. Radiographic changes associated with enthesopathy include bone erosion, bone proliferation or hyperostosis (thickening of cortical bone), sclerosis, fragmentation, and adjacent soft tissue mineralization. Enthesopathy can provide indirect evidence of other pathologic processes such as joint disease or ligamentous or tendinous injury.

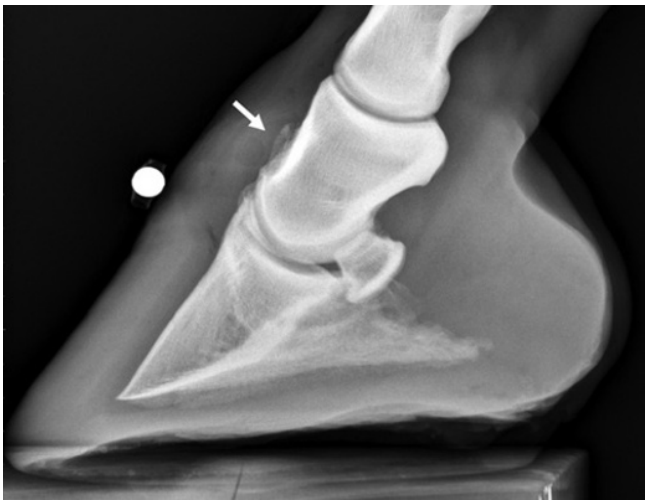

Figure 3.13. Lateromedial projection of the front foot with irregular osseous proliferation along the dorsal distal aspect of the middle phalanx (arrow), consistent with enthesopathy of the distal interphalangeal joint capsule. On magnetic resonance imaging of this region, marked diffuse articular cartilage damage was visualized within the joint.

Radiology of Bone

Fundamental Patterns of Bone Response

The response of bone to different pathologic processes is limited and consists in one or a combination of the following processes: new bone production/formation, bone resorption/destruction, or shape alteration. Bone remodeling and bone modeling are two terms that are often used interchangeably when referring to musculoskeletal radiology. Physiologically, osteoclastic and osteoblastic activities occur in both processes.

During the bone remodeling process, the osteoblasts and osteoclasts are coupled and act together; therefore, bone resorption and formation occur at the same time and at the same site on a bone surface.[18] On the other hand, during the bone modeling process, the bone alterations result from independent actions from osteoclasts and osteoblasts. This means that the bone resorption and formation may occur on different sites. In addition, modeling may cause large changes in bone structure, whereas remodeling will replace bone, maintaining the current amount of bone structure.[17] Therefore, the correct term for describing visible bone structural changes is usually modeling rather than remodeling.

Radiographically, new bone production is frequently manifested as a periosteal or endosteal reaction (adjacent to the cortex), new bone at periarticular margins or entheses, or increased bone opacity (sclerosis). Areas of bone destruction are seen as bone lysis (aggressive bone lesions or osteoarthritis [OA]) or decreased bone opacity (osteopenia). Pathologic shape alteration is commonly seen radiographically in, but not limited to, skeletally immature horses, usually secondary to physeal

VetBooks.ir

problems or abnormal weight bearing. To formulate a correct diagnosis, the clinician should note fundamental bone response patterns and distribution within bones and any associated soft tissue changes on equine limb radiographs. The clinician also should be able to differentiate whether these changes are a response to pathologic processes or secondary to normal bone modeling as adaptation to a particular athletic activity.

Periosteal Reactions

The periosteum is stimulated when elevated by hemorrhage, purulent material, edema, or infiltrating neoplastic cells. In the horse, direct trauma, extension of soft tissue infections, and avulsion of ligaments, tendons, and/or joint capsules are most frequently associated with periosteal new bone production. Periosteal bone production may be acute or chronic (Figure 3.14). Acute periosteal bone production has an irregular, indistinct border and may be continuous or interrupted, laminated, or speculated. Acute periosteal reaction is usually active. Chronic periosteal bone production has a smooth, well-defined border, is solid, and often blends with the adjacent cortex. This type of periosteal reaction is usually inactive and often indicates a healed process such as a healed fracture or previous active periosteal bone production that has changed to a chronic, probably inactive stage (Figure 3.14).

Cortical Changes

Cortical changes that can be identified radiographically consist of defects, erosions, lysis, and changes in thickness. Cortical defects seen most frequently in equine extremities are caused by fractures. Fractures must be differentiated from nutrient foramina (Figure 3.15), physeal lines, and edge enhancement shadows caused by superimposed bones. Long bone cortical stress fractures may not be evident in all cases as a distinct fracture line (Figure 3.16); a periosteal and/or endosteal reaction may be the only visible radiographic change (Figure 3.17). When a long bone fracture is suspected but not visible radiographically, it is essential to continue to treat the patient conservatively as though there were a fracture and utilize further imaging including nuclear scintigraphy and/or repeat radiographs in approximately 10 days.

Cortical lysis is usually caused by infection and typically has a permeative and/or moth-eaten pattern. A sequestrum also may be associated with a focal area of cortical lysis (Figure 3.18). In such cases, a dense sequestered piece of bone can be identified surrounded by a lytic zone (cloaca), which in turn is surrounded by bone sclerosis, producing an involucrum within the parent bone.

Cortical erosion changes can extend from either the endosteal or the periosteal surface. In the horse, they are most frequently encountered adjacent to the periosteal surface. Erosive changes with an irregular border usually result from infiltration into the bone and are most often caused by infectious processes. Cortical erosive areas with a smooth border are the result of pressure

Figure 3.14. Dorsolateral to palmaromedial oblique (DLPMO) projection of the metacarpus. Note the smooth periosteal reaction and cortical thickening of the mid-distal diaphysis of MCII, consistent with a chronic exostosis.

Figure 3.15. Lateromedial (LM) projection of the pastern. A radiolucent line is seen through the dorsal cortex of the mid portion of the first phalanx (arrow). This is a nutrient foramen that should not be mistaken for a fracture.

Figure 3.16. Craniolateral to caudomedial oblique projection of the tibia. A stress fracture of the tibia is present on the laterocaudal cortex of the mid-diaphysis. Note the smooth, thickened periosteal reaction with a faint radiolucent cortical fracture line (arrow). A subtle endosteal reaction is also present at that level. *Source:* Courtesy of New Bolton Center, University of Pennsylvania.

erosion (Figure 3.19), such as that seen with proliferative synovitis in the metacarpophalangeal or metatarsophalangeal joints.

Cortical erosions seen on the flexor surface of the navicular bone are common and significant sites of disease.[66] Flexor cortical erosive lesions most frequently begin by affecting the palmar fibrocartilage and subsequently create bone erosion.[7] However, it is also possible to have flexor cortical erosions as a result of pressure resorption from dilated synovial invaginations, possibly associated with distal interphalangeal synovitis, which affect the endosteal surface and then extend palmarly.[46] The palmoroproximal to palmorodistal oblique (skyline) of the navicular bone is an essential radiographic view to assess these types of lesions, should be standard in the foot protocol, and may require several varying angles to adequately assess the flexor surface (Figure 3.20).[27]

Cortical bone change is also associated with enthesopathy and can be proliferative, resorptive, or both. Joint capsule enthesopathies and the palmar ligaments of the pastern often are proliferative. Resorptive lesions are more frequently found at the insertion of the collateral ligaments on the distal phalanx (Figure 3.21) and the insertion of the impar ligament on the flexor surface of the distal phalanx.[10,65] The origin of the proximal suspensory ligament on the third metacarpal/metatarsal (MCIII/MTIII) bones and the insertion of the suspensory ligament branches on the sesamoid bones often have mixed resorptive and proliferative patterns.[19,55,57,60]

Cortical thickening is usually produced by increased weight bearing. Such changes in cortical width are frequently present with valgus or varus limb abnormalities or as an adaptive response to exercise.

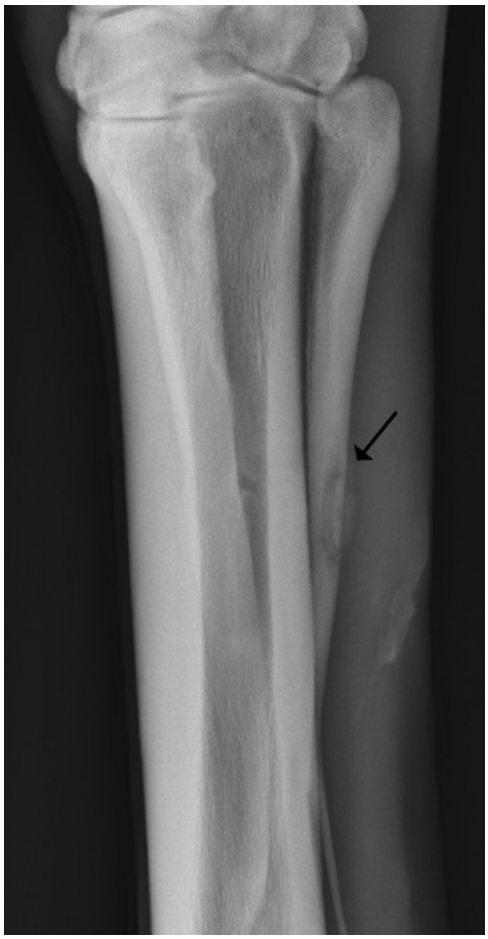

Figure 3.18. Dorsolateral to palmaromedial oblique (DLPMO) projection of the metacarpus showing a well-defined osseous body (sequestrum) surrounded by a radiolucent rim (cloaca) on the mid-diaphysis of MCIV. There is mild surrounding sclerosis and a small periosteal reaction just proximal to the cloaca, representing the involucrum (arrow).

Figure 3.19. Lateromedial (LM) projection of the metacarpophalangeal joint with marked supracondylar bone loss on the palmar cortex of distal MCIII (short arrow), secondary to chronic inflammation and effusion within the joint.

Figure 3.20. Palmaroproximal to palmarodistal oblique (Pa45Pr-PaDiO, skyline) projection of the navicular bone. On the flexor aspect of the navicular bone, note the poor corticomedullary definition, irregular medullary sclerosis, and cortical erosions consistent with advanced degenerative changes.

Trabecular Bone

Generalized bone opacity may be decreased or increased. Decreased bone density is seen secondary to chronic moderate to severe lameness resulting in decreased load bearing. The osteopenia that develops in these limbs can be recognized radiographically as a coarse trabecular pattern with or without thin cortices (Figure 3.22).

Increased bone opacity, often referred to as sclerosis, is identified radiographically with loss of trabecular pattern secondary to bone deposition within the medullary cavity (Figure 3.23). Sclerosis is a common adaptive response to load bearing and is frequently found in the third carpal bone and central and third tarsal bones (Figure 3.24). Increased bone density is also routinely seen at proximal MCIII or MTIII at the origin of the suspensory ligament.[23,56]

Radiographic Signs (Bone Response Patterns) with Osteomyelitis

Osteomyelitis in equine limbs may be hematogenous in origin or result from penetrating wounds or open fractures. The region affected depends on the source and route of infection. Both acute and chronic osteomyelitis can be identified radiographically (Figures 3.25 and 3.26). It generally takes 7–10 days after clinical signs of acute osteomyelitis are observed before the earliest detectable radiographic bone changes occur because at least 50% of mineral content must be depleted from the bone to be radiographically visible.

Because osteomyelitis can affect any bone in an equine limb and must be differentiated from other focal bone

VetBooks.ir

Figure 3.21. Dorsoproximal to palmarodistal oblique view of the distal phalanx. Osteolysis and irregular margins of the collateral ligament fossa (arrow) indicate resorptive enthesopathy. This finding was confirmed with magnetic resonance imaging.

lesions, it will be used to illustrate the use of radiographic signs or bone response patterns to arrive at a radiographic diagnosis. Identifying radiographic signs requires close inspection of the radiograph and is an important step in accurately establishing a specific or differential diagnosis.

The following are radiographic signs manifested by acute osteomyelitis:

- Soft tissue thickening adjacent to the bone is observed as increased opacity, mottling, and obliteration of adipose tissue in fascial planes.
- Periosteal new bone production. This new bone has an irregular, indistinct border and parallels the bone cortices. Subtle areas of subperiosteal bone lysis may be seen in association with the acute periosteal bone reaction. These changes are not usually seen until 7–10 days after clinical signs of the disease have been observed. As the disease progresses, the periosteal bone production parallels the cortex and spreads proximal and distal from the original infection site.
- Permeative lysis is observed as small round lucent areas, 2–3 mm in size, within cortical bone and may extend into the medullary cavity. A moth-eaten pattern of lysis with larger lucent areas can also be seen in acute and active aggressive lesions. These changes are usually seen in association with acute periosteal bone production.
- Areas of bone lysis within the physis, metaphysis, or epiphysis secondary to septic osteomyelitis in young animals are very aggressive and mostly destructive, giving little or no opportunity to the body to produce bone in the attempt to ward off the infection.

Figure 3.22. (A) Lateromedial (LM) and (B) dorsopalmar (DP) projections of a distal limb with rotating laminitis. Note the coarse trabecular pattern (more noticeable on distal P1 and proximal P2) secondary to disuse osteopenia from chronic non-weight-bearing.

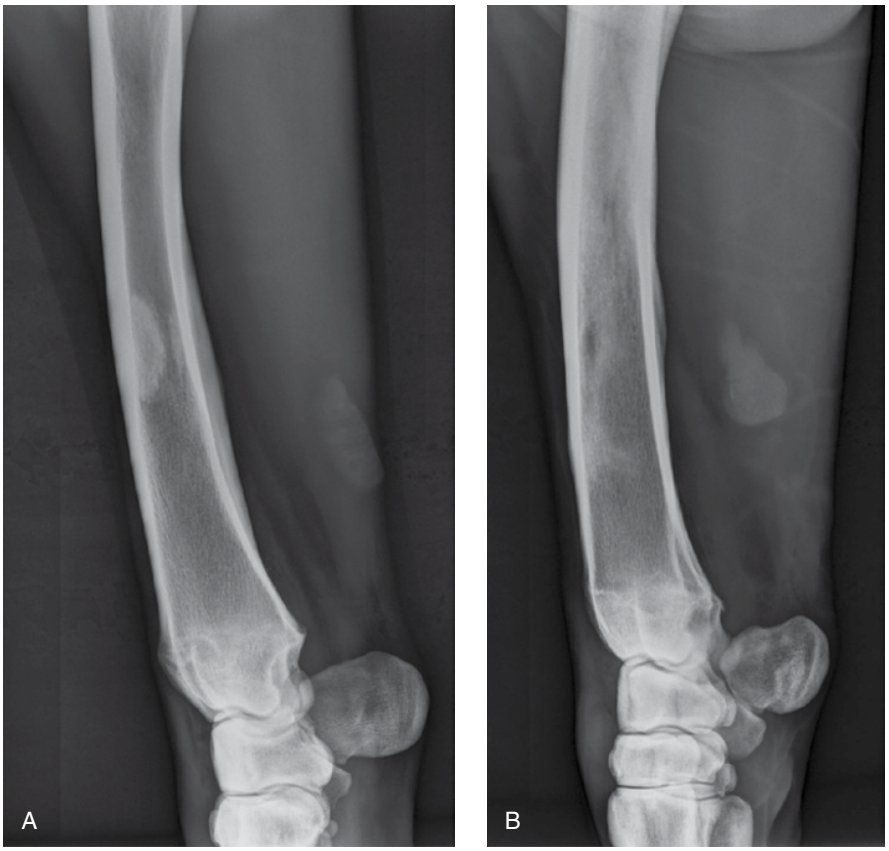

Figure 3.23. Lateromedial (LM) projections of the radius. Image (A) shows a well-defined, oval medullary sclerosis adjacent to the endosteal surface of the cranial mid-diaphysis and a similar elongated opacity adjacent to the caudal endosteal surface at the same level. Image (B) shows a diffused, irregular medullary sclerosis affecting mostly the proximal and mid thirds of the diaphysis. Nuclear medicine exams showed increased radiopharmaceutical uptake in both cases, which is consistent with enostosis-like lesions. *Source*: Courtesy of Dr. Jeremy D. Hubert.

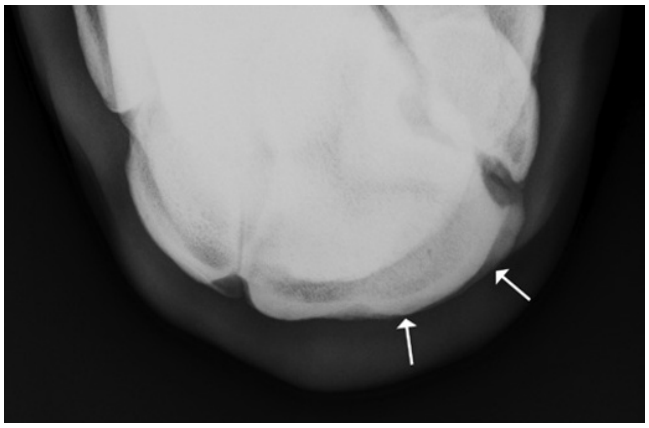

Figure 3.24. Flexed dorsoproximal to dorsodistal oblique (flexed D30Pr-DDiO) projection of the distal row of carpal bones. Note the sclerosis of the radial facet of the articular surface of the third carpal bone with partial loss of the corticomedullary definition (arrows).

Chronic osteomyelitis may have the following radiographic changes:

- Large cortical defects, some of which may be as large as 1 cm in size and can also involve the medullary cavity. Although rare, bone abscesses may appear as a geographic pattern of lysis represented by a single well-defined medullary lytic area with surrounding sclerosis.[24,64]

Figure 3.25. Dorsolateral to plantaromedial oblique (D35L-PlMO) projection of the tarsus, showing focal widening of the medial aspect of distal tibial physis with adjacent subchondral bone lysis and marked soft tissue thickening consistent with septic physitis. *Source*: Courtesy of Dr. Jeremy D. Hubert.

Figure 3.26. Lateromedial (LM) projection of the distal radius with radiographic changes, consistent with osteomyelitis. Note the irregular and discontinued periosteal reaction with lysis of the craniodistal cortex of the distal radius and adjacent ill-defined increased medullary opacity and soft tissue thickening. On the most proximal aspect of the lesion, the cranial cortex is wider and presents a circular mineral opacity with a surrounding radiolucent rim and sclerosis, suggesting the presence of a sequestrum (arrow). *Source*: Courtesy of Dr. Gary Baxter.

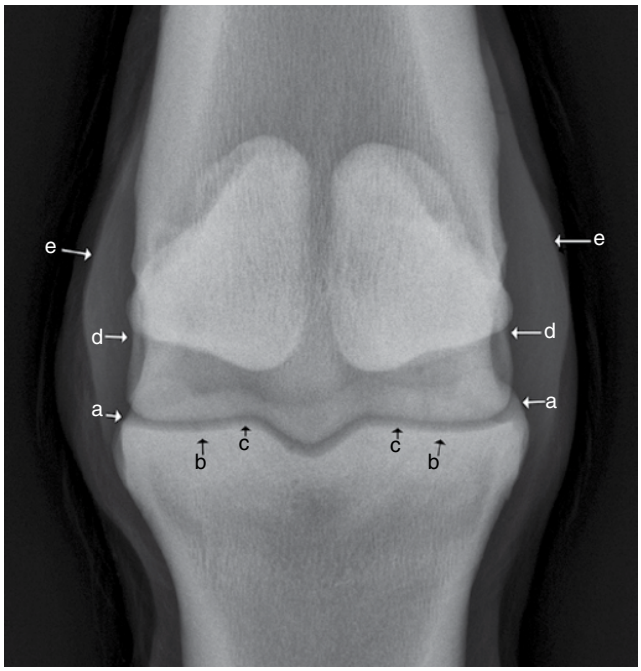

Figure 3.27. Dorsoproximal to distopalmar oblique (D30Pr-DiPaO) projection of a normal metacarpophalangeal joint, showing an example of the structures that should be evaluated around a joint. (a) Joint margins. (b) Subchondral bone. (c) "Joint space" (articular cartilage). (d) Areas for collateral ligament attachment. (e) Joint capsule and general joint alignment.

- Localized increased bone densities (sclerosis), which are produced within the host bone, e.g. thick cortices, and in which a sequestrum sometimes may be identified within the sclerotic and lytic bone patterns.
- Periosteal bone production, which is usually abundant with a well-defined irregular or smooth border.
- It is often impossible to determine radiographically whether chronic osteomyelitis is active or inactive. This diagnosis is best determined by physical examination, clinical signs, or other imaging techniques, such as nuclear scintigraphy.

Radiology of Synovial Joints

Radiographic evaluation of joints in the equine limb is an important part of the diagnostic workup for lameness and encompasses evaluation of multiple components, including soft tissue structures (both intracapsular and extracapsular); joint margins; subchondral bone; joint space and alignment; and ligament, tendon, and joint capsule attachment areas (Figure 3.27).

Normal Joint Structures

The joint capsule and periarticular soft tissue structures should not be distended. Fat bodies and adipose tissue within muscle fascial planes can be identified around some normal joints. Visibility and location of adipose tissue may change with inflammation or joint capsule distension or thickening. The normal location and the presence of fat bodies vary, depending on the joint and animal being examined.

Joint margins are bony regions at the edge of articular cartilage that also coincide with the edge of the subchondral bone. Articular cartilage, the periosteum, and the joint capsule meet in this region. In the normal joint, the margins are smooth and blend with the surrounding bone structures. Subchondral bone is a dense, compact bony zone 1–3 mm in width and adjacent to the articular cartilage. The subchondral bone surface adjacent to the articular cartilage is smooth and even.

The area referred to as radiographic "joint space" is not an actual space but is composed of articular cartilage with a thin layer of synovial fluid between the opposing cartilaginous surfaces. It appears radiolucent on a radiograph, compared with the adjacent radiopaque subchondral bone. The joint space should be of even thickness throughout a specific joint, but thickness differs from joint to joint; e.g. the distal interphalangeal joint space is wider than the proximal interphalangeal joint space, which is wider than the metacarpophalangeal joint space.

Ligaments, tendons, and the joint capsule, which attach periarticularly, add stability to the joint. The attachment areas vary with the joint and may be located at different distances both proximal and distal to the joint margins. It is important to know regions of insertion for ligaments and tendons around specific joints.

VetBooks.ir

The normal subchondral bone surfaces should align evenly. Positional changes of the horse or of the X-ray tube when the radiograph is made may make a normal joint appear slightly malaligned.

Radiographic Changes Associated with Joint Disease

Radiographs are a first-line screening tool for assessing joint disease. The radiographic manifestations of joint disease occur in the soft tissue and bone structures and may develop before or after clinical signs of the disease develop, depending on the type and severity of disease. Bone changes follow clinical signs in septic arthritis, whereas bony changes may either precede or follow clinical evidence of disease with OA.

Soft tissue changes associated with joint disease may be radiographically evident prior to bone change, although this is somewhat joint dependent. Common soft tissue abnormalities include periarticular soft tissue thickening, joint distension due to effusion and/or synovitis, and mineralization. The location of fat pads and adipose tissue in fascial planes can be used to evaluate periarticular swelling and joint capsule distension. Joint distension is more readily identified in some joints than others; for example, effusion of the fetlock joint is typically obvious, whereas distension of the medial or lateral femoral tibial joints is challenging to detect radiographically. Periarticular mineralization may be associated with numerous causes but in the horse is predominantly dystrophic or secondary to blunt soft tissue trauma.

Periarticular osteophyte formation is the most common change found on the joint margin in the OA process (Figure 3.28). Not all osteophytes are clinically significant, particularly when mild and/or when seen on low-motion joints. Marginal bone lysis can be found on joint margins in joints affected with more advanced OA and is also a hallmark finding for septic arthritis (Figure 3.29). In early stages, marginal changes may be subtle, but with advanced or more severe disease, the changes are easily identified.

Subchondral bone changes include sclerosis, lysis, and fragmentation (Figure 3.30). Subchondral bone sclerosis is often found as an adaptive response to exercise; however, with increasing sclerosis, the sclerosis changes from adaptive to maladaptive and can be associated with degenerative disease and increased risk of subchondral necrosis and fracture.[12,28,39,43] Subchondral bone lysis can have a local or general distribution within the joint and may be seen in association with subchondral bone fragments. Subchondral bone lysis may be present with septic arthritis, OA, and osteochondrosis, as well as secondary to trauma. While lysis is a defining characteristic of septic arthritis, subchondral bone lysis is also seen with OA, particularly in low-motion joints. OA of low-motion joints, particularly the distal tarsus and carpometacarpal joints, can present with extensive subchondral lysis, and it is important to differentiate this from a septic process. Localized, well-defined lytic

Figure 3.28. Lateromedial projection of the carpus. Moderate periarticular osteophytosis is present at the middle carpal and the carpometacarpal joints with mild sclerosis of the cuboidal bones involved.

Figure 3.29. Lateromedial (LM) projection of the distal limb showing radiographic changes consistent with advanced, severe septic arthritis. Note the severe irregular subchondral bone lysis on the adjacent articular surfaces of the distal interphalangeal (DIP) joint with marked articular cartilage loss, circumferential irregular periosteal proliferation, and the severe soft tissue thickening with irregular skin surface centered over the dorsal aspect of the DIP joint. In addition, there is a coarse trabecular pattern on P1 consistent with disuse osteopenia.

VetBooks.ir

Figure 3.30. Lateromedial (LM) projection of the distal limb. Severe chronic degenerative changes are present on the proximal and to a lesser degree the distal interphalangeal joints consistent with osteoarthritis (high and low "ringbone"). Note the marked undulating bone proliferation (osteophytes and enthesophytes) on the dorsal aspect of P1 and P2 and extensor process of P3; there is severe narrowing of the proximal interphalangeal joint with adjacent subchondral bone sclerosis. Enthesophytes are also seen on the palmar aspect of distal P1 and proximal P2. *Source*: Courtesy of Dr. Gary Baxter.

lesions are seen with osteochondrosis or repetitive trauma, which may develop into subchondral cyst-like lesions. Focal subchondral lytic areas associated with bone fragments are seen with osteochondritis dissecans and traumatic arthritis lesions from chronic microfractures in the subchondral bone.

The joint space width may be increased or decreased. Increased joint space associated with marked subchondral bone lysis can be seen with extensive septic arthritis (Figure 3.29). A decreased joint space, either general or localized within the joint, is associated with cartilaginous lesions and degeneration and occurs predominately with OA. Decreased joint space is usually accompanied by subchondral bone sclerosis (Figure 3.30). It is important to be sure that the patient is standing squarely to avoid positional joint space narrowing.[11]

Periarticular enthesophytes are usually associated with joint capsule, ligament, or tendon damage or avulsion from their bony attachments (Figure 3.13). The location, larger area of bone change, and typically more undulating margins of enthesophytes typically help distinguish them from osteophytes; however, in some locations such as the dorsoproximal third metatarsal bone, it can be difficult to differentiate enthesopathy from osteophytosis.

Alignment abnormalities may consist of subluxation or luxation of a joint or may simply result in an abnormal degree of flexion or extension of a joint in a resting position. Abnormal joint alignment may be associated with ligament laxity and/or injury (Figure 3.31); tendon

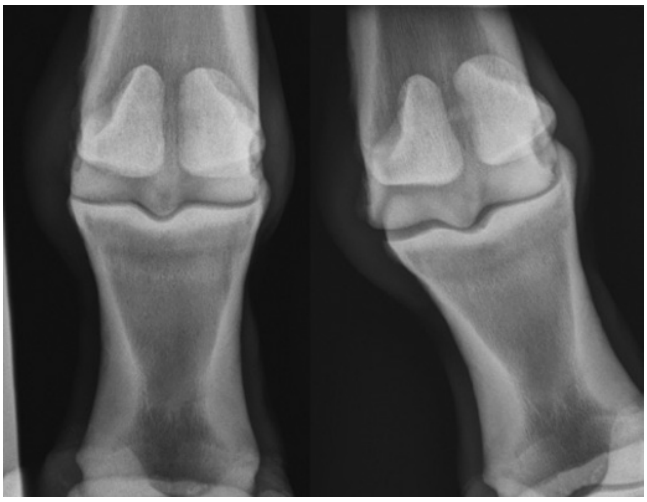

Figure 3.31. Medial (left) and lateral (right) stressed dorsopalmar views of the metacarpophalangeal joint. There is soft tissue swelling along the lateral aspect of the joint. On the lateral stress view, there is asymmetric widening of the lateral aspect of the joint. This is not seen on the medial aspect of the joint during medial stress. These findings are indicative of severe damage or rupture of the lateral collateral ligaments of the fetlock joint.

injury or contracture; abnormal bone growth, i.e. angular limb deformities in foals; and healed, malaligned fractures. Chronic alignment abnormalities predispose the joint to OA from abnormal weight bearing and stress distribution through the joint.

Radiographic Changes with Specific Joint Conditions

As discussed above, there are cardinal radiographic changes associated with joint disease. Some of the changes are seen across multiple types of joint disease, whereas other findings are predominant for specific types of pathologic processes. Below is a summary of typical radiographic findings of specific joint conditions.

Osteoarthritis

OA is a common pathologic process in horses. The changes seen radiographically are secondary to inflammation and degenerative processes within the joint, predominantly those affecting the articular cartilage. The degree of secondary change not only is somewhat dependent on the severity and chronicity of the disease process but also can vary by joint, as some joints are more prone to secondary osteoarthritic changes than others (Figures 3.28, 3.30, and 3.32). The following are radiographic changes seen in OA of the horse:

- Periarticular osteophytes.
- Subchondral bone sclerosis.
- Narrowed joint space, which may involve all or only part of the joint; distinct, smooth borders remain on the subchondral bone adjacent to the articular cartilage.
- Focal or multifocal, well-defined subchondral bone lysis, most frequently in low-motion joints.
- Degenerative subchondral cyst-like lesions secondary to chronic subchondral bone and articular cartilage injury.

VetBooks.ir

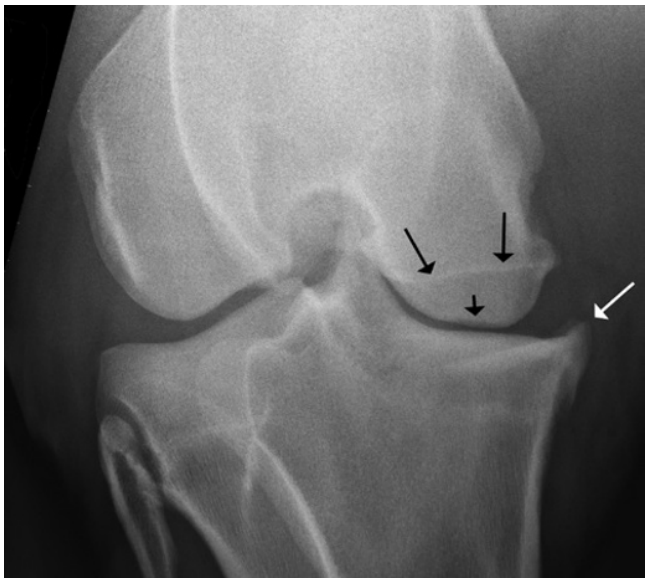

Figure 3.32. Caudocranial (Ca-Cr) projection of the stifle. A rounded periarticular osteophyte is present on the medial periarticular margin of the medial tibial condyle, consistent with osteoarthritis (white arrow). The articular surface of the medial femoral condyle has a slight concave defect (short black arrow). The horizontal radiopaque line on the cranial margin of the medial femoral condyle (long black arrows) indicates enthesophytosis at the insertion of the medial femorotibial and medial aspect of the femoropatellar joint capsules.

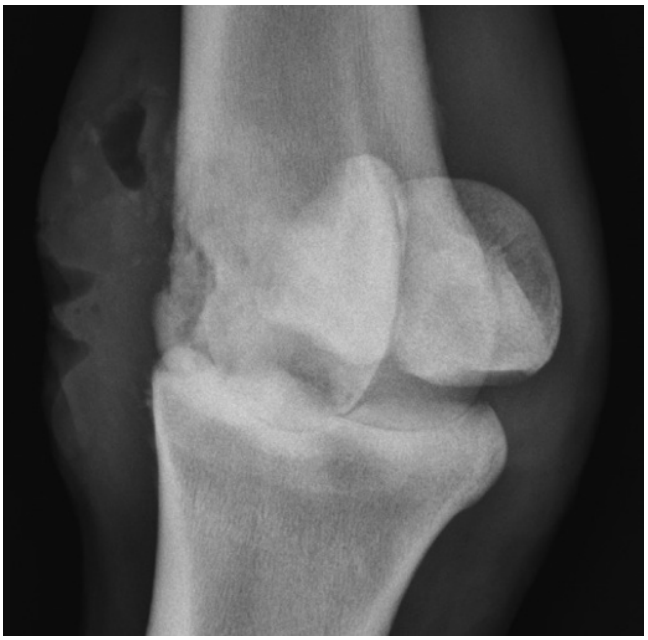

Figure 3.33. Dorsomedial to palmarolateral oblique (DMPLO) projection of the metacarpophalangeal joint. An area of permeative lysis is present on the dorsal aspect of the lateral condyle of MCIII. Marked narrowing of the joint space, mild irregular periosteal reaction on the dorsolateral aspect of proximal P1, and associated soft tissue thickening with subcutaneous gas are also present. These findings are consistent with septic arthritis.

Septic Arthritis

In foals, septic arthritis is most commonly hematogenous in origin. Septic arthritis in adult horses typically occurs from penetrating wounds, as an iatrogenic consequence of needle centesis or, less frequently, an extension of adjacent osteomyelitis or cellulitis. (Figures 3.29 and 3.33). The following are radiographic signs of septic arthritis:

- Periarticular soft tissue thickening and joint distension.
- Marginal bone lysis, which may occur early in the disease.
- Subchondral bone destruction, which may be an extension from or occur without the marginal lysis.
- Periosteal reactions, which may be adjacent to the joint but are generally distributed around the joint; when septic arthritis has occurred from extension of an adjacent osteomyelitis or cellulitis, the periosteal reaction may precede the intra-articular changes.

Osteochondrosis

Osteochondrosis is associated with regions of high predilection in specific joints, which should be observed when diagnosing the condition. In the horse, the stifle, tarsus, and fetlock are most commonly affected by osteochondrosis, although lesions can be found in all joints. It is caused by defective osteochondral development, which usually involves subchondral bone (Figures 3.34–3.37). The following are radiographic changes present with osteochondrosis:

Figure 3.34. Dorsolateral to palmaromedial (DLPMO) projection of the tarsus. There is a well-defined, irregular lucent line through the distal intermediate ridge of the tibia with an associated osseous fragment (arrow). There is mild sclerosis surrounding the lesion. This is a common site of osteochondritis dissecans (OCDs).

VetBooks.ir

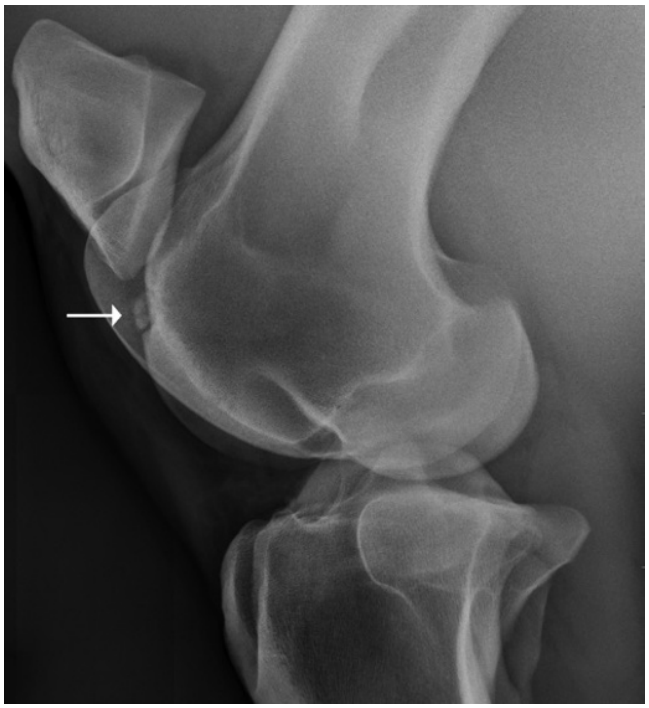

Figure 3.35. Lateromedial (LM) projection of the stifle. Note the well-defined, oval, osseous body associated with a concave subchondral bone defect on the lateral trochlea ridge (arrow), consistent with osteochondritis dissecans.

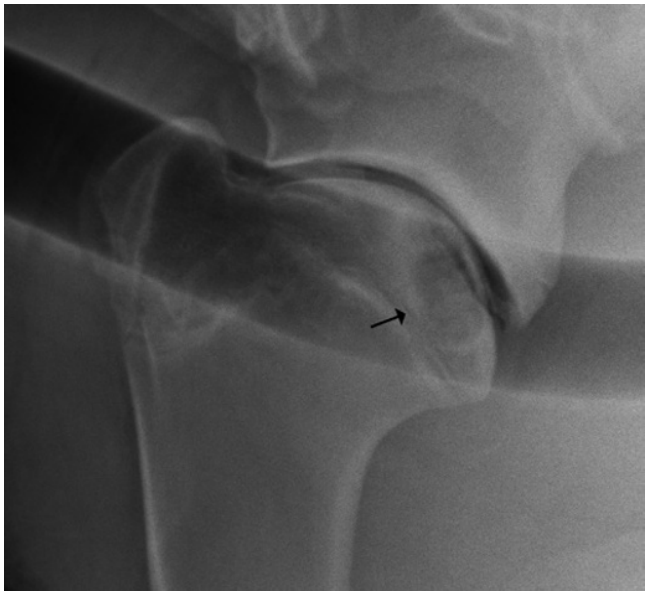

Figure 3.36. Mediolateral (ML) projection of the shoulder. A large radiolucent subchondral bone defect (cyst) surrounded by a rim of sclerosis is seen on the caudal aspect of the humeral head (arrow), consistent with osteochondrosis.

- Flattening of the subchondral bone surface with adjacent subchondral bone sclerosis.
- Localized subchondral bone defect, typically well defined and generally smooth.
- Osteochondral bone fragments, which are seen radiographically as osseous bodies representing osteochondritis dessecans.

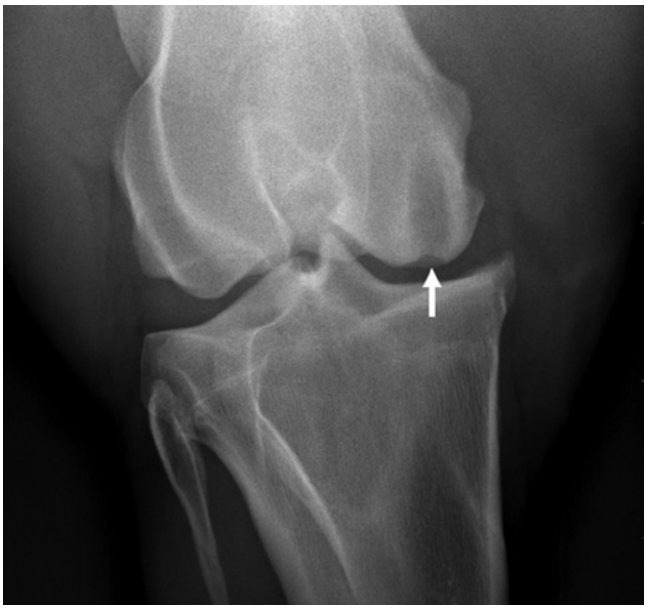

Figure 3.37. Caudocranial (CdCr) projection of the stifle. There is a large, well-defined ovoid radiolucent subchondral bone defect (cyst) surrounded by a rim of sclerosis in the medial femoral condyle (arrow). Subchondral cystic lesions of the medial femoral condyle can be a result of osteochondrosis or trauma.

- Secondary osteoarthritic changes that may also be present.
- Subchondral cyst-like lesions that may develop secondary to osteochondrosis.
- Joint distension may be present, particularly noticeable in the tarsocrural joint.

Traumatic Joint Disease

Traumatic joint disease is caused by repetitive trauma that causes microfracture and bone necrosis and can lead to subchondral lysis, cystic lesions, and fragmentation.[28] Areas of predilection for traumatic joint disease are the metacarpophalangeal joints (Figure 3.38) and carpus (Figure 3.39). Traumatic joint disease may also develop after hyperextension injury in joints such as the carpus, producing microfractures, subchondral bone lysis, and small subchondral bone fragments. The following are radiographic signs of traumatic joint disease:

- Focal subchondral bone lysis with indistinct borders
- Subchondral bone sclerosis
- Bone fragments, which may be adjacent to the subchondral bone lysis
- Incomplete articular fractures or subchondral fissures (stress fractures)
- Changes in contour of the bones, such as flattening of the articular surface

LIMITATIONS OF RADIOGRAPHY

Radiography is the most common imaging modality and is widely used for the diagnosis of musculoskeletal injuries. While an excellent screening tool, radiography has well-known limitations. Radiography allows identification of soft tissue thickening and indirect evidence of soft

VetBooks.ir

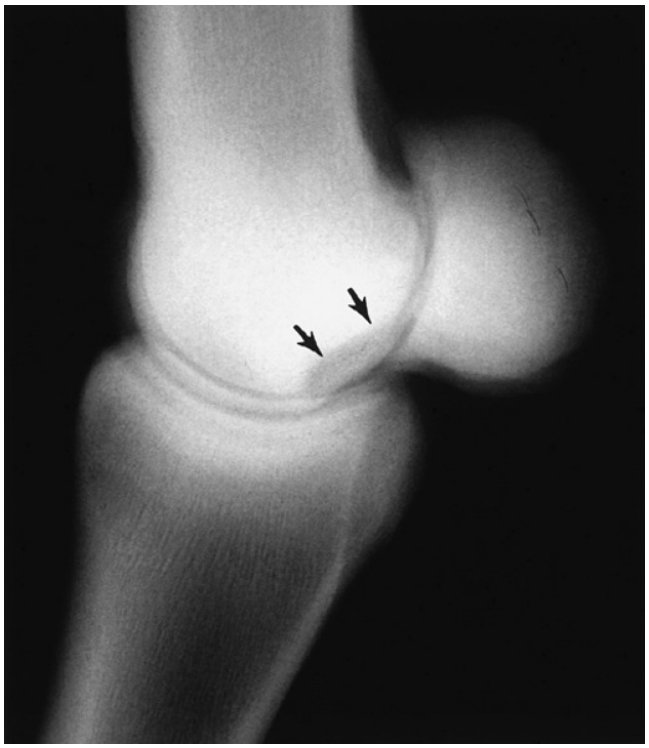

Figure 3.38. Lateromedial (LM) projection of the metacarpophalangeal joint showing palmar osteochondral disease of MCIII (arrows).

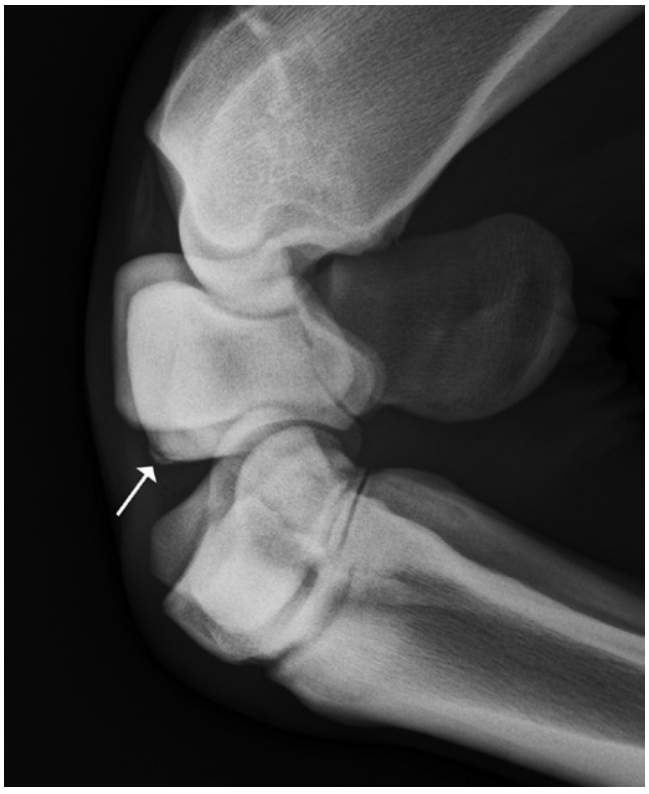

Figure 3.39. Flexed lateromedial (flexed LM) projection of the carpus. tissue injuries due to secondary bone change; however, there are marked limitations in the ability for radiography to evaluate soft tissue injures. In order to have the most accurate diagnosis and subsequently be able to provide the best care to the patient, visualization of architectural changes within the soft tissues is essential. Ideally, in these cases, other imaging modalities (i.e. ultrasound or MRI) should be considered to complement the radiographic findings.

Skeletal abnormalities are identified radiographically based on changes in bone density/opacity (reduced or increased) and shape. Because skeletal lesions may only be detected with radiographs after approximately 50% change in bone mineralization is present, some conditions such as acute osteomyelitis, early synovitis, early cartilage loss/erosive arthritis, and minimally or nondisplaced fractures may not be recognized on the initial radiographic exam. In cases of acute trauma, it may take up to 2 weeks before the bone changes are detected with plain radiographs. It is also possible to have relatively extensive articular cartilage damage with minimal radiographic changes. Therefore, when clinical signs and radiographic findings are incompatible, or radiographic findings are insufficient, further imaging with other modalities is often required.

In cases of comminuted fractures, it can be difficult to completely characterize the extent and orientation of the fracture radiographically. In these cases, computed tomography with multiplanar reconstructions should be considered for surgical planning.

In summary, the practitioner should be aware of the abovementioned limitations of radiography and that the combined results of different imaging modalities may be necessary to obtain a diagnosis. More important, it should always be remembered that radiographic changes do not necessarily represent lameness; therefore, a complete history and thorough physical and lameness examinations are imperative in every clinical situation.

NORMAL RADIOGRAPHIC ANATOMY

Recognition of normal radiographic anatomy and variations of normal in the mature and immature horse is essential in equine radiology to avoid erroneous diagnoses. The normal radiographic anatomy of horse extremities is presented for reference in the following pages (Figures 3.40–3.88). A diagram accompanies each of the radiographic projections, demonstrating the position of the X-ray machine and detector in relation to the anatomical site of interest, as well as the angle orientation of the X-ray beam. In addition, radiographic projections not commonly included in a standard examination are described. A brief explanation of the advantage of obtaining these projections is also included.

The nomenclature system used in this chapter is that proposed by the Nomenclature Committee of the American College of Veterinary Radiology,[40] which uses proper veterinary anatomic directional terms[26] and describes the direction in which the central X-ray beam penetrates the body part of interest, from the point of entrance to the point of exit (Figure 3.40). The standard abbreviation for the view is given in parentheses in the figure legends.

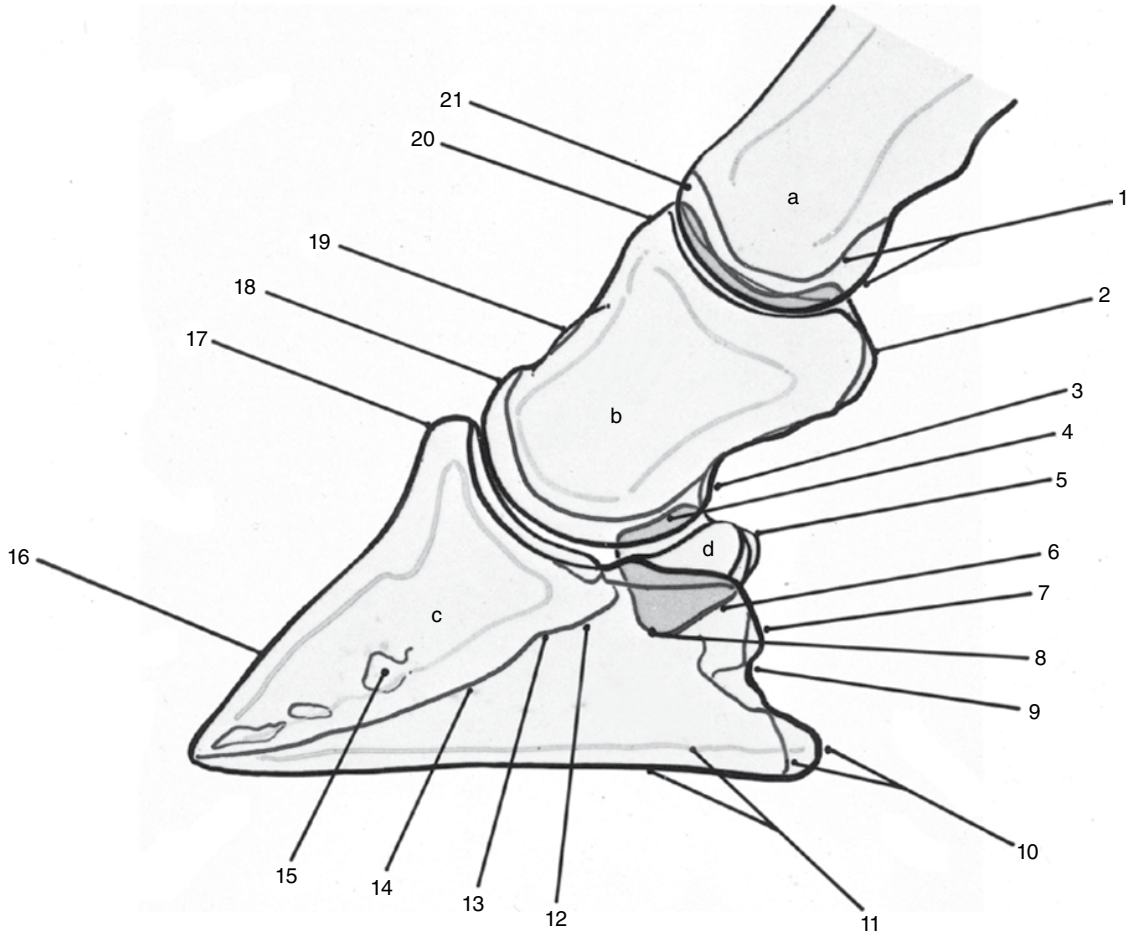

Figure 3.41. (*Continued*) Lateromedial (LM) projection of the distal phalanges and navicular bone. (a) Proximal phalanx, (b) middle phalanx (c) distal phalanx, and (d) navicular bone.

1. Palmar aspect of the medial and lateral condyles on the distal extremity of the proximal phalanx.
2. Transverse bony prominence on the proximopalmar aspect of the middle phalanx.
3. Superimposed medial and lateral condyles on the distopalmar aspect of the middle phalanx.
4. Articular surface of the navicular bone.
5. Proximal border of the navicular bone.
6. Flexor cortex and surface of the navicular bone; the medullary cavity (spongiosa) is the less opaque area in the center of the navicular bone.
7. Superimposed medial and lateral proximal parts of the palmar process on the distal phalanx. The size of this palmar process varies depending on the mineralization and ossification of the collateral cartilages. The palmar process also superimposes over the navicular bone, sometimes creating confusing opacities.
8. Distal border of the navicular bone, the border of which may appear as a distinct ridge or may blend with the contour of the navicular bone. Slight obliquity on the lateromedial projection alters the navicular bone's apparent shape.
9. Palmar process incisure.
10. Superimposed distal parts of the medial and lateral palmar processes on the distal phalanx.
11. Medial and lateral distal (solar) borders of the distal phalanx. On oblique projections, these borders may be separated farther.
12. Flexor surface of the distal phalanx, where the deep digital flexor attaches.
13. Semilunar line on the solar surface of the distal phalanx.
14. Opaque line representing the bone cortex on the concave solar surface of the distal phalanx.
15. Solar canal of the distal phalanx on end. This canal makes a semicircular loop in the distal phalanx, and its visibility depends on its size and the X-ray beam angle.
16. Dorsal surface of the distal phalanx.
17. Extensor process of the distal phalanx, which may have a single-humped, double-humped, or pointed appearance. The surface should always be smooth.
18. Dorsal extent of the distal articular surface on the middle phalanx. The slight projection on the articular margin should not be mistaken for an osteophyte.
19. Eminences for collateral ligament attachments from the distal interphalangeal joint. They may be prominent or small, but their surface should be smooth; they should not be mistaken for periosteal bone production.
20. Extensor process of the middle phalanx.
21. Distal dorsal articular surface of the proximal phalanx.

2. Medial and lateral depressions for attachment of collateral ligaments.
3. Proximal palmar border of the middle phalanx.
4. Articular cartilage thickness in the proximal interphalangeal joint space, which is approximately half the thickness of the articular cartilage in the distal interphalangeal joint.
5. Medial and lateral eminences for ligamentous and tendinous attachments on the proximal palmar aspect of the middle phalanx.
6. Proximal border of the navicular bone, which is seen with the least amount of distortion on this projection. It should be straight, smooth, and distinct.
7. Dorsal eminences on the medial and lateral aspects of the middle phalanx for attachment of the collateral ligaments of the distal interphalangeal joint.
8. Medial extremity of the navicular bone, which is slightly more rounded in appearance than the lateral extremity.
9. Proximal part of the medial palmar process on the distal phalanx.
10. Medial aspect of the distal articular surface on the middle phalanx.
11. Proximal articular surface of the distal phalanx; palmar and dorsal borders.
12. Fossa on the palmar medial surface of the distal phalanx.
13. Distal palmar border of the navicular bone, which cannot be adequately evaluated on this projection because of superimposition over the distal interphalangeal joint.
14. Extensor process for the distal phalanx.
15. Fossa on palmar lateral surface of the distal phalanx.
16. Proximal part of the lateral palmar process, the size of which depends on the extent of ossification in the cartilages of the distal phalanx. Separate ossification centers may occur in this region and should not be mistaken for fracture fragments.
17. Lateral extremity of the navicular bone, which has a sharper-angled appearance than the medial extremity.
18. Proximal articular surface (articular fovea) of the middle phalanx.
19. Distal articular surface of the proximal phalanx.

VetBooks.ir

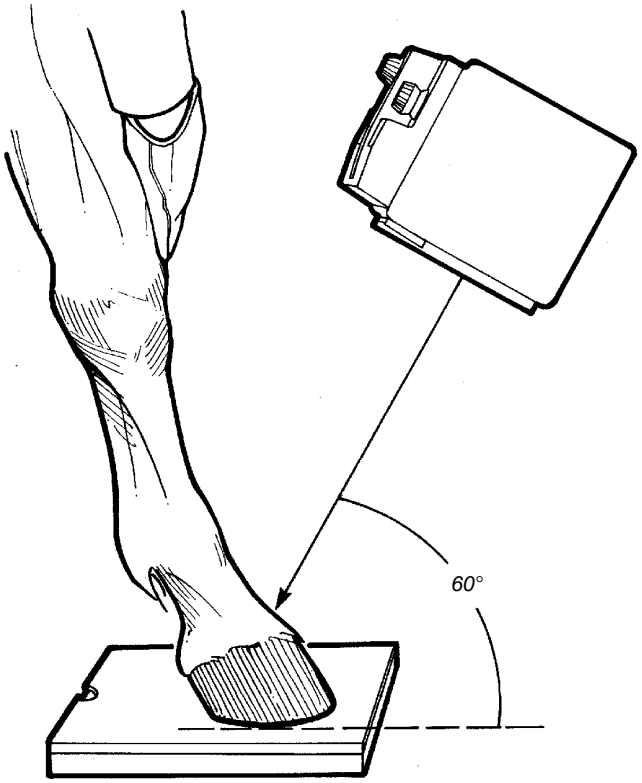

Figure 3.43.

VetBooks.ir

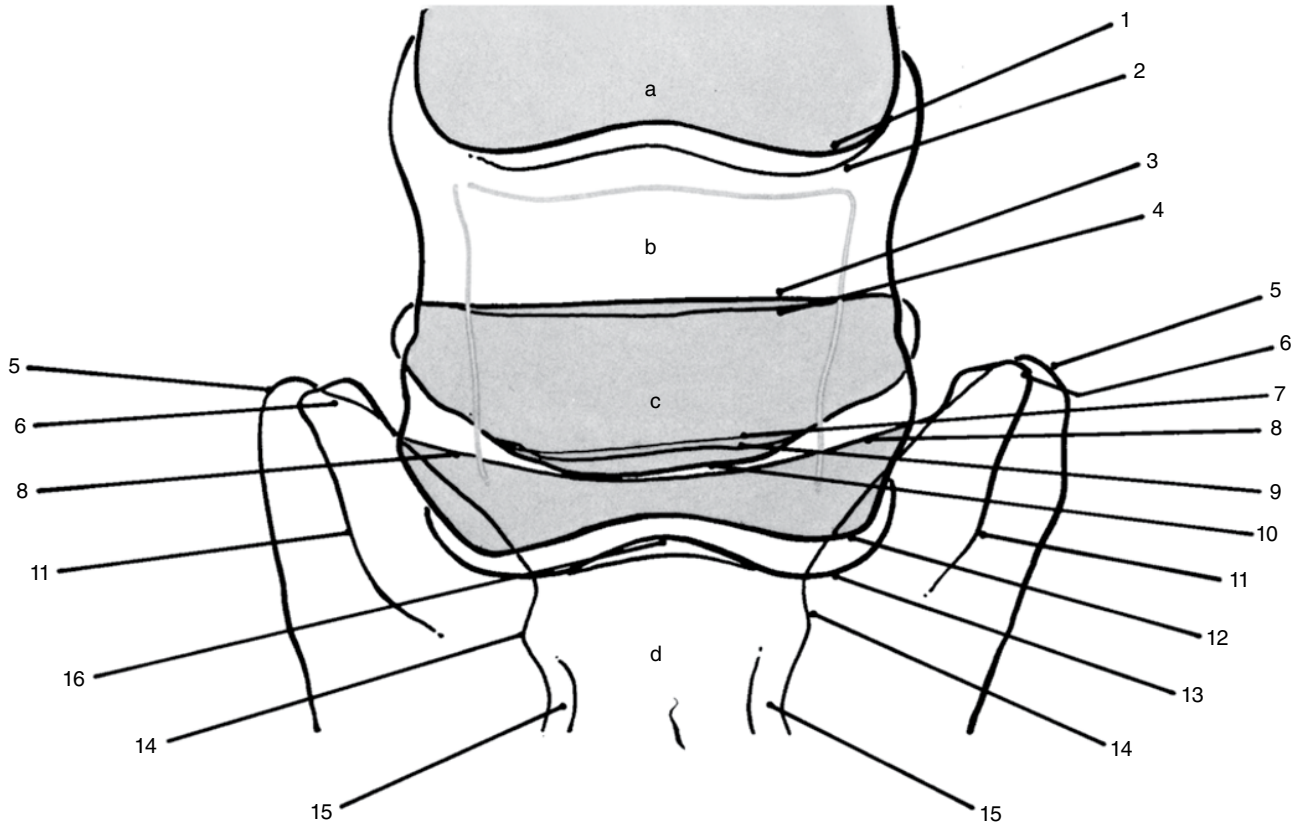

Figure 3.43. (*Continued*) Dorsoproximal to palmarodistal oblique (D60Pr-PaDiO) projection of the distal phalanx and navicular bone (foot). This projection is used extensively for evaluating the navicular bone. Position and exposure are critical for optimal visualization. (a) Proximal phalanx, (b) middle phalanx, (c) navicular bone (distal sesamoid bone), and (d) distal phalanx.

1. Distal articular surface of the proximal phalanx.
2. Proximal articular surface of the middle phalanx.
3. Proximal border of the flexor surface on the navicular bone.
4. Proximal border of the articular surface on the navicular bone, which often looks indistinct and slightly irregular on this projection because of the projection angle of the X-ray beam.
5. Distal part of the medial and lateral palmar processes.
6. Proximal part of the medial and lateral palmar processes.
7. Groove on the distal navicular bone between the flexor and articular margins. Vascular foramina are in this groove.
8. Palmar articular margin of the distal phalanx.
9. Distal margin on the navicular bone.
10. Distal margin of the flexor surface on the navicular bone.
11. Medial and lateral parietal sulci on the distal phalanx.
12. Distal articular surface of the middle phalanx.
13. Articular border of the distal phalanx.
14. Medial and lateral solar grooves on the solar surface of the distal phalanx.
15. Solar canal.
16. Extensor process of the distal phalanx.

VetBooks.ir

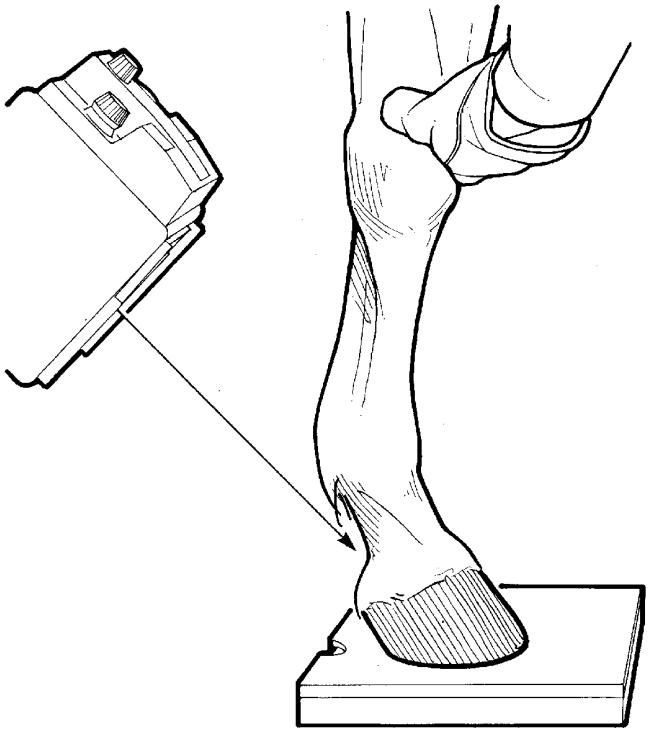

Figure 3.44.

VetBooks.ir

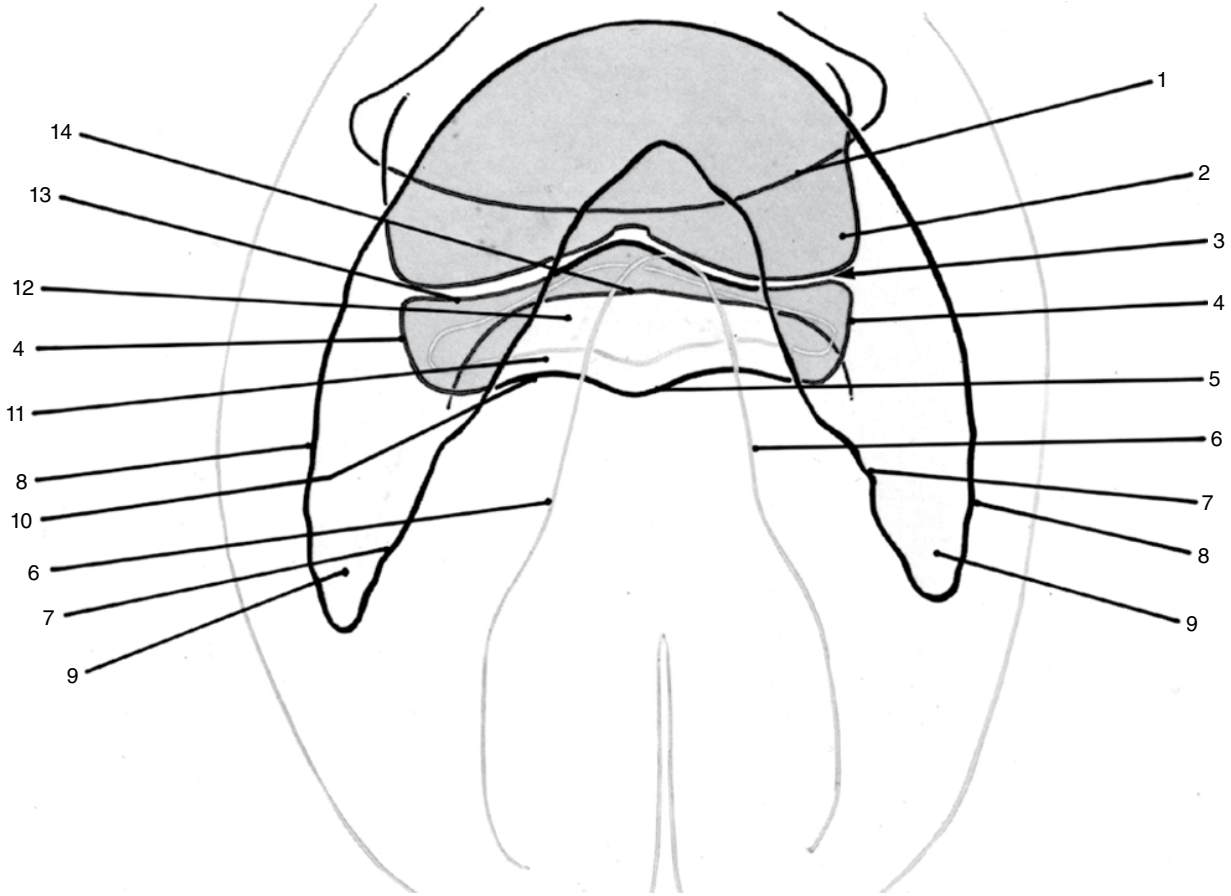

Figure 3.44. (*Continued*) Palmaroproximal to palmarodistal oblique (Pa45Pr-PaDiO) projection of the distal phalanx and navicular bone (foot). This projection shows the navicular bone with minimal superimposition over other bones. The angle of the X-ray beam and exposures are critical for eliminating projection artifacts, e.g. lack of good cortical and medullary cavity definition of superimposition of the distal phalanx over the navicular bone.

1. Palmar border of the middle phalanx.
2. Distal medial condyle of the middle phalanx.
3. Articulation between the navicular bone and the middle phalanx.
4. Medial and lateral extremities of the navicular bone.
5. Central eminence on the flexor surface of the navicular bone.
6. Collateral (paracureal) sulci of the frog.
7. Semilunar line on the solar surface of the distal phalanx.
8. Medial and lateral aspects of the solar border of the distal phalanx.
9. Distal part of the medial and lateral palmar processe
10. Flexor surface of the navicular bone.
11. Flexor cortex of the navicular bone.
12. Medullary (spongiosa) cavity of the navicular bone.
13. Articular surface of the navicular bone.

VetBooks.ir

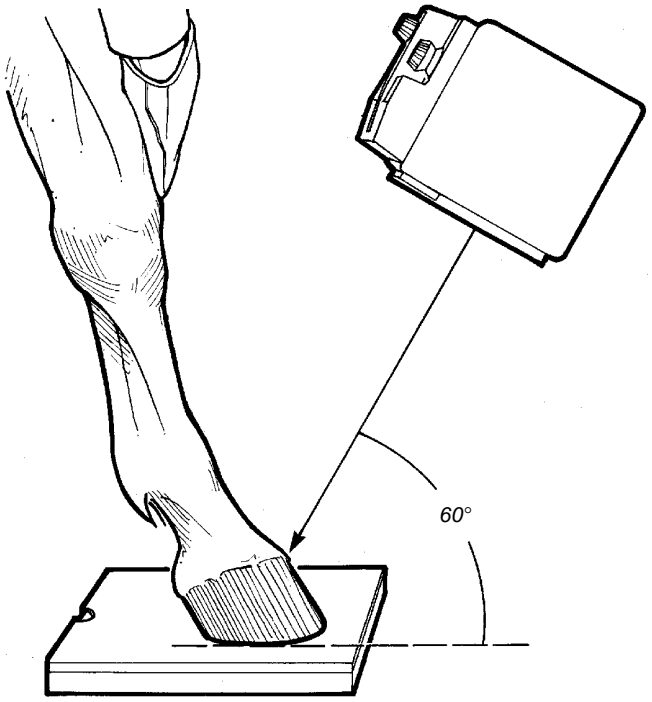

Figure 3.45.

VetBooks.ir

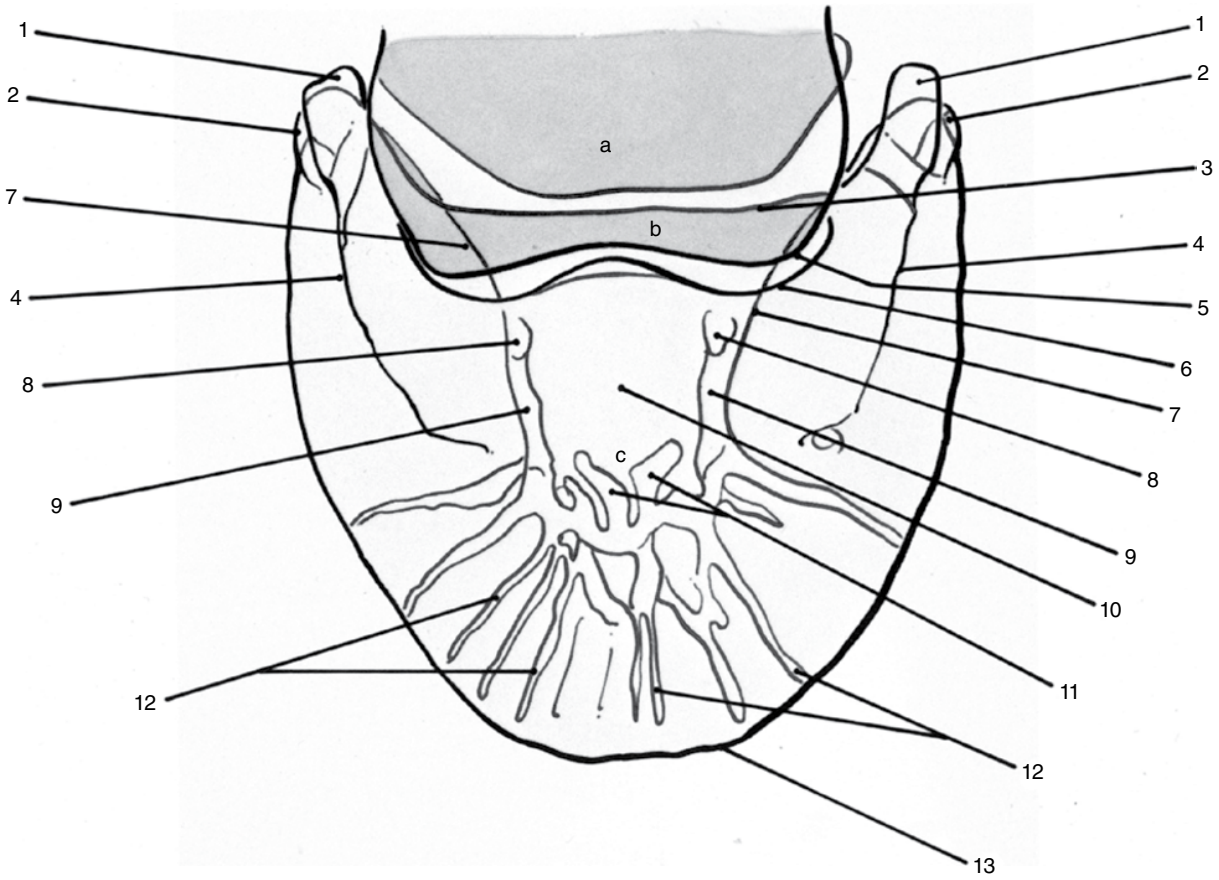

Figure 3.45. (*Continued*) Dorsoproximal to palmarodistal oblique (D60Pr-PaDiO) projection of the distal phalanx (foot). The X-ray beam for this projection is centered at the coronet, and the exposure is half that necessary for visualizing the navicular bone. (a) Navicular bone (distal sesamoidean bone), (b) middle phalanx, and (c) distal phalanx.

1. Proximal part of the medial and lateral palmar processes.
2. Distal part of the medial and lateral palmar processes.
3. Palmar articular margin of the distal phalanx.
4. Medial and lateral parietal sulci on the distal phalanx.
5. Distal articular surface of the middle phalanx.
6. Proximal dorsal margin of the articular surface of the distal phalanx.
7. Borders of the medial and lateral solar grooves.
8. Medial and lateral solar foramina.
9. Solar canal, the width and distinctness of which are variable in normal distal phalanges.
10. Flexor surface of the distal phalanx, where the deep digital flexor tendon attaches.
11. Vascular canals in the region of the solar canal.
12. Peripheral vascular canals. The vascular canals may be of variable width in normal distal phalanges. The peripheral solar border of the distal phalanx should be relatively smooth and symmetrical, although a slight irregular peripheral border may be considered normal in older animals.
13. Distal solar margin of the distal phalanx. The normal distal border of the distal phalanx may be convex or have some degree of concavity. A mid-distal notch, when present, is the crena marginis solaris.

VetBooks.ir

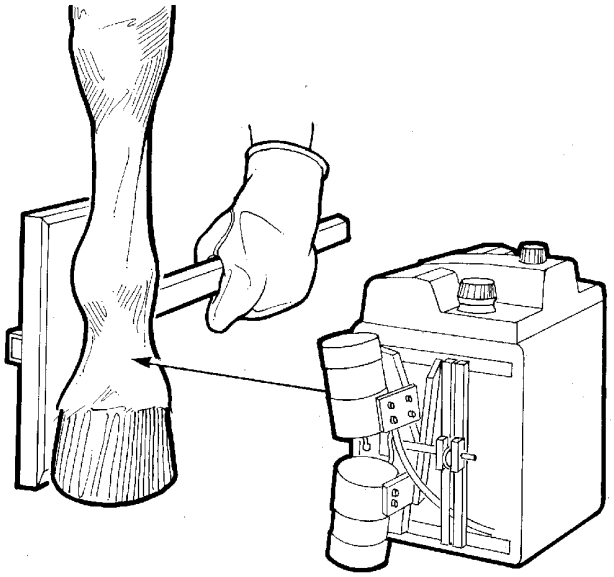

Figure 3.46.

VetBooks.ir

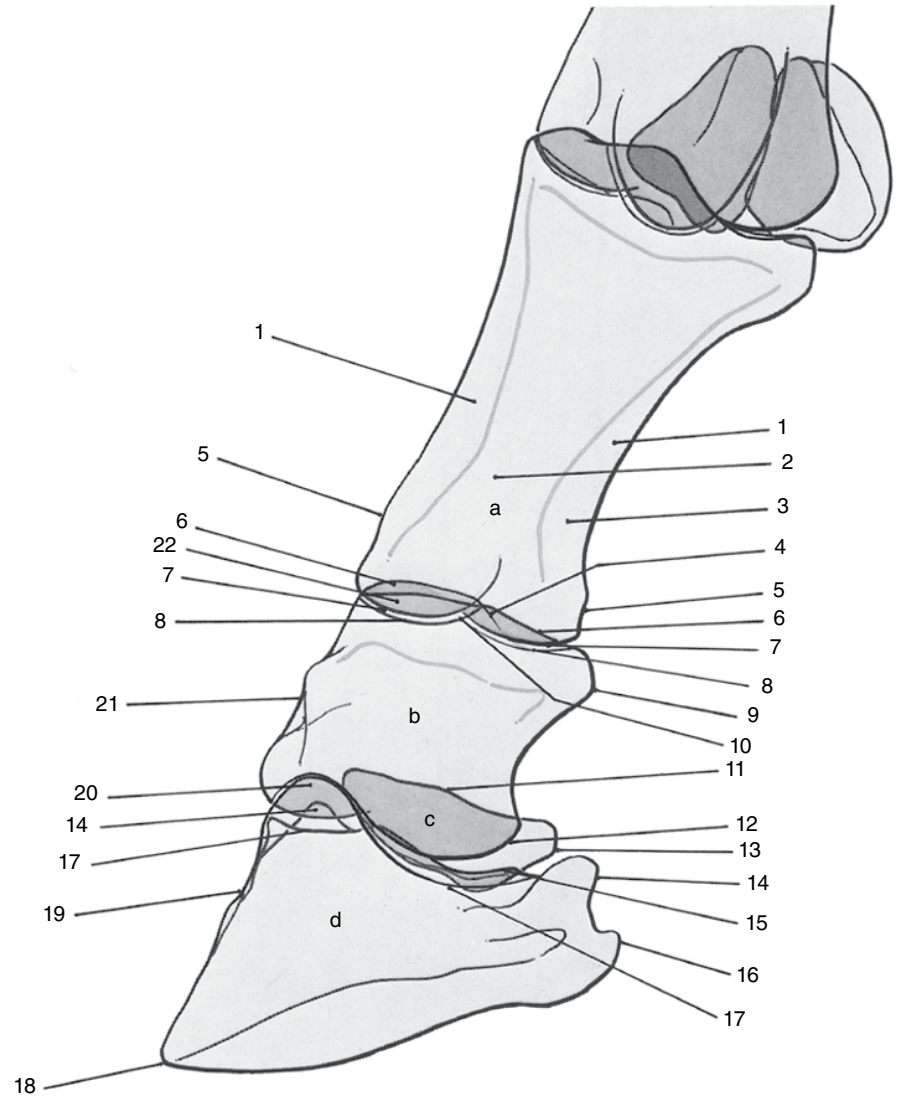

Figure 3.46. (*Continued*) Dorsomedial to palmarolateral oblique (D35M-PaLO) projection of the phalanges. (a) Proximal phalanx, (b) middle phalanx, (c) navicular bone, and (d) distal phalanx.

1. Mediopalmar and dorsolateral cortices of the proximal phalanx.
2. Medullary cavity of the proximal phalanx, which can sometimes be distinctly seen as a 2- to 3-cm lucency in the center of the proximal phalanx.
3. Surface for attachment of the middle (oblique) distal sesamoidean ligament.
4. Sagittal ridge on the proximal articular surface of the middle phalanx.
5. Eminences for attachment of the medial and lateral collateral ligaments of the proximal interphalangeal joint on the distal aspect of the proximal phalanx.
6. Palmar border of the articular fovea on the base of the middle phalanx.
7. Medial and lateral condyles of the distal aspect of the proximal phalanx.
8. Articular fovea on the base of the middle phalanx.
9. Medial proximal eminence for attachment of the medial collateral ligament and the medial branch of the tendon of the superficial digital flexor on the middle phalanx.
10. Sagittal ridge between the fovea on the base of the middle phalanx.
11. Proximal border of the navicular bone.
12. Distal medial condyle of the middle phalanx.
13. Medial extremity of navicular bone.
14. Proximal part of the medial palmar process of the distal phalanx.
15. Palmar part of the medial palmar process of the distal phalanx.
16. Distal part of the medial palmar process of the distal phalanx.
17. Medial and lateral aspects of the coronary border of the articular surface on the distal phalanx.
18. Solar border of the distal phalanx.
19. Depression and bony prominence on the lateral parietal surface of the distal phalanx for lateral collateral ligament attachment. The bony prominence has a smooth surface and should not be mistaken for bone production.
20. Extensor process of the distal phalanx.
21. Eminence on the dorsal surface of the middle phalanx for collateral ligament attachment, which has a smooth surface and should not be mistaken for periosteal bone production.
22. Dorsolateral articular border on the middle phalanx.

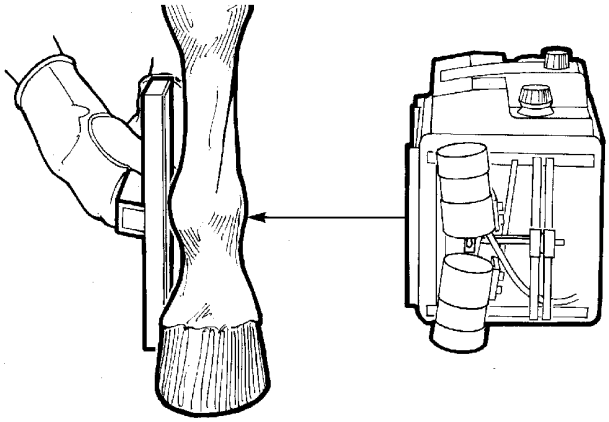

Figure 3.47.

VetBooks.ir

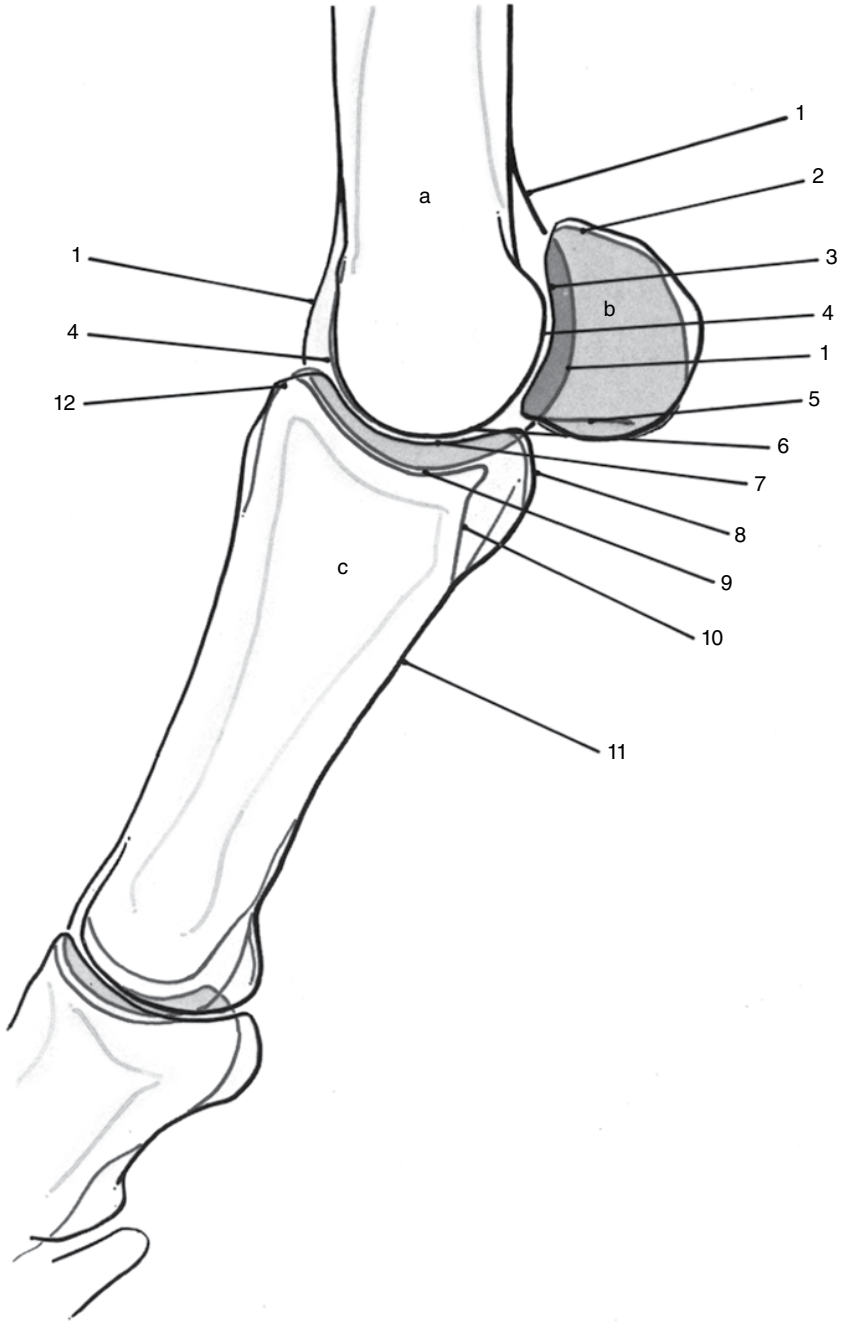

Figure 3.47. (*Continued*) Lateromedial (LM) projection of the metacarpophalangeal joint. (a) Third metacarpal bone, (b) proximal sesamoid bone, and (c) proximal phalanx.

1. Sagittal ridge on the distal extremity of the third metacarpal bone.
2. Apex of the superimposed proximal sesamoid bones.
3. Articular surface of the proximal sesamoid bones.
4. Articular surface of the superimposed medial and lateral condyles of the third metacarpal bone.
5. Superimposed base of the proximal sesamoid bones.
6. Transverse ridge on the distal articular surface of the third metacarpal bone, which divides the distal metacarpal articular surface into dorsal and palmar areas. It varies in size and visibility.
7. Superimposed medial and lateral articular fovea of the proximal phalanx.
8. Superimposed medial and lateral tuberosities on the proximal palmar aspect of the proximal phalanx for ligamentous attachment.
9. Sagittal groove on the proximal articular surface of the proximal phalanx, which articulates with the sagittal ridge of the third metacarpal bone.
10. Midpalmar surface of the proximal phalanx located between the lateral and medial tuberosities.
11. Palmar surface of the proximal phalanx, where the middle (oblique) distal sesamoidean ligament attaches.
12. Superimposed medial and lateral bony eminences for attachment of the extensor tendon on the proximal phalanx.

VetBooks.ir

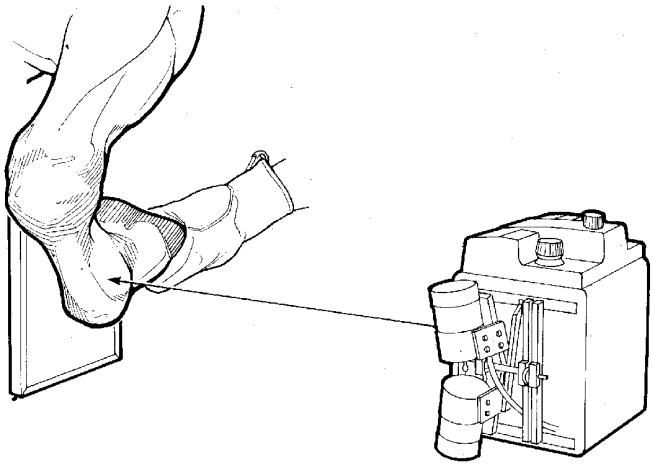

Figure 3.48.

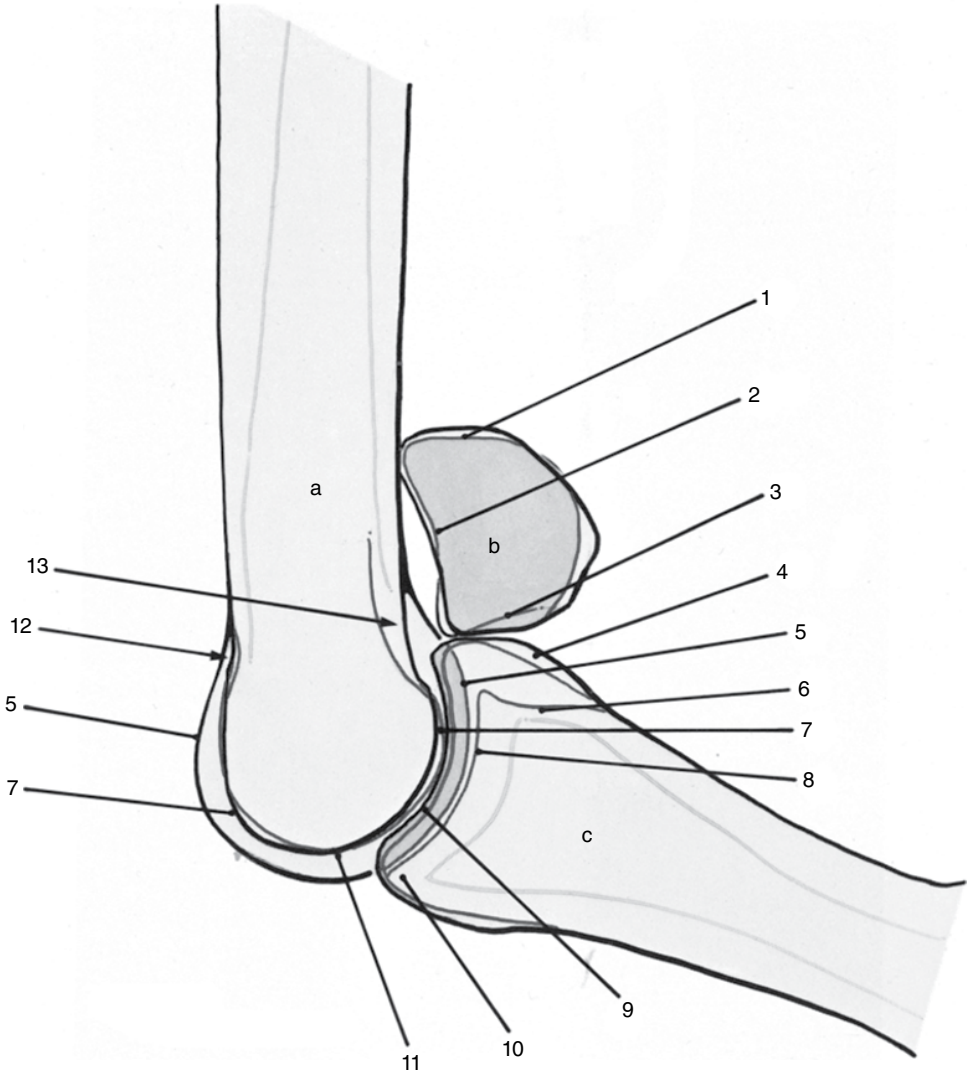
VetBooks.ir



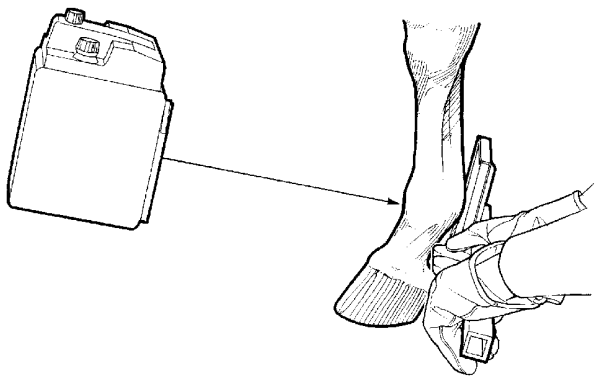


Figure 3.48. (*Continued*) Flexed lateromedial (flexed LM) projection of the metacarpophalangeal joint. This projection allows the most effective evaluation of the articular surface of the sesamoid bones, offers good visualization of small articular basilar sesamoid fractures and changes, and provides a distinct projection of the proximal tuberosities. Furthermore, the dorsal articular surface of the third metacarpal bone can be evaluated without superimposition of the proximal phalanx. (a) Third metacarpal bone, (b) proximal sesamoid bones, and (c) proximal phalanx.

1. Apex of the superimposed proximal sesamoid bones.
2. Superimposed articular surfaces of the proximal sesamoid bones.
3. Bases of the superimposed proximal sesamoid bones.
4. Superimposed medial and lateral tuberosities on the proximal caudal aspect of the proximal phalanx, where ligamentous attachments occur.
5. Sagittal ridge on the distal articular surface of the third metacarpal bone; the dorsal and palmar aspects are labeled.
6. Midpalmar surface of the proximal phalanx, located between the medial and lateral tuberosities.
7. Palmar and dorsal aspects of the superimposed medial and lateral condyles of the third metacarpal bone.
8. Sagittal groove on the proximal articular surface of the proximal phalanx, which articulates with the sagittal ridge on the distal third metacarpal bone.
9. Superimposed fovea (articular surface) of the proximal extremity of the proximal phalanx.
10. Superimposed medial and lateral parts of the extensor eminence of the proximal phalanx.
11. Transverse ridge on the distal articular surface of the third metacarpal bone, which separates the distal articular surface of the third metacarpal bone into dorsal and palmar parts.
12. Bony depression where the proximal dorsal recess from the metacarpophalangeal joint is located.
13. Bony depression where the proximal palmar recess from the metacarpophalangeal joint is located.

VetBooks.ir

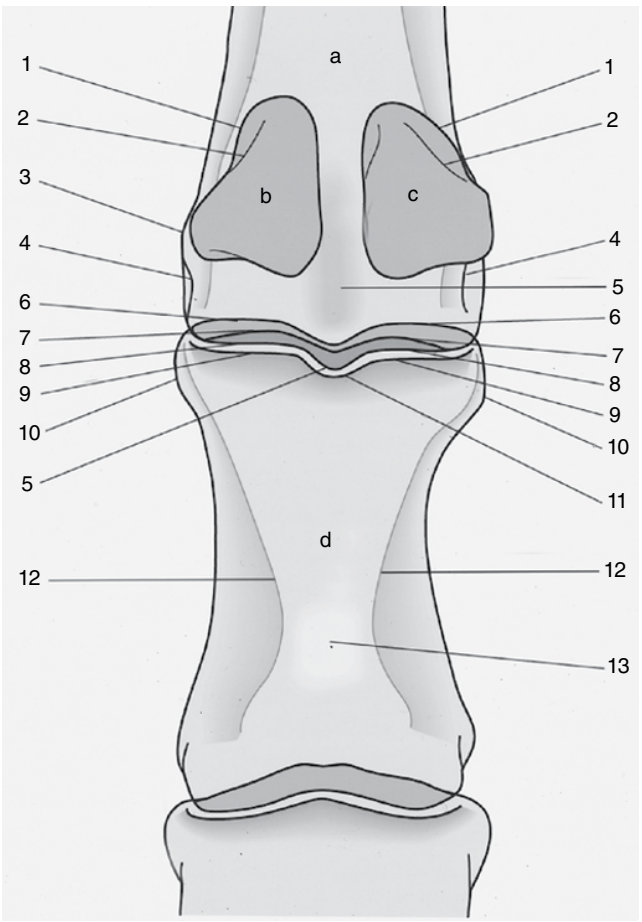

Figure 3.49. Dorsoproximal to palmarodistal (D30Pr-PaDi) projection of the metacarpophalangeal joint. (a) Third metacarpal bone, (b) lateral proximal sesamoid bone, (c) medial proximal sesamoid bone, and (d) proximal phalanx.

1. Peripheral abaxial margins of the proximal sesamoid bones. The peripheral margin of the medial proximal sesamoid bone is more convex than that of the lateral proximal sesamoid bone.
2. Abaxial margin of the surfaces of the medial and lateral proximal sesamoid bone.
3. Eminence for attachment of the lateral collateral ligament.
4. Depression on the medial and lateral aspects of the third metacarpal bone where collateral ligaments attach.
5. Sagittal ridge on the distal articular surface of the third metacarpal bone.
6. Medial and lateral palmar margins of the articular fovea on the proximal extremity of the proximal phalanx.
7. Medial and lateral dorsal margins of the articular fovea on the proximal extremity of the proximal phalanx.
8. Medial and lateral condyles (articular surface) of the third metacarpal bone.
9. Articular fovea on the proximal extremity of the proximal phalanx.
10. Medial and lateral palmar tuberosities on the proximal extremity of the proximal phalanx for ligament attachment.
11. Sagittal groove on the proximal articular surface of the proximal phalanx.
12. Bony ridges on the palmar surface of the proximal phalanx for attachment of the middle (oblique) distal sesamoidean ligament.
13. Medullary cavity in the proximal phalanx.

VetBooks.ir

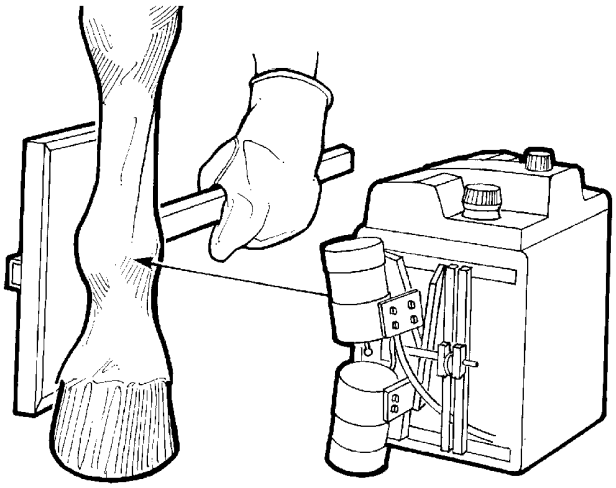

Figure 3.50.

VetBooks.ir

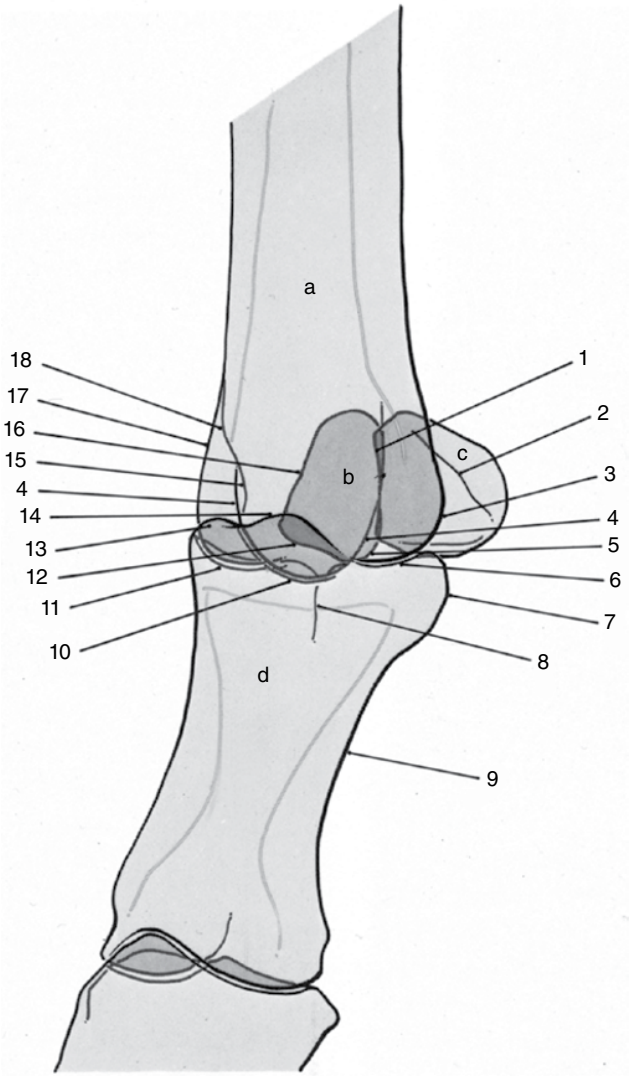

Figure 3.50. (*Continued*) Dorsolateral to palmaromedial oblique (D45L-PaMO) projection of the metacarpophalangeal joint. (a) Third metacarpal bone, (b) medial proximal sesamoid bone, (c) lateral proximal sesamoid bone, and (d) proximal phalanx.

1. Articular surface of the lateral proximal sesamoid bone.
2. The difference in radiographic opacity is caused by a difference in bone thickness on the lateral proximal sesamoid bone. The base and body are more opaque than the apex and peripheral border. The convex shape on the abaxial surface produces the distinct line between the two opacities.
3. Palmar surface of the lateral condyle distal aspect of the third metacarpal bone.
4. Palmar and dorsal aspects of the sagittal ridge on the distal third metacarpal bone.
5. Junction of the peripheral and basilar margins of the medial proximal sesamoid bone.
6. Lateral articular fovea of the proximal extremity of the proximal phalanx.
7. Lateral tuberosity on the proximal palmar aspect of the proximal phalanx.
8. Medial tuberosity on the proximal palmar aspect of the proximal phalanx.
9. Lateral bony ridge for attachment of the middle (oblique) distal sesamoidean ligament.
10. Sagittal groove on the proximal articular surface of the proximal phalanx.
11. Medial articular fovea of the proximal extremity of the proximal phalanx.
12. Basilar margin of the medial proximal sesamoid bone.
13. Medial dorsal margin of the articular fovea on the proximal phalanx.
14. Lateral dorsal margin of the articular fovea on the proximal phalanx. Both margins (13, 14) are visible on correctly exposed and positioned oblique projections of the metacarpophalangeal joint.
15. Depression (concave surface) for attachment of the medial collateral ligament on the distal third metacarpal bone. The visibility and distinctness of the concave line change on different projections. It may be more prominent on some examinations and not visible on others.
16. Abaxial articular margin of the medial proximal sesamoid bone.
17. Dorsal aspect of the medial condyle on the third metacarpal bone.
18. Eminence on the third metacarpal bone for attachment of the medial collateral ligament.

1. Abaxial surface of the medial proximal sesamoid bone.
2. Palmar surface of the sagittal ridge of the third metacarpal bone.
3. Medial proximal border of the proximal phalanx.
4. Lateral palmar eminence of the proximal phalanx.
5. Lateral condyle of the third metacarpal bone.
6. Proximal medial surface of the proximal phalanx.
7. Dorsal border of the medial condyle of the third metacarpal bone.

VetBooks.ir

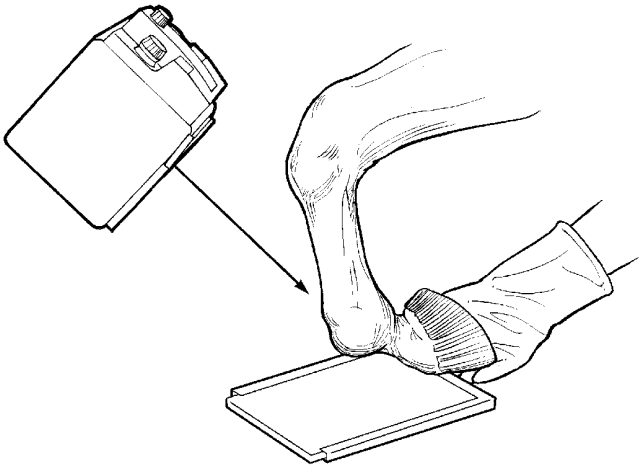

Figure 3.53.

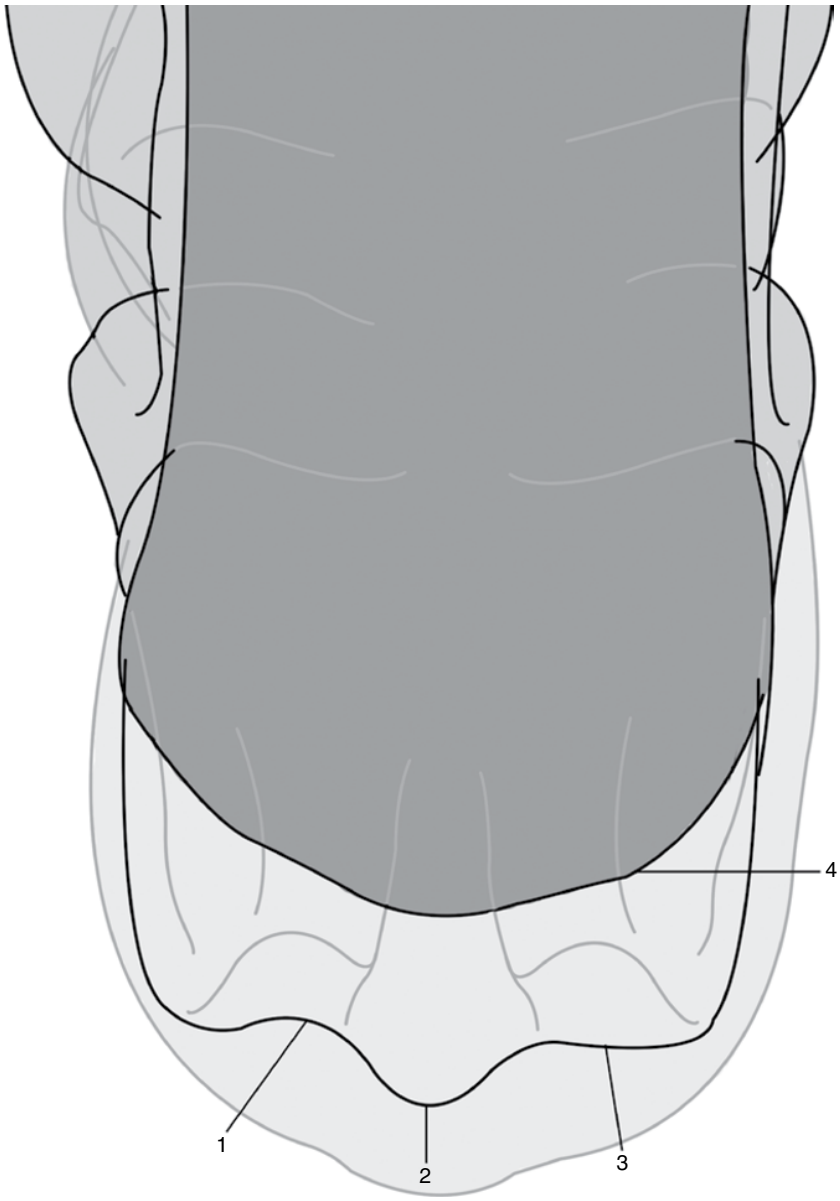
VetBooks.ir



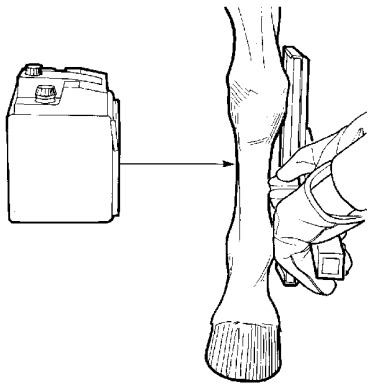


Figure 3.53. (*Continued*) Dorsoproximal to dorsodistal oblique (D45–70Pr-DDiO) projection of the metacarpophalangeal joint. In this projection, the flexed fetlock joint is held on top of the detector. The primary X-ray beam is directed distally in a 45–70° dorsoproximal dorsodistal direction and is centered on the dorsal aspect of the midsagittal ridge of metacarpus/metatarsus for evaluation of the dorsal articular surface of the condyle of MCIII/MTIII.

1. Articular surface of the lateral condyle of the third metacarpal bone.
2. Sagittal ridge on the distal articular surface of the third metacarpal bone.
3. Articular surface of the medial condyle of the third metacarpal bone.
4. Proximal dorsal aspect of the proximal phalanx.

VetBooks.ir

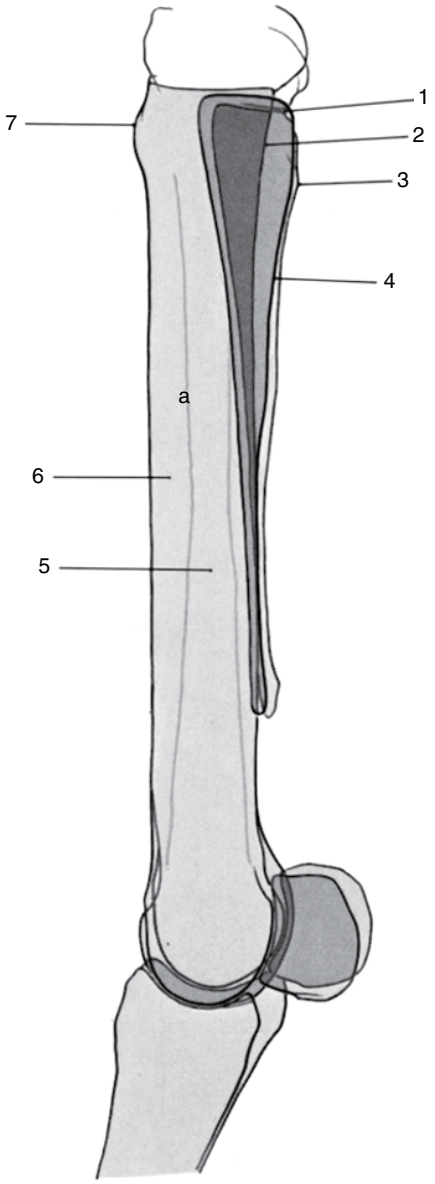

Figure 3.54. Lateromedial (LM) projection of the metacarpus.
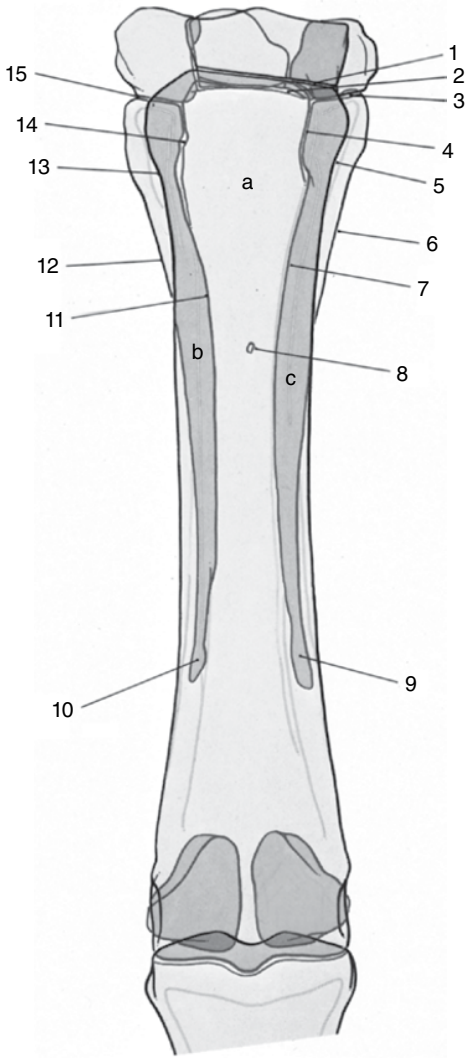
(a) Third metacarpal bone.

1. Articulation between the second carpal and the second metacarpal bone.
2. Proximal palmar surface of the third metacarpal bone, where the suspensory ligament (interosseous muscle) attaches. The nutrient foramen is frequently present on the palmar surface of the third metacarpal bone at approximately the junction of the proximal and middle thirds; it may be mistaken for a nondisplaced cortical fracture.
3. Palmar surface of the second metacarpal bone.
4. Palmar aspect of the fourth metacarpal bone. The superimposition of the cortices on the metacarpal bones produces longitudinal lucent lines that may be mistaken for longitudinal fractures.
5. Medullary cavity of the third metacarpal bone.
6. Dorsal cortex of the third metacarpal bone, which is fusiform in shape, i.e. thick in the center and thin toward both extremities.
7. Metacarpal tuberosity.

VetBooks.ir



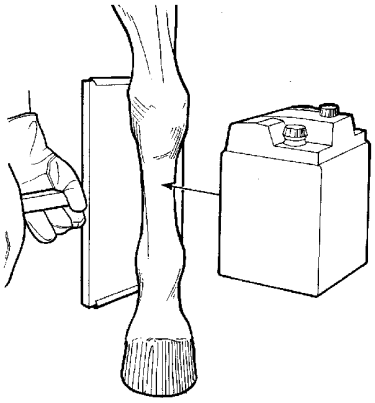


Figure 3.55. Dorsopalmar (DPa) projection of the metacarpus. (a) Third metacarpal bone, (b) fourth metacarpal bone, and (c) second metacarpal bone.

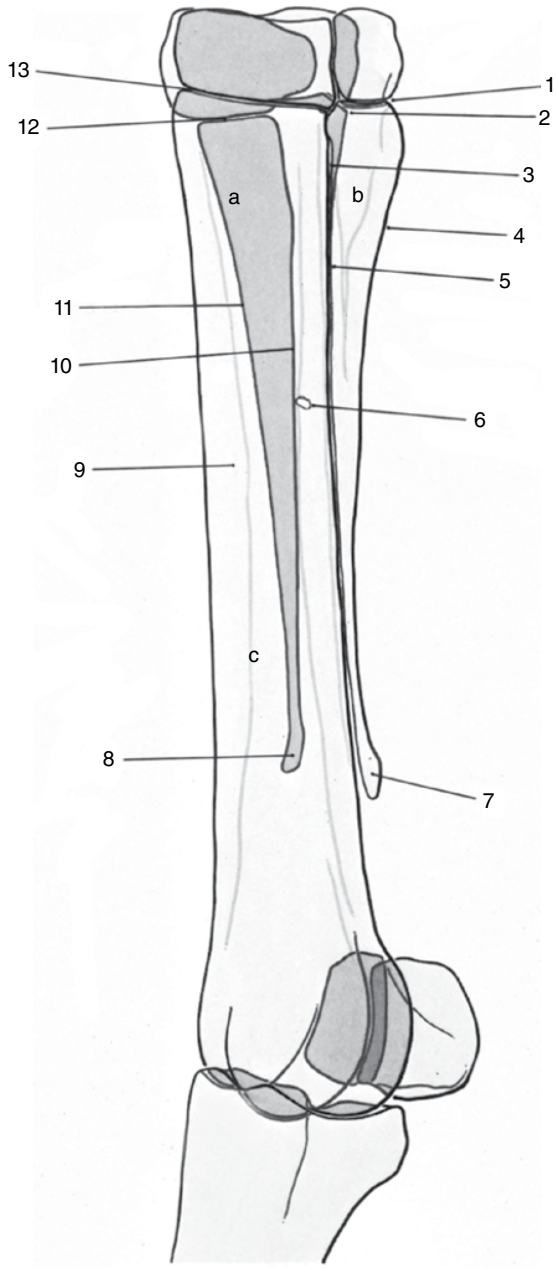
1. Dorsal aspect of the articulation between the third carpal and the third metacarpal bone.
2. Palmar aspect of the articulation between the third carpal and the third metacarpal bone.
3. Articulation between the second carpal and the second metacarpal bone.
4. Articulation between the second and third metacarpal bones.
5. Medioproximal border of the third metacarpal bone.
6. Abaxial border of the second metacarpal bone.
7. Axial border of the second metacarpal bone.
8. End-on projection of the nutrient foramen on the palmar surface of the third metacarpal bone.
9. Distal extent of the second metacarpal bone. The normal shape and position of this bone may be variable. The position may vary in axial and abaxial direction and in proximal or distal direction.
10. Distal extent of the fourth metacarpal bone. The normal shape and position of this bone may be variable. The position may vary in axial and abaxial direction and in proximal or distal direction.
11. Axial border of the fourth metacarpal bone.
12. Abaxial border of the fourth metacarpal bone.
13. Lateral border of the third metacarpal bone.
14. Articulation between the third and fourth metacarpal bones.
15. Articulation between the fourth carpal and the fourth metacarpal bone.

VetBooks.ir



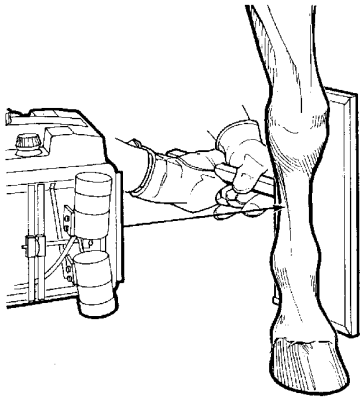


Figure 3.56. Dorsomedial to palmarolateral oblique (D55M-PaLO) projection of the metacarpus. (a) Fourth metacarpal bone, (b) second metacarpal bone, and (c) third metacarpal bone.

1. Articulation between the second carpal and the second metacarpal bone.
2. Proximal palmar medial angle of the third metacarpal bone.
3. Junction between the second and third metacarpal bones.
4. Palmar border of the second metacarpal bone.
5. Dorsal border of the second metacarpal bone.
6. Nutrient foramen on the palmar surface of the third metacarpal bone.
7. Distal end of the second metacarpal bone.
8. Distal end of the fourth metacarpal bone.
9. Dorsolateral cortex of the third metacarpal bone.
10. Palmar surface of the fourth metacarpal bone.
11. Dorsal surface of the fourth metacarpal bone.
12. Articulation between the fourth carpal and the fourth metacarpal bone.
13. Articulation between the third carpal and the third metacarpal bone.

VetBooks.ir

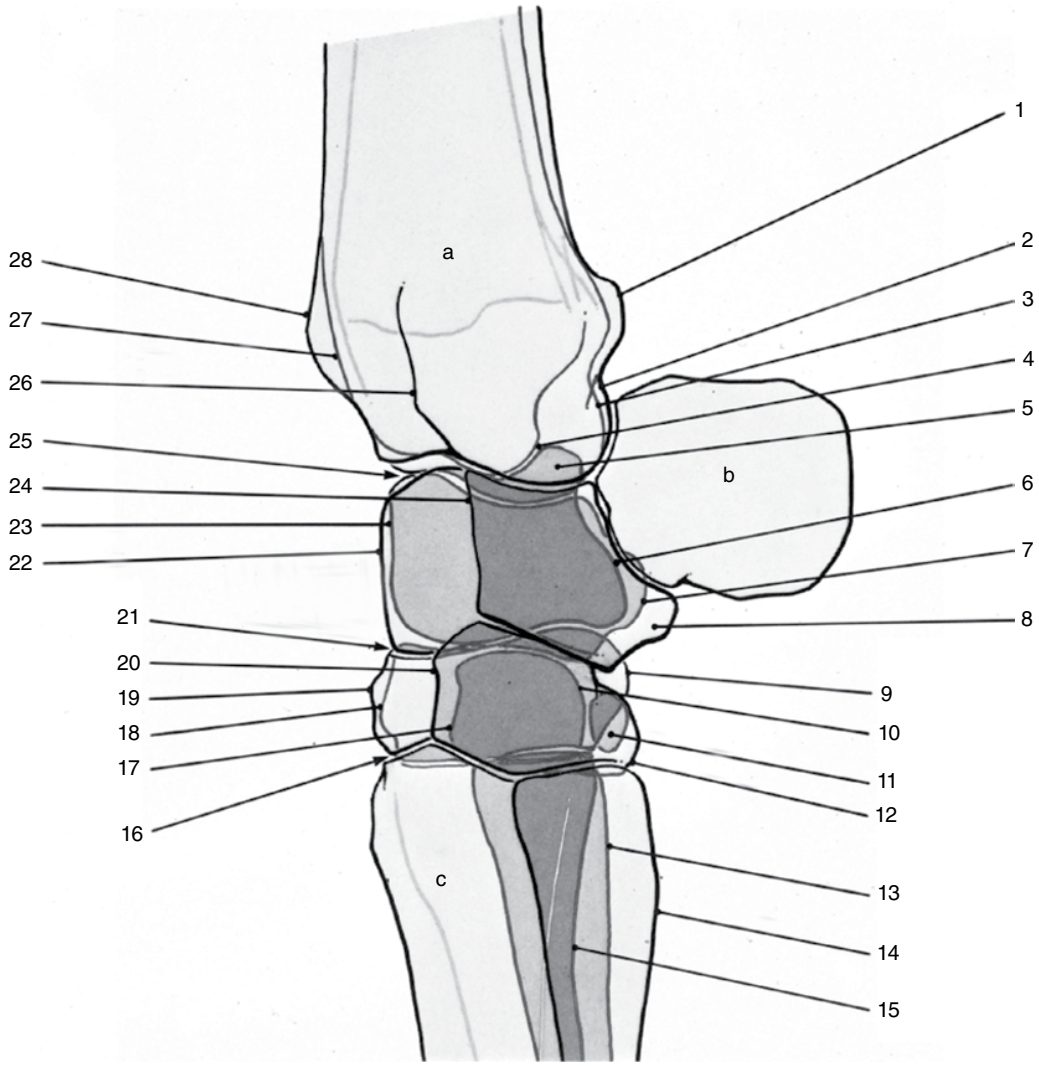

Figure 3.58. (*Continued*) Lateromedial (LM) projection of the carpus. The relative positions of the bony ridges of the distal cranial radius depend on the X-ray beam projection angle. (a) Radius, (b) accessory carpal bone, and (c) third metacarpal bone.

1. Transverse crest, which projects caudad from the closed distal radial physis.
2. Lateral facet of the radial trochlea (lateral styloid process), which articulates with the ulnar carpal bone.
3. Medial facet of the radial trochlea (medial styloid process), which articulates with the radial carpal bone.
4. Intermediate facet of the radial trochlea, which articulates with the intermediate carpal bone.
5. Tuberosity from the proximal palmar aspect of the intermediate carpal bone.
6. Palmar border of the intermediate carpal bone.
7. Palmar border of the radial carpal bone.
8. Palmar border of the ulnar carpal bone. The position of 6, 7, and 8 may change with slight changes in angulation of the X-ray tube or the horse's limb.
9. Palmar border of the third carpal bone.
10. Palmar border of the second carpal bone.
11. First carpal bone, which sometimes is not present.
12. Palmar border of the fourth carpal bone.
13. Proximal palmar border of the second metacarpal bone.
14. Proximal palmar border fourth metacarpal bone.
15. Proximal palmar border of the third metacarpal bone.
16. Carpometacarpal joint.
17. Dorsal border of the second carpal bone.
18. Dorsal border of the third carpal bone.
19. Transverse ridge on the dorsal border of the third carpal bone, which projects with varying degrees of prominence in each horse.
20. Dorsal border of the fourth carpal bone.
21. Midcarpal joint.
22. Dorsal border of the radial carpal bone.
23. Dorsal border of the intermediate carpal bone.
24. Dorsal border of the ulnar carpal bone.
25. Antebrachiocarpal (radiocarpal) joint.
26. Lateral bony ridge of the distal cranial radius, adjacent to the common digital extensor tendon.
27. Bony ridge of the distal cranial radius, adjacent to the medial border of the extensor carpi radialis tendon.
28. Bony ridge of the distal cranial radius between the common digital extensor tendon and the extensor carpi radialis tendon.

VetBooks.ir

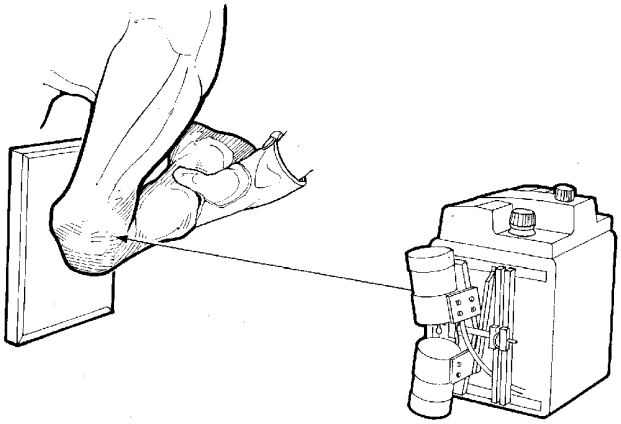

Figure 3.59.

VetBooks.ir

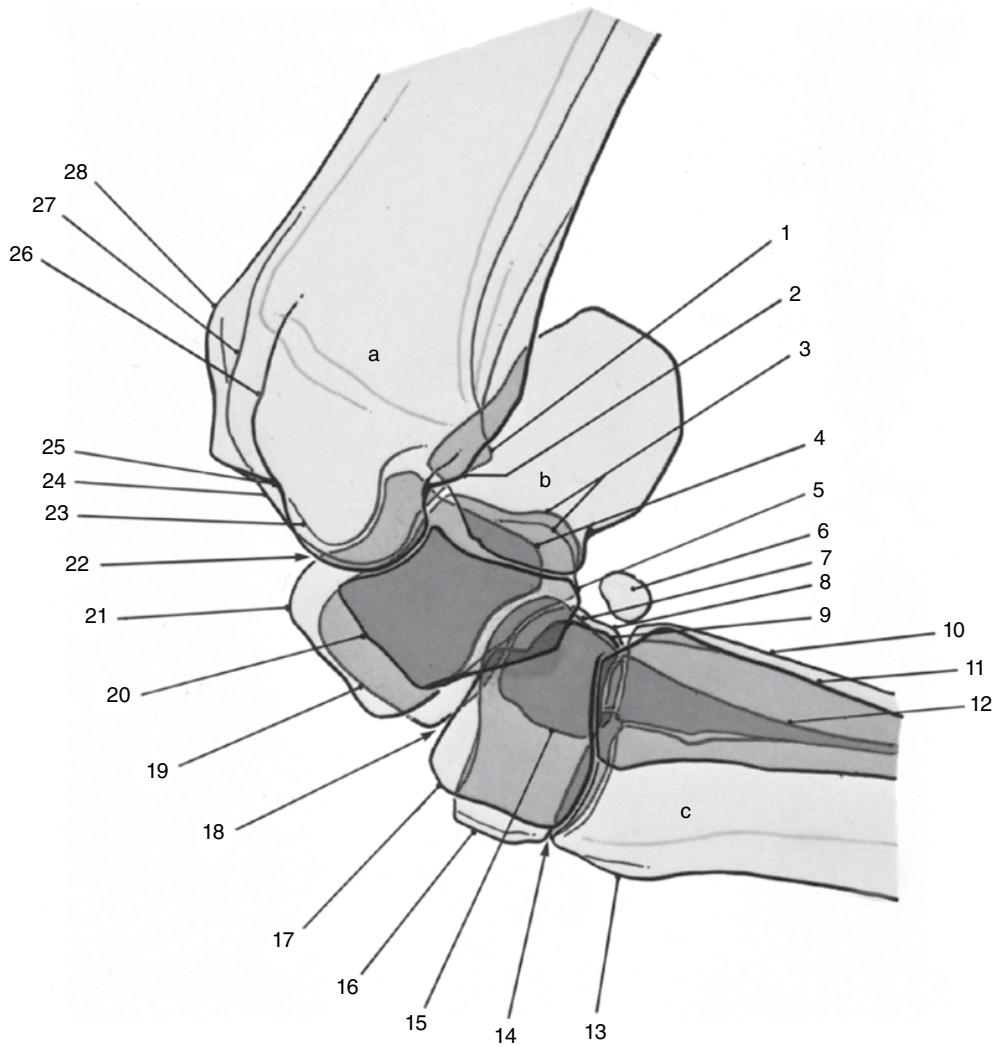

Figure 3.59. (*Continued*) Flexed lateromedial (flexed LM) projection of the carpus. The size and shape of the first and fifth carpal bones may vary, and sometimes the bones are absent. The palmar borders of the carpal and metacarpal bones are closely superimposed in this projection, and the positions may vary slightly with X-ray tube angulation and/or the horse's limb positions. Projection of the bony ridges and facets of the radial trochlea may vary with the positions of the limb and the angle of the X-ray beam. (a) Radius, (b) accessory carpal bone, and (c) third metacarpal bone.

1. Transverse crest, which projects from the caudal aspect of the closed distal radial physis.
2. Ridges produced by the caudal aspect of the medial (medial styloid process) and lateral (lateral styloid process) parts of the radial trochlea.
3. Palmar border of the radial carpal bone.
4. Palmar border of the intermediate carpal bone.
5. Palmar border of the ulnar carpal bone.
6. First carpal bone.
7. Palmar border of the fourth carpal bone.
8. Palmar border of the third carpal bone.
9. Palmar border of the second carpal bone.
10. Proximal palmar border of the second metacarpal bone.
11. Proximal palmar border of the fourth metacarpal bone.
12. Proximal palmar border of the third metacarpal bone.
13. Metacarpal tuberosity, which may vary in prominence.
14. Carpometacarpal joint. Numerous joint space lines are produced by the irregular contour of the bones forming this joint.
15. Dorsal border of the second carpal bone.
16. Dorsal border of the third carpal bone.
17. Dorsal border of the fourth carpal bone. The proximal dorsal aspect of the fourth carpal bone (17) projects proximal to the third carpal bone (16) on the flexed lateral projection.
18. Middle carpal joint.
19. Dorsal border of the radial carpal bone.
20. Dorsal borders of the ulnar carpal bone.
21. Dorsal borders of the intermediate carpal bone. The dorsal borders of the radial (19) and intermediate (21) carpal bones are closely superimposed and may vary slightly. The intermediate carpal bone usually projects proximal to the radial carpal bone on the flexed lateral projection.
22. Antebrachiocarpal (radiocarpal) joint.
23. Intermediate facet of the radial trochlea, which articulates with the intermediate carpal bone (21).
24. Medial border of the radial trochlea.
25. Lateral border of the radial trochlea.
26. Lateral bony ridge adjacent to the lateral border of the common digital extensor tendon.
27. Bony ridge adjacent to the medial border of the extensor carpi radialis.
28. Bony ridge between the lateral digital extensor tendon and the extensor carpi radialis tendon.

VetBooks.ir

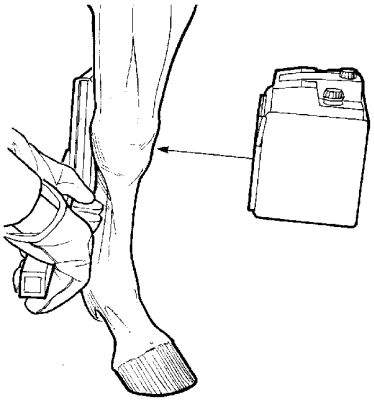

Figure 3.60.

VetBooks.ir

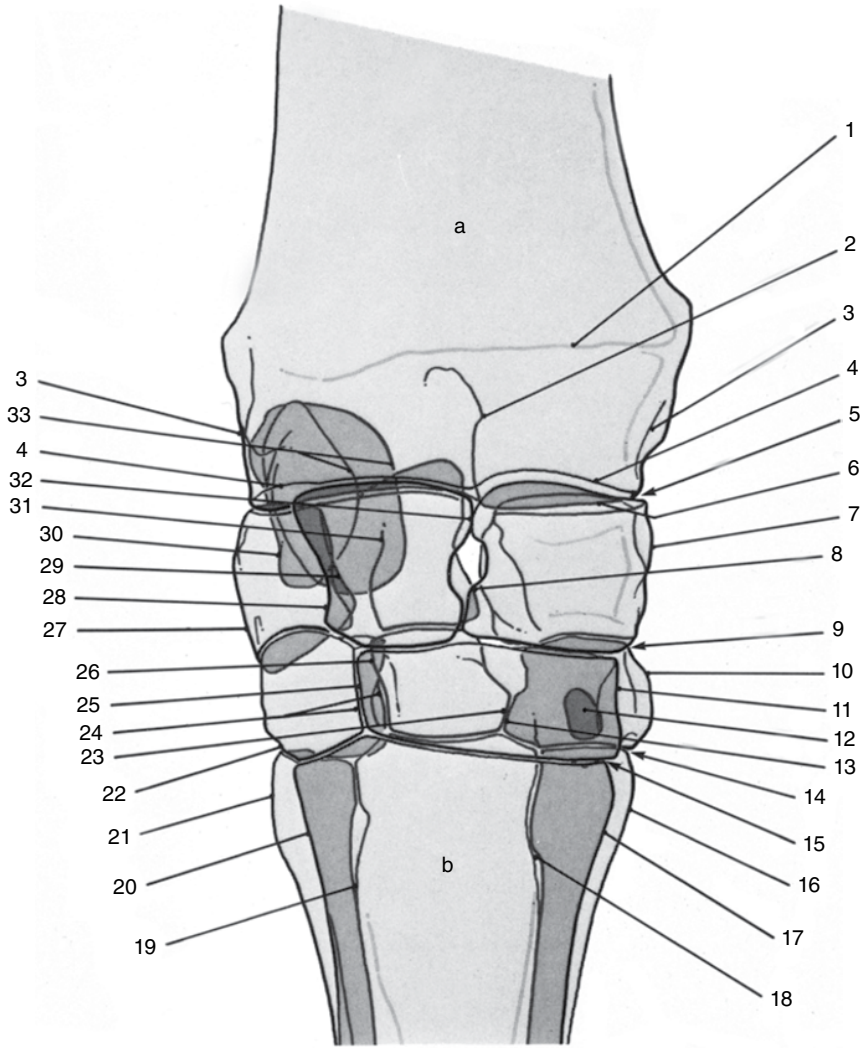

Figure 3.60. (*Continued*) Dorsopalmar (DPa) projection of the carpus. (a) Radius and (b) third metacarpal bone.

1. Physeal scar in the distal extremity of the radius after physeal closure.
2. Caudolateral border of the medial facet (medial styloid process) on the radial trochlea.
3. Depression in the medial and lateral styloid processes for attachment of medial and lateral collateral ligaments. Their appearances and apparent depths can change with a slight obliqueness of the limb.
4. Cranial articular margin on the distal radius.
5. Antebrachiocarpal (radiocarpal) joint.
6. Medial facet (medial styloid process) on the distal radial trochlea, which articulates with the radial carpal bone (7 and 8).
7. Medial border of the radial carpal bone.
8. Lateral border of the radial carpal bone.
9. Midcarpal joint. The different levels of the joint space are the result of many bones forming the articular surfaces and of slight angulation of the X-ray tube or positions of the horse's limb.
10. Medial border of the second carpal bone.
11. Dorsomedial border of the third carpal bone.
12. First carpal bone superimposed over the second and third carpal bone.
13. Lateral border of the second carpal bone.
14. Palmar aspect of the carpometacarpal joint space.
15. Dorsal aspect of the carpometacarpal joint space.
16. Proximomedial border of the second metacarpal bone.
17. Proximomedial border of the third metacarpal bone.
18. Articulation between the second and third metacarpal bones.
19. Articulation between the third and fourth metacarpal bones.
20. Lateral border of the third metacarpal bone.
21. Lateral border of the fourth metacarpal bone.
22. Lateral border of the fourth carpal bone.
23. Medial border of the palmar process on the third carpal bone.
24. Medial border of the fourth carpal bone.
25. Dorsolateral border of the third carpal bone.
26. Lateral border of the palmar process on the third carpal bone.
27. Lateral border of the ulnar carpal bone.
28. Lateral border of the intermediate carpal bone.
29. Medial border of the ulnar carpal bone.
30. Lateral border of the accessory carpal bone.
31. Lateral border of the palmar tuberosity on the intermediate carpal bone.
32. Medial border of the intermediate carpal bone.
33. Concave medial surface of the accessory carpal bone.

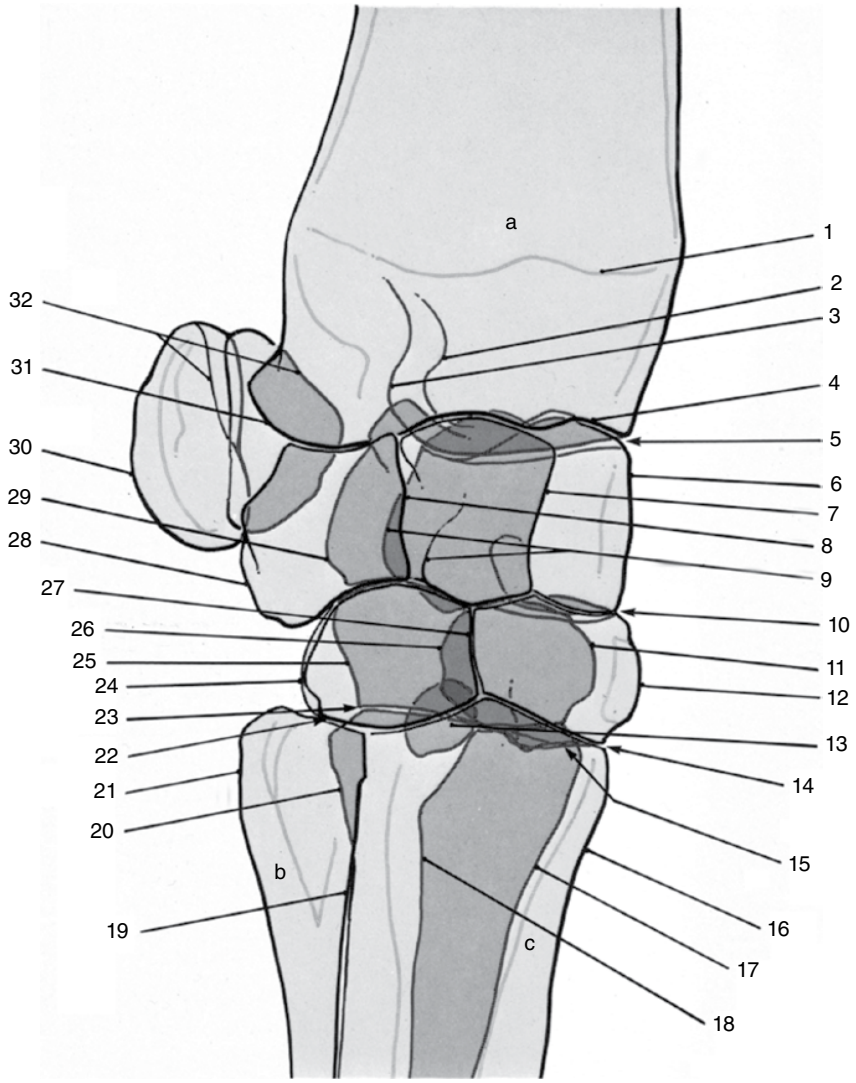

Figure 3.61. (*Continued*) Dorsolateral to palmaromedial oblique (D45L-PaMO) projection of the carpus. (a) Radius, (b) fourth metacarpal bone, and (c) third metacarpal bone.

1. Physeal scar remaining after distal radial physeal closure.
2. Caudal aspect of the intermediate facet on the radial trochlea.
3. Caudal aspect of the medial facet (medial styloid process) on the radial trochlea.
4. Cranial articular margin on the radial trochlea.
5. Dorsomedial aspect of the antebrachiocarpal (radiocarpal) joint.
6. Dorsomedial border of the radial carpal bone.
7. Dorsomedial border of the intermediate carpal bone.
8. Dorsomedial border of the ulnar carpal bone.
9. Tubercles on the palmar surface of the radiocarpal bone.
10. Dorsomedial aspect of the midcarpal joint.
11. Dorsomedial border of the second carpal bone.
12. Transverse ridge on the dorsomedial border of the third carpal bone.
13. First carpal bone, which is difficult to see on this projection because of superimposition.
14. Medial aspect of the carpometacarpal joint.
15. Dorsal aspect of the carpometacarpal joint. The multiple joint spaces are associated with the carpometacarpal joint and vary in appearance on different projection angles.
16. Dorsomedial border of the third metacarpal bone.
17. Dorsomedial border of the second metacarpal bone.
18. Palmarolateral border of the second metacarpal bones.
19. Dorsomedial border of the fourth metacarpal bone.
20. Palmarolateral border of the third metacarpal bone.
21. Palmarolateral border of the fourth metacarpal bone.
22. Palmarolateral aspect of the carpometacarpal joint between the fourth carpal bone and the third and fourth metacarpal bones.
23. Palmar aspect of the carpometacarpal joint between the third carpal and the third metacarpal bone.
24. Tubercle on the palmarolateral border of the fourth carpal bones.
25. Palmarolateral border of the third carpal bone.
26. Palmarolateral border of the second carpal bone.
27. Dorsomedial border of the fourth carpal bone.
28. Palmarolateral border of the ulnar carpal bone.
29. Palmarolateral border of the intermediate carpal bone.
30. Palmarolateral border of the accessory carpal bone.
31. Lateral facet (lateral styloid process) on the radial trochlea.
32. Medial, concave surface of the accessory carpal bone.

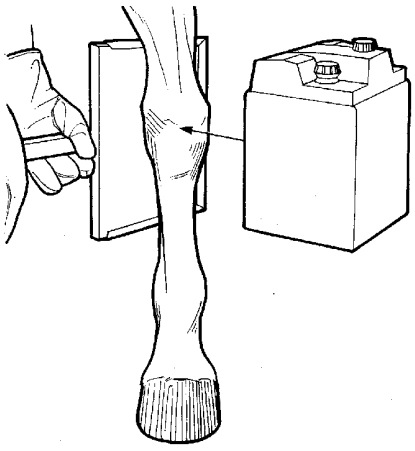

Figure 3.62.

VetBooks.ir

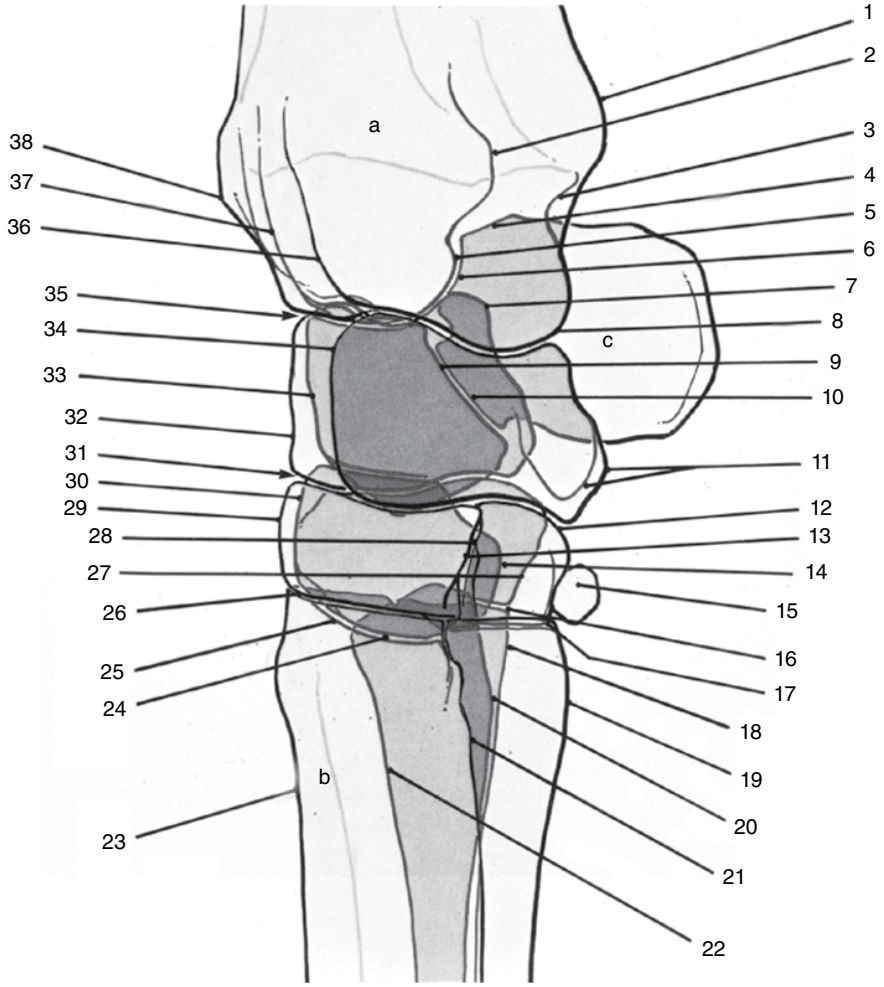

Figure 3.62. (*Continued*) Dorsomedial to palmarolateral oblique (D60M-PaLO) projection of the carpus. The relative positions of the bony ridges on the distocranial aspect of the radius change slightly with different X-ray beam projections. (a) Radius, (b) third metacarpal bone, and (c) accessory carpal bone.

1. Bony projection from the mediocaudal surface of the radius.
2. Transverse crest proximal to the lateral facet (lateral styloid process) of the radial trochlea.
3. Indentation proximal to the medial facet (medial styloid process) of the radial trochlea.
4. Proximal border of the accessory carpal bone.
5. Caudal border of the lateral and intermediate facets of the radial trochlea superimposed.
6. Proximal articular surface of the accessory carpal bone.
7. Palmaromedial border of the intermediate carpal bone.
8. Medial facet (medial styloid process) of the radial trochlea.
9. Palmaromedial border of the ulnar carpal bone.
10. Distal articular surface of the accessory carpal bone.
11. Palmaromedial border of the radial carpal bone.
12. Palmaromedial border of the second carpal bone.
13. Palmaromedial border of the third carpal bone.
14. Palmaromedial border of the fourth carpal bone.
15. First carpal bone.
16. Carpometacarpal articulation between the third carpal and the third metacarpal bone.
17. Carpometacarpal articulation between the second carpal and the second metacarpal bone.
18. Palmaromedial border of the third metacarpal bone.
19. Palmaromedial border of the second metacarpal bone.
20. Palmaromedial border of the fourth metacarpal bone.
21. Dorsolateral border of the second metacarpal bone.
22. Dorsolateral border of the fourth metacarpal bone.
23. Dorsolateral border of the third metacarpal bone.
24. Carpometacarpal articulation between the fourth carpal and the fourth metacarpal bone.
25. Carpometacarpal articulation between the fourth carpal and the third metacarpal bone.
26. Carpometacarpal articulation between the third carpal and the third metacarpal bone.
27. Palmaromedial border of the third carpal bone.
28. Dorsal border of the second carpal bone.
29. Dorsal border of the third carpal bone.
30. Dorsal border of the fourth carpal bone.
31. Dorsolateral aspect of the midcarpal joint.
32. Dorsal border of the intermediate carpal bone.
33. Dorsal border of the ulnar carpal bone.
34. Dorsal border of the radial carpal bone. The relative position and appearance of the dorsal borders of 32, 33, and 34 may change with slight projection differences of the X-ray beam.
35. Antebrachiocarpal (radiocarpal) joint.
36. Bony ridge forming the medial border of the groove for the common digital extensor tendon.
37. Bony ridge along the lateral border of the extensor carpi radialis tendon.
38. Bony ridge between the grooves for the common digital extensor and the extensor carpi radialis tendons.

1. Tuberosity on the distomedial aspect of the radius for attachment of the medial collateral ligament.
2. Junction between the radial and intermediate carpal bones.
3. Dorsal border of the radial carpal bone.
4. Dorsoproximal border of the radial carpal bone.
5. Medial facet (medial styloid process) of the radial trochlea.
6. Intermediate facet of the radial trochlea.
7. Dorsal border of the intermediate carpal bone.
8. Dorsal articular margin of the radial trochlea.
9. Dorsal border of the ulnar carpal bone.
10. Junction between the ulnar and intermediate carpal bones.
11. Tuberosity on the distal lateral radius for attachment of the lateral collateral ligament.
12. Lateral border of the accessory carpal bone.
13. Proximolateral border of the fourth metacarpal bone.

VetBooks.ir

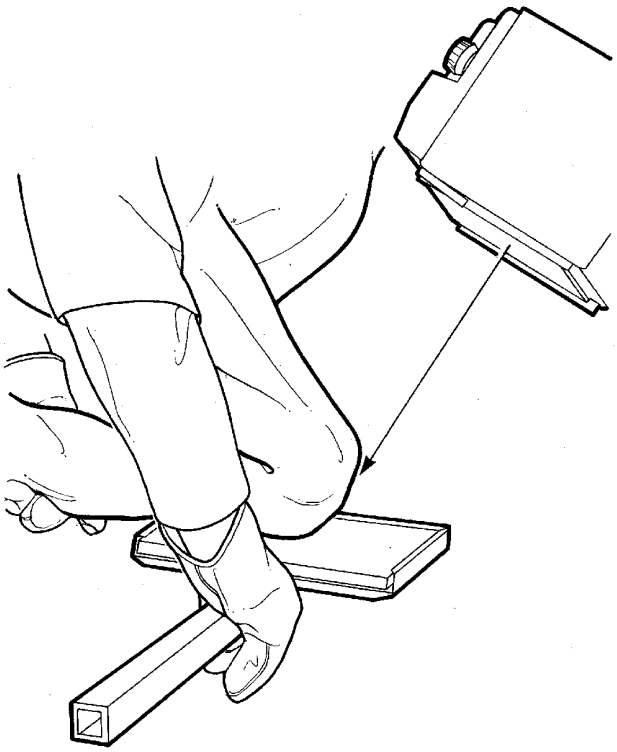

Figure 3.64.

VetBooks.ir

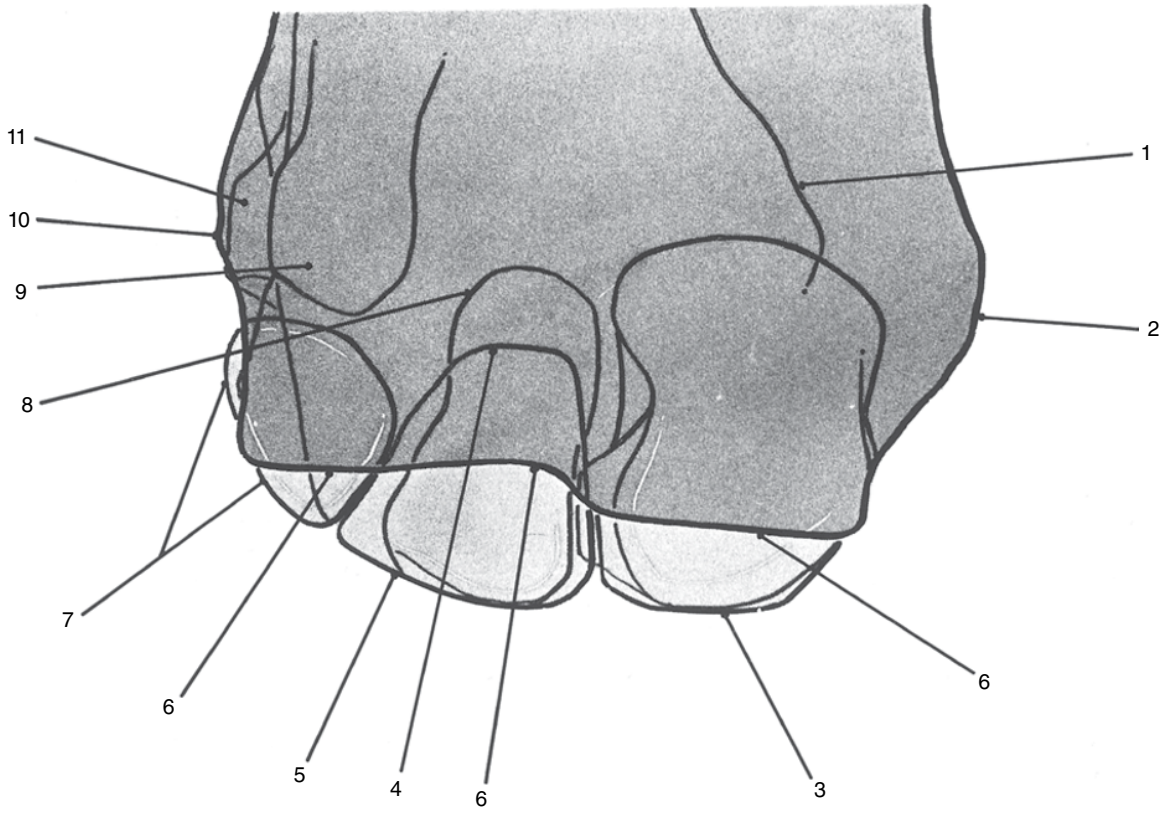

Figure 3.64. (*Continued*) Flexed dorsoproximal to dorsodistal oblique (flexed D55Pr-DDiO) projection of the proximal row of carpal bones. The position of the distal extremity of the radius relative to the proximal carpal bones varies with position of the horse's limb and the angulation of the primary X-ray beam. Slight changes in either may cause different degrees of superimposition of the radius and carpal bones.

1. Medial border of the second metacarpal bone.
2. Tuberosity on the distomedial aspect of the radius for attachment of the medial collateral ligament.
3. Dorsal border of the radial carpal bone.
4. Proximopalmar border of the intermediate carpal bone.
5. Dorsal border of the intermediate carpal bone.
6. Radial trochlea.
7. Dorsolateral border of the ulnar carpal bone.
8. Palmarodistal border of the intermediate carpal bone.
9. Proximal aspect of the fourth metacarpal bone.
10. Lateral tuberosity on the distal extremity of the radius for attachment of the lateral collateral ligament.
11. Accessory carpal bone.

VetBooks.ir

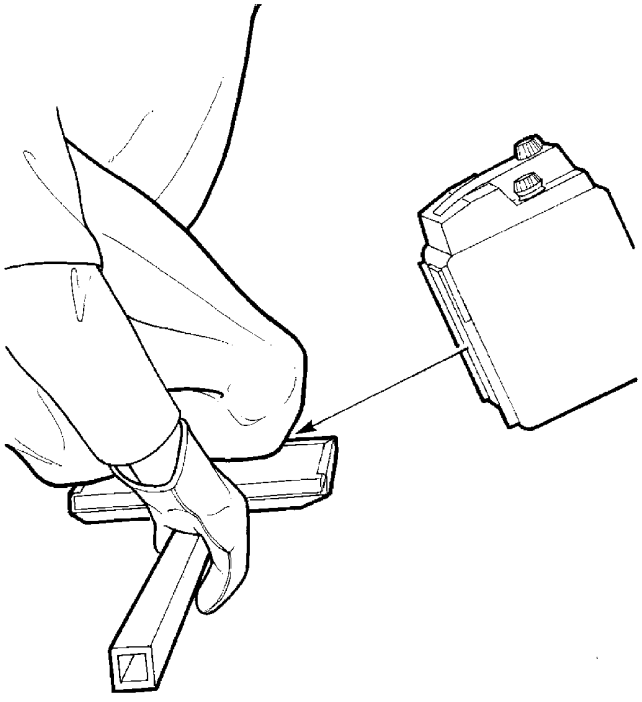

Figure 3.65.

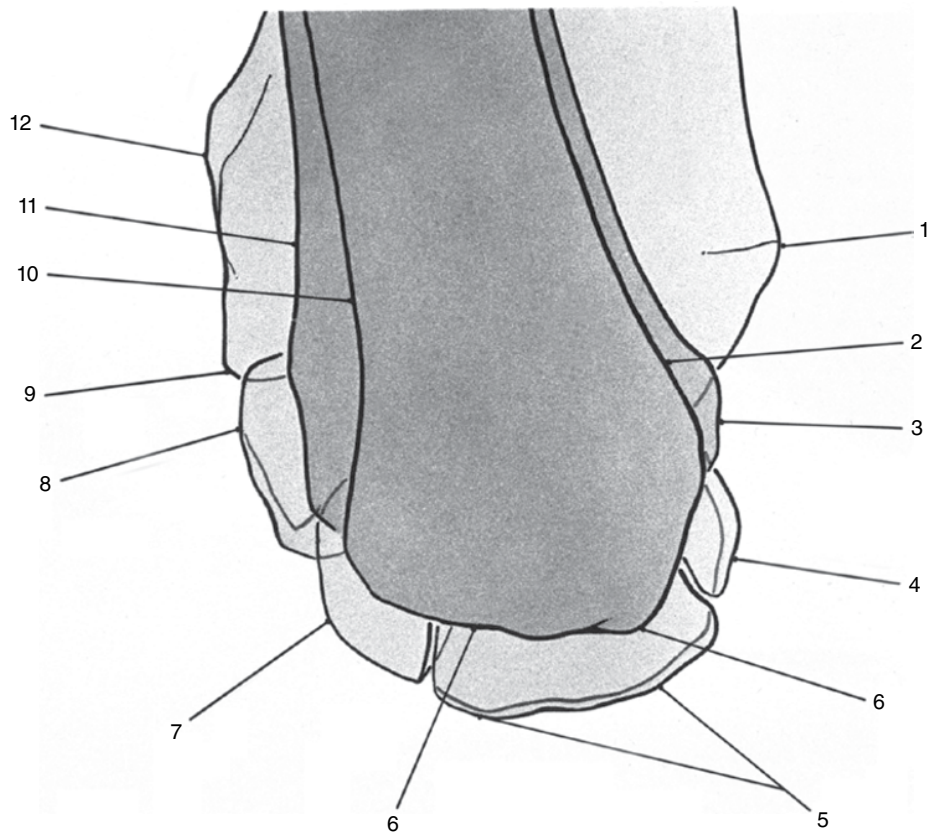
VetBooks.ir



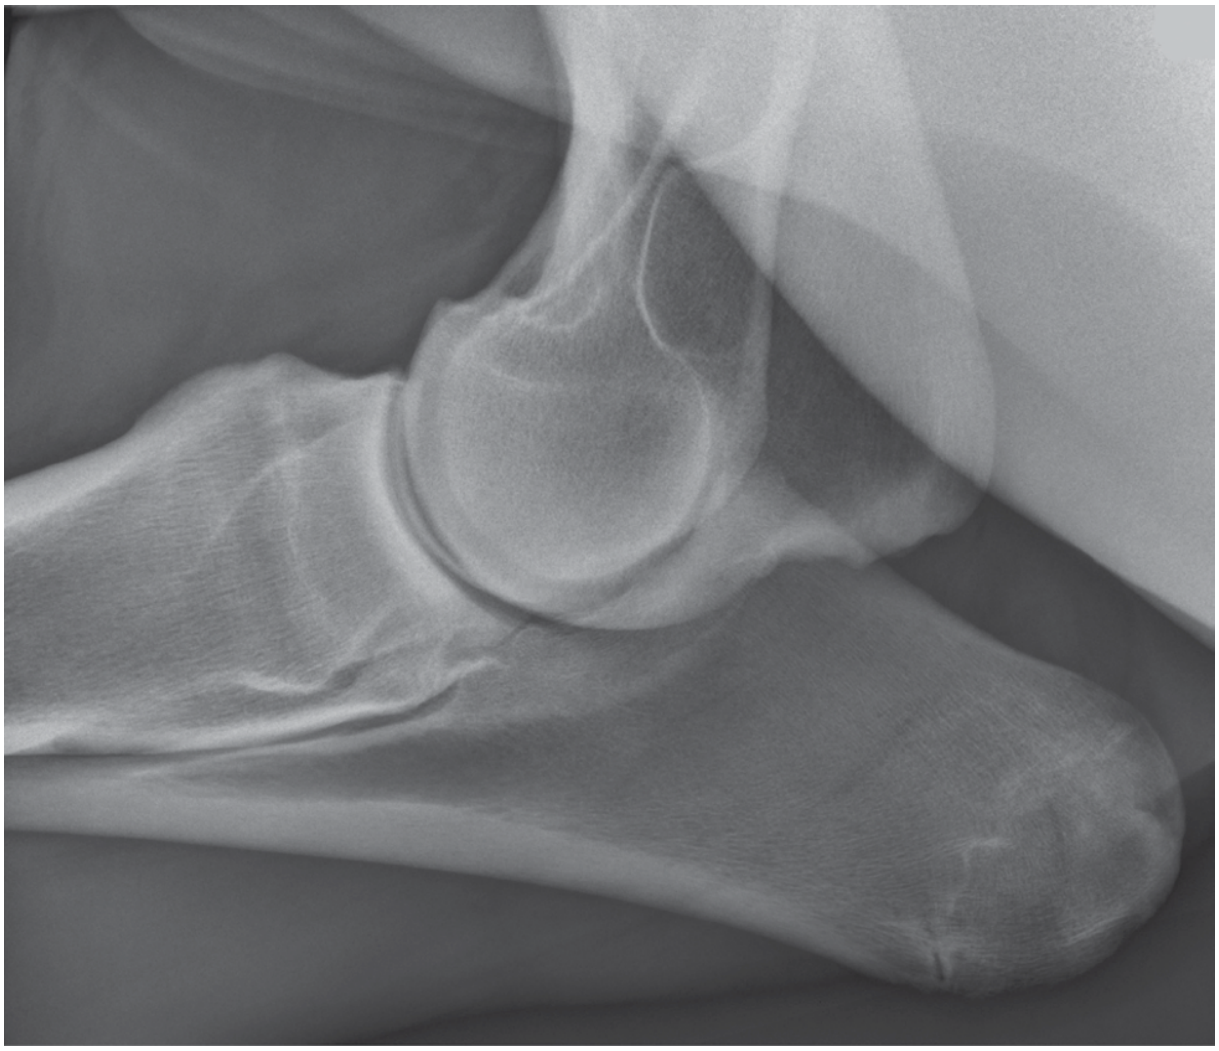


Figure 3.65. (*Continued*) Flexed dorsoproximal to dorsodistal oblique (flexed D30Pr-DDiO) projection of the distal row of carpal bones. The apparent shape of the third carpal bone may be changed by X-ray tube angulation and the position of the horse's limb and may appear more elongated than shown here. The dorsal cortex and medullary cavity should be evident on the medial aspect of the normal third carpal bone if properly positioned.

1. Medial tuberosity on the distal radius for attachment of the medial collateral ligament.
2. Medial border of the third metacarpal bone.
3. Medial border of the second metacarpal bone.
4. Second carpal bone.
5. Dorsal border of the third carpal bone.
6. Superimposed dorsal border of the proximal carpal bones and the third metacarpal bone.
7. Fourth carpal bone.
8. Lateral border of the accessory carpal bone.
9. Lateral aspect (lateral styloid process) of the radial trochlea.
10. Lateral border of the third metacarpal bone.
11. Lateral border of the fourth metacarpal bone.
12. Lateral tuberosity on the distal extremity of the radius for attachment of the lateral collateral ligament.

VetBooks.ir

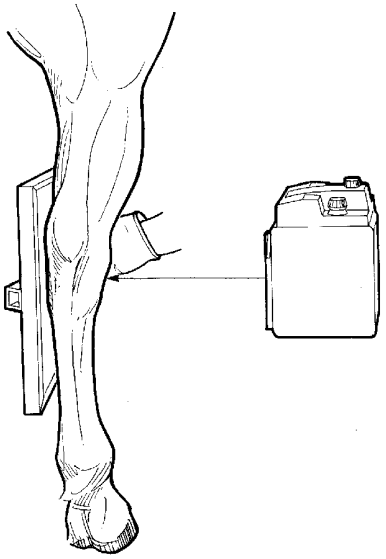

Figure 3.72.

VetBooks.ir

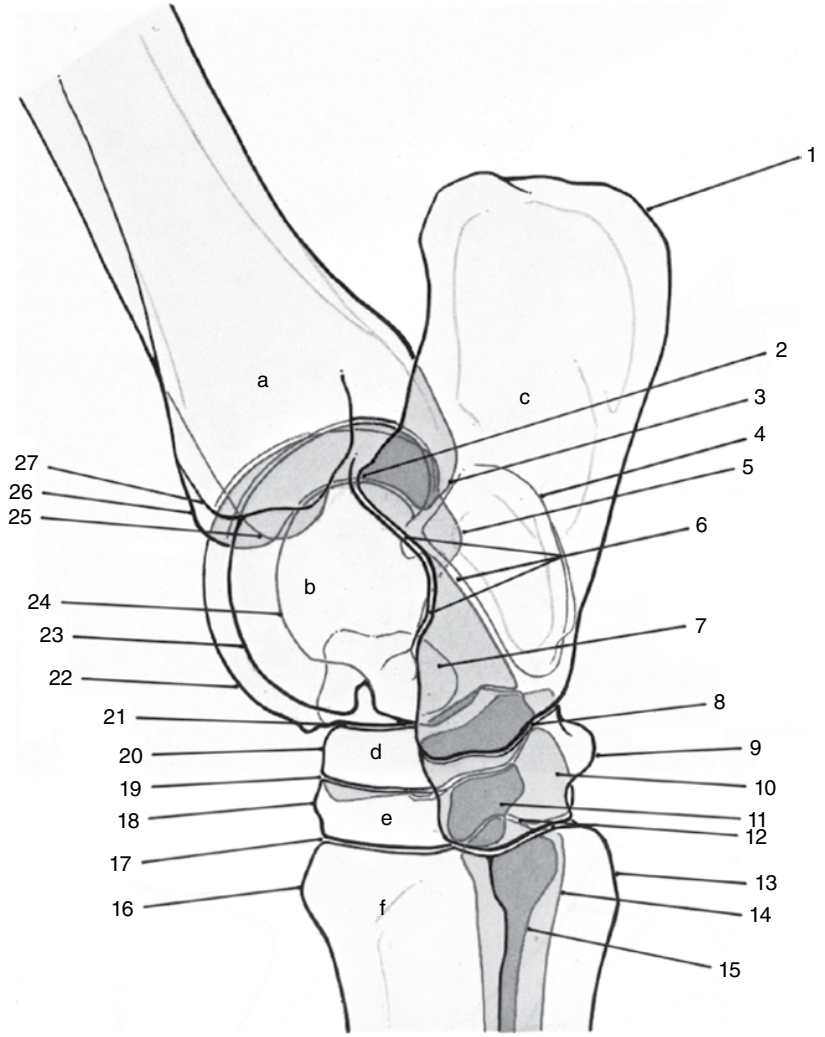

Figure 3.72. (*Continued*) Lateromedial (LM) projection of the tarsus. Depending on obliquity of the radiographic projection, the cranial borders of the malleoli and trochlear ridges may be in different relative positions. (a) Tibia, (b) talus, (c) calcaneus, (d) central tarsal bone, (e) third tarsal bone, and (f) third metatarsal bone.

1. Calcaneal tuber.
2. Coracoid process of the calcaneus.
3. Caudal intermediate part of the tibial cochlea.
4. Sustentaculum tali of the calcaneus.
5. Proximomedial tuberosity of the talus for ligamentous attachments (superficial short medial collateral ligament).
6. Articulation between the talus and the calcaneus. All of these joint surfaces may not be distinguishable on any one radiograph; they should not be mistaken for fractures.
7. Distomedial tuberosity of the talus for ligamentous attachment (dorsal tarsal ligament).
8. Articulation between the calcaneus and the fourth tarsal bone.
9. Plantar surface of the fourth tarsal bone.
10. Second tarsal bone. The first and second tarsal bones are fused and project as different densities because of superimposition.
11. First tarsal bone.
12. Plantar aspect of the tarsometatarsal articulations.
13. Plantar border of the fourth metatarsal bone. The fourth metatarsal bone is larger than the second metatarsal bone and projects on the plantar surface.
14. Plantar border of the second metatarsal bone.
15. Plantar border of the third metatarsal bone.
16. Dorsoproximal ridge on the third metatarsal bone for attachment of the tibialis cranialis.
17. Articulation between the third tarsal and the third metatarsal bone.
18. Dorsal border of the third tarsal bone.
19. Articulation between the third and central tarsal bones.
20. Dorsal border of the central tarsal bone.
21. Articulation between the central tarsal bone and the talus.
22. Medial trochlear ridge of the talus. The small bony projection on the distal part of the medial trochlear ridge is variable in size and shape and should not be mistaken for a periarticular osteophyte or any other bony abnormality.
23. Lateral trochlear ridge of the talus.
24. Depth of the trochlear groove between the trochlear ridges on the talus.
25. Distocranial border of the medial tibial malleoli.
26. Cranial intermediate part of the tibial cochlea.
27. Distocranial border of the lateral tibial malleoli.

VetBooks.ir

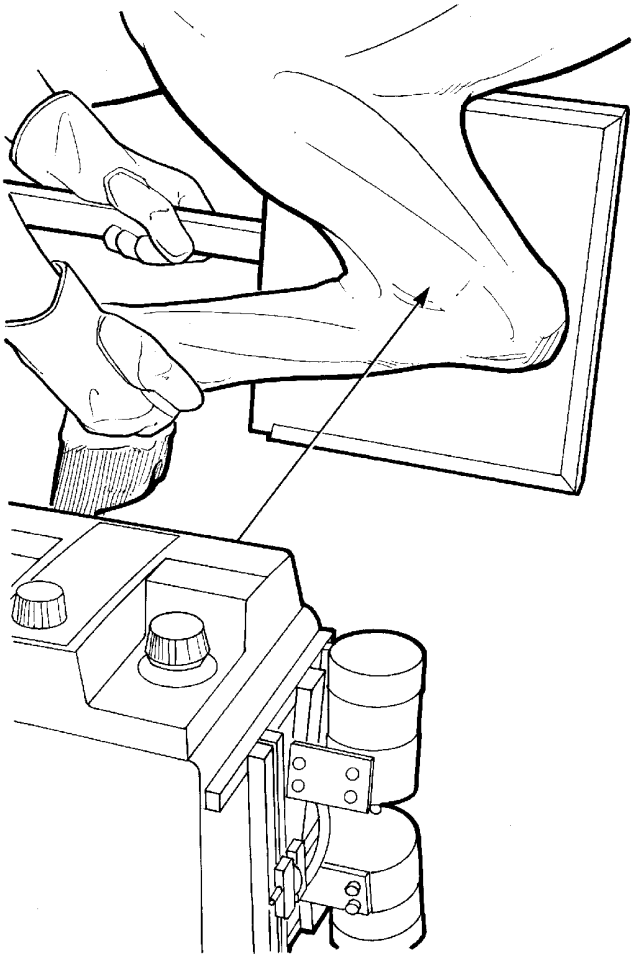

Figure 3.73.

VetBooks.ir

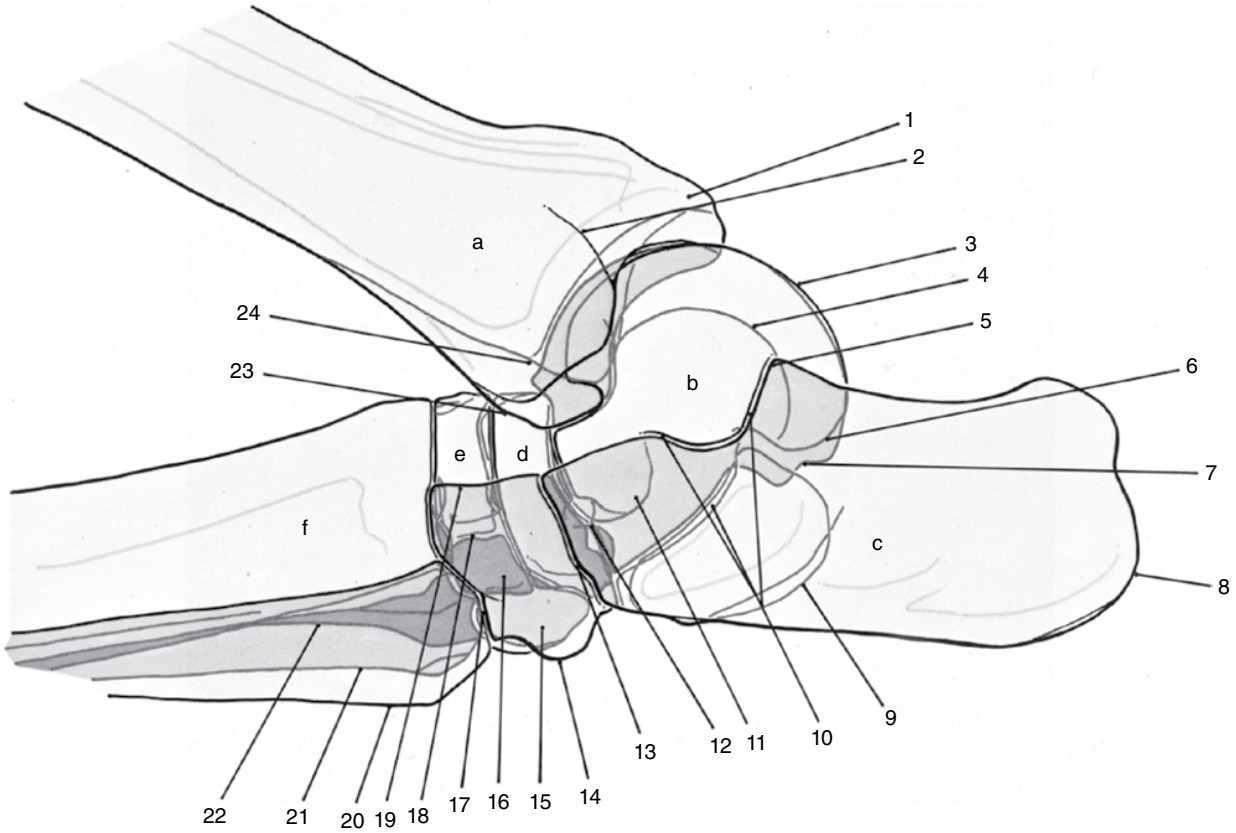

Figure 3.73. (*Continued*) Flexed lateromedial (flexed LM) projection of the tarsus. (a) Tibia, (b) talus, (c) calcaneus, (d) central tarsal bone, (e) third tarsal bone, and (f) third metatarsal bone.

1. Caudal intermediate part of the tibial cochlea.
2. Distocaudal border of the lateral tibial malleolus.
3. Superimposed medial and lateral trochlear ridges of the talus.
4. Depth of the trochlear groove between the trochlear ridges of the talus.
5. Coracoid process of the calcaneus.
6. Plantar border of the lateral trochlear ridge on the talus.
7. Plantar border of the medial trochlear ridge on the talus.
8. Calcaneal tuber.
9. Sustentaculum tali.
10. Articulations between the talus and calcaneus, the visualization of which depends on the projection angle.
11. Distomedial tuberosity of the talus for ligamentous attachment (dorsal tarsal ligament).
12. Articulation between the talus and the central tarsal bone.
13. Articulation between the calcaneus and the fourth tarsal bone.
14. Plantar border of the fourth tarsal bone.
15. Second tarsal bone. The first and second tarsal bones are fused.
16. First tarsal bone.
17. Tarsometatarsal articulation.
18. Junction between the first and third tarsal bones, which is not always distinctly visible. Do not mistake the junction, when present, for a slab fracture.
19. Dorsal border of the fourth tarsal bone.
20. Plantar border of the fourth metatarsal bone.
21. Plantar border of the second metatarsal bone.
22. Plantar border of the third metatarsal bone. The superimposed plantar border of the third metatarsal bone and the dorsal borders of the second and fourth metatarsal bones may produce pseudolongitudinal fracture lines.
23. Cranial intermediate part of the tibial cochlea.
24. Cranial border of the medial tibial malleolus.

VetBooks.ir

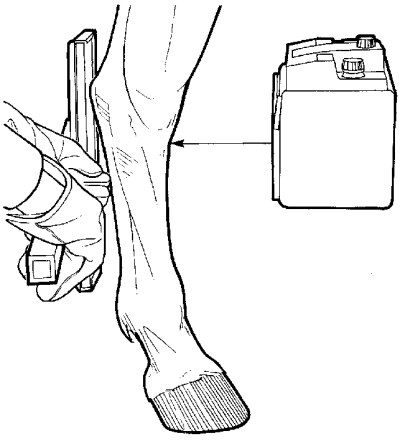

Figure 3.74.

VetBooks.ir

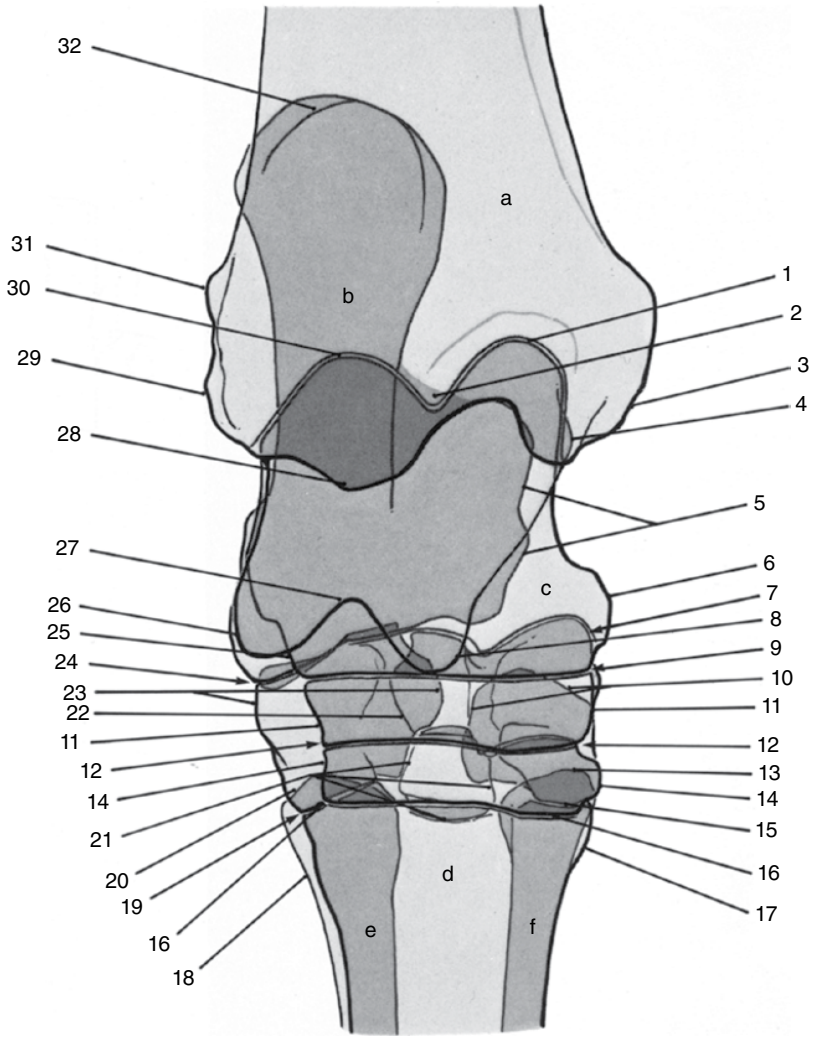

Figure 3.74. (*Continued*) Dorsoplantar (DPl) projection of the tarsus. The bones and joints of the tarsus are irregular and have complex shapes; thus, their appearance can vary with little change in projection angle. Therefore, careful observation is necessary when the tarsus is being evaluated radiographically. (a) Tibia, (b) calcaneus, (c) talus, (d) third metatarsal bone, (e) fourth metatarsal bone, and (f) second metatarsal bone.

1. Articulation between the medial trochlear ridge of the talus and the medial cochlear groove of the tibia (tarsocrural joint).
2. Intermediate ridge of the tibial cochlea.
3. Medial malleolus on the distal tibia, where the medial collateral ligaments attach.
4. Proximal medial tuberosity on the talus, where the superficial short medial collateral ligament attaches.
5. Sustentaculum tali.
6. Distal medial tuberosity on talus for ligamentous attachment.
7. Plantar medial aspect of the talocalcaneocentral (proximal intertarsal) joint.
8. Distomedial border of the medial trochlear ridge on the talus.
9. Dorsomedial aspect of the talocalcaneal central (proximal intertarsal) joint. The difference in position of the plantar and dorsal aspects of this joint is caused by the curved contour of the articular surfaces in the proximal intertarsal joint.
10. Medial and lateral borders of the second tarsal bone.
11. Medial and lateral borders of the central tarsal bone.
12. Articulation between the third and central tarsal bones (tarsodistal or distal intertarsal joint).
13. Proximal border of the second metatarsal bone superimposed on the first and third tarsal bones.
14. Medial and lateral borders of the third tarsal bone.
15. Articulation between the second metatarsal and the fused first and second tarsal bones.
16. Medial and lateral aspects of the articulation between the third tarsal and the third metatarsal bone.
17. Proximomedial border of the second metatarsal bones.
18. Proximolateral border of the fourth metatarsal bone.
19. Articulation between the fourth tarsal and the fourth metatarsal bone (tarsometatarsal joint).
20. Proximal border of the fourth metatarsal bone superimposed over the fourth tarsal bone.
21. Bony prominence on the plantar surface of the third tarsal bone.
22. Prominence on the plantar surface of the central tarsal bone.
23. Lateral and medial borders of the fourth tarsal bone.
24. Articulation of the fourth tarsal bone and the calcaneus (calceneoquartal or proximal intertarsal joint).
25. Distal lateral border of the talus.
26. Lateral trochlear ridge of the talus.
27. Groove between medial and lateral trochlear ridges on the talus.
28. Caudal aspect of the intermediate ridge on the tibial cochlea.
29. Cranial part of the lateral malleolus.
30. Articulation between the lateral trochlear ridge on the talus and the lateral tibial cochlear groove in the tarsocrural (tibiotarsal) joint.
31. Caudal part of the lateral malleolus.
32. Calcaneal tuber.

VetBooks.ir

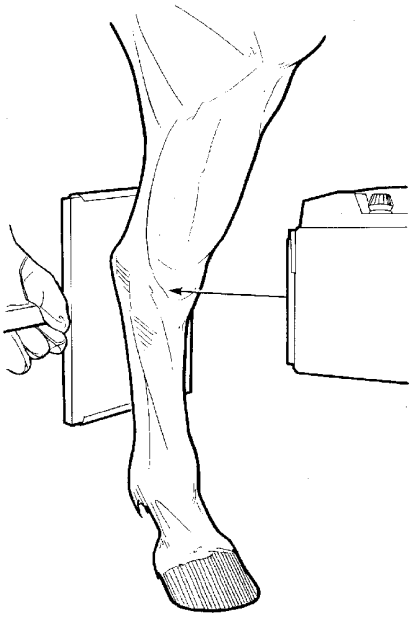

Figure 3.75.

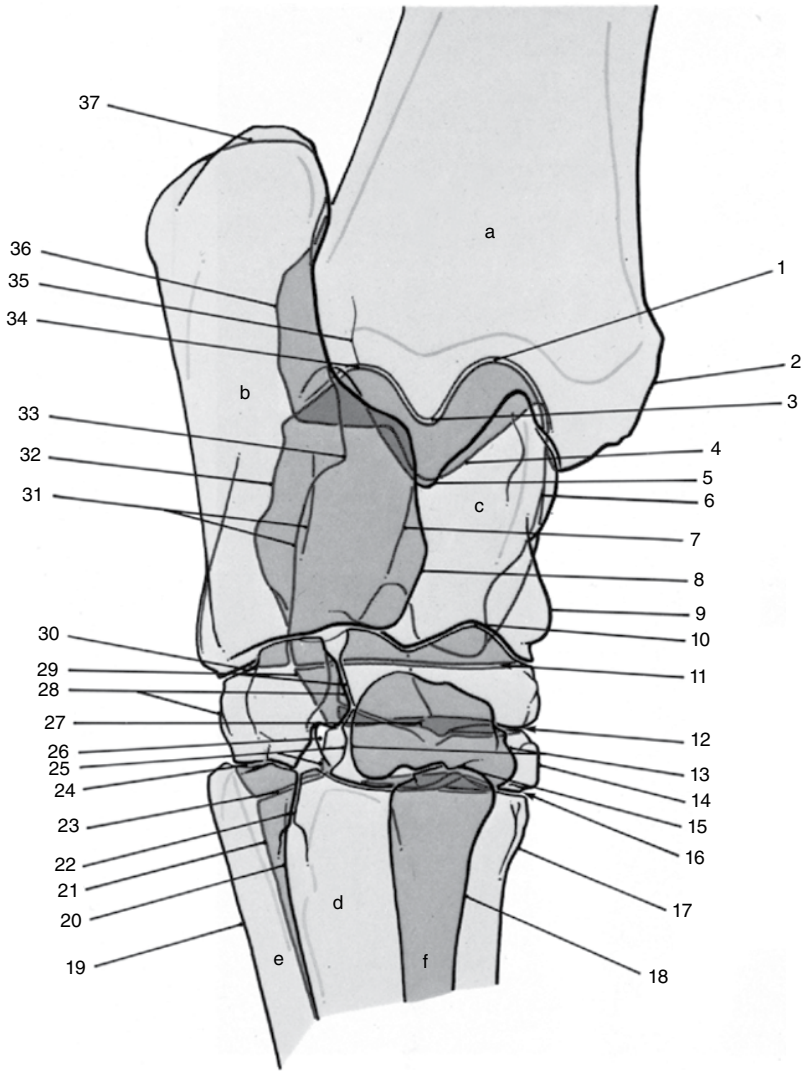
VetBooks.ir



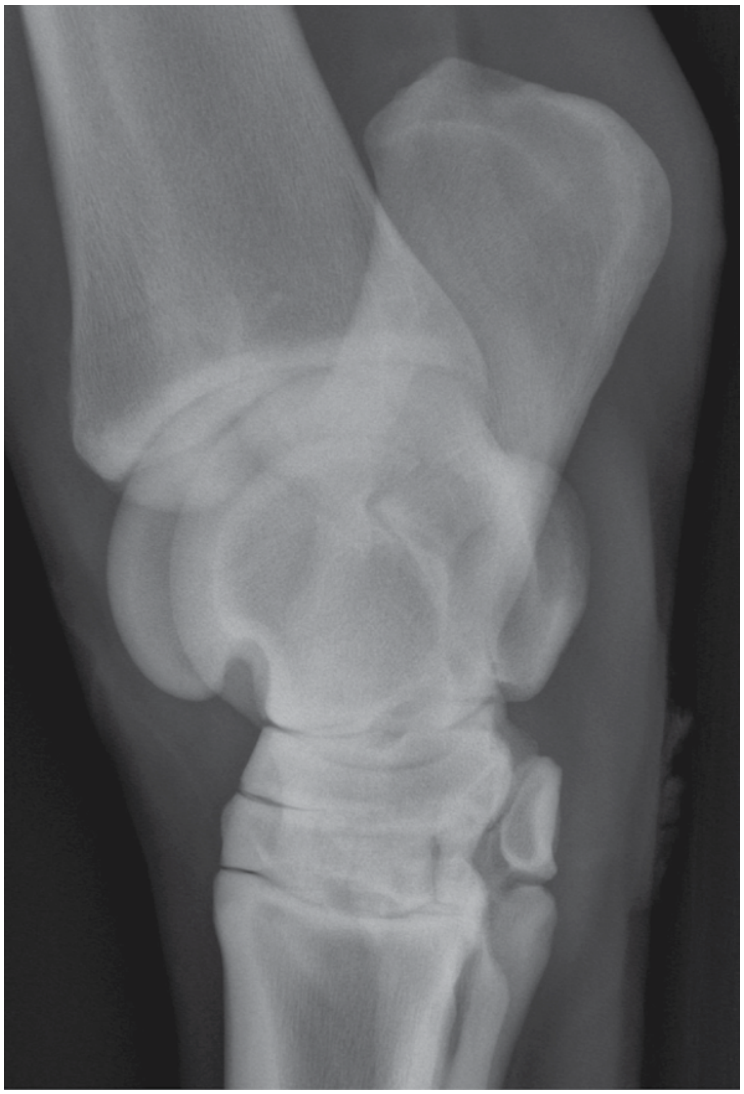


Figure 3.75. (*Continued*) Dorsolateral to plantaromedial oblique (D35L-PIMO) projection of the tarsus. (a) Tibia, (b) calcaneus, (c) talus, (d) third metatarsus, (e) fourth metatarsal bone, and (f) second metatarsal bone.

1. Articulation between the medial trochlear ridge of the talus and the medial tibial cochlear groove in the tarsocrural (tibiotarsal) joint.
2. Medial malleolus.
3. Articulation between the intermediate ridge of the tibial cochlea and the groove in the trochlea tali in the tarsocrural joint.
4. Cranial aspect of the intermediate ridge on the tibial cochlea.
5. Caudal aspect of the intermediate ridge on the tibial cochlea.
6. Medial trochlear ridge of the talus.
7. Lateral trochlear ridge of the talus.
8. Dorsomedial border of the sustentaculum tali.
9. Distomedial tuberosity of the talus for ligamentous attachment.
10. Plantaromedial aspect of the talocalcaneocentral (proximal intertarsal) joint.
11. Dorsomedial aspect of the talocalcaneocentral (proximal intertarsal) joint.
12. Dorsomedial aspect of the articulations between the central and third tarsal bone (centrodistal or distal intertarsal joint).
13. Medial and lateral borders of the fused first and second tarsal bones.
14. Prominent ridge for ligamentous attachment on the dorsomedial surface of the third tarsal bone.
15. Articulation between the fused first and second tarsal bones and the second metatarsal bone.
16. Dorsomedial aspect of the articulation between the metatarsal bone and the third metatarsal bone (tarsometatarsal joint).
17. Dorsomedial border of the third metatarsal bone.
18. Dorsomedial border of the fourth metatarsal bone.
19. Plantarolateral border of the fourth metatarsal bone.
20. Interosseous space between the third and fourth metatarsal bone.
21. Lateral border of the third metatarsal bone dorsal to the fourth metatarsal bone.
22. Articulation between the third and fourth metatarsal bone.
23. Articulation between the fourth tarsal and the third metatarsal bone.
24. Articulation between the fourth tarsal and the fourth metatarsal bone.
25. Plantarolateral and plantaromedial borders of the third tarsal bone.
26. Vascular tarsal canal, which encloses the perforating tarsal artery and vein and a deep perineal nerve branch. It may be more or less apparent on this projection, depending on the projection angle.
27. Nonvascular area between the central and the third tarsal bones. These nonarticular areas may simulate subchondral bone lysis and must be differentiated from erosion by their location.
28. Plantarolateral and dorsomedial borders of the fourth tarsal bone.
29. Plantarolateral and plantaromedial borders of the central tarsal bone.
30. Articulation between the calcaneus and the fourth tarsal bone (calcaneoquarteral or proximal intertarsal joint).
31. Borders of the sinus tarsi, which is a space between the calcaneus and talus that appears as a more or less lucent region.
32. Plantarolateral border of the sustentaculum tali.
33. Coracoid process of the calcaneus.
34. Articulation between the lateral trochlear ridge of the talus and the lateral tibial cochlear groove in the tarsocrural joint (tibiotarsal joint).
35. Cranial part of the lateral malleolus.
36. Caudal part of the lateral malleolus.
37. Calcaneal tuber.

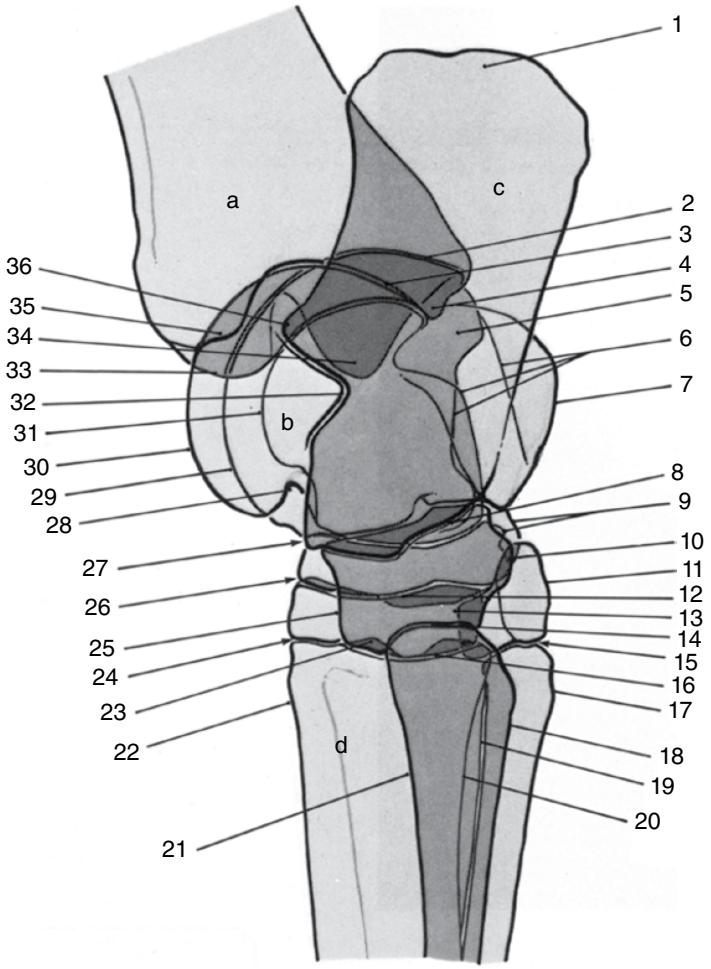

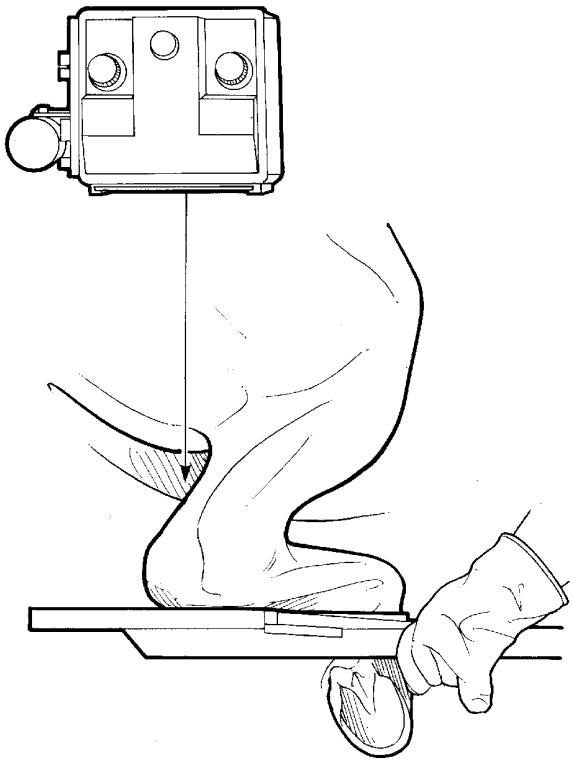

Figure 3.76. (*Continued*) Dorsomedial to plantarolateral (D55MPILO) projection of the tarsus. (a) Tibia, (b) talus, (c) calcaneus, and (d) third metatarsal bone.

1. Calcaneal tuber
2. Articulation between the medial trochlear ridge of the talus and the medial tibial cochlear groove of the tarsocrural joint.
3. Articulation between the lateral trochlea of the talus and the lateral tibial cochlear groove of the tarsocrural joint.
4. Caudal aspect of the intermediate ridge of the tibial cochlea.
5. Proximomedial tuberosity of the talus.
6. Plantar borders of the talus superimposed on the calcaneus.
7. Plantar border of the sustentaculum tali.
8. Nonarticular depression between the talus and the central tarsal bone. These nonarticular depressions, which appear more of less distinct depending on the angle of the X-ray beam projection, may simulate subchondral bone lysis.
9. Medial and lateral plantar borders of the central tarsal bone.
10. Plantar border of the fourth tarsal bone.
11. Plantar border of the fused first and second tarsal bone.
12. Area of nonarticular depression between the central and third tarsal bones.
13. Junction between the fused first and second tarsal bones and the medial plantar border of the third tarsal bone.
14. Articulation between the fourth tarsal and the fourth metatarsal bone.
15. Articulation between the fused first and second tarsal bone and the second metatarsal bone.
16. Articulation between the fourth tarsal bone and the third metatarsal bone.
17. Plantar border of the second metatarsal bone.
18. Plantar border of the fourth metatarsal bone.
19. Interosseous space between the second and third metatarsal bones.
20. Plantar border of the third metatarsal bone.
21. Dorsolateral border of the fourth metatarsal bone.
22. Dorsolateral border of the third metatarsal bone.
23. Nonarticular depressions in the adjacent surface of the third tarsal and the third metatarsal bone.
24. Dorsolateral aspect of the articulation between the third tarsal and the third metatarsal bone (tarsometatarsal joint).
25. Dorsolateral border of the fourth tarsal bone.
26. Dorsolateral aspect of the articulation between the central and the third tarsal bone (centrodistal or distal intertarsal bone).
27. Dorsolateral aspect of the talocalcaneal central (proximal intertarsal joint).
28. Notch at the distal aspect of the lateral trochlear ridge on the talus.
29. Medial trochlear ridge of the talus.
30. Lateral trochlear ridge of the talus.
31. Depth of the groove between the medial and lateral trochlear ridges on the talus.
32. Articulation between the talus and the calcaneus (talocalcaneal articulation), the visibility of which depends on the X-ray beam projection.
33. Cranial aspect of the intermediate ridge on the tibial cochlea.
34. Medial malleolus superimposed over the talus and calcaneus.
35. Lateral malleolus superimposed over the intermediate tibial cochlear ridge and the lateral trochlear ridge of the talus.
36. Coracoid process of the calcaneus.

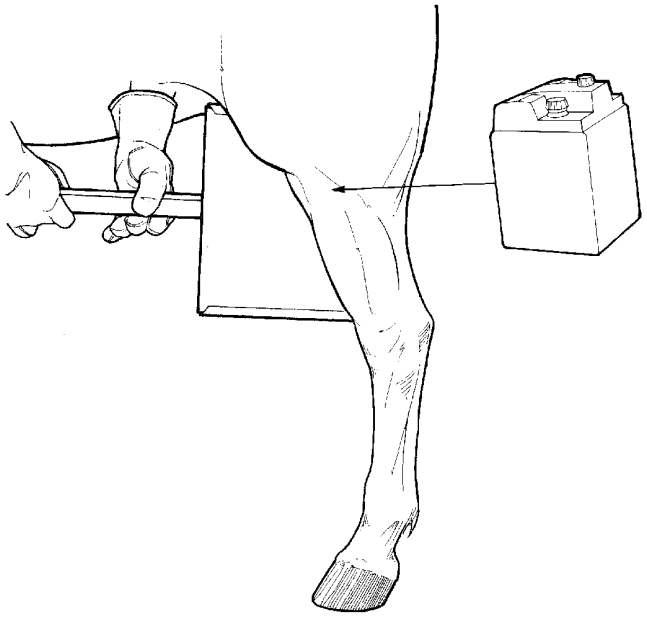

Figure 3.79.

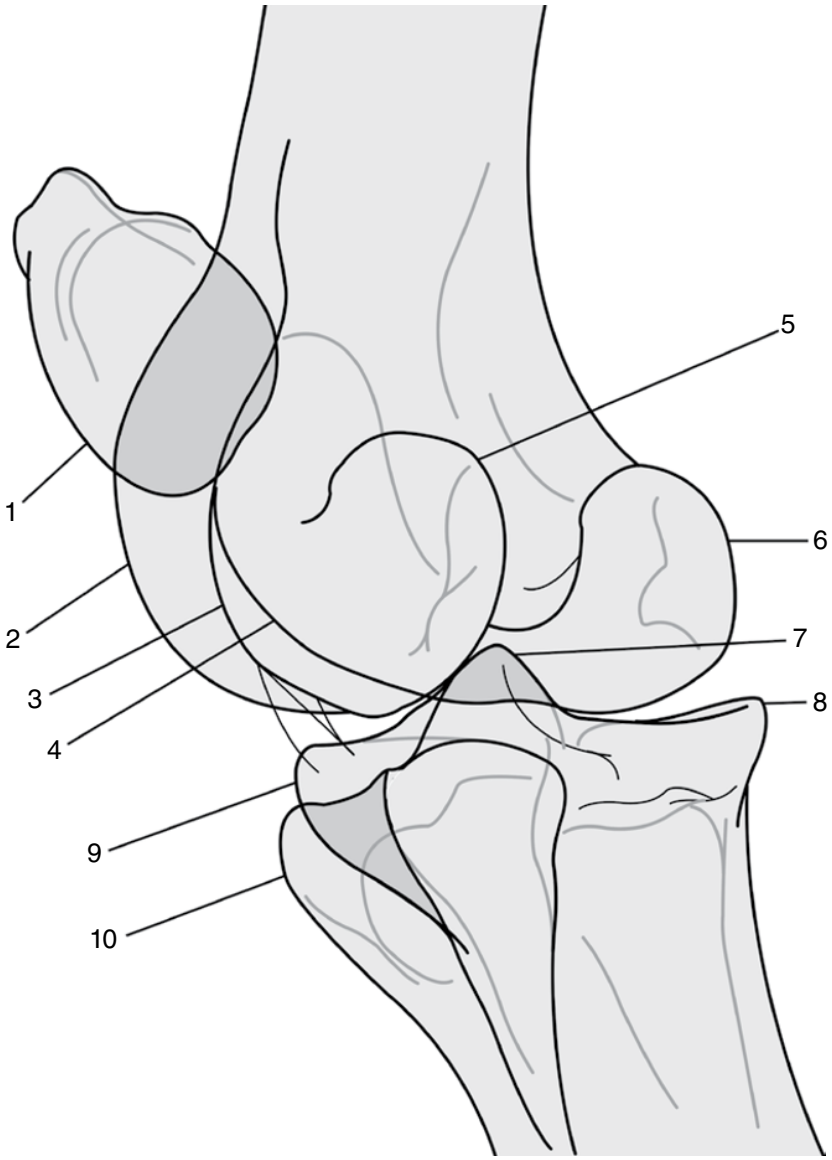
VetBooks.ir



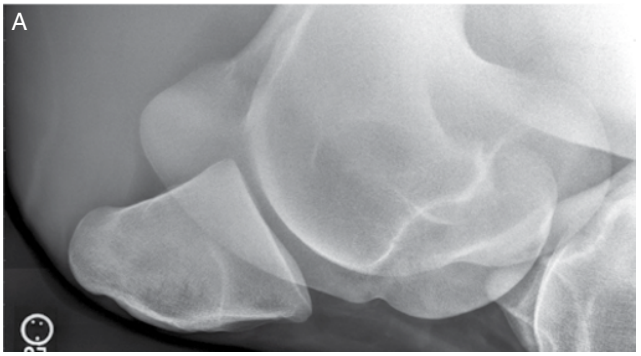


Figure 3.79. (*Continued*) Laterocaudal to craniomedial oblique (L45Ca-CrMO) projection of the stifle joint. From a straight lateromedial position, the primary X-ray beam is directed parallel to the ground with a 45° caudal angle and is centered on the caudal aspect of the stifle joint for a different approach in the evaluation of the medial femoral condyle. This projection also shows a large area of the weight-bearing articular surface of the medial femoral condyle free of superimposition with the lateral condyle and can be an alternative to the flexed projection. However, in both projections, the medial femoral condyle is projected differently, and one lesion may be seen in one and not the other.

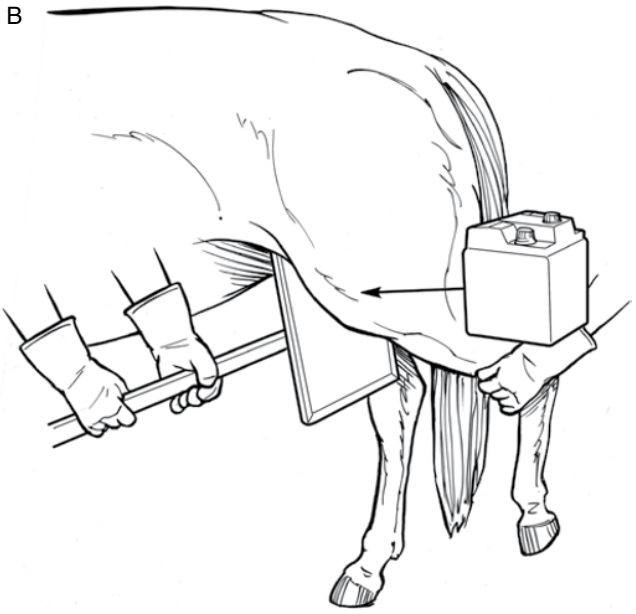
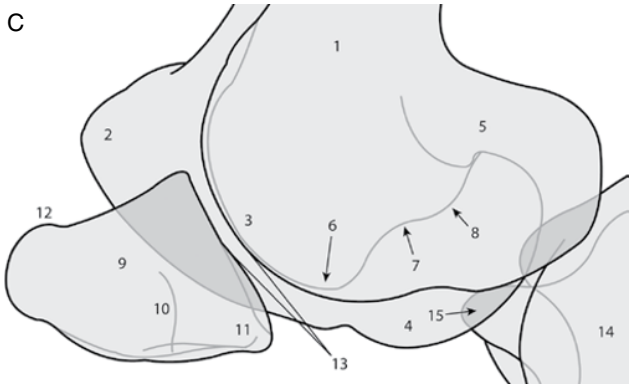
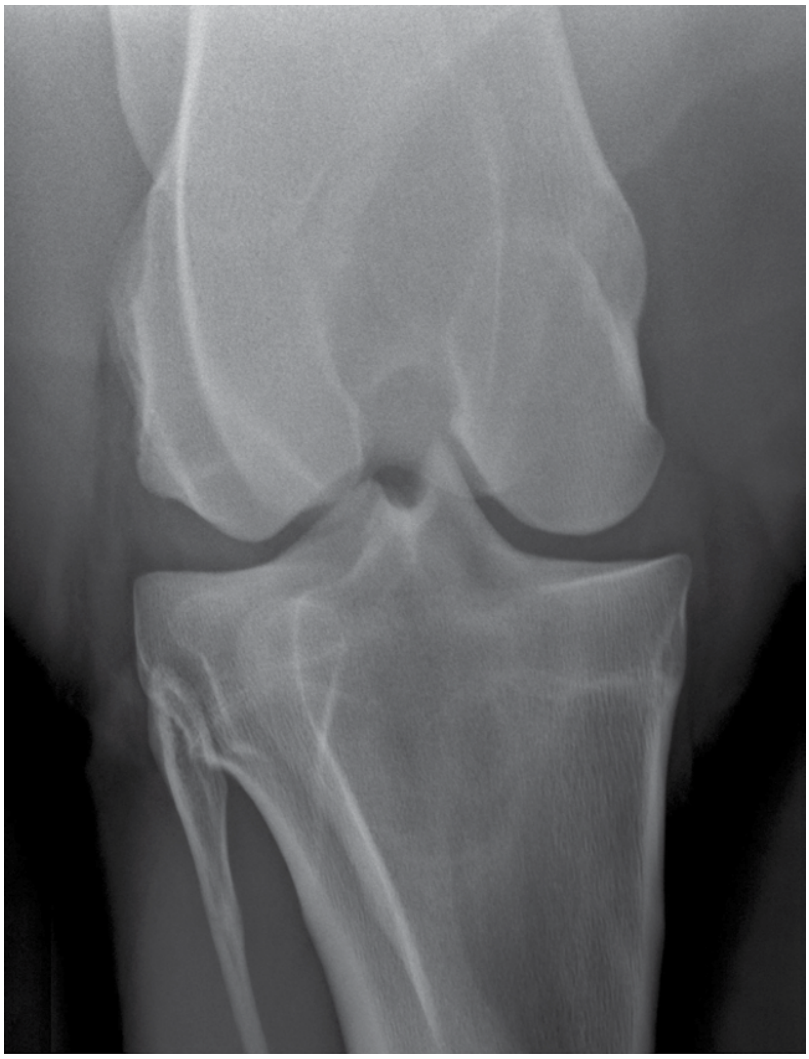


1. Patella.
2. Lateral femoral trochlear ridge.
3. Intercondylar groove.
4. Medial femoral trochlear ridge.
5. Lateral femoral condyle.
6. Medial femoral condyle.
7. Medial tubercle on the intercondyloid eminence of the tibia.
8. Medial tibial condyle.
9. Lateral tibial condyle.
10. Tibial tuberosity.



VetBooks.ir

Figure 3.80. (A, B, and C). Flexed lateromedial (flexed L0-20Cr-CaMO) projection of the femorotibial and femoropatellar joints (stifle). Projections (A and C) show the articular surface of the medial femoral condyle free of superimposition with other osseous structures. This projection can be performed in two different ways. The limb can be flexed and abducted and the X-ray beam directed parallel to the ground with a 0° to 20° laterocranial obliquity (B); if the limb cannot be abducted, an approximately 10° distal obliquity (L0-20Cr10Di-PrMO) should be added to the X-ray beam direction.



1. Femur

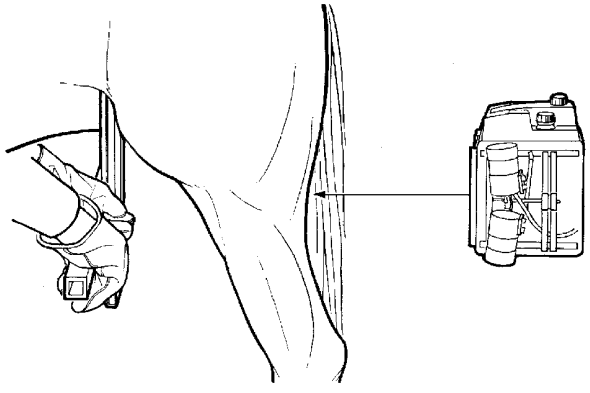

Figure 3.81.

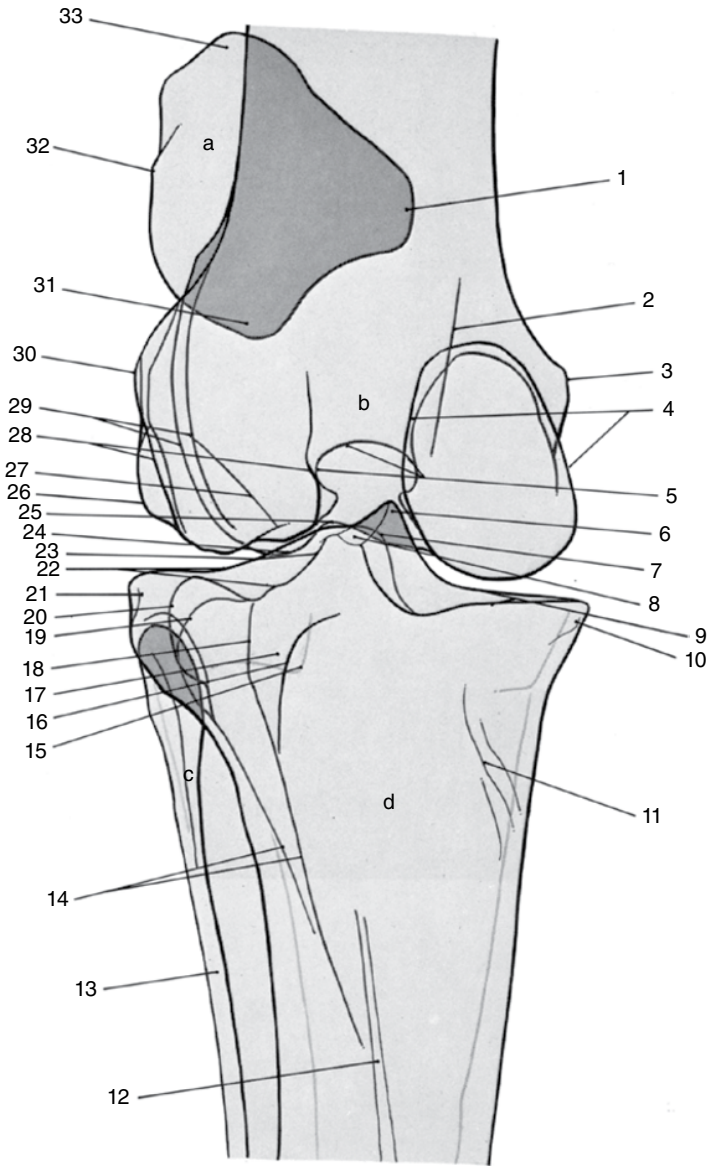
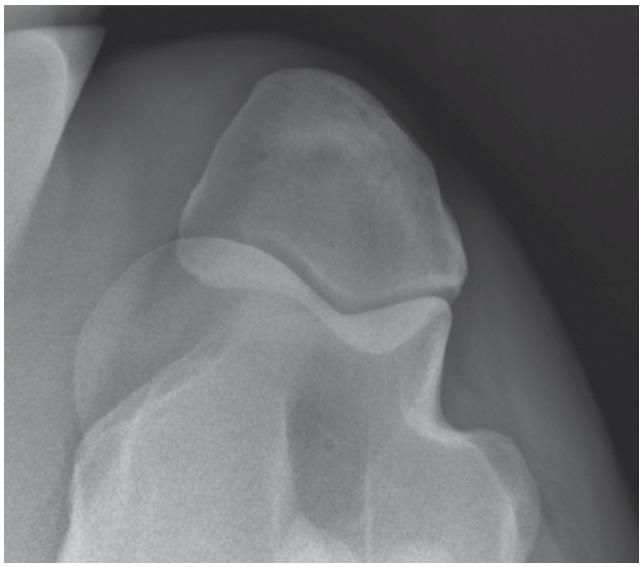
VetBooks.ir





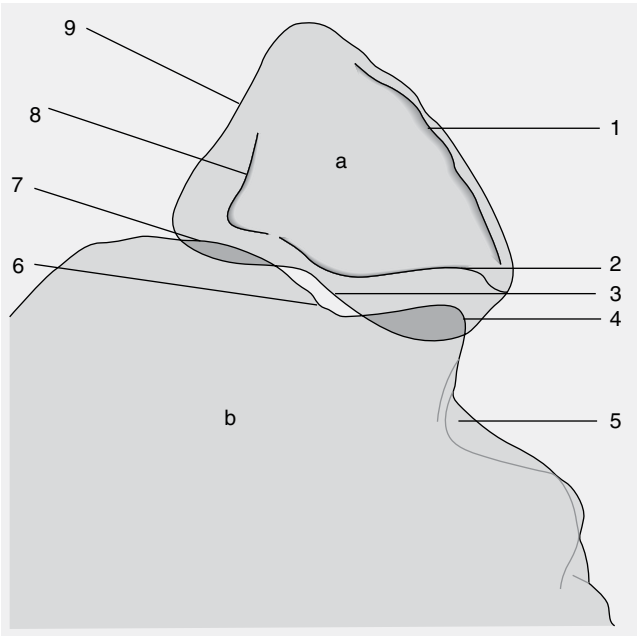


Figure 3.81. (*Continued*) Caudocranial (CaCr) projection of the femorotibial and femoropatellar joints (stifle). The entire patella may or may not be seen depending on the X-ray exposure. The patella is normally located to the lateral side of the distal aspect of the femur. The fibula may be a complete bone (as here), but it is usually rudimentary with only the proximal part present or with one or two transverse lines that give the mistaken appearance of fractures. (a) Patella, (b) femur, (c) fibula, and (d) tibia.

1. Medial angle of the patella. A large cartilaginous process extends from the medial angle of the patella and is not visible radiographically.
2. Lateral border of the medial trochlear ridge on the distal femur, the visibility of which depends on the X-ray exposure.
3. Medial epicondyle for ligamentous attachment.
4. Medial and lateral borders of the medial femoral condyle.
5. Intercondyloid fossa on the caudal aspect of the distal femur.
6. Medial tubercle on the intercondylar eminence of the proximal tibia.
7. Lateral tubercle on the intercondylar eminence of the proximal tibia.
8. Central intercondylar area.
9. Cranial and caudal borders of the articular surface of the medial tibial condyle.
10. Medial tibial condyle.
11. Tubercle on the caudal medial tibial surface.
12. Muscular lines on the caudal tibial surface.
13. Fibula.
14. Tibial crest.
15. Bony margin of the extensor sulcus.
16. Medial part of the tibial tuberosity.
17. Groove between the medial and lateral parts of the tibial tuberosity for the medial patellar ligament.
18. Medial border of the lateral part of the tibial tuberosity.
19. Cranial aspect of the lateral tibial condyle.
20. Lateral proximal border of the lateral part of the tibial tuberosity.
21. Caudal aspect of the lateral tibial condyle.
22. Cranial and caudal articular surfaces on the lateral tibial condyle.
23. Articular surface on the medial part of the lateral tibial condyle.
24. Distal aspect of the lateral trochlear ridge on the femur.
25. Distal aspect of the groove between the distal femoral trochlear ridges.
26. Lateral femoral epicondyle for ligamentous attachment.
27. Bony borders of the extensor fossa on the distal femur.
28. Lateral and medial borders of the lateral femoral condyle.
29. Lateral trochlear ridge on the distal extremity of the femur.
30. Proximolateral border of the lateral femoral condyle.
31. Apex of the patella.
32. Lateral angle and the patella.
33. Base of the patella.

ULTRASOUND

W. Rich Redding

VetBooks.ir

INTRODUCTION

Over the last several decades, ultrasound technology has dramatically improved. The current technology found in linear array ultrasound systems has progressed rapidly and are now very well suited for musculoskeletal examinations. Many of these high-end systems have 14–18-MHz linear tendon probes and 8–10-MHz microconvex probes with variable focusing capabilities with multiple frequencies available in each probe. In addition, mainframe ultrasound platforms have been reduced to the size of notebook-sized computers as well as advancements made in the miniaturization of electronics have reduced the quality differences between portable and stationary technologies. Ultrasonography is now considered the imaging modality of choice to evaluate soft tissue injuries in the horse.

Ultrasonography is a two-dimensional real-time imaging technique that utilizes the transfer and propagation of sound waves into soft tissue.[4,55,61,70,73,74,80] Ultrasound is defined as sound above the audible range. Ultrasound waves behave as classic sound waves that operate at frequencies spanning 1–22 MHz. These sound waves are mechanical waves that require some sort of medium to allow the waves to form and travel. The propagating medium determines how fast the sound wave travels, how easily the waves can be formed, and how well the traveling waves can remain together. Ultrasound machines produce sound waves of longitudinal orientation in which the elements of the medium are compressed and rarefied. The distance between the start of one cycle of compression and rarefaction and the next is considered the wavelength, and most wavelengths are 1 mm or less. Propagation speed of the ultrasound wave is determined by the density and stiffness of a given tissue with bone propagating at higher speeds, while fluid-filled structures propagate at medium speeds and air propagating at the lowest speeds. Because air has molecules that are relatively far apart, sound travels relatively slowly (approximately 330 m/s) in air. In soft tissue, the molecules are closer together allowing sound to travel faster with an average propagation velocity in soft tissues of around 1540 m/s.

Ultrasound waves lose energy to the medium in the form of heat through a process termed absorption. Absorption increases directly with distance and frequency. A transducer produces short bursts of specific frequency sound waves that are transmitted into the patient and reflected back when it interacts with different tissues and tissue interfaces. The transducer then detects the reflected sound waves, and these waves are converted to electrical energy. A computer plots the time the sound waves traveled along with the amplitude of the reflected sound waves. Echoes are produced at tissue interfaces of different acoustic impedance. Acoustic impedance is a measure of how easily waves can be formed and is dependent on sound velocity and tissue density. The greater the differences in acoustic impedance of the reflecting interfaces, the greater the intensity of the returning echo. Ultrasound waves are constantly encountering changes in soft tissue that can affect propagation of the sound wave, which cause scatter and a weakening of the return echoes. The brightness of the dot on the monitor screen correlates to the amplitude of the returning echo. Terms to describe the appearance of an image relate to the tissue's echo intensity or echogenicity. The echogenicity of a structure or the degree to which a structure reflects sound waves determines the brightness of objects on ultrasound. The strength of the reflective sound is displayed using a gray scale, where black indicates that no sound is reflected and white indicates that a large amount of the sound is reflected. The amount of reflected ultrasound received by the probe depends on the angle of incidence (the angle that the sound wave interacts with a structure) of the ultrasound beam transmitted by the probe. When the ultrasound beam is not perpendicular to a structure or portion of a structure (such as a tendon), a portion of the reflected ultrasound will be off angle and will not return to the transducer. As a consequence, a darker (hypoechoic) area will be seen in the image. Thus, during scanning, it is essential to maintain the ultrasound beam as perpendicular as possible to the structure being imaged. The appearance of darker (hypoechoic) areas in the image that result from the ultrasound beam not being perpendicular to the structure in question is designated anisotropism or off-normal incidence. This is especially common when imaging tendons and ligaments. Making sure that the ultrasound beam is perpendicular to the fibers of these structures can be accomplished by repositioning the probe, moving it closer to the tendon or ligament edges, and by slowly moving the probe in different angles while scanning. All this information is displayed as a cross-sectional image developed by an entirely different set of physical parameters of structures (objects) than those measured by other imaging modalities.

The piezoelectric crystals in the scan head determine the frequency of the sound wave. These crystals are man-made and designed to vibrate at specific frequencies and produce a consistent wavelength sound beam. These crystals also receive sound waves coming back from the tissues and convert them to electrical energy. The wavelength dictates the resolution and the energy contained by this sound beam. High-frequency transducers have smaller crystals, the sound pulses are closer together, and the wavelengths are shorter. The shorter the wavelength, the better the axial resolution, which is a measure of the ability to show two interfaces as separate along the axis of the beam. Axial resolution is determined by the wavelength (pulse length), and the wavelength is determined by the frequency. Lateral resolution is the minimum distance that two dots can be distinguished from one another in a plane perpendicular to the sound wave.

VetBooks.ir

Lateral resolution is best in the focal zone and is dependent on the width of the sound beam. The focal zones optimize the beam and can be positioned by the operator at any depth/level of the image. Deeper to the focal point, the ultrasound beam exponentially diverges, and therefore the lateral resolution becomes progressively inferior. Improving lateral resolution requires focusing the beam to the narrowest width possible. Axial resolution is usually superior to lateral resolution. Images should be obtained with the highest frequency probe possible to obtain the best resolution of the structure of interest. However, sound is attenuated at 1 dB/cm depth per megahertz (MHz). Higher frequencies are therefore attenuated at higher rates, which reduce the penetration of the sound wave. Lower frequencies are attenuated at lower rates, which allow them to penetrate deeper into tissue. The depth of a specific structure is then calculated based on the amount of time it takes for the transmitted ultrasound beam to be reflected and received back by the probe. The ultrasound travel time is calculated assuming that sound travels at the same velocity through all tissues. For any given image, sound can travel through fat, soft tissue, muscle, fluid, blood, and skin. These different tissues have different acoustic impedances (the speed that sound travels through the different tissues), and the ultrasound image will reflect each tissue type as a different shade of gray on the screen.

Over the past several decades, the transducer construction has evolved considerably in design, function, and capability from a single-element resonance crystal to a broadband transducer array of hundreds of individual elements. Flat-face linear (tendon) and convex (micro- and macro)variable focus probes are the most popular probes for musculoskeletal imaging. Transducers are typically described by the arrangement of the crystals in the probe. The specific arrangement creates the shape of the sound beam. A linear transducer has the piezoelectric crystals organized in a linear fashion and emits sound in succession. Linear transducers are more durable, have inherently better resolution, and have a flat, narrow face with approximately 4 cm of scanning surface. These probes give superior images at tissue depths of 2 cm or less due to less distortion and less artifact in the near field. Linear transducers can now be made to produce a sound beam that is wedge shaped through a process called virtual convexing. These transducers can provide a high-resolution image, but this technology compromises the ability to image rapidly moving structures (like the heart). Standoff pads are available that improve contact with the skin increasing the footprint and moves the superficial structures into the near-field focal zone and away from the near-field artifact.

Early ultrasound systems utilized a sector transducer that transmitted a wedge-shaped sound beam that was created by mechanically rotating the crystals. These probes were quite fragile, and the crystals could be easily dislodged by dropping the probe. They have been replaced by curvilinear transducers that are similar in design to the linear transducer except that the scan head is slightly curved. These are called convex and come in microconvex and macroconvex based on the size of the transducer curved surface. Microconvex probes have smaller field of view and higher frequencies (higher resolution with lower depth of penetration), while macroconvex probes have larger field of views and lower frequencies (lower resolution and deeper penetration). The microconvex probe is utilized when the skin is contoured (concave) and difficult to seat a flat-face transducer. The divergent beam allows the examiner to image from a smaller skin contact point. These convex probes can be more difficult to use because it is easier to inadvertently change the beam angle especially when doing longitudinal assessments of fiber alignment. A macroconvex curvilinear transducer is indicated for deeper musculoskeletal examinations and for general abdominal imaging, primarily focusing on the gastrointestinal tract. Many of these probes have multiple frequencies available that allows the examiner to change the frequency without needing to change the probe. Structures within 5–7 cm of the skin should be evaluated with transducers of a minimum of 7.5–10 MHz or higher. Structures within 7–14 cm should be evaluated with 5-MHz transducers. Anything deeper than 14 cm will require lower frequencies such as 2.5–3.5 MHz. A phased-array transducer has a relatively small rectangular, flat surface. In these transducers, the piezoelectric crystals are arranged in a rectangular shape and send out all the sound waves simultaneously. This allows imaging of rapidly moving structures (like the heart or vessels when using color flow Doppler), and it produces higher-contrast (black and white) images but with less resolution compared with the linear and curvilinear transducers. The flat surface of these probes makes it ideal for imaging between the ribs.

Imaging software for available diagnostic ultrasound is constantly evolving, and recent introductions such as harmonic imaging, compound imaging, and extended field of view are now quite common. Harmonic imaging can be used to produce a clearer image by reducing artifacts. This requires a specialized probe, but it generates an image from a fundamental frequency that is sent from the transducer. When this frequency interacts with an organ, it creates a resonance frequency that is twice the fundamental frequency. The benefit of this is that the resonance frequency that is used to generate the image is relatively high, giving better resolution, and only travels through the body once, so it is less prone to artifacts. Compound imaging is the capability to use ultrasound waves sent from multiple angles to evaluate the same region. This is intended to reduce artifacts and give a much more detailed view of a structure, although it is susceptible to blurring due to motion. Extended field of view allows a complete tendon to be imaged or provides the capability to image a structure or lesion that is larger than the field of view obtained by a given transducer. Three-dimensional imaging and contrast medium ultrasound imaging are also available, but at this time it has very limited use in the equine patient.

ULTRASOUND TO EVALUATE TENDONS AND LIGAMENTS

Ultrasonography has significantly advanced the diagnosis and management of a variety of musculoskeletal injuries in performance horses.[21,24,34,41,72–74,80] Ultrasonographic imaging of the musculoskeletal system will be discussed in this chapter, but the abdominal, thoracic, cardiac, and urogenital systems are also routinely

VetBooks.ir

evaluated with ultrasound. A working knowledge of the normal anatomy is critical for accurate tendon and ligament ultrasound examinations as well as those involving joints, sheaths, and bursae.[31,46,85,90,99] Ultrasonography is routinely utilized for defining morphological change in the superficial digital flexor tendon (SDFT) and deep digital flexor tendon (DDFT), the suspensory ligament (SL), the accessory ligament of the DDF (ICL), and the distal sesamoidean ligaments (DSLs) of the pastern region. The subcutaneous tissue, paratendinous tissue, and vessels should be assessed as well. While the objective is to evaluate the morphological characteristics of the soft tissues of the musculoskeletal system, the contour of the cortical bone in this region should also be evaluated. Most importantly, diagnostic ultrasound is the most useful and practical tool to monitor the repair of these structures and guide the rehabilitation of tendinous and ligamentous structures. Many other soft tissue structures can also be evaluated including muscle, musculotendinous junctions, tendon sheaths, and bursae associated with the tendons and ligaments. Joint injury (which will be discussed later in this section) is very effectively examined with radiography and ultrasonography. These imaging tools are considered complementary and provide more information about a region/joint than either tool used alone. Joint examination should include evaluation of the periarticular structures such as the collateral ligaments and extensor/flexor tendons, joint capsule, and joint fluid accumulations. Real-time imaging capability of ultrasonography allows the use of interventional techniques (like needle insertion for injection or aspiration/biopsy), which can provide additional clinical information.[10,16,60,93] Ultrasonography is also effective at evaluating a variety of other musculoskeletal problems such as fractures of long bones, osteitis/osteomyelitis, foreign body penetration, and implant infection, as well as being utilized intraoperatively to assist with some surgical procedures.[11,81,104]

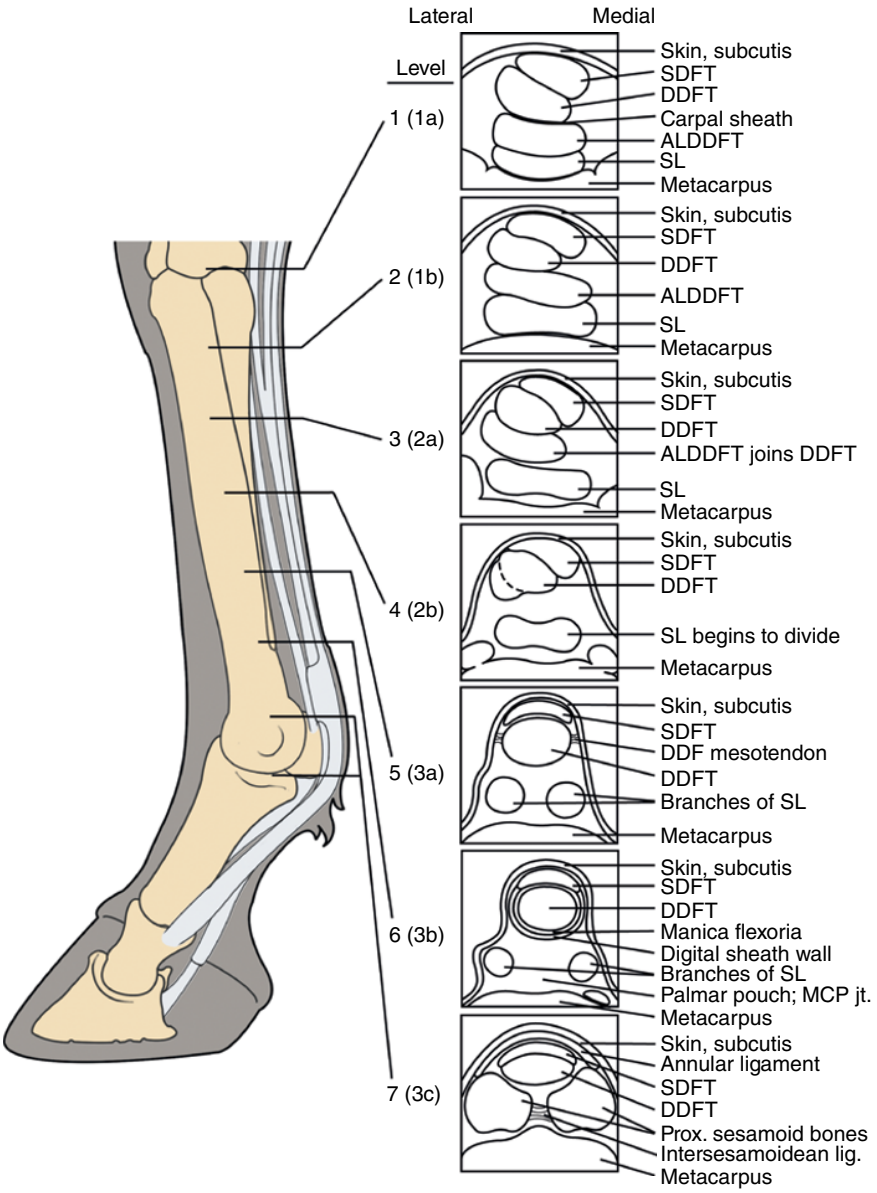
PATIENT PREPARATION AND SCAN PROTOCOL

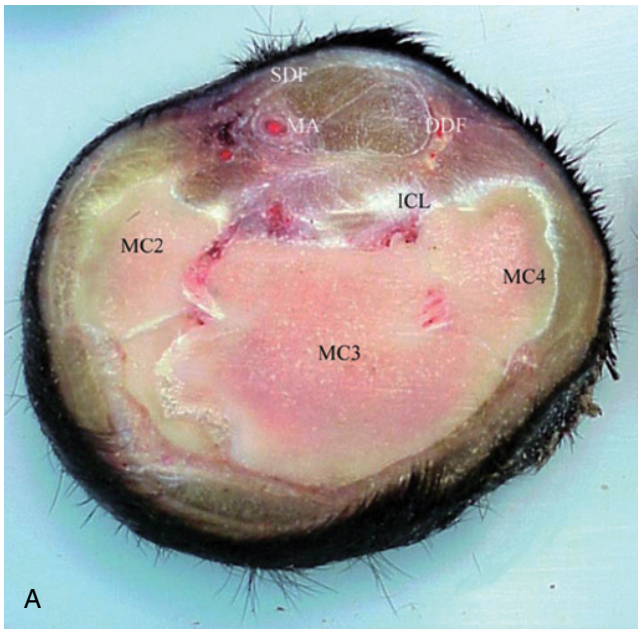
Confirmation that lameness is associated with a specific structure or area is critical. Localization of lameness should include a clinical examination with detailed palpation of the limb with diagnostic nerve blocks performed when necessary. In most instances, injection of diagnostic anesthesia into an area will not interfere with the ultrasonographic examination. Occasionally gas bubbles in the injectate may inhibit sound transmission and necessitate performing the exam on a subsequent day. Tranquilization may be necessary and can assist with uncooperative or anxious patients. Patient preparation is very important, and both limbs should be clipped and prepped as strain-induced tendon and ligament injury can occur bilaterally with one limb being more severely affected than the other. Shaving is frequently required to give a higher-resolution image. A scrub with a detergent is generally necessary to remove dirt and debris. Many clinicians do a 5-minute sterile prep with antiseptic solution/detergent followed by an alcohol rinse. Liberal use of ultrasound gel is important although excessive gel can cause a lateral image artifact that may compromise image quality. When clipping and shaving is not possible, then the limb should be thoroughly washed with warm water and detergent. Application of alcohol to the hair coat may enhance the sound transmission. To acquire the best image, a scan head with a frequency of at least 7.5 MHz but frequencies of 10–18 MHz is preferable. Low frame rates should be used to give higher-line density and improved resolution. Most superficial structures can be visualized at a scan depth of 2–4 cm often with the use of a standoff pad. The use of a standoff pad is helpful for the evaluation of superficial structures, such as the palmar or plantar annular ligament and the SDFT in the pastern region. A standoff pad is a gelatin-based pad that is placed between the probe and the skin surface. By increasing the distance between the probe and the skin surface, the near-field artifacts that are seen in the higher portion (near field) of the image are now at the level of the standoff pad instead of being over the structure of interest. In many cases, the footprint of the transducer is limited and restricts the ability to examine the medial and lateral margins of the tendons and ligaments. Utilizing a standoff may increase the footprint and improve the examination of the structures in the same field of view. However, manipulation of the probe to a more abaxial position with the probe angled more medially and laterally may be required to evaluate the peripheral margin(s) of a structure.

The ultrasound examination should be performed in a systematic manner with each structure evaluated from proximal to distal to ensure a complete and thorough tendon/ligament evaluation. The examiner should develop a systematic approach to screening the limb such as the technique described by Genovese and Rantanen.[40,41,72–74] This approach provides a survey of all structures including veins, arteries, subcutaneous tissue, paratendinous tissue, and bone contour at specific levels in the metacarpus/metatarsus. A standardized scanning protocol has numerous advantages, but most importantly it provides a means for clinicians to effectively screen the limb and as a tool to accurately communicate about their findings. This imaging protocol is based on the metacarpus length being approximately 24 cm in length or roughly three hand widths of a person's hand or 8-cm/hand breadth. The metatarsus is longer than the metacarpus and measures approximately 32 cm or roughly four hand widths in length. These zones are numbered 1–3 in the front limb and 1–4 in the hindlimb. Each of these zones are further subdivided into two equal zones named A and B (each being 4 cm) such that the front limb has zones 1A, 1B, 2A, 2B, 3A, and 3B. The area associated with the proximal sesamoid bones of the fetlock is considered zone 3C (or 4C in the hindlimb). Some authors utilize a simple numerical scheme with the front limb having levels 1–7 and the hindlimb having levels 1–9. These levels are the same zones mentioned above but without the letter designations (Figures 3.89–3.106).

To more completely assess the architecture of the SL branches, it is necessary to incline the transducer more medial to lateral or lateral to medial as the examiner progresses distally until they attach to the proximal aspect of their respective proximal sesamoid bone. The imaging protocol for the pastern is based on zones

VetBooks.ir





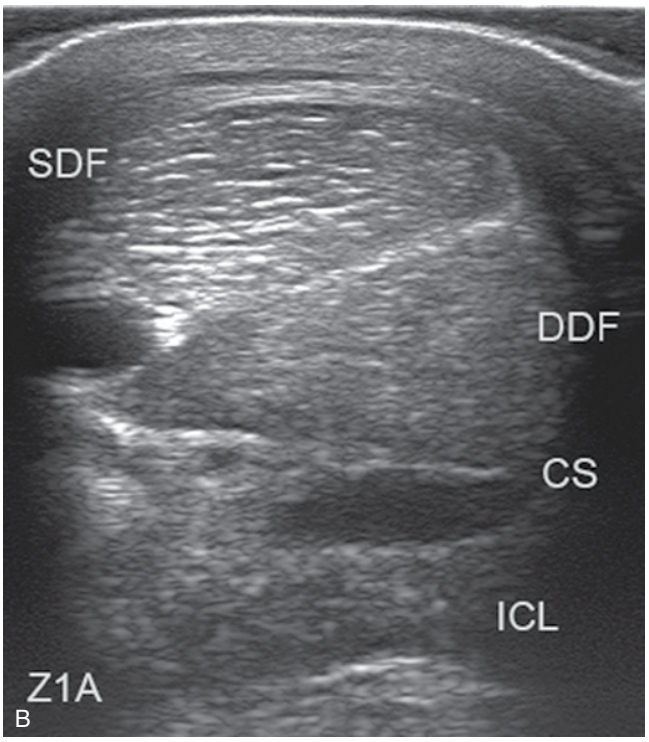


Figure 3.89. Ultrasonographic imaging of the metacarpus is based on the length being approximately 24 cm in length or roughly three hand widths of a person's hand (8 cm/hand breadth). These zones are numbered 1–3 in the forelimb. These zones are further subdivided into two equal zones named a and b (each being approximately 4 cm) such that the forelimb has zones 1a, 1b, 2a, 2b, 3a, and 3b. The area associated with the proximal sesamoid bones (PSB) of the fetlock is considered zone 3c. Some authors use a simple numerical scheme, with the forelimb having levels 1–7. The structures identified from the transducer to the palmar metacarpus are the SDFT, DDFT, ICL, and SL.

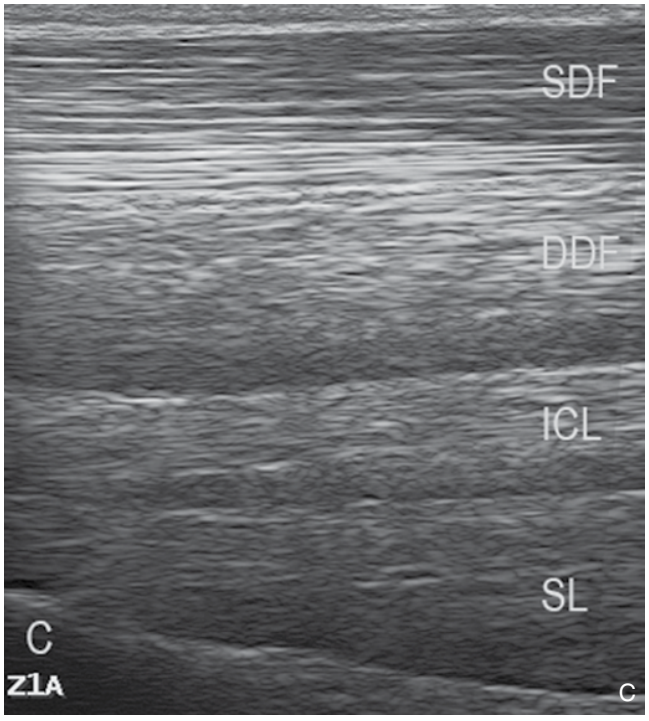
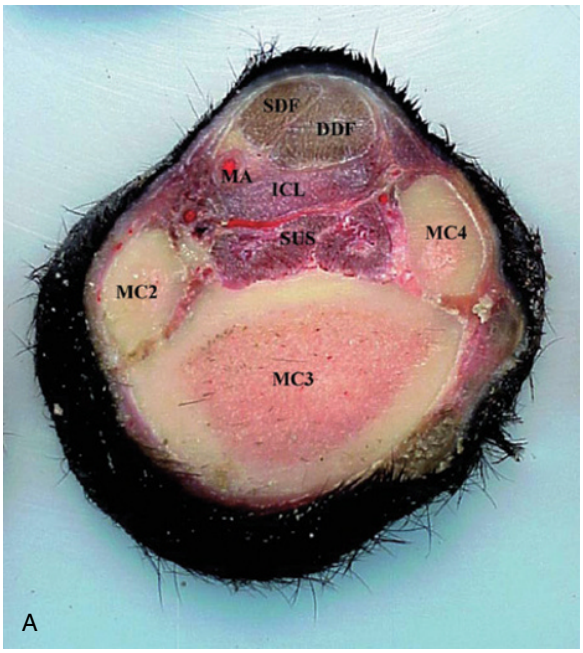
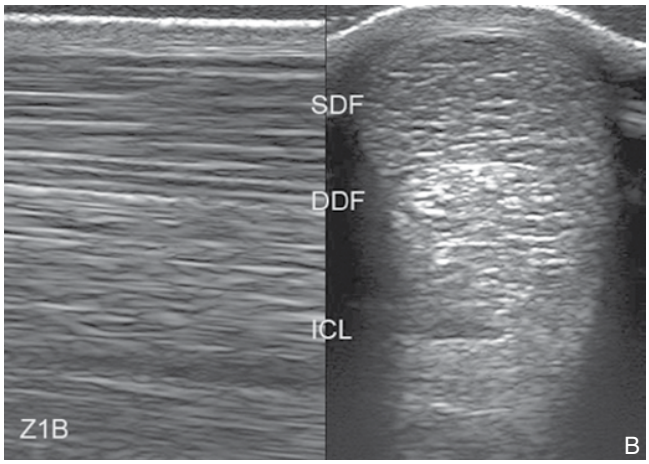
related to the proximal and middle pastern bones. The proximal pastern or P1 has 3 2-cm zones of associated with it and named P1A, P1B, and P1C. The middle pastern bone or P2 is shorter and has just 2 2-cm zones each associated with it and named P2A and P2B.[40] The overall length of the pastern and height of the collateral cartilages of the distal phalanx can significantly affect the ability to image the DDFT in zone P2A. To evaluate the origin of the oblique sesamoidean ligament (OSLs) on the distal aspect of the proximal sesamoid bone, it is necessary to incline the transducer more dorsally such that a medial to lateral or lateral to medial orientation is obtained. The pastern is more difficult to examine than the metacarpus because positioning the probe between the distal aspect of the sesamoid bones (and the ergot) and the proximal aspect of the collateral cartilages can be difficult. Placing the foot on a block of wood with the limb placed more caudal than the opposite limb increases the extension of the fetlock joint and places the axis of the pastern in a more upright position (Figure 3.107). In general, the DSLs and branches of the SDFT are smaller and inclined at different angles as they course to their insertions, which require that different scan planes will be used to evaluate each of these structures.

VetBooks.ir







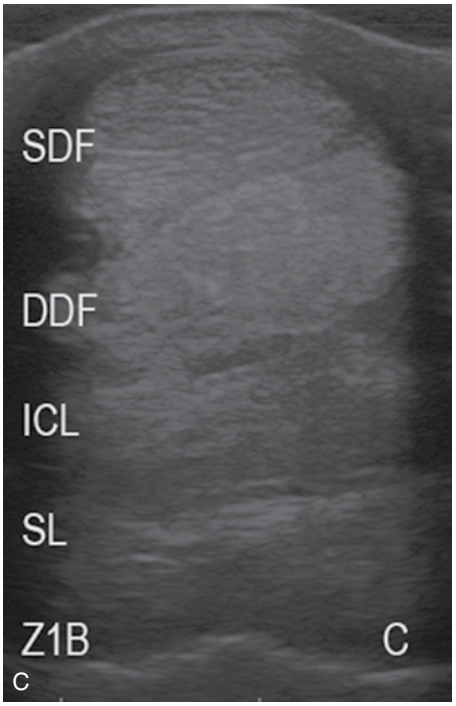


Figure 3.90. (A) In Z1A the SDFT is round but with a flat border dorsally where it is adjacent to the DDFT (A and B). The DDFT is rounded in shape. The ICL is located dorsal to the DDFT with the carpal sheath visualized as an anechoic triangular structure between these two structures (B). The SL is located dorsal to the ICL but may only have a few fibers apparent in proximal Z1A (C). The SL becomes more apparent, progressing distally in this zone. (C) This ultrasound image is taken at the proximal aspect of Z1A to correspond to the gross section slice plane that is close to the carpometacarpal joint. At this level, the ICL is the only structure apparent dorsal to the DDFT. The median artery and large metacarpal vein are prominent on the medial aspect of the DDFT. *Source:* US images courtesy of Dr. Caitlyn Horne.

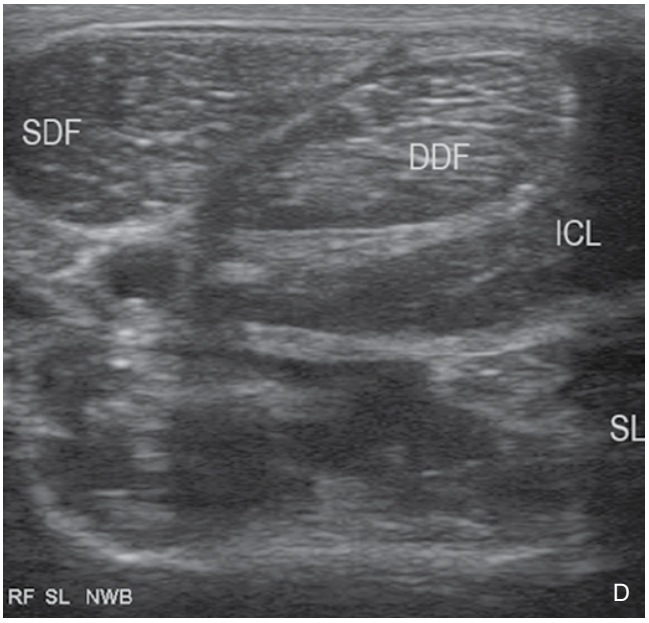
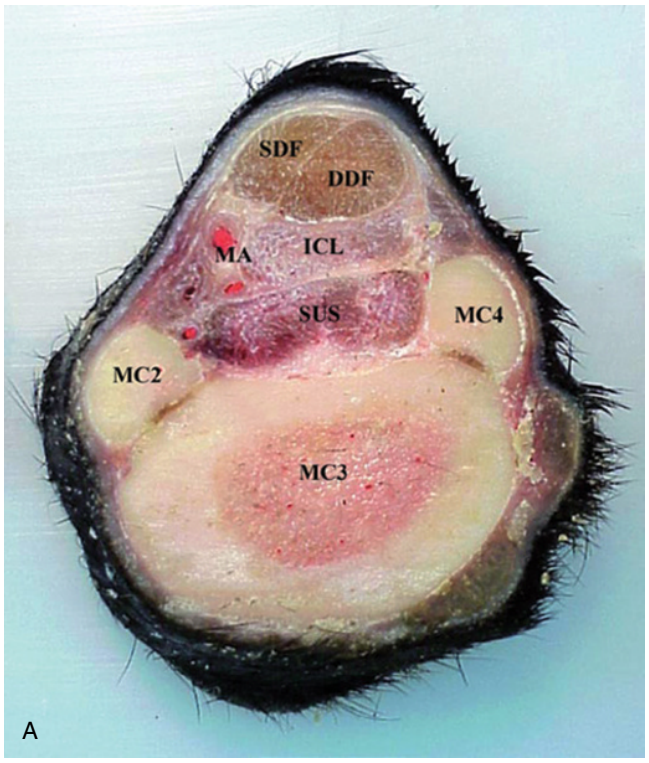
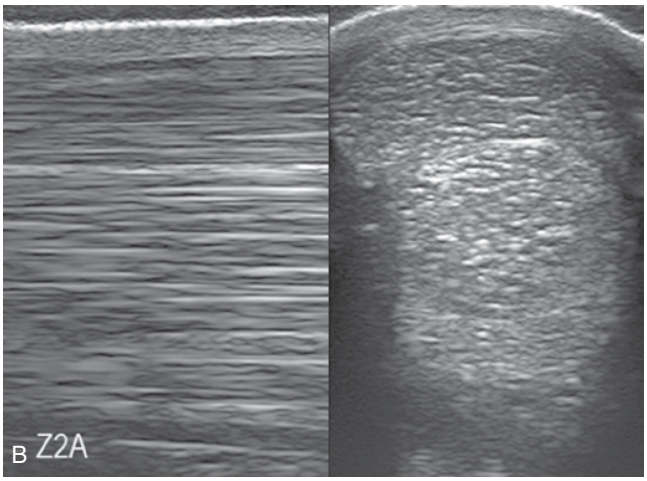
VetBooks.ir







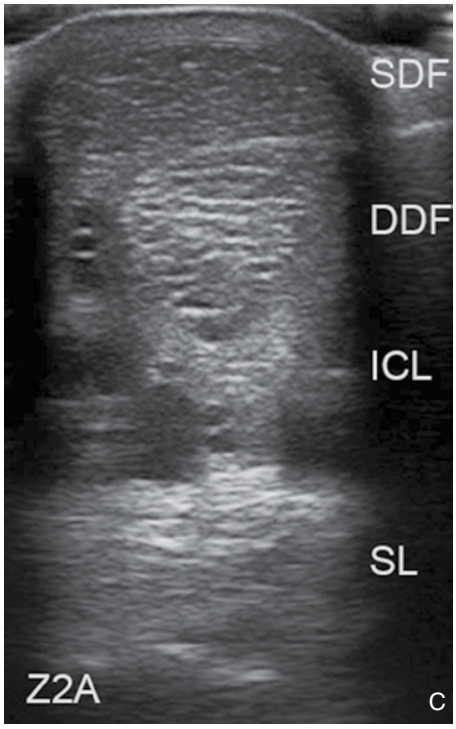


Figure 3.91. In Z1B the palmar metacarpal structures appear much as they did in zone 1A. The SDFT appears to flatten palmar to dorsal, and the DDFT becomes more rounded. The ICL becomes more inclined toward the DDFT. Fibers of the SL become more pronounced, and this structure widens medial to lateral (A). The SDF and DDF tendons should be evaluated with the focal zones placed at the appropriate level and often with a standoff pad in place (B). However, ultrasound imaging of the suspensory ligament in this area is often difficult due to a limited footprint (the SDF and DDF are not as wide as the SL) and the creation of edge artifacts and acoustic enhancement artifacts from more superficial structures (tendons and vessels) that can make evaluation of the SL difficult (C). Angled contrast ultrasound (ACUST) utilizes off-angled and non-weight-bearing imaging of the proximal suspensory to allow visualization of the muscle and fat bundles within the origin of the SL not normally evident in standard transverse ultrasound imaging of this area (D). *Source*: US images courtesy of Dr. Caitlyn Horne.

VetBooks.ir

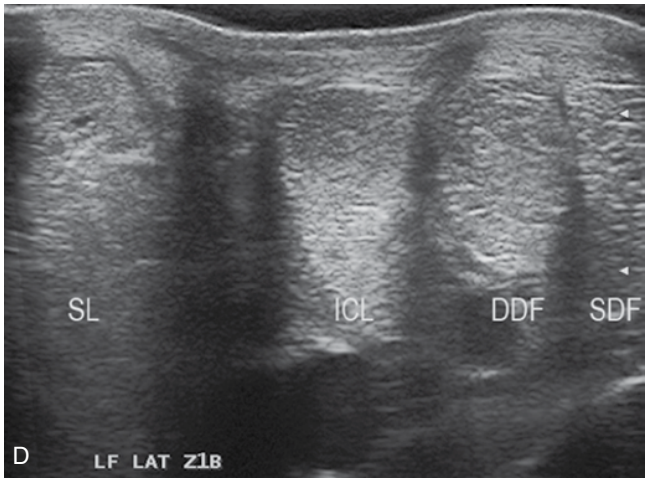

Figure 3.92. In Z2A the ICL narrows palmar to dorsal, and the SL increases in area, becoming more discreet and separated from the palmar cortex of MCIII (cannon bone). The large metacarpal vessels can be seen medially and laterally (A). These vessels also create edge and acoustic enhancement artifacts, compromising interpretation of the SL architecture. (B and C) These ultrasound images demonstrate these artifacts and also highlight the importance of focal zone placement. The focal zone in (B) is placed on the SDFT/DDFT junction with the deeper structures out of focus and poorly imaged, and the focal zone in (C) is placed at the level of the SL. Alternatively, an abaxial orientation (in a more lateral to medial or medial to lateral direction) of the transducer can sometimes allow a better interpretation of the medial and/or lateral border of the suspensory ligament body as evidenced in image (D). *Source:* US images courtesy of Dr. Caitlyn Horne.

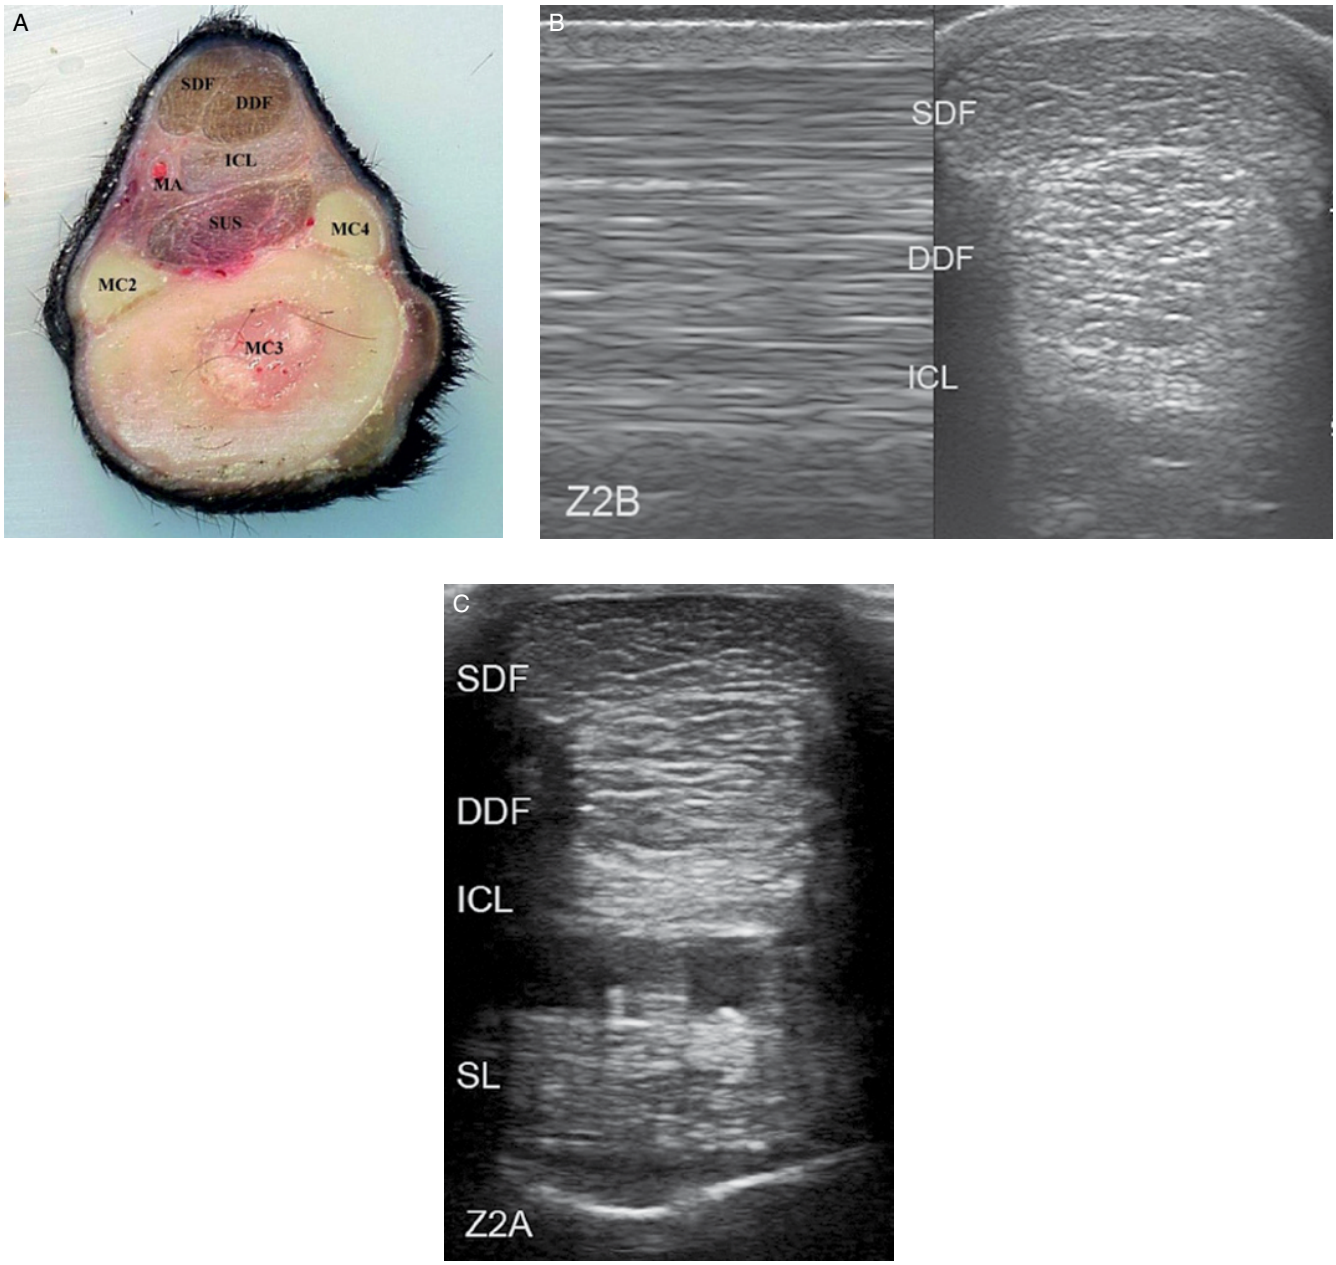
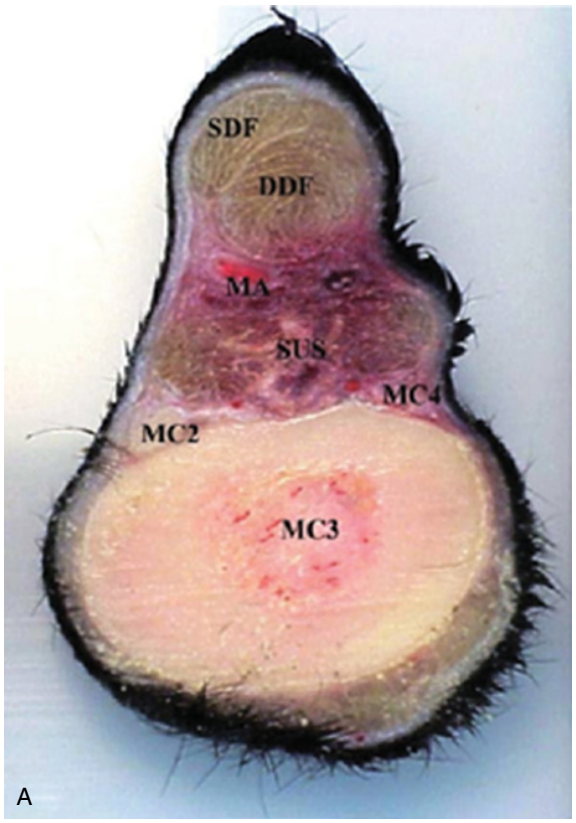
VetBooks.ir





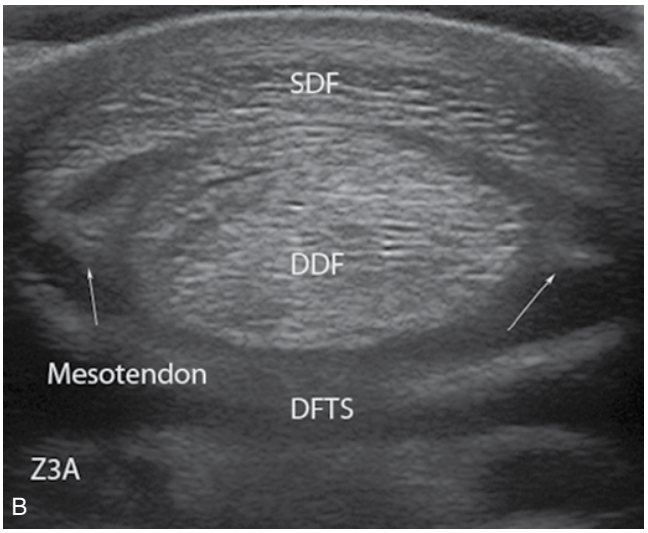


Figure 3.93. (A) In Z2B the SDFT becomes flatter, and the ICL remains distinct from but closely associated with the DDFT. The metacarpal vessels converge to midline between the ICL and the SL. (B) This ultrasound image with the focal zone placed superficially demonstrates the fibers of the SDFT/DDFT interface, while (C) shows focal zone at the level of the SL and the convergence of the large metacarpal vessels palmar to the SL. *Source*: US images courtesy of Dr. Caitlyn Horne.

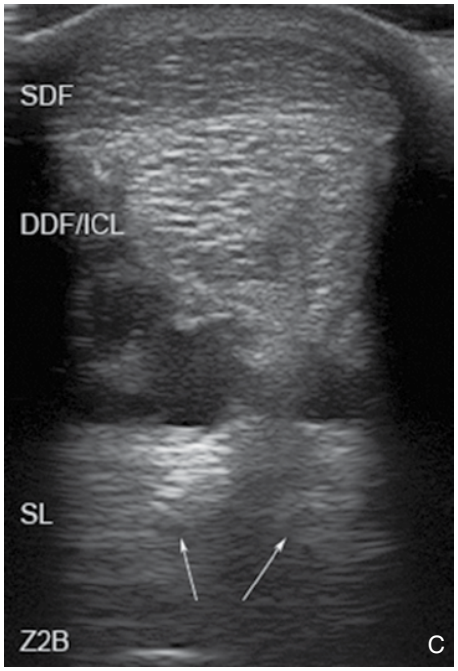
Obtaining a good-quality images in tissues of varying acoustic impedances is quite dependent on the ability of the ultrasonographer to appropriately adjust the machine and settings (transducer, frequency, depth, focal zones, and gain). The ultrasound probe is placed on the palmar surface of the limb with the beam oriented perpendicular to the longitudinal axis, as well as the transverse axis of the tendons or ligaments of interest with the limb in a weight-bearing position. Each structure should be examined on cross-sectional and on longitudinal orientation with appropriate placement of the focal zone(s) on the structure of interest at each location. The size, shape, margins, and echogenicity of the structures should be evaluated, and a measurement system, using distance (cm) or zones, should be used to obtain images at regular intervals. Comparison to the contralateral limb is important in all cases, even those with obvious injury in the primary limb. In the metacarpus each level should have two transverse scans performed. The first scan should have a standoff placed on the transducer with the focal zone(s) and transducer angle directed initially at the superficial digital flexor (SDFT) and deep digital

VetBooks.ir



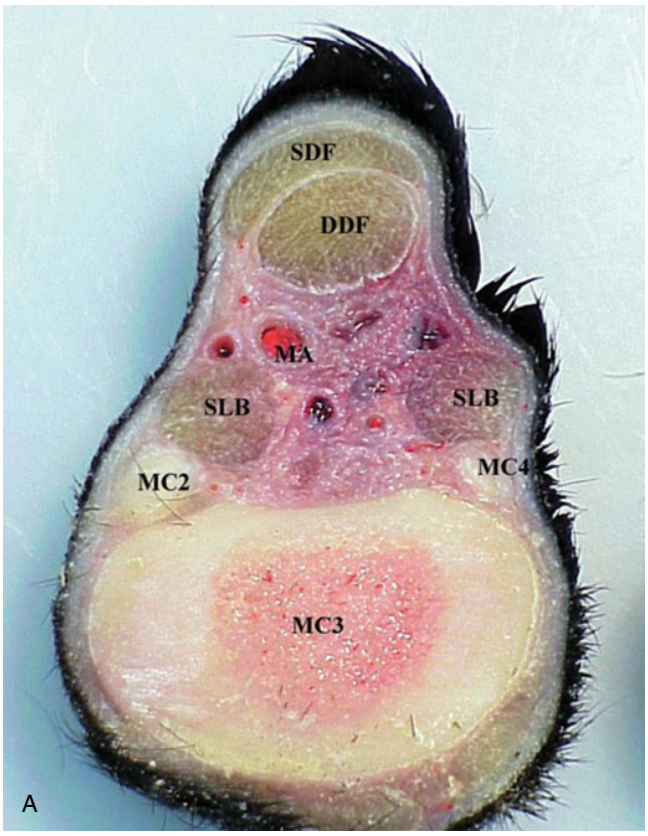


Figure 3.94. (A). In the proximal aspect of zone 3A, the SDFT thins and begins to expand medial to lateral and appears crescent shaped. The DDFT and ICL are beginning to blend together and can appear as one structure. In the proximal aspect of the DFTS, the DDF tendon receives mesotendinous attachments to the medial and lateral borders of which the medial mesotendon provides the predominant arterial blood supply to the DDF within the sheath (arrows) (B). In the proximal aspect of this zone, the SL has not divided and continues to appear as one structure. There may appear to be a hypoechoic area within the central aspect of the SL just prior to the formation of the branches, but this should not be confused with a lesion (C). *Source*: US images courtesy of Dr. Caitlyn Horne.

VetBooks.ir

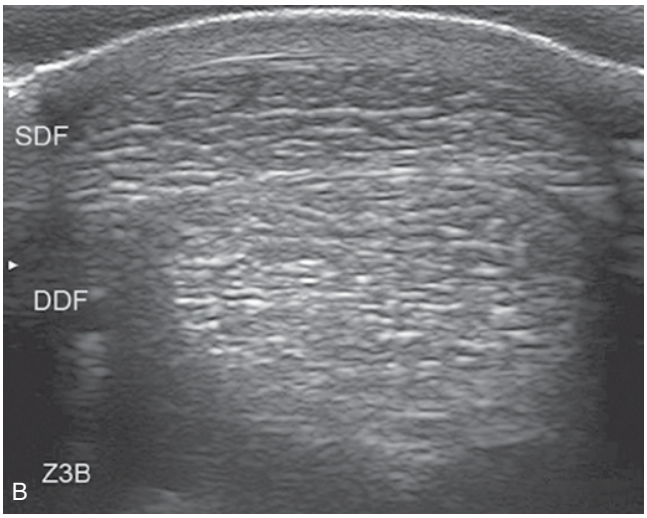

Figure 3.95. (A) The distal aspect of Z3A demonstrates the SDFT as elongated in a medial to lateral direction and the division (splitting) of the SL into branches (SLBs). (B) This ultrasound image with the focal zone(s) directed at the SDFT and DDFT demonstrates the widening of the SDFT and blending of the fibers of the DDFT and the ICL. *Source:* US images courtesy of Dr. Caitlyn Horne.

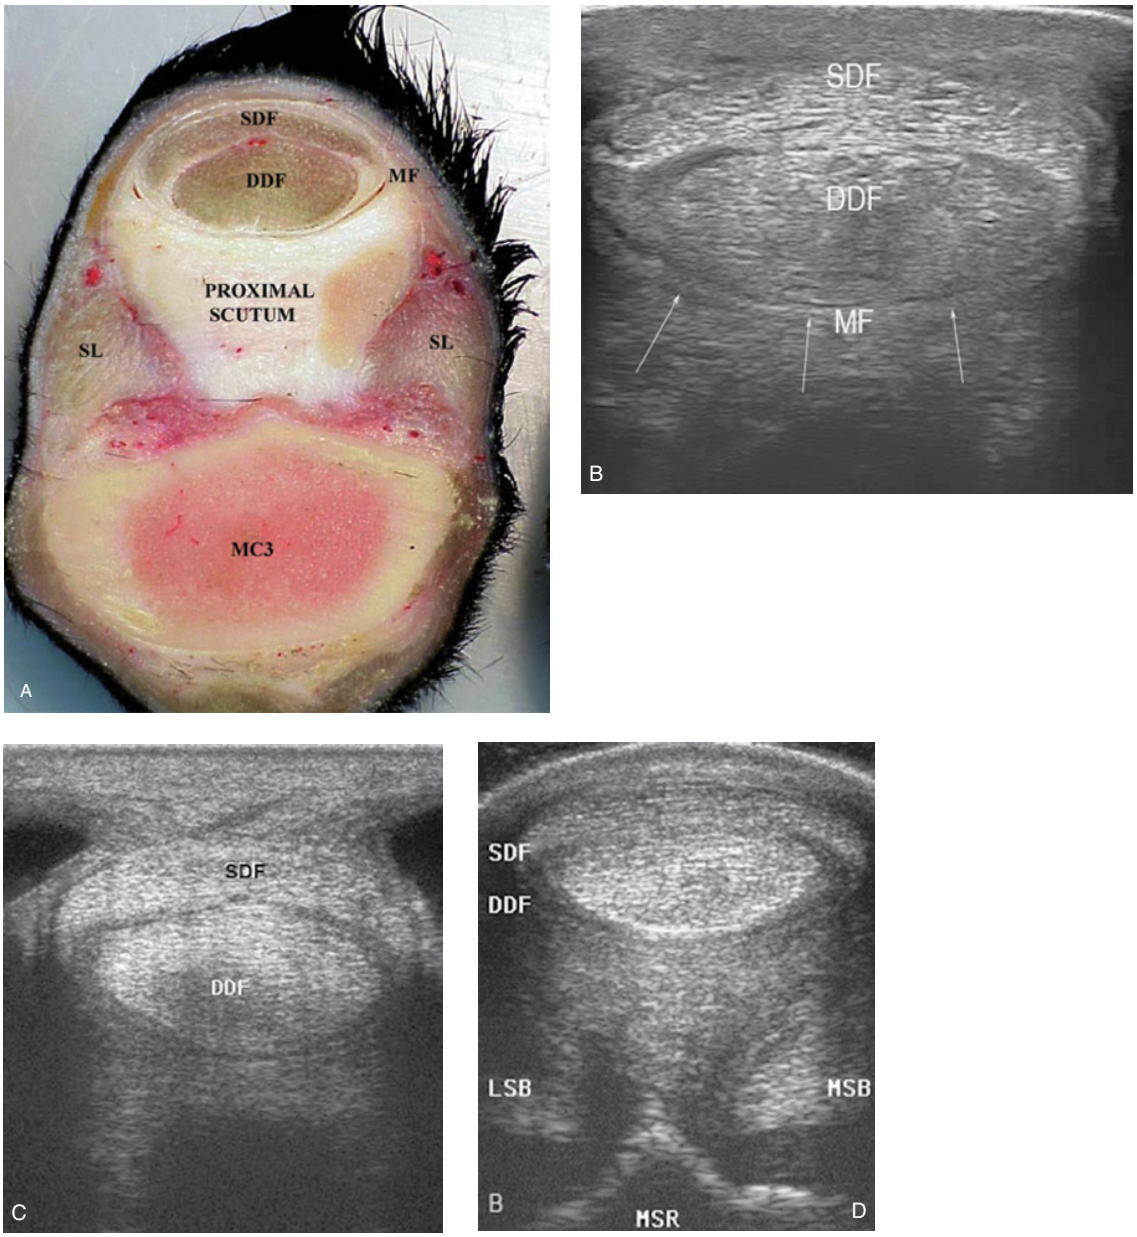
flexor (DDFT). The second scan should be acquired with or without a standoff with focal zone(s) and transducer angle directed at the ICL and SL (Figure 3.108). In some instances it may be helpful to utilize a microconvex transducer for this scan because the divergent beam can improve assessment of the medial and lateral borders of the SL. The transverse scan plane should be positioned such that the structures on the left side of the horse are placed to the left side of the screen. Some clinicians like to place the medial side of the limb on the left side of the screen and the lateral side of the limb of the right side of the screen.[80] In addition the sagittal scan plan should position structures of the proximal aspect of the limb to the left of the screen and structures to the distal aspect of the limb to the right side of the screen. Some clinicians place these structures opposite with the proximal aspect of the limb to the right of the screen.[80] Whatever protocol is utilized it should be done consistently with appropriate labeling on the recorded image.

Careful attention should be paid to all tendinous/ligamentous structures as multiple structures are often involved. The examiner should also be aware that an injury might extend proximally into the carpal sheath or distally into the digital sheath/pastern area. If an abnormality exists then the lesion should be mapped and measured in centimeters from a reference point such as the accessory carpal bone in the front limb and the point of the hock or tarsometatarsal (TMT) joint (head of the lateral splint) in the hindlimb. Measurement of the lesion should extend from the proximal aspect of the normal to the affected interface of the structure to the distal aspect of the lesion. The lesion should be evaluated on both cross-sectional and longitudinal scan planes. The lesions' maximum size should be determined and mapped. Echogenicity and fiber alignment should be subjectively evaluated throughout the abnormal tissue. Musculoskeletal scanning requires a technique that creates the maximum echogenicity in the structure being examined to prevent decreased echogenicity caused by variations in beam angle (anisotrophy) that could be mistaken for a lesion. Each image should be labeled with the date, owner's name, patient name, the limb being examined, and the location of the lesion(s). A description of the scan plane should be included in every image and every image recorded as part

VetBooks.ir



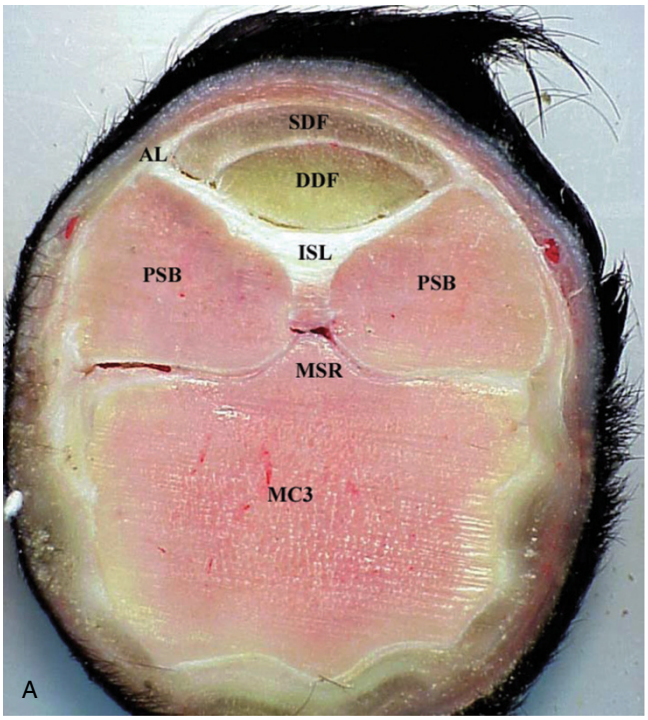


Figure 3.96. (A and B) Zone 3B is somewhat longer than the other zones, and several important landmarks can be seen in this area. The SDFT and DDFT widen in a medial to lateral direction. These structures can be difficult to image together, so each must be examined independently. The SDF tendon forms a ring around the DDF tendon called the manica flexoria. (B) This ultrasound image demonstrates a moderate amount of effusion within the DFTS and allows the natural axial connection of the DFTS to the palmar border of the SDFT proximal to the metacarpophalangeal (MCP) joint to be visualized (C). This axial attachment should not be considered an adhesion/abnormality. At the junction of Z3A and 3B after the SL divides into medial and lateral branches, the proximal scutum and palmar aspect of the fetlock joint just proximal to the PSBs can be seen (D). The proximal aspect of the midsagittal ridge of the palmar metacarpus can be seen through the proximal scutum. *Source*: US images courtesy of Dr. Caitlyn Horne.)

VetBooks.ir

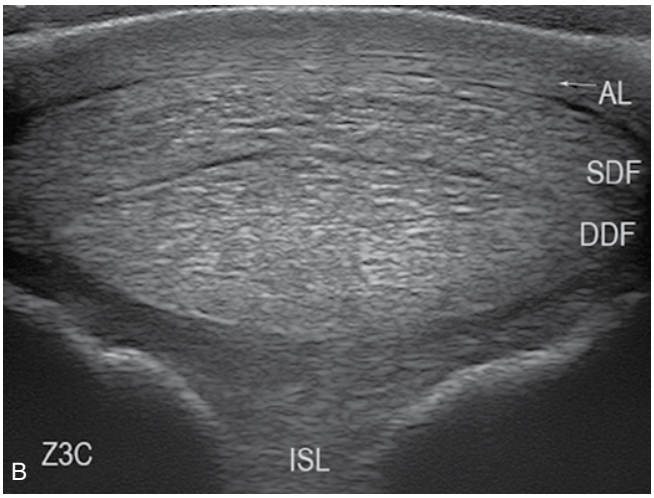

Figure 3.97. (A) Zone 3C begins at the level of the PSBs and extends through the fetlock canal. The primary annular ligament (PAL) extends from the palmarolateral to palmaromedial border of the PSBs (abaxial border of each PSB). (B) This ultrasound image demonstrates the PAL wrapping around the SDFT and DDFT to hold these tendons within the fetlock canal. It may be necessary to move the transducer in the medial to lateral plane and slightly rotate transducer to more effectively demonstrate the fibers of the PAL. A more abaxial orientation of the transducer should also be utilized to image the attachment of the PAL to the PSBs. *Source*: US images courtesy of Dr. Caitlyn Horne.

of the medical record. Documentation of the lesion location, lesion echogenicity, and extent or degree of change should be included on the image. Once the image has been labeled, it should be stored and maintained as part of the permanent medical record. Images can be stored as thermal prints (which degrade over time), as video recording, or as digital images for comparison at later examinations. Most current machines available provide software that allows the image to be traced, which provides a cross-sectional area (CSA) of the tendon/ligament and lesion. As mentioned earlier this is critical for the rehabilitation process.

Tendons and ligaments appear similarly as moderately echogenic structures with relatively well-defined margins due to their parallel fascicular arrangement. It is this arrangement of fibers, aligned to resist tensile forces, that creates the intense specular reflections (echoes) seen when the sound beam is perpendicular to the direction of the fascicles. The examiner must pay particular attention to the course of the tendon or ligament being imaged and maintain the transducer at 90° to the structure. The structures of the metacarpus/metatarsus and the pastern change orientation as they incline distally toward their insertion. To perform a complete examination each structure should be evaluated independently with careful attention being paid to correct beam angle and focal zone placement. The horse should be weight-bearing on the limb and the tendons and ligaments loaded during the ultrasound examination. Imaging while the horse is not bearing weight can create changes in shape and size of these structures. Not bearing full weight on the limb also can cause relaxation artifacts to occur within the tendons and ligaments being examined. Relaxation artifacts appear as hypoechoic areas within the normally bright specular reflections seen during routine examination of tendons and ligaments that can compromise the accuracy of the study. Relaxation artifacts can also occur in some abnormal conditions. For example, complete disruption of the suspensory apparatus relieves the tension in the straight sesamoidean ligament (SSL), resulting in relaxation artifacts in the SSL. This is also apparent when evaluating lacerations or rupture of a tendon/ligament that relaxes the tensile forces in the affected structures and can create relaxation artifacts most often proximal but also distal to the site.

There are some indications for off-weighted examination of some structures. Proximal annular ligament syndrome of the digital flexor tendon sheath frequently has a proliferative tenosynovitis that can obscure the borders of the SDF and DDF diminishing the ability of ultrasonography to define these structures as separate.

VetBooks.ir

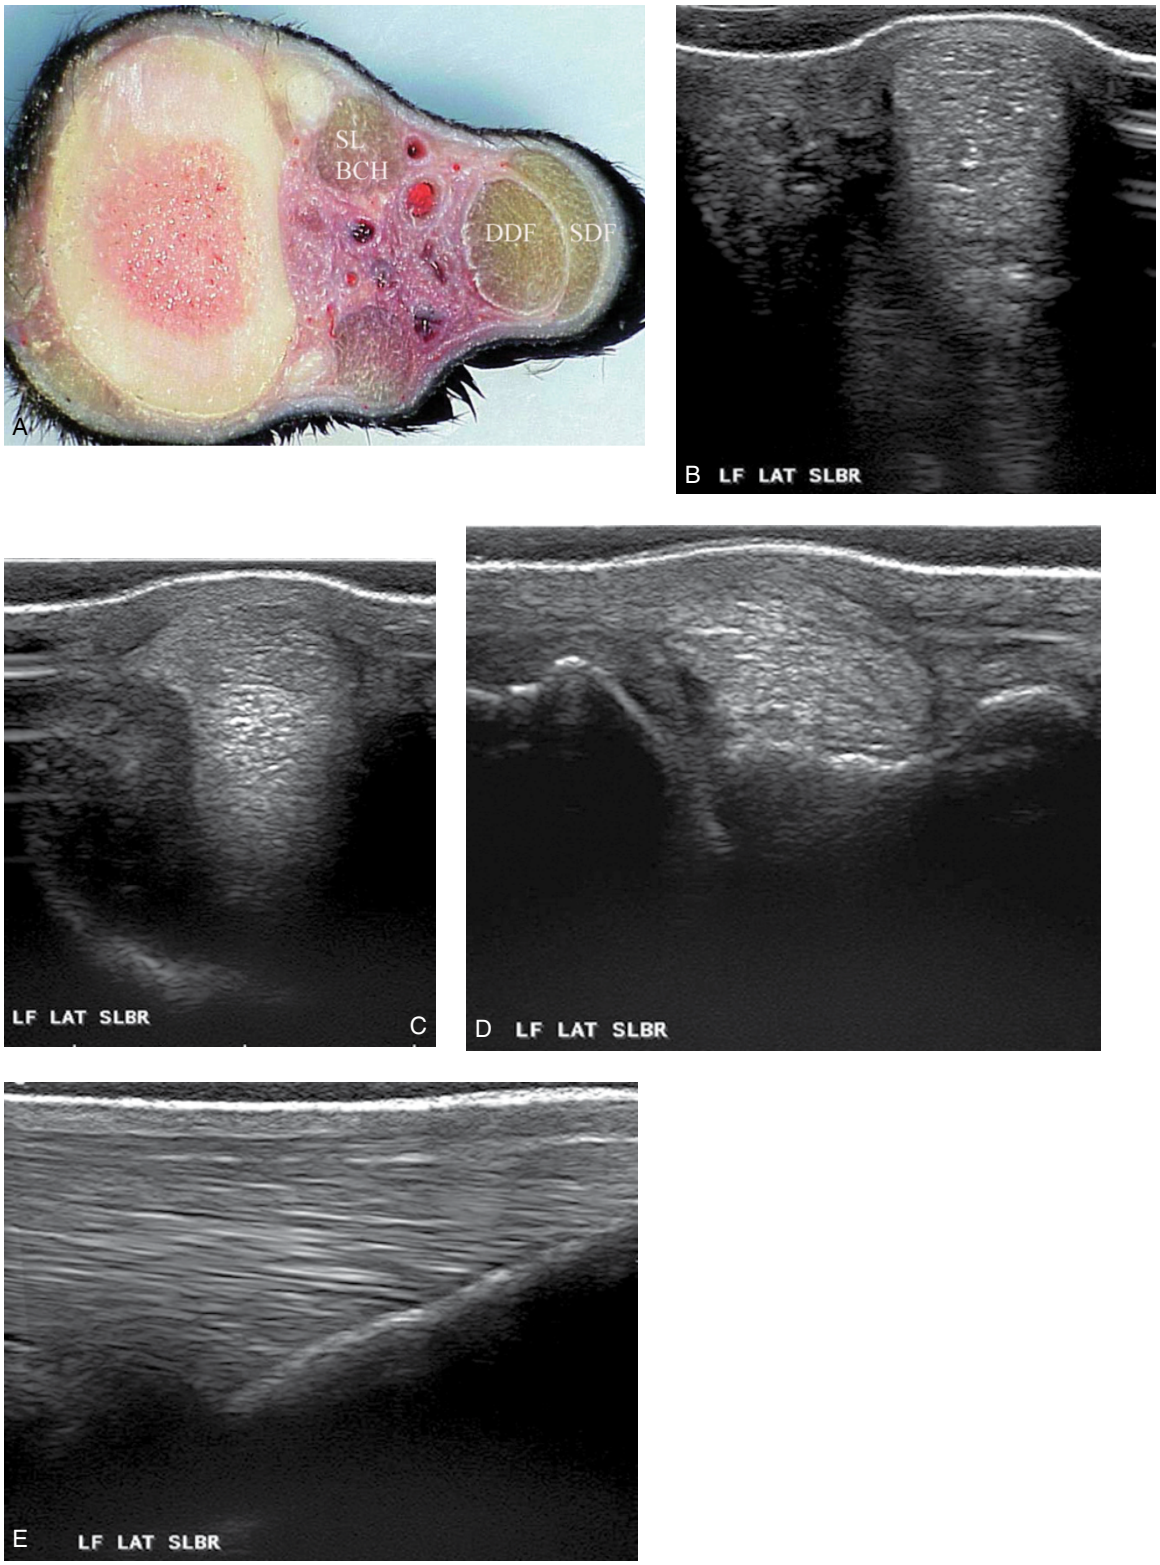

Figure 3.98. (A–E) The branches of the suspensory ligament (SLBs) are best imaged with the transducer placed more abaxially with a medial to lateral and/or lateral to medial orientation. These structures should be evaluated at the level where they begin to divide in distal 3A until their attachments to the PSBs. (B) Initially the SLBs have an oval shape. (C) Further distally the branch becomes somewhat D shaped. (D) The branch appears to rotate in a dorsal to palmar direction, becoming oval shaped just prior to their attachment onto the PSBs. (E) The SLBs should also be evaluated in the longitudinal plane from their beginning to their attachments to the PSBs. *Source*: US images courtesy of Dr. Caitlyn Horne.

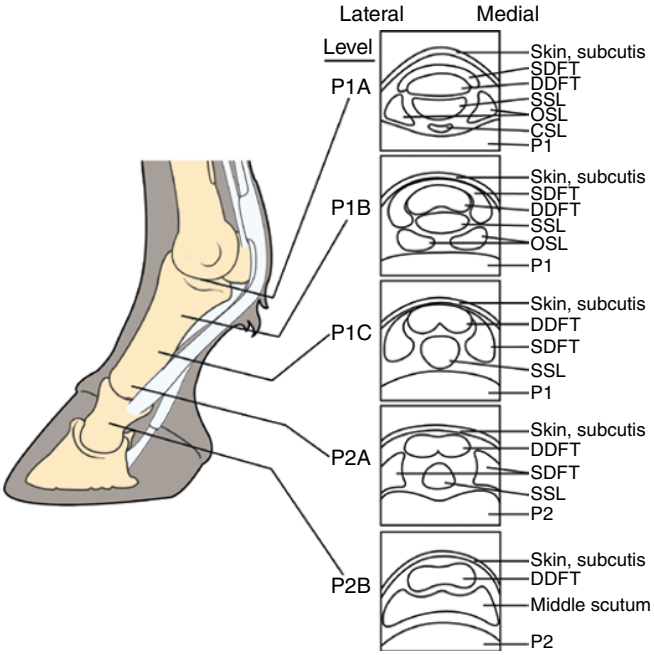
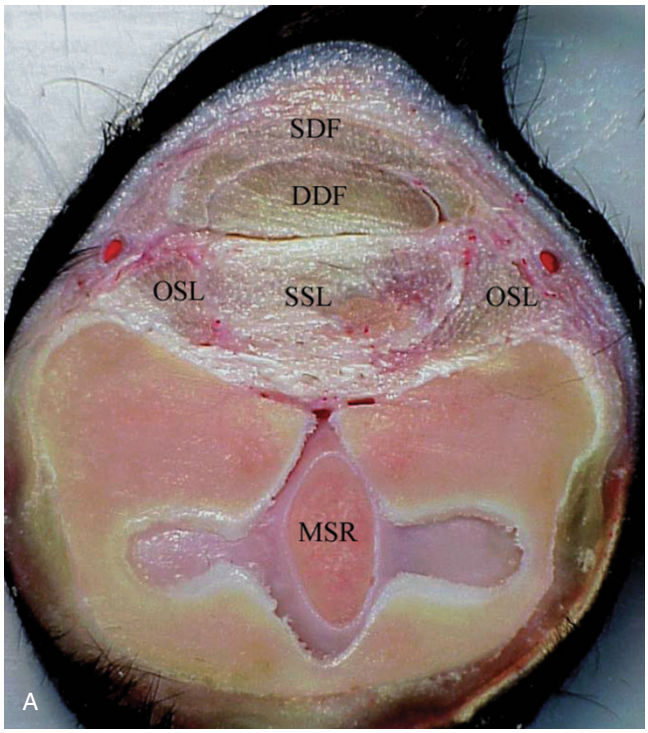
VetBooks.ir





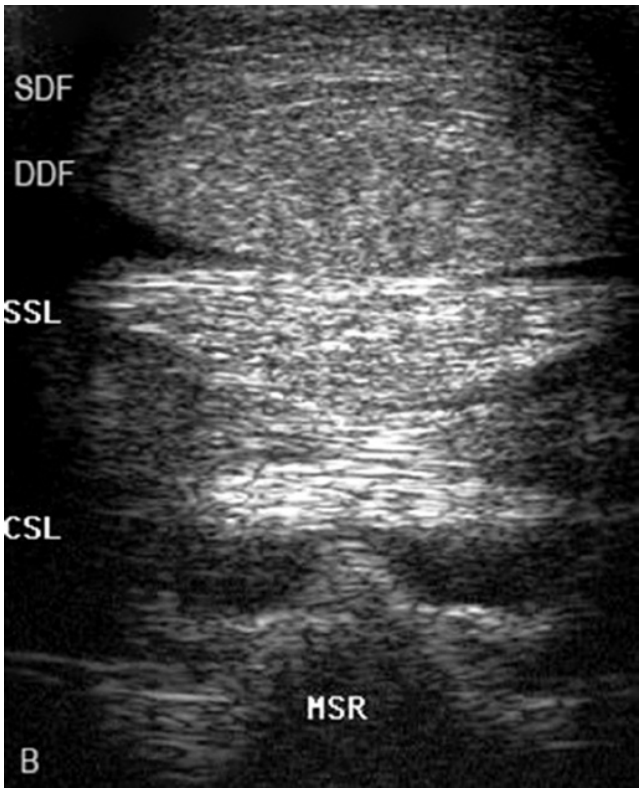


Figure 3.99. The SDFT and DDFT continue into the pastern. The DSLs (SSL, paired OSLs, and paired CSLs) originate on the PSBs and course distally onto insert on the distal aspects of P1 and P2. The SSL originates from the axial region of the PSBs and crosses the pastern joint onto insert on the palmaroproximal aspect of P2. The OSLs originate from the abaxial region of the PSBs and insert on the roughened triangular area of P1. The cruciate sesamoidean ligaments cross from the PSB to the contralateral aspect of palmaroproximal P1. The SDFT encircles the DDFT as they course out of the fetlock canal. The fibers of the SDFT incline abaxially, moving distally in the pastern to form teardrop-shaped branches that insert on the abaxial area of palmaroproximal P2. The DDFT continues distally and becomes bilobed in the midpastern area. The DDFT widens in a medial to lateral direction as it courses into the foot to insert on the distal phalanx (P3).

Off-weighted scan of this area is indicated to determine if adhesions may have developed between the flexor tendons within the digital flexor tendon sheath. Lifting the limb off the ground and placing the fetlock joint through a full range of motion while performing an ultrasonographic examination in longitudinal scan plane may be necessary to demonstrate a lack of independent movement of the tendons. A lack of independent movement suggests the formation of adhesions between these two structures. In addition, horses with proximal annular ligament syndrome may have a compartmentalization syndrome, which can compress the tendons obscuring significant pathology in the standing animal. Lifting the limb off the ground and placing through a range of motion while imaging in transverse scan plane may allow the architecture of the SDF and DDF to be assessed more completely.

Another indication for examining the limb while off-weighted is to perform angled contrast ultrasound technique (ACUST), which was reported to allow a more complete examination of the proximal SL.[24] When used ACUST is performed in conjunction with and following the examination with the standard ultrasound technique. This technique can provide more information about an injury than just the standard US examination. ACUST is performed with the limb off-weighted and with the probe manipulated off incidence. The ultrasound beam is first positioned perpendicular to the tendon or ligament to create maximum echogenicity, and this image is saved and then compared with an oblique angle of incidence image at the same level. The least amount of angle to produce a decrease in echogenicity of the tendon/ligament fibers should be used. Relaxation of the flexor tendons allows them to become hypoechoic and brings the suspensory closer to the transducer and within the focal zones of the transducer. ACUST allows the periphery of a structure to be seen more clearly, and this can be used to compare the shape of a structure to the normal side and to ensure that the examinations are being performed at similar levels of the tendon/ligament. Anisotropic properties of tendon and ligament fibers differ from that of adipose tissue and muscle that are found proximally in the SL. The echogenicity of muscle is much less dependent on beam angle compared with tendon and ligament fibers. The echogenicity of adipose tissue is not beam angle dependent. Injuries to the proximal suspensory can distort the fat/muscle bundles and their echogenicity as well as the perimeter of the proximal suspensory ligament (PSL). The principles of ACUST are now also utilized to evaluate a number of different tendinous/ligamentous structures. The appearance of an acute injury of a tendon/ligament is probably best determined with standard on angle technique, but as the tendon begins to repair, ACUST can help to delineate the development of scar tissue within a structure. Scar is more echogenic than normal collagenous tissue when examined off angle because the collagen fibers in scar tissue are initially randomly oriented and progressively remodel over time and with load. Normal collagen reflects sound away from the probe when off angle (appearing hypoechoic), making scar more conspicuous. ACUST can be used to characterize regions of pathologic change within a structure from normal anatomical variation. This technique can also allow better definition of the perimeter of a structure particularly when surrounded by peritendinous/periligamentous fibrosis. As an added benefit ACUST allows the examination of a structure without tension, making some lesions to become more conspicuous especially when adjacent fluid can enter regions of fiber disruption.

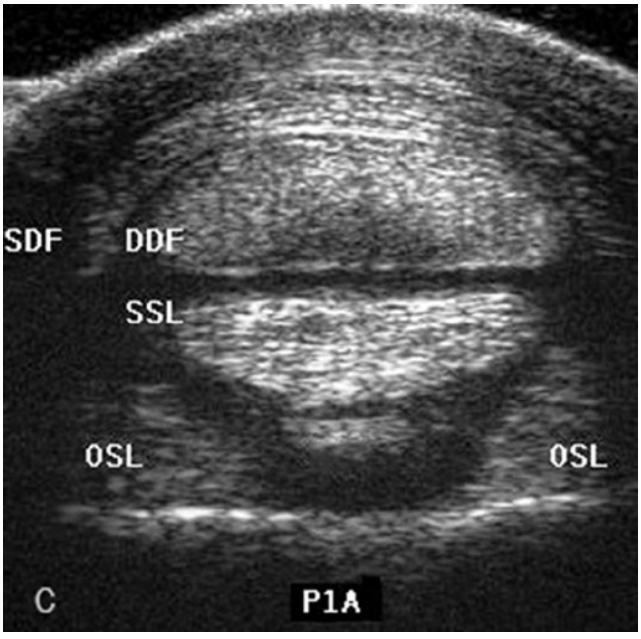

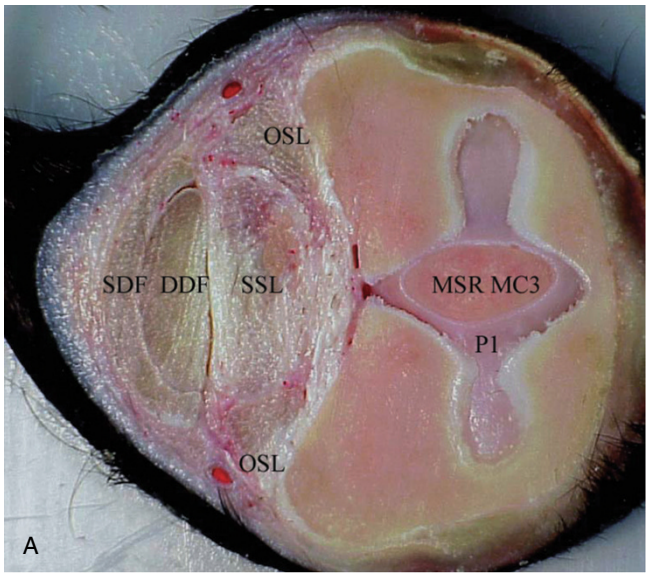

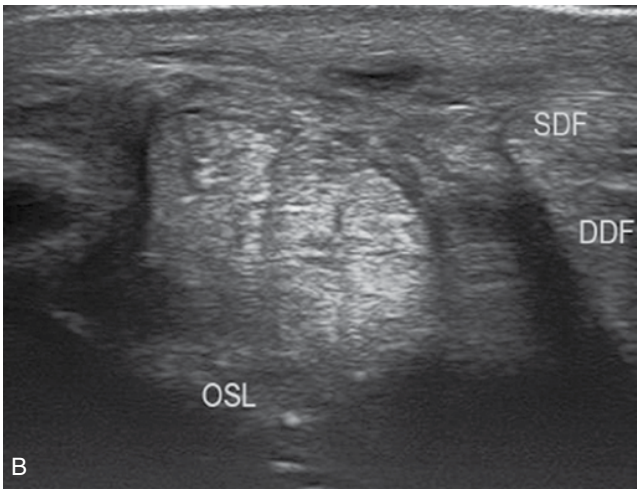

Figure 3.100. (A) In ZP1A the contour of the palmar border of the proximal P1 is a V-shaped hyperechoic line. From the midline position the OSLs are positioned on the abaxial surfaces of P1 (palmar tuberosities). The SDFT encircles the palmar/plantar border of the oval-shaped DDFT with a uniform palmar to dorsal dimension. The SSL is triangular in shape at its origin from the intersesamoidean ligament (ISL) and PSBs. (B) Angling the transducer proximad allows the distal aspect of the midsagittal ridge to be seen (B). The DDFT is oval at this level, while the SSL is triangular at its origin; the cruciate sesamoidean ligament (CSL) can be seen dorsal to the SSL (and the midsagittal ridge). (C) At the level proximal of P1, the DDFT and the SSL are easily imaged, but the OSL will require a more abaxial position of the transducer. *Source*: US images courtesy of Dr. Caitlyn Horne.

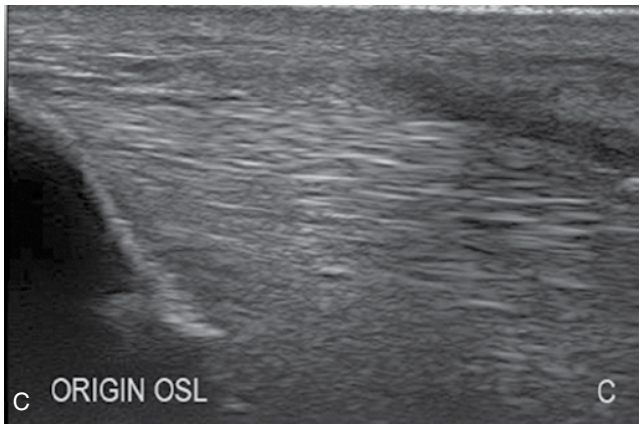
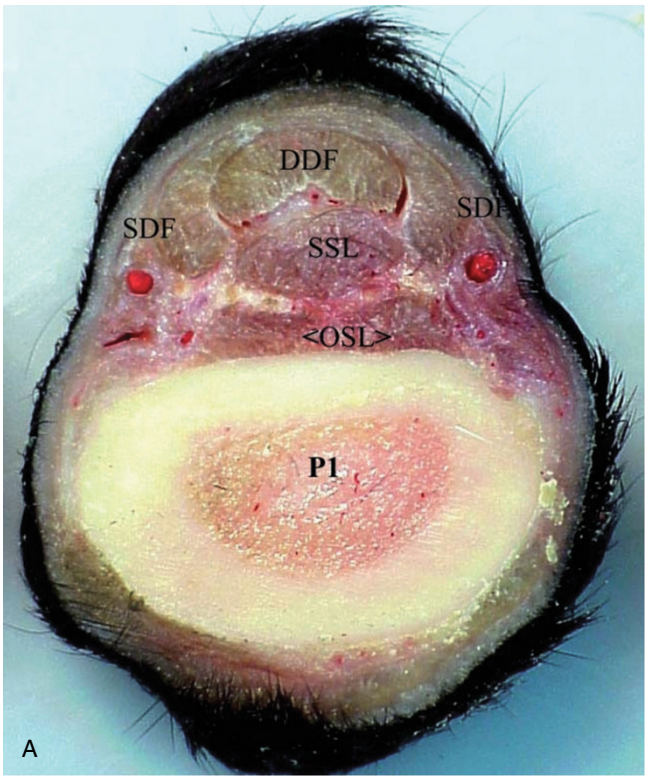
VetBooks.ir





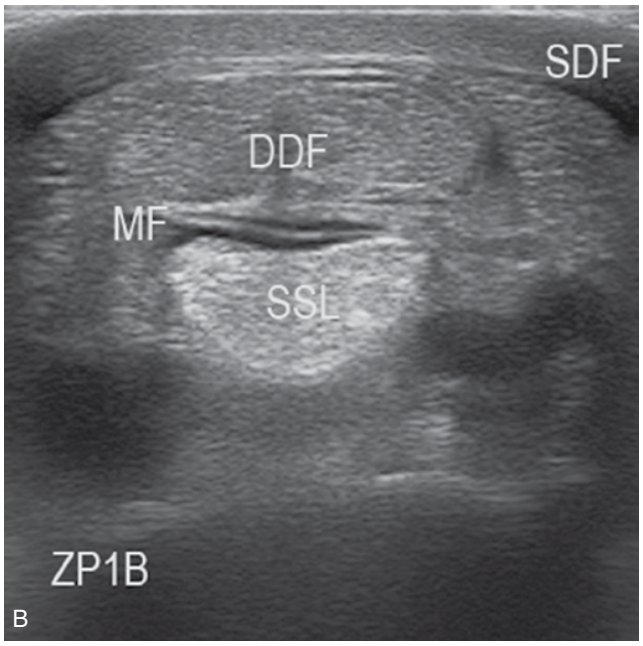


Figure 3.101. (A) To best image the origin of the OSLs, the transducer should be placed more abaxially and directed toward the base of the PSBs (similarly to the position for the SL branch examination). In transverse section the OSLs appear somewhat rounded at this level. (B) The transducer should also be placed longitudinally to image the origin of the OSLs to their respective PSBs. The longitudinal examination should image the insertion of the OSL onto the proximal sesamoid bone (C). *Source*: US images courtesy of Dr. Caitlyn Horne.

ULTRASONOGRAPHIC ASSESSMENT OF TENDON/LIGAMENT PATHOLOGY

Tendon and ligament injuries are recognized ultrasonographically by changes in size, shape, architecture, position (with respect to surrounding anatomy), and fiber alignment. Acute tendon injury manifests ultrasonographically as enlargement often with hypoechogenicity of the tendon/ligament architecture on cross section and the appearance of a striated or fibrillar pattern in the longitudinal images. These changes are often due to disruption of tendon matrix, the occurrence of intratendinous hemorrhage, and the intensity of the inflammatory response. Depending on the severity of injury, there may be changes in the overall shape, distortion of the margins/outline of the structure, and a change in the normal anatomical position in relation to other structures in that area. The most consistently diagnosed tendon and ligament injuries include enlargement and hypoechogenicity (indicating inflammation, edema, fibroplasia, and/or tearing) and enthesopathies. CSA measurements are considered a very sensitive indicator of inflammation, and the best way to assess increases in size is from the transverse images (Figure 3.109). Subtle enlargements of a structure may require comparison with the opposite limb. Any enlargement suggests structural thickening, and the rest of the examination should attempt to determine if the change is a result of acute, subacute, or chronic injury. Most current ultrasound machines have the capability to trace the CSA of the frozen image on the screen. Some machines have installed software that allows stored images to be processed after recovery and storage. Post-processing of the image to determine a CSA can be accomplished with digitizing software provided the images are stored as DICOMs; however this can be quiet time consuming (Dicom Works$_R$). Lesion CSA can be compared with the tendon/ligament CSA measurement to calculate the proportion of tendon involved. An accurate

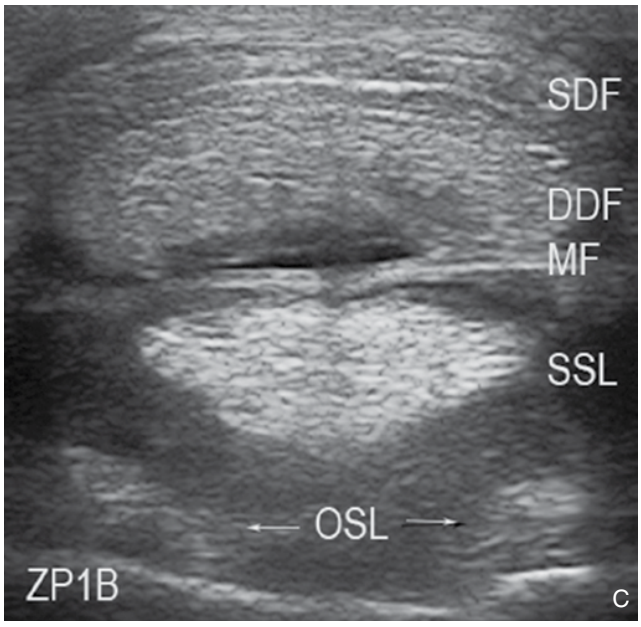

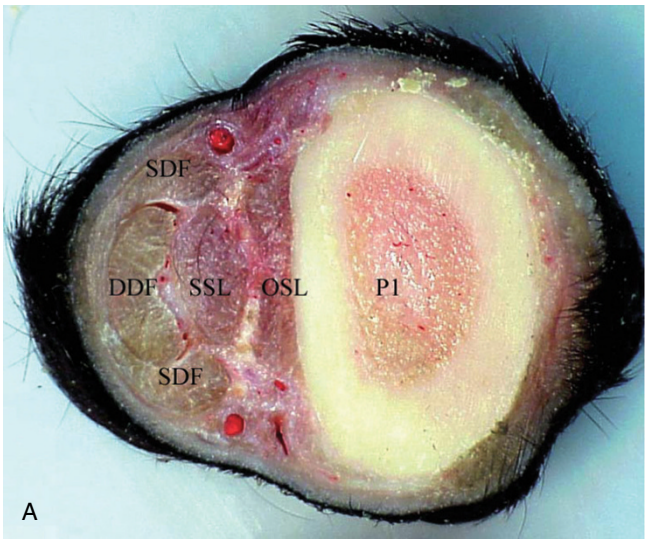

Figure 3.102. (A) Zone P1B is considered the middle of the proximal phalanx (P1). The bone contour of P1 is flat at this level. The fibers of the SDFT incline abaxially to the medial and lateral aspect of the DDFT as they begin to divide into branches. The DDFT develops a central depression on its dorsal surface and becomes bilobed in appearance. The SSL becomes more rounded in appearance. (B) The ultrasound image shows that the SSL appears hyperechoic relative to other structures. When the SSL is in focus, the DDFT is hypoechoic, necessitating that each structure be imaged independently. The SDFT branches cannot be adequately imaged with this transducer orientation and will require a more abaxial location of the transducer (Figure 3.103). As the SDF begins to form branches, it forms a distal ring of the manica flexoria dorsal to the DDF, and this should not be mistaken for an abnormality. (B) The OSLs incline more axially on P1 ultimately blending together to form a rectangular structure (C). *Source*: US image courtesy of Dr. Caitlyn Horne.

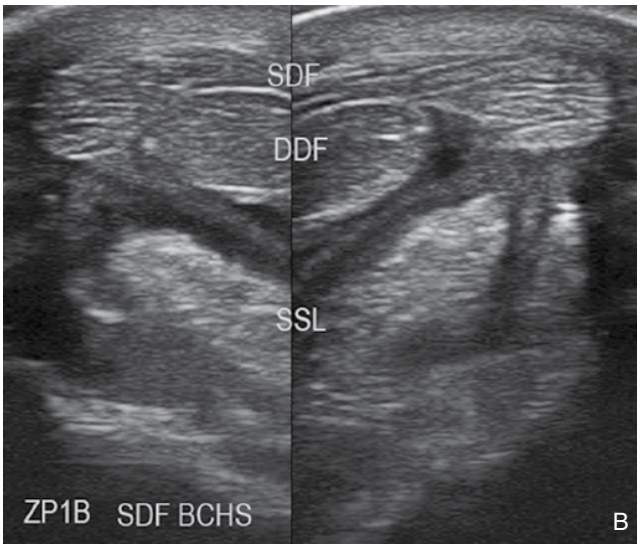
VetBooks.ir



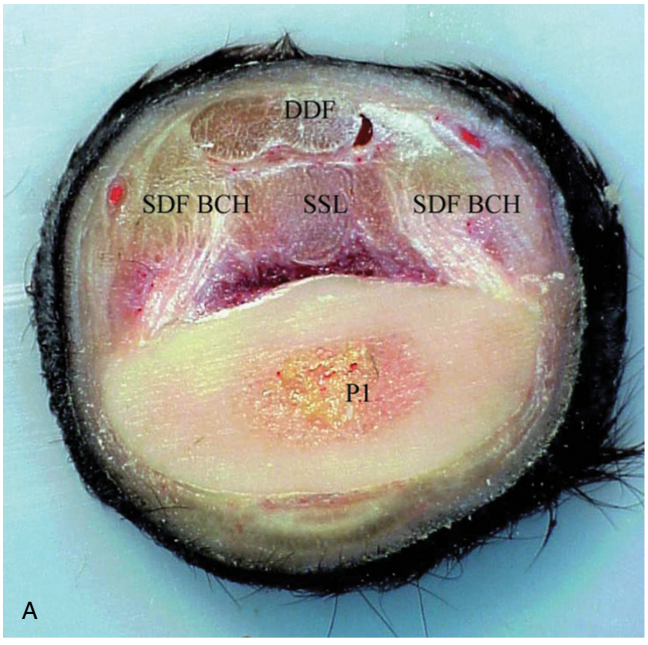


Figure 3.103. (A and B) To examine the SDFT branches, the transducer must be placed more abaxially, which allows the individual SDFT branches to be imaged as they incline to their insertion onto the medial and lateral aspects of proximal P2. *Source*: US image courtesy of Dr. Caitlyn Horne.

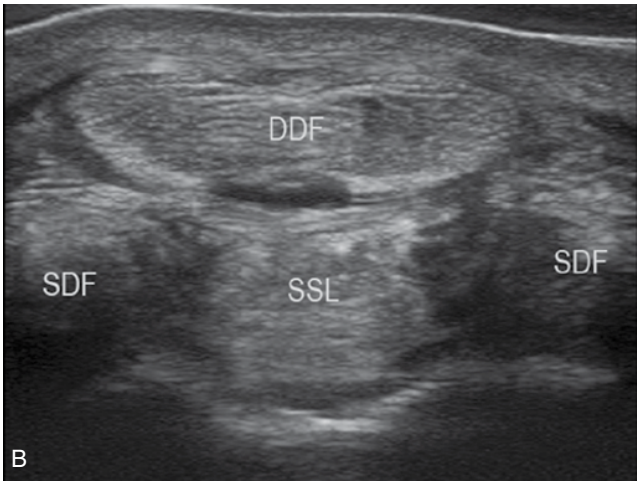

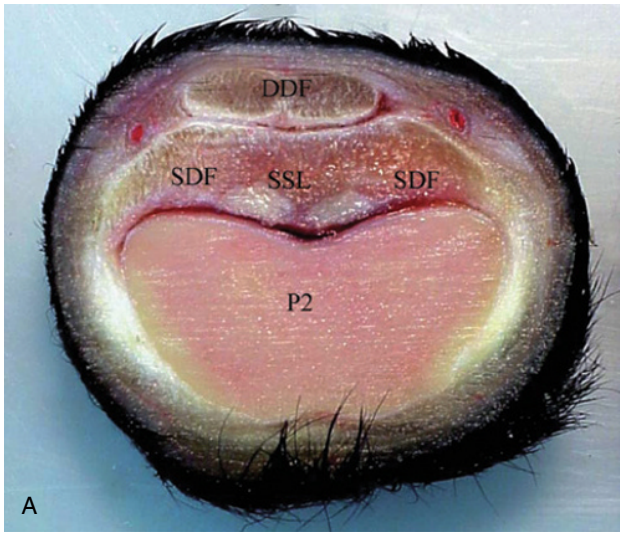

Figure 3.104. (A) In ZP1C the DDFT and the SSL are the only structures easily imaged when the transducer is on midline in a palmar position. The DDFT is bilobed and now expands in a medial to lateral direction. The SSL is rounded just prior to insertion onto palmar P2 and the middle scutum. (B) The SDFT branches are more abaxial and difficult to image with this transducer orientation. *Source*: US image courtesy of Dr. Caitlyn Horne.

CSA must be obtained as this measurement is often used in the rehabilitation of tendon and ligaments. CSA may increase for 2–3 weeks after an injury due to persistent inflammation. A repeat scan at 2 weeks will provide a more accurate assessment of maximum lesion and tendon CSA to compare back during rehabilitation. Normal values for Standardbred and Thoroughbred horses have been published.[80] If normal values for CSA for a structure are not available, they can be obtained from the opposite limb at the same level. As the tendon/ligament remodels the CSA will progressively diminish during the rehabilitation process. Increases in CSA during the rehabilitation period must be carefully assessed and often indicate that a reduction in the level of activity is warranted.

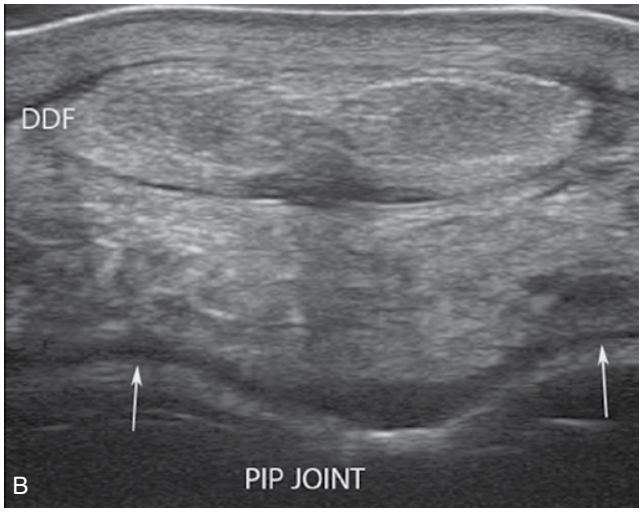

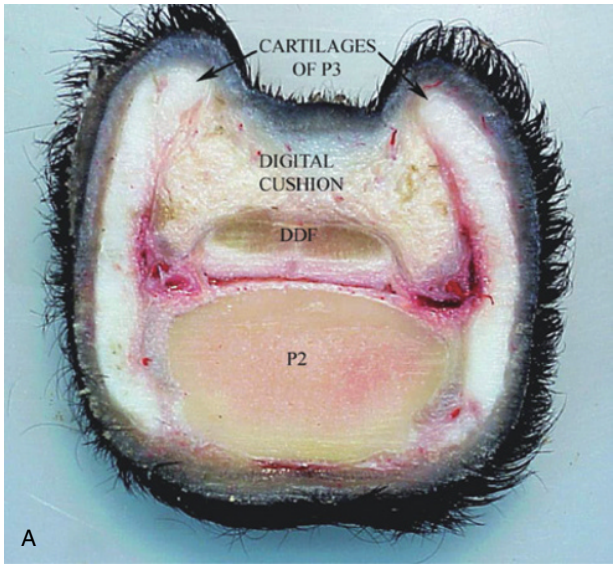

Figure 3.105. (A) Zones P2A and P2B are associated with the middle phalanx (P2). Zone P2A begins when the ultrasound examination visualizes the structures of the pastern crossing the proximal interphalangeal joint. The SSL, medial, and lateral SDFT branches and the axial and abaxial ligaments of the pastern joint blend together to form the cartilaginous attachment onto P2, called the middle scutum. (B) There is a normal hypoechoic area within the SSL just prior to insertion onto P2. The palmar/plantar aspect of the pastern joint including the articular cartilage can be seen (arrows). *Source*: US image courtesy of Dr. Caitlyn Horne.

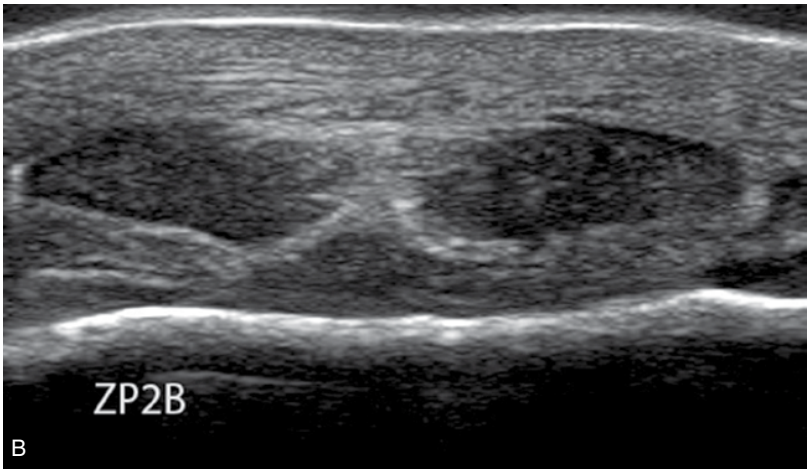

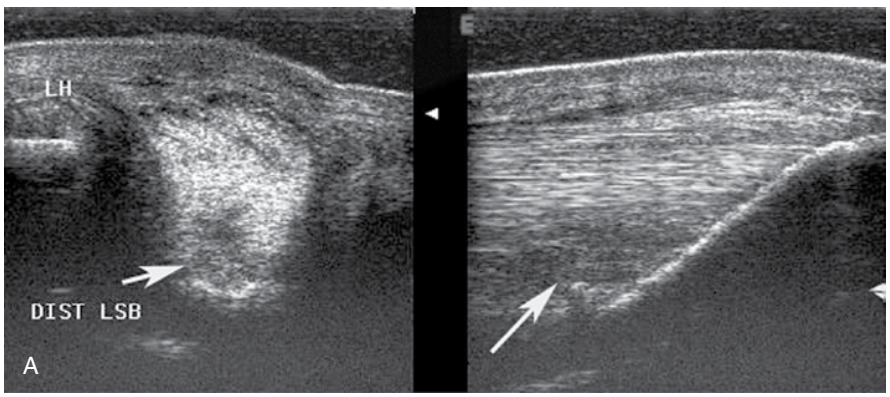

Figure 3.106. (A) Ultrasound imaging of Z2PB in the distopalmar aspect of P2 can be difficult due to the presence of the collateral cartilages of the distal phalanx. (B) The collateral cartilages interfere with proper placement of the transducer distal enough to assess the DDFT with a perpendicular orientation of the sound beam to the fiber pattern of the tendon. The shape of the DDF and some areas of scar (random disorganized fibrous material) can be assessed with this orientation. *Source*: US image courtesy of Dr. Caitlyn Horne.

Figure 3.107. Placing the limb on a small block with the leg more caudal allows a more comfortable examination of the structures of the pastern region. Notice the standoff pad placed over the probe to move the near-field artifact away from the superficial structures.

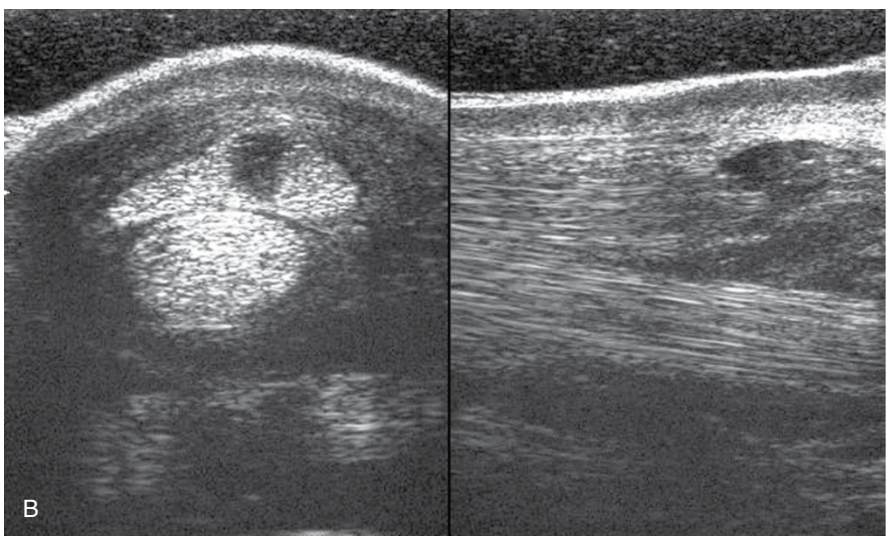

Figure 3.108. (A) Longitudinal and cross-sectional ultrasound image of a suspensory ligament attachment injury (arrows). Notice the loss of fiber pattern and the calcification at the attachment to the proximal sesamoid bone on transverse and longitudinal sections. (B) Longitudinal and cross-sectional ultrasound image of the SDFT with a core-type defect of the central aspect of the tendon.

VetBooks.ir

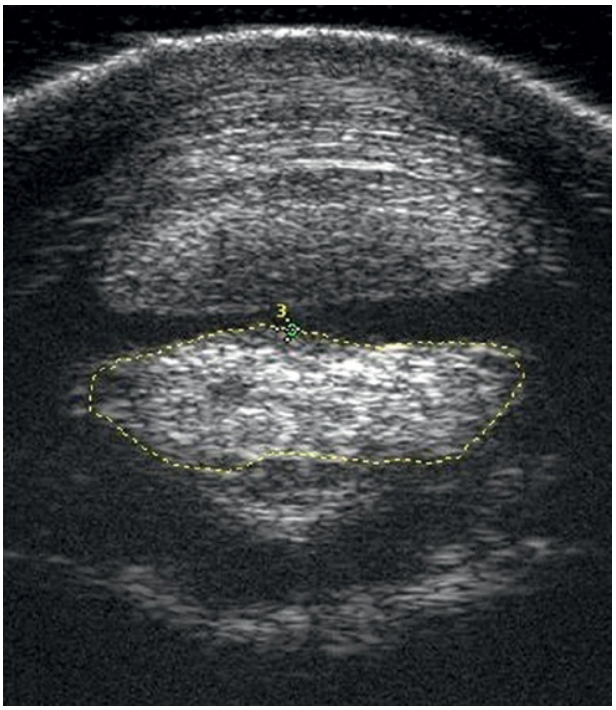

Figure 3.109. This is a straight sesamoidean ligament (SSL) injury. There is enlargement with an irregular outline associated with the heterogeneous appearance of the ligament. Tracing of the cross-sectional area is helpful to follow the rehabilitation process. Tendon and ligament damage is represented by changes in size, shape, architecture, position (with respect to surrounding anatomy), and fiber alignment.

The tendons and ligaments of the distal limb (and to certain extent proximal limb as well) have been found to have consistent but unique shapes at each level of the examination.[22,31,40,41,46,57,72–74,77,82,85,90,99] It is normal to have these structures change shape as they course distally in the limb. Therefore, if the examiner perceives a structure to have an abnormal shape, then it should be compared with the same structure in the opposite limb at the exact same level. It is also helpful in those horses with a change in shape to assess their position with respect to the surrounding anatomy. Architecture (or texture) is a subjective assessment of the ultrasound image attempting to describe morphological change or damage. Terms used to describe the architecture of an image relate to the tissue's ultrasonographic intensity. Architectural change is described as a change in echogenicity or the whiteness/brightness of a structure. Echogenicity is a function of each structure's particular density based on several things including cellular composition, fiber alignment, and blood supply. Alterations in echogenicity are subjective interpretations and have been described with the terms isoechoic, anechoic, hypoechoic, and hyperechoic. Isoechoic implies a normal echogenicity, while hypoechoic and hyperechoic implies less than and more than isoechoic, respectively. Anechoic implies the structure (or lesion) is mostly black. Fluid is often considered anechoic. In general, the denser the structure is, the more echoes it returns, and the whiter the structure appears.

Fibers have a parallel alignment in most normal tendon and ligamentous structures. The fibers of tendinous tissue are more uniformly distributed, while the fibers in ligamentous tissue are more multidirectional. This parallel fiber bundle alignment is best assessed on longitudinal images. Injury to and inflammation of tendons and ligaments can disrupt fiber bundle alignment. Subtle changes in fiber alignment are best seen on the longitudinal plane images. More severe fiber bundle alignment changes can begin to be appreciated on transverse images. The longitudinal image must be obtained through the affected tissue as seen on transverse images. Damage seen on cross section should be confirmed on longitudinal orientation. Fiber disruption seen as echolucent areas surrounding the fibers is compatible with hemorrhage and edema seen with acute injuries. Nonparallel or random fiber alignment without echolucent fluid content is compatible with chronic injury. Tendon injury can be focal or generalized such that the distribution of fiber damage can be quite variable. Fibroblasts migrate into the damaged area and begin to deposit collagen and form granulation tissue. This collagen is laid down randomly, and cross-links are produced between the fibers. This random disorganized tissue appears hypoechoic on ultrasound and can persist for some time post-injury. Rehabilitation with increasing levels of exercise precipitates remodeling of the collagen and a return of the echogenicity and alignment toward normal.

LIMITATIONS OF ULTRASONOGRAPHY

The quality of the image is directly related to the operator, the equipment, and the anatomical area being examined. This imaging tool is influenced by the skill of the operator more than any other imaging technique. The operator is responsible for positioning and steering the sound beam as well as determining the equipment settings during image acquisition. Artifacts are easily produced and can create inaccuracies in the image that can significantly compromise interpretation. It is also recognized that ligaments have normal anatomical variation in their fiber orientation and this can cause inconsistencies in their echogenicity on ultrasound examination (such as in the collateral ligaments of the distal interphalangeal joint). Artifacts most often involve operator error and an assortment of sound–tissue interactions that may or may not be controllable. One common but easily correctible artifact is created by inadequate skin preparation. Inadequate skin prep leads to poor transmission of sound and a corresponding dark image. The limb should be clipped and prepped to maximize skin contact and sound transmission. High-frequency transducers produce better images but often require shaving the area to be examined with a razor. Improving skin–transducer contact is critical to obtain the best images possible. Another common artifact frequently created by the operator occurs when the ultrasound beam is off incidence to tendinous/ligamentous structures and tissue interfaces. Off incidence artifact

VetBooks.ir

occurs when the ultrasound beam is not at 90° to the fibers of the target structure that reflect the returning echoes away from the transducer. This creates a hypoechoic area that mimics a lesion(s) within the targeted structure. Improper gain and power settings and inappropriate focal zone position can also lead to suboptimal images. Near-gain and power settings that are set too high reduce the ability to differentiate the tissues. Gain settings should be adjusted to produce a uniform gray scale across the entire image. Focal zones are variable in number and position and should be adjusted to the level of the specific structure(s) to optimize the image quality.

Artifacts that are created by sound–tissue interactions include acoustic enhancement, refractive scattering (edge artifacts), reverberation, and acoustic shadowing. Acoustic enhancement occurs when sound passes through a fluid structure. Fluid attenuates sound less than soft tissue. Enhancement results from relatively increased amplitude of deeper echoes by an overlying structure of low attenuation. This creates the appearance of increased echogenicity of the tissue deep to the fluid-filled structure (far-field enhancement). The most common structures that can cause enhancement artifacts in the musculoskeletal examinations are veins and arteries. Refractive artifacts are generated from the edge of a curved surface and are created because part of the sound beam is refracted off the curved structure and does not return to the transducer. Shadow artifacts are displayed distal the lateral margins of curved or cystic structures. Edge artifacts are consistent and particularly troublesome when examining specific anatomical locations. The SDF, DDF, and ICL are superimposed over the SL in the metacarpus and metatarsus, and the size differential (SL is wider than the SDF/DDF/ICL) between these structures allows refractive or edge artifact to occur in the SL. In addition, the presence of vessels over the SL creates enhancement artifacts in the image. The proximal plantar metatarsal region is another good example of how these artifacts can affect the quality of the ultrasonographic examination of the origin of the SL (Figure 3.110). At this location there are large oval/rounded structures of different echogenicity (SDF, DDF, ICL, and origin of the SL) all with a slightly different fiber orientation and acoustic impedances. The operator must find an acoustic window that minimizes the interference of the splint bones as well as prevents or limits the development of refraction and enhancement artifacts from the overlying tendons and vessels. Dilatation of the vessels in this area due to the inflammatory response of the damaged SL makes scanning this area even more problematic and significantly compromises interpretation of the SL morphology. Scanning at a more plantaromedial to dorsolateral oblique orientation may be necessary to improve image quality, but the experience of the operator scanning areas such as the proximal plantar metatarsus will improve the diagnostic accuracy of the ultrasound exam, but the image may still be suboptimal.

Injuries to the tendons inside of the digital sheath can cause considerable synovial reaction, which may be associated with annular ligament constriction syndrome[28,33] (Figure 3.111). Because the SDF and DDF tendons and the macular flexoria exist inside the fetlock

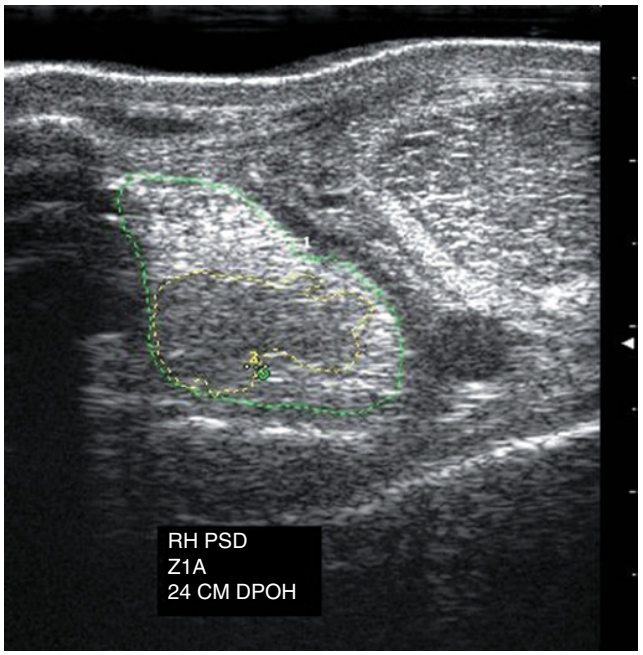

Figure 3.110. Transverse scan of the proximal plantar metatarsal area with the inherent artifacts that occur in this area due to edge shadowing, acoustic enhancement, and acoustic shadowing that occur because of the bony anatomy and overlying SDF and DDF and vessels. This lesion was found to be a false positive when the horse had a normal MRI examination of this area. The operator must find an acoustic window that minimizes the interference of the splint bones as well as prevents or limits the development of refraction and enhancement artifacts from the overlying tendons and vessels.

canal with the restricting annular ligament, it may be difficult to visualize certain types of injuries with ultrasonography. Recent introduction and use of tenoscopy or endoscopy to explore the sheaths and bursae of the equine limb have allowed comparison of ultrasonography and tenoscopy for identifying tendon/ligament injury.[37,75,76,92,104] Tenosynovitis of the DFTS may result from tears in the DDFT or SDFT, manica flexoria, or other structures that communicate with the synovial fluid and thus can generate an intense synovial response in a sheath or bursa. However, these lesions can be identified confidently only by tenoscopy, which also permits appropriate lesion management.[92] Longitudinal tears of the DDFT should also be suspected if ultrasonographic changes are present lateral or medial to the border of the DDFT, but tenoscopic examination of the tendon sheath is essential to establish an accurate diagnosis and an effective treatment.[104]

Ultrasound remains a practical, inexpensive, and readily accessible imaging technique for soft tissue injuries of the horse. However, with the recent introduction of magnetic resonance imaging (MRI) to equine musculoskeletal imaging, soft tissue and bone injuries can be evaluated in detail not capable with any other imaging technique. MRI is now considered the gold standard to assess lameness originating from the carpus and tarsus distally (especially of the foot within the horny hoof capsule), but it is not always practical or necessary to make a diagnosis. Lesion(s) seen with standard ultrasonographic imaging are not typically candidates for

VetBooks.ir

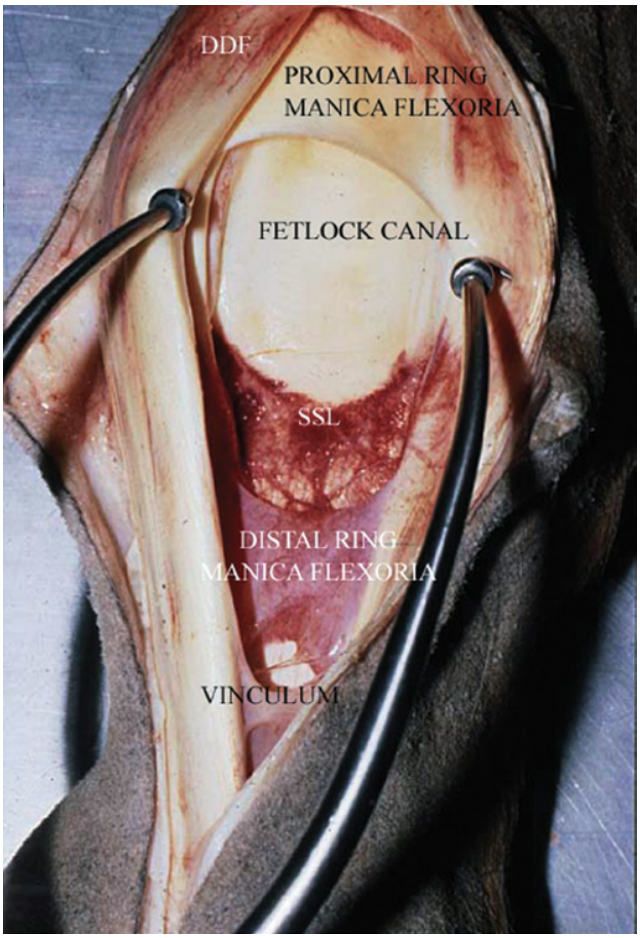

Figure 3.111. The structures within the digital flexor tendon sheath (DFTS) are exposed via a longitudinal incision through the annular ligament and the SDFT at the level of the fetlock joint. The unique anatomy at this level begins with the mesotendinous attachments (not seen in this section) to the DDFT at the medial and lateral borders in the proximal sheath. Progressing distally the SDFT produces the proximal ring of the manica flexoria encircling the DDFT. Just distal to the manica flexoria, the SDFT and DDFT are bound within the fetlock canal by the primary annular ligament (PAL), which has been incised in this section. Just distal to the fetlock canal, the SDFT makes another ring (smaller) around the DDFT called the distal ring of the manica flexoria. Just distal to this ring, the vincula attach to the midline of the DDFT on its dorsal border.

MRI examination. While ultrasonography and MRI remain the optimal choices for soft tissue imaging, it remains unclear in all cases which is the most effective imaging tool. In humans there are many studies that have been performed that compare the diagnostic accuracy and utility of ultrasound compared with MRI for a variety of orthopedic problems. These studies are lacking in horses and need to be performed. A limited number of studies have been performed and have looked at the collateral ligaments of the distal interphalangeal joint and the proximal plantar region.[6,35,36] In those studies a negative ultrasound study does not rule out an abnormality and positive ultrasonographic needs to be regarded with caution. It is hoped that further experience comparing ultrasound with MRI along with the completion of more comparative studies between MRI and ultrasound will identify specific indications for each imaging modality and improve our capabilities as ultrasonographers.

ULTRASOUND TO EVALUATE JOINT INJURY

Joint injury, osteochondrosis, and degenerative joint disease are significant causes of lameness in the horse.[68,69] An accurate diagnosis of the cause of joint pain can prove critical for selecting the most appropriate treatment(s) and rehabilitation. Intra-articular diagnostic anesthesia should be utilized to localize a lameness to a particular joint. Radiology, ultrasonography, thermography, nuclear imaging, CT, and MRI all have a place in lameness diagnostics, and each may be warranted in selected cases.[50,62] However, many of the joint problems seen in the horse can be effectively imaged with a combination of radiographs and ultrasound. Good-quality baseline images are critical to provide a diagnosis but also will be helpful in reevaluation of the joint in the future. The radiographic exam is most effective at evaluating the bony structure of the joints of the equine limb. In some joints, there can be poor correlation between clinical and radiographic findings, or the radiographic study may be inconclusive.[55,62] In these types of cases the cause of lameness is presumed to be soft tissue injury, and often empirical treatment is instituted. A complete ultrasonographic exam is indicated in these cases to evaluate the periarticular tendons and ligaments, the joint capsule, and the joint fluid, as well as to provide valuable information about the cartilage and subchondral bone surface.[2,17–20,58,78,79] Ultrasonography has the added advantage of providing immediate, detailed information through a range of motion (in extension and flexion). However, ultrasound provides a relatively limited field of view when compared with other imaging techniques making global survey of a joint to be time consuming. When used in combination, radiography and ultrasonography are complementary and can supply more information about an orthopedic problem than when each modality is used alone.

The clinician must understand the advantages and limitations of each imaging modality as well as the appearance of the normal anatomy and pathophysiology characteristic with each technique. When utilizing diagnostic ultrasound to evaluate joints, it is necessary to become familiar with the appearance of many of these structures in transverse, longitudinal (sagittal), and frontal planes. Normal anatomical variations exist, and it is important that the clinician recognizes these variations as normal to prevent developing an inaccurate diagnosis. The opposite limb can and should be used for comparison when possible recognizing that disease can occur at the same location in the opposite limb.

In general, the stability of a joint is provided by the congruent contours of the joint surfaces of the bony column, the collateral (and in some joints the intra-articular) ligaments, the integrity of the joint capsule, and the surrounding tendons and ligaments. In the proximal limb, various muscle groups and tendons that cross the joints provide additional stability. Most joints of the appendicular skeleton in the horse are designed to work in the sagittal plane with flexion and extension being the

VetBooks.ir

predominant range of motion. This necessitates a joint to have a redundant joint capsule at the dorsal and palmar/plantar surfaces. In addition, tendon and ligaments that pass over joints with a wide range of motion typically have sheaths or bursae to allow these structures to effectively glide across the joint surface throughout their full range of motion. In addition, many tendons that cross a joint have retinacular bands and/or annular ligaments to maintain the position of these structures through the range of motion of that joint. Development of fluid or effusion within the joint in any of these structures needs to be accurately defined to effectively manage the cause of the effusion.

INDICATIONS FOR ULTRASONOGRAPHY OF JOINTS

The use of diagnostic ultrasound is an excellent adjunct to the radiographic examination of a joint. While the soft tissue structures associated with the joint can be carefully evaluated, ultrasound examination can prove superior at detecting bony changes such as the early periarticular changes (osteophyte) manifested in osteoarthritis than radiographic examination. Ultrasonography can be utilized in the examinations of a joint to assess the cartilage, subchondral bone surface, and some of the intra-articular soft tissues of the joint. A complete ultrasonographic examination of joints requires examination of the joint in a weight-bearing position as well as imaging the joint in flexion (or through a range of motion). In joints that commonly manifest articular cartilage damage such as the fetlocks and carpi, the major weight-bearing regions of the joint that are not accessible with ultrasound when the limb is weighted should be examined during joint flexion. Hyperextension injuries that impact the dorsal articular surfaces of the joint (such as the medial and lateral proximodorsal proximal phalanx in the fetlock) can also be more easily identified with the joint flexed.

Joints with radiographically obvious lesions should not be excluded from an ultrasound examination because coexisting soft tissue-type problems may alter the prognosis. Some bony abnormalities evident on radiographic exam are related to soft tissue attachment sites and require an ultrasound examination to more carefully assess the extent of soft tissue injury (i.e. apical sesamoid fracture should be assessed for the degree of SL involvement to provide a more accurate prognosis). Some intra-articular fragments may occur due to avulsion of soft tissue attachments (i.e. lateral or medial malleolar fragments with collateral ligament attachments), and ultrasound can help determine the full extent of injury to these structures. Ultrasound can also assist with the surgical approach to the fragment by documenting the position as intra- or extra-articular and fixed or mobile. Ultrasonography of a joint injury is definitely indicated when the radiographic study is inconclusive especially when there is synovial effusion, joint capsule thickening, or focal swelling of any of the soft tissue structures associated with the joint (osteochondrosis, intra-articular ligament pathology, periarticular tendon or ligaments, etc.). In addition, there are some regions of the limb where diagnostic radiographs can be difficult to obtain (such as the pelvis and coxofemoral joint). Ultrasonography has proven very helpful to assess both the soft tissues and bony contours of this joint.

The diagnostic workup of a joint may utilize ultrasound to guide interventional procedures to improve the clinical information in the workup of a joint. Visualization of needle placement into the joint can document the placement of local anesthetic or medication into the appropriate structure (joints, sheaths, or bursae) particularly in areas where it can be difficult to ensure accurate needle placement (navicular bursa, articular facets of the cervical spine, shoulder joint, bicipital bursa, coxofemoral joint, etc.).[10,16,56,60,93] Documenting needle placement and seeing that the injection is within the synovial space (of joints, sheaths or bursae) are important to reduce false-positive and false-negative results. Collection of fluid samples can be directed by ultrasonography improving the recovery rate in situations like septic arthritis. Ultrasound of a joint may guide the surgical approach to and/or the intraoperative retrieval of bony fragments (i.e. lateral malleolar fractures of the distal tibia).

Lacerations and puncture wounds to the distal limb can traumatize tissue and introduce contaminates such as hair or debris into a synovial structure. Such foreign material can act as a nidus for infection and inflammation inducing immediate and delayed immune responses. Wounds or punctures that are close to a joint should be carefully evaluated for communication with and possible contamination of the joint. The ultrasonographic appearance of hair shafts within synovial structures has recently been reported in horses. Ultrasonographic evidence of intrasynovial contamination should direct the clinician to be more aggressive at removing the offending material.

EQUIPMENT AND TECHNIQUE

The same equipment utilized for tendon and ligament examinations is ideal for joint evaluations. The joint should be prepared as for a tendon or ligament examination with the joint being clipped (and possibly shaved, depending on the operator's preference); cleansed to remove dirt, hair, and other surface debris; and liberally coated with a conducting gel. Most joint examinations will require clipping and prepping the entirety of the joint surface. The majority of the structures evaluated during joint ultrasonography are superficial in location well within the focal zones of most high-frequency transducer. Flat-face linear transducers of 10–18 MHz are often used because of superior near-field resolution and broad field of view. It is helpful in evaluating most of the structures of the joint at a scan depth of 2–4 cm. Standoff pads move the superficial structures out of the near-field artifact and into the near focal zone of the probe. Standoff pads also improve the footprint by conforming to the skin surface. Lower-frequency transducers (5 or 7.5 MHz) may be necessary to image deeper aspects of the joint such as the caudal aspect of the stifle. In the proximal limb the joints are farther from the skin due to muscle coverage. The overlying muscle mass provides a good window for the

VetBooks.ir

sound transmission to the deeper aspects of the joint. However lower-frequency probes may need to be used, which have poorer resolution and somewhat compromised image quality. Microconvex or macroconvex probes have the added advantage of a divergent beam that allows image acquisition from a smaller skin contact point.

Joint ultrasound requires a specific knowledge of the anatomy of the joint. Unlike the palmar/plantar metacarpal exam where the transverse images are typically acquired first, it is helpful to begin the examination of many joints in the longitudinal scan plane. Identifying the articular surfaces of a joint provides orientation for the rest of the examination. Global assessment of a joint can be time consuming requiring multiple scan plane. The extensor and flexor surfaces (and the corresponding soft tissues such as the extensor/flexor tendons that cross these areas) and the collateral ligaments and the articular surfaces (weight-bearing and non-weight-bearing areas) of the joint all should be examined. For example, examination of the fetlock, which is considered a simple joint, is divided into quadrants. The quadrants of the fetlock are dorsal, palmar/plantar, medial/lateral, and a dorsomedial/dorsolateral scan plane.[23,27] In more complex joints additional scan planes may be indicated due to additional structures associated with the joint (i.e. the stifle has the patellar ligaments, long digital extensor tendon, popliteal tendon, etc.). This emphasizes that the examiner must have developed experience in the use of ultrasound and knowledge of the anatomy of the joint being examined.[3,9,12,13,15,16,25–27,32,42,44,64,66,71,83,84,86,88,89,93,95–98,100,103]

All tendinous or ligamentous structures should be evaluated in both transverse and longitudinal scan planes. A description of the scan plane used to acquire the image should be documented on the stored image. Scan planes should be labeled similar to the nomenclature utilized for radiographic projections. These oblique projections are described by the direction that the central ray of the primary beam penetrates the body part of interest, from the point of entrance to the point of exit. Soft tissue structures should be examined first followed by the cartilage and subchondral bone surfaces. Much of the cartilage and subchondral bone surface in the non-weight-bearing areas can be imaged in the standing horse. However, dynamic examination of the cartilage and subchondral bones surfaces of the weight-bearing areas of the joint requires lifting the limb, placing the probe on the dorsal joint surface all the while attempting to place the probe 90° to the subchondral surface while flexing and extending the joint. While this maneuver requires considerable practice, it can be expedited by having someone hold the limb (or placing the limb in a stand) while the examiner positions the transducer while manipulating the limb. Maximally flexing the leg is necessary to access the major weight-bearing areas of a joint. Unfortunately, flexion of an inflamed joint will likely be resented making it more difficult to evaluate the weight-bearing surface.

The joint examined and the area of interest within the joint are, in many cases, directed by the signalment (and by any prior radiographic findings). For example, racehorses have a high incidence of problems involving the dorsal articular surfaces of the high-motion joints, particularly the fetlock and carpus; younger horses may have developmental orthopedic disease that, when involving a joint, frequently involves the trochlear ridges of the stifle, the distal intermediate ridge of the tibia, or the trochlear ridges of the talus; Warmbloods often have a similar distribution of osteochondrosis lesions, and they also tend to develop periarticular changes in the coffin, pastern, and fetlock joints. In each case, it is important to perform as complete an examination of the joint as possible because many joint conditions involve multiple structures and/or multiple areas of the joint. For example, osteoarthritis tends to cause cartilage degeneration and thinning in the loaded areas of the articular surface. Along with these cartilage changes, periarticular remodeling occurs in the form of osteophyte and/or enthesophyte formation. Joint capsule thickening, with or without metaplasia, is also a common feature of osteoarthritis. Many of the osteochondral fractures that occur in the joints of performance horses occur on the dorsal surface due to hyperextension of the joint. But hyperextension may also cause damage to the palmar/plantar soft tissues (flexor tendons, SL, and distal sesamoidean ligaments), which can significantly alter the prognosis.

Dynamic examination of the joint as described for the examination of the weight-bearing cartilage allows the evaluation of redundant parts of the joint capsule in high-motion joints. For example, the dorsal surface of the fetlock joint has redundancy of the joint capsule that is relaxed when the horse is bearing weight on the limb. Flexion of the fetlock tenses the dorsal aspect of the joint capsule, allowing better evaluation of this part of the joint. Tearing of the dorsal joint capsule is more accurately imaged if the structure is under tension while the joint is in flexion. Flexion and extension of the joint during ultrasonographic examination can also be helpful in demonstrating mobility of an osteochondral fragment and in evaluating fluid movement within the joint.

The same joint on the contralateral limb should serve as a comparison when evaluating articular and periarticular structures. However, there are two precautions: (1) the examiner must make certain to use the same orientation of the transducer and image the contralateral joint at exactly the same location when making comparisons, and (2) some joint conditions, in particular osteochondrosis in young horses and osteochondral fragmentation in racehorses, can be bilateral.

The major obstacle to the effective use of diagnostic ultrasound in the examination of joints is the need to understand the unique anatomy of each joint and appreciate how the various tissue types are influenced by sound–tissue interactions. It is also important to understand the information and misinformation (artifacts) created during any ultrasound evaluation (see limitations of ultrasound earlier in this chapter). There are many texts that describe the anatomy of specific joints in the horse[31,46,85,90] and the use of diagnostic ultrasound in the examination of joints.[2,17,18,20,21,38,39,58,68,69,78,79,101,102] It is recommended that these textbooks be available as reference materials to assist with the examination. Descriptions of the ultrasonographic examination of the specific joints are beyond the scope of this chapter and will not be discussed. However, a discussion of some general features unique to the use of ultrasound in the examination of joints follows.

VetBooks.ir

ULTRASONOGRAPHIC APPEARANCE OF PERIARTICULAR STRUCTURES

Collateral Ligaments

The joints of the appendicular skeleton in the horse are designed to work predominantly in the sagittal plane with flexion and extension as the primary range of motion. A major component of the stability of a joint is provided by the periarticular soft tissues but in particular the collateral ligaments. The collateral ligaments are designed to impart stability to the joint throughout its entire range of motion. This unique task is accomplished either with paired structures (i.e. multiple bundles of the fetlock, tarsal joints) or by unpaired structures (i.e. single bundle of coffin joint). Knowing the anatomic arrangement of the collateral ligaments of each specific joint becomes extremely important as the ultrasonographic appearance of these ligaments is determined by the fiber orientation. Most of the collateral ligaments have a uniform fascicular orientation and, therefore, a homogeneous ultrasonographic appearance. Some have a mixed fascicular arrangement, which gives them a heterogeneous appearance. The lateral collateral ligaments of the stifle, hock, and elbow and the collateral ligaments of the fetlock and carpus have spiral or crossed fibers.[23] This mixed arrangement of fascicles within the CLs is one of the arrangements that allow the collateral ligaments to function in both extension and flexion (Figure 3.112). In the tarsocrural joint, the superficial collateral ligaments are under tension while the limb is extended and relaxed, whereas while the limb is flexed, the short collateral ligaments are tensed only when the tarsus is flexed.[99] Therefore, the short collateral ligaments should be examined while the leg is flexed. (See tarsus and tibia in Chapter 5 for more information.)

Tendons and Ligaments

As discussed previously tendons and ligaments appear as moderately echogenic structures with relatively well-defined margins, and injury is recognized with ultrasound by changes in size, shape, architecture, position, and fiber alignment. Ultrasonographic examination of the tendons at the level of the joint is no different except from a couple of perspectives. First, the examiner must pay particular attention to the course of the tendon or ligament as it courses over a joint because there can be quite remarkable changes in direction. This becomes important in that the transducer must constantly be adjusted to maintain a perpendicular orientation to the structure to prevent beam angle artifact. Second, while injury is recognized as in other areas, the periarticular portions of tendons have sheaths (and occasionally bursae) associated with them. Injury to these tendons/ligaments may also manifest as effusion within the sheaths or bursae. To confuse the matter even more, the effusion may occur without structural damage to the tendon or ligament. Therefore, effusion of the sheaths and bursae associated with these structures requires careful evaluation to define the cause and to differentiate the fluid accumulation as separate from joint effusion.

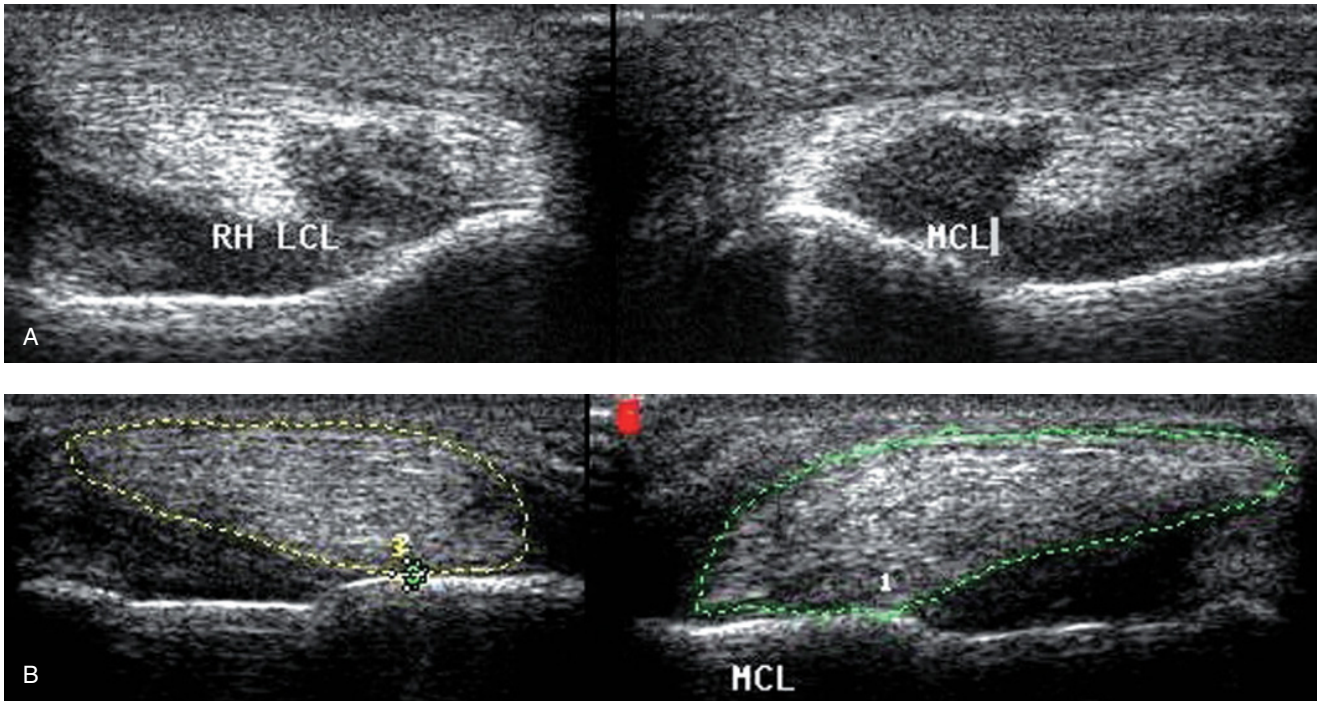

Figure 3.112. A mixed arrangement of fascicles within the CLs of many joints is one of the unique arrangements of ligaments that allow a collateral ligament to function in both extension and flexion. This mixed arrangement of fibers can produce a heterogeneous appearance of the collateral ligament on ultrasound examination. (A) This is a transverse ultrasound image of the CLs of the fetlock joint that appears to have a hypoechoic lesion within the dorsal aspect of the medial CL. However, the lateral CL has the same appearance and similar cross-sectional area, suggesting that this is a variation of normal in this horse. (B) This transverse image of an MCP CL demonstrates a thickened CSA with a heterogeneous fiber pattern, consistent with chronic desmitis.

ULTRASONIC APPEARANCE OF THE JOINT

Joint Capsule, Synovium, and Synovial Fluid

The joint capsule is primarily connective tissue with low cell density. The joint capsule is continuous with the periosteum or perichondrium, but it does not insert directly at the perimeter of the articular cartilage (Figure 3.113). There tends to be redundancy of the joint capsule in the high-motion joints, such as the fetlock, carpus, tarsus, and stifle. In fact, this redundancy can cause relaxation artifacts if the redundant aspect of the joint is examined in the weight-bearing position rather than during flexion. Inflammatory conditions within the joint can cause capsular changes that include thickening (initially due to hemorrhage and edema, and later fibrosis), calcification, and insertional capsulopathies (enthesophytes). Osteoarthritis in high-motion joints typically involves periarticular changes that begin with congestion and thickening of the joint capsule. The synovial membrane becomes hyperplastic, and in more chronic cases, synoviocyte metaplasia may lead to the formation of synovial chondromas, which are seen as nodules of cartilage. These nodules may undergo endochondral ossification, resulting in ovoid radiodense bodies within the joint capsule.

Synovitis is an early response to joint injury and usually progresses to capsulitis; however, thickening of the thin synovial membrane is difficult to appreciate ultrasonographically. Synovial effusion is helpful in assessing synovial membrane proliferation and thickening. In cases of severe synovitis, synovial fluid that is fibrinous, cellular, or hemorrhagic can cloud evaluation of the joint capsule and synovium.

There is usually minimal synovial fluid in a normal joint, so the joint capsule and synovium are normally in close apposition with the articular cartilage. Synovial fluid accumulation occurs with many abnormal joint conditions, so thorough evaluation of the various articular structures is indicated when synovial effusion is present. The ultrasonographic properties of the synovial fluid can help assess the nature of the fluid (Figure 3.114). Effusion associated with acute synovitis typically is anechoic, with occasional fibrinous accumulations. Hemorrhage or sepsis increases the cellularity and fibrin deposition within the joint and appears as echogenic fluid. Ultrasonography can aid in aspiration of synovial fluid by identifying areas of fluid accumulation. Utilization of this technique, particularly in the deeper joints such as the hip and the shoulder, can minimize trauma to the joint and reduce the potential for blood contamination of the fluid sample.

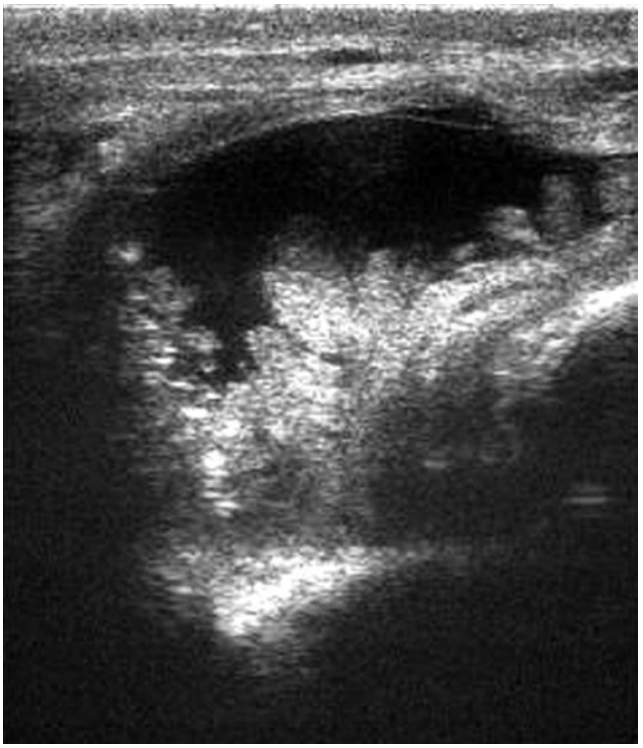

Figure 3.114. Synovial fluid accumulation occurs with many joint, sheath, or bursal conditions. A thorough evaluation of the various structures of the joint or synovial sheath is indicated when effusion is present. This image demonstrates a proliferative synovial membrane from a chronic synovial effusion that was due to a previously undiagnosed osteochondrosis lesion of the medial malleolus of the tibia.

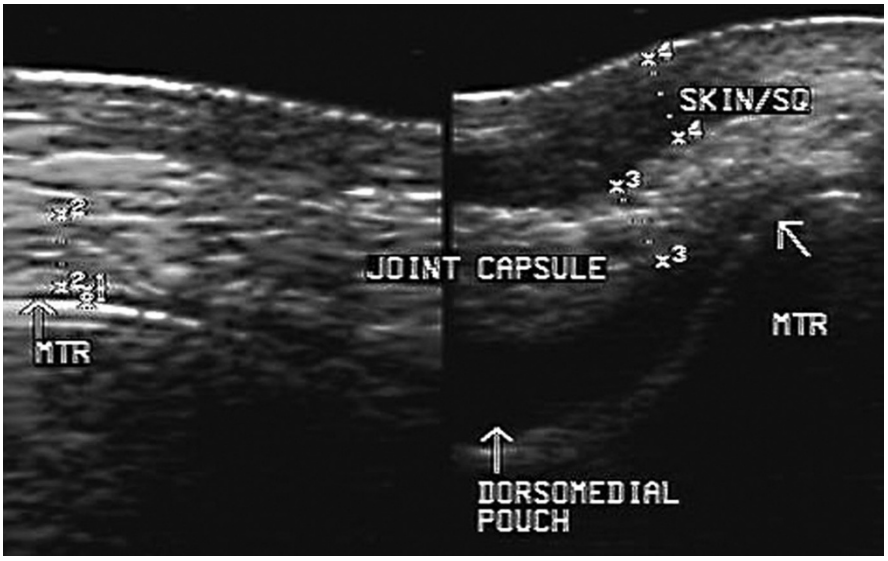

Figure 3.113. Ultrasound image of the dorsomedial aspect of the tarsocrural joint. There is mild edema of the subcutaneous tissues and synovial effusion within the joint, allowing visualization of the joint capsule. Fluid accumulation within the joint can allow delineation of the synovium.

VetBooks.ir

Articular Cartilage and Subchondral Bone Surface

With ultrasonography, reflections of the sound beam occur at interfaces between tissues of different material densities. Articular cartilage is predominantly water producing a sonolucent (anechoic to hypoechoic) image between the echogenic joint capsule/synovium and subchondral bone; however, the distinction between joint fluid and cartilage cannot always be appreciated. The ultrasound beam cannot pass through the bone, so the subchondral bone interface is seen as a dense, hyperechoic line that follows the normal contour of the joint surface. Normally, there are distinct soft tissue–cartilage and cartilage–bone interfaces. When synovial fluid is seen between the synovial membrane and the cartilage surface, the interface between the fluid and the cartilage may create a thin, echogenic line.[17]

To accurately define the thickness and to detect changes in surface and internal characteristics of cartilage, the sound beam must be perpendicular to the cartilage surface. Normal articular cartilage thickness in horses remains to be well defined in all but a few joints. A recent study in healthy adult horses showed that the mean cartilage thickness on the lateral and medial trochlear ridges of the talus and on the distal intermediate ridge of the tibia was 0.57, 0.58, and 0.70 mm, respectively.[97] The trochlear ridges of the talus were chosen in that study because of the high incidence of osteochondrosis and the potential for cartilage thickening at these sites. Fetlock cartilage thickness was found to be thicker proximally (0.8 mm) more than distally (0.4 mm).[23] In humans, cartilage thickness varies somewhat between joints and even within a particular joint. For example, in the human knee the cartilage thickness on the femoral condyles normally ranges from 1.2 to 1.9 mm, with cartilage thickness on the medial condyle being less than that on the intercondylar notch and the lateral condyle.[2] From the limited number of equine studies and based on clinical impression, there is also variation in cartilage thickness both between and within joints in horses. Compare, for example, the difference in articular cartilage thickness between the lateral and medial trochlear ridges of the femur in the normal femoropatellar joint. The cartilage is thinner on the medial trochlear ridge; this is normal and should not be mistaken for a pathologic process.

Normal Variations

Articular cartilage has a fairly uniform thickness and a smooth contour. There are however a couple of areas where cartilage thickness and contour vary normally. Synovial fossae occur in some joints being bilaterally symmetrical and most often located in a non-weight-bearing part of the articular surface (e.g. humeroradial, tarsocrural, and coxofemoral joints). If an area is found that is of concern, the same site in the opposite limb should be evaluated for comparison (bearing in mind that some developmental lesions often occur bilaterally). The articular cartilage at the perimeter of a concave epiphysis and the cartilage at the center of a convex epiphysis are thickest.[55]

Immature Cartilage and Bone

Epiphyseal cartilage ossifies from a secondary ossification center, and the carpal and tarsal bones ossify by endochondral ossification. Ossification radiates out toward the articular surface so that articular cartilage of immature joints can appear thickened and the interface with the subchondral bone irregular. A more distinct cartilage–subchondral bone interface develops with maturity. Thus, measurements of articular/epiphyseal cartilage thickness in foals may vary greatly with age and possibly with the joint involved. In neonates, articular/epiphyseal cartilage thickness on the medial trochlear ridge of the femur can be as much as 25 mm; the articular cartilage is about 1 mm thick, and the remaining thickness is unossified epiphyseal cartilage, although the differentiation between the two types of cartilage is not appreciable ultrasonographically.[31] The thickness of articular cartilage can be quite variable depending on the stage of development and the amount of calcification that exists. As epiphyseal ossification continues, the thickness of cartilage covering the epiphyseal bone decreases.[38,39]

Osteochondral Lesions

Ultrasonography complements radiography in the early diagnosis of osteochondrosis in growing animals. In young horses, articular cartilage lesions associated with osteochondrosis can cause significant joint effusion, and in many cases, there are thickened cartilage or osteochondral fragments either *in situ* or free-floating within the joint. Areas of thickened cartilage or osteochondral fragment(s) are often apparent over an irregular subchondral bone surface (Figure 3.115). This irregular surface is thought to be associated with a continuum of changes that occur in the development of osteochondrosis lesions starting with a linear fissure or fold formation in the thickened articular cartilage that can progress to an undermined cartilage flap with lysis of the underlying bone.[68,69] Developmental abnormalities in the articular cartilage and subchondral bone can occur bilaterally, so use of the contralateral limb for comparison may be misleading.

Clinical signs often precede radiographic evidence of osteochondrosis in young horses. Radiographic assessment of osteochondrosis lesions commonly underestimates the extent of the articular lesion when compared with what is seen arthroscopically. Ultrasonography has proven to be a very useful imaging technique to evaluate the cartilage/subchondral surface and is indicated in any young horse with joint effusion suspected of having osteochondrosis. Serial examination of affected joints can be useful when deciding whether surgery is necessary. Progression of an osteochondrosis lesion is a good indicator for surgical debridement. When serial examination demonstrates a static osteochondrosis lesion or even progression to a normal cartilage–subchondral bone surface, surgery may not be indicated.

Osteoarthritis

Osteoarthritis manifests as thinning and erosion of the articular cartilage and progresses to osteophyte formation and periarticular soft tissue changes such as enthesis new bone at the joint capsule attachments. In the horse early cartilage thinning has been difficult to identify ultrasonographically. More advanced stages of the disease may be easier to demonstrate in the high-motion joints

VetBooks.ir

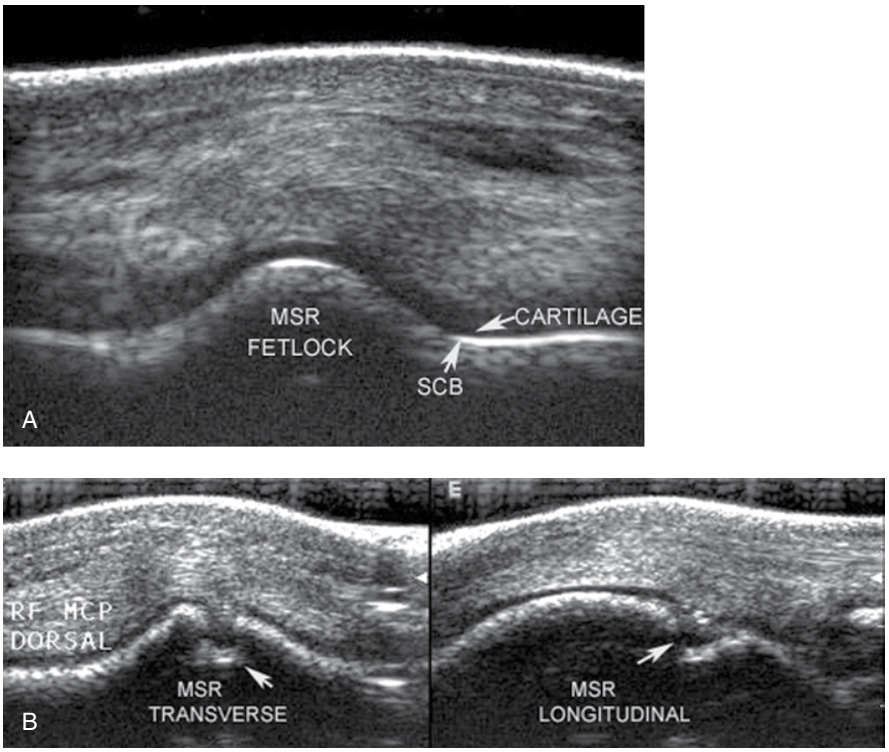

Figure 3.115. Osteochondrosis in the developing animal manifests articular cartilage lesions that are often associated with significant joint effusion, and in many cases there are cartilage or osteochondral fragments either *in situ* or free-floating within the joint. (A) This is a transverse ultrasound image of the dorsal aspect of a normal MCP joint. The anechoic cartilage is seen overlying the hyperechoic subchondral bone surface. Notice the smooth subchondral surface of the normal joint. (B) This transverse and longitudinal ultrasound image demonstrates an irregular subchondral surface of the sagittal ridge of this MCP joint, consistent with osteochondrosis.

particularly when the joint capsule is seen to be in close contact with the subchondral bone surface when pressure is applied with the transducer. The advanced stages of the disease often manifest significant soft tissue changes such as enthesis new bone and periarticular lipping. In the low-motion joints, such as the distal hock joints and the pastern, ultrasonographic evidence of osteoarthritis generally is limited to periarticular changes as access to the cartilage surface is limited. A study in humans showed that ultrasound was useful in identifying early osteoarthritis of the knee.[58] Changes included a decrease in cartilage thickness and blurring of cartilage margins that made cartilage measurements less precise. In general, ratings of clarity and sharpness correlated better with clinical status than absolute thickness of the articular cartilage in that study. Further experience with ultrasonographic examination with higher frequency transducer will hopefully allow similar criteria to be established for horses. Subchondral bone sclerosis is also a feature of osteoarthritis, but cannot be detected with ultrasonography because the sound beam does not penetrate the subchondral bone surface. However, except in foals, the subchondral bone surface should be uniform.

Subchondral Bone Cystic Lesions

Horses with lameness that improves after intra-articular anesthesia of a joint should have a radiographic and ultrasonographic examination performed.[101] Ultrasonography should be utilized to evaluate the intra-articular environment. Flexing the joint as best as possible and placing the probe perpendicular to the subchondral bone surface facilitate evaluation of the weight-bearing area of the joint. The joint most commonly examined for subchondral cyst formation is the medial femoral condyle of the stifle (Figure 3.116). Cartilage lesions with underlying subchondral bone defects are readily identified and their size and position documented with ultrasonography. Subchondral cystic lesions are also readily identified and help characterize the size of the cyst opening and depth of the cyst. Some clinicians have reported using ultrasound to guide the placement of a needle percutaneously into the cyst cavity. Treatment is directed at placing various medications directly in the cystic cavity (corticosteroids, bone marrow, stem cells, etc.).[102] As in other joint injuries, radiographic and ultrasonographic examination is complementary and should be performed together. Identifying a specific injury within these joints may preclude the use intra-articular injection of anti-inflammatories and direct the clinician to explore the joint arthroscopically.

Menisci

The equine stifle has two menisci that are composed of specialized fibrocartilage. A frontal ultrasound scan (lateral to medial or medial to lateral longitudinal orientation) of the femorotibial joints produces the best images of the menisci and collateral ligaments of the stifle. The menisci have a triangular shape and a homogeneous

VetBooks.ir

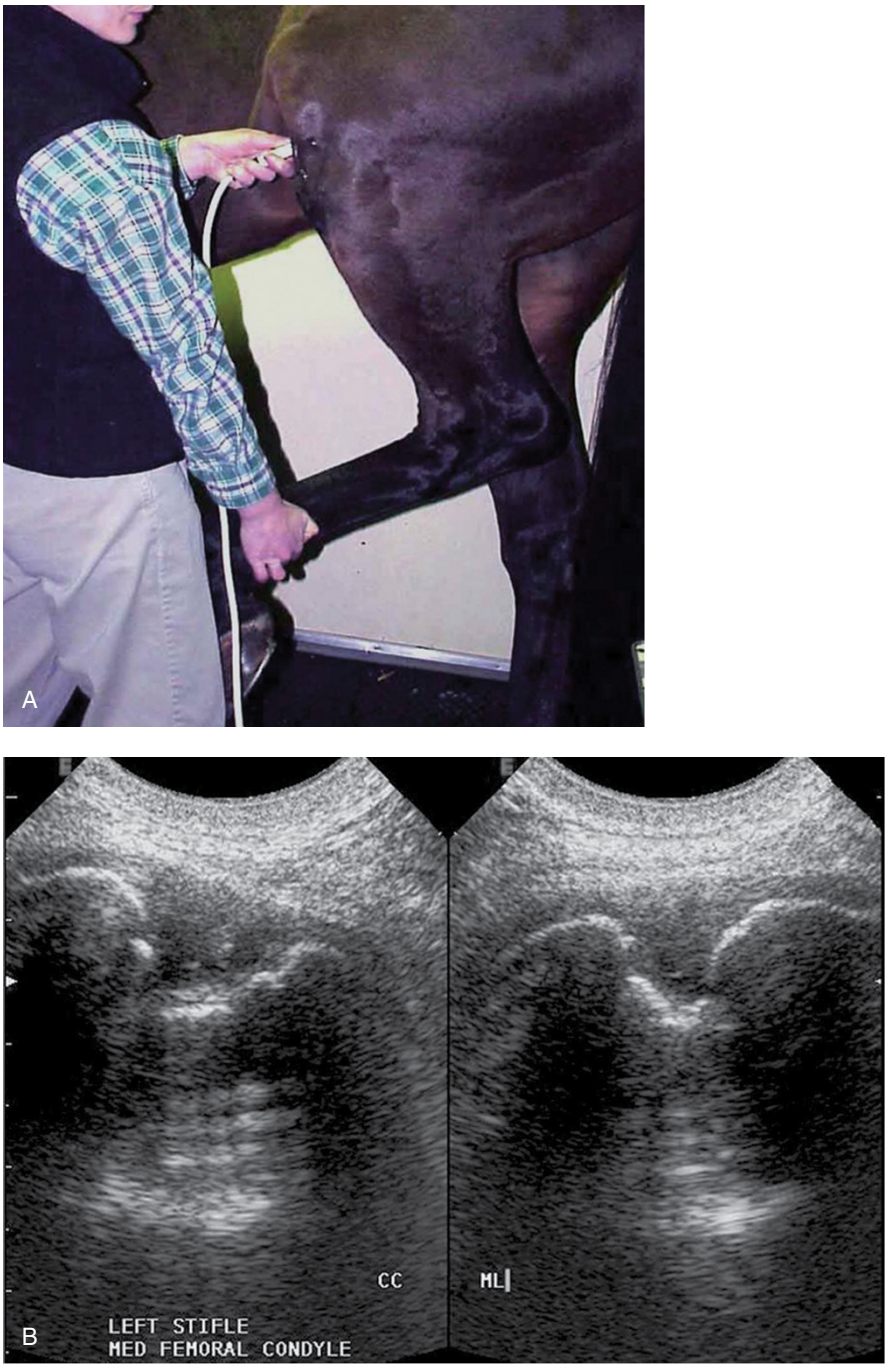

Figure 3.116. (A) The weight-bearing area of the medial condyle is evaluated by flexing the stifle and placing the probe between the medial and middle patellar ligaments just above the tibial crest. (B) The ultrasound image demonstrates a large subchondral defect in the medial femoral condyle of the femur, consistent with a subchondral cystic lesion.

appearance when the transducer is perpendicular to their abaxial border. A complete description of the ultrasonographic examination of the stifle is presented in various texts and should be studied before the examiner attempts to evaluate the stifle.[17,20] Meniscal evaluation is enhanced by fluid accumulation within the joint. A complete assessment of the entire meniscus is essential and should include the cranial and caudal horns. Cranial lateral and cranial medial horns are visible from between the lateral and middle patellar ligaments and between the medial and middle patellar ligaments in the standing horse. The cranial and caudal horns of the meniscus have a similar ultrasonographic appearance when imaged from the cranial and caudal aspects of the joint and with the stifle flexed. Documentation of caudal horn involvement with ultrasonography indicates that exploratory arthroscopy should also involve a caudal approach because damage to the caudal horn of the meniscus often is not appreciated via the normal cranial arthroscopic approach to the femorotibial joint. Damage

VetBooks.ir

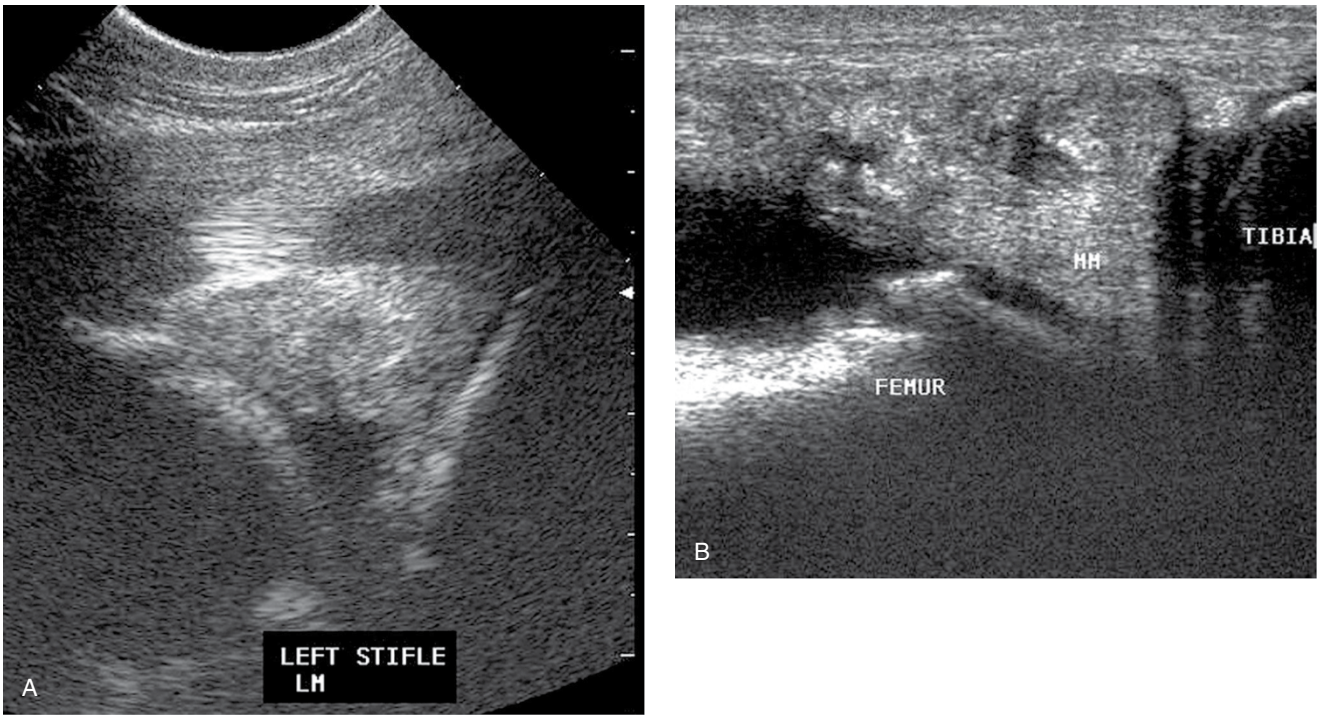

Figure 3.117. Damage to the medial meniscus is manifested ultrasonographically by a change in size, shape, echogenicity, or position relative to the femoral condyles and proximal tibia. (A) This ultrasound image of a damaged meniscus demonstrates an axial injury of the meniscus. (B) This image represents a more severe injury of the meniscus with prolapse of the meniscus.

to the meniscus is manifested ultrasonographically by a change in size, shape, echogenicity, or position relative to the femoral condyles and proximal tibia (Figure 3.117). Hyperechoic areas casting shadows are indicative of calcification and suggest chronic damage. Loss of the normal triangular shape is indicative of tearing. Linear hypoechoic images indicative of tears may be seen crossing horizontally through the medial meniscus (MM) and are best identified with the stifle in slight flexion. Large hypoechoic areas in cross section can be associated with chronic lameness and compatible with edema, fiber disruption, and degenerative processes. Extrusion of part of the meniscus from its normal position can occur if the damage is severe. Collapse of the joint space and joint effusion may also be appreciated when both the collateral ligaments and menisci are involved. When synovial distension is extensive and the synovial membrane is thickened, a hypoechoic space can be identified between the MM and the superficial structures (fascia and medial collateral ligament [MCL]). This gap between the MM and the MCL is abnormal, because these two structures normal are adhered to each other.

Identifying Incomplete Ossification

Ultrasonography can be useful in determining the stage of endochondral ossification in young foals. It is particularly useful for identifying incomplete ossification of the cuboidal bones in the carpus or tarsus of neonates. Unlike radiography, ultrasonography provides the information immediately in a field situation, allowing appropriate treatment or management changes to be instituted without delay.

CONCLUSIONS

Ultrasonography is vastly underutilized in the clinical assessment of joint problems in horses. A complete radiographic study of a joint can demonstrate osseous lesions, but it gives little information about the articular cartilage and soft tissue structures of the joint, which are important sites of pathology in most types of joint disease. These tissues are readily imaged using ultrasonography (within the anatomical limitations of the particular joint being imaged). Arthroscopy allows direct visualization of lesions found on radiography and assessment of the articular cartilage surfaces and other intra-articular structures. However, arthroscopy requires general anesthesia and it is invasive and expensive. Ultrasonography is noninvasive, rapidly performed, widely available, well tolerated by the patient, and inexpensive.

Ultrasonography offers many advantages in the clinical assessment and management of joint problems in horses. Ultrasonography can potentially detect lesions not evident radiographically allowing treatment to be instituted and/or management changes made that would slow or arrest lesion progression and prolong the useful life of the horse. In particular, ultrasonography may identify soft tissue and cartilage defects over radiographically normal bone that may not otherwise be identified only at surgery or postmortem examination. Although the initial ultrasound exam may not always provide a specific diagnosis, repeat ultrasound examination may reveal early changes indicative of a potentially serious joint problem. In humans, ultrasonography is purportedly a more sensitive indicator of early osteoarthritis than is radiography.[58] It allows monitoring of lesion progression or

VetBooks.ir

resolution over time, which can aid surgical decision-making, direct management, and rehabilitation strategies and increase the understanding of joint disease in horses.

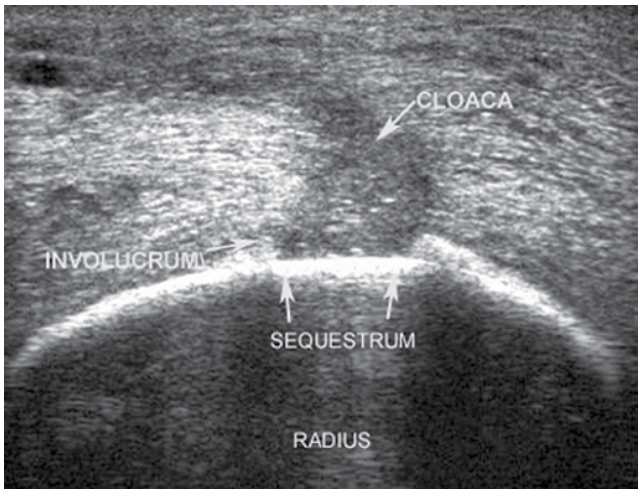
Ultrasonography can enhance the equine practitioner's ability to accurately diagnose and manage joint-related problems in performance horses. However, it is only one tool at the clinician's disposal; clinical acumen and selective use of other imaging modalities are needed to accurately diagnose many types of joint disease. Currently, the gold standard for assessing soft tissue injuries in humans is MRI. However, in human medicine, ultrasonography remains a very useful imaging modality for evaluating the popliteal space, knee, patellar tendon, shoulder (especially the rotator cuff), and neonatal hip. Extensive use of ultrasonography in the examination of equine joints has already demonstrated the sensitivity of this modality in defining articular lesions not apparent radiographically. In time, there will undoubtedly be certain joint conditions in horses that will most readily be identified with ultrasonography.

OTHER INDICATIONS FOR ULTRASONOGRAPHY OF THE MUSCULOSKELETAL SYSTEM

Evaluation of Bone

Bone appears as a bright hyperechoic line with a strong acoustic shadow. This is due to the high acoustic impedance when compared with the soft tissues. The bone surface appears to be of uniform thickness. Ultrasonography has proven useful in the diagnosis of fractures particularly in areas that are not readily accessible to radiographic examination such as the pelvis, femur, scapula, humerus, and spine. Ultrasonography is often utilized in conjunction with nuclear scintigraphy to focus on areas of bone injury not apparent on radiographs. Fractures can be seen as an anechoic to hypoechoic line that is visible in the cortical bone. Often there is displacement (distraction) of the bone edges evident along the cortical margin.

Osteitis and osteomyelitis can also be evaluated with diagnostic ultrasound and appears as a fluid interface at the bone surface.[81] Acute trauma may have hemorrhage at the bone surface that can appear similarly to osteitis and may indicate more detailed radiographs to rule out a fracture. A repeat scan should be performed in 4–5 days to document resolution or resorption of the hemorrhage of the fluid interface. Progression to osteitis is demonstrated by the persistence of fluid, which can vary from hypoechoic to anechoic and may contain hyperechoic echoes consistent with gas in the fluid. Hypoechoic tracts that begin at or just under the skin surface can occasionally be seen tracking to the bone surface. The bone surface may begin to demonstrate a raised area of periosteal new bone production consistent with involucrum formation at the margins of the sequestrum or bone fragment(s). These periosteal changes can be seen earlier with ultrasound than radiographs. Sequestra appear as hyperechoic structures that cast acoustic shadows (Figure 3.118). Sequestra typically remain adjacent to parent bone and are surrounded by hypoechoic to anechoic fluid. Occasionally the sequestra can be seen displaced from the involucrum and lying in the tract leading to the skin surface. Areas with a predisposition to form sequestra include the metacarpal/metatarsal bones, spine of the scapula, and



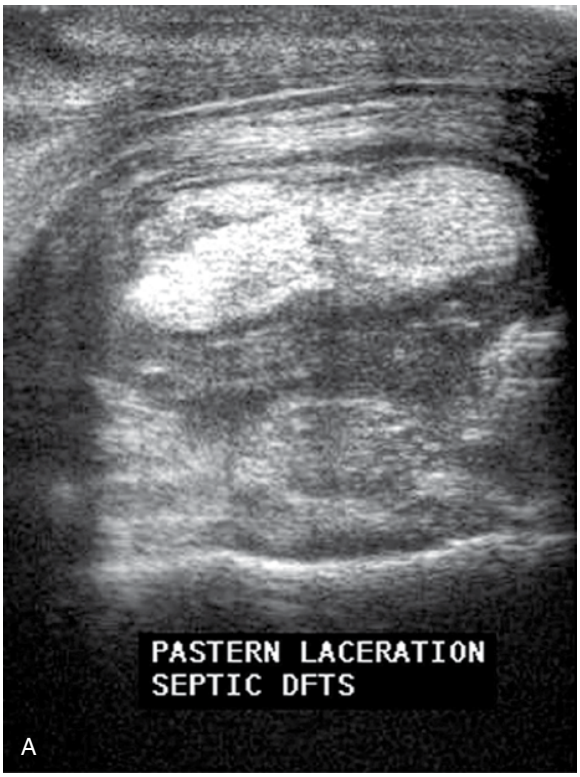


Figure 3.118. This horse had a draining tract of the medial radius. Radiographs were suggestive but not conclusive for a sequestrum, but ultrasonography proved to be diagnostic. There are small gas shadows within the middle of the tract (cloaca) that courses from surface of the radius to the skin. New bone is being deposited at the periphery of the sequestrum. The margins of the sequestrum have raised periosteal new bone production consistent with involucrum formation. Sequestra appear as hyperechoic structures that cast acoustic shadows. These periosteal changes can be seen earlier with ultrasound than radiographs.

medial aspect of the radius, but any area with cortical bone that is close to the skin surface may develop a sequestrum. Ultrasonography is also helpful to assess fractures that have been repaired with internal fixation. In the early postoperative period, the repair will appear much like acute trauma cases with hemorrhage and edema surrounding the implants. However, 5–7 days postoperatively this fluid interface should begin to become more organized unless there is increased motion or infection of the repair. If this fluid interface persists and the animal manifests systemic signs such as pain, heat and swelling at the incision site, fever, and/or lameness, then infection of the implants should be suspected.

Evaluation of Punctures and Lacerations

Ultrasonography has proven particularly helpful to define the extent of soft tissue damage incurred during wounding from a puncture or a laceration. Lacerations over the extensor or flexor tendons in the distal extremities require careful examination of the tendons to document involvement and then determine the extent of damage incurred at wounding (Figure 3.119). Also, because these tendinous structures are frequently associated with sheaths and bursa, it is important to determine if these synovial structures are involved. The wound should have a sterile prep applied to the wound margins and the wound bed flushed with a balanced electrolyte solution to clean dirt and debris from the wound. Sterile lubricant can be applied to the wound bed and a sterile glove or sheath placed over the probe. The probe can then be placed into the wound to exam the structures deep within the wound bed. Air introduced into the wound may block sound transmission and compromise the study, which can be performed on another day after keeping the wound under a bandage. Documentation of tendon

VetBooks.ir

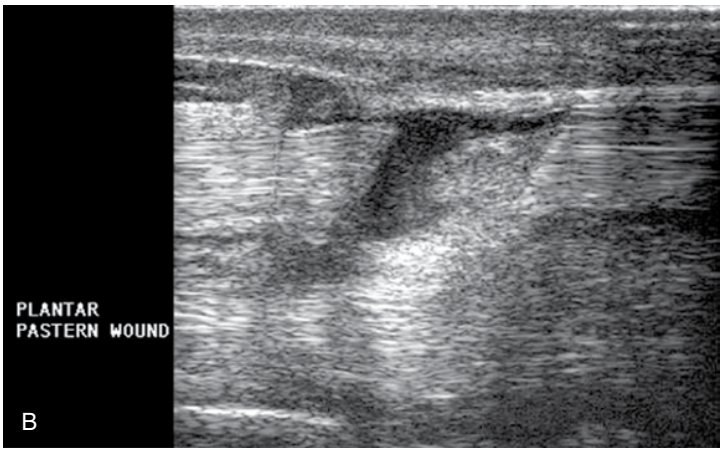

Figure 3.119. Lacerations over the extensor or flexor tendons of the distal extremities require careful examination of the tendons and any associated sheaths/bursae to determine the extent of damage incurred at wounding. (A) Transverse ultrasound image of a DDFT injury in the pastern. There is a proliferative response within the DFTS that suggests an active inflammatory process. Due to the penetrating injury, sepsis is likely. (B) Longitudinal ultrasound image of a laceration that demonstrates a severe DDFT injury. There is complete transaction of the DDFT with retraction of the proximal stump of the tendon.

or sheath involvement significantly changes the management of these types of wounds. Diagnostic ultrasound can be useful to identify synovial distension and assess the character of the synovial fluid. An increase in cellularity and fibrin content in the synovial fluid increases its echogenicity. The presence of gas shadows suggests either an open joint space or the presence of gas-producing organisms in the joint fluid. Treatment must be directed at eliminating any foreign material, reducing bacterial numbers, removing contaminated and devitalized material, and neutralizing and eliminating inflammatory enzymes and other inflammatory products. Puncture wounds involving the tendons and ligaments around the joint can significantly affect the prognosis.

A recent report looked at seven horses that had wounds close to a synovial structure (joint or sheath) and found that it was possible to see hair shafts within the wound and within the synovial lining.[65] These findings support the use of ultrasonography as a valuable diagnostic tool in wounds that may have breached a synovial structure. The presence of hair and/or foreign material in horses with signs of inflammatory or septic synovitis/tenosynovitis often suggests that aggressive measures be taken to eliminate the material.

Evaluation of Muscle

Acute muscle injury occurs due to blunt trauma, violent contraction against resistance, and myositis. Muscle has a heterogeneous appearance with hypoechogenic muscle fibers laced with and surrounded by fascia, connective tissue, and fat. On transverse images normal muscle has a marbled or speckled appearance.[81] Each muscle has a fairly unique appearance that can change between weight-bearing and non-weight-bearing. More severe muscle injuries may have fluid-filled areas with loculation visible suggesting significant muscle fiber tearing and hemorrhage. Minor injuries can be more difficult to define because ultrasonographic changes are less obvious. Minor injuries may simply manifest an enlargement of the muscle belly with very little loss of the normal striated muscle pattern and a decrease in echogenicity. The paired structure on the opposite limb should be used for comparison (Figure 3.120). Ultrasonography can be utilized to monitor the repair process. The hematoma will be slowly resorbed and the area gradually filled in with granulation tissue. The infiltration of fibrocytes and capillaries create a more heterogeneous appearance to the muscle injury over time.

Fibrotic myopathy is a chronic muscle condition that is probably the result of multiple previous acute muscle injuries that healed with exuberant scar. This scar creates a restricted gait where the limb is rapidly slapped to the ground at the end of swing phase (described as goose stepping). Palpable muscle scarring can usually be found within the semimembranosus, semitendinosus, and occasionally the gracilis muscles. The ultrasound appearance of this mass is consistent with excessive fibrosis seen as hyperechogenic areas within the body of the muscle. There may be hyperechogenic

VetBooks.ir

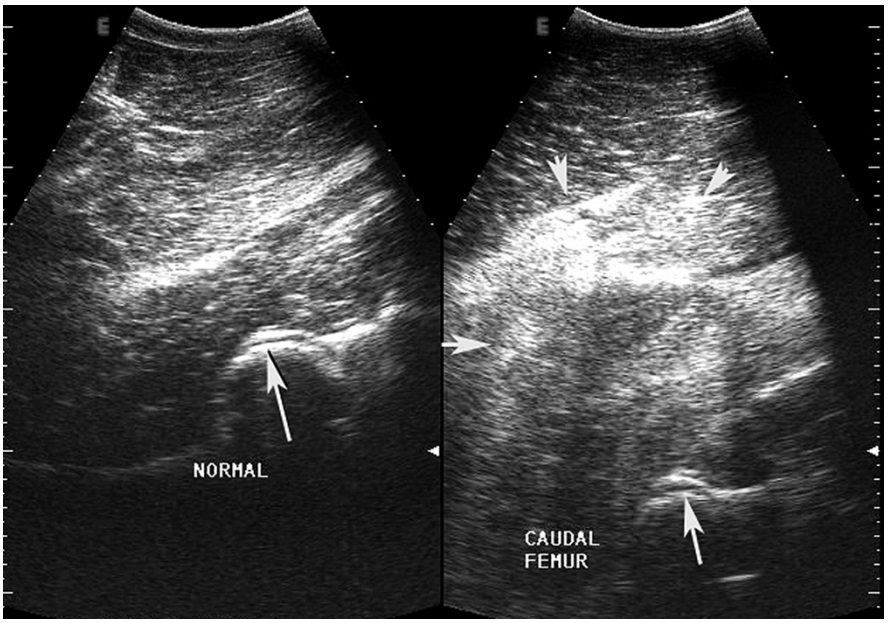

Figure 3.120. This is a longitudinal ultrasound image of the caudal aspect of the distal femur of the stifle. The cartilage covering the caudal condyle is apparent (lower arrows). Proximal is to the left, and distal is to the right. This horse incurred a caudal reciprocal apparatus breakdown, and the gastrocnemius muscle can be seen to have significant damage (smaller arrows surrounding the damaged area).

areas suggestive of mineralization or dystrophic calcification that cast acoustic shadows within or adjacent to the affect tissue.

Evaluation of Foreign Bodies

A number of different materials when introduced into the soft tissues can create a significant foreign body reaction in the horse. The most common foreign bodies include wood, lead (bullets or buckshot), metallic objects (such as wire or fencing materials), glass, plant material, hair, and suture material (Figure 3.121). Wood appears as a linear hyperechoic structure that casts a strong acoustic shadow. The most common wood foreign bodies are associated with fencing materials that splinter after penetrating the skin. It is important to carefully evaluate the wounded area for multiple wood splinters before initiating retrieval as air introduced into the wound either at wounding or during surgery can block ultrasound transmission further limiting the evaluation of tissues deep to it. Bullets and metallic structures can appear to have variable shapes and contours, but like wood these objects can cast strong acoustic shadows. However, plant material and hair appear to have small hyperechoic shadows that may or may not cast acoustic shadows. This hyperechoic material is usually seen within a hypoechoic tract. Metals such as surgical instruments appear similarly and cast strong acoustic shadows that can be utilized to the clinician's advantage when ultrasound-guided retrieval is utilized. Placement of an instrument such as a mosquito forcep around the foreign body can easily be seen until the air/gas is introduced. If retrieval of the foreign body is more complicated, then the area should be mapped out with ultrasonography before retrieval.

Figure 3.121. This horse had a draining tract at the shoulder region. There appears to be a dense foreign body several centimeters deep, consistent with a bullet. The surgical approach to the foreign body was mapped out with ultrasonography intraoperatively.

NEW DIRECTIONS IN THE USE OF ULTRASOUND

Ultrasound-Guided Injections

Diagnostic ultrasound can enhance the accurate placement of a needle into a specific site. Real-time needle tracking allows the needle to be visualized entering a target area (Figure 3.122). For example, the correct placement of diagnostic analgesia will help improve the accuracy of diagnosing the cause of lameness, and placing medication or regenerative therapy (platelet-rich plasma [PRP], stem cells, and interleukin receptor antagonist protein [IRAP]) directly into a lesion will enhance the successful treatment of that injury. In veterinary medicine there are several reports evaluating the use of diagnostic ultrasound to inject the navicular bursa, cervical articular facets, scapulohumeral joint, coxofemoral joint, and the sacroiliac joint.[5,10,14,16,60,93] Competency in ultrasound-guided injection technique begins with a comprehensive knowledge of the anatomy of the area both grossly and as seen with ultrasound. A reasonable amount of skill is required to handle a transducer focused on the area of interest while driving a needle within the ultrasound beam. Depth of the structure to be injected should determine the angle the needle must take to hit the structure. To increase the degree of difficulty, ultrasound-guided injections are frequently done while maintaining sterile technique (the probe is covered with a sterile ultrasound covers). As a means to improve needle placement and minimize damage to vessels in the area, a Doppler examination (color or power) can help determine a path for the needle free of vessels that may not be obvious on gray scale. As will be discussed in a later section on Doppler examination of soft tissue injury, power Doppler (PD) can provide some insight of where within a structure an injection should be directed to have the most advantageous effect.

Figure 3.122. The image demonstrates the use of ultrasound to guide the placement of a probe (in this picture a probe that utilizes ultrasound energy to remove damaged tissue), instrument, or more routinely a needle into a specific area of tendon/ligament damage.

Sterile technique requires a large area of skin prep with chlorhexidine detergent and alcohol rinse. It is advisable to disinfect the probe and cable with a disinfectant before placement of a sterile probe cover or surgical glove. The examiner should view the area between the probe and the structure to be injected. Previewing the area and knowing the pertinent local anatomy are critical to avoid penetration of key structures (vessels and nerves). It is best to mapped out the approach that will be taken to drive the needle to the target. A decision should be made about utilizing short axis or long axis visualization of the needle. The examiner should use the nondominant hand to manipulate the probe and scan the target keeping 2–3 fingers of the probe hand in contact with the patient's skin. Most often the needle should cross the longitudinal plane of the sound beam, and the examiner then must make short axis slides of the probe to keep the needle in view. Placing the needle in the plane of the sound beam (long axis) is preferred during most procedures because the needle tip and shaft are visualized throughout the entire procedure. Some ultrasound probes have a needle guide that can be attached directly to the transducer for accurate placement of the needle. Alternatively, and probably more commonly, the needle may be placed freehand. Either way, the needle should be visualized throughout the procedure. The shortest pathway to the target should be selected avoiding regional neurovascular structures. Deeper injections require more skill as tracking the needle can be more challenging and requires better technique. Some alternative techniques to improve ultrasound-guided injections include using beam steer, scoring the needle with scalpel, using reflective facet tip needles, and placing the bevel of the needle up. Another option though not preferable is to use a blinded technique whereby a needle is placed into the area of the synovial structures. If no fluid is retrieved, then the needle position is evaluated with ultrasound to confirm the correct placement. If it appears that the needle is position correctly, then fluid can be injected to confirm the correct position within the joint or any indication that repositioning the needle is necessary.

MRI/Ultrasound Fusion: Navigational Ultrasound

MRI/ultrasound fusion imaging or navigational ultrasound imaging is a novel imaging technique developed to combine cross-sectional imaging (CT or MRI) with real-time ultrasound. This technique has been developed and utilized in the human medicine to sample abnormal masses within the liver, kidney, and prostate. The technique was developed to guide the sampling and radiofrequency ablation of masses that were invisible

VetBooks.ir

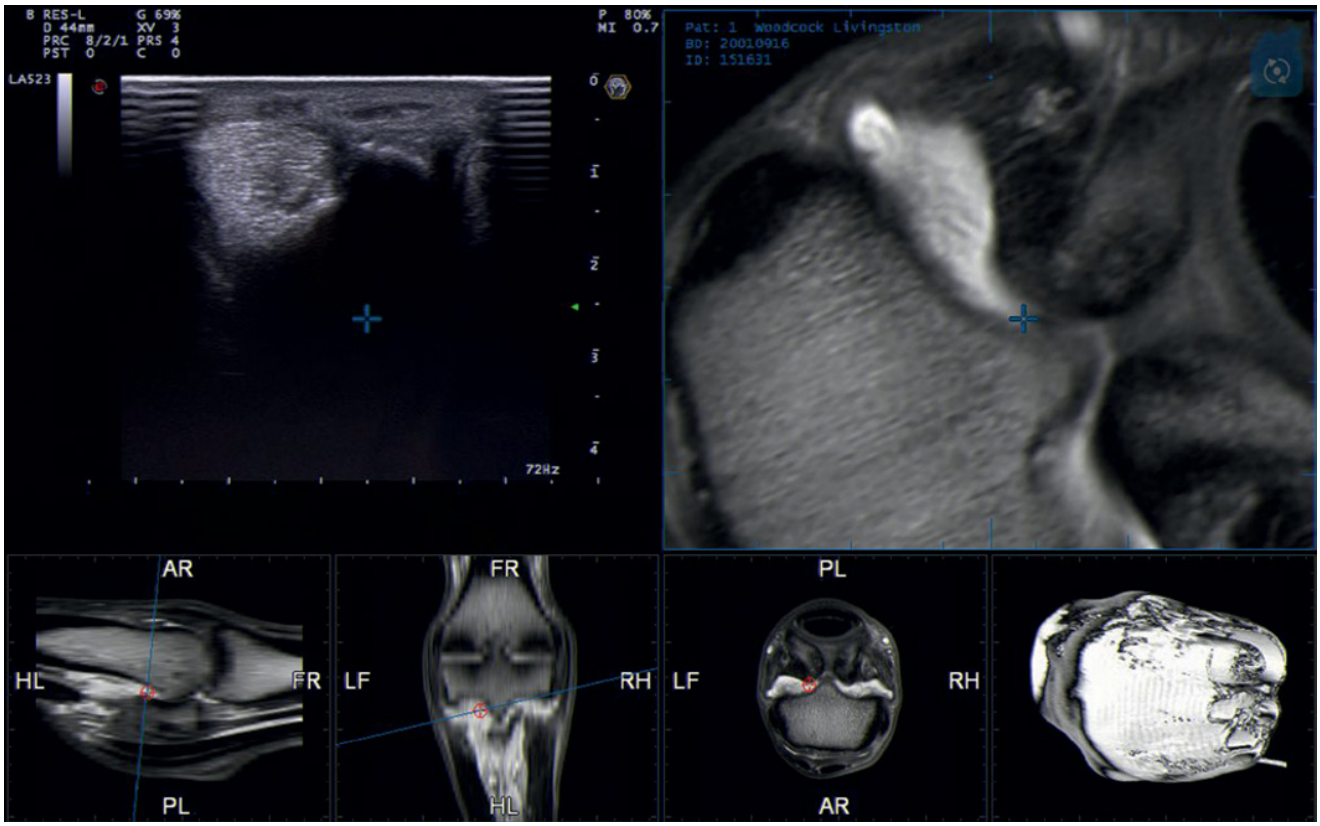

Figure 3.123. Navigational ultrasound fuses the real-time ultrasound capability with the MR sequence of an area to more accurately demonstrate a lesion that is difficult to see with ultrasound.

to ultrasound. It has been shown not only to improve sampling accuracy but also to decrease procedure risk and time.[1,45,47,87,106]

This technology has recently been utilized in horses that have had an MRI (high-field) examination of a region.[54] Candidates for this technology were animals with MRI lesions that were difficult to detect with ultrasound (Figure 3.123). Navigational ultrasound was utilized to combine the accuracy of MRI for lesion detection with use of real-time ultrasound examination to guide interventional procedures into these lesions. Navigational ultrasound has proven to be quite successful at guiding the accurate placement of a needle or instrument (tendon splitting knife, radiofrequency probe, Tenex$_R$ probe) into a lesion. The needle can be placed into sites of active inflammation within a lesion (increased T2 hyperintensities on MRI). The needle placement and injection of regenerative therapies (PRP, IRAP, and fat-derived or mesenchymal stem cells) into a lesion can be visualized. The volume of the injectate can be assessed and leakage minimized. In some other cases the fusion directed the placement of an instrument in the surgical approach to a lesion(s).

To perform a navigational ultrasound, the transverse PD sequence of a study acquired by a Siemens Symphony 1.5 T was imported into a Biosound MyLab Twice in which the navigational software has been installed. A magnetic field is established around the extremity with the placement of a GPS device at the level of the lesion. A magnetic sensor is positioned on the ultrasound transducer and allows the transducer to be tracked within the magnetic field of the GPS system. The MRI sequence is scrolled to visualize a predetermined anatomic location (usually on the immovable bony column) close to the MRI target lesion. This same anatomic site is then identified with the ultrasound on transverse view. The same procedure is performed on longitudinal view. Co-registration of this anatomic site on both transverse and longitudinal planes now blends the ultrasound image and the corresponding image on MRI in whatever orientation the transducer moves within then magnetic field. Once this has been completed, the MRI study tracks along with the ultrasound transducer as it is moved within the magnetic field of the GPS demonstrating the real-time ultrasound image superimposed over the MRI sequence. The software within the ultrasound allows the MRI and ultrasound images to be superimposed and blended, which makes this technique very useful to allow the direct comparison of the pathology seen in these structures with these different imaging technologies.[45,54,106] Navigational ultrasound has proven to be quite helpful to treat those lesions that ultrasound examination doesn't accurately portray the lesion(s) as seen on MRI.

Elastography to Evaluate Soft Tissue Injuries

Elastography is a new ultrasonographic technique that allows an examiner to evaluate the mechanical properties of soft tissues.[8,51,67] This technique estimates tissue strain, where strain is defined as the fractional change in length of a tissue when an external force is applied. Elastography evaluates tissue motion as compression is applied to the tissue using manual compression with the ultrasound transducer. The tissue displacement causes a measureable displacement of the ultrasound waves. Soft, deformable structures, such as damaged or inflamed tissues, cause greater displacement of sound waves than hard, rigid structures. Elastography can therefore provide information about the behavior of internal soft tissue structures when compressed. Since pathologic tissues often exhibit altered mechanical properties, elastography allows the differentiation between normal and diseased tissues due to the differences in these elastic properties. With elastography, compression (in a transverse or longitudinal plane) is applied with the ultrasound probe, and tissue displacement is measured by comparing the echo signals before and after compression. This is in contrast to conventional grayscale ultrasonography that only evaluates tissue morphology and the differences between acoustic impedance of adjacent structures.

Elastography was initially used in humans to help differentiate benign from malignant nodules in the breast, prostate, thyroid, liver, and lymph tissue and for evaluating hepatic fibrosis.[67] Recently, elastography was used to evaluate this technology in musculoskeletal injuries in humans primarily the Achilles tendon.[29,30] The evaluation of acute injuries with elastography can reveal significantly increased softness in areas of hematoma and fiber disruption. Serial elastographic examinations can detect the tissue becoming progressively stiffer with healing.

An initial study was performed to determine the feasibility, reproducibility, and repeatability of elastography and to establish the normal elastographic appearance of the tendons of the equine metacarpus.[52] A group of sound horses without evidence of musculoskeletal pathology were evaluated with standard grayscale ultrasound, and elastographic evaluations were performed using an ultrasound scanner (MyLab 70 ultrasound system Biosound Esaote Inc. Indianapolis, IN) with a 6–18-MHz linear probe using a previously described technique. Elastographic images of the SDF and DDF tendons and the branches of the SL were evaluated quantitatively and qualitatively.

An extension of that study in normal horse was performed in horses with clinical conditions found with grayscale ultrasound. This study attempted to characterize elastographic findings of clinical cases with soft tissue injuries of the distal limb and to evaluate the differences in the elastographic appearance of acute versus chronic injuries.[53] Horses were evaluated throughout their rehabilitation and assessed for changes in the ultrasonographic and elastographic appearance over time. These findings were correlated with clinical healing. This study found that compression elastography corresponded well with clinical evaluation using grayscale ultrasound (Figure 3.124). Acute lesions were significantly softer than subacute/chronic lesions when

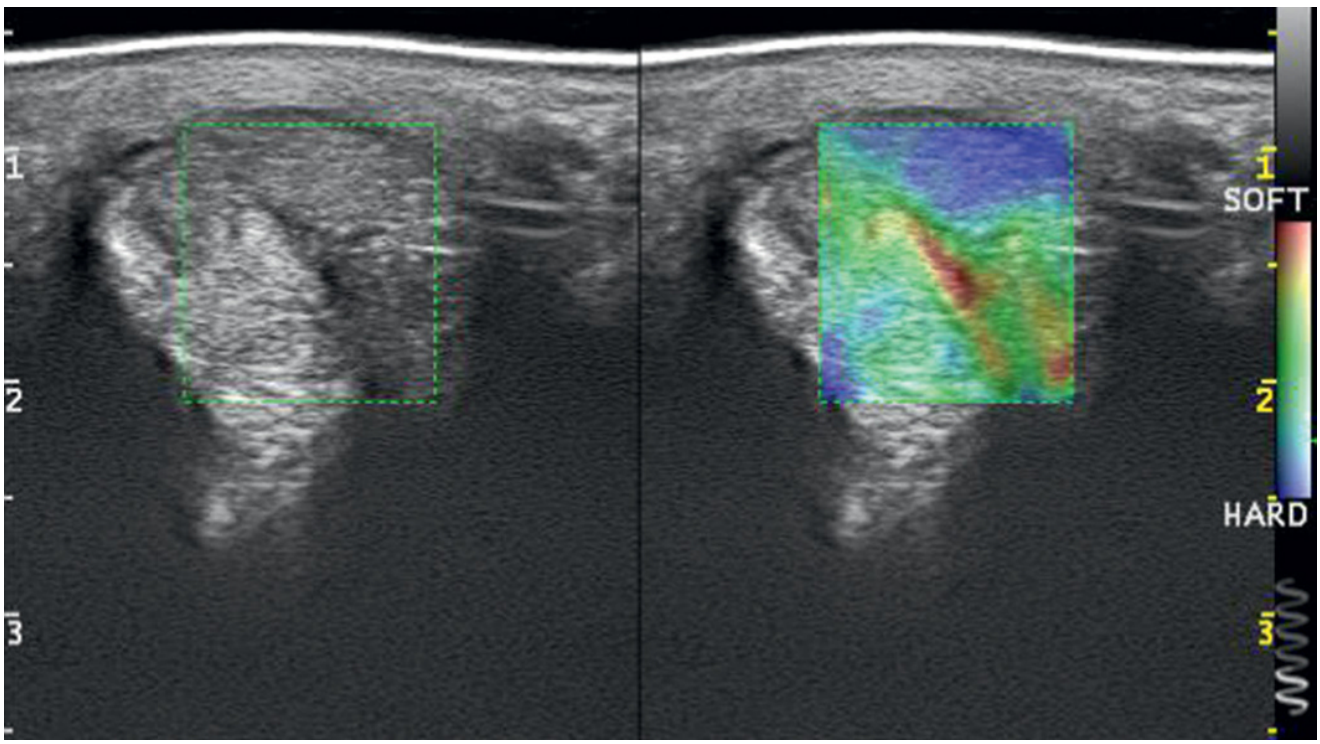

Figure 3.124. Elastography, a new software program available in some advanced ultrasound systems that can measure the strain within that structure and portray the softness of a structure displayed by a difference with color codes.

VetBooks.ir

evaluated with elastography. These injuries showed a progressive increase in stiffness of acute lesions over time. Most lesions of the suspensory ligament branches (SLBs) nearest to the insertion on the proximal sesamoid bone were detectable with elastography in longitudinal orientation with the limb weight-bearing. Lesions of the SLBs nearest to the insertion were only reliably detectable in transverse orientation when the limb was off-weighted. It should be noted that lesions of the PSL, which caused detectable changes with elastography, were moderate in size and severity, while small lesions of the PSL near the origin were not detectable using elastography or with grayscale ultrasound.

The main limitations of elastography are related to the operator-dependent elastographic images that are obtained. Manual compression and tissue displacement are difficult to standardize. This study found elastography to be a valuable and complementary imaging modality for soft tissue lesions of the equine distal limb. These findings would suggest that incorporating elastography into routine US examinations may be of benefit for characterizing the age of the injury or the stage of healing. Elastography may also prove to be valuable for guiding rehabilitation by monitoring the stiffness of lesions over time.

Color Doppler Ultrasound to Evaluate Tendon and Ligament Injury

Currently, grayscale ultrasonography is the most popular means of diagnosing equine tendon/ligament injuries and is the most practical soft tissue imaging tool available to the equine practitioner.[80] Acute tendon injury manifests ultrasonographically as enlargement often with hypoechogenicity of the tendon/ligament architecture on cross section and the appearance of a striated or fibrillar pattern in the longitudinal images. These changes are due to disruption of tendon matrix, with intratendinous hemorrhage and edema. In more severe injuries there may be changes in the overall shape, distortion of the margins/outline of the structure, and a change in the normal anatomical position in relation to other structures in that area. Typical for any wound, a tendon or ligament injury precipitates an increase in blood flow during the acute inflammatory phase. Depending on the severity of the injury, the inflammatory phase is usually short lived and blends into the subacute fibroblastic phase of tendon healing. Within a few days of injury, there is a pronounced angiogenic response with an increase in the synthesis of collagen during the fibroproliferative tissue. The fibroblastic phase of tendon healing merges with the remodeling phase with a gradual transformation of collagen type III to type I as the scar tissue matures. This corresponds to a gradual reduction in blood flow.[33,43,91] Currently serial grayscale ultrasound imaging is the tool of choice at providing important morphologic information especially during this remodeling phase and has been found to be quite useful to assess and monitor healing of soft tissue injuries. However, few studies have evaluated blood flow in equine tendon and ligament injury.[48,49,59,94,105]

Soft tissue injuries such as acute tendon and ligament lesions rely on vascularization for cell recruitment and to provide humoral mediators, growth factors, and nutrients. Blood flow begins to increase in the early inflammatory stage, peaks in the fibroblastic phase, and gradually subsides during the remodeling phase. Tendons and ligaments receive blood supply from three potential sources. The primary supply is intratendinous coming predominantly from the musculotendinous junction and from its osseous insertion. Within a sheath, tendons have blood vessels entering the tendon via mesotenonous attachments. Outside of the sheath blood vessels can enter the tendon from the paratenon. The relative contribution of the blood supply from these different sources depends on the specific structure and the location within that structure. Some areas within tendinous structures are thought to be at risk of injury due to a reduction in blood flow in specific areas of the tendon (i.e. SDFT in mid-metacarpus DDFT in the fetlock region).[94] For the metacarpal region of the SDFT, the intratendinous supply is considered the most important source of blood supply as necrosis was only achieved by ligation of the blood vessels within the tendon whereas stripping the paratenon had no effect.[48] The blood flow in the SDFT has been recorded between 1 and 2 mL/min/100 g, which is similar to the blood flow of resting skeletal muscle and has been shown to increase two-fold with exercise.[94,105] Injury to the SDF tendon was associated with an even greater increase in blood flow (>300%). A recent study described the microvascular anatomy of the SL of the equine forelimb and found an abundant intraligamentous microvascular supply throughout its entire length. The absence of an obvious hypovascular area suggests that regional variations in healing rates of the SL are probably not associated with the microvasculature anatomy.[53] Alterations in vasculature are emerging as important diagnostic and prognostic findings in tendon injuries in both equine and humans (Figure 3.125). Neovascularization plays an important role in tendon healing with proper blood supply required for adequate healing and the quality of repair related to the amount of neovascularization as seen in Achilles tendons in humans.[63]

In humans color Doppler (CD) is widely used in cardiovascular examinations to evaluate changes in blood flow. It is utilized to visualize both the velocity and the direction of the blood flow that has been proven to be quite helpful in the diagnosis of venous thrombosis, atherosclerotic changes in the carotids, and arterial aneurysms. High-definition CD can allow the examination of very small vessels in the near field, making it possible to visualize vessels with CD that are not visible with grayscale US. One equine study utilized CD to assess vascular flow after surgically created SDF tendinitis were treated with PRP and found increased blood flow out to 23 weeks in the treated limbs.[7] The use of CD in the evaluation of horses with tendon/ligament injury can prove to be problematic due to the creation of artifacts that occur due to probe position. In addition, blood flow in the tendon/ligaments of horses can be different in weight-bearing and non-weight-bearing positions. Consistent use of CD in equine injuries can hopefully provide information to help stage an injury (acute, chronic, and acute on chronic) and to assess quality of repair.

Power Doppler (PD) is an even more sensitive Doppler method to study the flow of red blood cells

VetBooks.ir

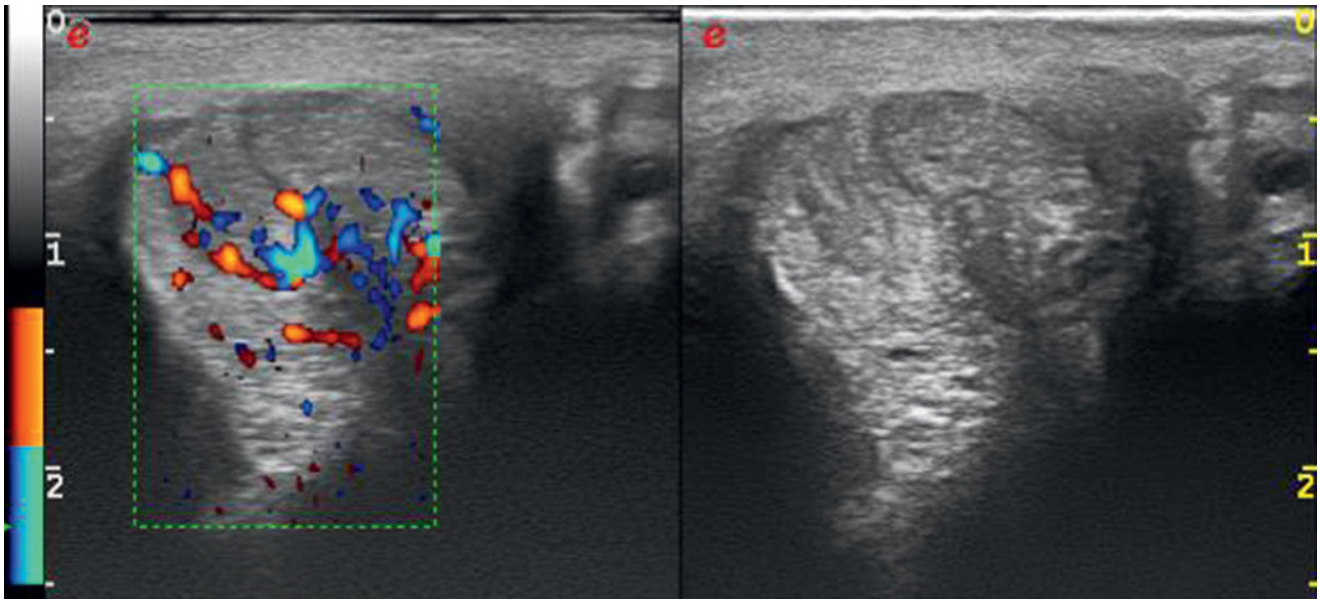

Figure 3.125. Blood flow of a tendon or ligamentous structure can be evaluated by the use of color flow and/or power Doppler. The demonstration of blood flow in a structure can be utilized to help assess the age of a lesion (acute injuries have a more active increase in blood flow than chronic injuries) and can be useful to guide rehabilitation of soft tissue injuries (reduction in blood flow with healing and remodeling).

within the intravascular spaces. PD sonography is a newer technique that displays the strength of the Doppler signal in color, rather than speed or direction information. It has three times the sensitivity of conventional color Doppler for detection of flow and is particularly useful for the evaluation of regional perfusions of small vessels and those with low-velocity flow. PD (unlike CD) is independent of velocity and direction of flow, so there is no possibility of signal aliasing. It is also independent of angle and allows detection of smaller velocities than CD. PD can consistently demonstrate blood flow in smaller vessels (hyperperfusion) that is associated with musculoskeletal inflammatory disease that can provide a useful adjunct to grayscale sonographic examination. The use of PD can increase the specificity of an US examination by helping to differentiate vascular tissue from other types of tissue debris (blood clot, fibrin, and effusion). Increased perfusion is usually evident in the vicinity of tendon injury and within the area of suspected tendinitis.

PD examinations are performed by utilizing a high-frequency linear probe (6–18 MHz) with the Doppler frequency set at 6.3 MHz and a pulse repetition frequency (PRF) maintained at 500 Hz. A region of interest is selected (often a rectangle that centers on the soft tissue structure(s) being evaluated). Most often a standoff pad is not utilized, and care must be taken not to press too firmly that can collapse the vessels. Color gain should be adjusted to a level just below that at which all color noise disappears from the region of interest. Horses are evaluated while standing on the limb, and this is compared with when the horse is not weight-bearing. The degree of flexion of the distal limb may influence blood flow in some instances. It should be recognized that blood flow is increased after exercise and may influence the PD evaluation.

Normal tendons/ligaments exhibit little blood flow in the smaller vessels. Pathologic flow is considered to occur when there is a significant (subjectively) overall increase in vessel number within the affected tendon/ligament and also within the paratendinous/paraligamentous structures. Flow patterns can range from an increased number of discrete, visible small vessels to a soft tissue "blush" appearance presumably due to an increased density of very small vessels (microvascular flow). In addition to cases of tendon injuries within synovial sheaths or bursae, there can be an increase in vessel number and blood flow in the wall of the synovial structure that is considered pathologic. When the US examination documents an alteration of blood flow, it should be compared with the asymptomatic contralateral limb.

Serial grayscale ultrasound in combination with PD examinations is proving to be quite valuable in diagnosing acute and chronic injuries and to guide rehabilitation during the progressive loading of the injured structure(s). Potential limiting factors in the use of PD include the need for some form of standardization of the examination technique and technical parameters utilized in performing a PD assessment as this examination can be significantly affected by operator experience and training, as well as by the quality of the US machine and image processing.

NUCLEAR MEDICINE/SCINTIGRAPHY

VetBooks.ir

Kurt Selberg, Elizabeth Acutt, and Alejandro Valdés-Martínez

Nuclear medicine techniques image the blood flow to bone as well as the function or the physiological activity of bone with minimal anatomic detail compared with ultrasound, computerized tomography (CT), and magnetic resonance imaging (MRI) produce images that reveal anatomic detail. Nuclear medicine imaging is one tool that may augment but does not replace the basic lameness examination.[10,58,61,65,74,80,81,95,99] This chapter discusses the principles of, techniques of, indications for, and interpretations of nuclear medicine imaging in the evaluation of the musculoskeletal system of horses.

PRINCIPLES OF NUCLEAR MEDICINE

Nuclear medicine imaging, also known as scintigraphy, is based on the functional distribution of a radiotracer also known as radiopharmaceutical in the body. The radiotracer is made of a radionuclide, most commonly Technetium-99m (^{99m}Tc), and is labeled to a pharmaceutical, which determines the target tissue of the radiopharmaceutical in the body. Technetium-99m decays by emitting a 140-kEv γ-ray. A γ-ray is identical to an X-ray, except that it originates from the nucleus of an unstable atom (^{99m}Tc in this case) as the atom strives toward a more stable state. Nuclear medicine imaging can also be described as an emission imaging technique because the image is made by γ-rays that are emitted by the ^{99m}Tc inside the horse. Radiography is considered a transmission imaging technique because the X-rays that produce the image are transmitted through the patient.

The pharmaceutical part of the radiopharmaceutical determines the distribution of the tracer radionuclide in the body. There are various molecules or cells that can be labeled. Red blood cells can be labeled for the evaluation of the circulating blood compartment, most commonly to study cardiac function. Intravenous administration of ^{99m}Tc-pertechnetate ($^{99m}Tc0_4$) or ^{99m}Tc-labeled red blood cells (^{99m}TcRBCs) is scintigraphic techniques looking at the perfusion (blood flow) of soft tissue structures such as the joints of the distal limbs. White blood cells can be selectively labeled with ^{99m}Tc-hexamethylpropyleneamine oxime (HMPAO) to look for areas of active inflammation/infection.[9,51,63] ^{99m}Tc-labeled biotin (^{99m}TcEB1) has also been used to detect soft tissue inflammation in horses.[46] Renal function can be studied using ^{99m}Tc-diethylenetriamine pentaacetate (DTPA), and quantitative hepatobiliary studies can be performed with ^{99m}Tc-disofenin. Functional lung ventilation studies have been described using aerosolized ^{99m}Tc-DTPA[58] and lung perfusion with ^{99m}Tc macroaggregates of albumin (MAA).[8] Although each of these techniques uses ^{99m}Tc, the distribution of the radiotracer varies, based on the biokinetics of the pharmaceutical or cell to which the ^{99m}Tc has been labeled.

The most common use of nuclear scintigraphic exams in the equine is orthopedic related. Bone scans are conducted using radiolabeled polyphosphonates, which have a high affinity for the Ca-hydroxyapatite molecules in bone. Images made at 2–4 hours' postinjection are a representation of the uptake pattern in the bones. A very predictable uptake pattern is seen in normal animals, and abnormal radiotracer is seen with increased or decreased blood flow or increased osteoblastic activity. Either ^{99m}Tc-oxidronate (HDP) or ^{99m}Tc-methylene diphosphanate (MDP) is administered intravenously at a dose of about 0.35-mCi/kg or 12.95-MBq/kg body weight. ^{99m}Tc-HDP has the advantage of faster soft tissue clearance, thus allowing image acquisition to begin sooner after injection.[4] A second advantage of ^{99m}Tc-HDP is improved visualization of bones surrounded by large amounts of muscle, e.g. spine, pelvis, and hips. An average 450-kg horse receives about 160 mCi (5.92 GBq) of the radiolabel. The dose rate can be adjusted for age, i.e. increased by about 10% in older patients and decreased by about 10% in juveniles because of the difference in metabolic activity of bone tissue. Approximately 50% of the injected radiolabel is excreted in the urine, which results in the effective $T_{1/2}$ being shorter than the natural $T_{1/2}$.[70]

A nuclear medicine evaluation of the musculoskeletal system may consist of three phases. Phase 1, known as the blood flow or vascular phase, represents the radiotracer in the blood vessels before diffusion into the extracellular fluid. It lasts for 1 or 2 minutes after injection. The body region to be evaluated must be positioned in front of the γ camera at the time of injection, and dynamic rapid frame acquisition is made as the radiolabel perfuses the vasculature. Multiple images are acquired over the first few minutes while the radiolabel is within the vascular system, before diffusion into the extravascular space occurs. The vascular phase is used to compare the blood flow, especially to the distal limbs, e.g. in cases of degloving injuries, but it can also be used to document perfusion deficits in different anatomical regions.

Phase 2, known as the pool or soft tissue phase, represents the radiopharmaceutical distribution in the extracellular fluid and is visualized from 3 to approximately 10 minutes postinjection. This phase is used to evaluate blood flow to soft tissues. An increased signal is observed with hyperemia due to edema, inflammation, etc. Increased radioactivity during the pool or soft tissue phase is best used in the distal limbs and has been associated with navicular bone disease, inflamed joints, tendinopathy, and desmopathy.

Early intense bone uptake of the radiopharmaceutical (^{99m}Tc-HDP or ^{99m}Tc-MDP) can sometimes be seen as soon as 5 minutes after injection, especially in cases of intense delayed phase bone uptake, e.g. fractures or infectious processes. This can sometimes make the evaluation of soft tissues challenging at best, if not impossible. A scintigraphic technique for looking at soft tissues only, without any possibility of bone uptake, is to use $^{99m}Tc\text{-}O_4$ (pertechnetate, unlabeled to a pharmaceutical)

VetBooks.ir

administered intravenously and images made as soon as radiopharmaceutical equilibrium in the extracellular space is achieved. A similar dose to that of the bone-scanning agents is recommended. ^{99m}Tc-RBC is another alternative for evaluating blood perfusion to soft tissues without the risk of bone uptake overlap.[83]

Phase 3, known as the delayed or bone phase, occurs several hours later when approximately 50% of the injected radiotracer has attached to the bone. The remainder of the tracer is excreted by the kidneys in the first 1 or 2 urine voids' postinjection. The uptake pattern of normal bone is quite predictable and is described later in this chapter. The diaphysis of long bones has the least uptake, and greatest uptake of the tracer occurs in the juxtaphyseal and subchondral bone in normal subjects. Increased radiotracer by or near the joints during the delayed (bone) phase has been related to osteoarthritis (OA), various enthesopathies, periarticular bone sclerosis, septic arthritis, etc. These changes from the normal radiotracer pattern are discussed later in this chapter.

RADIATION SAFETY AND PROTECTION

ALARA means that the radiation dose to which one is exposed will be kept "As Low As Reasonably Achievable." These procedures and protocols are intended to protect the clinician, others, and the environment from unnecessary risks due to radiation exposures.

Film badges (personal dosimeters) should be worn to monitor the total cumulative radiation dose. Finger (ring) thermoluminescent dosimetry (TLD) film badges should be worn by personnel preparing and injecting the pharmaceutical.

Eating, drinking, or smoking while handling a radioactive patient or radioactive materials is not permitted.[98] Lead or tungsten syringe shields are designed to help reduce the radiation dose to the fingers.

The nuclear medicine clinician should be conscious of two basic methods of exposure to ionizing radiation: internal contamination and external radiation. Care must be taken to avoid internal contamination through the accidental ingestion of the radionuclide. Latex gloves should always be worn when working with radiopharmaceuticals or radioactive patients.

External radiation occurs when one is in the immediate vicinity of the horse, for example, when scanning. The three basic rules of radiation safety are "time, distance, and shielding." Therefore, the time spent with the horse should be only that necessary for performing the study. Doubling the distance between the horse and the personnel reduces the radiation exposure by one fourth. Similarly, the exposure is quadrupled by halving the distance from the horse. Standing 1 m away from the horse significantly reduces the radiation exposure to personnel. For example, the exposure rate at the surface of a horse of 6.6 mrem/h decreases to 1.3 mrem/h at 1 m. Wearing a lead apron also reduces overall exposure while working with a radioactive patient by filtering lower emitted energies.

After the horse has been released, the stall is closed off for an additional 24 hours before it is cleaned. This allows four more half-lives of natural decay of the ^{99m}Tc that was excreted via the urine, reducing the exposure to the personnel even further (ALARA). Radiation safety rules may vary from state to state; therefore, the practitioner should consult the local radiation safety officer and comply with the specific state regulations.

IMAGING EQUIPMENT

The gamma camera contains a collimator made of small holes in a lead plate that allows only perpendicular γ-rays through. This reduces scatter, thereby improving image resolution. The γ-rays interact with a fluorescent crystal (a thallium-activated sodium iodide crystal is commonly used), changing the γ-energy to light photons. The light photons interact with a photocathode, generating electrons that are amplified by an array of photomultiplier tubes. The *x*–*y* coordinates of the electrons are then recorded, and the image is reconstructed. The resultant image represents the geographic distribution of the radiotracer in the horse. Images can be acquired in several matrices (64×64, 128×128 and 256×256) (Figure 3.126). A 256×256 matrix to optimize image resolution.

Various techniques have been devised to suspend the gamma camera such as a stationary actuated lift or track-and-column mounted detectors (Figure 3.127).[69] The tract system can moved around the horses, whereas in the stationary system, the horse is moved around the camera.

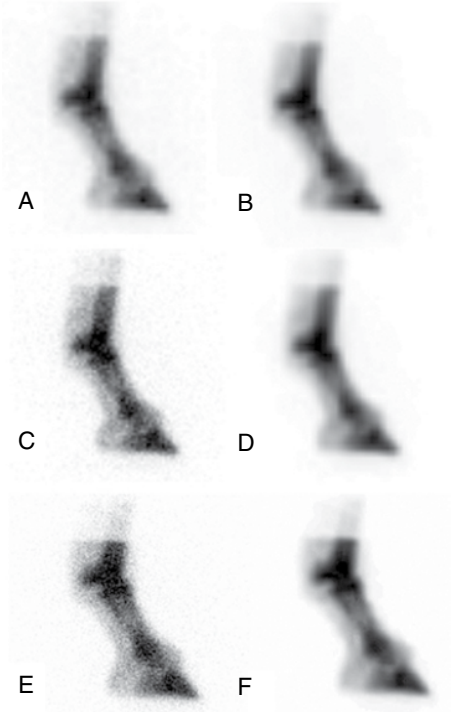

Figure 3.126. Image of right front foot acquired using several matrices. (A) 64×64. (B) 64×64 with statistical and heuristic image noise extraction (SHINE) processing, a technique designed to reduce the Poisson noise contained within the image, preserving resolution and contrast. (C) 128×128. (D) 128×128 (SHINE). (E) 256×256. (F) 256×256 (SHINE).

VetBooks.ir

Figure 3.127. A gamma camera mounted on a lift system with a yoke and track system that can be used to move the camera in different directions anywhere around the horse.

The gamma camera computer acquires the data and reconstructs the images and sends the digitized images to the processing computer. That computer is usually dedicated to the nuclear medicine facility and is used to perform post-processing of the images. Post-process may include segmentation of certain anatomic regions, addition of color palates, application of image transformation to improve signal in remove noise, and application of regions of interest. The standard image format (.dcm or .xds) is then sent to an archival system to review and store.

The equipment needed for a nuclear medicine imaging service consists of relatively high technology electronic instrumentation and must be maintained appropriately under controlled temperature to ensure that optimal diagnostic images are acquired. Although the maintenance of the equipment is beyond the scope of this text, it should be noted that image quality and resolution can be affected by, among others, one or more of the following factors:

1. Insufficient counts, e.g. too short acquisition time, too low ^{99m}Tc dose, extravascular injection of radiopharmaceutical, inadequately peaked camera
2. Incorrect collimator
3. Inadequate correction floods
4. Motion of patient, camera, or both
5. Excessive distance between gamma camera and patient

Table 3.1. Suggested minimum image acquisition counts.

Body region	Number of counts (×1,000)
Foot	100–150
Carpus	100–150
Elbow	150–200
Shoulder	200–300
Tarsus	150–200
Stifle	150–200
Sacroiliac area	200–300
Spine	200–300
Soft tissue (pool) phase image	75–100
Motion correction acquisition	2 seconds/frame for 40–50 frames

Image acquisition is determined either by the number of counts or the acquisition time. The greater the number of counts/image, the better the image quality, excluding motion artifact. A certain minimum number of counts is needed for a diagnostic image, and more counts result in a superior image. Table 3.1 offers suggestions for minimum counts/image. A longer image acquisition time is needed for more counts/image, although at some stage a long image acquisition time becomes impractical due to patient motion and time imaging. However, the nuclear medicine software can analyze images using algorithms, which are designed to remove artifact or noise to improve image quality. Using these computer algorithms to filter noise can be particularly useful when subtle pathologic change is present or if adequate counts cannot be obtained due to patient disposition.[31]

The risk with limiting the acquisition to a certain number of counts (as opposed to time) is that if there is urine contamination under a foot or another limb or the urinary bladder is in the field of view, then the counts recorded by the acquisition computer will include these aberrant γ-rays, which do not contribute to image quality. This will "steal" counts from the remaining anatomy and diminishing the number of γ-rays used for image reconstruction. This problem may be overcome with segmentation or repeat images of the areas' post cleaning. Typically, the number of counts gives more uniform images throughout the exam. Current software can acquire images with and without the imaging algorithm to improve image quality; however this is typically done in a dynamic acquisition at 2 seconds/frame for 40 frames.

METHOD FOR A SCINTIGRAPHIC EXAM OF THE MUSCULOSKELETAL SYSTEM

The radiolabeled pharmaceutical, either ^{99m}Tc-MDP (methylene diphosphonate) or ^{99m}Tc-HDP (oxidronate), is generally used at a dose of 0.35 mCi/kg (12.95 MBq/kg).

VetBooks.ir

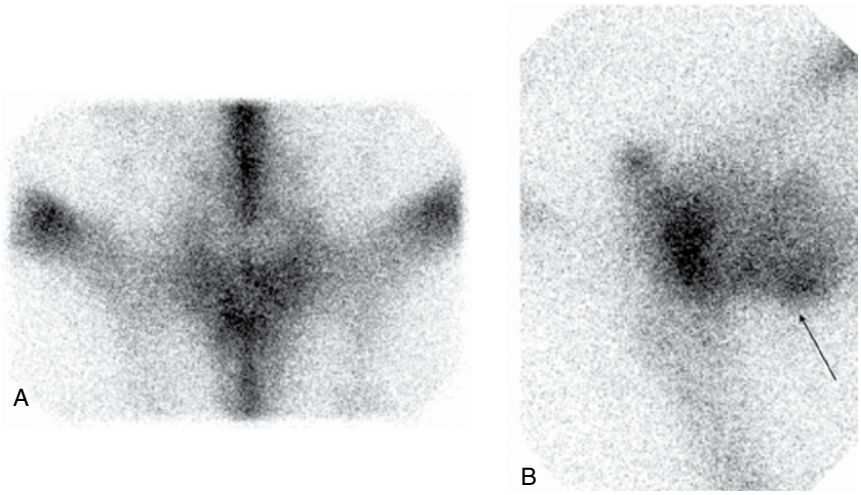

Figure 3.128. Delayed phase dorsal (A) and lateral (B) views of the pelvis of a normal horse. Note the diffuse abnormal radiotracer seen in the region of the sacrum on the dorsal view that corresponds to radioactive urine in the urinary bladder, as seen on the lateral image (arrow).

The radiolabel must be given intravenously; otherwise, slow release of the ^{99m}Tc will result in suboptimal images due to continuous release and thus high levels of circulating radioactivity. Patient control is very important because images generally take about 60–90 seconds to acquire. Chemical restraint is useful in reducing patient motion. Standing sedation protocols often vary among institution but often include alpha-2 antagonist with or without an opiate. Image processing software packages have integrated motion correction tools that allow some degree of motion with minimal or no image deterioration.

Imaging Technique

The radiotracer is given intravenously, and the blood flow (phase 1) images are acquired immediately if required. Pool phase images are acquired within the next 10 minutes if desired. Pool phase images must be limited to about three or four anatomical regions to ensure that they are completed before significant bone uptake occurs. Delayed phase images are acquired from 2 to 4 hours after injection to allow an optimal bone-to-soft tissue ratio. Furosemide may be given IV 60–90 minutes before the delayed phase starts if lumbar spine, pelvis, and stifle images are being acquired. This increases the chances of voided bladder because the ^{99m}Tc-HDP is excreted by the kidneys and urine in the bladder obscures visualization of the stifles, lumbosacral junction, sacroiliac (SI) joints, and the coxofemoral joints (Figure 3.128).

Lateral images of the limbs are made, being careful to position the camera lateral to the region being imaged (which is not necessarily lateral to the horse). Dorsal views of the carpi are generally performed. Orthogonal views of a lesion should always be attempted to help document the third dimension. Lead sheets are used to shield scatter radiation from the other limbs (Figure 3.129). Lead also should be placed medial to the olecranon and the stifle to shield the sternum and the penis/urinary bladder, respectively. Slightly overlapping the views will ensure that no area is left unscanned.

Figure 3.129. Gamma camera positioned in a pit below floor level for the lateral view of the right fore distal limb. Lead shielding is used to block out the contralateral limb.

There can be soft tissue uptake during the soft tissue (pool) phase up to 14 or 17 days after intra-articular or perineural anesthesia, respectively.[90,91] Local nerve blocks (intra-articular or perineural) do not, however, affect bone uptake in the delayed phase.[37]

VetBooks.ir

The following views are recommended for the full evaluation of the thoracic and pelvic limbs and spine using a detector with a 20-inch (50-cm) field of view.

Thoracic Limb

Lateral and dorsal views of the foot (these views include distal metacarpus, metacarpophalangeal joint, and phalanges), solar distal phalanx, lateral and dorsal carpus, lateral and cranial humerus, and lateral scapula. The metacarpus is included in the views of the foot and the carpus, the radius and elbows are included in the views of the carpus and humerus, and the shoulder is included in the views of the humerus and scapula. If an area of abnormal uptake is seen in the metacarpus, radius, or elbow, or in an area where only lateral views were obtained, additional images including orthogonal views centered over the areas of interest should be acquired.

Pelvic Limb

Lateral and plantar foot (these views include distal metatarsus, metatarsophalangeal joint, and phalanges), lateral and plantar tarsus, lateral and caudal stifle, lateral femur, right and left lateral, right and left dorsal oblique (RDO/LDO) hip, dorsal pelvis, caudal pelvis, and (RDO/LDO) sacrum. The metacarpus is included in the views of the foot and the tarsus, and the tibia is included in the views of the tarsus and stifle. As on the thoracic limb, if an area of abnormal radiotracer is seen on the metatarsus, tibia, or femur, additional images including plantar/caudal views centered over the area of interest should be obtained.

Spine

Right and left lateral views of the cervical spine (cranial, mid, and caudal), RDO/LDO cranial thoracic spine, RDO/LDO caudal thoracic spine, RDO/LDO lumbar spine, RDO/LDO lumbosacral junction (Figure 3.130), dorsal pelvis, caudal pelvis (tail on detector, TOD), and RDO/LDO sacrum. Lateral and dorsal views of the spine are less effective due to the great distance that the camera is from the vertebra. They can, however, be included as orthogonal views when a lesion is found. A point source, also known as fiducial marker, (e.g. cobalt marker or the syringe and needle that was used for the ^{99m}Tc-HDP injection, sealed in a latex glove) can be placed along the dorsum of the back to localize the exact position of a lesion, which is then marked with a permanent marker.

Figure 3.130. Gamma camera positioned for the right dorsal oblique (RDO) view of the thoracolumbar spine.

Foot

Different options exist for obtaining lateral, dorsal, and palmar views of the feet. In some institutions, the nuclear medicine suite has a pit in the floor into which the gamma camera is lowered to have it centered over the distal limb (Figure 3.131). In these cases, the horse is positioned to obtain lateral, dorsal, and palmar views. These views can also be made by placing both forefeet (or both hindfeet) on a wooden box about 25 cm high if a pit is not available. The top of the box should be strong enough (3.75-cm or 1.5-in., plywood) to support a large horse. The gamma camera can then be lowered to acquire the views. Construction of a platform for the horse to stand on during the entire exam can also be used. At these facilities the camera moves around the

Figure 3.131. Gamma camera positioned in a pit below floor level for the dorsal view of both fore distal limbs. Lead shielding is used to block out the hindlimbs to avoid shine through radiation and improve image quality.

VetBooks.ir

Figure 3.132. Gamma camera positioned for the solar view of the right forefoot.

horse and is placed where needed, including below foot level for lateral, dorsal, and palmar views of the foot. An alternative option is to have a ramp on which the horse can place the front feet or hindfeet. Both the platform and ramp take up more space, and in most cases the horse cannot remain still on it for the entire examination.

Solar views of the feet (for the navicular bone) are best made by stretching the forefoot out cranially and placing it on the camera face that has a plexiglass covering to protect the collimator (Figure 3.132). The solar view of the feet has been shown to be more sensitive for the evaluation of the navicular bone than the lateral view.[45] The camera is positioned face up in front of the horse, with the surface of the camera at or just below the level of the carpus. A solar view of the hindfoot is done less frequently and can be made by stretching the limb caudally, placing the foot on a wooden box and positioning the camera behind it. An alternative method is to have a pit in the floor into which the camera is placed face up. The pit is covered with appropriate material, and the horse stands over the camera. While it is easier to position the horse over the pit than to stretch the foot out forward and hold it on the camera, the downside is superimposition of the pastern and fetlock over the navicular bone region.

INDICATIONS FOR NUCLEAR SCINTIGRAPHY OF THE MUSCULOSKELETAL SYSTEM IN HORSES

Vascular Phase (Phase 1)

The vascular phase is an excellent technique for the evaluation of blood flow to specific areas and in the evaluation of trauma to the distal extremities or to areas where inadequate blood perfusion is suspected such as laminitis, frost bite, and vascular trauma from breakdown injury. The vascular phase can also be helpful in documenting aortoiliac thromboembolism. Increased blood flow to a particular region may be associated with acute inflammatory conditions or infectious processes. In most institutions, the vascular phase is not included as part of a routine scintigraphic exam of the musculoskeletal system.

Soft Tissue Phase (Phase 2)

Soft tissue phase (pool phase) images provide more useful information in cases of acute lameness, particularly in the distal limb, because of the ability to identify changes (especially increases) in blood flow to local areas. For example, hyperemia of the synovium or joint capsule secondary to acute synovitis/capsulitis, or at the proximal attachment of the suspensory ligament due to acute desmopathy and periligamentous inflammation, may be detected during the soft tissue phase.[28] Focal areas of trauma can also be evaluated for altered soft tissue perfusion. It can sometimes be difficult to differentiate between early bone uptake by a lesion and increased blood flow to an area. Therefore, the more accurate soft tissue phase images are those done with pertechnetate ($^{99m}TcO_4$) or labeled RBCs (^{99m}Tc-RBC) and not with a bone-seeking radiolabel.

The practitioner should be aware that detection of increased blood flow to a specific region is more common in acute conditions, and a negative result on a soft tissue phase does not rule out a subtle or more chronic injury.

Delayed Phase (Phase 3)

Delayed phase images provide information for evaluation of the skeleton. The high sensitivity of this phase to detect early changes in bone metabolism before these changes are radiographically evident makes this

VetBooks.ir

part of the study most useful for evaluation of acute lameness, e.g. incomplete or stress fractures in racehorses or high-performance horses. The delayed phase may also help in the diagnostic workup of horses presenting for other reasons such as ill-defined lameness or lameness that is difficult to diagnose with regional anesthesia, multiple causes of lameness in the same limb or different regions of the body, acute lameness of unknown origin, recheck of known lesion (to follow progress of healing), evaluation of the physiologic activity of radiographic lesions, and evaluation of areas that are difficult to radiograph such as the proximal thoracic and pelvic limb, spine, and pelvis including the SI and coxofemoral joints. Delayed phase imaging is also useful for the assessment of bone viability and as a general survey in prepurchase examinations. Soft tissue uptake in the muscles, seen during the delayed phase, can be seen in cases of rhabdomyolysis[13,59] or dystrophic mineralization of soft tissues (Figure 3.133).

A scintigraphic examination should not replace a complete physical and lameness examination. When evaluated as a stand-alone technique, nuclear scintigraphy does not meet the requirement for a diagnostic test.[65] False-negative scintigraphic results do not rule out a possible source of lameness suspected during clinical evaluation of the patient.

NORMAL BONE SCAN

Vascular phase images are best viewed as a cine loop on the acquisition computer (a computer software application that allows the images to be viewed sequentially in rapid order). A composite of vascular phase images also can be generated, and it should show good perfusion. When looking at the distal limbs, try to have both limbs in a dorsal or palmar/plantar view and look for perfusion symmetry. Composite images of the distal aorta should show the bifurcation of the aorta into the internal and external iliac arteries (Figure 3.134).

Soft tissue (pool) phase images of the foot show some vascular activity, but the fetlock and pastern regions should have homogeneously smooth uptake (Figure 3.135). The palmar/plantar blood vessels are seen as a distinct linear activity, and the coronet also has increased activity due to a vascular plexus. Additionally, the distal phalanx has a generous blood supply to the sensitive laminae, and increased activity is seen. Soft tissue images proximal to the carpus or tarsus are usually unrewarding due to the normal radiotracer of overlying musculature.[24]

Normal delayed phase uptake patterns vary among horses, depending on the patient's age, breed, and

Figure 3.133. Figure 3.135. Soft tissue (pool) phase view of a normal left forefoot, showing vascular activity on the palmar aspects proximal and distal to the fetlock and in the area of the coronary band (arrows). Note that the fetlock and pastern regions have homogeneously smooth uptake.

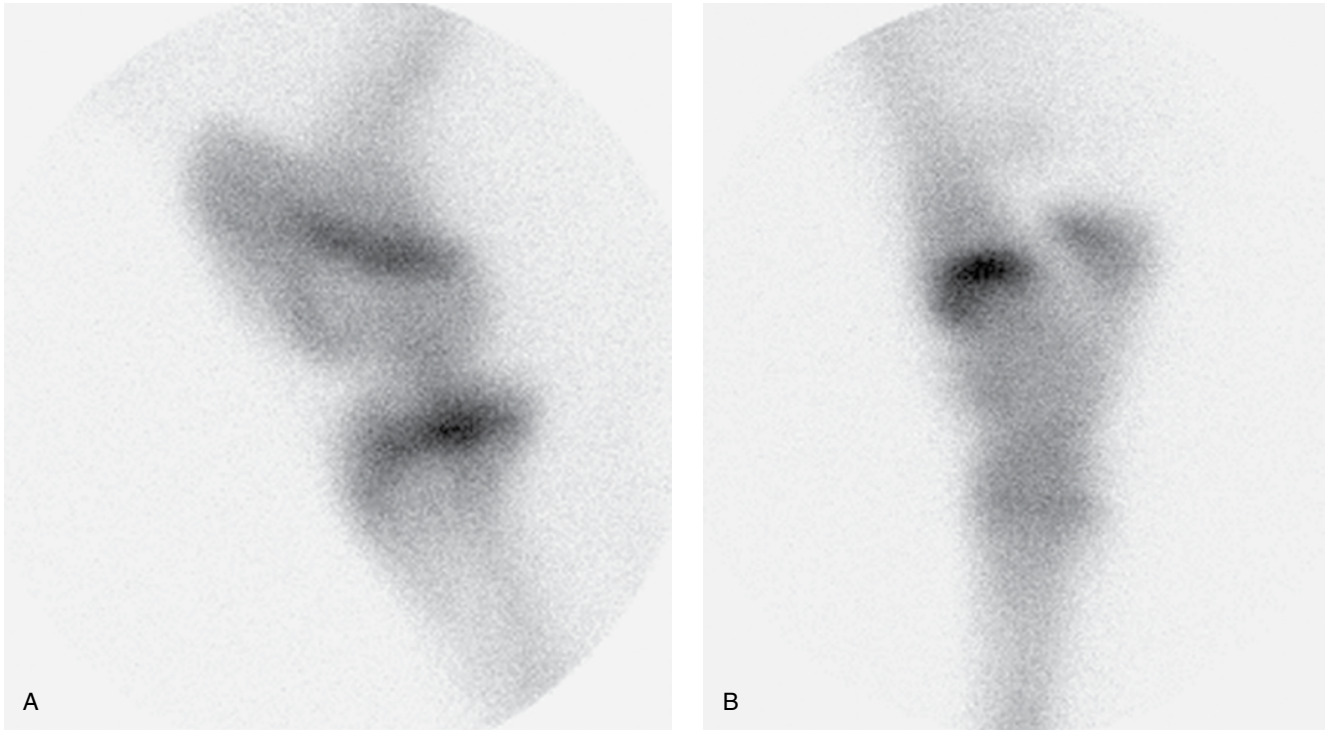

Figure 3.136. Delayed phase lateral views of the left stifle (A) and left tarsus (B) of a normal skeletally immature horse, showing normal intense radiotracer in the region of the physes. *Source*: Courtesy of Dr. Erik Bergman.

occupation.[96] For example, in athletic horses, most of these normal variations represent an exercise-induced bone remodeling secondary to an ongoing bone response to stress and do not necessarily produce clinical signs of lameness. Skeletally immature animals normally have bilaterally symmetric increased areas of uptake at growth plates and secondary centers of ossification (Figure 3.136).

VetBooks.ir

The diaphyses of long bones have less uptake than other parts of the bones, due to relatively low metabolism in the diaphyses of normal subjects. The uptake should, however, be smoothly homogenous with no focal areas of increased uptake. Contralateral imaging can be useful when evaluating borderline lesions. Physes, epiphyses, and apophyses demonstrate increased uptake due to increased metabolic rates of bone tissue in these regions.

Distal Limb (Foot, Pastern, and Fetlock)

On the lateral view, a normal horse has similar uptake in the coffin, pastern, and fetlock joints. The navicular bone should not be seen as a distinct entity due to a homogeneous uptake with the rest of the distal phalanx (Figure 3.137). Normal mild decreased uptake in the metacarpal condyles, when compared with the proximal phalanx and sesamoid bones, has also been reported.[100] The dorsal view (plantar view if evaluating the pelvic limbs) is useful for comparison of ipsilateral structures in the same image (Figure 3.138).

The solar view of a normal horse has a very uniform pattern of uptake with less than 10% change between the regions of the navicular bone, deep digital flexor tendon (DDFT) insertion, toe, and medial and lateral aspects of distal phalanx (Figure 3.139).[21] Mild increases in radiotracer can be seen at the insertion of the DDFT or the lateral or medial aspects of distal phalanx secondary to foot conformation. Radiotracer is often seen in the medial aspect of the distal phalanx, palmar cortex of the proximal phalanx, and proximal sesamoid bones as horses start into training.[35]

Figure 3.137. Delayed phase lateral view of the distal limb of a normal horse. Note the similar uptake between the fetlock, pastern, and coffin joints.

Figure 3.138. Delayed phase dorsal view of both fore distal limbs of a normal horse (SHINE processing in place). The uptake should be uniformly similar between both limbs.

Figure 3.139. Delayed phase solar view of a normal horse. Note the homogenous uptake throughout the entire image without distinction of any particular area.

Incidental bilateral focal increase radiotracer can be seen at the dorsal mid aspect of the proximal phalanx in dressage, show jumping, or eventing horses (Figure 3.140).[6] The palmar or plantar cortices may also show focal abnormal radiotracer. The etiology of this uptake is likely due to adaptive remodeling from a normal response to training.

VetBooks.ir

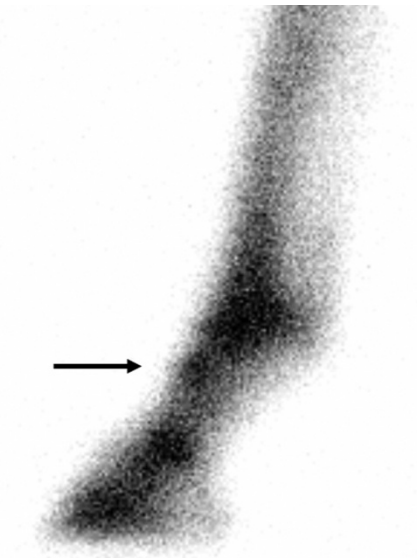

Figure 3.140. Delayed phase lateral view of the left distal limb of a normal horse. The focal moderate radiotracer on the dorsoproximal diaphysis of P1 (arrow) is a normal finding as a response to the athletic activity usually seen bilaterally in performance horses.

Figure 3.141. Delayed phase lateral view of the left metacarpus of a normal horse. Note the uniform uptake along the diaphysis.

Metacarpus and Metatarsus

There should be a uniform uptake along the diaphysis of the metacarpus and metatarsus with no distinction between the second, third, and fourth metacarpal bones (Figure 3.141).

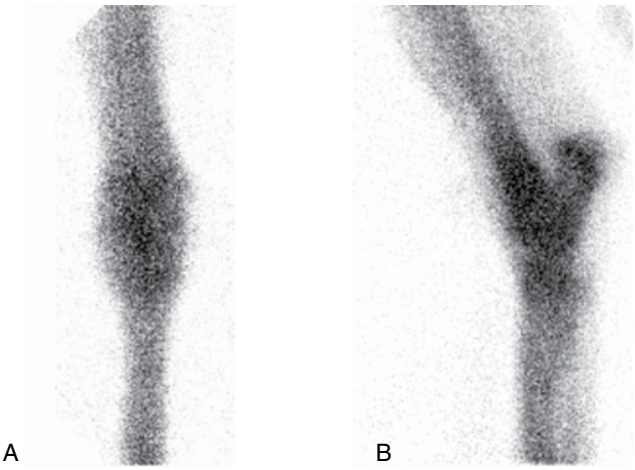

Figure 3.142. Delayed phase dorsal view of the carpus (A) and lateral view of the tarsus (B) of a normal horse.

Carpus and Tarsus

Normal radiotracer distribution is uniformly greater in the carpal and tarsal bones when compared with the diaphysis of the metacarpus and radius or metatarsus and tibia, respectively (Figure 3.142). Focal areas of increased radiotracer in the cuboidal bones are typically considered abnormal. However, a general increase in the distal row of carpal bones can be seen as horses begin or are in early training.[35]

Upper Limb Long Bones

The distal physis of the radius and tibia can be seen with an increased uptake for several years after radiographic closure. The radial physis can be seen past the age of 8 years. Growth is no longer occurring at these sites, but there is still sufficient osteoblastic activity to differentiate the physis from the adjacent metaphysis and the epiphysis. The increased radiotracer in those areas is the result of different histologic architecture after closure, which exposes more bone crystal to diphosphonate binding.[96] A uniform pattern of uptake should be seen along the diaphysis of the normal tibia[97] and radius. The deltoid tuberosity is easily visualized as an area of greater radiotracer on the cranioproximal cortex of the humerus due to the closer proximity of the bone to the gamma camera (Figure 3.143). The third trochanter is an important landmark and should be seen as an area of greater radiotracer because of proximity to the camera. The cranial and caudal parts of the greater trochanter should be identified as separate structures (Figure 3.144).

Elbow, Shoulder, and Stifle Joints

Increased radiotracer is often seen in the radioulnar joint of normal elbows (Figure 3.145). The normal shoulder joint demonstrates increased uptake in the areas of the greater and lesser tubercles and the humeral head (Figure 3.146). The glenoid cavity, however, should have less activity than the humeral head.

VetBooks.ir

VetBooks.ir

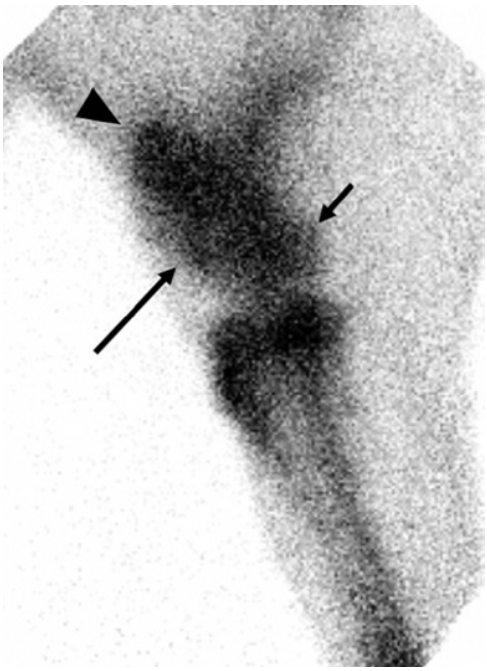

Figure 3.147. Delayed phase lateral view of the stifle joint of a normal horse. Note the uniform uptake between the patella (arrowhead), trochlea (large arrow), and condyles (small arrow).

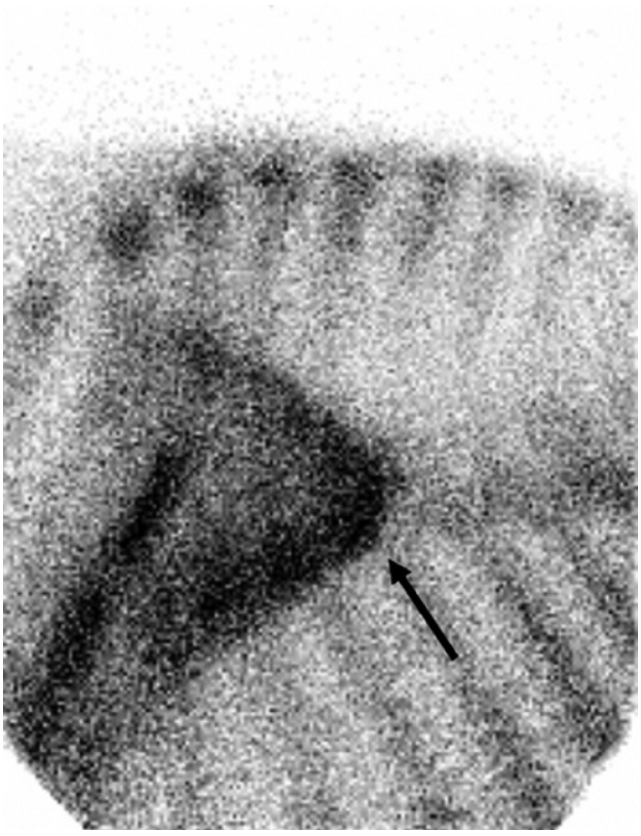

Figure 3.148. Delayed phase lateral view of the scapula of a normal horse. Note the spine of the scapula and a superimposition artifact (arrow) created by overlap between the caudodorsal angle of the scapula and the thoracic vertebral bodies.

A similar uptake between the patella, trochlea, and condyles should be seen in the stifle joint (Figure 3.147). However, in adult horses it is also normal to see a mild increases in radiotracer on the patella secondary to adaptive bone remodeling.[26] In immature horses, a normal bilobed appearance of the proximal tibia is commonly seen, corresponding to the center of ossification of the tibial tuberosity and the superimposition of the caudal tibial plateau and the head of the fibula.[26,71] Adult horses show less uptake at the tibial tuberosity than the caudal tibial plateau/fibular head region. In addition to the superimposition of the head of the fibula and the caudal aspect of the tibial plateau, increased radiotracer in this region is also attributed to the weight-bearing and greater load transmission in this area.[26]

Scapula

The scapula should be easy to visualize, and in some cases the withers can be evaluated at the same time (Figure 3.148). Superimposition artifact from the withers and thoracic spine often occurs on images of the scapula, creating an area of perceived increased uptake. The caudal border and the spine of the scapula have normally greater uptake than the supra- and infraspinatus fossae.

Pelvis, SI, and Coxofemoral Joints

The dorsal view of the pelvis is often used for the evaluation of the tuber sacrale and SI region. The uptake is normally increased due to the close distance and minimal soft tissue attenuation between the sacral tuberosities and the γ-ray detector (Figure 3.149). The tuber sacrale in the young horse is well defined. This tends to diminish with age, having more radiotracer lateral to the tuber sacrale. The SI joints can be evaluated on a dorsal view or a dorsal 45° oblique view. Asymmetric uptake can be better visualized on the dorsal oblique view, and

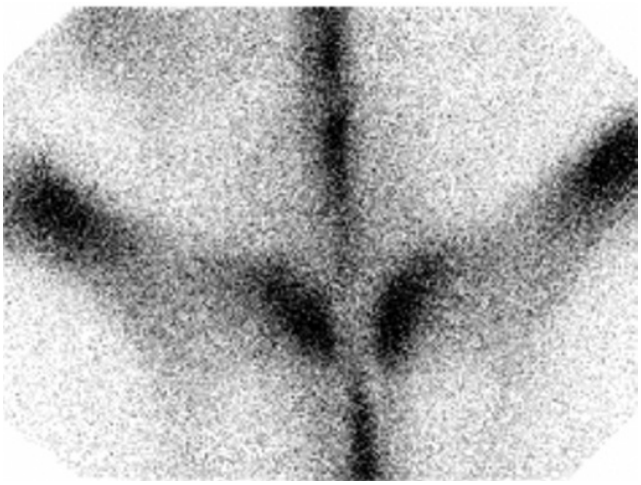

Figure 3.149. Delayed phase dorsal view of the sacrum of a normal horse. The two oval and symmetric focal areas of increased radiotracer correspond to the sacral tuberosities. The relative distinction of this area diminishes with age.

VetBooks.ir

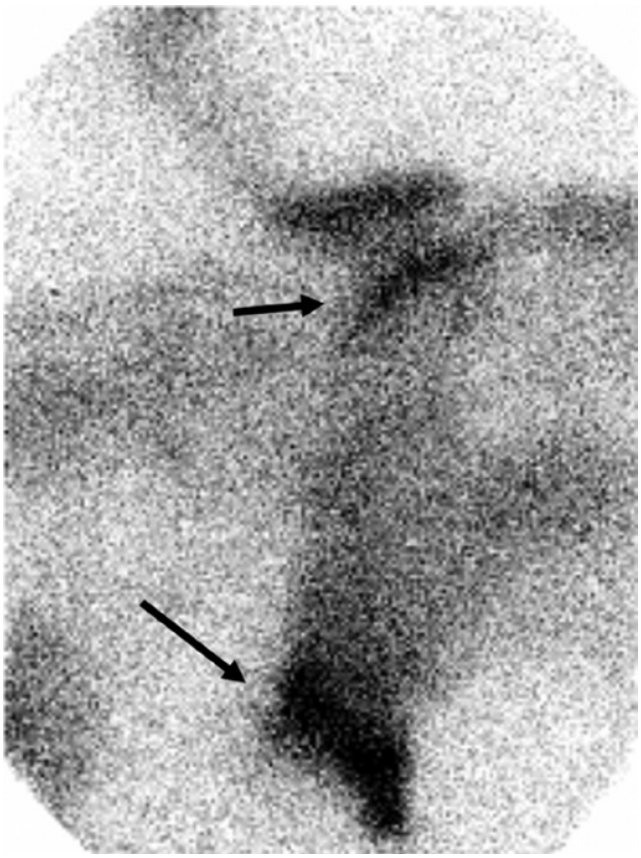

Figure 3.150. Delayed phase oblique view of the sacroiliac joint of a normal horse. Note the sacral (small arrow) and iliac (large arrow) tuberosities.

the entire extent of the joint can be better seen on the oblique view with less superimposition of pelvic canal structures (Figure 3.150). Although the dorsum of the sixth and seventh lumbar vertebrae and the sacrum can also be seen on the dorsal view, the spinous processes are best evaluated on the dorsal oblique views.

The caudal view of the pelvis (tail-on detector view, TOD) helps in the evaluation of the floor of the pelvis and the tuber ischia and proximal aspect of the femurs (Figure 3.151). The camera is positioned caudal to the pelvis of the horse for the TOD view. Ensuring the gamma camera is equidistant from the left and right tuber ischii during the acquisition of this view will reduce false-positive increase radiotracer due to asymmetric distance from the camera. Asymmetric uptake by the tuber ischii is considered abnormal. Angling the camera dorsally (slope of the rump) should be done if the urinary bladder interferes with the image. This projects the bladder above the tuber ischii.

Lateral images of the coxofemoral joint should identify the cranial and caudal portions of the greater trochanter and third trochanter of the femur (Figure 3.152). Commonly, increased radiotracer is seen in the coxofemoral joint region on the lateral view because the cranial part of the greater trochanter (convexity) is partially superimposed over the joint region. Dorsal oblique views (approximately 45°) of the coxofemoral joint allow improved visualization of the femoral head and neck and acetabular region

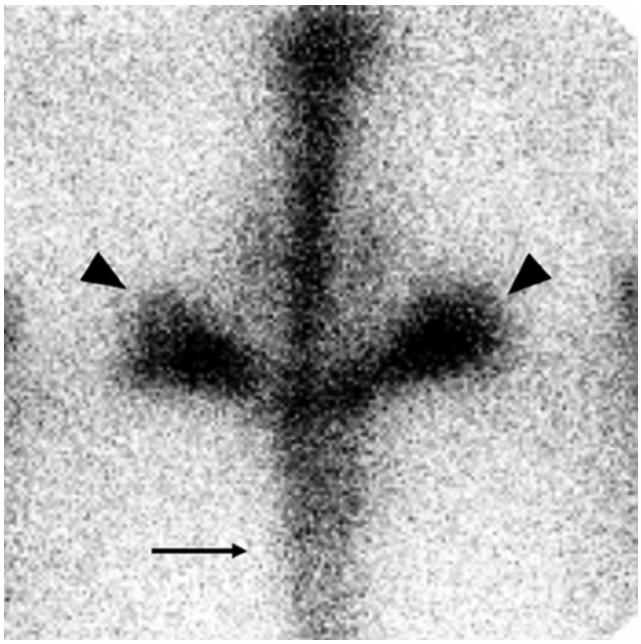

Figure 3.151. Delayed phase tail on detector (TOD) view of a normal horse. Note the good visualization of the floor of the pelvis, especially the symmetric ischiatic tuberosities (arrowheads). The tail is seen as a midline structure (arrow).

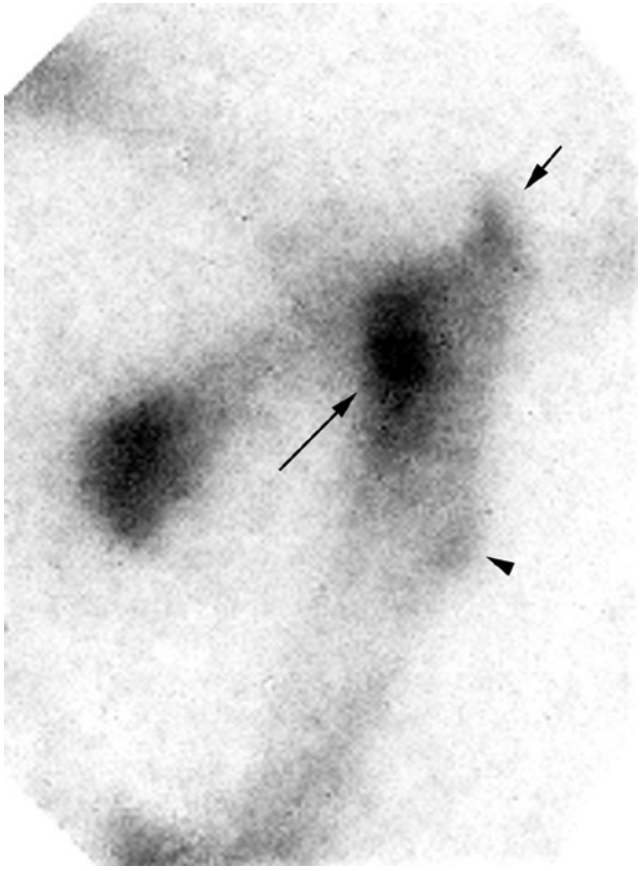

Figure 3.152. Delayed phase lateral view of the left coxofemoral joint of a normal horse. Note the cranial (large arrow) and caudal (small arrow) parts of the greater trochanter and the third trochanter (arrowhead) as separate structures.

VetBooks.ir

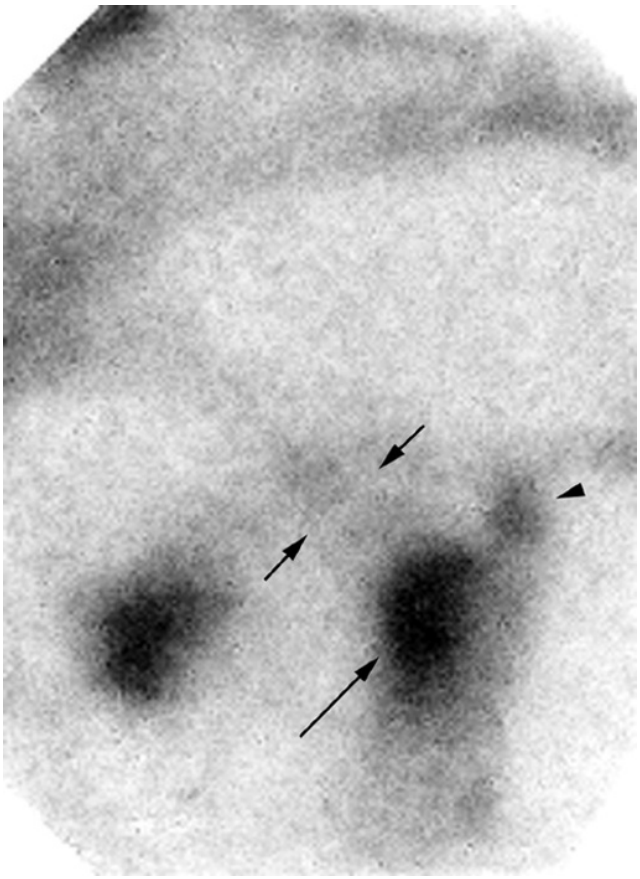

Figure 3.153. Delayed phase oblique view of the left coxofemoral joint of a normal horse. The coxofemoral joint is located between the two small arrows and is not superimposed over the greater trochanter. The cranial and caudal parts of the greater trochanter (large arrow and arrowhead, respectively) are still visualized as separate structures.

without superimposition of other structures (Figure 3.153). The normal acetabulum should not be seen as a separate entity (i.e. the acetabulum should not have a signal greater that of the ilium). Urine in the urinary bladder sometimes obscures visualization of the hip joint and can be mistaken for disease. Dorsal or caudal views of the hip region should be made to differentiate the urinary bladder (a midline structure) from the coxofemoral joints.

Spine

Lateral images of the cervical spine should show similar uptake between articular facets and their corresponding vertebral bodies with the exception of the C6–C7 articular facets. Typically a relatively higher uptake is seen in the body of C6 due to the shorter and thicker transverse processes. Similar uptake should be seen between cervical articular facets at adjacent levels (Figure 3.154). The region of the dens usually has a greater radiotracer than the surrounding bony structures (Figure 3.155).

The thoracic and lumbar spine can be evaluated with lateral images; however, the large rib cage and epaxial musculature maintain a great distance between the vertebrae and the γ-ray detector, making subtle areas of increased uptake difficult to detect. Therefore, LDO and

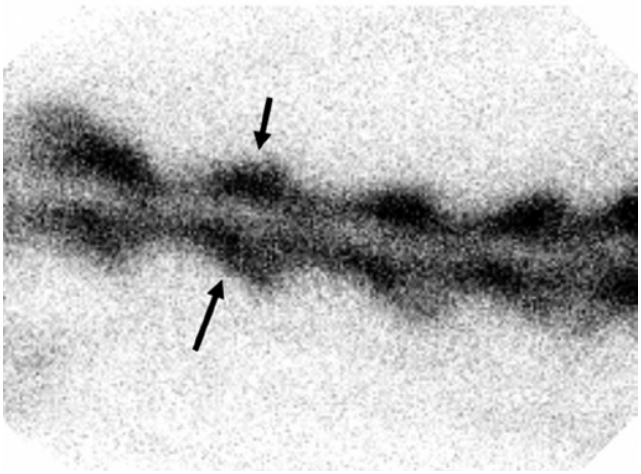

Figure 3.154. Delayed phase right lateral view of the mid-cervical region of a normal horse. Note the similar uptake between the articular facets (short arrow) and the vertebral body (large arrow).

RDO images are invaluable for the evaluation of the spine (Figure 3.156). When obtaining the dorsal oblique view, care should be taken when evaluating the caudal thoracic vertebrae for superimposition of the vertebral bodies and the normal increased uptake in the right kidney. Overlap should exist between views to include all anatomical regions. Resolution of the dorsal spinous and transverse processes should be possible in all horses; however, patients greater than 1,500 lbs. can be so bulky that the γ-rays may be reduced or attenuated significantly enough to reduce dorsal spine and transverse process resolution. The most dorsal aspect of the spinous processes of the withers usually have normal intense focal areas of radiotracer (Figure 3.157). Adjacent spinal units should have similar amounts of uptake to each other. Be sure to evaluate the dorsal spines, articular facets, and transverse processes of the entire spine, including the sacrum and tail head (sacrococcygeal region).

The dorsal view provides limited information in most clinical cases. However, soft tissue and delay phase dorsal views should be obtained when a lesion is suspected after clinical evaluation.

Although the distribution of the radiopharmaceutical in the normal horse, young and old, is predictable, experience is necessary for interpreting bone scans. Comparing the relative uptake in opposite limbs, or comparing images from horses of a similar age, can assist in arriving at significant conclusions.

It is important to look at relative uptake between structures on the same image and then compare it with the ratio between the same structures on the contralateral image. This is important because of the phenomenon that occurs when an entire leg might have less uptake than the opposite limb. In these cases it is inappropriate to compare the uptake of, for example, the fetlock of one limb with the uptake of the fetlock of the other. It is more accurate to evaluate the uptake ratio between the fetlock and the pastern region in one limb and compare it with the same ratio in the other limb. This reduces the overreading of radiopharmaceutical uptake disparities that occur as natural phenomena or

VetBooks.ir

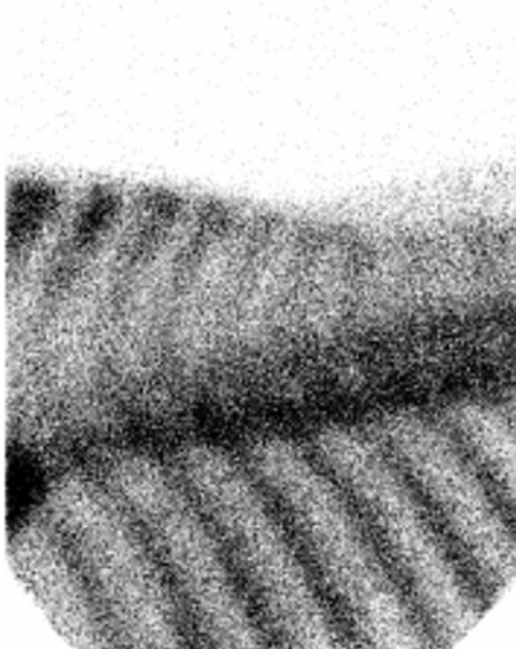

Figure 3.156. Delayed phase dorsal oblique view of the thoracic spine of a normal horse. Note the good resolution of the dorsal spinous processes and the ribs.

as image acquisition artifacts (for example, camera-body-distance inequalities, collimator decentering, etc.). The same interpretation philosophy of comparing relative uptake ratios should be used in other body regions. Generally speaking, the more intense the uptake, the more severe the condition.

SCINTIGRAPHIC SIGNS OF DISEASE

Vascular Phase

Increased blood flow can be seen as a subacute or chronic response to trauma during the healing phase.

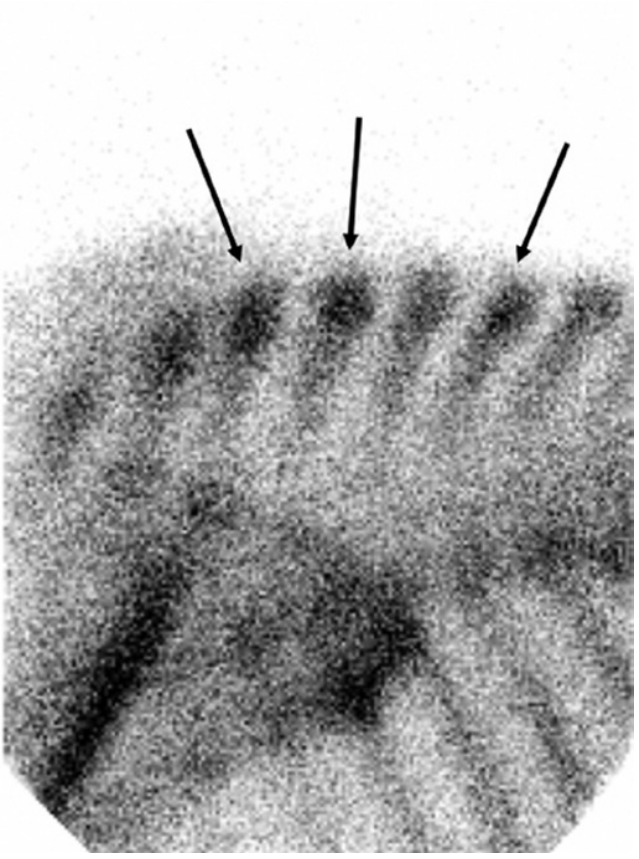

Figure 3.157. Delayed phase left dorsal oblique (LDO) view of the cranial thoracic spine of a normal horse. Note the normal radiotracer at the summit of the spinous processes of the withers (arrows).

Vascular imaging is useful to determine the amount of perfusion to the distal extremity and can therefore help determine the best therapy as well as prognosis. It generally takes about one minute for the leading edge of the tracer to reach the distal limb. The radiopharmaceutical can reach the distal limb quicker if the horse is sedated with acepromazine.[78]

The images can be viewed either individually or as a composite image, or the data from the individual images can be displayed in the form of a graph. Figure 3.158 illustrates the composite image of the vascular phase of a horse that suffered from a near-degloving injury to the distal left metacarpus 1 week prior. Ninety images of 2 seconds each were acquired after the intravenous administration of about 150 mCi ^{99m}Tc-O_4. The study was performed to evaluate whether there was blood flow to the pastern region.

The composite image shows increased blood flow to the distal metacarpus, where granulation tissue had already started to form. The pastern, however, showed more blood flow than the (normal) contralateral pastern region. This was thought to be due to reflex hyperemia secondary to the healing process and was considered a positive sign, indicating that there was good blood flow to the foot. Figure 3.159 is a graphical representation of the vascular phase. The curve represents the amount of

VetBooks.ir

radioactivity in the left and right pastern regions, determined by the region of interest that was drawn around them. Each data point on the curve is 1 of the 90 images. Quantitation of the respective blood flow can be done by determining the area under the curve of each pastern and calculating the percentage of total flow. Empirical evaluation of the images is generally sufficient in most clinical cases.

Decreased blood flow to a region is often associated with nonviable bone or other tissue. Although rare, this can be used to evaluate large sequestra, cases of severe blood flow compromise from a traumatic/degloving injury (especially distal limb), or different conditions such as aortoiliac thrombosis.[18]

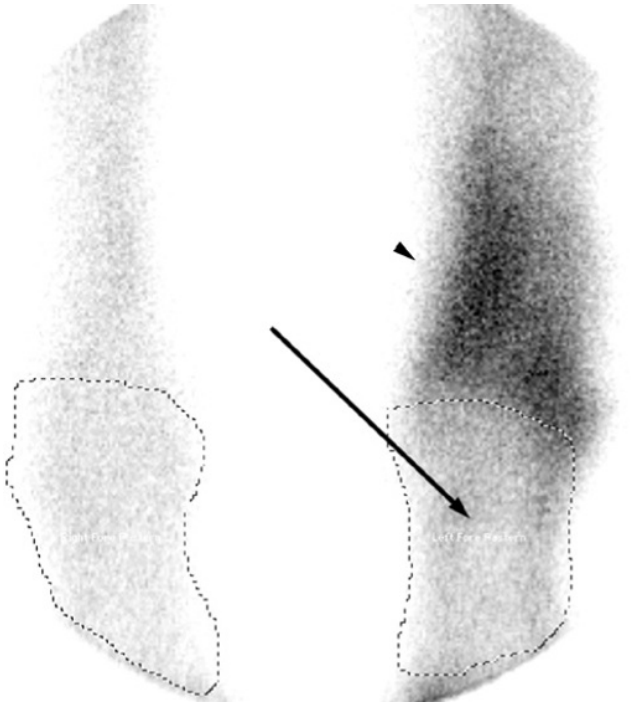

Figure 3.158. Composite vascular phase dorsal view of the pastern area of a horse 1 week after a near-degloving injury to the distal left front cannon bone region, showing moderately increased blood flow to the left pastern region (arrow) and markedly increased blood flow to the distal left cannon bone region (arrowhead).

Soft Tissue Phase

Increased activity in soft tissues is a good method to document increased blood flow to specific regions, for example, joints with synovitis/capsulitis. In these cases, nuclear scintigraphy is sensitive at detecting increased periarticular blood flow around inflamed joints before radiographic changes of OA are evident. Fetlock joint capsulitis has a region greater radiotracer over the joint when compared with the distal metacarpal region and proximal phalanx (Figure 3.160; compare with normal, Figure 3.135). Increased soft tissue phase uptake with a normal delayed phase image is compatible with a more acute degenerative condition, whereas if it is accompanied by increased uptake in the delayed phase, the condition is probably more chronic in nature.

Soft tissue phase imaging may be helpful in diagnosing enthesopathy and desmopathy of the proximal attachment of the suspensory ligament. These injuries may not be evident on ultrasound or radiographic studies. Deep lying regions, for example, the coxofemoral and SI joints, are difficult if not impossible to evaluate during the soft tissue phase because of the meager nature of the signal and the large amount of

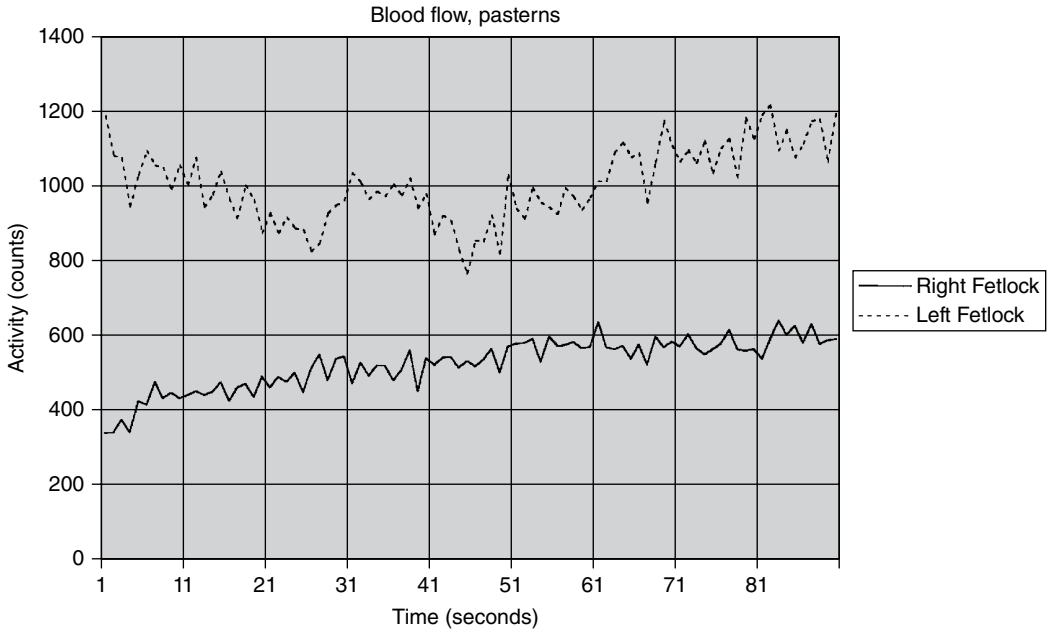

Figure 3.159. Graph of the data from the composite image shown in Figure 3.158, confirming that the left fetlock region had more blood flow than the right one.

VetBooks.ir

other tissues between the hip and the camera. These tissues make up several half-value layers (a layer of tissue resulting in the reduction of the signal by one half), which attenuate the beam significantly before reaching the gamma camera.

Figure 3.160. Soft tissue (pool) phase image of the left forefoot, showing increased blood flow to the fetlock region (arrow), which is suggestive of hyperemia associated with joint synovitis and/or capsulitis. Figure 3.135 provides the normal comparison.

Care must be taken to not overinterpret soft tissue phase images when severe increased uptake is also seen in the delayed phase images. Soft tissue phase "hot spots" in these cases often represent early bone uptake. For example, the soft tissue image in Figure 3.161a probably represents early bone uptake of the radiopharmaceutical by the proximal phalanx because of the intense uptake seen in the proximal phalanx in the delayed phase (Figure 3.161b). This horse had a fissure fracture of P1 that was also seen radiographically (Figure 3.161c).

Delayed Phase

Regions with increased blood flow and osteoblastic activity demonstrate increased uptake of the radiopharmaceutical. The severity or intensity of the increased uptake can vary and is often associated with conditions such as fractures, stress fractures, OA, enthesopathy, osteomyelitis, and neoplasia. Fractures and infectious processes have similar scintigraphic behavior in most bones, and in some cases it is difficult to differentiate between the two conditions. Therefore, correlation with clinical signs and other imaging findings is extremely important for making the diagnosis.

The amount of abnormal radiotracer that a fracture demonstrates may help determine the time of onset (acute vs. chronic) or the nature (pathologic vs. traumatic) of the fracture. Chronic and subacute fractures (older than 48 hours) have intense increased uptake due to the considerable osteoblastic activity (Figure 3.162). Acute fractures have less radiotracer because it takes approximately 24 hours for the osteoblastic activity to be greater than surrounding bone. In fact, acute

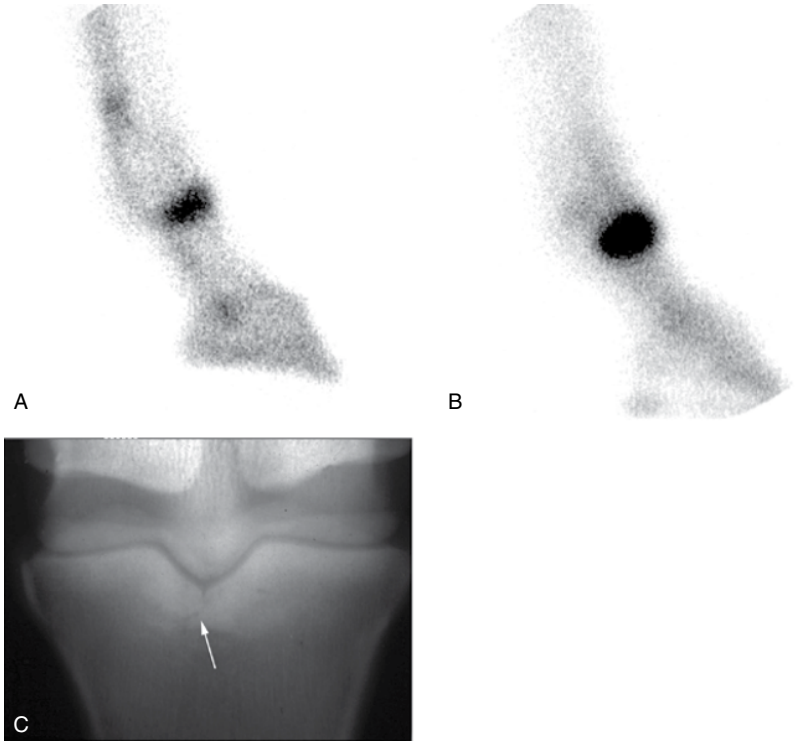

Figure 3.161. Right forefoot of a horse suffering from a chronic proximal first phalanx fracture. (A) Soft tissue (pool) phase image showing marked increased blood flow to the proximal portion of the first phalanx. (B) Delayed phase image showing marked abnormal radiotracer by the proximal portion of the first phalanx. (C) Radiograph showing a proximal first phalanx fracture (arrow). The radiotracer seen in the soft tissue image likely represents early radiopharmaceutical uptake by the bone, not just increased blood flow, because of the marked abnormal radiotracer seen in the delayed phase image.

VetBooks.ir

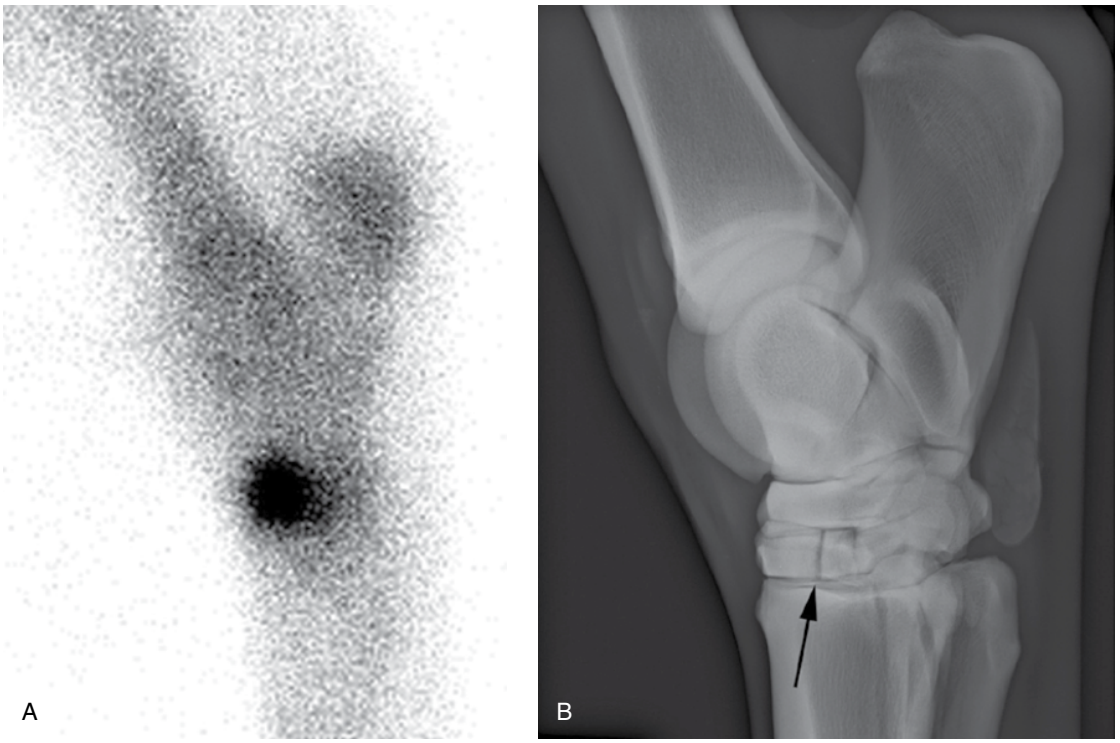

Figure 3.162. (A) Delayed phase lateral view of the left tarsus of a horse with focal and intense abnormal radiotracer in the region of the distal tarsus corresponding to a third tarsal bone fracture. (B) Lateromedial radiograph of the same tarsus showing the well-defined radiolucent fracture line extending from the proximal to the distal articular surfaces of the third tarsal bone, consistent with a slab fracture (arrow). *Source*: Courtesy of Dr. Erik Bergman.

traumatic fractures less than 24 hours' duration fail to show increased tracer uptake when compared with adjacent bone. Figure 3.163 is a delayed phase image of a comminuted middle phalangeal fracture 48 hours' post-injury. Although mild increased uptake is seen, the fracture is best diagnosed due to anatomic abnormality and not its physiologic peculiarity. Compare this with Figure 3.161, a chronic proximal phalangeal fracture with intense uptake but minimal anatomic displacement. Fracture uptake in humans is expected at about 24 hours' post-injury (although it takes longer in older patients) and is expected to last for 6–12 months or longer in older patients.[88] The uptake by a fracture should decrease over time as fracture healing occurs.

Multifocal areas of abnormal radiotracer have been described with different diseases such as enostosis-like lesions,[7,66] hypertrophic osteopathy,[50] neoplasia,[27,43] and horses with a bone fragility disorder,[2] a recently reported condition of unknown etiology that affects the axial and proximal appendicular skeleton. Figure 3.164 shows intestinal adenocarcinoma metastases to the ribs and distal left humerus. The same horse also had metastatic disease to several cervical, thoracic, and lumbar vertebrae, multiple ribs, and the sternum.

Localized delayed phase uptake of the radiopharmaceutical by soft tissues is not commonly seen and can occur with various conditions, e.g. dystrophic mineralization of ligament and tendon injuries, regional anesthesia,[1] rhabdomyolysis,[13,41,59] and repeated intramuscular injection of butorphanol[49] (Figures 3.133, 3.165,

Figure 3.163. Delayed phase image of a comminuted left front middle phalangeal fracture 48 hours' post-injury. Anatomic displacement is apparent, although radiopharmaceutical uptake is only mildly increased.

and 3.166). Rhabdomyolysis (tying up) is seen as linear or diffuse uptake patterns in the muscles, such as the gluteals, semimembranosus, and semitendinosus.

ABNORMAL CONDITIONS FOR SPECIFIC ANATOMICAL REGIONS

Distal Limb (Foot, Pastern, and Fetlock)

The distal phalanx and navicular bone can experience different pathologic conditions involving the osseous anatomy or the multiple soft tissue structures related to them. Radiographic changes of the navicular bone can be difficult to interpret because many different architectural variations have been seen in both lame and sound horses.[44] The presence of increased radiotracer in the navicular bone region in the delayed phase is highly sensitive for the diagnosis of active navicular disease,[92] especially when solar views are obtained.[45] Remember that the navicular bone should not be seen as a separate entity on the normal foot; therefore, abnormal radiotracer in that region is indicative of active disease (Figure 3.167). Laminitis results in moderate to severe radiopharmaceutical uptake in the distal aspect of the distal phalanx, seen on both the lateral but especially the solar view (Figure 3.168). Other conditions, such as P3 osteitis, P3 fractures, and subsolar bruising, can also appear as areas of variably radiotracer uptake (Figures 3.169 and 3.170).

Figure 3.167. Delayed phase solar view of the left forelimb, showing a focal and intense radiotracer in the region of the navicular bone, consistent with navicular disease.

Figure 3.168. Delayed phase solar view of the right hindlimb, showing intense radiotracer along the distal portion of P3, compatible with laminitis.

A normal scintigraphic image does not show a discrete insertion of the DDFT on P3 and collateral ligaments of the distal interphalangeal (DIP) joint. However, the anatomical location of these structures can be identified, especially on solar views (Figure 3.171). If possible,

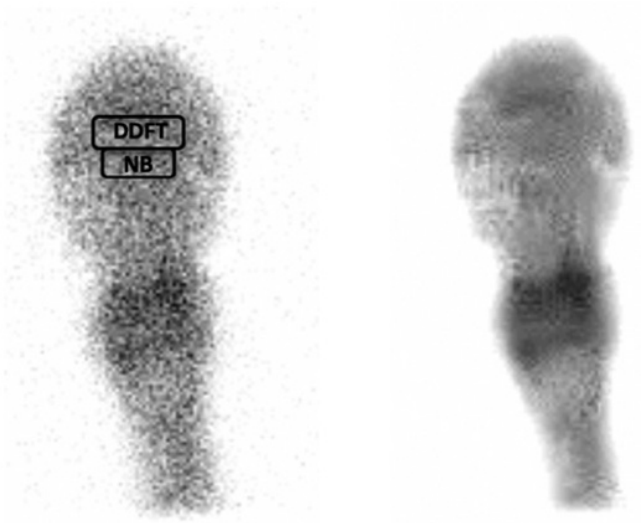

Figure 3.171. (A) Delayed phase solar view of a normal horse. Note the uniform uptake along the entire image. NB = navicular bone area and DDFT = deep digital flexor tendon area. (B) SHINE-processed image.

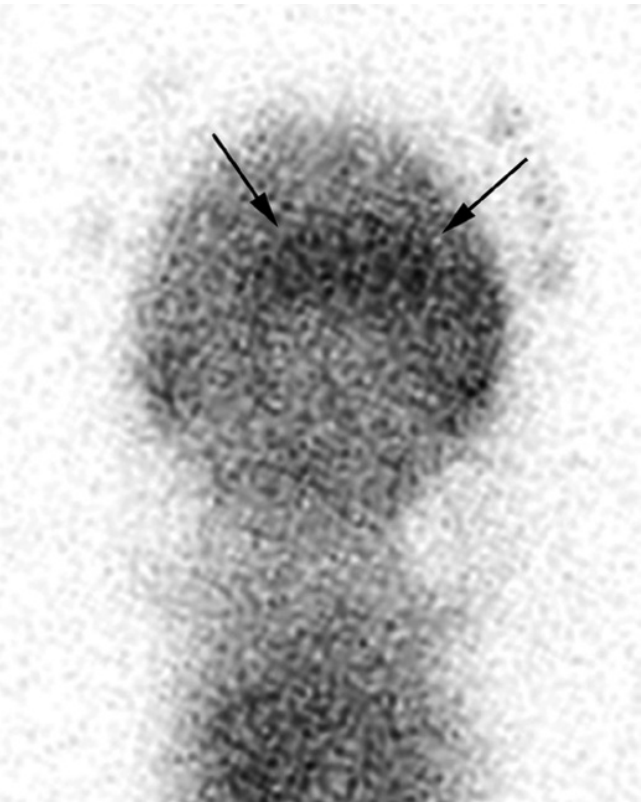

Figure 3.172. Delayed phase solar view of a horse with moderate diffused uptake in the region of insertion of the DDFT (arrows), suggesting enthesopathy. *Source*: Courtesy of Dr. Erik Bergman.

abnormal uptake at these sites should also be documented on the lateral and dorsal/palmar views. Areas of increased radiotracer in these regions in combination with a positive response to local anesthesia help to identify active pathologic changes (Figure 3.172). These changes could be further characterized with MRI.

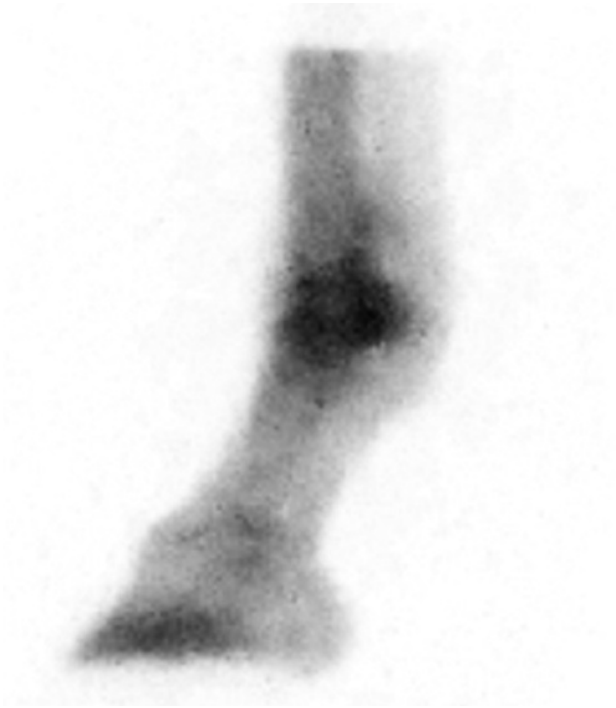

Figure 3.173. SHINE-processed delayed phase lateral view of the left fore distal limb of a horse showing diffuse radiotracer in the fetlock joint region, consistent with osteoarthritis. Note the difference in uptake between the abnormal fetlock and the normal proximal and distal interphalangeal joints. *Source*: Courtesy of Dr. Kent Allen.

OA of the DIP, proximal interphalangeal (PIP), and fetlocks joint can be identified when increased radiotracer is seen at these regions, typically areas along the dorsal aspect of the joint, when compared with the adjacent joints. There can also be relative increased radiotracer ratios in the opposite limb (Figure 3.173).

The proximal articular surface of the first phalanx is a common location for abnormal radiotracer that represents active injuries to the subchondral bone that in many instances are not detected radiographically and would benefit from additional studies such as computed tomography and MRI.[25,53,73] The proximal sesamoid bones are also susceptible to inflammatory changes that may appear as areas of increase radiotracer, which likely are related to stress from the different ligamentous attachments (Figure 3.174). Injuries to the axial border of the proximal sesamoid bones are usually, but not necessarily, traumatically induced, involving the intersesamoidean ligament, and can be the result of septic or nonseptic inflammation.[12,23,51,101]

Metacarpus and Metatarsus

Areas of increase radiotracer are often seen in the distal cannon bone of racing Thoroughbreds and Standardbreds. Both front limbs and hindlimbs can be affected, but Thoroughbreds more frequently show increase radiotracer in the distal metacarpus and Standardbreds in the distal metatarsus.[5,55] Stress remodeling and incomplete condylar fractures are common attributable pathologic changes for this increase uptake.[55,72,75]

VetBooks.ir

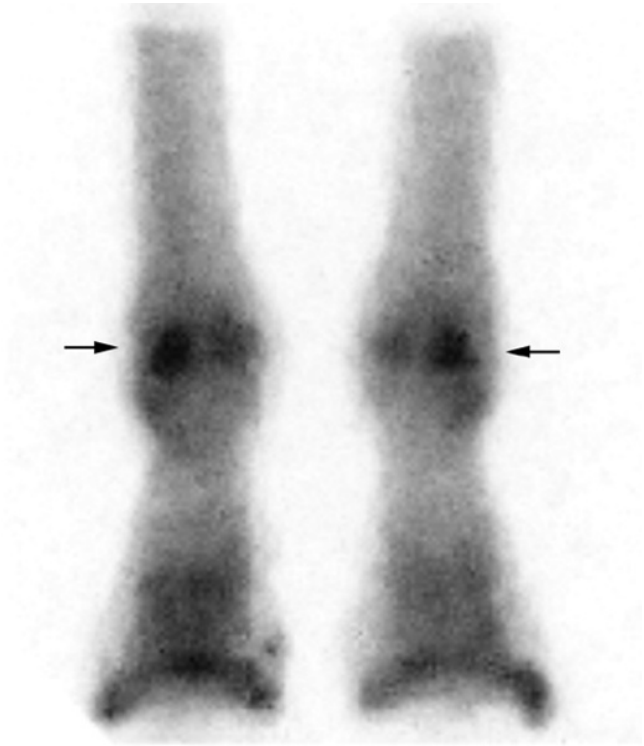

Figure 3.174. SHINE-processed delayed phase dorsal view of both front distal limbs of a horse with focal and intense radiotracer in the region of the lateral sesamoid bones (arrows), consistent with sesamoiditis. *Source*: Courtesy of Dr. Kent Allen.

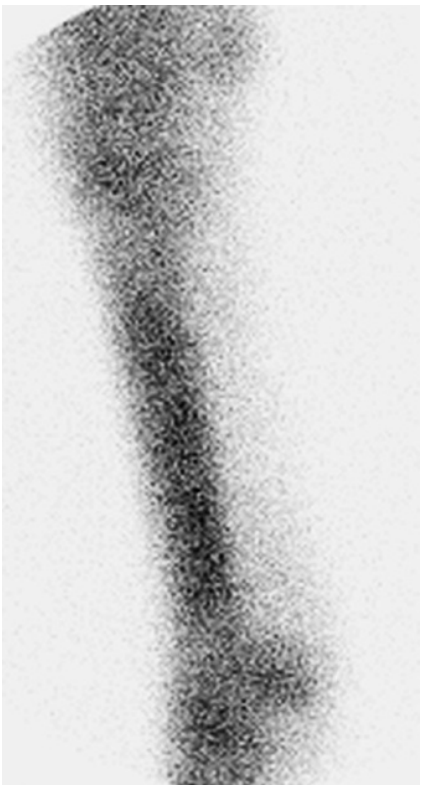

Figure 3.175. Delayed phase lateral view of the left metacarpus of a horse showing diffuse abnormal radiotracer along the diaphysis of MCIII, compatible with dorsal metacarpal disease ("buckshins"). *Source*: Courtesy of Dr. Erik Bergman.

Diffuse dorsal metacarpal increased radiotracer is common in racing horses and represents reactive periostitis or stress remodeling[47] (Figure 3.175). Focal and intense areas of radiotracer on the dorsal cortex of the cannon bone are likely indicative of a stress fracture (Figure 3.176).

Increased radiopharmaceutical uptake on the palmar or plantar proximal cannon bone is a common finding in cases of desmitis at the origin of the suspensory ligament that produces stress reaction or avulsion fracture on the bony attachment[28] (Figure 3.177).

Carpus

Exercise-induced bone remodeling is seen frequently on the third carpal bone, especially in Standardbreds,[30] but it may be seen in other racing breeds and Warmbloods. The increased radiotracer on the third carpal bone corresponds to sclerosis or fractures seen in radiographs (Figure 3.178).

Proximal Limb Long Bones

Stress fractures are common injuries seen on the tibial and humeral diaphyses in racing horses[62] that appear as a focal and intense areas of radiotracer located near a cortical margin. Humeral stress fractures are more common in Thoroughbreds than Standardbreds.[48] Common sites of tibial stress fractures in Thoroughbreds include the lateral cortex of the mid-diaphysis, caudal cortex of the proximal diaphysis, and less commonly the medial cortex of the distal diaphysis (Figure 3.179).[54,62] Stress fractures in the humerus occur at the cranio- and

caudodistal, caudoproximal, and less commonly craniproximal cortices (Figure 3.180).[62] Stress fractures of the radius are less common being reported to have a mid-diaphyseal occurrence.[52] Focal increase radiopharmaceutical uptake in the medullary cavity of long bones was first described as "bone infarcts"[68] and subsequently as enostosis-like lesions (Figure 3.181).[7,66] These lesions are frequently seen in the tibia, radius, humerus, and MCIII/metatarsal bones. Radiographically, the lesions appear as well-defined areas of increased opacity in the medullary cavities. It appears to be a transient condition with the lesions resolving in follow-up radiographic and scintigraphic examinations. The pathophysiology of these lesions is not well understood, and it has been reported that not all of the lesions are associated with lameness.[7,65]

Increased radiotracer on the caudal aspect of the distal femoral diaphysis just proximal to the stifle joint on a lateral view and localized laterally on the caudal view has been seen in cases of injury to the origin of the gastrocnemius muscle.[87]

Elbow

Ulnar fractures are relatively common, especially in young horses.[14] Other traumatic injuries such as Salter–Harris fractures and subluxations can also occur. These injuries are usually diagnosed clinically and radiographically. However, fractures can sometimes be very small or minimally displaced; in such cases scintigraphy may add useful information in the diagnosis. Osteomyelitis secondary to trauma to the proximal radius with possible progression to septic elbow arthritis has been documented as a large and intense area of radiotracer in that region.[86] Radiographically, these lesions may be subtle or not apparent if the infection has not advanced enough to cause substantial bone lysis.

Subchondral bone cysts and cartilage lesions may not show scintigraphic abnormalities unless the underlying subchondral bone is affected.

Shoulder and Scapula

Injuries to the shoulder and scapula in the horse are uncommon. Fractures of the greater tubercle may occur, but frequently the diagnosis is based on clinical evaluation in combination with radiography or ultrasonography.[57,94] An area of increased radiotracer in the cranioproximal humerus may represent a fracture of the tubercle(s) or extension of an infectious/inflammatory process related to the bicipital bursa (Figure 3.182). An unusual case of abnormal radiotracer in the cranioproximal humerus corresponding to a cyst-like lesion of the intermediate tubercle in absence of bicipital bursitis was reported.[67] In general, subchondral bone cysts and small cartilage defects are lesions that are not detected scintigraphically unless there are inflammatory changes extending to the adjacent subchondral bone.

The supraglenoid tubercle is the most frequent location for a traumatic fracture of the scapula.[19,20] Complete fractures of the neck and body of the scapula have also been reported sporadically.[19,20] The scintigraphic diagnosis of stress fractures of the scapula has been documented in a report of two cases in which the location of the focal and intense radiotracer corresponding to the fractures was located in the caudal midbody and the ventral aspect of the neck, respectively.[15]

Tarsus

Distal tarsal radiotracer is usually seen in jumping horses, followed by racing Standardbreds and less commonly Thoroughbreds.[5,29,30] The increased radiotracer can be unilateral or bilateral; a distribution along the entire area of the distal tarsal region of the dorsal aspect is the most common pattern.[60] Increased radiopharmaceutical uptake in the distal tarsal region corresponds to OA or degenerative changes that may or may not be radiographically apparent (Figure 3.183). Talocalcaneal OA is rare but has also been documented as focal and intense radiotracer predominantly medially and more plantar and proximal than distal tarsal radiotracer (Figure 3.184).[77]

Scintigraphy is very useful in localizing fractures of the central and third tarsal bones, especially when the fracture is not displaced, hence radiographically occult.[84] These horses have a history of acute onset of lameness, usually following exercise. The fracture will appear as a focal and intense region of radiotracer in the mid to distal tarsal region. Incomplete sagittal fracture of the talus

is a rare condition in horses and can be a diagnostic challenge because the patient can present without evidence of soft tissue swelling or tarsocrural joint effusion.[16]

A focal and moderate to intense area of radiotracer at the level of the proximal talus should lend suspicion to a sagittal fracture, which is not always evident on radiographs.[16] A similar pattern of abnormal radiotracer was also reported on a 2-year-old Thoroughbred with unusual osteochondral lesions at the proximal articular margin of the medial trochlear ridge of the talus.[76] Osseous cyst-like lesions in the tarsus have been described as focal areas of abnormal radiotracer in the distal tibia (medial or lateral malleoli or intermediate sagittal ridge) or talus.[36] Adding a flexed lateral view to the routine scintigraphic exam protocol of the tarsus can help to differentiate whether the abnormal radiotracer is located in the distal tibia or the talus.

Stifle

Medial femoral condyle subchondral bone cysts are one of the most common pathologic changes seen in the stifle joint of horses. However, as previously mentioned, these lesions do not appear as areas of abnormal radiotracer unless an osteoblastic response or juxta-cyst osteosclerosis occurs in the adjacent subchondral bone (Figure 3.185). A case of a yearling horse with radiographically evident bilateral enlarging subchondral bone cysts after surgical debridement was reported to have normal postoperative follow-up scintigraphic examinations, despite the persistence of lameness localized to the stifle joints.[79] It was proposed that the lesions were mostly osteoclastic; hence no abnormal radiotracer was observed. Subchondral cystic lesions can also appear in the proximal tibia secondary to osteochondrosis or as a manifestation of OA, which scintigraphically may exhibit focal abnormal radiotracer.[89]

Ligamentous/tendinous avulsions may be suspected when a localized area of abnormal radiotracer is seen at an enthesis during the delayed phase. In these cases, other approaches such as ultrasound, MRI, or arthroscopy should be considered for better evaluation of the soft tissues.

Pelvis, SI, and Coxofemoral Joints

Complete, stress, and avulsion fractures at different anatomical locations in the pelvic region have been documented as areas of abnormal radiotracer in delayed phase scintigraphy.[11,13,38,64] Injuries to superficial structures such as the tuber coxae, ischial tuberosity, dorsal sacrum/tail head, greater trochanter, and third trochanter can be the result of direct trauma, often blunt in nature, from a kick, trailer accident, or self-inflicted as can occur from rapid movement or falling accidents. Fractures of the tuber coxae and tuber ischium can be detected by the intense abnormal radiotracer (Figure 3.186) and the possible asymmetric location of the radiotracer between affected and unaffected sides in cases of displaced fractures. Decreased uptake of a fractured tuber coxae has been associated with a ventrally displaced fracture fragment.[13] Oblique views of the pelvis are very useful for evaluating the iliac wing in suspected cases of stress fractures.[42] Trochanteric bursitis is more common in Standardbred racehorses, usually as a result of trauma, either direct or related to stress from racing.[56] Most of the time the lesion involves soft tissue structures, but in some cases the subchondral bone and cartilage overlying the greater trochanter are injured, and a focal abnormal radiotracer is seen over the greater trochanter (Figure 3.187).

Coxofemoral joint pathology is very difficult to assess with dorsal views due to the great γ-ray attenuation from the superimposed musculature. Forty-five degree oblique views are very useful in cases of suspected hip pathology (Figure 3.188).[13]

The SI region is also susceptible to pathologic change commonly attributed to regional SI desmopathy or arthropathy. Injuries to the sacral tuberosity at the origin of the SI ligaments have been described as abnormal radiotracer at the affected enthesis[25] possibly with the tuberosity being displaced cranially.[13] The SI joint can be evaluated on the dorsal oblique view and the straight dorsal view.[32] The straight dorsal view is better to compare left and right on the same image; however, the oblique view gives a better evaluation of the extent of

joint surface because it appears wider and in some cases helps to avoid superimposition of the urinary bladder. Areas of abnormal radiotracer at the SI joint region are often correlated with SI joint pain/injury (Figure 3.189).[22,93] However, increased radiotracer in the SI region has also been found in normal horses and those in which the lameness was attributed to a different anatomical region.[13,25] Variations on the anatomical conformation of the sacral wings and the cranial sacral borders may also play a role in the pattern of radiopharmaceutical uptake.[39] Areas of abnormal or increased radiotracer in the SI region should be interpreted with caution, and the diagnosis of pathology should not be based on the scintigraphic findings alone because of the lack of a "gold standard" and the possibility of false-positive results.[3,25]

In general, the results of pelvic scintigraphic evaluations should be strongly correlated with clinical and physical exam findings and supported, as frequently as possible, with ultrasound or radiography and/or local anesthesia.

Spine

Degenerative changes in the spine are most commonly associated with impingement of the dorsal spinous processes (kissing spines), as well as OA of the articular facets. Impingement of the dorsal spinous process is common on the thoracic and lumbar spine. Good-quality radiographs of these regions, especially

VetBooks.ir

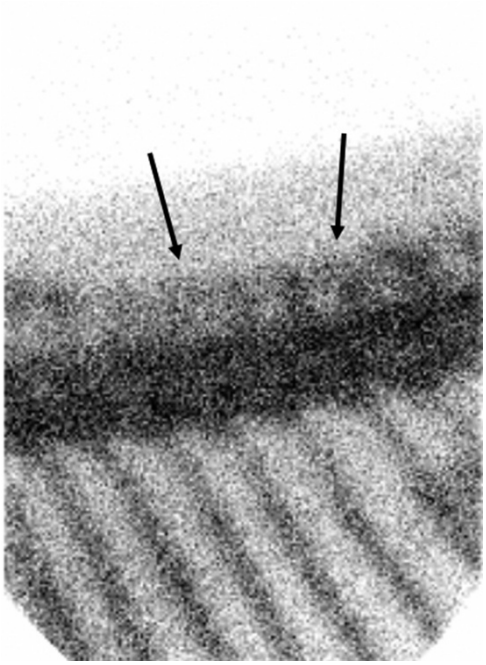

Figure 3.190. Delayed phase LDO view of the mid-thoracic vertebrae of a normal horse. Note the relative increased uptake of the vertebral bodies when compared with the corresponding dorsal spinous processes (arrows).

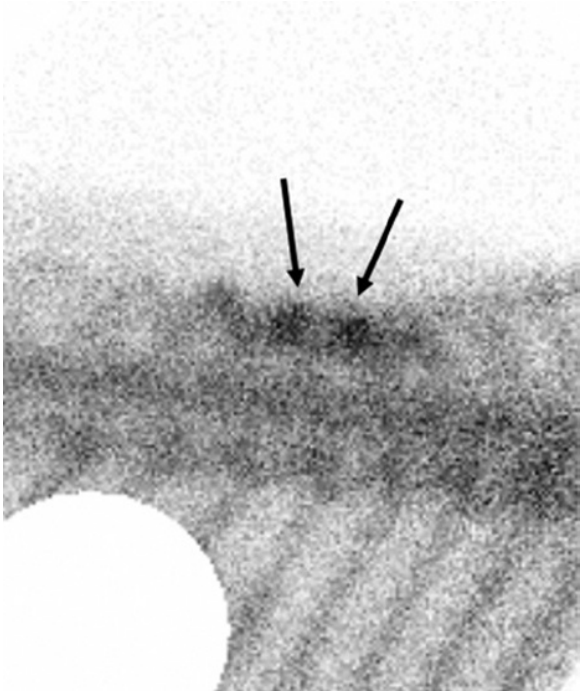

Figure 3.191. Delayed phase LDO view of the mid-thoracic vertebrae of a horse, showing focal and intense abnormal radiotracer at least two adjacent dorsal spinous processes (arrows), suggestive of impingement.

the lumbar spine, can be very difficult to obtain because of the large amount of musculature causing considerable scatter radiation and because if the technique is increased, the most dorsal aspect of the dorsal spinous processes can be overexposed. This makes the scintigraphic evaluation of the spine an invaluable tool for evaluation of the back (Figure 3.190). LDO and RDO views of the spine are the best, although straight lateral and dorsal views are made if a lesion is found. Areas of mild abnormal radiotracer at the dorsal aspect of the spinous processes can be seen in horses with no clinical signs of back problems; therefore, these findings should be interpreted with caution.[33,34] Focal and intense areas of radiotracer can be seen with fractures, severe impingement with or without ligamentous damage, osteomyelitis, or neoplasia (Figures 3.191 and 3.192). Diagnostic differentials should be made, taking into consideration history, physical/clinical exam, and blood analysis.

Increased radiotracer in the cervical articular facets is most commonly seen in cases of OA. The increased radiotracer can be identified when the bone activity in the region of the articular facets is greater than in the corresponding vertebral body or adjacent joints. Affected cervical vertebral facets may be unilateral or bilateral, and more than one joint may be affected (Figure 3.193). Therefore, left and right views should be obtained, and the practitioner should be aware of the possibility of multiple adjacent sites affected and not rely only on the comparison of adjacent joints for increased radiotracer in the evaluation.

Increased radiotracer in the vertebral bodies is uncommon and has been reported with spondylosis deformans[17] and cases of discospondylitis.[40,85]

LIMITATIONS OF NUCLEAR MEDICINE

As mentioned previously, nuclear medicine traces physiologic processes in the different body systems and therefore has a high sensitivity in detecting early changes in the metabolism. This is the main reason why nuclear scintigraphy of the musculoskeletal system is an invaluable diagnostic tool in equine lameness. However, the specificity of bone scintigraphy is very low in the majority of cases. During the evaluation of the bone scintigraphy results, the practitioner should be aware that an area of increased radiotracer only means that there is an area of increased osteoblastic activity in a particular region. If the increased radiotracer is considered pathologic, in most situations, a list of differential diagnoses should be made and further imaging performed to gain a better idea of the anatomical changes of the affected region.

In general, bone scintigraphy is used to localize an area of abnormal bone metabolism that may explain the source of lameness and not necessarily the specific pathologic change. There are some cases in which the diagnosis can be made from the bone scintigraphy results. For example, one can diagnose a stress fracture in a sound racehorse that becomes lame immediately after a training session or a race and has a focal increased radiotracer in the diaphysis of the tibia. On the other hand, if a similar area of increased radiotracer is found in a retired older horse that spends most of the time in the pasture, other differential diagnoses should be considered, such as blunt trauma with or without a fracture, enostosis-like lesion, osteomyelitis, or neoplasia.

False-negative results occur secondary to many different reasons and can be considered as a limitation of bone scintigraphy. For example, a bone lesion with minimum uptake in the proximal region of a limb may not be apparent due to the significant γ-ray attenuation produced by the surrounding musculature. As in cases of subchondral bone cysts, cartilage or meniscal injuries will likely give a false-negative result if the adjacent bone is not affected.

In summary, the practitioner should be aware of the potential limitations when interpreting the results of a nuclear scintigraphic examination; correlate them with the signalment, history, clinical signs, and physical/lameness exam findings; and consider further diagnostics when appropriate.

VetBooks.ir

INTRODUCTION

Computed tomography (CT) is a cross-sectional imaging technique, relying similarly to radiography, on differential X-ray attenuation by the tissues being imaged. Images are acquired as slices of the anatomy of the imaged subject, providing three-dimensional (3D) information. These slices of anatomy are obtained by rotating an X-ray generator around the imaged body area and recording attenuation of the X-ray beam at multiple different angles. The attenuation data are then digitally processed to reconstruct an image.

The imaging principles, relying on X-ray attenuation, are similar to radiography. CT is excellent at imaging bones, with dense bones appearing white (hyperattenuating), whereas gas will show up black due to a lack of X-ray attenuation. Soft tissue structures will display an intermediate (gray) opacity. Based on calibration of the attenuation data, CT is better than radiography at identifying small differences in tissue density. For this reason, tendon, synovial fluid, and connective tissue can be differentiated on CT, while they typically have the same opacity on radiographs. CT also presents the advantage over radiographs to eliminate superimposition of structures. The combination of the increased contrast resolution and abolition of superimposition explain why CT detects lesion not recognized on radiographs.

CT has been used in the horse since the late 1990s, mostly for head and distal limb imaging. Due to technological progress, CT cost and availability have greatly improved in the recent years. Also modification of the size and configuration of the scanners have led to the development of new clinical applications, such as imaging of the neck and more proximal areas of the limbs.

In this chapter, the basic principles of CT will be described along with the different systems that are available. The clinical applications of CT will be limited to musculoskeletal imaging due to the focus of this publication. Imaging of the equine head, although a major indication for CT imaging, will not be covered.

EQUIPMENT AND PRINCIPLES OF CT

Classic CT scanners consist of a gantry, containing a rotating X-ray generator and an array of detectors, and a table translating the patient through the gantry for image acquisition. Obviously, the standard human table needs to be adapted to the size and weight of the equine patient. This is typically accomplished by adding a large table top over the human table but presents a technological challenge as the patient needs to be moved precisely through the gantry during image acquisition. A few commercial solutions are available, but many systems rely on custom-made tables. An interesting variation in the scanner design is the configuration of a few systems having a translating gantry. In these systems, the patient remains stationary during image acquisition as the gantry itself travels over the area to be imaged. The horse can be positioned on a standard equine table, simplifying the logistics.

In addition to the table design, the gantry diameter is a limitation to the range of body areas that can be imaged. Most classic human gantries have a diameter of 55–75 cm, limiting applications in horses to the distal limbs and head to cranial neck (typically to the level of the third or fourth cervical vertebrae). Larger gantries have been designed for bariatric human patients with a diameter up to 90 cm. These systems provide the ability to image larger body areas such as the equine caudal neck and stifles. Most recently scanners designed for intraoperative use in human neurosurgery even offer larger gantries, with a diameter over 100 cm.

The recent development of cone-beam CT technology brought versatility in the design of scanners. Cone-beam scanners use a flat panel detector, similar to a digital radiography plate. This allows modification of the configuration of the classic gantry with asymmetric shape and larger aperture. A robotic arm CT system has also been developed: the classic gantry has been replaced by two robotic arms, one carrying the X-ray generator and one the detector plate. This potentially provides more versatility for scanning standing horses and imaging larger areas. Cone-beam CT provides an excellent spatial resolution, but limitations exist regarding contrast resolution and sensitivity to motion.

As an X-ray-based imaging technique, the generator current intensity (mA) and voltage (kV) are important technical parameters for CT similar to radiography. Additional parameters, including slice thickness, reconstruction algorithm, field of view, and matrix size, are also important to understand the optimization of CT image quality. Depending on the type of tissue imaged, the technique will be different.

In order to optimize images for bone, it is important to have a high spatial resolution and sharp edges. This is typically achieved with using thin slices, an edge enhancement algorithm, a small field of view, and a large matrix (Figure 3.194). The slice thickness in standard multislice CT is typically less than 1 mm, classically 0.65 mm. The in-plane spatial resolution is governed by the matrix size and the reconstruction field of view. Most CT images will use a 512 × 512 matrix. The pixel size is obtained by dividing the field of view by the matrix size. This is important to keep in mind as most classic CT scanners can image a 50-cm field of view; however in the configuration the pixel size will be ~1 mm (500/512). Reducing the field of view to 25 cm, which is usually enough to cover the limb anatomy to image, permits bringing the pixel size to 0.5 mm (250/512), doubling the in-plane spatial resolution. The edge enhancement algorithm is a filter that is applied to the acquired data to help make the image edges more

VetBooks.ir

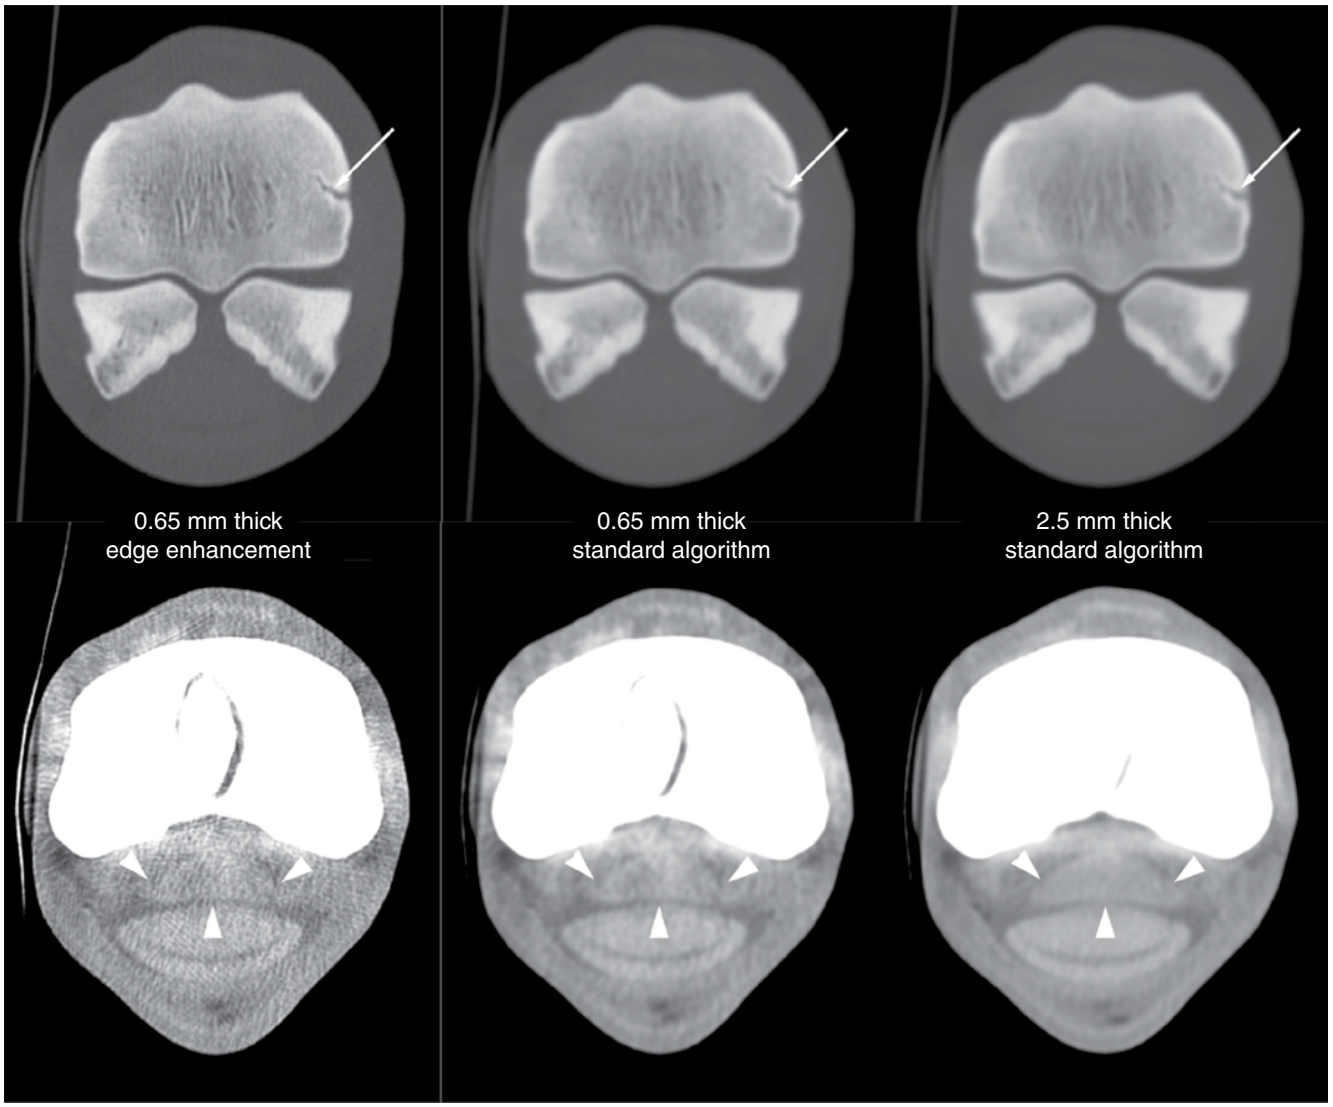

Figure 3.194. Effect of slice thickness, algorithm, and window on CT image appearance.Transverse CT images through the distal third metacarpal bone (top row) and the proximal aspect of the proximal phalanx (bottom row). The top row is displayed in a bone window (window level [WL] 600, window width [WW] 2,600) and the bottom row in a soft tissue window (WL 40, WW 350). Notice how bone detail can be appreciated in the top row, whereas the bone appears uniformly white on the bottom row. Inversely tendons and ligaments can be appreciated in the bottom row but appear uniformly gray on the top row. All the images were acquired at the same time but were reconstructed with different slice thickness and algorithms as displayed in the figure. The 0.65-mm-thick slice with edge enhancement is best at depicting fine bone detail such as small vascular canal (arrow, top left). The ligamentous structures are best defined using a 2.5-mm-thick slice with a standard algorithm as illustrated by the appearance of the straight distal sesamoidean ligament (arrow heads) in the bottom right image.

conspicuous. This gives a sharper look to the image and facilitates the identification of fracture lines or small osteophytes.

The approach to soft tissue imaging is different. Although high spatial resolution and sharp edges generally seem appealing in terms of image quality, they come with the downside of creating a "noisy" image. Signal-to-noise ratio is an important characteristic of an image. It corresponds to the amount of information in a specific voxel that relates to the actual property of the tissue versus the amount of information that is randomly generated. In a more practical way, in an image with a high signal-to-noise ratio, pixel representing the same tissue will display the same shade of gray. However, if the signal-to-noise ratio is low ("noisy image"), two pixels representing the same tissue might display a different shade of gray. This leads to a heterogeneous, grainy image, and subtle changes in signal intensity cannot be recognized. For bone imaging, the key is the high spatial resolution to identify small changes at the surface of the bone, and the lower signal-to-noise ratio is not an issue as a lot of natural contrast is present in the image to define the margins of the bone. For soft tissue imaging, however, the emphasis needs to be placed on contrast resolution, rather than spatial resolution. The difference between normal and abnormal tissues results in only a slight difference in attenuation of the X-rays. It is important to decrease the noise to be able to recognize these. A standard or "soft" algorithm will avoid the noise created by the edge enhancement. Also using a larger slice

VetBooks.ir

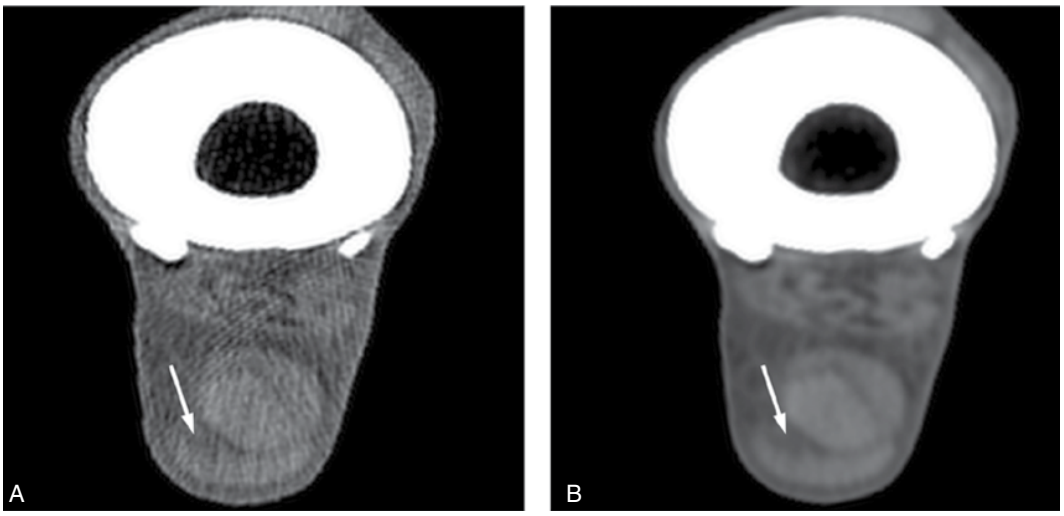

Figure 3.195. Effect of algorithm and slice thickness on lesion detection.Transverse CT images through the mid-level of the left metacarpus of a 15-year-old Warmblood gelding. Medial is to the left. Both images are displayed in a soft tissue window (WL 100, WW 300). The image on the left was reconstructed as 0.65-mm-thick slice with edge enhancement, whereas the image on the right has a 2.5-mm thickness and a standard algorithm. Notice the difference in visualization of a lesion at the dorsomedial border of the superficial digital flexor tendon (arrow). The noise present in the image on the left compromises the recognition of the lesion.

thickness leads to a larger voxel, which also improves the signal-to-noise ratio. Our preferred image technique for tendon assessment is a 2.5 mm thick in a standard algorithm (Figures 3.194 and 3.195).

These specific details of image acquisition suggest that different images are needed to assess both bone and soft tissue. The good news however is that a lot of these differences are part of the "post-processing" of the images. This means that different images can be obtained from a single acquisition, avoiding the need to perform multiple scans and decreasing radiation exposure. The reconstruction algorithm can be modified post acquisition. Multislice CT scanners also allow modification of the slice thickness post acquisition.

In addition to the acquisition parameters, understanding the viewing parameters, mainly the "window," is important. Each pixel in the image is attributed a CT value measured in Hounsfield units (HU). CT scanners are calibrated so that pure water has a HU equal to 0. Soft tissue structures typically range between 30 and 100 HU, fat is negative (from –300 to –20), air is about –1,000, and bone varies from 300 to 2000. When the image is displayed on a viewing device, the operator can choose how the gray scale of the viewing device will represent the different HU. An option can be to display the entire range, with the lower HU being attributed the darker shade of gray and the higher HU the lighter one; however in this configuration, tissues with close HU values will not be distinguished from each other. It can be advantageous to choose to spread the gray scale over a limited part of the range of HU. This is where the concept of "window" comes into play. A window is defined by a width and a level expressed in HU. If one is interested in assessing the soft tissue, since the HU of interest will be limited to a short range in the lower positive values, a classic window would have a level of 40 and a width of 350. This means that the gray scale will be spread between HU values of –135 and +215 (40 – 350/2; 40 + 350/2). Any HU lower than –135 will show up as black; any HU higher than +215 will appear white. The advantage of this window is that an HU of 0 will have a shade of gray visibly different than an HU of 50. On the other hand, in order to look at bone structures, where a large range of high HU exist, there is a need to use a higher level and a larger width. A level of 600 with a width of 2,600 is a good example. In this scenario however, a difference of 50 HU might not be visible (Figure 3.194).

CT images can simply be displayed the way they are acquired, as transverse images through the body area being imaged, but most viewing software applications offer the ability to reformat the images in different planes. The multiplanar reformatting tool (MPR) typically offers the ability to navigate the data set in three orthogonal planes (Figure 3.196). This is a very useful display format to understand the 3D appearance of lesions. 3D volume rendering is another technique that can be useful for 3D assessment of osseous structures. It is a popular viewing system for surgical planning of complex fracture repair (Figure 3.196). 3D rendering is however of limited value for soft tissue imaging due to the need for high contrast between the different structures for proper 3D visualization.

CLINICAL USE OF CT IN EQUINE ORTHOPEDIC IMAGING

Classic examples of using CT for equine orthopedic work are imaging of complex fractures for surgical planning (Figure 3.196) This is used most commonly for fractures of the phalanges and cuboidal carpal or tarsal bones. Many other clinical scenarios can also benefit from the use of CT, as CT has been shown to identify findings not detected on radiographs.[3] For example, non-displaced fractures of the central tarsal bone can be quite challenging to recognize radiographically but are usually quite evident with CT[8,13] (Figure 3.197).

VetBooks.ir

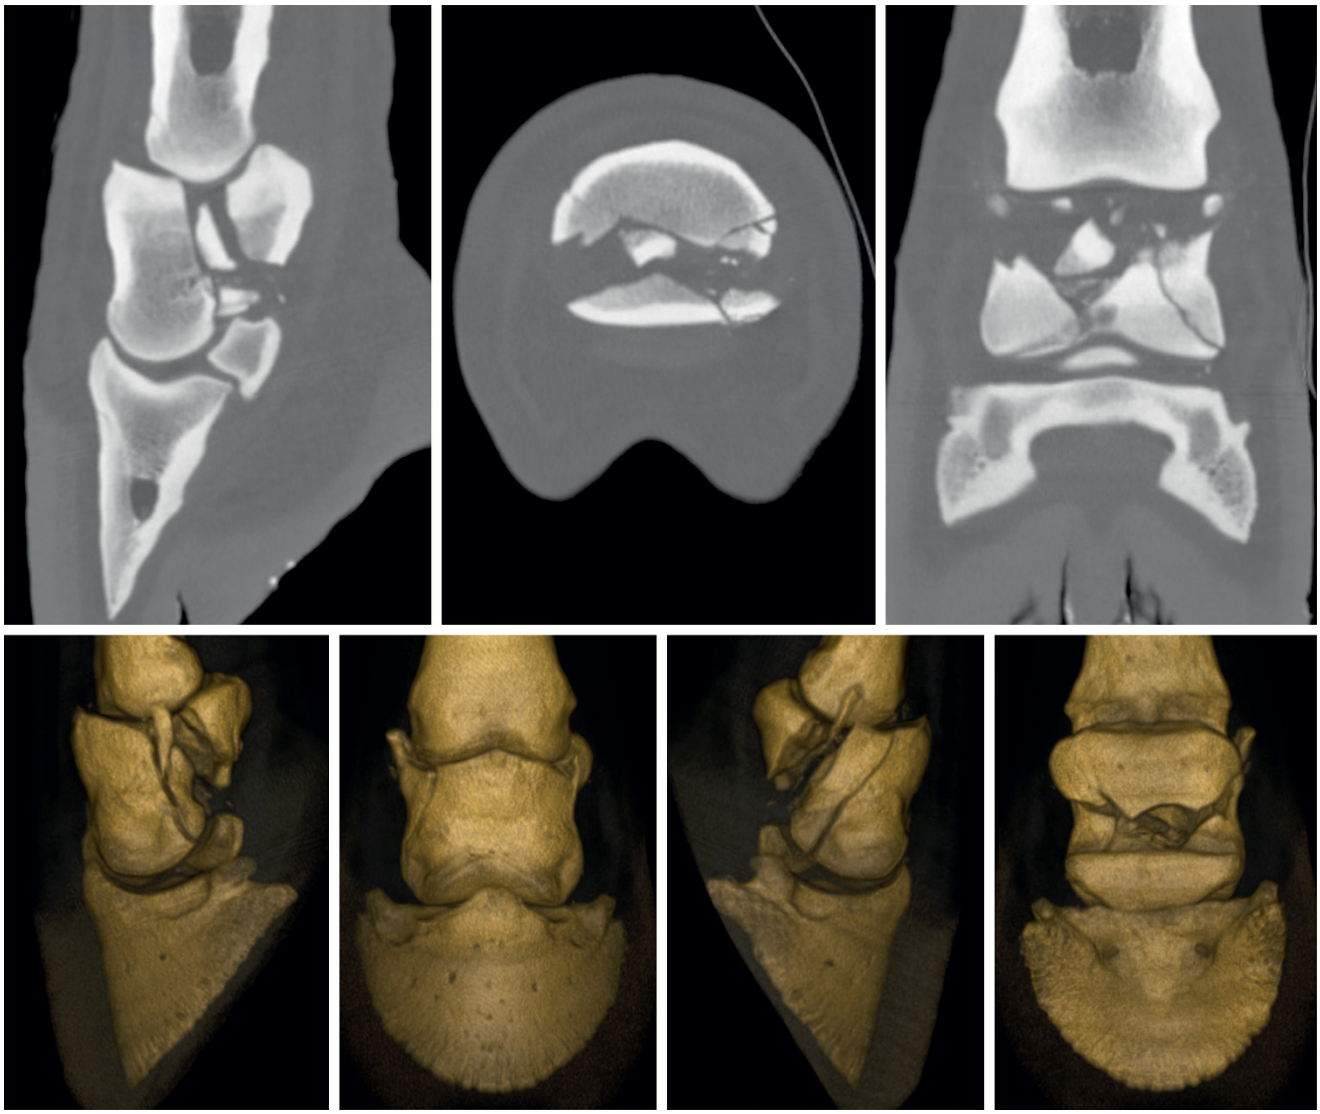

Figure 3.196. MPR and 3D rendering of a middle phalanx fracture.CT images of the left hind pastern of a 5-year-old Warmblood gelding with a complex, comminuted fracture of the middle phalanx. The top row presents multiplanar reformatted images displayed in the sagittal (left), transverse (center), and dorsal plane (right). This display provides the best assessment of the position of the different fragments. The bottom row displays four different projections of three-dimensional (3D) rendering. The 3D rendering has the advantage to provide a similar visualization to what would be seen during surgery. The information about the internal configuration of the fracture is however lost in this display.

CT is also particularly convenient to image complex structures where several abnormalities might be present concurrently such as in the foot[23,24,26] or the suspensory ligament origin.[15] In addition to providing improved assessment of the navicular bone when compared with radiographs, CT allows detection of lesions at ligamentous attachments such as the collateral ligaments of the distal interphalangeal (DIP) joint or the distal sesamoidean impair ligament, as well as assessment of the subchondral bone, the hoof wall, and the soft tissue including the tendons (Figure 3.198).

CT is also quite useful for assessment of the hoof and related structures. Keratinized structures are difficult to appreciate on MRI as they present a hypointense signal similar to the surrounding air, whereas on CT, the keratin is hyperattenuating to the soft tissue, leading to excellent visualization of the hoof wall. For this reason, CT is the imaging technique of choice for surgical planning for resection of keratomas (Figure 4.58).[12] Keratomas have a typical heterogeneous hyperattenuating appearance, and their connection with the hoof wall can be well appreciated. CT can be used for guidance to mark the localization of the keratoma on the hoof wall, in order to optimize the size and localization of the hoof wall resection (Figure 4.59).

Joint assessment is another area where CT can be quite useful. CT is excellent at assessing the subchondral bone and is beneficial in recognizing and characterizing subchondral resorptive lesions, for example, in the sagittal groove of the proximal aspect of the proximal phalanx, and other cyst-like lesions[10] (Figure 3.199). The classic radiographic findings of osteoarthritis, including

VetBooks.ir

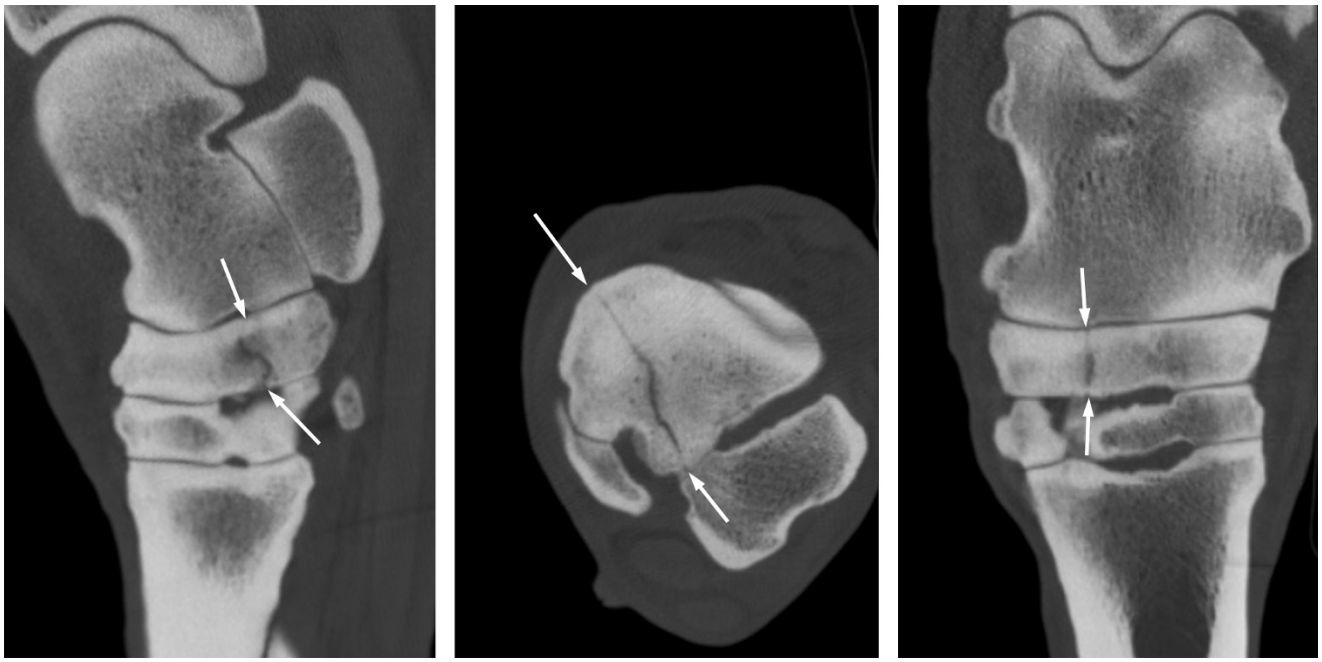

Figure 3.197. MPR of a non-displaced central tarsal bone fracture.Multiplanar reformatted CT images of the left tarsus of a 7-year-old Warmblood. A well-defined radiolucent fracture line is seen through the central tarsal bone, extending from the proximal to the distal articular surface, with a dorsomedial to plantarolateral orientation. (Arrows) Sclerosis is also recognized at the dorsomedial aspect of the central tarsal bone. This type of fracture is typically difficult to recognize on radiographs, and CT is often key in their characterization.

periarticular osteophytes, bone sclerosis, and joint space narrowing, can be also be clearly detected on CT with a better accuracy than with radiographs[18] (Figure 3.200).

The caudal cervical area has been recognized as a site that can be responsible for front limb lameness that can be difficult to localize. Although CT availability to image this area remains limited, a few reports have demonstrated its potential feasibility. It is likely that CT will play a major role in imaging of the caudal cervical spine in the future, due to the lack specificity of radiographic findings of this area.

CONTRAST-ENHANCED CT

Iodinated contrast material is commonly used in CT, either to detect lesions that were not identified without contrast or to gain additional information, especially regarding staging (acute vs. chronic) of lesions identified precontrast. Contrast can either be administered intravascular or intrasynovial depending on the indication. Due to the large dose that would be needed to perform systemic contrast administration (typically 500–1,000 mL), a peripheral arterial injection technique has been developed.[4] This technique has been used for assessment of tendon and ligament lesions, evaluation of local inflammation or sepsis, and evaluation of limb perfusion in horses with laminitis. Intrasynovial administration of contrast not only is used for joints (arthrography) to assess the cartilage for defects or thinning but also can be performed in a tendon sheath and bursa (bursogram) to detect superficial irregularities of tendons. Other indications for intrasynovial administration is to assess intra-articular ligaments (mostly in the carpus and stifle) and to evaluate synovial involvement of a wound or foreign body penetration.

CT Angiography

An arterial catheter is needed for contrast administration.[19] The technique was initially described with placing an 18-gauge catheter in the medial digital palmar artery just distal to the carpus using ultrasound guidance. Due to occasional poor perfusion of the lateral aspect of the foot using this approach, catheterization of the median artery at the distal antebrachium is now usually preferred.[9] The iodinated contrast medium, diluted 1 : 1, is injected using a power injector, starting a few seconds before imaging and continuing at a rate of 2 mL/s during the image acquisition.[19] Typically 60 mL of contrast is sufficient to cover the entire acquisition time.

Normal tendons and ligaments enhance mildly with an increased in HU of 10–20 compared with the precontrast images.[19] A few specific areas are known to have normal higher enhancement due to physiologic higher blood supply, such as the DDFT at the distal aspect of the metacarpus. Abnormal enhancement has been described using different patterns: central–peripheral, diffuse, or neovascularization[9,24] (Figure 3.201). The presence and type of enhancement is useful in characterizing the type and the chronicity of the lesion. Lack of enhancement suggests chronicity to a lesion. Peripheral enhancement is associated with central necrosis and lack of tissue repair.[9]

In cases of abscesses or penetration of foreign bodies ("street nail"), contrast-enhanced CT can be helpful in identifying focal inflammation helping to recognize penetrating or draining tracts and to assess for synovial involvement (Figure 3.202).

VetBooks.ir

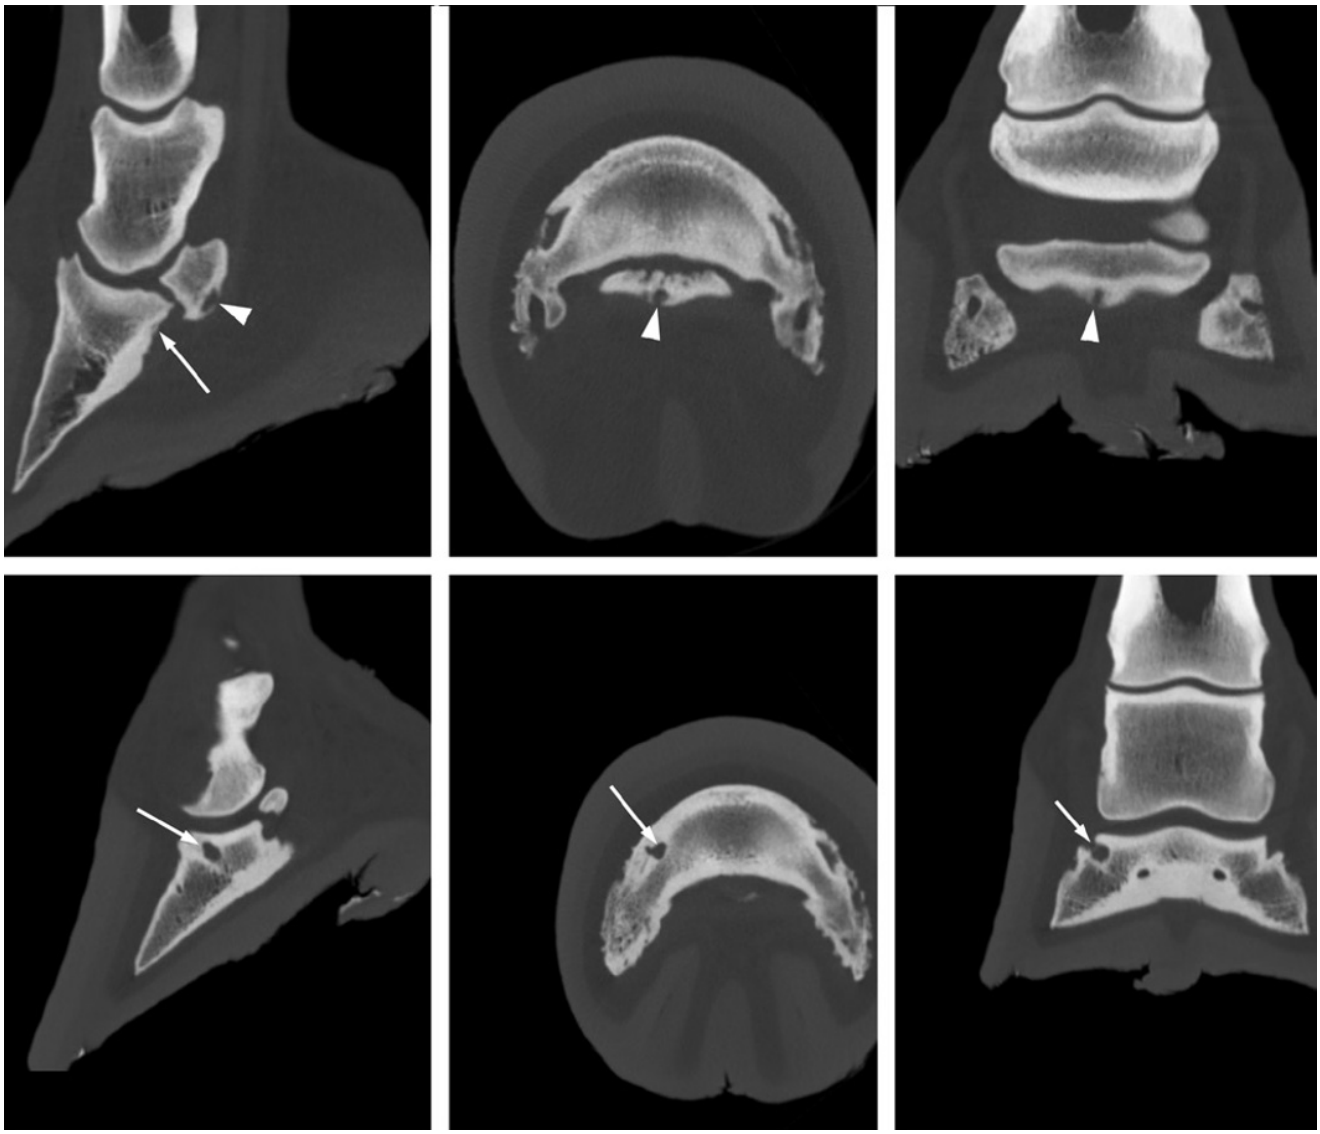

Figure 3.198. MPR of a front foot of a horse with chronic lameness.Multiplanar reformatted CT images of the right front foot of an 18-year-old Tennessee Walking horse with chronic right front lameness localized to the foot. Lateral is to the right. Multiple abnormalities are identified. There is focal osseous resorption of the central distal aspect of the flexor cortex of the navicular bone (arrow heads). Irregular contour of the flexor surface of the distal phalanx is present at the site of attachment of the distal sesamoidean impar ligament (top row, arrow). Focal osseous resorption is also identified at the attachment of the lateral collateral ligament of the DIP joint on the distal phalanx (bottom row, arrows).

CT angiography has also been used to evaluate the perfusion of the hoof wall in cases of laminitis.[14] In severe chronic cases, areas of ischemia and necrosis can be identified. In the acute phase, increased permeability of the capillary vessels can be recognized with increased retention of iodinated contrast in the lamina.

CT Arthrography and Bursography

As for all synovial punctures, the site of injection needs to be aseptically prepared. Nonionic iodinated contrast is preferred to ionic iodinated contrast in synovial cavities as it results in lower inflammation of the synovium and less intrasynovial dilution.[2] Contrast medium should be diluted prior to injection to avoid streaking artifacts. A concentration of 100–150 mg of iodine per mL is most commonly used,[7,25] but further dilutions have also been used.[11] The volume obviously depends on the joint or synovial structure injected. Adequate distension should be obtained. For examples, 20 mL has been used for the metacarpophalangeal joint,[11,17] 12 mL for the middle carpal joint and antebrachiocarpal joint,[7] 60 mL for the lateral and medial femorotibial joints,[25] and 80 mL for the femoropatellar joint.[25]

Cartilage surface irregularities, focal cartilage defects, or cartilage thinning can be appreciated with CT arthrography. The spatial resolution of the images will be key in the detection of focal defects. Differences in spatial resolution can explain the discrepancy in the literature regarding the ability of contrast CT to detect cartilage defects. Older studies using lower spatial resolution concluded a lack of sensitivity of the CT arthrography to

VetBooks.ir

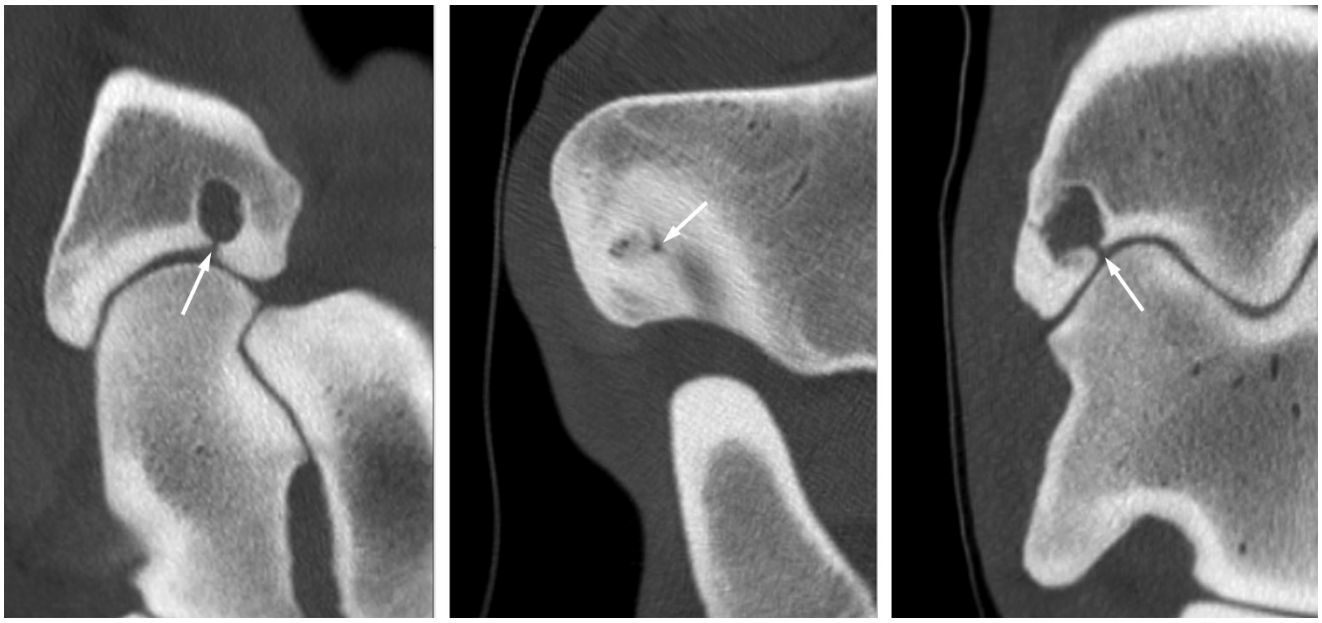

Figure 3.199. MPR of a cyst-like lesion of the distal tibia.Multiplanar reformatted CT images of the right tarsus of an 11-year-old Warmblood. There is a well-defined round lucent area in the lateral distal aspect of the tibia, with a minimal rim of sclerosis and a narrow communication with the joint through the abaxial subchondral bone of the lateral cochlear groove (arrow). CT is the ideal modality to fully characterize the configuration of such a lesion.

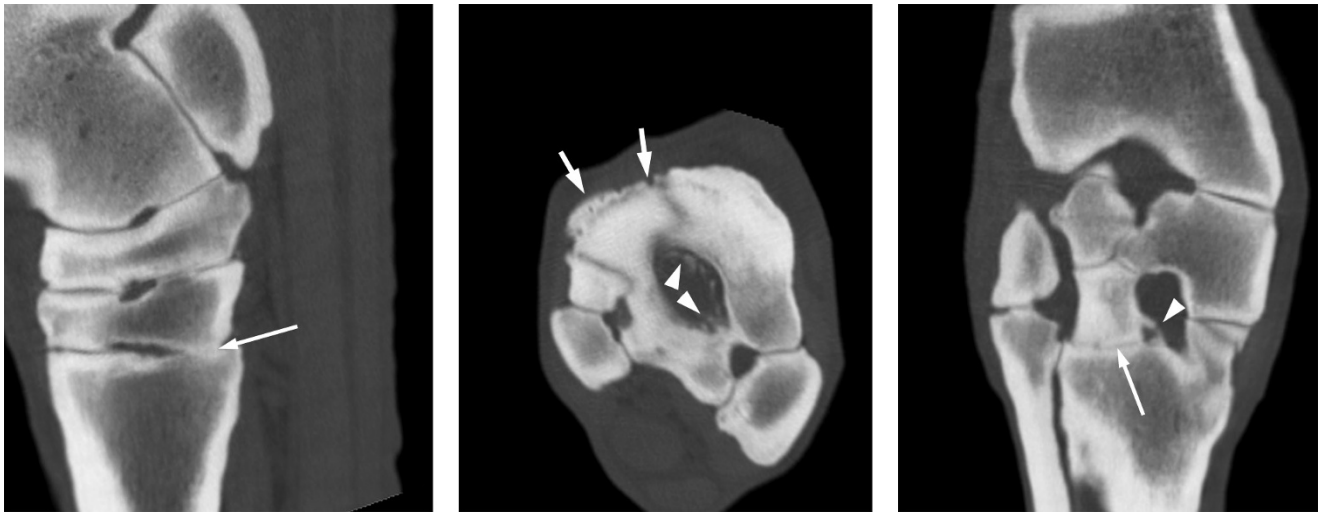

Figure 3.200. CT MPR of osteoarthritis of the tarsometatarsal joint.Multiplanar reformatted CT images of the left tarsus of an 8-year-old Quarter Horse gelding. Medial is to the left. There is marked narrowing of the plantar joint space of the tarsometatarsal joint (arrow), with adjacent sclerosis of the subchondral bone. There is periarticular osteoproliferation at the dorsomedial aspect of the proximal third metatarsal bone. There is enthesophytosis of the intertarsal ligament attachments on the third tarsal and metatarsal bones (arrowheads). CT allows a very specific characterization of the findings associated with osteoarthritis of the tarsometatarsal joint.

detect cartilage defects,[17] whereas recent studies with higher spatial resolution (voxel size 0.2 × 0.2 × 0.3 mm) found an 82% sensitivity.[11] This latter study actually demonstrated that the sensitivity for identification of cartilage defects with CT arthrography (82%) was higher than the sensitivity using a 3T MRI system (41%). This can be attributed to the difference in spatial resolution between the two systems (3T MRI, 0.4-mm pixel; CT, 0.2-mm pixel).[11] With high-resolution images, the use of multiplanar reformatting is very helpful in identifying cartilage abnormalities (Figure 3.203).

CT arthrography of the carpus allows assessment of the intercarpal ligaments, particularly the lateral and medial palmar intercarpal ligaments.[7] CT imaging of the stifle remains limited due to size considerations, and typically larger gantries are needed. CT stifle arthrography has shown promising results for the evaluation of the cruciate ligaments.[5,16,25] Superficial lesions of the

VetBooks.ir

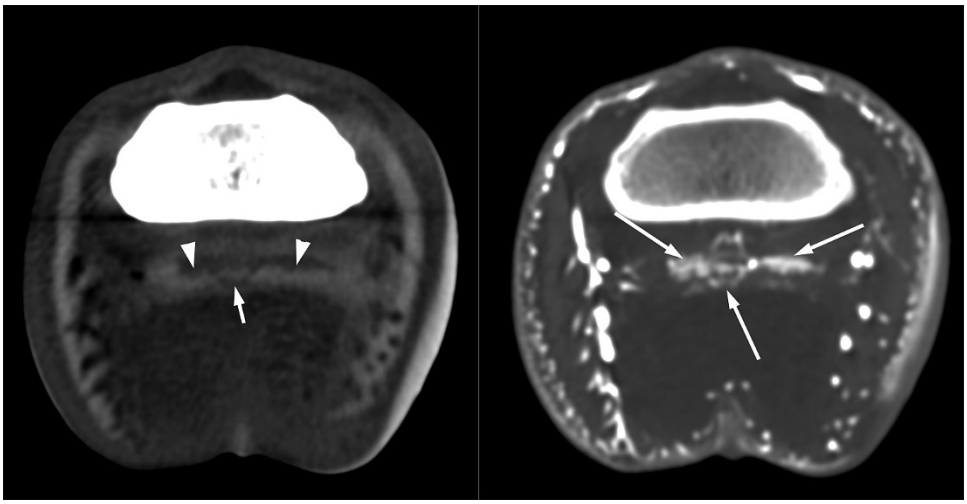

Figure 3.201. Deep digital flexor tendon lesion with arterial contrast enhancement. Transverse pre-contrast (left) and post-arterial contrast (right) CT images through the middle phalanx of a 22-year-old Quarter Horse mare. There is irregularity of the dorsal margin of the DDFT in the navicular bursa (arrow heads). A focal hypoattenuating area is present in the central palmar aspect of the tendon. (Short arrow) All these areas demonstrate marked contrast enhancement (arrows), suggesting the presence of active lesions.

deep and superficial digital flexor tendons can also be better characterized with injection of contrast within the digital sheath.[1] Navicular bursograms have been used to identify dorsal fibrillation of the DDFT or adhesion to the navicular bone.

Similarly to what is more commonly done with radiography, distension of a synovial structure with iodinated contrast medium to assess for communication of a wound or penetrating injury can be performed with CT. This increases the sensitivity of the procedure and often improves the characterization of penetrating or draining tracts. This is of particular value with penetrating injuries of the foot with suspicion of involvement of the navicular bursa.

POSITRON EMISSION TOMOGRAPHY

A recent interesting addition to CT is the development of equine positron emission tomography (PET). PET is a cross-sectional nuclear medicine imaging technique. In a way PET is to scintigraphy, what CT is to radiography. It provides similar type of information but resolves the issue of superposition. PET also has the advantage of having higher spatial resolution than scintigraphy. Several PET tracers can be used, providing information not only about bone lesions but also soft tissue lesions. PET presents functional information but does not include anatomical detail. For this reason, PET is usually combined with CT. The PET data can be fused with the CT images to demonstrate the presence of active lesions. The first equine PET scan was performed in 2015 using a portable compact PET scanner designed to image the human brain.[20]

Currently the main equine PET application is the use of the 18F-sodium fluoride (18F-NaF) radiotracer to detect areas of bone remodeling. 18F-NaF gets integrated into the hydroxyapatite matrix of bone at sites of bone turnover. This was shown useful to detect enthesiopathy or early subchondral remodeling that was not recognized with CT or MRI[21] (Figure 3.204). Also, when chronic osseous lesions are detected with CT, the presence or absence of 18F-NaF uptake allows to differentiate between active and inactive processes. 18F-NaF PET was shown particularly helpful in a Thoroughbred racehorse population to detect early stress remodeling with a higher sensitivity than all other imaging modalities. In particular PET detected focal 18F-NaF uptake in the proximal sesamoid bones of racehorses in training at sites known for catastrophic breakdown.[22] PET has the potential to become a useful tool in the prevention of catastrophic injuries.

18F-Fluorodeoxyglucose (18F-FDG) is another PET tracer commonly used in oncology imaging. 18F-FDG not only is a radioactive glucose and is not specific of neoplastic disease but also can be used to image inflammation. Limited information is currently available about 18F-FDG PET in the horse, but an exploratory study demonstrated values of the technique for assessment of tendon injuries and for laminitis research.[20] 18F-FDG leads to distinction between active and inactive tendon lesions,[6] which is of particular interest for follow-up on tendon healing and for assessment of chronic lesions (Figure 3.205). Similarly, PET could become a useful research tool in horses with laminitis to quantify and monitor the level of inflammation present in the lamina.

CONCLUSION

CT is not as commonly used as MRI for equine musculoskeletal imaging, but its role should not be overlooked. MRI tends to be preferred due to its ability to image both bone and soft tissue, but with proper understanding of CT technique and use of iodinated contrast

Articular cartilage defect of the distal interphalangeal joint.Multiplanar reformatted CT images of the left front foot of a 10-year-old Warmblood gelding, post-intra-articular injection of iodinated contrast material in the DIP joint. Medial is to the left. There is evidence of focal extension of the contrast material within the region of the medial articular cartilage of both the middle and distal phalanges, suggesting the presence of cartilage defects (arrows). This lesion could not be recognized with the realization of the arthrogram.

agent, pertinent soft tissue information can be obtained with CT. The comparison of the two modalities regarding bone imaging is interesting: CT has been classically considered the ideal technique for bone imaging with high contrast obtained from mineralized tissue and high spatial resolution available. However, CT suffered from the limitation of not being able to recognize acute "bone edema"-type lesions identified with MRI. The introduction

VetBooks.ir

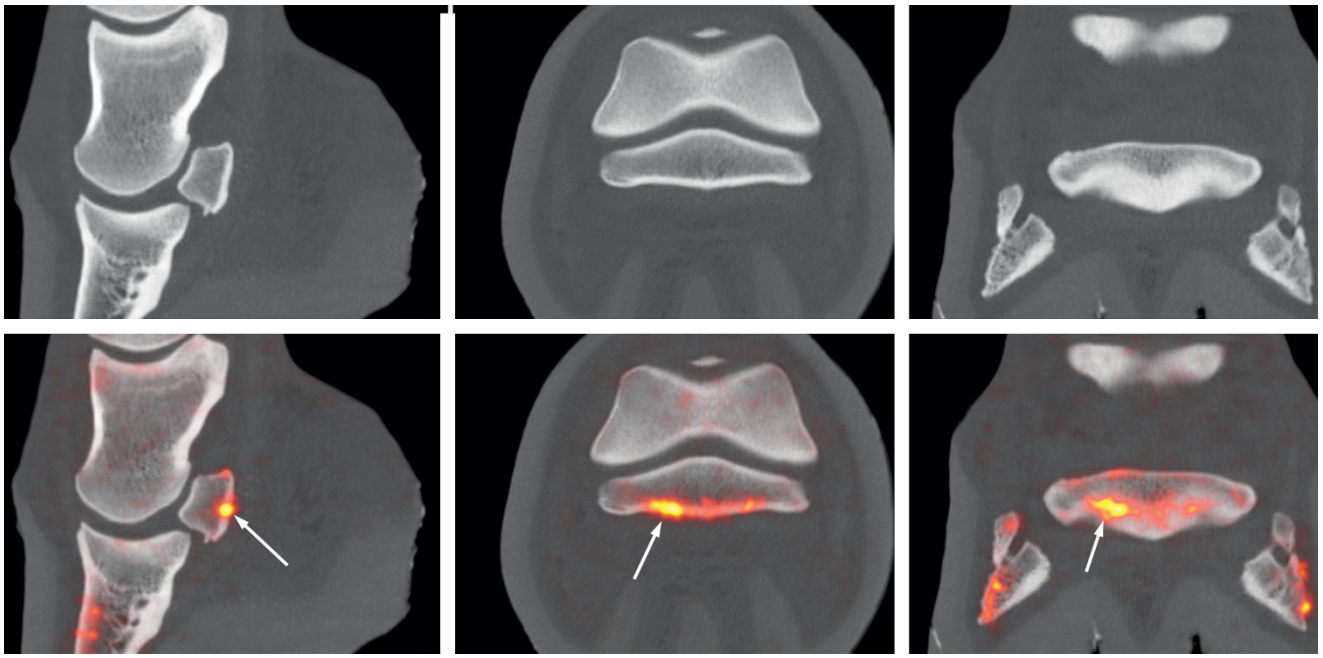

Figure 3.204. 18F-NaF PET CT of mild navicular remodeling.Multiplanar reformatted CT (top) and fused 18F-NaF PET/CT (bottom) images of the left front foot of a 10-year-old Warmblood with lameness localized to the foot. Medial is to the left. There are no significant abnormalities of the navicular bone on the CT images, but the PET demonstrates marked focal uptake of the flexor cortex of the navicular bone, worse medially. (Arrow) This indicates early remodeling of the navicular bone.

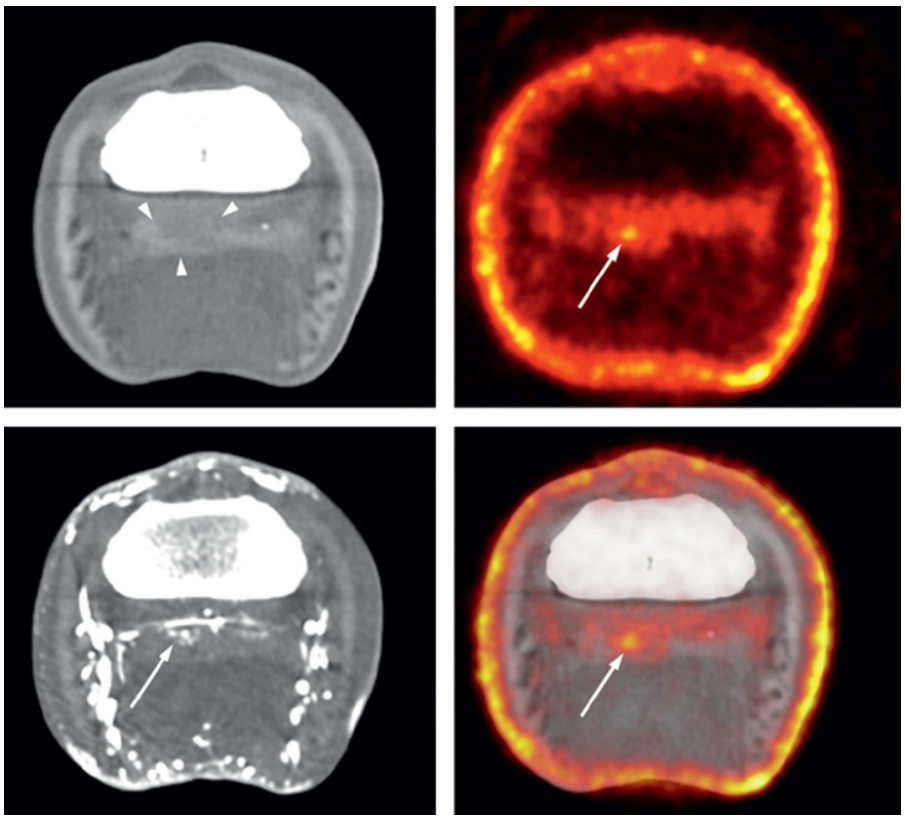

Figure 3.205. Deep digital flexor tendon lesion imaged with 18F-FDG PET/CT.Transverse CT (top left), 18F-FDG PET (top right), arterial contrast CT (bottom left), and fused PET/CT (bottom right) images of the right front foot of a 22-year-old Quarter Horse mare through the middle phalanx. Lateral is to the left. The lateral lobe of the DDFT appears enlarged with irregular margin on the pre-contrast CT (arrowheads). There is marked focal 18F-FDG uptake of the lateral lobe of the tendon (upper right arrow). Arterial contrast enhancement is also present on CT. Note that on arterial contrast CT, both the lesions and adjacent vessels demonstrate enhancement(lower left arrow), whereas on the PET images only the lesion shows increased uptake (lower right arrow).

VetBooks.ir

of 18F-NaF PET to equine imaging provides an opportunity to combine the excellent bone structural representation of CT with very sensitive information regarding acute bone changes. The combination of CT with PET potentially makes it the ideal technique for bone imaging.

CT also has a clear advantage over MRI residing in the speed of acquisition, allowing imaging of larger areas. For example, it is possible to image from the carpus to the distal extremity with CT in a couple of minutes. Imaging this same area MRI would take hours and require multiple studies. The ability to image the distal limb standing has been an important factor to the development of equine MRI. As a few CT concepts now suggest that standing CT imaging might become more widely available, it is possible that the use of CT in the years to come will be drastically changed by technology evolution.

MAGNETIC RESONANCE IMAGING

Michael Schramme and Emilie Segard-Weisse

INTRODUCTION

Magnetic resonance imaging (MRI) is a multiplanar cross-sectional imaging modality that uses the inherent magnetic properties of tissue and is fast becoming the gold standard for diagnosis of musculoskeletal injury of the distal limb in horses. MRI allows soft tissue and bone structures to be evaluated in ways not possible with other imaging modalities. The information obtained is based on the structure and biochemical environment of hydrogen atoms in the tissues.

Because of its unique mode of image acquisition and construction, it is important to understand the factors that influence the MR signal characteristics that produce the diagnostic images and to learn the strengths and weaknesses of the technique. The clinician must understand the basic physics and the basic sequences used for acquisition in order to comprehend the relationship between signal abnormalities and pathology and distinguish between signal abnormality and artifact and between signal change and normal anatomical variation. The increasing use of MRI in equine sport medicine requires every equine practitioner to have a basic knowledge of MRI interpretation. The importance of correlating the MRI findings with results of the clinical examination, diagnostic analgesia, and other imaging modalities, in order to determine the clinical significance of each suspected lesion, cannot be overstated.

Accurate knowledge of the advantages and disadvantages of MRI helps the clinician to make the correct imaging choices for the benefit of patients and clients. MRI is not a substitute for in-depth clinical investigation and conventional imaging techniques, and many diagnoses can continue to be made without MRI. Nonetheless, the use of MRI has highlighted the limitations of both radiography for imaging bone and ultrasonography for imaging soft tissue lesions. MRI has proven to be particularly helpful in patients in which the lameness has been localized to a certain area of the distal limb, but radiography and ultrasonography do not show an abnormality that explains lameness in a satisfactory manner.

GENERAL PRINCIPLES AND PHYSICS OF MRI

The generation of an MR image is based on the movement of hydrogen atoms generating a measurable electrical current in the body. MRI produces a grayscale image of tissue hydrogen protons by placing them in a strong magnetic field, exposing them to a radiofrequency (RF) pulse and measuring the magnetic resonance caused in the tissues in response to this pulse. A computer interprets the data and creates images that display the different resonance characteristics of different tissue types on a gray scale.

The resonance that is measured originates from the magnetic properties of the positively charged proton in the nuclei of hydrogen atoms in biological tissues. When exposed to a short RF pulse specific for hydrogen, which is emitted by the RF coil, hydrogen nuclei absorb this pulse and change their alignment within the main magnetic field. Following discontinuation of the RF pulse, the hydrogen nuclei resume their previous orientation of parallel alignment with the main magnetic field, thereby transitioning from a high-energy to a low-energy state. This transition results in energy release that is used to generate an electrical signal. The exchange of energy between different spin states is called the resonance and thus the name MRI. The time required for the hydrogen nuclei to resume equilibrium within the main magnetic field is the relaxation time, measured in milliseconds. The relaxation of hydrogen nuclei can be divided into two separate components, the longitudinal (T1) and transverse relaxations (T2). T2 is much shorter than T1. Most tissues can be characterized by their T1 and T2 signal properties. Protons are present in different densities and with different T1 and T2 properties between different tissues, thereby producing contrast differences between tissues on MR images. The degree to which the hydrogen protons are bound within a tissue determines their relaxation time. Protons in fluid or fat return to alignment quickly, whereas those in organized tendinous, ligamentous, or osseous tissue return slowly.

As fat and water both contain a large amount of mobile hydrogen atoms, the strength of the resonance signal also depends on the amount of fat and water in the tissue. High signal areas are white, and low-signal areas are black.

EQUIPMENT, HIGH- AND LOW-FIELD MAGNETS, AND RF COILS

The basic components of MR imaging are an RF shielded room, a body with mobile protons, a magnet generating a strong magnetic field, an RF coil to add energy to the protons to make them move, a receiver coil to collect the electrical signal generated by the moving protons, and a computer with acquisition software to time these events and generate an image from the electrical signals.

Magnetic field strength is expressed in tesla units. One tesla (T) is approximately 20,000 times the strength of the earth's magnetic field. High-strength magnetic fields measure in excess of 1T, low-strength fields less than 0.5T, and mid-strength fields between 0.5 and 1T. Superconducting, closed, cylindrical bore magnets (Figure 3.206) generate high-strength magnetic fields, while resistive or permanent, open magnets (Figure 3.207) produce low-strength fields. Signal strength is proportional to the strength of the magnetic field. Consequently low-field systems generate less tissue signal, require longer acquisition times, and produce lower-resolution images. The uniformity or homogeneity of the main magnetic field is higher in closed than in open magnets.

Figure 3.206. A Siemens Magnetom Skyra 3T high-field magnet (Siemens, Malvern, PA) used for MRI of horses under general anesthesia. The horse is positioned in lateral recumbency with the lame limb lowermost. The region of interest in the limb, in this case the foot, is positioned in the isocenter of the magnet.

Figure 3.207. The Hallmarq Equine Limbscanner® (Hallmarq Veterinary Imaging, Guilford, UK) is an open, low-field magnet, mounted vertically at floor level and allows MRI to be performed on standing, sedated horses. *Source*: ©GuildfordPhotographer, courtesy of Hallmarq Veterinary Imaging.

Image quality and resolution increase with increasing magnetic field strength and increasing field homogeneity. Both high-field and low-field MRI systems are currently in clinical use for horses.

Though 1.5 T is still considered the standard for high-field imaging of horses (Figure 3.206), short bore 3.0 T magnets with large bore size (70 cm) and flared ends are now available for clinical imaging, some even reaching up to and including the stifle region. The area of the limb to be imaged must be positioned in or near the isocenter of the cylindrical bore of the magnet, which lies at the intersection of all three gradient coils and is

VetBooks.ir

Figure 3.208. The G-Scan Vet® (Universal Medical Systems, Inc. Solon, OH) is an open, 0.25-T low-field magnet that can be rotated from a horizontal to a vertical position to accommodate imaging of the horse's head, neck, and stifle more easily. *Source:* Courtesy of Dr. Martin Waselau.

the optimal position for imaging. This requires the horse to be recumbent and therefore under general anesthesia, which increases the cost and the risk of the procedure. Although high-field magnets are generally capable of imaging limbs of horses from the carpus and tarsus distally, this capability is limited by how far the horse can be pulled into the bore of the magnet. Therefore, not all high-field magnets are equal in this respect. Positioning in isocenter is more difficult in longer and narrower cylindrical bores than in some short bore magnets with flared ends. In addition, some high-field magnets have a much tighter imaging window around the isocenter than others, which makes it harder to pull areas of interest further proximal than the fetlock region into the imaging window.

Low-field MRI of horses is currently performed with permanent, open magnets with a field strength ranging from 0.20 to 0.31T. One open, low-field MRI scanner designed specifically for imaging distal limbs of standing, sedated horses (EQ2 – Hallmarq Veterinary Imaging, Guilford, UK) is mounted vertically at floor level (Figure 3.207). However, imaging of areas proximal to the fetlock region is prone to motion artifact with these units. Other low-field magnets (O-Scan Equine®, Vet MR Grande®, and G-Scan Vet®, Universal Medical Systems, Inc. Solon, OH) are oriented horizontally on a pedestal and require horses to be placed under general anesthesia. The O-Scan Equine® is a small magnet with an opening of 18 × 34 cm that is self-shielded within its own RF shielding cage with an internal thermostatic control system and can be used in any nonspecialized room. The G-Scan Vet® can be rotated from a horizontal to a vertical position to more easily accommodate imaging of the horse's head, neck, and stifle (Figure 3.208).

Low-field magnets produce a lower signal-to-noise ratio resulting in reduced image resolution and detail. Although many lesions have a higher conspicuity on high-field images, several studies have shown that low-field magnets are capable of producing diagnostic quality images of the distal limb, metacarpus/metatarsus, carpus, tarsus, and stifle. However, a high-field system is required to identify certain structures and lesions, especially those related to articular cartilage.[173,188,193]

Horses undergoing MRI must have all metal and ferrous material removed to avoid interference with the magnetic field and generation of susceptibility artifacts. This includes shoes, nails, metallic debris in the nail holes and sole, and the occasional metallic implant. Other ferromagnetic materials such as horse support tables and anesthetic equipment may interfere with the homogeneity of the magnetic field and should be avoided in the RF-shielded MRI room.

SEQUENCES AND PROTOCOLS FOR EQUINE MRI

MRI examinations rely on the use of several different acquisition sequences.[184] Each sequence name describes the RF pulse applied, the weighting of that pulse, and the associated magnetic field gradients. Different sequences used in conjunction to image a given anatomical area define the imaging protocol. It is necessary to use several sequences in multiple image planes within a protocol in order to identify pathological conditions accurately. The common categories of conventional MRI sequences are spin echoes (SE), turbo spin echoes (TSEs), gradient recalled echoes (GRE) and short tau inversion recovery sequences (STIR). The difference between these MR sequences lies in the method and timing of how the RF signals are pulsed into the tissues and how the resonance is collected to generate an image.

Fast spin echo (FSE) or TSE sequences are used as a more practical alternative to SE to reduce acquisition times while maintaining signal-to-noise ratio. The purpose

VetBooks.ir

of GREs is to decrease acquisition times further and to allow three-dimensional (3D) volumetric acquisitions with thin slices. This is especially useful in standing MRI where motion artifacts and relatively low signal-to-noise ratio are of concern. However, the advantage of fast 3D acquisition of gradient echoes comes at the expense of disadvantages like decreased soft tissue contrast, increased susceptibility to magnetic field inhomogeneities, and susceptibility artifacts. Most current clinical protocols in horses use a mixture of FSE and GRE sequences.

As many lesions tend to have increased signal intensity on MR images while at the same time fat retains high signal intensity in all sequences, eliminating the high signal intensity from fat (fat suppression) markedly increases the ability of recognizing high signal intensity from a lesion on an MR image. Fat suppression can be achieved by inversion recovery (STIR) or by a process of fat saturation.

As a result of fat suppression, adipose tissue appears black instead of white, making fluid the only remaining source of high signal on a fat-suppressed image, amidst dark bone, soft tissues, and fat. Fat suppression is commonly used in orthopedic imaging for the detection of abnormal fluid in bone (e.g. the navicular bone).

Depending on whether T1 or T2 relaxation is measured during acquisition, sequences are called T1 weighted, T2 weighted, or proton density (PD) weighted (between both T1 and T2). T1 and T2 relaxation times have characteristic values for each type of tissue and can be used in combination to describe the magnetic properties of all tissues (Table 3.2) (Figure 3.209). PD images display any change in the density of protons as a change in signal intensity.

An imaging protocol or series of different sequences is typically grouped together to image a region of interest. Both high- and low-field musculoskeletal protocols typically include PD spin echo, T2-weighted FSE, short tau inversion recovery (STIR) FSE, and T1- and T2*-weighted 3D GRE sequences.

PD images are easiest to evaluate ligament and tendon margins and symmetry. T2-weighted images are useful for looking at fluid in soft tissues thanks to their high fluid contrast. However, T2-weighted images show minimal shades of gray resulting in poor definition of soft tissue margins. STIR images show fluid in bone and soft tissues most easily because of their high fluid contrast, but they have a low resolution. T2*-weighted or spoiled T1-weighted GRE sequences are used in 3D acquisitions for evaluation of the fine anatomical detail in thin tissue slices.

The choice of protocol is determined by the type of magnet (high or low field), the manufacturer's sequence library, the region under scrutiny, and the preference of the attending clinician. Consequently, protocols may differ between hospitals and clinicians. With an endless number of combinations of sequences, weightings, and section planes available, it is tempting to continue scanning every patient until the clinician feels all questions have been answered. However, this approach lacks consistency and may cause problems. Sequences and section planes should be standardized to allow for consistent comparison between limbs and between horses. Moreover, excessive scanning times and prolonged recumbence within a confined magnet space with limited padding can result in post-anesthetic complications. A routine high-field MRI examination takes approximately 60–90 minutes to complete.

For optimal assessment of an anatomical region, images are generally obtained in three orthogonal planes, sagittal, dorsal, and transverse. Sagittal images serve as anatomical reference images for transverse sections. Transverse images are most useful to the identification of pathology, and the presence of asymmetry between the medial and lateral halves of the images may help identify lesions. Dorsal images are useful for definition of joint space width and cartilage thickness and also serve as reference images for transverse section planes.

ARTIFACTS OF MRI

MRI produces a wide range of artifacts and variations that can confuse the interpreter. In addition, MRI is susceptible to artifacts that are created by acquisition of images at oblique angles. Even slightly asymmetric positioning of image slices can create significant problems of image interpretation. Consequently, MRI is an imaging technique that can easily lead the examiner to overinterpret images as well as miss lesions.

Artifacts can be classified as motion artifacts, magnetic field heterogeneity artifacts, and digital imaging artifacts.

Motion artifacts generally result in ghosting, which results from displaced reduplications of the image in the phase-encoding direction, or in marked blurring of the image. Swaying of a standing sedated horse results in blurring of images, which may render the entire sequence nondiagnostic. STIR sequences are worst affected by this type of motion artifact. Respiration and blood flow can cause multiple motion ghosting in anesthetized patients (Figure 3.210).

Artifacts from magnetic field inhomogeneity lead to image distortion or alterations in signal intensity and are more common in low-field than high-field magnets. Temperature fluctuations, the presence of ferrous metal, and even some wound sprays or frog packing materials like blue Play-Doh may create field inhomogeneities. Magnetic susceptibility artifacts are a form of field inhomogeneity artifact as they are caused by the presence of materials with different susceptibility to magnetization, like ferrous metals or iron in hemoglobin and hemosiderin in tissues (Figure 3.211).[181,186] GREs are particularly susceptible to these artifacts. Feet should be radiographed routinely prior to MRI to ensure that all metal fragments and debris have been removed from the hoof wall.[185]

Chemical shift artifacts are caused by the presence of fat and water adjacent to each other. Protons from water and fat have different precession frequencies that causes the position of fat signal to shift in the frequency-encoding direction of the image relative to the position of water signal. The shifting of fat signal to a different location can results in spatial misregistration. This artifact is

VetBooks.ir

Table 3.2. The signal intensity of different tissues in different contrast weightings.

Sequence	T2	T1	Proton density	Inversion recovery
Cortical bone	Black	Black	Black	Black
Cancellous bone	Light gray	Light gray	Light gray	Light gray
Cartilage	Dark gray	Light gray	Gray	Gray
Tendon	Black	Black	Black	Black
Ligament	Black	Gray to black	Black	Black
Fat	Light gray	White	White	Black
Fluid	White	Dark gray	Light gray	White

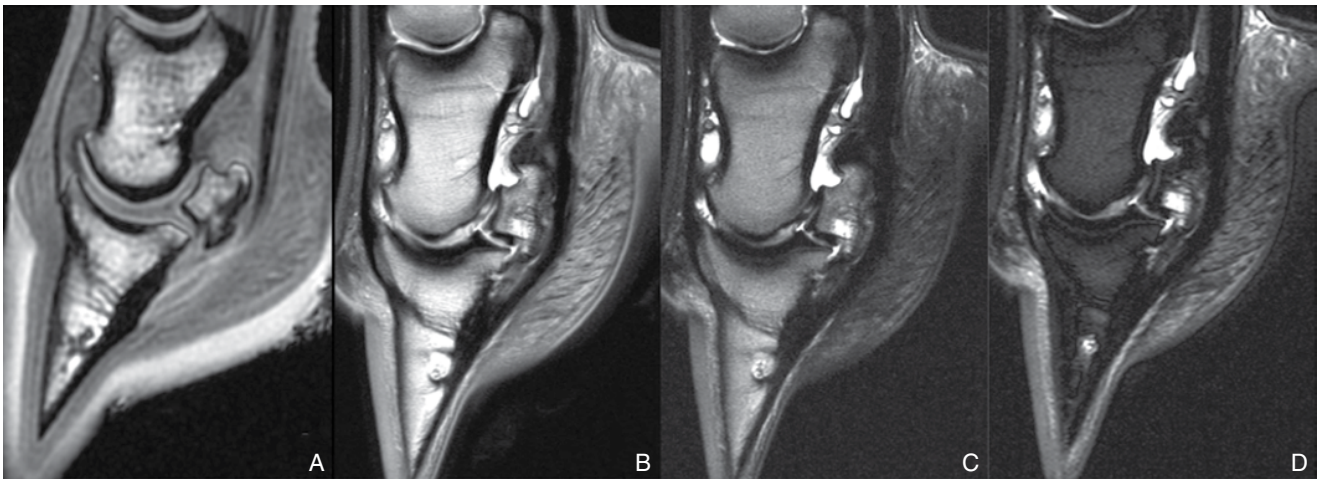

Figure 3.209. T1-weighted (A), proton density (B), T2-weighted (C), and short tau inversion recovery (STIR) sagittal images of the foot of a horse with navicular bone disease. Cortical bone, tendons, and ligaments are black on all sequences. On the T1-weighted image (A), fat is white, and fluid is dark gray. On the proton density image (B), fat is white, and fluid is light gray. On the T2-weighted image (C), fat and fluid are white. On the STIR image (D), fat is black, and fluid is white. In general, T1-weighted and PD images show anatomical detail well, while T2-weighted and inversion recovery images show less detail but have higher fluid contrast.

most obvious on high-field images. A specific fat/water phase cancelation artifact occurs in T2* images with echo time (TE) around 13 obtained with the Hallmarq MR system (Hallmarq Veterinary Imaging, Ltd. Guilford, UK).[189] In areas of medullary bone (e.g. in the navicular bone) with an equal amount of water and fat, signals from both fat and water cancel each other out and are replaced with an area of zero signal (black) in the medullary cavity of the affected bone. This can lead to an erroneous diagnosis of low signal in bone as sclerosis when it actually represents fluid.

Magic angle artifact causes a sudden increase in signal on T1, PD, and T2* sequences in tendons and ligaments where collagen is orientated at an angle of around 55° to the main magnetic field (Figure 3.212). This magic angle effect must be recognized as it can mimic lesions in tendons and ligaments. It is most obvious on high-field images of the distal part of the deep digital flexor tendon (DDFT) toward its insertion on the distal phalanx[31,176] or on low-field images of the lateral lobe of the DDFT where it courses palmar to the navicular bone.[177] Magic angle effect has also been described in low-field images of the superficial digital flexor tendon,[163] the oblique distal sesamoidean ligaments[171,172], and the collateral ligaments of the distal interphalangeal (DIP) joint.[74,171,178] The collateral ligaments of the DIP joint are also susceptible to magic angle artifact in high-field magnets, dependent on the orientation of the limb relative to the long axis of the bore of the magnet.[192,194] In a standing sedated horse with the limb abducted, the structures specifically at risk are the lateral collateral ligament of the DIP joint, the lateral lobe of the DDFT, and the medial oblique distal sesamoidean ligament. Magic angle artifact is particularly noticeable in sequences with a short TE (T1 and PD sequences) and is less evident on sequences with long TE (T2 images). Magic angle artifact can be reduced on T2-weighted images by increasing TE time.[194]

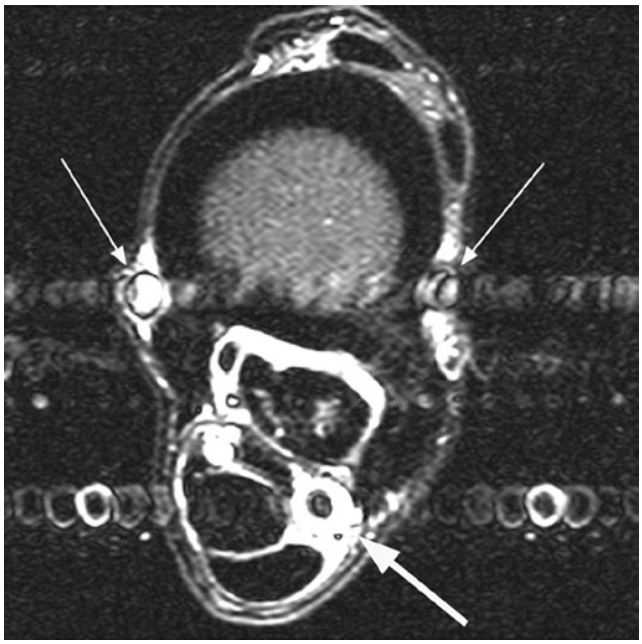

Figure 3.210. Transverse short tau inversion recovery (STIR) image of the right hind proximal metatarsal region. Multiple motion ghosting caused by blood flow results in displaced reduplications of the images of the lateral and medial dorsal metatarsal arteries (narrow arrows) and the medial metatarsal artery (broad arrow) in the phase-encoding direction.

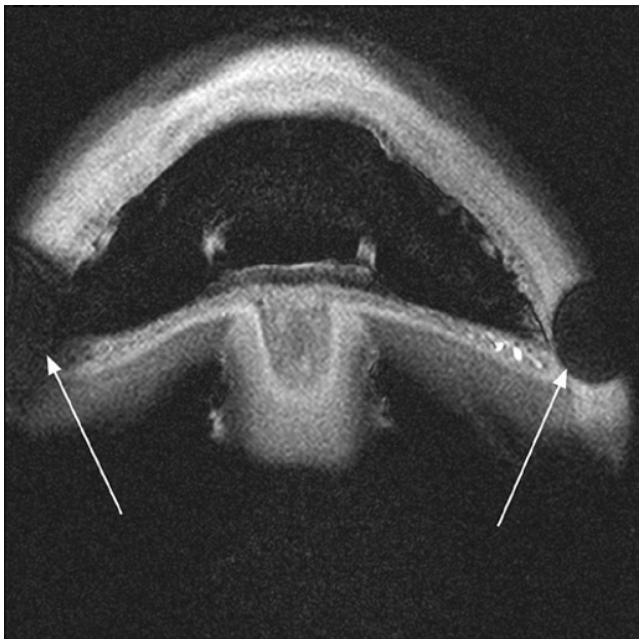

Figure 3.211. Transverse T1-weighted fast low-angle shot (FLASH) image with fat saturation of a foot at the level of the insertion of the deep digital flexor tendon to the distal phalanx. The presence of small amounts of metallic debris in nail holes has resulted in areas of zero signal and image distortion around the ferrous material (arrows).

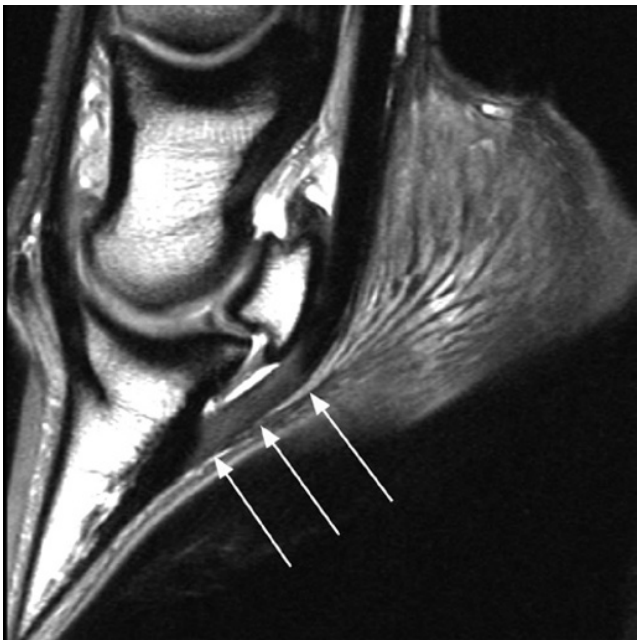

Figure 3.212. Sagittal proton density image of the central part of the foot of a forelimb. The magic angle effect causes an abrupt increase in signal intensity of the deep digital flexor tendon from the distal border of the navicular bone distally to its insertion to the distal phalanx (arrows).

Partial volume averaging artifacts occur when the different signal intensities of more than one tissue type within the same tissue slice are digitally averaged, resulting in a misleading shade of gray. This artifact results in blurring of the margins of structures, disappearing of small structures, and image inaccuracies. Any structure with an edge or curved surface crossing multiple voxels or small structures that partially cross or cut between two slices are susceptible to the volume averaging effect. For example, it may be impossible to distinguish the margin of articular cartilage when imaging the articular surfaces of the equine metacarpophalangeal joints (Figure 3.213). For curved articular surfaces, the artifact can be reduced by positioning individual slices perpendicular to the articular surface at multiple points.

Phase wrap artifacts occur when a portion of the object that lies outside the field of view is represented out of position in the image. Gibbs truncation artifacts or Gibbs ringing artifacts are seen when lines of bright signal are repeated parallel with an interface of abrupt signal change between two objects of markedly different signal intensity in the image. Temperature artifacts occur especially in inversion recovery sequences because the optimal inversion time for suppression of fat or fluid signal is affected by temperature. Abnormal temperature changes in tissues because of inflammation, alterations in vascular flow, or frozen storage may therefore result in insufficiently suppressed fat signal and give a false impression of pathology.[2,21,22] RF interference or zipper artifacts occur when electromagnetic energy from outside the magnet (e.g. electronic equipment in the scan room or an open door) finds access past Faraday's cage. It appears as a line of increased signal of one or two pixels wide through the image.

VetBooks.ir

Figure 3.213. Sagittal proton density image of the central part of the fetlock of a forelimb. The slice is positioned immediately adjacent to the sagittal ridge of the distal aspect of the third metacarpal bone. The articular cartilage layers of the third metacarpal bone and the proximal phalanx are poorly distinguishable from each other and from adjacent subchondral bone (arrow). The margins are blurred due to volume averaging effect of slices across the curved articular surfaces.

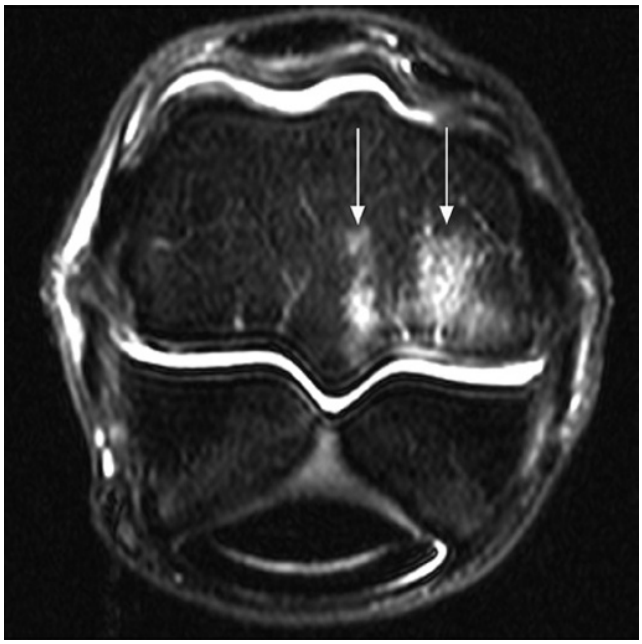

Figure 3.214. Transverse short tau inversion recovery (STIR) image of the distal aspect of the right third metacarpal bone at the level of the proximal sesamoid bones. There are hyperintense areas of abnormal intraosseous fluid in the palmar aspect of the lateral condyle and sagittal ridge of the third metacarpal bone (arrows).

INTERPRETATION OF MUSCULOSKELETAL MR IMAGES

"Signal intensity" describes the shade of gray of a specific tissue on an MR image (Table 3.2). Bright or white signal is described as hyperintense or as having high signal intensity. Dark or black tissues are hypointense or have low signal intensity. Isointense is used as a comparative term for two tissues that have similar signal intensity. Unlike other diagnostic imaging modalities, MRI is unique in that it produces images in which the same tissue may have a different appearance (signal intensity) depending on the sequence used for image acquisition.

Injury results in changes in biochemical composition and fluid content and therefore signal intensity of tissues. Bone sclerosis, increased tissue fluid, and presence of fibrous tissue can be readily detected because of alterations in signal intensity. For a complete assessment of injury, images must be analyzed in all pulse sequences and planes.

In general, fluid is hypointense on T1-weighted and hyperintense on T2-weighted and PD images. Increased protein or cellular content in fluid can lead to increased signal intensity of fluid on T1-weighted images. On T2-weighted images, the presence of blood leads to a relative decrease in signal intensity compared with fluid. Immature granulation tissue has high signal intensity on T2- and T1-weighted images, whereas mature fibrous tissue has low signal intensity on T2-weighted images but can retain higher signal intensity in T1-weighted images.[195]

Normal cortical bone is uniformly black on all sequences and has clearly defined margins. Cancellous bone is more heterogeneous gray because of the presence of adipose and connective tissues in addition to mineralized trabeculae. Bone remodeling can result in changes in bone contour, the presence of cancellous bone fluid and cancellous bone mineral densification. Changes in trabecular architecture are visible as loss in signal homogeneity and thickening or loss of trabeculae. The presence of abnormal fluid in bone is recognized as a combination of high signal on fat-suppressed and T2-weighted images and low signal on T1-weighted images (Figure 3.214). It may also produce a specific fat/water phase cancelation artifact in the standing low-field 0.27 magnet. Although this combination of signal changes is commonly referred to as a bone marrow lesion, bone edema, or bone bruising, it has been shown to reflect a wider range of possible pathologic changes including bone necrosis, hemorrhage, inflammation, replacement of trabeculae by fibrosis, fat necrosis, and bone edema.[148,200] Even so, the ability to detect the presence of fluid in bone makes MRI extremely sensitive in the early diagnosis of bone injury. Generalized osseous fluid with markedly increased STIR signal throughout the entire spongiosa may also be one of the earliest signs of osteomyelitis or may accompany septic synovitis of an adjacent synovial cavity (Figure 3.215).[62,67,191]

Areas of increased density or mineralization of cancellous bone (sclerosis) are characterized by low signal on both T2- and T1-weighted images (figure 3.216). Sclerosis is visible on MR images before it becomes visible radiographically. Damage to bone can also occur at the origin or insertion of ligaments and tendons and

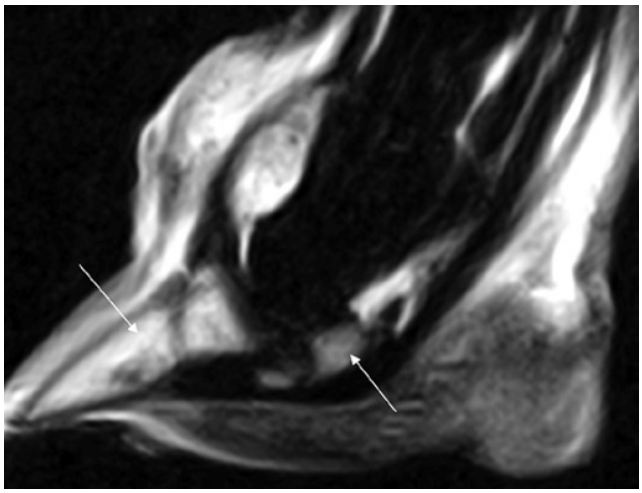

Figure 3.215. Sagittal low-field STIR FSE image of the left front foot of a show jumper with septic synovitis of the distal interphalangeal joint and navicular bursa following a nail puncture of the sole. There is marked and extensive increased signal intensity (osseous fluid) throughout the spongiosa of both the distal phalanx and the navicular bone (arrows). *Source*: Courtesy of Dr. Marieke Zimmerman.

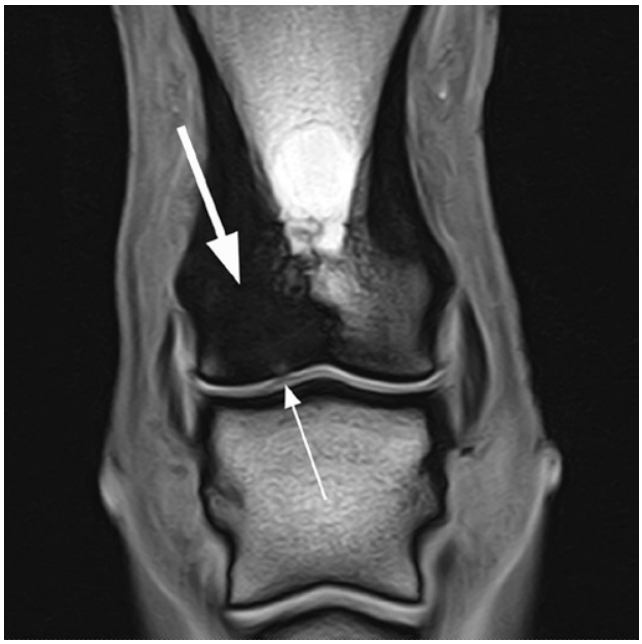

Figure 3.216. Dorsal T1-weighted spoiled gradient echo image of the proximal interphalangeal joint of the right forelimb of a horse with septic arthritis of 5 weeks' duration. There is a small, focal, hyperintense subchondral bone lesion (narrow arrow) surrounded by a wide area of extensive loss of signal from the cancellous bone of the laterodistal aspect of the proximal phalanx (broad arrow). When accompanied by a similar loss of signal in paired T2-weighted images, this indicates increased density or mineralization of cancellous bone (osteosclerosis).

may consist of localized osseous fluid, bone lysis, sclerosis, enthesophyte formation, or endosteal reaction. Occasionally an osseous cyst-like lesion can be observed at the attachment site of a ligament or tendon. Fractures are seen as defects in the bone contour and structure and

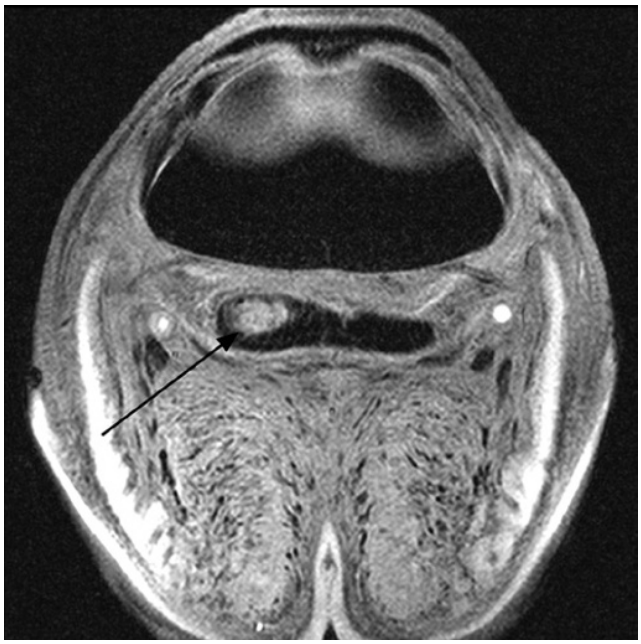

Figure 3.217. Transverse T1-weighted fast low-angle shot (FLASH) image with fat saturation of the right front foot at the level of the middle phalanx of a horse with acute onset foot lameness. There is abnormal signal hyperintensity in a large core lesion of the medial lobe of the deep digital flexor tendon (arrow).

as lines of high signal on T2-weighted and fat-suppressed images. There may be osseous fluid, sclerosis, or both in the parent bone. Incomplete stress fractures may be difficult to discern if they are limited to cortical bone only.[83]

Normal tendons emit zero signal on T1- and T2-weighted images. Normal ligaments produce more signal variation than tendons and vary from light gray to black because they are often composed of fiber bundles with different orientations, which makes them more susceptible to magic angle effects than tendons. The degree of signal variability is dependent on the specific ligament, the density of collagen bundles, and the sequence used for imaging. GRE sequences are inherently more prone the magic angle effect and produce less soft tissue contrast. Therefore T2-weighted FSE sequences should always be included when evaluating ligaments for possible injury.

In general, a localized increase in signal intensity in tendons or ligaments indicates tissue damage. Mild damage may be detected by the presence of periligamentous signal increase on T2-weighted images. More severe damage is characterized by either focal or diffuse intratendinous or intraligamentous increase in signal intensity (Figure 3.217). This may be accompanied by enlargement and shape changes. A partial tear may result in thinning, elongation, or a wavy or partially interrupted contour of a ligament or tendon. With complete tears, the contour is interrupted by a visible defect, and stumps may be present at the ligament or tendon ends. In the acute and subacute stages of tendon or ligament injury, signal increase is present in both T1- and T2-weighted images, due to the presence of fluid associated with acute collagen necrosis and inflammation.

VetBooks.ir

At later stages of fibrosis and healing, T2 signal progressively returns to normal, while T1 signal hyperintensity persists, often indefinitely.[19,78,88,160] Due to the persistence of signal abnormalities in injured tendons and ligaments, MRI may not be able to establish when a patient with a tendon or ligament injury can safely resume sporting activities. One study found that horses whose hyperintense tendon or ligament lesions had resolved on STIR images were significantly more likely to be sound than horses whose lesions persisted on STIR images.[78] On the other hand, tendon or ligament lesions that were visible only on T1 GRE images remained of uncertain clinical significance as a continued association with lameness was possible. In another study of clinical core lesions in the digital part of the DDFT, tendons with fascicular necrosis had signal increase on fat-suppressed images and T1-weighted images, whereas signal intensity in fat-suppressed images was normal in core lesions with fibroplasia rather than necrosis.[19] Similarly, the presence of increased signal on fat-suppressed images was associated with the most severe histological grades of collagen fiber disruption in one study of human Achilles tendinosis.[86]

Normal articular cartilage has medium signal intensity on PD images, medium to high signal intensity on T1-weighted images, and medium to low signal intensity on T2-weighted images. It can be clearly defined from hypointense subchondral bone and from synovial fluid, which is hypointense on T1-weighted images and hyperintense on T2-weighted images. 3D T1-weighted gradient and spoiled GRE sequences with fat suppression and thin slices (1–2 mm) have been found to be most useful for morphological evaluation, defining margins and thickness of equine articular cartilage in the DIP,[133,149] metacarpophalangeal,[135,136,143] and carpal joints[120] and in the navicular bursa.[159] Cartilage damage can be visualized directly as a change in signal, thickness, and/or surface contour of cartilage. Surface irregularities may indicate the presence of superficial fibrillation, but more substantial lesions (erosions and wear lines) can be visualized as defects in the cartilage surface contour. These cartilage defects allow pooling of synovial fluid, which results in focal T2 and STIR signal hyperintensity and T1 signal hypointensity inside the normal cartilage contour (Figure 3.218). Full-thickness cartilage defects are sometimes (but not always) accompanied by signal changes of subchondral bone, including thickening and irregularity of the borders of the subchondral bone plate and focal bone edema, that may draw attention to the less obvious cartilage signal changes. Although MRI has been reported as a good imaging modality for evaluation of articular cartilage, accurate MRI evaluation of degenerative and traumatic cartilage lesions in distal limb joints of horses can remain difficult,[80,130,136,143,174,175,180] especially in the absence of concurrent subchondral bone abnormalities.[193]

Cartilage imaging difficulties arise mainly from the thickness (lack thereof) of equine distal limb cartilage that is frequently too thin for the spatial resolution of clinical MRI systems. In addition, the articular surfaces of equine distal limb joints are markedly curved. Both factors promote partial volume averaging across image slices resulting in blurring of cartilage margins.

Figure 3.218. Dorsal short tau inversion recovery (STIR) image of the right fore fetlock of a horse with acute right fore fetlock lameness. There is abnormal signal hyperintensity at the level of the articular cartilage proximal to a small subchondral bone irregularity in the proximomedial articular surface of the proximal phalanx (arrow). There is mild signal hyperintensity in the subchondral bone adjacent to the articular cartilage hyperintensity. Necropsy confirmed the presence of a full-thickness cartilage injury at this site.

This artifact can be reduced by the use of thin, high spatial-resolution.[149]

New sequences aimed at improving morphological evaluation of articular cartilage are constantly evolving and under investigation. Even so, recent studies highlight the ongoing difficulties with MRI evaluation of cartilage morphology, even with current high-field systems.[80,95]

Quantitative MRI of articular cartilage aims to identify molecular alteration in the matrix before morphological changes occur.[81,129,130] Techniques like T2 mapping[196] and delayed gadolinium-enhanced MRI of cartilage (dGEMRIC)[15,33,34] have no clinical application in the horse at present but continue to be investigated for future use. Specifically, dGEMRIC[81,98,129] may prove to be helpful as an indicator of early degenerative changes associated with loss of proteoglycans from the extracellular matrix.

Normal synovial fluid has high signal intensity on T2-weighted images and low signal intensity on T1-weighted images. Joint capsule has medium to low signal intensity on all sequences. Joint effusion results in displacement of the joint capsule margins. Increased protein or hemorrhage in the synovial fluid may cause an increase in T1 signal and a decrease in T2 signal intensity of the fluid. Chronic hemarthrosis may result in the presence of small susceptibility artifacts on GRE images due to the presence of hemosiderin in the synovial membrane.

Blood in the lumen of a normal artery or vein may appear as low intensity, high intensity, or mixed intensity signal depending on the imaging parameters and blood

VetBooks.ir

flow characteristics. Hemorrhage can be differentiated into acute and chronic stages on MR images.[117] In the acute stage, hemorrhage is like other fluids, hypointense on T1-weighted images and hyperintense on T2-weighted images. After approximately one week, methemoglobin release leads to increased T1 signal intensity. In the chronic stage, hemosiderin will cause zero signal areas to appear due to susceptibility artifacts especially on GRE images.[20] Susceptibility artifacts may persist indefinitely at the site of previous hemorrhage due to injection, surgical intervention like arthroscopy, or injury.[181] The center of old hemorrhage may remain hyperintense on T1-weighted and T2-weighted images due to persistence of methemoglobin.

CONTRAST MRI TECHNIQUES

MRI contrast medium was developed to enable differentiation between two tissues with similar MR characteristics by differentially increasing their signal intensity in the presence of injury. Gadolinium is a paramagnetic contrast agent that enhances T1 relaxation and thus shortens T1 relaxation times, resulting in increased signal in tissues containing this element on T1 images.

Post-contrast fat-saturated T1-weighted sequences are obtained following intravenous administration of gadolinium diethylenetriaminepentaacetic acid (0.02 mmol/kg IV)[64] or gadopentetate dimeglumine (0.1 mL/kg IV).[85] Local intravenous delivery of gadopentetate by regional limb perfusion with a tourniquet in the mid-metacarpal region may provide similar results with lower dosages of contrast agent (5 mL gadopentetate diluted with 5 mL of physiological saline per distal limb).[1] Gadopentetate dimeglumine leaks into the extracellular compartment to become detectable on MR images following tissue injury with inflammation and capillary breakdown.[63] In horses' feet, significant contrast enhancement has been observed in tendinopathy lesions of the deep digital flexor, desmopathy lesions of the distal sesamoidean impar ligament and the collateral sesamoidean ligaments, synovitis (also septic) of the DIP joint, and palmar erosions of the flexor cortex of the navicular bone (Figure 3.219).[85,154] In the brain, gadolinium causes significant enhancement of inflammatory and neoplastic lesions because of their increased vascularity and ability to break down the blood–brain barrier.[64,109]

Direct MRI arthrography with a saline–gadopentetate dimeglumine mixture (1.0 mL gadopentetate dimeglumine/250 mL saline; 2–4 mmol/L) has been used in the assessment of complex intra-articular soft tissue structures in human patients. With respect to cartilage imaging, MRI arthrography has reportedly resulted in at least 10% improvement in chondral lesion detection relative to conventional MRI studies.[97,181] Higher concentrations cause signal blackout and nondiagnostic images due to strong magnetic susceptibility effects. Better cartilage contrast may be achieved following direct MRI arthrography with saline than with gadolinium,[35,100,102,159] as saline (hypointense) results in better image contrast between cartilage (medium high to high signal) and synovial fluid than gadolinium (hyperintense) on T1 images.[159] Distension of the navicular bursa or DIP joint with 0.9% saline revealed adhesion formation, DDFT injury, and fibrocartilaginous damage to the navicular bone.[16,100,102]

Indirect MRI arthrography is performed following intravenous injection of paramagnetic MRI contrast media as indicated above. Similar sensitivities and specificities have been reported for indirect MRI arthrography when compared with direct MRI arthrography in the diagnosis of intra-articular soft tissue injuries like tears of the rotator cuff, glenoid labrum, and menisci.[201]

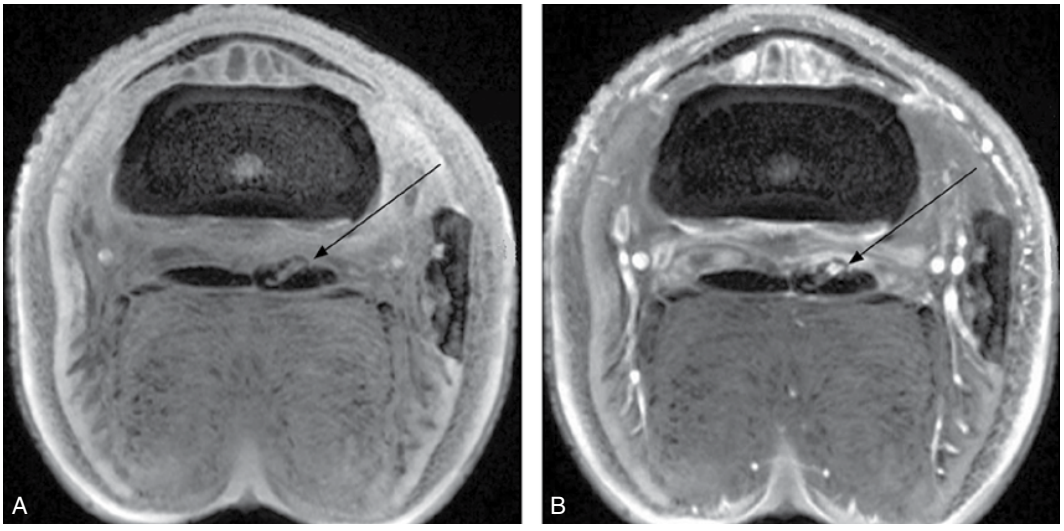

Figure 3.219. Transverse volumetric interpolated breath-hold examination (VIBE) images at the level of the middle phalanx of the right front foot of a horse with chronic foot lameness, before (A) and after (B) intravenous administration of gadolinium contrast material. There is an area of abnormal signal hyperintensity in the lateral lobe of the deep digital flexor tendon at the level of the proximal border of the navicular bursa (arrow). This lesion is enhanced by the administration of intravenous contrast as the relative signal intensity of the core lesion is increased in Figure B (arrow). Source: Courtesy of Dr. Carter Judy.

Since cartilage has limited ability to repair itself, it is useful to determine its biochemical composition early on in clinical disease. One study showed that naturally occurring osteoarthritis significantly affects cartilage relaxation times as determined by dGEMRIC in the DIP joints of horses.[15]

HOW TO READ AN EQUINE MRI STUDY

A standard MRI protocol produces hundreds of high-detail images, each of which may contain important information. In order to turn this information into a useful diagnosis, a methodical and consistent approach should be used to reading the MRI study. Any suspect abnormality should be defined by signal intensity, size, shape, and contour in comparison with normal. Throughout the evaluation process the clinician should cross reference any suspected signal abnormality in two ways, i.e. by anatomical cross referencing and by contrast cross referencing. Anatomical referencing is performed by comparing the appearance of a suspected lesion with its appearance in other image planes of the same contrast weighting. Contrast cross referencing refers to the process of comparing the signal intensity of a suspected lesion in a PD or T1-weighted image with its signal intensity in the corresponding T2-weighted and fat-suppressed images. As a general rule, an abnormality should be identifiable in at least two different imaging planes and two different contrast weightings for it to be considered a "true" lesion. If an abnormality can only be seen in one pulse sequence in one orientation, then there is a high likelihood that the finding is an artifact.

Frequently more than one "true" lesion is identified during an MRI examination, causing a diagnostic dilemma, as not all apparent abnormalities are equally associated with pain and lameness and "normal" signal variation may occur. The clinician needs to decide on the likely hierarchy of clinical significance of lesions encountered, in light of the clinical exam findings and current knowledge of which MRI lesions are most common.

INDICATIONS, CASE SELECTION, ADVANTAGES, AND DISADVANTAGES OF MRI

MRI is indicated when a lameness problem has been localized to an anatomical area and other imaging modalities have failed to provide an unequivocal diagnosis. Lameness should first be localized to an anatomical area because unlike nuclear scintigraphy, MRI is not a screening technique. Accurate knowledge of the localization of the cause of lameness, as well as the pitfalls encountered with diagnostic analgesia is indispensable when interpreting MR images. These rules apply, even in the face of newer, more powerful 3 T magnets with faster scanning times now allowing routine screening of the foot, pastern, and fetlock regions in horses with distal limb lameness with only short general anesthesia times.

MRI is particularly useful in anatomical areas where conventional imaging modalities have limitations, like the foot, the palmar/plantar soft tissues, and the joints of the distal limbs. Ultrasonography is limited by the hoof capsule in lameness of the foot. Ultrasonographic findings may be equivocal in lameness associated with the palmar/plantar soft tissues of the distal limb. Radiography is incapable of detecting subtle or early cartilage or subchondral bone abnormalities in joint lameness. Radiographic abnormalities are also absent in many forms of osseous trauma (e.g. bone contusions, bone edema, occult subchondral bone loss). Although MRI is the only imaging modality that can assess all tissues in a single examination, the availability of MRI should not result in the omission of radiographic and ultrasonographic examinations. MRI should not replace but rather complement radiographic and ultrasonographic findings. Information obtained from radiographic, ultrasonographic, and scintigraphic examinations helps in the interpretation of MRI findings and a full set of diagnostic images always provides a better basis for an accurate diagnosis. Radiography in particular has better bone versus soft tissue contrast when compared with MRI and is therefore more sensitive to subtle bone contour changes like osteophytes, enthesophytes, and small osteochondral fragments. Ultrasonography gives a better representation of fiber pattern in tendons and ligaments and is not plagued by magic angle and flow artifacts that occur in structures like the suspensory ligament branches or distal sesamoidean ligaments, especially during standing MRI.

There are numerous advantages of MRI over other imaging modalities. MRI does not use ionizing radiation. It has high intrinsic contrast and resolution, particularly for soft tissues, resulting in good anatomic separation between different tissues. Next to anatomic information, MRI also displays information that is pathophysiologic. As a 3D cross-sectional imaging modality, MRI is able to scan an object in any image plane.

The main disadvantages of MRI are its cost (installation and running costs), its still limited availability, its limited accessibility mostly restricted to comfortable examination of the distal limbs for standing magnets, its poor suitability as a screening technique (unlike CT), the need for general anesthesia with high-field magnets, the relatively lower tissue signal and interference of patient movement with low-field magnets, and the need for dedicated specialist training. Image quality can be influenced by many different parameters, including time, signal-to-noise ratio, size of the object of interest, slice thickness, field of view, and other imaging specifications. In addition, MRI gives rise to a number of unfamiliar imaging artifacts that may mimic the presence of lesions or render a scan nondiagnostic. It is important to know how signal characteristics are influenced by all of the abovementioned parameters, so that the clinician can assure high image quality. The large number of images generated with each study also makes interpretation time consuming.

MAGNETIC RESONANCE IMAGING OF THE FOOT AND PASTERN

Introduction

MRI has become the gold standard of diagnosis in horses with foot lameness, because of its higher sensitivity and specificity than radiography, ultrasonography,

VetBooks.ir

and scintigraphy for lesions responsible for lameness, resulting in a more accurate, early diagnosis and prognosis and allowing for the selection of the most appropriate specific treatment protocol. Many of the causes of foot lameness we know today thanks to the use of MRI, can only be identified conclusively with MRI.

One study, using cadaver limbs of horses with distal limb lameness, found that anatomical structures appeared similar in both high-field and low-field systems but that the margins of some structures were less clearly defined with low-field MRI likely due to partial volume effect.[122] It was concluded that the level of detection of moderate to severe lesions in the foot was similar between high- and low-field systems. However, small tendon, articular cartilage, ligament, and bone lesions were better detected using a high-field system.[122]

There have been several reports on the incidence of injuries diagnosed with both low- and high-field MRI systems in horses with foot lameness. Some of these[24,46,48,75,103,113,157,168,179] are summarized in Table 3.3. Overall, injury of the DDFT was the most prevalent lesion, while navicular bone lesions were the next most common diagnosis followed by injuries of the collateral ligaments of the DIP joint. Abnormalities in the DIP joint and navicular bursa were diagnosed frequently in low-field studies but less commonly in high-field studies. Injuries to all other structures occurred with markedly lower frequency, generally in less than 10% of horses. The absence of significant abnormalities was mentioned in up to 14% of horses in four studies in which an MRI diagnosis was not made. Although MRI is the most sensitive and specific diagnostic modality for the diagnosis of injuries of a3l tissues in the horse's foot,[121] not all causes of foot lameness can be readily identified (Table 3.3).

MRI Abnormalities in the Foot

Tendinopathy of the DDFT

The normal DDFT can be clearly recognized as a well-delineated, bilobed, double elliptical structure of homogeneous low signal (black) with a hyperintense midline septum. From the navicular bone distally, the midline septum is no longer visible, and the tendon becomes progressively flatter to finish in a crescent-shaped distal insertion on the distal phalanx. A generalized signal increase in the portion of the tendon comprised between the distal border of the navicular bone and its insertion to the distal phalanx can be caused by the magic angle effect (Figure 3.212). The appearance of the normal DDFT has a strong left to right limb as well as medial to lateral lobe symmetry in both signal intensity and cross-sectional area measurements.[119] The tendon contains a dorsal layer of high T1 and PD signal both at the level of the navicular bone and proximal to the navicular bone.[17,159]

Tendon lesions are characterized by focal or linear, marginal or central, intratendinous signal increase on both T1 and T2 images, variably accompanied by some enlargement of the affected lobe in the acute stage of injury.[43] Lesions may occur distal to the navicular bone at the insertion on the distal phalanx, at the level of the flexor surface of the navicular bone, at the level of the collateral sesamoidean and T-ligaments in the proximal recess of the navicular bursa, or at any combination of these three levels at the same time. Lesions are usually restricted to one lobe but may change their morphology while transitioning from one level to another. There is a good correlation between the MRI appearance of tendon lesions and their pathological classification into core lesions (Figure 3.220), parasagittal plane splits and tears (Figure 3.221), insertional lesions (Figure 3.222), and dorsal surface erosions and fibrillations (Figure 3.223).[18,32,121,156,158] Generalized T1 signal increase in one tendon lobe may constitute an artifact rather than diffuse tendinopathy.[177] Insertional enthesopathy can result in cortical irregularity, caused by focal bone resorption or enthesophyte formation at the insertion of the tendon to the flexor surface of the distal phalanx, and in diffuse osseous signal change in the palmar aspect of the distal phalanx, caused by osseous fluid or sclerosis. Dorsal lesions may be accompanied by adhesions between the dorsal surface of the tendon and the palmar surface of the collateral sesamoidean and impar ligaments within the navicular bursa. Torn collagen fibers arising from the tendon's damaged dorsal surface may recoil proximally in the navicular bursa, resulting in the dorsal protrusion of a tendon granuloma into the proximal recess of the navicular bursa.[170] Adhesions are suspected when one or more bands of hypointense (T2) or hyperintense (T1) material are present between the dorsal surface of the DDFT and the collateral sesamoidean ligaments, obliterating the normal synovial fluid signal in this space. Sometimes lack of separation extends across the entire surface of both structures in the proximal recess of the navicular bursa. Other signs of navicular bursitis accompanying lesions of the dorsal surface of the intrabursal portion of the tendon include fluid distension of the proximolateral and proximomedial pouches of the bursa (proximolateral pouch is always larger) and thickening and proliferation of the bursal synovium in the proximal recess of the navicular bursa. Thickening of the collateral sesamoidean and distal impar ligaments may also be seen. Resorptive lesions of the flexor cortex of the navicular bone are frequently accompanied by fibrous adhesions between the eroded bone surface and the dorsal surface of the tendon. Unfortunately, adhesion detection is difficult in the absence of normal synovial fluid volume between the opposing structures in the navicular bursa, as may occur in chronic bursitis with synovial proliferation. Distension of the navicular bursa or DIP joint with 4–6 mL of 0.9% saline is useful as it should cause separation of the tendon from the collateral sesamoidean ligaments and the navicular bone if no adhesions are present.[100,102,159] Lack of separation after injection is indicative of fibrous adhesions between adjacent structures.

It may be possible to use T1-to-T2 signal differences to estimate the age or stage of healing of a tendon lesion.[160] Early tendinopathy has been characterized by increased signal in T2, STIR, and T1 images. In the chronic stages of tendon healing by fibrosis, signal intensity in core lesions generally decreases in T2 images but remains high in T1 and PD images.[160]

Lesions of the Navicular Bone

MR images of the navicular bone in horses with navicular bone disease may show one or more of three main abnormalities: remodeling changes in the medulla, degenerative changes of the flexor border, and osteochondral fragmentation of the distal border.[49] The most common type of abnormality seen in the navicular bones of horses with recent onset navicular syndrome was STIR signal hyperintensity in the medullary cavity of the navicular bone with or without additional areas of T2 and PD signal hypointensity[152] (Figure 3.224), but this STIR signal increase is more reliably assessed on FSE than on GRE images.[138] It has been speculated that osseous fluid in the medulla may be an acute inflammatory or post-traumatic finding in horses with recent onset navicular syndrome.[152] However, in pathological studies, MRI evidence of "bone marrow lesion" was associated not only with acute inflammation but also with evidence of hemorrhage, interstitial edema in medullary fat, prominent capillary infiltration in marrow fat, thinning of trabeculae and widening of intertrabecular spaces, medullary fibrosis, chronic osteonecrosis, and, in some horses, adipose tissue necrosis.[17,32,58] In one pathological study, all but one horse with medullary STIR signal hyperintensity had concurrent chronic degenerative changes of the flexor surface of the navicular bone.[158] On the other hand, pathological studies have not included horses with recent onset lameness, and it therefore remains possible that medullary STIR hyperintensity can represent acute inflammatory fluid in the spongiosa of the navicular bone.[152] This possibility is supported by the frequent observation of osseous fluid signal in the spongiosa of the navicular bone without concurrent abnormalities of the distal border or flexor surface on MR images. In such horses, it is difficult to differentiate between abnormal osseous fluid of an acute post-traumatic nature and osseous fluid accumulation associated with a chronic degenerative process on a single examination. As acute, post-traumatic osseous fluid (e.g. a bone contusion) tends to resolve with rest, in contrast to the persistence of degenerative osseous fluid, this distinction requires one or more follow-up MRI examinations to be performed.[190]

Figure 3.224. Sagittal short tau inversion recovery (STIR) image of the foot of a horse with lameness that is abolished by anesthesia of the palmar digital nerves. There is marked STIR hyperintensity of cancellous bone in the medullary cavity of the navicular bone (arrow) indicating the presence of abnormal medullary fluid, medullary fibrosis, or medullary fat necrosis.

Medullary STIR signal hyperintensity may be focal near the distal or palmar border of the navicular bone, or extend from the distal border in a vertical band along the palmar cortex to the proximal border of the bone, or spread diffusely throughout the medullary cavity. Based on the extent and intensity of STIR signal increase, medullary bone edema can be graded from mild to severe. Lower grades of medullary STIR signal hyperintensity have been encountered in non-lame control limbs, but severe medullary edema was strongly associated with the presence of lameness.[121,152] Areas of signal hypointensity may also be seen in the medullary cavity of the navicular bone and may be focal or diffuse. Loss of T1 signal may either represent replacement of medullary fat by fluid or bone densification, while loss of T2 and PD signal indicates the presence of bone densification and sclerosis or even replacement of medullary trabecular bone by compact lamellar bone, usually as a consequence of marked trabecular thickening in response to degenerative changes of the flexor surface of the navicular bone.[4,158]

In horses with chronic navicular syndrome, the most common MRI abnormality was the presence of abnormal signal hyperintensity at the level of the flexor border of the navicular bone (Figure 3.225).[158] This can be a subtle, focal increase, caused by synovial fluid pooling at a site of palmar fibrocartilage loss and thinning, best seen on sagittal PD or T2-weighted images. MRI bursography with saline has been shown to improve the conspicuity of fibrocartilage lesions.[159]

A normal shallow, smooth depression is present in the middle third of the palmar sagittal ridge of up to 50% of normal navicular bones.[197] This is also characterized by pooling of synovial bursal fluid but should not be confused with a degenerative lesion of the palmar fibrocartilage. Even so, this normal synovial depression may be the site of early bone degeneration in some horses with navicular bone disease. The presence of osseous fluid signal on STIR images within the flexor cortex and spongiosa adjacent to the synovial depression in the sagittal ridge is a likely sign of early bone degeneration. Signal increase at the flexor surface can also be more extensive and extend deeper within the cortical bone of the flexor cortex when cortical bone erosion is present (Figure 3.225). Focal bone loss from the flexor surface is best seen on fat-suppressed images in high-field studies and transverse high-resolution T1 images on low-field standing MR images. These flexor cortex lesions may not be easily detected radiographically.[165] In affected horses, MR images usually show concurrent irregularity of the normally smooth endosteal surface of the flexor cortex, especially opposite the site of focal signal increase of the palmar surface. Fibrocartilage and cortical bone loss at the palmar aspect of the flexor surface of the navicular bone is

Figure 3.225. Sagittal proton density image of the foot of a horse with chronic navicular bone degeneration. There is localized signal hyperintensity in the distal third of the flexor border of the navicular bone due to loss of cortical bone and the presence of fibrous tissue and bursal synovial fluid in the defect (arrow). There is diffuse loss of signal in the medullary cavity of the navicular bone due to osteosclerosis. There is loss of separation between the palmar surfaces of the thickened collateral sesamoidean and distal sesamoidean impar ligaments on the one hand and the dorsal surface of the deep digital flexor tendon on the other, suggestive of abnormal adherence between these structures.

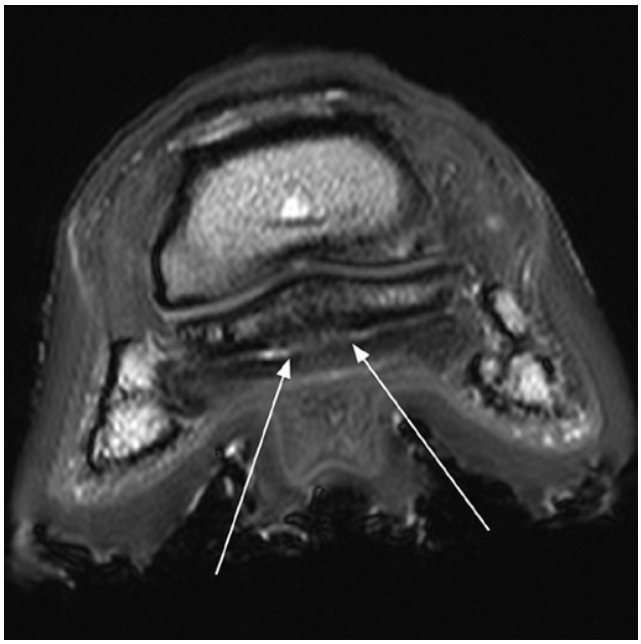

Figure 3.226. Transverse T2* gradient echo image of the foot of a horse with chronic navicular bone disease. The palmar border of the navicular bone is irregular due to degenerative erosion of the flexor cortex. There is sclerosis of the medullary cavity of the navicular bone. The normal hyperintense synovial fluid layer separating the palmar border of the navicular bone from the dorsal surface of the deep digital flexor tendon is interrupted by hypointense fibrous adhesions between both surfaces (arrows).

frequently accompanied by fibrillation of the dorsal aspect of the DDFT. Areas of advanced fibrocartilage and cortical bone loss from the flexor surface of the navicular bone are prone to adhesion formation between the dorsal surface of the DDFT and the exposed area of bone (Figure 3.226).

Another form of degenerative navicular bone disease may be caused by the presence of osseous fragments at the distal border of the navicular bone (Figure 3.227).[8–10,50] Especially large fragments may induce a focal remodeling response in the distal margin of the navicular bone, resulting in localized osseous fluid with STIR signal hyperintensity, irregular thickening of cortical bone, and formation of an osseous cyst-like lesion.[9] A distal border fragment accompanied by focal medullary bone edema, an osseous cyst-like lesion, or thickened cortical bone at the distal border of the navicular bone is likely to be associated with lameness. Even so, distal border fragments may be asymptomatic,[198] especially when they are smaller and if there is no MRI evidence of remodeling of the distal border of the navicular bone adjacent to the fragment.

In horses with a complete navicular bone fracture, MRI can demonstrate the fracture configuration on 3D images and elucidate if fracture fragments have lacerated the surface of the DDFT, prior to possible attempts at surgical repair. Fractures must be distinguished from bipartite navicular bones for the purpose of prognosis and treatment planning.[76]

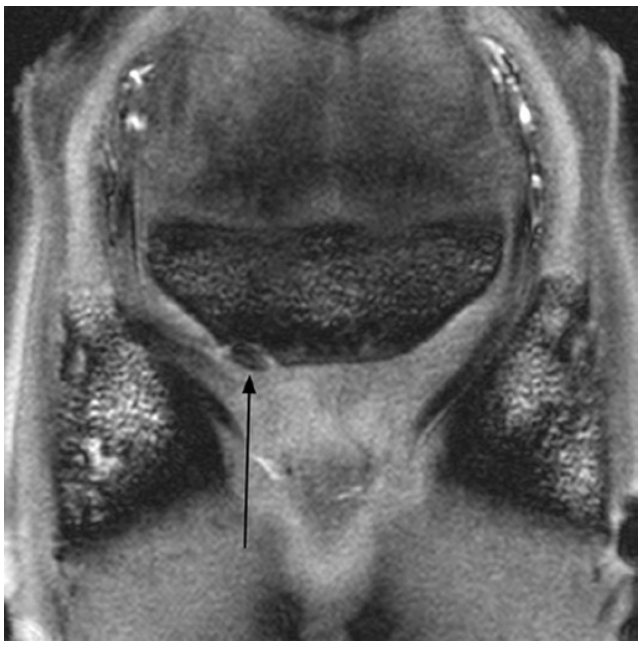

Figure 3.227. Dorsal T1-weighted fast low-angle shot (FLASH) image at the level of the navicular bone, oriented parallel with its flexor surface. The narrow slice thickness and orientation of this sequence allow for identification of an osseous fragment at the lateral angle of the distal border of the navicular bone (arrow).

Lesions of the Distal Sesamoidean Impar Ligament

The distal sesamoidean impar ligament is outlined by hyperintense fluid signal from the DIP joint dorsally and the distal recess of the navicular bursa distally. It is composed of individual fiber bundles with synovial interdigitations of the DIP joint and small branches of the palmar digital arteries. The heterogeneous structure with multiple fluid–fiber interfaces in this small ligament results in a high susceptibility to partial volume averaging. Therefore, focal high signal within the impar ligament must be interpreted with caution because of normal signal variation. One study found no significant correlation between the MRI appearance of the impar ligament itself and the presence of histological abnormalities.[50] Moreover, the ligament is thicker and its palmar border more intimately apposed to the dorsal border of the DDFT axially than abaxially, which may confound identification of ligament thickening and adhesion formation. A diagnosis of desmitis of this ligament is rare and rarely considered the primary cause of lameness, except in the presence of distal border fragments or cystic lesions in the distal border of the navicular bone.[50]

Unequivocal MRI signs of impar ligament injury include marked thickening, extensive adhesion of the palmar surface of the ligament to the dorsal surface of the DDFT with loss of normal fluid space in the distal recess of the navicular bursa, and osseous signal abnormalities at the insertion of the ligament to the distal phalanx. The latter include focally increased fluid signal, increased mineralization, entheseous new bone production, and focal osteolysis with formation of a cyst-like lesion (Figure 3.228).[199] Generalized thickening of the impar ligament and adhesions between the impar ligament and the DDFT occur most commonly in association with navicular bursitis accompanying marked pathology of the DDFT or the navicular bone and may be an integral part of secondary generalized bursal inflammation.

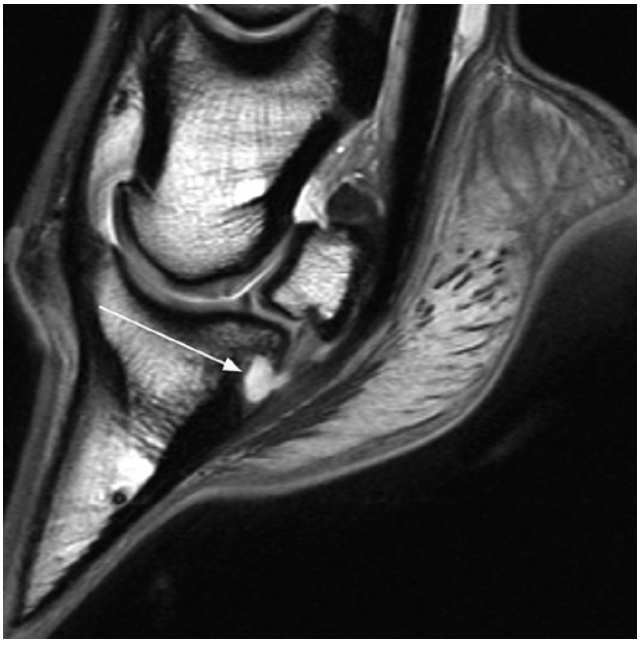

Figure 3.228. Sagittal proton density image of the central part of the foot of a horse with chronic foot lameness. There is localized signal hyperintensity in an osseous cyst-like lesion at the insertion of the distal sesamoidean impar ligament to the distal phalanx indicating chronic enthesopathy of this ligament (arrow).

Lesions of the Collateral Sesamoidean Ligaments

It has been reported that the paired collateral sesamoidean ligaments have uniform low intensity signal in all image sequences and are symmetrical in thickness medially and laterally.[152] However, the presence of signal increase is a common normal variation on all contrast weightings, especially near the insertion to the proximal border of the navicular bone.[17,176] The dorsal and palmar borders of the ligaments are clearly demarcated by high fluid signal in the palmar recess of the DIP joint and the proximal recess of the navicular bursa.

Collateral sesamoidean ligament injury may be evident as an altered shape with focal or diffuse signal increase in the body of the ligament. Asymmetric thickening is most easily identified when the paired ligament is normal (Figure 3.229). Generalized thickening of the ligament with loss of separation from the dorsal surface of the DDFT, possibly with adhesions, occurs most commonly in association with chronic navicular bursitis secondary to tendinopathy or degenerative navicular bone disease.

Primary collateral sesamoidean ligament injury is rare except in one report of horses with hindfoot lameness.[11]

Lesions of the Navicular Bursa

Pooling of hyperintense fluid can normally be observed in the proximolateral and proximomedial pouches of the navicular bursa and to a lesser extent between the DDFT and the distal impar ligament distally. There should be visible separation between the dorsal surface of the DDFT and the palmar surfaces of the collateral and distal impar sesamoidean ligaments in normal navicular bursae, apart from the areas of attachment between these structures by the normal proximal and distal synovial membrane reflections in the sagittal midline of the navicular bursa.

Navicular bursitis results in effusion with enlargement of the proximolateral and proximomedial pouches of the bursa and sometimes in dorsal deviation of the central part of the collateral sesamoidean ligaments or the distal impar ligament. The proximolateral recess of an inflamed navicular bursa is always more distended than the proximomedial recess. Fibrous scar tissue can occur in the proximal and distal recesses of the bursa and is indicative of chronic bursitis. Lack of separation between the dorsal surface of the DDFT and the palmar surface of the collateral sesamoidean ligaments may be suggestive of adhesion formation.[79] Simple distension of the navicular bursa is a frequent nonspecific finding in many horses irrespective of the primary injury site.[46] It is rarely considered the primary cause of lameness.[152]

VetBooks.ir

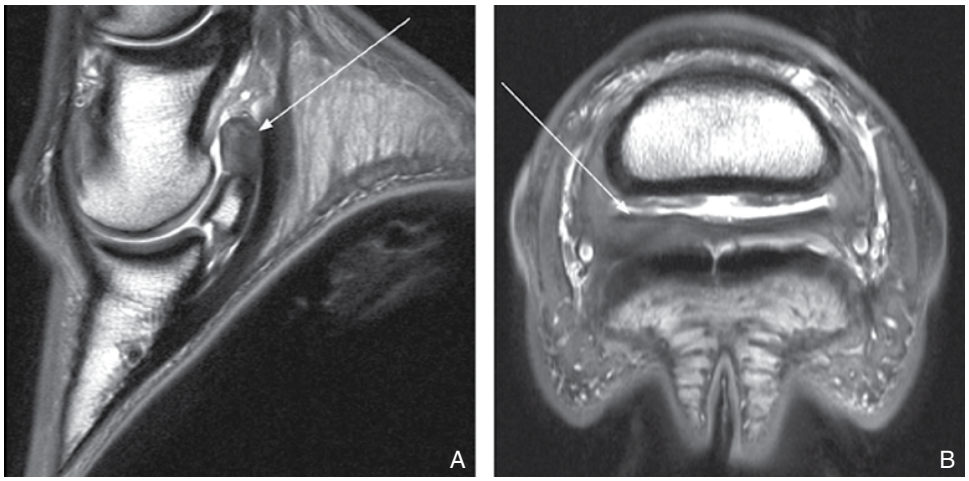

Figure 3.229. Sagittal proton density image lateral to the sagittal midline (A) and transverse proton density image at the level of the proximal aspect of the navicular bursa (B) of the left foot of a horse with chronic lameness that can be eliminated by anesthesia of the palmar digital nerves. The lateral collateral sesamoidean ligament contains areas of increased signal intensity and is markedly thickened (arrows) in comparison with the medial ligament. Swelling has resulted in loss of separation between the palmar surface of the lateral collateral sesamoidean ligament and the dorsal surface of the lateral lobe of the deep digital flexor tendon. The presence of adherence between both structures cannot be ruled out.

Lesions of the Collateral Ligaments of the DIP Joint

Normal collateral ligaments can be seen as well-delineated elliptical structures of homogeneous to mildly heterogeneous signal with smooth osseous margins at the origin and insertion on most transverse MR images. Focal or diffuse signal increase in collateral ligaments is a common sequel of magic angle artifact, especially in T1, T2*, and PD images and results in a high incidence of signal variation in these structures.[74,171,177,178,192] The lateral collateral ligament is most commonly affected by this artifact in standing horses. The fiber arrangement and curvature within the periphery of the proximal segments of the collateral ligament may give rise to a central region of nonuniform low signal intensity with a rim of intermediate to high signal intensity at the level of the middle phalanx due to magic angle effect that can be confused with a desmopathy on both low- and high-field images.[90,192] Therefore, suspected signal changes in a collateral ligament must always be evaluated in transverse T2-weighted FSE images, if possible with a long echo time, in order to verify if signal increase is truly caused by tissue damage and not by magic angle artifact. High signal on a T1-weighted GRE sequence that is not accompanied by high signal on the corresponding T2-weighted and STIR images is not a reliable indicator of injury.

On dorsal images obtained in an image plane parallel with the direction of the collateral ligaments and perpendicular to the solar surface of the foot, the collateral ligaments appear as curved, banana-shaped bands of homogeneous, low T2 signal.

Lateromedial size and shape differences between paired ligaments are possible due to anatomical variation and adaptive change. Signal asymmetry at the proximal aspect of the collateral ligaments may also occur due to uneven length or thickness of collateral ligaments.[44,53,117]

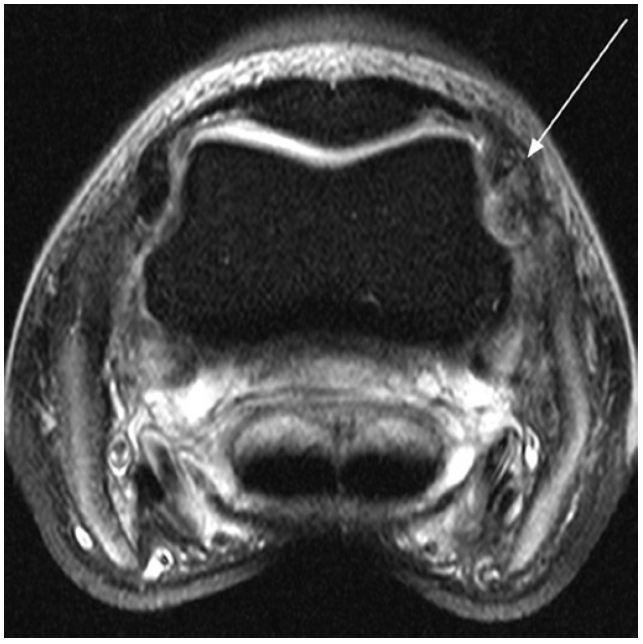

Figure 3.230. Transverse proton density image with fat saturation oriented parallel with the solar surface of the foot of a horse with collateral ligament injury of the distal interphalangeal joint. The affected collateral ligament is enlarged, and its margins are irregular (arrow). There is loss of architecture, and irregular areas of signal hyperintensity are dispersed throughout the cross section of the ligament (arrow).

Desmopathy is characterized by increased cross-sectional area, irregular contour, and increased signal intensity of the collateral ligament (Figure 3.230).[44,73] The medial collateral ligament is more frequently affected than the lateral.[44,53] Abnormal signal increase can be diffuse or focal and is best recognized on transverse T2 FSE

VetBooks.ir

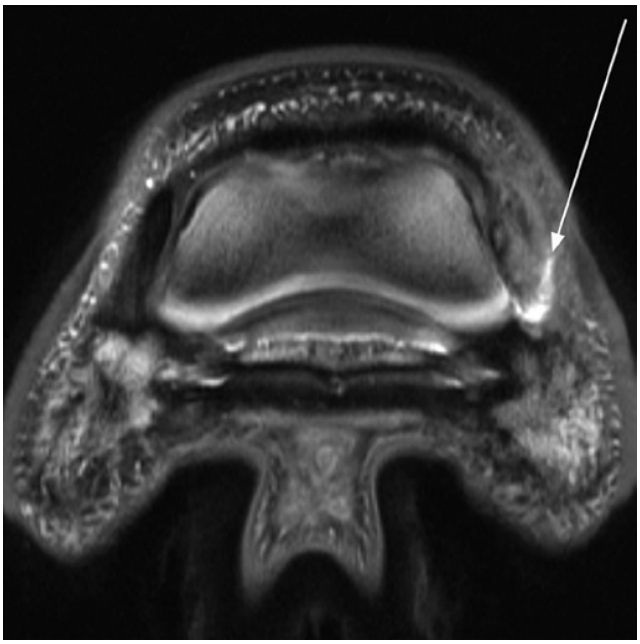

Figure 3.231. Oblique transverse proton density image of the foot of a horse with collateral ligament injury of the distal interphalangeal joint. Slice direction is perpendicular to the flexor surface of the navicular bone. There is pooling of hyperintense synovial fluid in a defect resulting from avulsion of collateral ligament fibers from their insertion on the distal phalanx (arrow). There is enlargement, loss of architecture, increased signal intensity, and loss of margination of the affected ligament. The hyperintense fluid outlines the distal stump of the torn collateral ligament (arrow).

Figure 3.232. Sagittal short tau inversion recovery (STIR) image of the central part of the right foot of a horse with lameness that can be abolished with intra-articular anesthesia of the distal interphalangeal joint. There is a focal signal hyperintensity within the hyaline cartilage layer of the distal articular surface of the middle phalanx (arrow). This focal signal increase is caused by pooling of synovial fluid within an articular cartilage defect. An oblique full-thickness cartilage cleft was identified at necropsy.

or STIR images. Desmopathy may be accompanied by thickening of periligamentar structures, one of which is the chondrocoronal ligament. Osseous damage at the origin or, more commonly, at the insertion of a collateral ligament causes signal alteration in the adjacent bone. In 45% of cases of collateral ligament disease, osseous abnormalities were identified on MRI.[39] These osseous abnormalities can consist of entheseous new bone, cortical and endosteal irregularities or defects, osseous cyst-like lesions, and increased mineralization or osseous fluid occupying cancellous bone in the palmar process adjacent to the insertion of the collateral ligament. Partial or complete avulsion of a collateral ligament from its insertion on the distal phalanx results in pooling of hyperintense joint fluid in the defect, outlining the distal stump of the torn collateral ligament (Figure 3.231). Collateral desmitis of the DIP joint may occur in conjunction with ossification of the collateral cartilages.[55,56,105] Osteoarthritis or misalignment of the DIP joint caused by subluxation associated with collateral ligament injury may occur but are rare. Marked widening of the joint space may indicate joint instability associated with severe collateral ligament injury, but this sign should be assessed with caution as asymmetric weight-bearing or positioning of the limb also results in an asymmetric joint space.

Due to the highly common normal signal variation, it may be difficult to establish the clinical significance of mild signal changes in collateral ligaments.

Lesions of the DIP Joint

The presence of joint distension can be readily deduced from enlargement of the dorsal and palmaroproximal outpouchings of the DIP joint with fluid. Distension may cause palmar deviation of the axial part of the collateral sesamoidean ligaments. Distension of the dorsal joint pouch is generally more prominent in standing horses than in recumbent horses. Distension of the DIP joint is a frequent nonspecific finding in many horses irrespective of the primary injury site.[46,152]

The DIP joint usually has smoothly curved articular surfaces that make it difficult to assess the articular cartilage accurately due to partial volume averaging, so that focal cartilage defects may be missed. Thinner slice thickness is helpful in reducing this artifact and improving cartilage definition. Dorsal and sagittal T1 high spatial resolution slices are used for cartilage assessment with the 0.27T low-field magnet on standing horses.[149] On these high-resolution images, the articular cartilage layers are clearly distinguishable as two distinct layers of high signal separated by a thin line of intermediate signal representing synovial fluid in the joint space.[133,149] Careful slice-per-slice comparison with the contralateral normal limb is necessary.

Generalized cartilage disease in osteoarthritis may be observed as loss of cartilage surface definition, loss of visual distinction between the two cartilage layers, cartilage surface irregularity, or generalized thinning of the

VetBooks.ir

articular cartilage layer. The resulting narrowing of the joint space width may be an early sign of osteoarthritis,[149] but this sign is only reliable if the horse is either bearing weight symmetrically in a low-field magnet or the foot is supported with the limb held straight in a high-field magnet. In MRI of standing horses bearing weight evenly, generalized loss of articular cartilage may result in malalignment between the middle and distal phalanges.[149]

Focal cartilage lesions are recognized as focal increase (T2, PD, or STIR images) or decrease (T1) in signal intensity caused by pooling of synovial fluid in a cartilage defect (Figure 3.232). Not all focal cartilage defects cause lameness, and many focal cartilage defects occur without signal alteration in the adjacent subchondral bone.[179] Nonetheless, altered thickness of the subchondral bone plate, increased STIR signal in subchondral bone, and endosteal irregularity may be useful indicators for the presence of an adjacent area of cartilage damage.

Focal osseous cyst-like lesions confluent with an articular cartilage and subchondral bone defect and containing increased T1, T2, and STIR signal can be present in the central part or close to the palmar border of the weight-bearing surface of the distal phalanx, where they cannot be detected radiographically. There may be a variable amount of osseous fluid in the trabecular bone of the distal phalanx peripheral to the osseous cyst-like lesion. Small osseous cyst-like lesions or focal depressions in the subchondral bone with a corresponding cartilage defect may occasionally be seen in the central portion of the sagittal midline groove of the distal articular surface of the middle phalanx. These lesions are frequently an incidental finding, unrelated to foot lameness.

Osteophytes may be visible as small spur formations on the extensor process of the distal phalanx, the palmar margin of the middle phalanx, and the dorsoproximal border of the navicular bone. They are most easily identified on T2* images, but radiographs are generally more sensitive for the identification of osteophytes than MR images.[149]

Septic arthritis can cause specific MRI abnormalities that may allow early and accurate diagnosis of synovial sepsis.[62,67,191] Most striking is generalized diffuse STIR signal increase in the distal phalanx, middle phalanx, and/or navicular bone. Other changes include heterogeneous synovial fluid signal, capsular thickening, synovial proliferation, cartilage loss, focal subchondral bone lysis, and early sequestrum formation. Post-gadolinium imaging may highlight fibrin deposition and result in synovial membrane enhancement.

Lesions of the Distal and Middle Phalanges

Osseous trauma to the phalanges results in more or less extensive osseous fluid. Signal intensity may initially also be high on T2-weighted sequences and gradually diminishes as reactive mineralization (sclerosis) occurs in the area of the bone bruise. There is usually associated increase in radiopharmaceutical uptake on scintigraphic images. Bone bruises of the phalanges occur mostly in the region of the palmar process of the distal phalanx[46] or the dorsodistal aspect of the middle phalanx.[134,189] Bone bruises of the palmar processes of the distal phalanx can be associated with irregularity of the cortical margin and disruption of the adjacent laminar architecture. Chronic bone mineral density increase of a palmar process of the distal phalanx may be the result of a chronic bone bruise, or may be associated with collateral ligament injury. Bone bruising of the dorsodistal aspect of the middle phalanx[134,189] (Figure 3.233) usually involves a well-circumscribed area of cancellous bone adjacent to the dorsal half of the DIP joint and can be located axially or abaxially in the middle phalanx. The presence of osseous fluid in this location may be associated with concurrent increased osseous fluid in the spongiosa of the navicular bone.

Osseous fluid in the distal phalanx may also be secondary to primary injuries of the foot like collateral desmopathy, osteoarthritis of the DIP joint, extensive ossification of the cartilages of the foot, osseous cyst-like lesions,[107] and space-occupying lesions.

Generalized osseous fluid in the distal and/or middle phalanges with markedly increased STIR signal throughout the entire spongiosa may also be one of the earliest signs of osteomyelitis (e.g. associated with a puncture wound). However, a similar pattern of generalized osseous fluid in the spongiosa of one or both phalanges may be seen in the presence of severe regional inflammation as caused by a joint flare or septic arthritis of the DIP joint.[62,67,191]

MRI may identify incomplete or complete fractures of the phalanges that are not visible radiographically because the fracture plane does not coincide with the direction of the standard radiographic projections. A predilection site for fractures of the distal phalanx has been described at the base of an ossified ungular cartilage

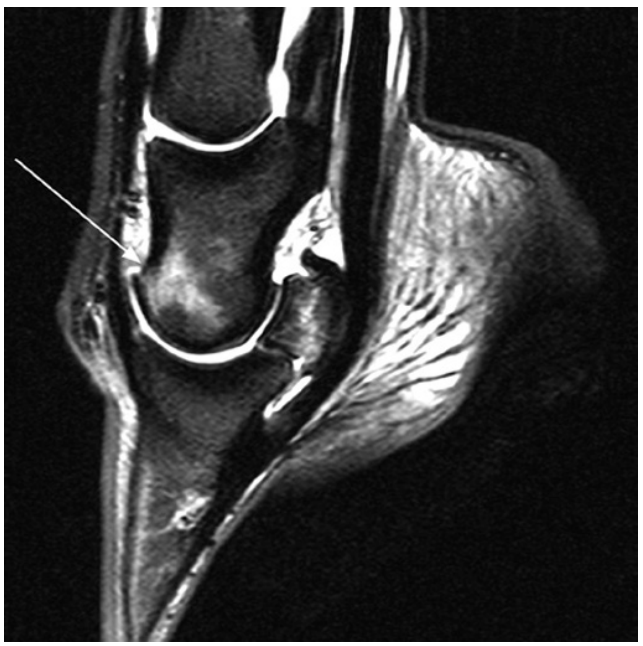

Figure 3.233. Sagittal short tau inversion recovery (STIR) image of the central part of the foot of a horse with acute onset foot lameness. There is an area of marked signal hyperintensity at the dorsodistal aspect of the middle phalanx adjoining the articular surface of the distal interphalangeal joint (white arrow). This appearance is suggestive for the presence of bone edema or a localized bone bruise of the middle phalanx.

VetBooks.ir

(sidebone).[162] These stress fractures may be incomplete or complete and are usually accompanied by extensively increased bone mineral density (sclerosis) of the palmar process and the ossified ungular cartilage. They are non-articular, simple, and non-displaced fractures but frequently involve the fossa of the collateral ligament of the DIP joint. They have a predictable proximodistal course with a palmar to dorsal and axial to abaxial orientation. Enlargement and signal abnormalities were seen in the ipsilateral chondrocoronal, chondrosesamoidean, collateral sesamoidean, and collateral ligaments of most horses and thought to contribute to the pain causing lameness.[162]

Lesions of the Ungular Cartilages

Primary injuries of unossified ungular cartilages and their related chondrocoronal and chondrosesamoidean ligaments are uncommon. Diagnosis depends on MRI that reveals a markedly thickened, hypervascular cartilage with irregular contours and diffusely increased STIR signal intensity.[45] Occasionally the thickened, inflamed cartilage may appear malaligned and displaced relative to its attachment site on the palmar process of the distal phalanx.

Ossification of one or both cartilages of the foot is usually characterized by continuity of normal bone structure from the proximal portion of the palmar process through the ossified cartilage with a hypointense outer rim of cortical bone surrounding a hyperintense spongiosa. However, trauma to an ossified cartilage may result in increased bone mineral density (sclerosis) combined with focal or diffuse osseous fluid and is characterized by increased STIR signal and reduced T1 and T2 signal either at the base of the ossified cartilage or at the junction between two separate centers of ossification. Increased mineralization may also be an incidental finding but usually then without osseous fluid. Trauma to an ossified cartilage may be accompanied by thickening and signal abnormalities in the chondrosesamoidean and chondrocoronal ligaments. Collateral desmitis of the DIP joint may also occur in conjunction with severe ossification of the collateral cartilages.[45,55,105]

Fracture results in a clear linear hyperintensity at the base of an ossified cartilage surrounded by osseous modeling, including osseous fluid, although clear differentiation between trauma to the junction between separate centers of ossification and a fracture is not always easy.[55,162]

Quittor or infection of an ungular cartilage is characterized by thickening of the infected cartilage and increased STIR signal. There may be evidence of fluid tracts or fluid pooling with focal high or heterogeneous T2 and STIR signal intensity within the cartilage and surrounding soft tissues. MRI examination may also reveal variable involvement of other soft tissue and osseous structures of the foot in addition to infection of the ungular cartilages. Preoperative MRI was shown to facilitate and guide the surgical approach to and postoperative management of quittor in patients.[112]

Lesions of the Hoof Wall and Space Occupying Lesions

MRI has revealed soft tissue changes of the dorsal hoof wall in acute and chronic phases of laminitis.[3,72,118] High-field MR images (4.7T) of the developmental stage of laminitis were able to show loss of normal corium architecture, loss of lamellar architecture, increased signal intensity in the dermis including in the lamellae, and focal areas of separation between the epidermal and dermal lamellae in the stratum lamellatum, resulting in an increased ratio (>0.7) between the width of the stratum lamellatum and the total dermal width (stratum lamellatum + stratum reticulare).[3] Similar but more pronounced findings were seen in chronic laminitis due to displacement of the distal phalanx with more obvious separation between dermal and epidermal lamellae and the formation of a triangular wedge of lamellar regeneration.[89,118] Additional findings were circumscribed areas in the hoof wall of low intensity representing gas, circumscribed areas of high signal intensity representing abscess formation, irregularity of the cortical outline of the distal phalanx, increased osseous fluid palmar to the dorsal cortex of the distal phalanx, and increased size and number of vascular channels in the distal phalanx.[89,118]

Mild focal disruption of interlamellar alignment or focally increased dermal fluid may be seen as an incidental finding not related to lameness. Focal or linear hemosiderin accumulation in the dermis from old trauma may cause a signal void.

Space-occupying masses in the stratum medium or lamellatum of the hoof wall, containing a variable amount of keratin, may be a cause of lameness or an incidental finding on MR images. MRI reveals a smoothly demarcated hoof wall lesion replacing the normal architecture of the dermis of the hoof wall or sole with deformity of the adjacent surface of the distal phalanx. The signal characteristics of these space-occupying masses vary from an area void of signal or with hypointense signal on any sequence to an area of heterogeneous mixed signal intensity in T1- and T2*-weighted images and hypointensity in STIR sequences (Figure 3.234).[101,104,106] This signal variation is likely to reflect the degree of keratinization in the mass. While true keratomas usually result in a well-circumscribed hypointense circular area protruding into the dermis and osseous defect, the signal intensity of granulomas and fibrous or fibrovascular masses tends to be more heterogeneous and mixed.[7,101,106] Adjacent intermediate or high STIR signal intensity in the trabecular bone of the distal phalanx is indicative of reactive inflammatory osteitis. The tomographic slicing produced by MRI has been useful for precise anatomical localization and surgical planning of hoof wall mass removal.[68,106]

Puncture Wounds of the Sole

MRI has been shown to be an excellent modality for diagnosing penetrating foot injury in the horse.[20,92] Injuries from penetrating foreign objects in the foot often result in focal areas of hypointense signal traversing the soft tissues on the palmar aspect of the foot in all image sequences. Signal hypointensity of these tracts is explained in acute stages as a signal void due to air or ferrous material and in chronic stages due to hemosiderin,[20] which may persist indefinitely as a sign of previous penetrating injury. In one large, retrospective study of horses with synovial sepsis following a penetrating injury, MRI was able to identify injury to the DDFT, the

VetBooks.ir

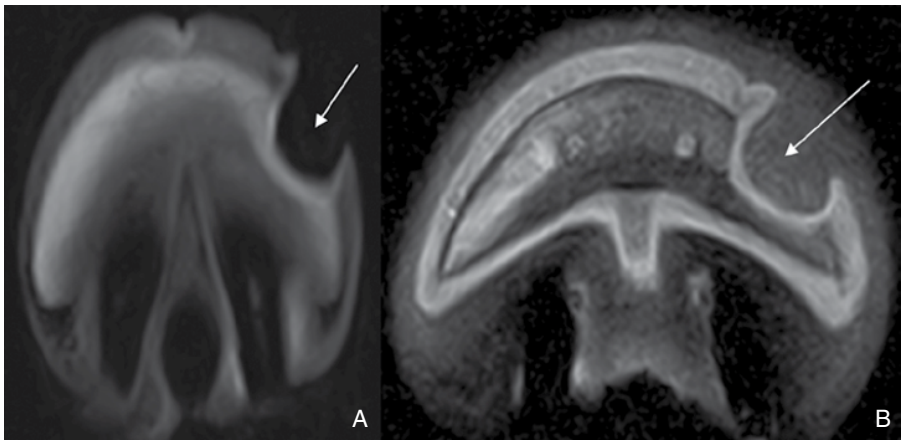

Figure 3.234. Low-field transverse horizontal T2 FSE (A) and transverse oblique T1 GRE (B) images of a horse with a keratoma of the hoof wall. There is an extensive circular area of T2 signal void (left arrow) and T1 signal hypointensity intruding from the hoof wall into the dermis and corresponding large but smooth osseous defect (right arrow).

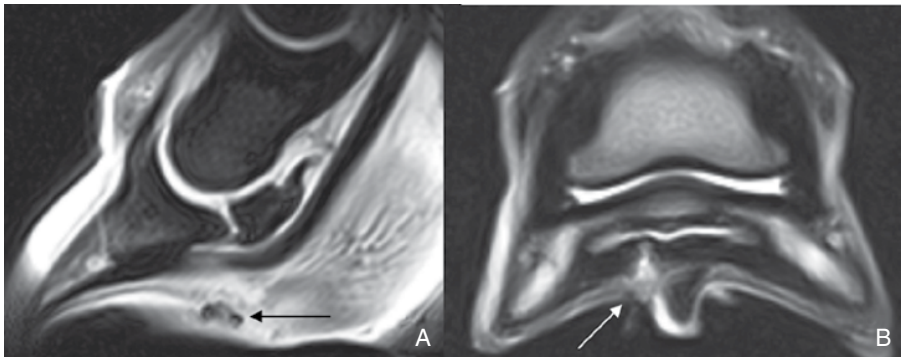

Figure 3.235. Low-field sagittal T2* GRE (A) and dorsal T2 FSE (B) images of horse with a nail puncture of the lateral sulcus of the frog. There are susceptibility artifacts in the frog tissue caused by either hemosiderin or metallic debris in the penetrating tract (black arrow). Linear T2 signal hyperintensity suggests there is fluid in the tract that continues into a parasagittal breach of the lateral lobe of the deep digital flexor tendon (white arrow).

navicular bone, and the DIP joint.[65] MRI not only allows assessment of tract direction and depth but is the only imaging technique that permits early recognition of tendon disease (Figure 3.235), osseous injury, and involvement of surrounding soft tissue structures. Another study highlighted the importance of using T2 FSE sequences to look at tendon boundaries and determine tendon involvement because signal voids created by ferrous material or hemosiderin can preclude full assessment of the tendon on GRE sequences.[155,181]

Generalized osseous fluid in the distal phalanx and navicular bone with markedly increased STIR signal throughout the spongiosa of these bones may be one of the earliest signs of synovial sepsis of the navicular bursa and/or DIP joint or of osteomyelitis.[191] This appearance of generalized "bone edema" should alert the clinician to the likelihood of penetration of at least one synovial cavity (Figure 3.215).

Gadolinium contrast fistulography may be useful to improve the identification of fistulous tracts in the foot.[66]

Lesions of the Proximal Interphalangeal Joint

Lesions in the proximal interphalangeal joint are rare. Occasionally focal subchondral bone damage with osteolysis and associated osseous fluid may be a cause of lameness. Osseous cyst-like lesions may be an incidental finding. Osteophytes may be visible at the joint margins, but radiography is generally more sensitive for this finding of osteoarthritis than MRI.

Lesions of the Digital Annular Ligaments

Isolated cases of desmopathy of the distal and proximal digital annular ligaments,[36] the axial and abaxial palmar ligaments of the proximal interphalangeal joint, the proximal ligament of the digital cushion, the chondrocompedal ligament, and the chondrosesamoidean ligament have also been observed. MRI characteristics of desmopathy are focal or diffuse thickening, focal or diffuse areas of signal hyperintensity within the ligament at the level of the proximal interphalangeal joint, and occasionally adhesion formation.[36]

Lesions that are Poorly Detectable with MRI

Some tissue abnormalities in the foot do not show up well on MR images. Abnormalities of the hoof and sensitive laminae of the solar and heel regions of the foot may not result in obvious signal abnormalities. Although some marked subsolar abscesses or bruises may result in dermal and osseous signal increase in the solar region of the foot, many horses with solar pain responsive to application of hoof testers have unremarkable foot MR images. Similarly, many horses with poor dorsopalmar foot balance resulting in palmar heel pain produce unremarkable MRI scans. Early hyaline or fibrocartilage degeneration of the DIP joint or navicular flexor surface as well as mild fibrillation of the dorsal surface of the DDFT in the navicular bursa may also be difficult to identify.[158]

MAGNETIC RESONANCE IMAGING OF THE FETLOCK REGION

Introduction

Conventional imaging techniques have limitations in the fetlock region. Radiography and scintigraphy are not capable of detecting early cartilage loss and subchondral bone injury without marked structural bone damage or demineralization.[54,166,202] Ultrasonographic evaluation lacks sensitivity for injuries of the suspensory branches and the straight and oblique distal sesamoidean ligaments.[152,172] Hence MRI is being used routinely to diagnose the causes of lameness in the fetlock region of horses. The primary indication for MRI is pain localized to the fetlock region with diagnostic analgesia, without sufficient radiological or ultrasonographic abnormalities to explain the degree of lameness. The increasingly frequent use of MRI to elucidate distal limb lameness has revealed that lameness caused by pain in the fetlock region may be abolished not only by an abaxial sesamoid nerve block in the majority of horses[35,51] but also, though less frequently, by a palmar digital nerve block.[37] Unfortunately, this regularly causes confusion as to which region of the distal limb should be evaluated first with MRI in horses that are presented with a history of lameness resolution following either of these nerve blocks. Experience with such patients teaches that horses presented with a history of a negative response to a palmar digital nerve block but a positive response to an abaxial sesamoid nerve block are much more likely to have a primary fetlock lesion than a foot lesion responsible for the lameness.[35]

The normal MRI anatomy of the fetlock joint has been described, using both high- and low-field images (MRI abnormalities in the fetlock region).[173] Several studies have documented the incidence of MRI diagnoses in the fetlock region (Table 3.4).[70,90,144] Types and incidence of lesions in the fetlock differ depending on horse breed and athletic activity. In a study of 40 horses from a variety of breeds and disciplines, half the horses

had subchondral bone abnormalities of the distal metacarpus and one third lesions of the distal sesamoidean ligaments.[70] However, in a different MRI study of 232 horses, also from a variety of breeds and disciplines, subchondral bone abnormalities were very uncommon, while more than half the horses were lame because of distal sesamoidean ligament injuries.[90] On the other hand, an MRI study of 131 racing Thoroughbreds with fetlock lameness reported almost exclusively osseous injuries, including subchondral bone trauma and incomplete stress fractures.[144] In both mixed breed studies,[70,90] distal sesamoidean ligament desmitis was the most common soft tissue injury, while other soft tissue injuries of the suspensory branches, collateral ligaments, intersesamoidean ligaments, and flexor tendons also occurred but with much lower frequency. Cartilage lesions, osteoarthritis, and osteochondral lesions were also reported. Combinations of injuries were common in the fetlock region, with 63% of horses in one study being identified with multiple MRI abnormalities.[70] Most common was the combination between subchondral bone lesions and injuries involving components of the suspensory apparatus.[70] Abnormalities of the subchondral bone and lesions of the distal sesamoidean ligaments have also been documented in other MRI reports.[54,151,172] Although subchondral bone injuries have been diagnosed with standing low-field MRI,[166] soft tissue abnormalities are much less commonly identified using standing low-field MRI.[144] The most common MRI diagnosis in racing Thoroughbreds was palmar/plantar osteochondral disease (POD) of the MCIII/MTIII, present in more than half of the horses examined.[144] Fractures were also much more commonly diagnosed on MR images of the fetlock of racing Thoroughbreds compared with other disciplines.[140,141,144,183] Soft tissue injuries were identified in less than 10% of racehorses with fetlock lameness,[144] although another more recent study found evidence of periarticular soft tissue injuries in 21% of racing Thoroughbreds and 37% of racing Standardbreds, but these were rarely considered the main cause of lameness (Table 3.4).[139]

MRI Abnormalities in the Fetlock Region

Subchondral Bone Abnormalities of the Metacarpal/Metatarsal Condyles

The normal subchondral bone thickness of the distal aspect of the MCIII/MTIII varies from dorsal to palmar and from abaxial to axial, being thinnest axially and thickest in the middle of each condyle, especially toward the palmar aspect.[47] Subchondral bone thickness of the distal aspect of the MCIII/MTIII is likely to change as it adapts to the type of exercise the horse performs. The subchondral bone thickness of the proximal phalanx increases slightly toward the palmar aspect of each condyle. There is reasonable lateromedial symmetry in subchondral bone thickness of both the MCIII/MTIII and the proximal phalanx. The increased use of MRI has highlighted the importance and high prevalence of bone sclerosis and bone marrow lesions in subchondral bone injury in the fetlock of horses.[42,51,69,139]

Abnormal MRI signal in POD lesions of the condyles of the MCIII/MTIII is manifested as diffuse or focal signal increase in fat-suppressed images consistent with bone marrow lesion or bruising and diffuse T1, PD, and T2 signal decrease consistent with trabecular thickening and osteosclerosis (Figure 3.236). Osseous fluid appears more commonly in the acute stage of injury, while

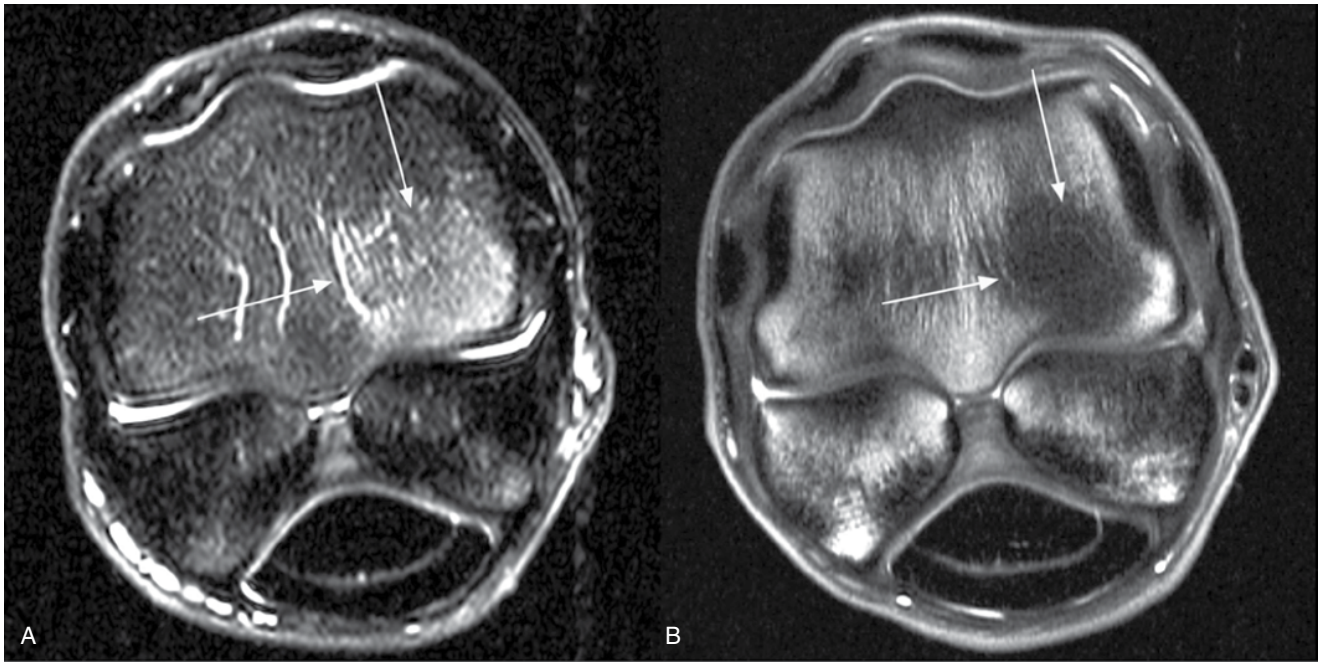

Figure 3.236. Transverse short tau recovery (STIR) image (A) and transverse proton density image (B) at the level of the proximal sesamoid bones of the right fore metacarpophalangeal joint of two different 3-year-old racehorses with fetlock lameness and abnormal MR signal in the palmar aspect of the lateral condyle of the third metacarpal bone. STIR signal hyperintensity suggestive of abnormal bone fluid is present in Figure A (arrows), while an area of signal hypointensity indicates the presence of palmar osteosclerosis in Figure B (arrows).

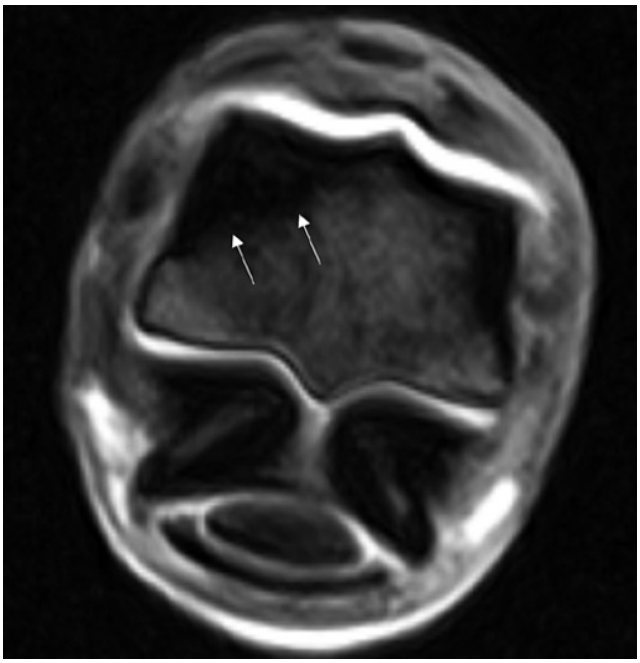

Figure 3.237. Transverse low-field T2* GRE image of the right metacarpophalangeal joint of an 9-year-old Warmblood. There is broad triangular area of low signal intensity containing a central zone of mixed signal intensity in the dorsal half of the medial condyle (arrows) of the third metacarpal bone, an appearance characteristic of dorsal osteochondral disease with mixed osseous fluid and sclerosis.

sclerosis reflects more chronic bone damage with reactive remodeling. Focal signal hyperintensity on all sequences within the sclerotic subchondral bone, adjacent to the joint margin of the affected condyle, is caused by trabecular necrosis in the center of the POD lesion.[176] When located close to the articular surface, osteonecrosis may lead to secondary articular cartilage loss, subchondral bone collapse, and joint contour deformity.

Location, severity, and extent of subchondral bone changes in the fetlock differ between Thoroughbreds, Standardbreds, and sport horses.[42,139,144] In racing Thoroughbreds and racing Standardbreds, bone signal changes were predominantly located in the palmar/plantar aspect of the distal condyle of the MCIII/MTIII (POD lesion), most commonly with biaxial distribution.[54,139,144,166,202] An MRI-based grading scale from 0 (normal) to 5 (markedly abnormal) to assess the severity of POD lesions has been proposed recently based on the abovementioned signs of disease caused by high-magnitude cyclical loading.[140,141]

Osseous changes (fluid and/or osteosclerosis) in the dorsomedial aspect of the condyles or dorsal sagittal ridge of the MCIII/MTIII occur much less frequently in racing Thoroughbreds[144] but have a high prevalence in racing Standardbreds[139] and sport horses[42] (Figure 3.237). In sport horses, especially show jumpers, dorsal bone marrow lesions of the metacarpal condyles are very common, though not always related to lameness.[42] Even though the authors did not find an association,[42] it is generally felt that the higher-grade lesions with extensive dorsomedial sclerosis and sometimes severe and extensive osseous fluid are more likely to be clinically significant than lower-grade lesions in this location.

Normal, parallel, linear areas of increased signal intensity on T2 and STIR images and decreased signal intensity on T1 images may be present in the palmar region of the distal metaphysis and epiphysis of the MCIII/MTIII. This "tiger-stripe" appearance is due to hypervascularity or congestion of the nutrient vessels that appear as well-defined hyperintense lines emanating from the palmar aspect of the metaphyseal region coursing in a dorsodistal direction into the condyles of the MCIII/MTIII. An increase in number, size, and conspicuity of these vessels may occur in the presence of chronic remodeling/sclerosis of the distal condyles or capsulitis with distension of the joint.

The ability of MRI to predict which horses are at risk of developing complete condylar or proximal sesamoid bone fractures has been studied extensively.[140,141,147,182,183] Despite conflicting information on a clear association between sclerosis and the ability to predict condylar fracture formation, there was an overall higher grade of osseous fluid (bone marrow lesion) and bone densification (sclerosis) in the condyle of bones with a condylar fracture, than in the condyles of the limbs of control horses.[140,141,182,183] There was also a higher grade of bone marrow lesion in the fractured condyle than in the corresponding condyle of the contralateral limb.[141] Recent studies have emphasized the important role of MRI in early detection of bone marrow lesions (osseous fluid) as a prodromal sign of condylar fracture.[141,144] Short unicortical fissures of the condylar groove have also been recognized as a prodromal pathology of condylar fractures that may be present for weeks to months, and MRI has been shown to be helpful in their early detection.[147]

Osseous Trauma of the Proximal Phalanx

Proximal phalangeal subchondral bone injuries diagnosed on MRI most often involve the sagittal groove area in all types of horses. The MR appearance of sagittal groove injuries has included osseous fluid, bone contusions, osteosclerosis, focal bone loss due to osteonecrosis, short incomplete midsagittal fractures, and osseous cyst-like lesions.[51,69,139,144] It is uncertain whether a continuum exists between these different injuries in nonracehorses as differences in characteristics have been suggested between lesions occupying the dorsal half of the sagittal groove (incomplete fracture) and those located in its center (sagittal groove trauma), even though the latter may also but rarely progress to fracture.[30,51,69,99]

Variable standing low-field MRI characteristics of acute or chronic presentations of sagittal groove trauma in mature Warmblood horses[69] (Figure 3.238) have been described as high signal on fat-suppressed images (osseous fluid), low signal on all sequences (sclerosis), ill-defined subchondral bone loss, focal subchondral bone defects, and short incomplete linear hyperintensity extending through the subchondral bone into the trabecular bone of the sagittal groove. In addition, all horses had abnormal bone mineral densification of the dorsal aspect of the sagittal ridge of the MCIII/MTIII and the majority also had signs of concurrent

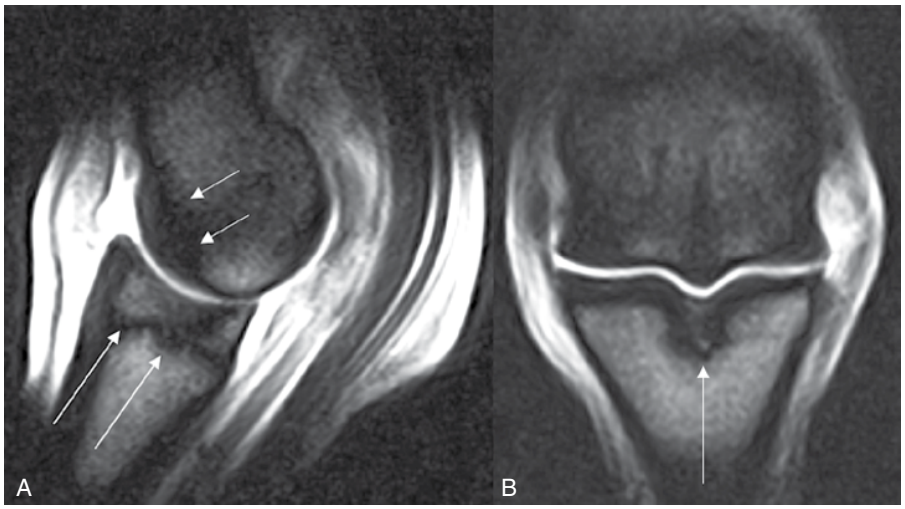

Figure 3.238. Sagittal (A) and dorsal (B) low-field T2* GRE images of the left metacarpophalangeal joint of an 11-year-old Warmblood with lameness due to sagittal groove trauma of the proximal phalanx. There is a large area of high signal intensity with a margin of low signal extending in a dorsopalmar direction along the base of the sagittal groove (lower left arrows). A similar signal abnormality can be seen on the dorsal image (right arrow). This fat/water cancelation artifact is characteristic for abnormal osseous fluid accumulation (bone contusion). Notice also the area of low signal (sclerosis) occupying the dorsal aspect of the sagittal ridge of the third metacarpal bone (upper left arrows).

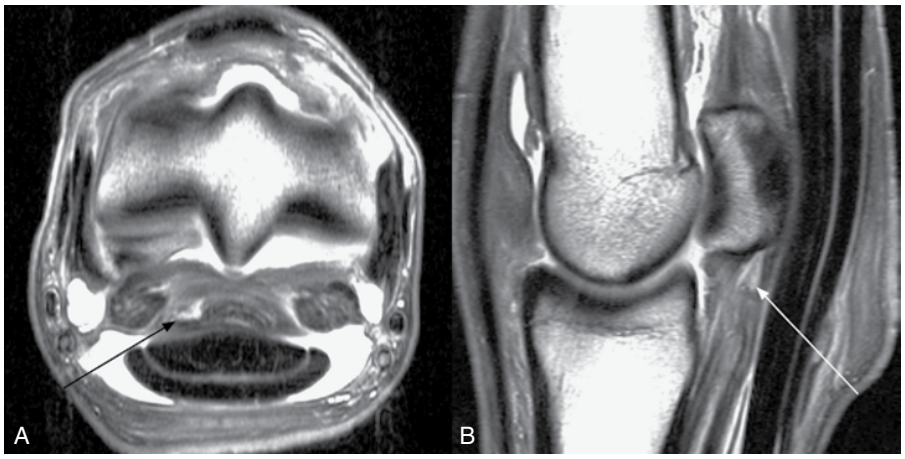

Figure 3.239. Transverse and sagittal proton density images of the metacarpophalangeal joint of a horse with chronic fetlock lameness. There is abnormal focal signal hyperintensity within the proximolateral aspect of the straight distal sesamoidean ligament indicative of local fiber disruption (black arrow). The lesion originates at the distal border of the lateral proximal sesamoid bone and extends 11 mm distally (white arrow).

osteoarthritis (osteophytes and synovitis).[69] Abnormal bone signal persisted at the sagittal groove of all horses with recheck MRI examinations.

Incomplete sagittal fractures of the proximal phalanx have been described mainly in racehorses and more recently also in sport horses.[58,69,91,99,144] MRI reviews of sagittal groove trauma in sport horses report incomplete sagittal fractures in 20,[69] 28,[99] and 50%[51] of patients, characterized by linear increased signal intensity in the subchondral bone in T1- and T2-weighted images.

Bone marrow lesions (osseous fluid) with or without loss of bone mineral density, extending distally from the joint surface through the subchondral bone of the medial glenoid of the proximal phalanx, have also been observed as a cause of fetlock lameness.[70,137,139,144]

Distal Sesamoidean Ligament Injuries

The straight distal sesamoidean ligament has a heterogeneous MRI appearance with multiple high and low signal areas spread throughout most of its length.[172] A normal, small homogeneous triangular signal hyperintensity exists at the insertion of the straight distal sesamoidean ligament onto the middle phalanx. The oblique distal sesamoidean ligaments have heterogeneous signal intensity throughout their entire length to the insertion. The lateral oblique distal sesamoidean ligament is frequently larger and more hyperintense than the medial ligament.[172] In a standing horse, images of the proximal third of the oblique distal sesamoidean ligaments are susceptible to magic angle effect, especially medially, resulting in increased signal intensity in the ligaments, thereby confounding image interpretation.[171] The signal heterogeneity of the distal sesamoidean ligaments varies between individual horses.[172] Normal signal heterogeneity should not be confused with the presence of a lesion. Abnormal signal intensity in a lesion of the distal sesamoidean ligaments commonly covers a larger cross-sectional area than the focal signal hyperintensities caused by normal signal variation.[172] Lesions within the oblique and straight distal sesamoidean ligaments can result in discrete or diffuse areas of signal hyperintensity within the body or along the edge of the affected ligament. One or multiple small core lesions with focal signal increase may be observed in affected ligaments, extending from 5 to 30 mm in a proximodistal direction (Figure 3.239). Enlargement of a ligament may also occur with or without abnormal signal increase, but this finding is less consistent. In one study, 30% of distal sesamoidean ligaments affected with desmitis were not enlarged.[70] Lesions may occur biaxially or bilaterally.

VetBooks.ir

The location of lesions within distal sesamoidean ligaments and the distribution of lesions varies between studies.[70,90,151,172] Straight sesamoidean desmitis occurs more commonly in the distal part of the ligament, proximal to its insertion on the middle phalanx,[151,172] although proximal lesions near the origin were most common in another study (Figure 3.239).[70] Oblique distal sesamoidean desmitis can occur proximally or throughout the entire length of the ligament.[70,90,151,172] Cruciate distal sesamoidean desmitis is very rare.[144,172]

Reports suggest that distal sesamoidean desmitis is frequently regarded as the primary cause of lameness,[70,90,151] although one author considered lesions to be the sole cause of lameness in only 2 of 58 horses with evidence of desmitis.[172] The majority of horses with oblique or straight distal sesamoidean desmitis diagnosed with MRI do not have a palpable enlargement, nor do they show any ultrasonographic abnormalities.[70,151,172]

Suspensory Ligament Branch Injuries

The suspensory ligament branches are paired triangular structures of low signal intensity that flatten in a dorsopalmar direction and widen lateromedially as they move distally toward their insertion on the proximal sesamoid bones. The margins of the branches are sharply delineated. Close to the insertion, the branches become D shaped on cross section, and faint, linear, high intensity, dorsopalmar striations appear near the ligament–bone interface, possibly associated with the presence of adaptive fibrocartilaginous metaplasia at the insertion. A small hyperintense indentation may be present in the palmar border of the normal suspensory branch immediately proximal to its insertion.

Generally, there is a good correlation between the presence of (even mild) MRI abnormalities in a suspensory branch and the ultrasonographic appearance of fiber abnormalities in that branch. Lesions are characterized by an intraligamentous focus of signal hyperintensity in PD, T2, and STIR images, usually near the palmar/plantar border of the affected branch, with or without enlargement of that branch (Figure 3.240). The clinical significance of mild signal changes in the suspensory branches is not always clear, but they may be the only finding in an otherwise normal MRI examination of a horse whose lameness was abolished by a low four-point nerve block. During standing low-field MRI, false signal increase in one or both suspensory branches may be caused by vascular flow artifact or magic angle artifact, even on transverse T2 FSE images.

Injuries of the Proximal Sesamoid Bones

Abnormal MRI signal in the proximal sesamoid bones includes osteosclerosis, STIR signal hyperintensity consistent with osseous fluid or contusion, and focal trabecular bone loss. Standing low-field MRI has been helpful in identifying osseous cyst-like lesions at various locations in the proximal sesamoid bones, involving the articular surface, the axial border, the abaxial surface, or the base.[108] Enthesopathy at the damaged attachment site of a sesamoidean ligament may result in trabecular bone loss leading to an osseous cyst-like lesion of the proximal sesamoid bone (Figure 3.241). Bone mineral

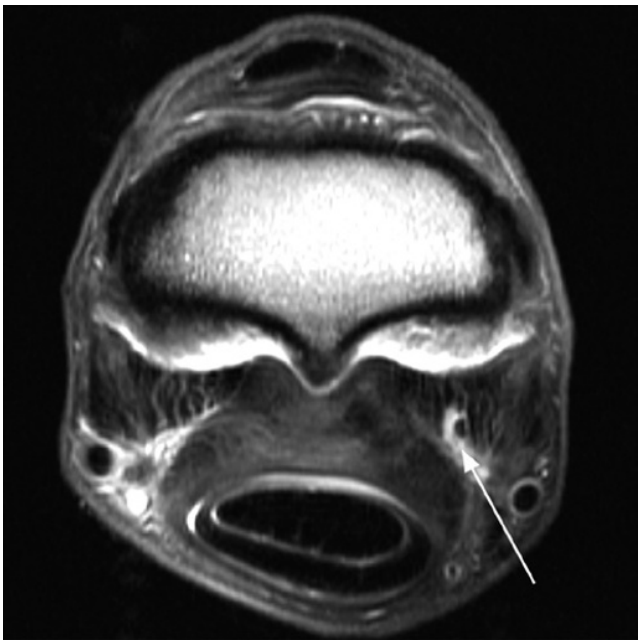

Figure 3.240. Transverse proton density image of a metatarsophalangeal joint of a horse with lameness localized to the fetlock region. There is a small, linear hyperintensity reflecting the presence of a tear in the plantar border of the lateral branch of the suspensory ligament (arrow).

There is focal and intense signal hyperintensity at the base of the medial proximal sesamoid bone (arrow) indicative of a small osseous cyst-like lesion associated with a small vertical tear of the straight distal sesamoidean ligament.

VetBooks.ir

densification of 75% or more of a proximal sesamoid bone or continuous dorsal to palmar bone mineral densification, as identified on standing low-field MR images, was considered to be associated with an increased risk of catastrophic fracture of the proximal sesamoid bones.[140]

Injuries of the Intersesamoidean Ligament

Intersesamoidean desmopathy results in a large or small, focal, central area of signal hyperintensity within the damaged portion of the intersesamoidean ligament in T1, T2, PD, and STIR images (Figure 3.242). Hyperintense lesions associated with focal trabecular bone loss may be found along the axial margin or at the apex of the proximal sesamoid bones in association with intersesamoidean ligament injury. Injuries may also result in small avulsion fracture fragments of the axial margin. Intersesamoidean ligament injury can affect one or both proximal sesamoid bones.

Axial osteitis of the proximal sesamoid bone and necrosis of the intersesamoidean ligament characterized by hyperintense signal may also be a complication of focal sepsis of hematogenous or unknown origin, and the distinction between septic and traumatic lesions may be difficult to make, even on MR images.

Osteophyte formation at the proximal and distal margins of the sesamoid bones may be present in association with osteoarthritis of the fetlock joint.

Osteoarthritis and Articular Cartilage Abnormalities

The distal articular surface of the MCIII/MTIII in the fetlock joint is the most difficult to image with MRI because of its curvature and the thin articular cartilage layer. The ability to assess cartilage injuries in this joint challenges the limits of MRI systems and the capability to resolve fine detail.[193] A focal, irregular island of fluid hyperintensity associated with pooling of synovial fluid in a chondral defect can sometimes be recognized on transverse PD, T2, or STIR images that are located exactly parallel with and through the affected articular surface (Figure 3.243). Cartilage defects have been identified on all articular surfaces in the fetlock joint.[70] Overall, high-field MRI tends to underestimate the number of cartilage lesions, the size of the lesions, and the extent of cartilage loss in the fetlock joint compared with arthroscopic findings, gross examination, or histology.[70,132,136] The sensitivity of MRI is particularly decreased when chondral lesions are linear in nature.[136,193] There is a major effect of field strength on detection of articular cartilage lesions in the fetlock joint, with markedly decreased accuracy of standing low-field MRI.[193] In an *ex vivo* study comparing the effect of sequence selection and field strength on detection of osteochondral defects in the metacarpophalangeal joint, experimentally created articular cartilage defects were not identified on low-field images.[193]

A specific focal cartilage defect at the dorsodistal abaxial aspect of the medial metacarpal condyle has been described as a chondral delamination injury of the equine distal metacarpus caused by calcified cartilage fracture.[110] The lesion is characterized by intense focal STIR signal increase in the subchondral bone subjacent to the cartilage defect and by pooling of synovial fluid inside the contours of the cartilage defect on MRI images.

Osteophytes may be seen as contour changes of the proximal and distal articular margins of the proximal sesamoid bones and the dorsoproximal, lateral, and medial margins of the proximal phalanx. Osteophytes may be more easily recognized on radiographs due to the radiographic summation effect and the better radiographic contrast between cortical bone and soft tissue attachments at the joint margins.[70] However, osteophyte scores were significantly higher on MR images than on radiographs in a study comparing imaging modalities for the assessment of noncartilaginous changes in equine metacarpophalangeal osteoarthritis.[135,137] The authors reported a particular central subchondral osteophyte type that could only be diagnosed with high-field MRI or computed tomography.[135] Central subchondral osteophytes were described as focal hypointense protuberances projecting from the subchondral plate of the palmarodistal aspect of the metacarpal condyle into the overlying articular cartilage.

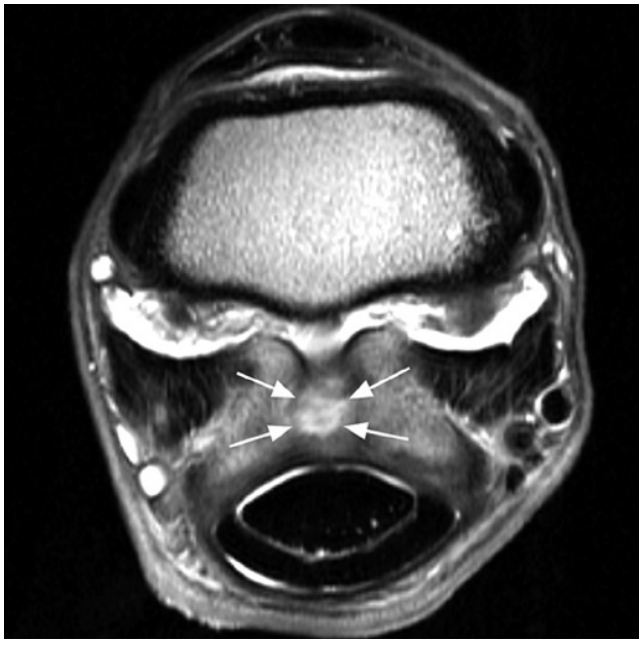

Figure 3.242. Transverse proton density image at the level of the apices of the proximal sesamoid bones of a horse with acute severe metacarpophalangeal joint lameness. There is a circular area of signal hyperintensity indicative of fiber disruption and desmitis in the intersesamoidean ligament (arrows).

Osteochondral Fragmentation

Some osteochondral fragments from the dorsoproximal margin of the proximal phalanx and the basilar margin of the proximal sesamoid bones that are not visible radiographically may be recognized as focal areas of osseous hypointensity separated from parent bone on all sequences. Osseous fragments may be difficult to distinguish from end-on blood vessels near joint margins as both may appear hypointense on MR images. Avulsion fragments are always difficult to differentiate from the

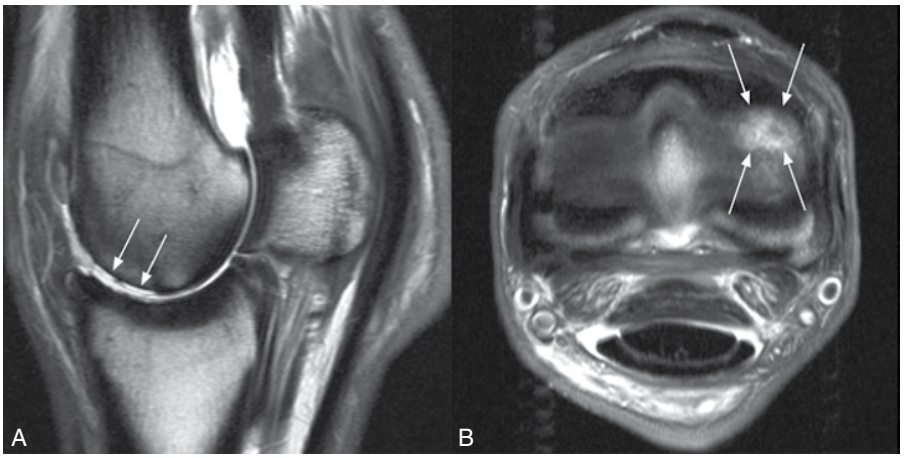

Figure 3.243. Sagittal and transverse proton density images of the fetlock of a horse with chronic metacarpophalangeal joint lameness. There is an elliptical area of full-thickness cartilage loss on the dorsodistal aspect of the medial condyle of the third metacarpal bone (arrows). This is characterized by replacement of the normal hypointense cartilage layer with pooling of hyperintense synovial fluid in the cartilage defect (arrows). A wavy, thin, hypointense line overlying the cartilage defect may indicate the presence of pannus tissue along with synovial fluid (A). An irregular island of fluid hyperintensity associated with pooling of synovial fluid in the chondral defect can be recognized on the transverse PD image that runs through the affected joint surface (B).

tendon or ligament in which they are embedded, due to the similarities in signal intensity between bone, tendon, and ligaments.

Abnormalities of the Digital Flexor Tendon Sheath

Injuries of the digital flexor tendons in the digital flexor tendon sheath may be recognized as dispersed small, focal areas of signal hyperintensity, distinct hyperintense core lesions, thickening of the affected lobe(s), and/or longitudinal parasagittal or frontal splits of the lateral or medial border of the tendon with partial separation of the tendon margins (Figure 3.244). Lesions of the DDFT within the digital flexor tendon sheath may continue distally into the navicular bursa and the insertion on the distal phalanx. Lesions of the superficial digital flexor tendon within the digital flexor tendon sheath may extend into one of the branches of the tendon and its insertion on the middle scutum. Areas of signal hyperintensity and contour changes of the flexor tendons within the digital sheath are most obvious in transverse fat-suppressed T1 spoiled gradient-echo (SPGR) images and frequently not visible ultrasonographically. Increased fluid distension and intrathecal soft tissue proliferation of the digital flexor tendon sheath and thickening and signal change in the palmar annular ligament of the fetlock have also been recognized.[70]

Figure 3.244. Transverse fast low-angle shot (FLASH) image with fat saturation immediately distal to the base of the proximal sesamoid bones of a horse with chronic lameness localized to the digital flexor tendon sheath. There is a small linear hyperintensity (arrow) that was revealed to be a longitudinal tear of the lateral margin of the deep digital flexor tendon extending 3.5 cm proximodistally into the fetlock canal. The detached lateral margin of the tendon is slightly displaced. This lesion was treated successfully by tenoscopic removal.

Collateral Ligament Injuries

Collateral desmitis is characterized by enlargement of the superficial or deep part of the collateral ligament relative to the contralateral limb and by the presence of signal hyperintensity in T2 and PD images in the affected part of the ligament. Signal increase may be difficult to recognize in the deep part of the collateral ligament as this structure frequently appears hyperintense on PD and T1-weighted MR images, due to the presence of magic angle effect caused by the oblique fiber orientation in the deep part of the collateral ligament. Evidence of endosteal irregularity may be present at the origin of a collateral ligament. A small avulsion fragment at the base of the epicondylar fossa in association with collateral desmitis has been described.[70]

MAGNETIC RESONANCE IMAGING OF THE METACARPAL AND METATARSAL REGIONS

Introduction

Lameness caused by pain associated with the proximal palmar metacarpal and plantar metatarsal regions is common in equine athletes. Some of the causes of lameness in this region are difficult to diagnose accurately because affected horses frequently have no or equivocal radiological or ultrasonographic signs of disease. It may thus not always be possible to distinguish between normal anatomy, imaging artifacts, and structural abnormalities of the suspensory ligament using ultrasonography.[52] The tomographic nature of MRI allows assessment of size and signal changes within the complex anatomy of this region and results in good soft tissue contrast and detail without superimposition.

There have been several reports with widely varying results on the incidence of injuries diagnosed with both low- and high-field MRI systems in the metacarpal and metatarsal regions (Tables 3.5 and 3.6).[5,6,28,93,128] In general, transverse MRI slices that are aligned perpendicular to the long axis of the cannon bone (parallel with the carpometacarpal/tarsometatarsal joint) are most useful for diagnosis.

In the forelimb (Table 3.5), the reported distribution of MRI abnormalities appears to depend on field strength of the system used. A very low incidence of soft tissue injury in the proximal metacarpal region has been reported in a low-field study,[128] while high-field studies consistently indicate much higher numbers of injuries of the accessory ligament of the DDFT and the suspensory ligament.[5,28] This may be explained by easier recognition of bone signal change than soft tissue change in standing low-field MR systems, because motion artifact in standing patients can lead to poor recognition of anatomical detail as well as of signs of injury in soft tissue structures. Motion artifact results in blurring of signal and loss of contour definition of the muscle and adipose tissue bundles within the suspensory ligament. Inability to accurately define these muscle and adipose tissue bundles hampers the ability to distinguish these bundles from areas of fiber damage in the collagenous part of the suspensory ligament. Lesion occurrence in forelimbs is also heavily influenced by the horse's discipline and age. A recent high-field study showed a much higher prevalence of osseous abnormalities of the third metacarpal bone in young Quarter horses used for cutting than previously reported in studies of mixed breed sport horse populations.[5,28]

As the only retrospective MRI studies of the metatarsal region available have been performed with high-field magnets,[6,28,93] a comparison between low- and high-field injury prevalence is not possible for the hindlimb (Table 3.6). However, given that motion artifact tends to be more pronounced in standing MRI of the hindlimb than the forelimb, the same concerns apply. By far the most common injury in the proximal metatarsal region is desmopathy of the proximal part of the suspensory ligament with or without an enthesis injury of the third metatarsal bone at the attachment of the suspensory ligament. The high occurrence of MR abnormalities of the distal tarsal region in horses with lameness localized to the proximal plantar metatarsal region with diagnostic anesthesia illustrates the concern that local anesthetic techniques lack specificity for accurate localization of pain causing lameness in this area.[6,93]

MRI Abnormalities in the Proximal Metacarpal/Metatarsal Regions

Proximal Suspensory Desmopathy

The normal MRI anatomy of the fore and hind suspensory ligaments has been described in detail.[14,59,94,124,127] The normal suspensory ligament is a low signal intensity structure of hypointense dense collagen fibers, interspersed with two centrally located high signal intensity tissue bundles, that each contain sparse muscle fibers surrounded by a layer of loose and adipose connective tissue and neurovascular structures. Normal cross-sectional areas have been defined for the proximal part of the suspensory ligament in the forelimb and vary from 1.61 to 1.90 cm^2 in one study[5] and from 1.94 to 2.32 in another.[127] There is considerable variation between horses in the MRI appearance of the proximal portion of the forelimb suspensory ligament,[124] due to the variation in the amount, shape, and signal intensity of the muscle and fat tissue bundles.[127] Within these bundles, high signal intensity areas correspond to adipose tissue and intermediate signal intensity areas to muscle tissue. The large variability in the MRI appearance of the proximal portion of the forelimb suspensory ligament in non-lame horses should be borne in mind when interpreting MR images of lame horses.[127] Therefore, comparison with the contralateral limb or with published reference images may be useful to help with interpretation of suspected MRI changes.[124]

In hindlimbs, the suspensory ligament starts as a narrow triangular band, evolves into a right-angled triangle that is wider on the lateral aspect than medially, and contains a dorsal central cleft dividing it in two lobes. At 4 cm distal to the tarsometatarsal joint, it becomes oval to bean shaped and separates away from the plantar cortex of the third metatarsal bone to continue distally, while both lobes merge into one oval ligament.[161] Normal cross-sectional areas have been defined for the proximal part of the suspensory ligament and have varied from 1.12 to 2.23 cm^2.[161] Injuries of the proximal part of the suspensory ligament may result in enlargement, contour changes, focal and diffuse signal increase, and periligamentous fibrosis.

Abnormalities are best seen in transverse PD images. Lesions can be graded as mild, moderate, or severe, depending on the abnormal signal intensity and the proportion of total cross-sectional area of the ligament affected.

Enlargement of the cross-sectional area of the suspensory ligament may vary from mild to severe, but because of the variation in size within limbs and between horses, this feature should be interpreted with caution especially when the enlargement is mild.[5,93,127,161] Even though marked enlargement may result in a decrease of the space between the dorsal margin of the suspensory ligament and the palmar or plantar surface of the bone, periligamentous fibrosis and adhesion formation are uncommon features of proximal suspensory desmopathy.

[b] Western cutting horses only.

Contour changes or loss of a distinct border are common[28] and usually accompany areas of focal or diffuse signal increase in the dense collagenous regions of the ligament. Focal or diffuse areas of signal increase reflect disruption of the dense hypointense collagenous tissue.[28,93] Signal increase has been described predominantly in the central and centrolateral dense collagenous portions of hind suspensory ligaments (Figure 3.245).[93] In one report, lesions extended on average 13.2–51.1 mm distal to the tarsometatarsal joint with lesion length varying from 4.3 to 107 mm.[93] In the forelimbs of young Quarter horses used for cutting, signal increase was seen predominantly at the dorsal margin of the proximal portion of the ligament, either confined to the medial bundle or involving the entire dorsal margin.[5] Although signal changes due to fiber disruption mainly affect the dense collagenous part of the suspensory ligament, muscle and fat bundles may be included in the disease area in severe cases, where the area of signal increase exceeds 30% of the cross-sectional area of the ligament with loss of normal architecture.[5,6,93] Decrease in size or signal of the central normal muscle and fat bundles may be caused by relative enlargement of the peripheral collagenous areas of the ligament.[28] Recently, an association has been suggested between proximal suspensory pain and signal changes and histological abnormalities of the fat and muscle bundles without involvement of the dense collagenous tissue in the proximal portion of the suspensory ligament of hindlimbs.[60,61] However, given the normal signal variation of these fat and muscle tissue bundles, the study's bias toward limbs with moderate to severe ultrasound changes, the lack of agreement between microscopic lesions of the muscle bundles and moderate to severe echogenicity changes of the collagen fiber pattern, and the lack of agreement between documented microscopic lesions of muscle and fat bundles and previous high-field MRI descriptions of proximal suspensory desmopathy,[6,28,93] a better understanding of these findings, their prevalence, and significance is required.

In many cases, evidence of enthesis bone injury at the level of attachment of the suspensory ligament to the

proximal palmar/plantar aspect of the cannon bone is seen concurrently with proximal desmopathy (Figure 3.246). The concurrent presence of bony and ligamentous changes appears to be more common in forelimbs than hindlimbs, especially in young Quarter horses used for cutting.[5]

Adhesions of the Suspensory Ligament

In normal forelimbs, a space of loose connective tissue with high signal intensity exists between the medial border of the suspensory ligament and the second metacarpal bone.[124,127] The lateral border of the suspensory ligament is overall closer to the fourth metacarpal bone and may in some areas contact the bone. The same applies in the hindlimb, where the suspensory ligament is positioned more laterally on the plantar aspect of the cannon bone than in forelimbs and the lateral border of the ligament contacts the fourth metacarpal bone between 0 and 2 cm and again between 8 and 12 cm distal to the tarsometatarsal joint.

The tomographic nature of MRI allows for visualization of the margins of the entire suspensory ligament. This has enabled a more definitive diagnosis of adhesions between ligament margins and exostoses of the second and fourth metacarpal and metatarsal bones,[203] where ultrasonography is unable to determine the existence of abnormality. Adhesions lead to suspensory desmitis through tearing of the adhered ligamentous fibers with resulting inflammation and lameness. Loss of normal space between the suspensory ligament and a splint bone, in conjunction with signal or contour changes of the suspensory ligament and bone proliferation on the surface of that splint bone, is strongly suggestive of adhesion formation. Adhesions may be visible as a tissue band of low signal connecting the ligament to an area of osseous proliferation on the axial surface of a splint bone. However, these findings should be interpreted with caution because normal fibers of the suspensory ligament have been shown to originate from the proximal part of the fourth metatarsal bone and the lateral margin of the normal suspensory ligament is overall

VetBooks.ir

closer to and may contact the fourth metacarpal and metatarsal bones.

Osseous Injury of the Third Metacarpal/Metatarsal Bone

The normal proximal palmar/plantar metacarpal/metatarsal cortex has a uniform thickness and smooth periosteal and endosteal surfaces, although mild endosteal and periosteal irregularity may be seen in some horses.[124] The smoothness of the palmar/plantar cortex at the origin of the suspensory ligament is difficult to evaluate, because both the cortex and the suspensory ligament have low signal intensity and cannot be distinguished from one another. Between 3 and 5 cm distal to the carpometacarpal joint, the metacarpal cortex is slightly thicker medially than laterally.

Bone injury at the site of attachment of the suspensory ligament not only occurs most frequently in combination with proximal suspensory desmitis but also can be seen as an isolated injury.[5,28,93,127] Abnormalities indicative of enthesis bone injury at the origin of the suspensory ligament include abnormal medullary signal hypointensity on transverse PD and T2-weighted images indicative of increased bone density (sclerosis) (Figure 3.246), medullary signal hyperintensity on STIR images and fat/water cancelation artifact on T2* images compatible with the presence of abnormal bone fluid, or a combination of both sclerosis and fluid. Horses with chronic suspensory ligament lesions tend to have more sclerosis often with thickening of the proximal palmar/plantar cortex and an irregular endosteal or periosteal contour due to new bone formation (Figure 3.246). The palmar/plantar cortex may further contain focal high intensity signal indicative of trabecular bone resorption resulting in an altered contour with a focal concave bone defect.

Primary bone injuries without suspensory ligament abnormalities can also occur in the proximal palmar/plantar aspect of the bone, with a similar range of MRI abnormalities indicating fluid, sclerosis, or both. The exact cause of these bone injuries is unknown, but a mechanism of repetitive cortical fatigue or stress injury seems likely,[115,151] especially in horses that perform strenuous exercise at high speed or over long distances, even though the injury has been documented in many different types and breeds.[115] MRI signs of traumatic bone bruising and remodeling appear predominantly on the medial palmar aspect of the proximal portion of the metacarpus but not limited to the attachment area of the suspensory ligament and have been described in young racing Thoroughbreds,[114,150] horses used for endurance racing,[29] and Western cutting horses.[5] In a more advanced form of this traumatic fatigue injury, incomplete vertical or oblique hairline fractures of up to 9 cm length may develop in the proximopalmar medial aspect of the third metacarpal bone.[82,114,115]

Isolated bone marrow lesions in the medullary cavity of the third metacarpal/metatarsal bones can occur in close relation to the nutrient foramen and intramedullary blood vessels as can focal enostosis-like lesions.

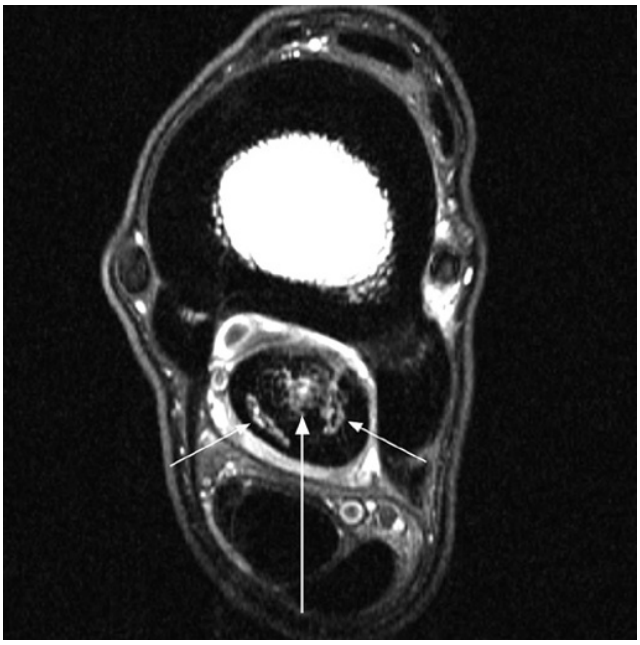

Figure 3.245. Transverse proton density image of the proximal metatarsal region of the right hindlimb of a horse with mild to moderate proximal suspensory desmitis. There is an abnormal area of diffuse signal increase in the central part of the suspensory ligament (long arrow). This must be distinguished from the two normal focal areas of high signal intensity associated with two muscle and fat tissue bundles in the suspensory ligament (short arrows).

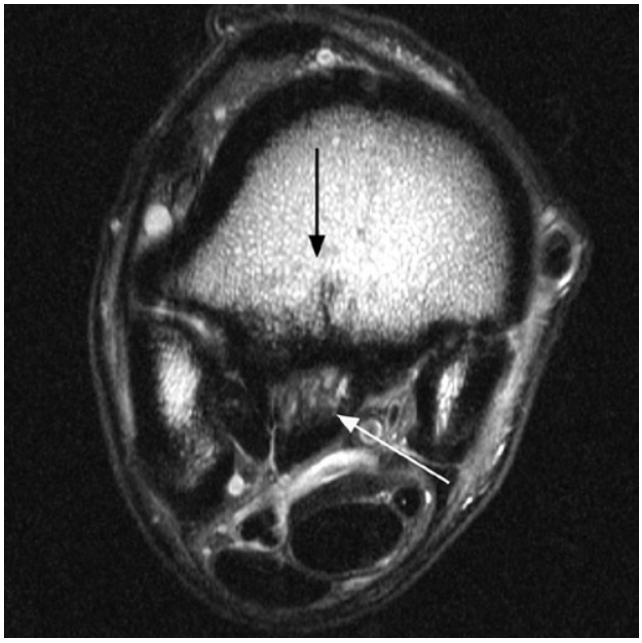

Figure 3.246. Transverse proton density image of the proximal metatarsal region of the left hindlimb of a horse with marked proximal suspensory desmitis and enthesopathy of the proximal plantar metatarsal cortex. There is a large central area of abnormal signal hyperintensity in the suspensory ligament (white arrow). There are irregular areas of low signal in the medullary cavity of the third metatarsal bone reflecting the presence of osteosclerosis (black arrow). The plantar metatarsal cortex is thickened and has an irregular endosteal margin.

VetBooks.ir

MRI evidence of traumatic bone injury is not only limited to the proximal palmar/plantar aspect of the third metacarpal/metatarsal bones but also has been encountered in the dorsal third metacarpal/metatarsal bone, as well as in the proximal aspect of the splint bones.[29,93]

Desmopathy of the Accessory Ligament of the Deep Digital Flexor Tendon

The accessory ligament of the DDFT often has heterogeneous signal intensity when examined in either a high-field or a low-field magnet.[125] In a cadaver MR imaging study, the majority of accessory ligaments had low to intermediate signal intensity but contained oblique bands of high signal intensity crisscrossing through the ligament. This was thought to be caused by the presence of thick collagen bundles arranged in large crimps, crossing obliquely and randomly through this ligament, thereby causing extensive magic angle effects.[125] Moreover, the cross-sectional area of the accessory ligament varied widely ranging from 68.1 to 299 mm^2 in its most proximal 7 cm. In addition, the authors cautioned that the presence of normally attached fibrous bands and the large variability in signal intensity and size of the accessory ligament in non-lame horses should be borne in mind when interpreting MR images of lame horses.[125]

MRI signs of desmitis were size increase and focal to diffuse intraligamentous signal hyperintensity.[28] Lesions generally extend from 1 to 4 cm distal to the carpometacarpal joint. Comparison with the contralateral limb was considered essential to allow detection of subtle signal and size changes. In this study, desmitis of the accessory ligament was the most common MRI finding in horses with proximal metacarpal region lameness. However, this observation has not been supported by others,[5,128] who never mentioned desmitis of the accessory ligament when discussing injuries in the proximal metacarpal region.

Abnormalities of the DDFT or the suspensory ligament may accompany desmitis of the accessory ligament.[142] In horses with chronic desmitis, irregularity of the borders of the ligament and loss of the distinct high signal border between the accessory ligament and the DDFT may occur. Low signal scar tissue bridging the hyperintense space between the ligament and the flexor tendons may be indicative of adhesion formation but must be distinguished from the normal fibrous bands on the lateral aspect of the ligament.[125]

Other Abnormalities

Other injuries have been reported in horses with lameness localized to the proximal palmar/plantar metacarpal/metatarsal region with diagnostic analgesia with a much lower incidence than those listed above (Tables 3.6 and 3.7). Mostly these findings involve the distal tarsal and carpal joints (see "MRI Abnormalities of the Carpal Region and MRI Abnormalities of the Tarsal Region") and indicate the lack of specificity of diagnostic analgesia of the proximal metacarpal and metatarsal regions.[6,93]

Occasionally focal fiber disruption without thickening is recognized with MRI in the SDFT or DDFT in the absence of ultrasonographic abnormalities.[41,93,150] MRI is not used routinely for the diagnosis of injuries of the flexor tendons in the metacarpal region as this is mainly done with ultrasonography. However, MRI may be more sensitive than ultrasonography for monitoring tendon repair.[86,88,160] The T2 versus T1 signal differences in healing tendon may prove to be helpful in planning the rehabilitation of horses with tendon injuries more accurately.[160,190]

Osseous and soft tissue abnormalities of the second and fourth metacarpal bones (exostosis, synostosis, osteitis) and their interosseous ligaments (syndesmopathy) have been reported as very common in two studies of proximal metacarpal MRI.[5,128] These include irregularities of the periosteal and endosteal aspects of the cortex, osseous fluid, and/or sclerosis, increased intraligamentous STIR signal and enthesophyte formation at the origin, and insertion of the interosseous ligaments. Synostosis may lead to osseous fusion between the second or fourth and the third metacarpal bones. These abnormalities are common in young horses, especially endurance and race horses, and their clinical significance as a cause of lameness is not always clear.

MAGNETIC RESONANCE IMAGING OF THE CARPAL REGION

Introduction

Practical problems may arise when scanning limb areas proximal to the third metacarpal and metatarsal regions with both high-field magnets or low-field standing systems. It can be difficult to position the carpus or tarsus in the isocenter of most long, closed-bore, high-field magnets. When MR images are obtained on standing sedated horses with low-field open magnets, increased movement at these proximal levels can render diagnostic quality imaging difficult, in spite of advances in motion correction software. This problem does not appear to occur with the horse's limb positioned under general anesthesia in an open low-field magnet, provided that the magnet opening is sufficiently wide to accommodate the area of interest.

Most carpal injuries can be sufficiently evaluated using radiography, ultrasonography, and scintigraphy. Consequently, few clinical reports of *in vivo* MRI results in horses are available,[128,146,175] and cadaveric studies have been used to describe the normal low- and high-field MRI anatomy of and signal distribution in the carpus.[71,116,120,126] MRI was able to identify several ligaments that cannot be shown with other imaging techniques (except CT arthrography), including the transverse intercarpal ligaments, the radiocarpal ligament, the short palmar carpal ligaments, and the carpometacarpal ligaments.[71,126] Transverse MRI images are typically most useful to evaluate the soft tissues of the carpal region.

Even though diagnosis of carpal lameness can usually be made with conventional imaging modalities, MRI of the carpus may be useful when no imaging abnormalities are present, when the degree of lameness does not

VetBooks.ir

correlate with imaging findings, or when the pattern of diagnostic anesthesia is unclear due to confusion between the responses to subcarpal nerve blocks and intercarpal joint anesthesia.

Lesions detected with MRI in horses with carpal lameness have included bone sclerosis and/or osseous fluid, osteochondral pathology, fractures, ligament injuries, and injuries of the carpal canal.[116,128] The most commonly detected abnormality in the carpus in one low-field study was decreased T1 and T2 signal intensity (sclerosis) in the medial aspect of the carpal bones. Less common were signal abnormalities between the second and third carpal bones.[128]

MRI Abnormalities in the Carpal Region

Osseous and Osteochondral Pathology

Carpal bone sclerosis is well recognized in racing Thoroughbreds and Standardbreds, but its clinical significance is not always clear. The third and radial carpal bones are most commonly affected.[128] Sclerosis without osseous fluid may represent adaptive remodeling changes following repetitive loading, or may be a cause of lameness,[128] especially when the area of sclerosis is extensive. Sclerosis with osseous fluid represents nonadaptive bone damage and is more closely associated with lameness. Extensive sclerosis may lead to focal trabecular bone resorption and necrosis resulting in a focal subchondral area of signal increase representing bone resorption within the low intensity sclerotic area.

Extensive sclerosis may also be associated with osteochondral damage of the adjacent articular surface of the intercarpal or radiocarpal joints, and the articular cartilage should be assessed carefully for thickness and signal changes. Cartilage damage should be considered in the presence of subchondral bone edema or focal subchondral bone loss.

Carpal bone chip fractures are seen as a focal area of low signal intensity separated from the parent bone by a line of higher signal representing fluid in the fracture gap. There may be osseous fluid, sclerosis or both in the parent bone. The tomographic nature of MRI may help identify complex or hidden fracture lines that are not readily visible on conventional radiographic projections. This information may help in planning for surgical treatment of palmar fragments or comminuted fractures.

Soft Tissue Injuries

A variety of ligaments exist within and around the carpal joints. Injuries of intercarpal ligaments cannot be identified ultrasonographically, and diagnosis relies on arthroscopic or tomographic imaging with CT arthrography or MRI.[71,116] Intercarpal ligament damage may be seen as loss of the linear structure of the ligament with either increased signal intensity within the ligament on both T1- and T2-weighted images, or low signal intensity on T1-weighted images with high signal intensity on T2-weighted images because of ligament disruption and infiltration of synovial fluid into the defect. The diagnosis is facilitated if there are enthesis abnormalities of the intercarpal ligaments' attachment sites to the carpal bones, like osseous fluid, osseous resorption, or osseous proliferation. Damage to collateral ligaments is best assessed ultrasonographically because of their superficial location. Generalized signal increase in a ligament may reflect fiber disruption, but signal heterogeneity may exist in normal ligaments.

Injuries of the flexor tendons or the accessory ligament of the DDFT may be seen within the confines of the carpal sheath.[145] However, areas of injury with intratendinous signal increase must be distinguished from persistent muscular tissue, which may require contralateral comparison.[126] Injuries of the accessory ligament are sometimes limited to its origin on the palmar aspect of the third carpal bone, causing osseous irregularities of the attachment site as well as signal and size changes of the ligament itself.

MAGNETIC RESONANCE IMAGING OF THE TARSAL REGION

Introduction

MRI of the tarsus can be useful because of the limitations of other imaging modalities for the diagnosis of early or focal osteoarthritis, cartilage erosions, focal subchondral bone lesions, sclerosis, bone contusions, fractures, osseous cyst-like lesions, and intertarsal ligament injuries.[40,123]

The same limitations apply to scanning the tarsal region as apply to the carpal region, i.e. motion artifact from swaying is (even more) common on standing low-field images of the upper hindlimb and positioning near the isocenter may be impossible in closed high-field magnets.

Equine tarsal MRI anatomy has been described in detail using both low- and high-field systems.[12,16,26,27,57,94] In the normal tarsus, articular cartilage of the distal tarsal joints is very thin, which does not allow for distinction of proximal and distal cartilage layers in these joint spaces.[7] Subchondral bone plates of the distal tarsal bones and the third metatarsal bone have homogeneous, low signal intensity with a regular osteochondral junction and a smooth but undulating deep border.[26,27] In sport horses that undergo high intensity training, subchondral bone thickness is greater medially in the distal intertarsal joint and laterally in the tarsometatarsal joint.[25] This repeatable thickness pattern of subchondral bone is lost in horses with distal tarsal lameness.[25,26]

Ligaments of the tarsus typically have low signal intensity in all sequences; however, multiple areas of increased signal intensity have been identified at specific locations (like in the short and long medial collateral ligaments) and were attributed to focal magic angle effects associated with variable orientation of collagen fibers within the ligaments.[12] The talocalcaneal ligament has heterogeneous signal intensity in all sequences, due to infiltration of a mixture of joint fluid and fat between the collagen fibers of the ligament.[12] The accessory ligament of the DDFT varies in size and signal intensity. The long plantar ligament comprises a number of related parts, separated by lines of high signal intensity corresponding with fibrous septa. The plantar aspect of this ligament has uniformly low signal intensity in all

VetBooks.ir

sequences, but the dorsal half is more heterogeneous with multifocal spots or lines or bands of higher signal intensity.[59]

MRI of the tarsal and proximal metatarsal regions is frequently performed together, as diagnostic anesthesia is insufficiently specific for accurate localization of pain causing lameness in this area.[6,93] In one study, 47% of horses with a positive response to subtarsal perineural diagnostic anesthesia were found to have a primary lesion in the distal tarsal joints, while 33% of horses with a positive response to intra-articular anesthesia of the distal tarsal joints were diagnosed with proximal suspensory desmitis.[6] Therefore, MRI protocols should be adopted to allow for complete evaluation of both anatomic regions in horses where pain has been localized to this area and conventional imaging techniques produce negative or equivocal results.

Several clinical reports and one large case series of *in vivo* tarsal MRI have become available in recent years.[6,13,23,33,40,41,57,93,96,131,167,169] The prevalence of MRI lesions of the distal tarsus detected with a high-field magnet was reported for 125 limbs of 103 horses with lameness originating from the distal tarsal/proximal metatarsal area. Osteoarthritic changes of the distal intertarsal and tarsometatarsal joints were the most common findings, including sclerosis of the third and central tarsal bones in 54% and 100% of limbs, respectively, osteophytes at the margins of the distal intertarsal or tarsometatarsal joints in 51% and 70% of limbs, respectively, and articular cartilage damage or subchondral bone lysis of the same joints in 42% and 51% of limbs, respectively. Degenerative changes of osteoarthritis (osteolysis and loss of joint space) were also found in 65% limbs between the central and fourth, central and second, third and second, and third and fourth tarsal bones. Suspensory ligament desmopathy was found in 53% of limbs in this study, suggesting that multiple abnormalities of the distal tarsal joints and the proximal part of the suspensory ligament were frequently identified simultaneously in this population of predominantly Western performance horses. No retrospective MRI studies are available to document the prevalence of injuries of the proximal tarsal region.

MRI Abnormalities in the Tarsal Region

Osteoarthritis

The superiority of MRI over other imaging modalities to detect early changes of osteoarthritis in the tarsus has been clearly demonstrated.[6,26,40,96] Periarticular new bone formation, joint space narrowing, subchondral sclerosis, and subchondral bone lysis may be seen in the tarsometatarsal, distal intertarsal, and rarely proximal intertarsal joints. In a study of 38 Icelandic horses, the most commonly detected MRI lesions observed in 42 distal intertarsal joints classified as osteoarthritic were mineralization front defects, joint margin lesions, and articular cartilage lesions.[96] An association has been reported between MRI abnormalities of the intertarsal interosseous ligament region and osteoarthritis of the distal intertarsal joint.[6,169]

MRI changes of osteoarthritis may also occur in the vertical contact areas between the various tarsal bones (Figure 3.248) and in the talocalcaneal joint (Figure 3.247). However, mild subchondral bone contour irregularities, sclerosis, osteophytes, and intertarsal ligament changes may be seen in non-lame horses, and their presence should not be overinterpreted as clinical disease.

Figure 3.247. Sagittal proton density image of the tarsus of a horse with osteoarthritis of the talocalcaneal joint. There is localized loss of joint space and subchondral bone margins in the center of the joint. This lesion is surrounded by a wide irregular area of signal loss reflecting reactive osteosclerosis in both the talus and the sustentaculum tali of the calcaneus (arrows).

Osseous Trauma

Osseous trauma related to trabecular microfracture, bone edema, or hemorrhage characterized by high STIR signal in bone can occur in the central, third, and fourth tarsal bones[6,13](Figure 3.249) as well as in the talus or calcaneus.[93,202] Osseous fluid in the vicinity of the intertarsal foramen may represent an intertarsal ligament enthesopathy.

The most common finding on MR images of the tarsus of horses with tarsal pain is sclerosis of the central and/or third tarsal bones, characterized by low signal intensity in the medulla and/or subchondral bone region.[6,40]

Fractures

Incomplete or complete vertical fractures of the central (or third) tarsal bone are usually stress fractures and may not always be detected radiographically.[6,40] These fractures are identified on MR images as a line of high signal intensity in most imaging sequences but especially on T1 images, where they are generally surrounded by an area of low signal intensity representing osseous fluid surrounding an acute fracture or sclerosis surrounding stress fractures or chronic fractures.[6] MRI may also be useful for identification of non-displaced

VetBooks.ir

fractures of the talus or calcaneus that are not readily visible radiographically.[33]

Osseous Cyst-like Lesions

Osseous cyst-like lesions occurred in 22% of limbs in one MRI study of horses with distal tarsal region lameness and were approximately equally distributed between the third and central tarsal bones.[6] They may also occur in the fourth tarsal bone or in the distal tibia at the apex of the parasagittal grooves that articulate with the trochlear ridges of the talus. Osseous cyst-like lesions have intermediate to high signal intensity surrounded by low signal intensity of sclerotic bone. They may be incidental findings in the tarsal bones, especially if there are no signal alterations in the surrounding bone. Reactive signal changes that represent more significant bone damage are osseous fluid or extensive sclerosis in surrounding bone. Osseous cyst-like lesions are usually associated with an articular surface defect.

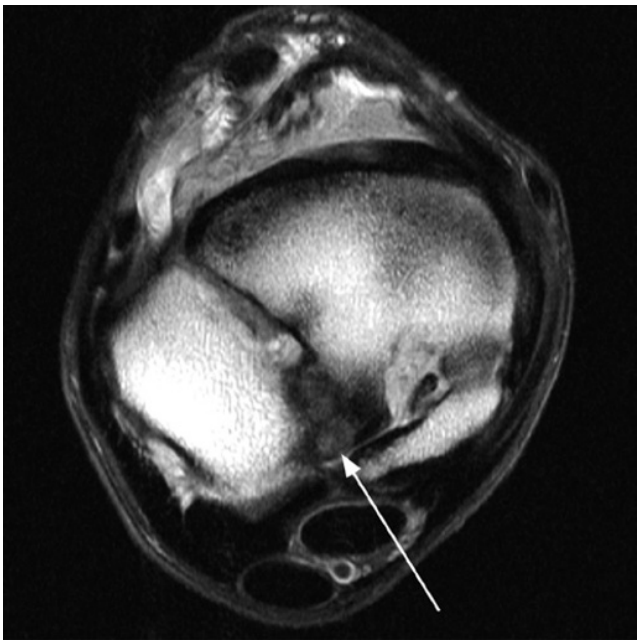

Figure 3.248. Transverse proton density image through the proximal row of tarsal bones of the left tarsus of a horse with focal osteoarthritis of the articulation between the central and fourth tarsal bones. There is loss of joint space and subchondral bone outline surrounded by a margin of irregular osteosclerosis of the fourth and central tarsal bones (arrow).

Intertarsal Ligament Injury

Lesions of the intertarsal interosseous ligament occurred in 33% of horses with distal tarsal region lameness.[6] Lesions have been described as either signal increase[57] or signal decrease[6] in the ligament with loss of normal ligament architecture. Changes of the ligament fossa include thickening and irregular contour of the subchondral bone and narrowing to even total obliteration of the fossa by new bone production. Osseous fluid and/or sclerosis may be present in the third and central tarsal bones either side of the ligament fossa (Figure 3.249). Abnormalities of the ligament and the ligament fossa typically occur concurrently. Severe changes of desmopathy and enthesopathy are invariably accompanied by degenerative changes of the distal intertarsal joint.[6]

Other Soft Tissue Injuries of the Tarsus

Care is required when interpreting signal increase because several ligaments in the tarsus are subject to magic angle artifact, both in standing and recumbent MRI, which can overlap with certain types of injury.[12] Anecdotal reports have illustrated medial and lateral collateral ligament injuries.[167] Hyperintense core lesions of the long plantar ligament may also occur, and

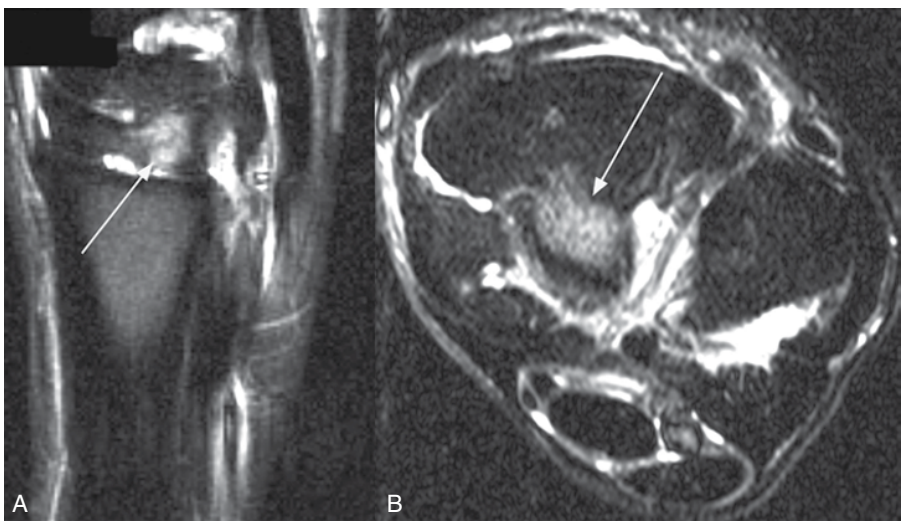

Figure 3.249. Sagittal (A) and transverse (B) short tau inversion recovery (STIR) images of the right tarsus of a horse with acute onset hindlimb lameness. There is abnormal intraosseous signal hyperintensity (osseous fluid) in the plantar aspect of the third tarsal bone (arrows), compatible with bone edema or a bone bruise.

VetBooks.ir

lameness may be abolished by anesthesia of the deep branch of the lateral plantar nerve.

Injuries of the tarsal sheath portion of the DDFT (lateral digital flexor) have been reported at the level of the distal tarsus[41] and at the level of the sustentaculum tali.[123] Chronic calcaneal bursitis may be accompanied by focal cortical bone loss from the tuber calcis with generalized reactive osseous fluid throughout the proximal portion of the calcaneus.

MAGNETIC RESONANCE IMAGING OF THE STIFLE REGION

Introduction

MRI examination of the stifle has enormous potential for improved diagnosis of injuries of this complex joint as many of the soft tissue structures of the joint cannot be evaluated comprehensively with any other imaging modality. MRI provides a more complete evaluation of the stifle than exploratory arthrosocopy.[87]

MRI of the stifle has rarely been possible in live horses. However, recent equipment improvements both in low- and high-field magnet design have made the stifle accessible to routine MRI examinations under general anesthesia. Clinical MRI of the stifle in selected horses has been possible in ultrashort to short, wide bore (70 cm) high-field magnets (1.5-T Siemens Magnetom Espree™; 3.0-T Siemens Verio™ Open-Bore system, Siemens Medical Solutions Inc., Malvern, PA, USA).[84] Moreover, technical innovation allowing for rotation of open magnets has now made stifle MRI accessible to all horses under general anesthesia with a 0.25-T low-field MRI system (Figure 3.208; Rotating Vet MR Grande XL, Esaote, SpA, Genova, Italy), with the exception of particularly short-legged horses or ponies.[111]

Different stifle MRI protocols have been suggested for high-field[38,77,87] and low-field magnets.[153,186] Contrast enhancement with gadopentetate dimeglumine administered intravenously has also been useful to clarify further lesions in the stifle.[87] Various imaging planes with the joint in flexion and extension have been evaluated.[38]

The MRI anatomy of the stifle has been described in cadaver limbs using both high-field and low-field magnets.[38,77,153] Both systems allowed for detailed evaluation of all soft tissue structures of the stifle. In addition, MR images provided excellent resolution of articular cartilage and subchondral bone.[38,77] The unique shape and fiber orientation of the menisci predisposed to the effects of magic angle, specifically between the deep external and shallow internal margins and at the junction between the horns and the respective meniscotibial or meniscofemoral ligaments.[38] In another study using a 0.25-T low-field open magnet, MR imaging findings in 10 fresh cadaver stifles of asymptomatic horses correlated well with gross and histopathological findings. Irregular areas of signal increase in all patellar ligaments corresponded to adipose tissue infiltrating between the collagen bundles. The authors concluded that the study supported the use of low-field MRI for detection of stifle joint lesions in horses, even though the pathologies observed had been subclinical.[153]

The incidence of MRI lesions of stifles examined in an 0.25-T low-field open magnet was recently reviewed in two studies.[111,187] In one study of 61 horses with stifle lameness, meniscotibial ligament degeneration, fibrillation, and tearing were the most common abnormality (87%), closely followed by osteoarthritis (74%).[111] Degeneration or tearing of a meniscus (56%) or cruciate ligament (59%) were also common. Less frequently observed were bone marrow lesions or bone contusions (30%), tibial enthesopathy of meniscotibial ligament insertions with cystic bone degeneration (18%), subchondral bone defects or osseous cyst-like lesions of the tibial or femoral condyles (21%), and collateral desmopathies (10%). Another study, including 70 horses with stifle lameness without conventional imaging abnormalities, identified meniscal lesions as the most common abnormality (95%).[187] Cartilage fibrillation or defects (66%), bone contusions (50%), and cruciate ligament abnormalities (43%) were also commonly encountered. Although these observations suggest that many of these lesions were not only very common but also present concurrently, the clinical significance of some low-field MRI abnormalities in the stifle has been questioned previously.[153]

MRI Abnormalities in the Stifle Region

Meniscal and Meniscal Ligament Injuries

The obvious advantage of MRI is that it can evaluate the entire meniscus including areas not visible arthroscopically or ultrasonographically, as well as internal lesions that do not reach the articular surfaces. An increase in internal signal or anatomical disruption of the normally hypointense triangular structure of the meniscus is indicative of damage (Figure 3.250). Intrasubstance signal increase without signs of synovitis or cartilage damage is considered a degenerative change.[111] However, it should be remembered that menisci are also prone to magic angle effects as a cause of signal increase.[38] Meniscal injuries are best recognized on PD or T2 sagittal or frontal images.[87] Damage to the meniscotibial or meniscofemoral ligaments can occur in isolation or with concurrent meniscal damage. MRI changes include intra-substance signal increase or loss of architecture, loss of margin definition or fraying, and tears.[111] Osseous resorption and degenerative cyst formation can occur as a manifestation of enthesopathy at the tibial insertions of the meniscotibial ligaments cranial to and on either side of the medial intercondylar eminence of the tibia.

Cruciate Ligament Injuries

It has been stated that both cruciate ligaments should be uniformly hypointense on PD and T2 images and that the caudal cruciate ligament can be used as a reference structure to assess signal change in the cranial cruciate.[87] However, others have claimed that the cranial cruciate ligament has low to intermediate signal intensity in its proximal half, while its distal half has intermediate to high signal corresponding to twisting of the ligament fibers from proximal to distal and the presence of shallow striations and fanning of the ligament.[38]

Dorsal proton density image with fat saturation (A) and dorsal short tau inversion recovery (STIR) image (B) of the left stifle of a horse with a tear of the cranial horn of the medial meniscus (white arrow). There is intraosseous signal hyperintensity in the medial femoral condyle and the axial margin of the medial tibial plateau suggestive of abnormal bone fluid (black arrows). *Source*: Courtesy of Dr. Carter Judy.

Moreover, the cranial cruciate ligament is supposed to be heavily subjected to magic angle artifact in closed high-field magnets with the patient in lateral recumbency.[87] Magic angle effect was also consistently seen in the cranial cruciate ligament with the horse in dorsal recumbency and the stifle positioned in extension in an open low-field 0.25-T magnet. Therefore, the internal signal of the ligament should never be assessed on T1 images only,[87] but evaluation should also include short TE sequences. Thickening of the cranial cruciate ligament with internal signal changes in T1 and PD images has been described as the most consistent finding in cranial cruciate ligament injury.[87] Increased STIR or T2 signal was rarely present, possibly because of the chronic course of the lameness in such patients before MRI was undertaken.[87] Other MRI findings associated with cruciate ligament injury include joint effusion and osseous fluid at the femoral origin and/or tibial insertion of the affected cruciate ligament.[87,111] Although one low-field study almost always found concurrent meniscal abnormalities in horses with cruciate ligament injury,[187] others have not shared this observation using high-field MRI.[87] Caudal cruciate ligament injuries are generally considered to be rare.[87]

Bone Contusions

Bone contusion, bone edema, or bone marrow lesions are a common finding in the femoral and tibial epiphyses, either as a primary abnormality or in association with other injuries of the stifle (cruciate or meniscal injuries, osteochondritis dissecans, cartilage erosions, and osseous cyst-like lesions).[111,187,188] Primary bone contusion generally develops as a consequence of subchondral bone trauma, and osseous fluid signal typically begins in the subchondral region and radiates into the trabecular bone of the medullary cavity.

Cartilage Lesions

Cartilage erosions are readily visible in the stifle thanks to the innately thicker cartilage than in distal limb joints. Focal cartilage erosions are more easily recognized than generalized thinning of degenerative cartilage. Invariably cartilage erosions are accompanied by an increase in subchondral fluid and STIR signal intensity.[87]

THERMOGRAPHY

TRACY A. TURNER

VetBooks.ir

Thermography is the pictorial representation of the surface temperature of an object.[9,21] It is a noninvasive technique that measures emitted heat. A medical thermogram represents the surface temperatures of skin making thermography useful for the detection of inflammation. This ability to noninvasively assess inflammatory change makes thermography an ideal imaging tool to aid in the diagnosis of certain lameness conditions in the horse.[1,9,10,12–14,20,21,24]

Thermography was first used in veterinary medicine 45 years ago. Originally, its use was limited for the most part to university hospitals or large referral practices. But over the last 20 years, thermography has been used practically in equine medicine. This is a physiological imaging modality that requires a learning curve for interpretation, but it offers the operator new insight into their patients.

THERMOGRAPHIC INSTRUMENTATION

Thermographic instrumentation in the past has been divided into contacting and noncontacting devices.[15] However, in the 1990s, a new technology using focal plane array detectors made all older thermographic devices obsolete with regard to equine veterinary use. Focal plane array detectors are uncooled technology. This technology employs special lenses to focus infrared radiation on a series of detectors. These instruments are self-contained and highly portable.

One of the most important factors to consider before purchasing a thermographic camera is the spectral range.[15] For medical use the range of 8–14 μm is ideal because this is the peak emissivity of skin. From a practical standpoint, there is also less environmental artifact at this range. The author prefers real-time thermography versus still thermography because real-time thermography eliminates any problems with motion, makes thermographic assessment more dynamic in that the operator can immediately observe change, and allows for faster imaging. Sensitivity refers to the amount of temperature difference that can be detected; uncooled units can differentiate 0.1 °C, which is sensitive enough for medical uses. The final factor is portability and durability. Uncooled cameras utilizing the focal array technology are very portable and durable because of no moving parts.

PRINCIPLES OF USE

The circulatory pattern and the relative blood flow dictate the thermal pattern, which is the basis for thermographic interpretation.[6,8,21] The normal thermal pattern of any area can be predicted on the basis of its vascularity and surface contour. Skin overlying muscle is also subject to temperature increase during muscle activity. Based on these findings, some generalizations can be made regarding the thermal patterns of a horse: The midline will generally be warmer,[9,21] and this includes the back, the chest, between the rear legs, and along the ventral midline (Figure 3.251). Heat over the legs tends to follow the routes of the major vessels, the cephalic vein in forelimb, and the saphenous vein in the hindlimb.

On the dorsal view of the distal limb, the metacarpus (metatarsus), fetlock, and pastern appear relatively cool because the image recorded is away from the major blood supply. Thermographically, the warmest area in the distal limb is around the rich arteriovenous plexus of the coronary and laminar corium located proximally on the hoof wall. Normally, there is increased warmth between the third metacarpus and flexor tendons, following the route of the median palmar vein in the forelimb and the metatarsal vein in the hindlimb. Over the foot, the warmest area corresponds to the coronary band. From the palmar (plantar) aspect, the tendons are relatively cool, and the warmest area is consistently

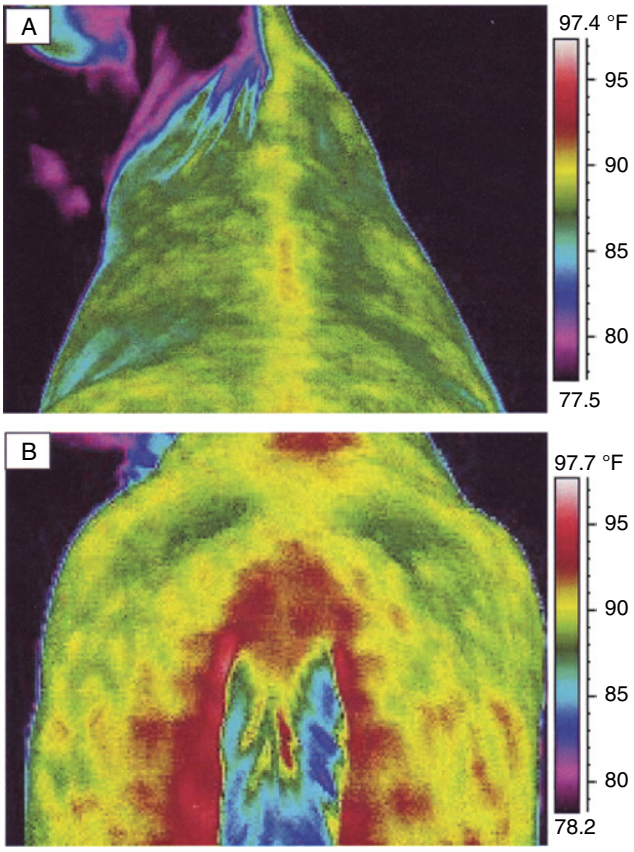

Figure 3.251. Normal back (A) and croup (B) thermograms of a horse. Note the back is warm down the center with isothermic bands around it. The croup forms a "T" of uniform temperature between the tuber coxae and the midline.

VetBooks.ir

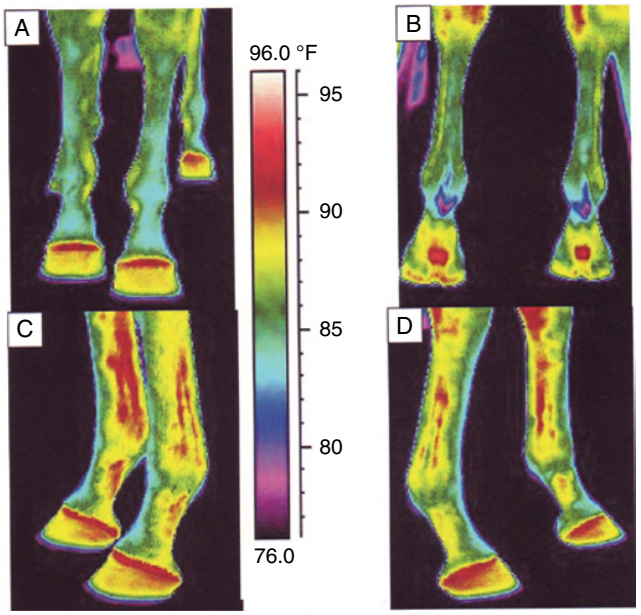

Figure 3.252. Normal distal limb of a horse. The warmest areas follow the vasculature. Abnormalities are heat where it is not expected or changes in the normal thermal pattern. Essentially, if the image is not normal and cannot be explained as an artifact, then it represents abnormal thermography. (A) Dorsal view. (B) Palmar view. (C) Left side. (D) Right side.

between the bulbs of the heel along the midline (Figure 3.252).

Injured or diseased tissues will invariably have an altered circulation.[21] One of the cardinal signs of inflammation is heat, which is due to increased circulation. Thermographically, the "hot spot" associated with the localized inflammation will generally be seen in the skin directly overlying the injury.[1,3–5,9–14,20,21,23–25] However, diseased tissues may in fact have a reduced blood supply either due to swelling, thrombosis of vessels, infarction of tissues, or change in sympathetic tone.[14,21] With such lesions the area of decreased heat is usually surrounded by increased thermal emissions, probably due to shunting of blood.

To produce reliable thermographic images, certain factors need to be controlled: motion, extraneous radiant energy, ambient temperature, and artifacts.[15] Motion can be controlled by immobilizing the horse in stocks or using a qualified handler. The use of real-time thermography eliminates the need for complete immobilization. Chemical restraining agents to keep the horse from moving should be avoided because these drugs affect the peripheral circulation and cardiovascular systems that could cause false thermal patterns to be produced; however, the author has not encountered this. To reduce the effects of extraneous radiant energy, thermography should be performed under cover shielded from the sun.[21] Preferably, thermography should be done in darkness or low-level lighting. Ideally, ambient temperature should be in the range of 20 °C (68 °F), but any temperature as long as the horse is not sweating is acceptable. Heat loss from sweating does not occur below 30 °C (86 °F), as radiation and convection are responsible for heat loss below that temperature. Very cold environmental temperatures may cause vasoconstriction of the lower legs and interfere with imaging. In these cases, low-level exercise to stimulate vasodilatation is necessary. The thermographic area ideally should have a steady, uniform airflow so that erroneous cooling does not occur. Practically, the horse should be kept from drafts. Likewise, the horse should be allowed 10–20 minutes to acclimate to the environment or room where thermography is performed. Artifacts are extraneous sources on the skin that can cause irregular images. Among these are debris, scar tissue, hair length, liniments, leg wraps, and equipment.[21] To avoid artifacts, make sure all subjects are groomed and free of leg wraps and equipment for 2 hours whenever possible. Hair insulates the leg and blocks the emission of infrared radiation. But, as long as the hair is short and of uniform length, the thermal image produced is accurate. The skin should always be evaluated for changes in hair length that may cause false "hot spots" in the thermogram.

Multiple thermographic images of a suspect area should be made.[25,26] The area in question should be evaluated from at least two directions approximately 90° apart, to determine if a "hot spot" is consistently present. The horse's extremities should be examined from four directions (circumferentially).[21] Significant areas of inflammation will appear over the same spot on each replicate thermogram.

There are at least four ways in which thermography can be utilized in equine veterinary practice. The first is as a diagnostic tool. In these cases, thermography is a physiologic imaging method where a 1.0 °C difference between two anatomically symmetrical regions indicates a region of inflammation.[15] A decrease in temperature is just as important as an increase in temperature. The image will identify an area of interest to pursue with an anatomic imaging method such as ultrasonography and/or radiography.

The second method is to enhance the physical examination. In this case, thermography is used to identify changes in heat and therefore locate "areas of suspicion".[15] Thermographic cameras are easily 10 times more sensitive than the hand in determining temperature differences. This method simply helps identify asymmetry, and then the practitioner must utilize the information to determine the actual cause and significance of the temperature difference.

The third method of using thermography is in a wellness program. In this method, horses in training are followed on a routine basis, once weekly.[22] In the author's experience, thermographic changes often occur 2 weeks prior to clinical changes. In these cases, thermography can be used to identify subclinical problems, and then training alterations can be made so that injury may be avoided altogether.

The fourth method is in the regulation of equine events.[15] Presently, thermography is used by the *Federation Equestre Internationale* (FEI) and the *United States Department of Agriculture* (USDA) to enforce regulations. The instrument is used as a screening tool to determine potential misuse. In these cases, the final determination is made by a group of examining veterinarians.

VetBooks.ir

SPECIFIC APPLICATIONS FOR LAMENESS DIAGNOSTICS

The Examination

If thermography is to be used, all bandages and leg wraps should be removed 2 hours before the examination. The horse should be thoroughly brushed to remove any dirt and debris. Thermography is best performed after the clinical examination has been performed (including watching the horse move, palpation, and manipulations) but before nerve or joint diagnostic analgesia. The horse is brought into a covered area away from direct sunlight and any breezes. A 10-minute acclimatization period is allowed, and then a systematic examination of the horse is performed using the thermographic camera.[15]

The camera is positioned 90° to the area of interest, and the sequential images are taken. The limbs are examined from all four directions, the neck from both sides (ventrally), the torso from both sides (dorsally and ventrally), the shoulders from the front and both sides, the hips from both sides and the back, and the head from both sides (dorsally and ventrally). Each of the images is then assessed in relation to the findings of the clinical examination of the horse.

The Foot

Thermography of the hoof has been useful for the diagnosis and evaluation of several conditions of the foot.[9,13,21] Laminitis, palmar foot pain, subsolar or submural abscesses, corns, and any other inflammatory condition of the hoof are specific conditions where thermography provides valuable information concerning the disease. Obviously, thermography is not needed to definitively diagnose these problems. Thermography does however provide additional information that is helpful in localizing the problem, assessing the degree of inflammation associated with it, and deciding the best course of treatment. Thermographic evaluation is particularly helpful with early or occult conditions of the foot, where the physical and/or radiographic examination findings are inconclusive.

Normally, the coronary band is the warmest area of the leg, and because of this, inflammation of this area can be difficult to detect.[9] The hooves should be thermographically compared in several ways. Comparisons should be made between all four hooves, front to front and front to rear. A difference of more than 1 °C between hooves is significant. In cases where all 4 feet are involved, comparisons of the hoof temperature with the temperature of the area between the bulbs of the heel should be made.

Laminitis is characterized by inflammation of the laminar structures of the hoof. Laminitis can be divided into four phases—developmental, acute, chronic, and post-chronic—and each of the phases has characteristic thermal information. The developmental stage has been studied thermographically the least. During the developmental stage there are no clinical signs, but the thermal image changes. There are progressive periods of vasoconstriction followed by periods of profound vasodilatation; the heat seen gets hotter and broader following each vasoconstrictive period. During the acute phase a change in the thermal pattern of the hoof wall is useful in recognizing laminitis. Generally, the coronary band is 1–2 °C warmer than the remainder of the hoof. An inflammatory problem is indicated when the hoof begins to approach the temperature of the coronary band. Thermography can also be very beneficial in the progressive evaluation of the contralateral limb where support limb laminitis is potential sequelae. Thermography makes it possible to detect inflammation in the contralateral foot well before lameness is evident. Preventative therapy can therefore be instituted sooner in the course of disease and hopefully before the laminitis is irreversible. The chronic phase is characterized by progressive displacement of the third phalanx. The thermal image is the opposite of the acute phase. As the coffin bone displaces, the vasculature is pulled further away from the surface causing the thermal image to appear progressively cooler. That is, the coronary band is more difficult to distinguish from the remainder of the hoof wall. Finally, the post-chronic phase is seen when the laminae have healed, but vascular changes (damage) persists secondary to coffin bone displacement. Thermal imaging can be useful to identify the vascular damage that has occurred. These will be areas of intense cold, which will identify the areas of vascular damage.

Thermography is also an excellent method of evaluating the patient with palmar foot pain syndrome.[20] The author has never identified a consistent thermal pattern associated with these cases but has been able to characterize reduced blood flow to the caudal hoof and to identify thermal stresses associated with hoof imbalance and superficial inflammatory disease. Thermography is one of the few methods that can readily determine the relative blood flow to the palmar foot area. This is accomplished by evaluating the foot thermographically both before and after exercise. The normal horse will sustain a 0.5 °C increase in temperature of the foot after exercise, but about 40% of horses with palmar foot pain syndrome will not sustain this increase in the caudal foot due to the low blood flow. This is in sharp contrast to other focal inflammatory conditions of the hoof such as bruises, or fractures, which are characterized by focal areas of increased temperature that correspond to the site of injury. Exercise in these cases intensifies the "hot spot."

Hoof abscesses before they drain are often seen as relatively cold areas. This is due to the pressure caused by the abscess that decreases the circulation to the abscessed area. The hoof capsule is a closed environment, and the swelling that occurs due to the abscess is seen thermographically as an abnormal cold area. Once the abscess opens and the pressure is relieved, the cold area changes to a hot area.

Joint Diseases

Joint inflammation produces characteristic thermal patterns. The best view to study most joints is from the dorsal aspect.[13,23] Typically, the normal joint is cool compared with the surrounding structures. An exception to this rule is the hock, which has a vertical "hot spot" along the medial aspect that corresponds to the saphenous vein (Figure 3.253). As a joint becomes inflamed, the thermal pattern changes to an oval area of increased

VetBooks.ir

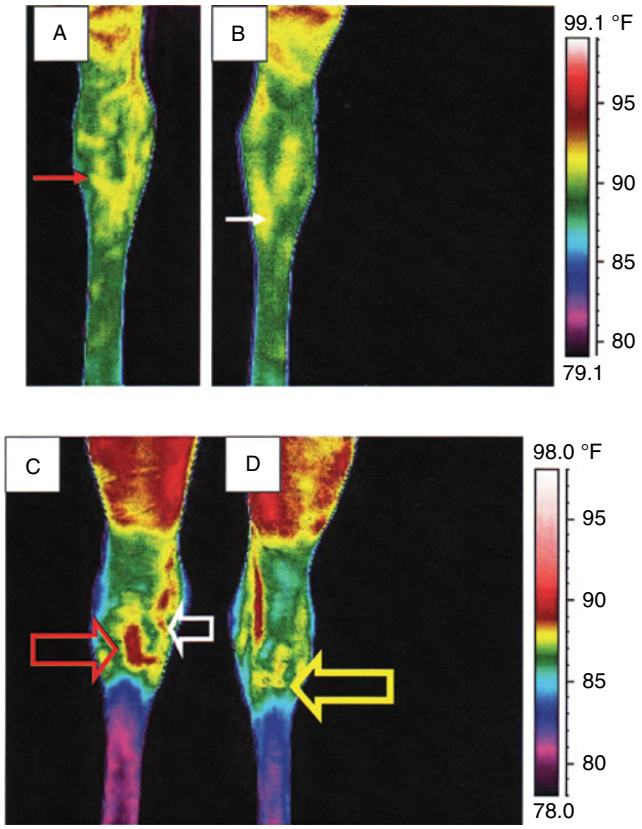

Figure 3.253. Thermal views of the dorsum of the hock of two different horses. (A) Right hock of horse 1. (B) Left hock of horse 1. (C) Right hock of horse 2. (D) Left hock of horse 2. (B) is the most normal thermogram; the white arrow indicates the saphenous vein and the warmest area. Image (A) shows a horizontal line (red arrow) indicating early lower tarsal joint inflammation. Images (C) and (D) show variations of distal hock inflammation. Image (C) shows the horizontal line and area over the central hock, which are hotter (hollow red arrow) than the area of the saphenous (hollow white arrow). Image (D) shows that the distal hock is a horizontal line (hollow yellow arrow).

temperature that is centered over the joint and widest horizontally medial to lateral. The exception to this rule is the joints of the distal limb, where the thermal pattern associated with inflammation of this joint is a circular pattern. The areas of joint capsule attachment tend to be "hotter," but the center of the joint is relatively "cooler". This may be due to joint swelling or pressure and subsequent loss of microcirculation (Figure 3.254). No specific correlation can be made between heat and joint damage. The temperature of the joint appears to be related to many factors: the chronicity of the problem (the more chronic the problem, the less heat), the degree of synovial involvement, the actual amount of cartilage damage, and the presence or absence of osteochondral fragments. These factors have a complicated interaction, and all affect the inflammatory response of the joint temperature. The degree to which each affects this response has yet to be determined.

Thermal patterns of joints have been shown to change 2 weeks before the onset of clinical signs of lameness.[22,24] In this manner, thermography can be used to assist training and help prevent serious injuries. By locating inflammation before clinical signs are evident, training programs can be changed to reduce stress on the inflamed area, thereby preventing serious injury.

Long Bone Injuries

Thermography is of less value in the diagnosis of most long bone problems. Since thermography evaluates skin temperature, a bone needs to be in relatively close contact with the skin to affect its temperature.[3] Consequently, bones that are heavily covered with muscle cannot be as accurately assessed by thermography. Thermography is best utilized to evaluate dorsal metacarpal disease or stress fractures of the radius or tibia.

Dorsal metacarpal disease, the so-called bucked shin complex, is categorized into three grades.[7] Grade 1 is characterized by eliciting pain upon palpation of the cannon bone, but radiographic evidence of bone pathology cannot be identified. Grade 2 is characterized by pain over the cannon bone, but there is radiographic evidence of subperiosteal callus. Finally, grade 3 is characterized by cannon bone pain and radiographic evidence of a stress or fatigue fracture. Grades 2 and 3 may be indistinguishable, and radiographic confirmation of a stress fracture may not be possible for 2–3 weeks. Thermal variations between the latter two may help differentiate grade 3 lesions earlier than radiographs. Grade 1 and 2 diseases are characterized by "hot spots" located midshaft over the dorsal cannon bone. The "hot spot" is generally 1–2 °C warmer than the surrounding tissues. In contrast, the grade 3 disease has "hot spots" that are not centrally located and are usually seen on the lateral and medial views in addition to the dorsal view. These areas are characteristically 2–3 °C warmer than the surrounding tissues. Since thermographic changes typically precede radiographic changes by 2 weeks,[13] with accurate thermography, a tentative diagnosis can be made earlier and appropriate treatment measures taken sooner.

Tendon Injuries

Thermal patterns of the normal flexor tendons are bilaterally symmetrical and consist of elliptical isothermic zones.[11,12] The lowest temperature is centered over the palmar aspect of the tendons, and the peripheral areas near the carpus and fetlock are approximately 1 °C warmer.

Acute tendinitis invariably causes a "hot spot" over the site of the tendon lesion[12] (Figure 3.255). The "hot spot" of a tendon lesion can usually be demonstrated up to 2 weeks before physical evidence of swelling and pain around the tendon. Therefore, tendon lesions of potentially clinical significance can be identified, and adjustments in the training protocol can be made to prevent further damage to the tendon.

As the tendon heals, the thermal pattern becomes more uniform but remains abnormally elevated, when compared with normal tendon.[12] As the lesion heals and scar tissue is deposited, the skin over the injured area may actually show a decrease in temperature, whereas the remaining neovascularized tendon continues to have increased thermal emissions. During the assessment of

VetBooks.ir

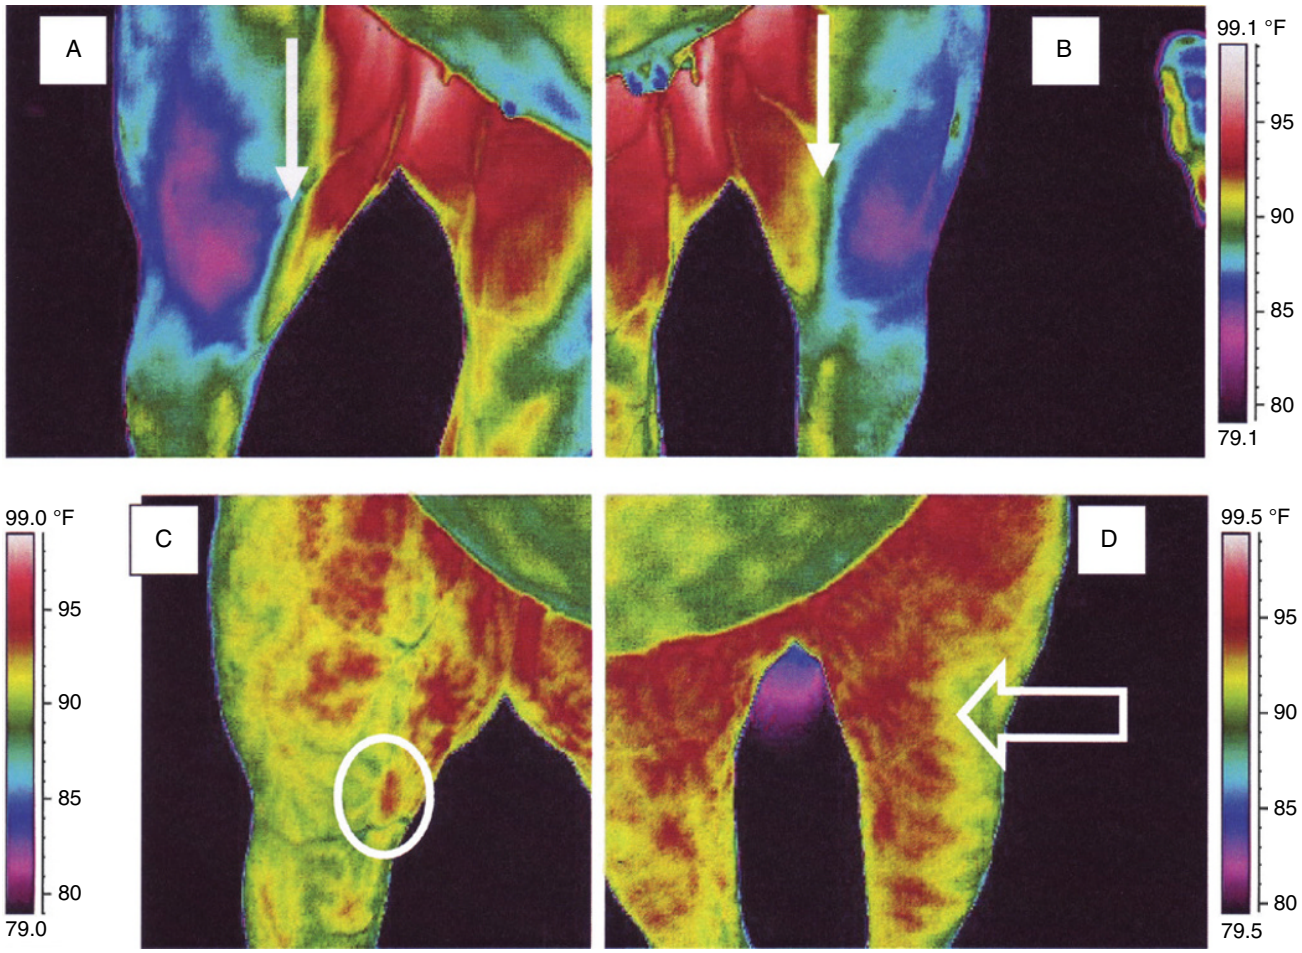

Figure 3.254. Normal right (A) and left (B) cranial stifle thermograms. The thermal pattern on the inside of the stifle is warm, and there is a line of demarcation in the area of the medial patellar ligament (arrow), and the front of the stifle is relatively cool. (C) and (D) represent abnormal thermograms of two different horses. Horse (C) shows a focal hot spot (circle) over the distal medial stifle; radiographs revealed a cyst-like lesion in the medial tibial plateau. Horse (D) shows a pattern that has heat from the medial side covering half the cranial aspect (hollow arrow). This horse had very noticeable effusion but no radiographic changes.

healing, the thermal changes do not correlate well to the structural reorganization of the tendon matrix as assessed by ultrasonography.[2,4] The reason is that as the tendon undergoes neovascularization, the thermal pattern diffuses, so there is no longer a "hot spot". But, if one compares healing tendon to a normal tendon, there is overall increased thermal emissions from the damaged tendon. Mechanical stress proximal to the injury can aggravate the existing tendon damage. Again, thermography can detect these areas of proximal stress before they cause a clinical problem, and therefore specific imaging can be used to decide if a therapeutic desmotomy should be performed.

Ligament Injuries

Thermographically, ligament injuries will appear very similar to tendon injuries. "Hot spots" can be expected to be centered over the injured area (Figure 3.255). An exception to this is in some high suspensory injuries of the metacarpi; the dorsal thermal image of the injured leg shows a focal "hot spot" located proximally on the cannon bone. This is interesting considering the inflammation and pain would be expected to be on the palmar aspect of the limb. Clinically, thermography is most useful when trying to correlate if there is heat associated with a sensitive ligament. This is particularly true of the suspensory ligament where the clinical significance of palpable sensitivity within the body of the ligament can be difficult to determine. Thermography can be used to determine if there is inflammation associated with the sensitivity. Similarly, "splints" or metacarpal callus can cause suspensory desmitis, and thermography can detect if there is inflammation associated with the suspensory ligament adjacent to the "splint." These indications would apply to any ligament.

Muscle Injuries

Thermography may have its greatest clinical application in the assessment of individual muscle injuries that are difficult to diagnose.[14,19] Even though serum muscle enzyme elevation may nonspecifically indicate muscle damage, the specific muscle or muscles damaged may be difficult to identify. Thermography offers two types of information important in the evaluation of muscle

VetBooks.ir

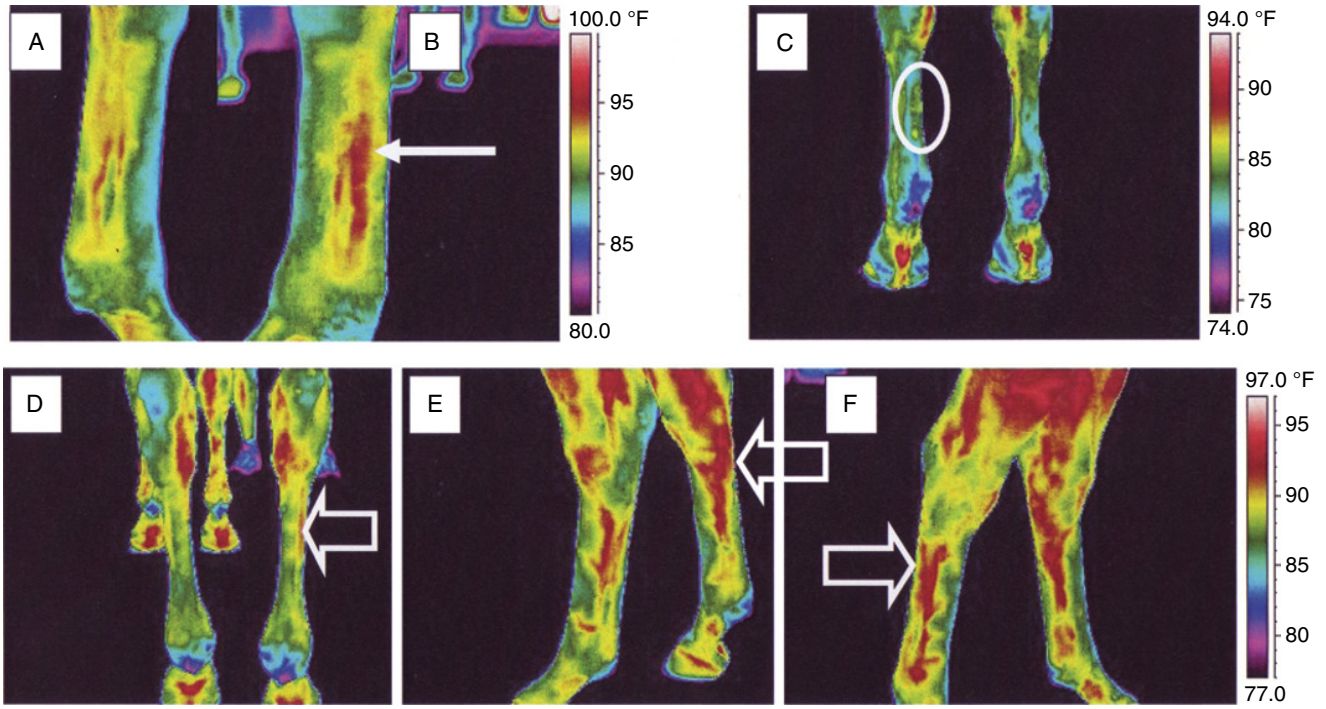

Figure 3.255. Abnormal thermograms. (A) Normal medial aspect of the left fore of a horse. (B) Abnormal medial aspect of the right fore of the same horse. The hot area (arrow) centered over the suspensory ligament was shown via ultrasonography to be due to suspensory desmitis. (C) Superficial digital flexor tendon lesion (circle) was confirmed sonographically. (D–F) Three views of the same horse showing a high suspensory ligament lesion confirmed ultrasonographically (hollow arrows).

injury: First it can locate an area of inflammation associated with a muscle or muscle group, and second it can illustrate atrophy well before it becomes apparent clinically.

Muscle inflammation will be most commonly seen thermographically as a "hot spot" in the skin directly overlying the affected muscle.[14,19] On a rare occasion, swelling and edema in the affected muscle will be severe enough to inhibit blood flow through the muscle. In this case the injured muscle will be seen thermographically as a "cold spot." Thermographic evaluation of muscle must be made from the right and left sides. These comparison images should be nearly identical. Consistent variations from side to side would indicate muscle damage located at either the "hot" or "cold spot."

The most common cause of muscle inflammation is muscle strain.[19] A classification of first-, second-, or third-degree strain injuries, described in human athletes, has been applied to horses.[14] Muscle strains have not been commonly documented in the forelimb. The author has most commonly identified pectoralis and shoulder extensor myopathies. Thermographic description of muscle strains of the back and hindlimb muscles have been best described.[14,19] These strains have been termed croup and caudal thigh myopathies. Croup myopathies are actually strains of the longissimus, the origin of the gluteus medius (level of the sacroiliac), the body of the gluteus medius, the insertion of the gluteals on the greater trochanter, and the third trochanter of the femur. Caudal thigh myopathies consist of injuries to the biceps femoris, semitendinosus, or semimembranosus muscles. Injuries to the biceps femoris and semimembranosus most commonly are midbody muscle strains, but semitendinosus injuries usually occur at the musculotendinous junction.

Back Problems

Diagnosis of injuries to the vertebral column can be aided through thermography.[13] Many of these injuries are undiagnosed, or the diagnosis is delayed because radiography of the equine spine is difficult and/or may require general anesthesia. Thermography offers a distinct advantage as it is best performed on the standing animal and in suspect cases may be used as a general screening test to determine if referral for radiography is warranted. Injuries to the vertebral column are characterized by either "hot spots," "cold spots," or "root signatures."

Thermography has been used to identify six different back injuries: overriding dorsal spinous processes (kissing spines), dorsal spinous ligament injuries, muscle pain, withers injuries, sacroiliac problems, and saddle fit problems.[16] The author uses two different thermal images to assess the back: one a thoracolumbar view and the second a croup view.[16] The thoracolumbar view shows the withers and the sacrum and is especially good for looking at the mid back region. The croup view is best for evaluating the sacroiliac region. The thermal pattern is the most important aspect of assessing the thermogram of the back. It must be remembered that thermography establishes the location of a possible problem but does not characterize the lesion. However, there are certain thermal patterns that have been seen consistently with particular back problems.

VetBooks.ir

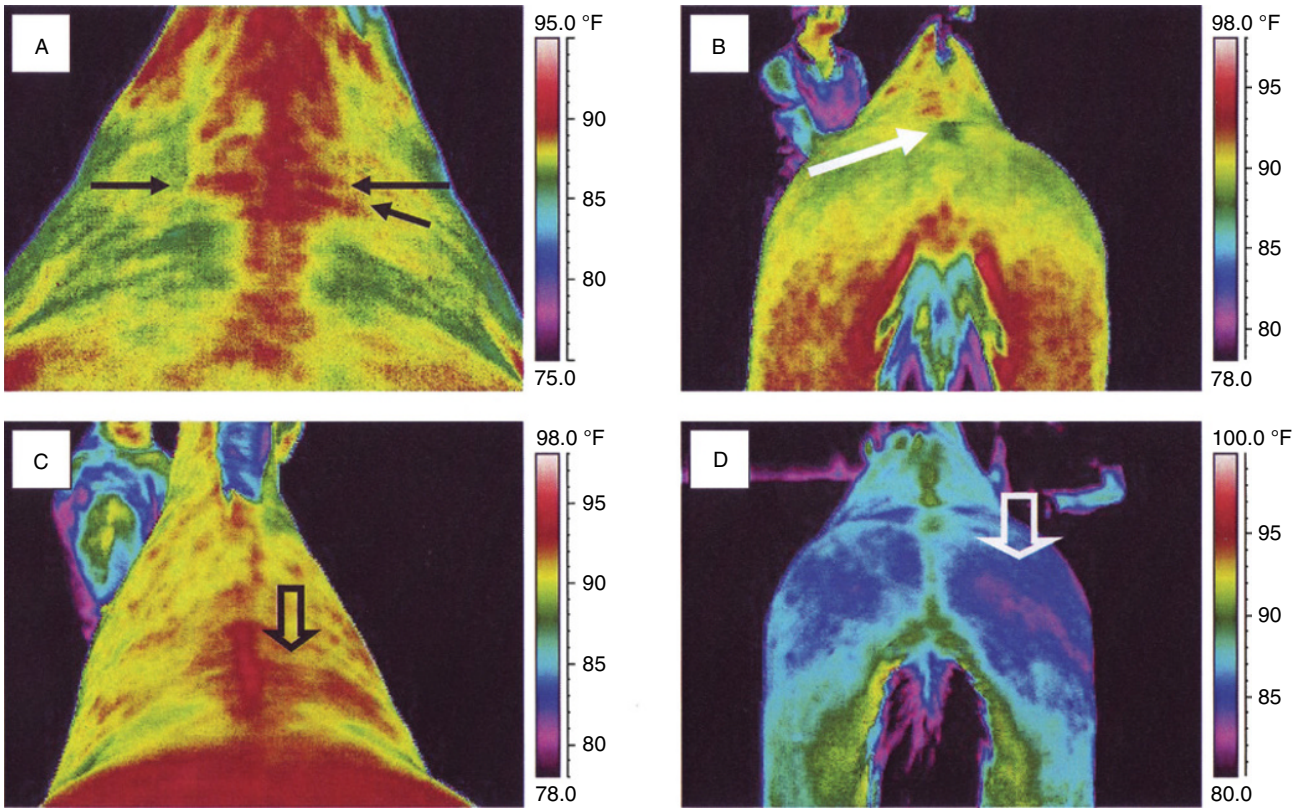

Figure 3.256. (A) Thermogram typical of overriding spinous processes in the horse's back. Note the horizontal hot spots (black arrows); overriding spinous process was confirmed radiographically. (B) Thermogram depicting a cold area over the tuber sacrale (white arrow). This is seen whenever the horse does not bend its back normally and has been associated with thoracolumbar and sacroiliac pain. This horse had evidence of sacroiliac desmitis on ultrasonography. (C) A back with heat over the right epaxial muscles (hollow black arrow), which correlated with palpable pain on the same area. (D) Nonspecific thermal pattern over the croup that shows thermal asymmetry with the right side being colder (white hollow arrow). When this pattern is seen, the lame leg is the cold leg and is thought to be associated with decreased use.

The normal back thermal pattern is warmest down the midline, cooling slightly in the lumbar region, warm from tuber coxae to tuber coxae and over the tuber sacrale, and the same warmth down the middle of the croup (Figure 3.251).[16] The warm area has symmetric isothermic bands on either side. Any variation of this pattern is either due to an artifact (thin hair, rubbed area) or pathologic process. If the lesion occurs along the midline of the thoracolumbar area, radiographs of the thoracolumbar spine are indicated. If the lesion occurs off the midline or in the croup region, we usually image the area with ultrasonography.

Overriding spinous processes or kissing spine has been associated with any one of three different thermal patterns.[18] Pattern 1 is a hot streak perpendicular to the thoracic spine (Figure 3.256), pattern 2 is a cold streak perpendicular to the thoracic spine, and pattern 3 (the most common) is a combination hot spot–cold streak pattern over the back. Our practice has evaluated over 150 cases over a 5-year period of time and has determined that the sensitivity of thermography to diagnose overriding spinous process is 99%; however, the specificity was only 70%. This resulted in a positive predictive value of 91% compared with the positive predictive value of palpable pain in the thoracolumbar area for kissing spine of 67%.

Dorsal spinous ligament injuries have not presented with that type of pathognomonic thermal pattern.[16] Thermographic changes associated with this injury have been increased heat, decreased heat, or simply an abnormal back thermogram. The lesion in our hands has been detected using ultrasonography after knowing there is an abnormal thermogram.

Muscle injuries of the thoracolumbar region also do not have characteristic thermograms.[16] Typically, however, the thermal patterns will show either hot spots or cold spots off the midline (Figure 3.256). It is in these regions we have concentrated sonography to determine if muscle lesions can be seen. Withers injuries have all shown hot spots in the area of the withers but nothing more characteristic than that. The croup muscles will show some specific changes.[14]

Sacroiliac region thermography has shown several different patterns.[16] The most common pattern is a cold area centered over the region of the tuber sacrale (Figure 3.256). This finding of cold is hypothesized to be due to lack of normal movement in the sacroiliac region. This lack of movement can be either due to primary pathology or secondary to other causes of the horse not moving normally through the pelvic region. This has been consistent with our clinical findings as well. Specifically, we have found that only about half the horses exhibiting this thermal pattern actually show

VetBooks.ir

pain in the sacroiliac area. In addition, sonographic evaluation reveals pathology in only about half the cases, and this pathology usually looks chronic in nature. We have identified both thinning and thickening of the cross-sectional diameter of the dorsal sacroiliac. In cases with a cold area and palpable pain, we will sonographically examine the sacroiliac region. On the other hand, if there is no pain or the horse moves normally through the pelvis, we look for other causes of loss of back mobility. Pathology is seen much more commonly if the area over the tuber sacrale is hot or if there is a hot spot centered over one tuber sacrale or the other. The pathology varies from hypoechoic areas within the dorsal sacral ligaments to generalized edema in the region. This thermographic pattern is almost always associated with either pain or marked stiffness in the sacroiliac region.

Saddle fit thermography is very interesting and requires multiple examinations.[17] In evaluating the dynamic interaction between the saddle and the horse's back, thermography will show not only the heat generated in contact areas on the saddle but also the physiologic effects of the saddle on the horse's back. Our protocol is to perform a baseline thermographic examination of the horse's back and again after the horse has been worked under saddle. The horse should be saddled with a simple cotton pad with the girth tightened as it would be for riding. The horse is then lunged for at least 20 minutes. The horse should be exercised at its normal gaits (walk, trot, and canter) and equally in both directions. Both the bottom of the saddle and the horse's back are evaluated. The most important criterion for the saddle is thermal symmetry. In regard to the horse, due to the heat generated by the saddle, the horse's midline is now colder than the other structures under the saddle. In addition, the examiner is looking for focal hot spots, particularly along the spine, or hot or cold spots over the musculature. These abnormalities indicate problems caused by the saddle. The assessment is then repeated after a similar exercise session with the rider mounted. This evaluation allows consideration of the effect of the rider on the horse's back.

CHAPTER

Lameness of the Distal Limb

NAVICULAR REGION/PALMAR FOOT

Randy B. Eggleston and Gary M. Baxter

NAVICULAR SYNDROME/DISEASE

Navicular disease or syndrome remains one of the most controversial and common causes of intermittent forelimb lameness in horses between 4 and 15 years of age.[35,115,121] It is estimated that the syndrome is responsible for one-third of all chronic forelimb lameness in horses.[23,115] Quarter horses, Thoroughbreds, and Warmbloods, particularly geldings, appear to be at greatest risk, whereas the syndrome is rarely diagnosed in ponies or Arabian horses.[35,115] A recent study that evaluated a large population of horses with foot lameness in the United Kingdom also indicated that there was increased risk of foot pain associated with breed, occupation, age, and body weight–height ratio.[83] The disease has been shown to have a hereditary predisposition possibly due to limb conformation of the horse or to the specific shape of the navicular bone.[12,30,31] The shape of the proximal border of the navicular bone has been determined to be inherited in Dutch Warmblood horses, and horses with an undulating or concave proximal border are more predisposed to the disease.[30,31,96] Other factors such as faulty conformation, hoof imbalances, improper or irregular shoeing, and exercise on hard surfaces are also believed to predispose and aggravate the condition.[88,115,121] Although the hindlimbs can be affected, it is rare, and navicular disease is primarily considered a problem of the forelimbs.

There is some debate as to the proper nomenclature to use when diagnosing a horse that blocks to palmar digital (PD) anesthesia. The early diagnosis of navicular disease ("disease" implies a specific sign or symptom and a specific location) was based on abnormalities present on the navicular bone seen radiographically. However, a significant number of affected horses had normal radiographic findings, which led to the suspicion of soft tissue injuries, giving rise to the term navicular syndrome.[2,100,101] Many horses with bilateral foot pain have concurrent soft tissue and navicular bone abnormalities, also suggesting that navicular syndrome may be more appropriate in the majority of horses. The term "palmar foot syndrome" has also been recommended based on the variety of pathological entities that can be identified in lame horses that improve following PD anesthesia (Box 4.1).[35,46,96] This diagnosis seems most appropriate for those horses that do not have definitive navicular bone involvement or disease. Making a diagnosis of navicular syndrome or palmar foot syndrome is a bit arbitrary, but it avoids labeling horses as having navicular disease when the lameness could be due to many other sources in the foot. As our imaging capabilities have improved, there has been a growing appreciation for the variety of soft tissue abnormalities that are associated with palmar foot lameness, with or without concurrent navicular bone involvement.[39,100,101]

Navicular disease/syndrome has been defined as a chronic forelimb lameness associated with pain arising from the navicular bone and closely related structures including the collateral suspensory ligaments (CSLs) of the navicular bone, distal sesamoidean impar ligament (DSIL), navicular bursa, and the deep digital flexor tendon (DDFT).[35,36,42,100,101] Horses with primary DDF tendinitis within the foot are usually not considered to have navicular disease/syndrome.[35] The disease is characterized by degenerative changes in the structure, composition, and mechanical function of the cartilage, subchondral bone, and surrounding soft tissues of the

Box 4.1 Abnormalities that may exist in horses classified as having navicular disease, navicular syndrome, palmar foot syndrome, or palmar heel pain

1. Navicular disease: radiographic, CT, or MRI abnormalities within the navicular bone
2. Desmitis/trauma of the podotrochlear apparatus
   a. Collateral suspensory ligaments (CSL) of the navicular bone
   b. Desmitis of the distal sesamoidean impar ligament (DSIL)
   c. Desmitis of the distal digital annular ligament
3. Tendonitis of the DDFT: usually at three locations
   a. The insertion
   b. Palmar to the navicular bone
   c. Proximal to the navicular bone
4. Desmitis of the collateral ligaments (CLs) of the DIP joint
5. Navicular bursitis
6. Synovitis/capsulitis/OA of the DIP joint
7. Primary hoof imbalances (improper trimming or shoeing)
8. Hoof capsule and/or heel distortions

navicular apparatus.[46,49,96] However, documenting many of these abnormalities in horses that do not have radiographic abnormalities requires advanced imaging such as computed tomography (CT) or magnetic resonance imaging (MRI).[101] In addition, hoof imbalances, hoof capsule distortion, contracted or sheared heels, etc. may be the sole cause of lameness without abnormalities within the deeper structures of the foot.[4,25,115]

The bottom line is that not all horses with lameness conditions associated with the palmar aspect of the foot should be labeled as having navicular disease or syndrome. Some clinicians feel that navicular disease/syndrome should be reserved for horses with chronic bilateral forelimb lameness that fit a very specific set of diagnostic criteria.[115] Most horses with true navicular disease have a bilateral forelimb lameness that switches to the opposite limb after a low PD block, pain on hoof testers across the central or cranial aspect of the frog, and some evidence of radiographic abnormalities within the navicular bone. However, hoof tester sensitivity may be variable, and based on recent MRI studies, the lack of radiographic abnormalities does not rule out navicular bone pathology.[2,35,100]

Etiology

The two proposed causes of navicular disease are vascular compromise and biomechanical abnormalities leading to tissue degeneration.[6,22,23,43,71,82,88,96,97,115,119,136] With the vascular theory, thrombosis of the navicular arteries within the navicular bone, partial or complete occlusion of the digital arteries at the level of the pastern and fetlock, and a reduction in the distal arterial blood supply due to atherosclerosis was thought to result in ischemia of the navicular bone.[22,23,97] The vascular theory has not withstood scientific scrutiny because of failure either to reproduce the disease by altering blood flow or to identify histological tissue changes compatible with the theory.[96,97,119] In addition, increased bone remodeling/modeling and vascularization have been demonstrated in horses with navicular disease.[22,82,136] The increased vascularization was shown to be a combination of active arterial hyperemia and passive venous congestion. Obstruction of the venous outflow was thought to result in venous congestion, increased bone marrow pressure, and pain.[86,88,117]

There is increasing evidence that abnormal nonphysiological biomechanical forces leading to tissue degeneration is the most likely cause of navicular disease.[6,16,45,70,88,97] Forces exerted on, or experienced by, the navicular bone and the podotrochlear apparatus are central to these biomechanical studies. Abnormal forces on the navicular bone could arise from either excessive physiological loads applied to a foot with normal conformation or normal loads applied to a foot with abnormal conformation.[61,119] Poor hoof conformation and balance, particularly the long-toe, low-heel hoof conformation accompanied by the broken-back hoof-pastern axis, have historically been considered major risk factors for the development of navicular disease. This concept has withstood the test of time, supporting the theory that excessive and repetitive forces applied to the distal third of the navicular bone by the DDFT are a major contributor to the disease. Further supporting this is the finding that the force exerted on the navicular bone is negatively correlated to both the angle between the third phalanx (P3) and the ground and the ratio between heel and toe height.[32,47,51,61] Extreme cases of collapsed or underrun heels can result in a negative palmar/plantar angle where the palmar/plantar margin is lower than the dorsal margin of the distal phalanx (Figure 4.1). This type of conformation greatly increases the contact stress on the navicular bone by the DDFT. In contrast, heel elevation is used to treat horses with navicular disease and is thought to decrease the tension on the DDFT, which reduces the forces applied to the navicular bone.[51,96,132]

The location of the navicular bone between P3, the second phalanx (P2), and the DDFT suggests that it functions primarily as a buffer to spread forces among the anatomical structures.[96] It ensures that the DDFT maintains a constant angle of insertion, and the distal aspect of the bone must withstand great forces during the propulsive phase of the stride.[13,17,28] A study in isolated limbs using pressure-sensitive film documented that the contact load on the navicular bone and associated joints was highest during dorsiflexion (extension) of the limb, which corresponds to the end of the stance phase or the beginning of the propulsion phase.[17] However, in another study, both force and stress on the navicular bone in horses with navicular disease were approximately double those of normal horses during the early stance phase of the stride.[133] This was associated with greater tension on the DDFT, which the authors attributed to contraction of the deep digital flexor muscle in the early stance phase. Contraction of the deep digital flexor muscle was thought to help avoid heel-first landing in an attempt to unload the heels, but this appears to simultaneously increase the forces on the navicular bone.[96,133]

It has been estimated that the peak forces on the navicular bone approximate 0.67× body weight during the walk and 0.77× body weight at a slow trot.[88,115] However, the forces applied to the navicular region are influenced not only by body weight but also by limb and

foot conformation and the type of work performed by the horse. Factors such as excessive body weight, small feet, broken pastern angles, long toes, low heels, hoof imbalances, and work on hard surfaces are likely to increase the forces per unit area of the navicular bone and podotrochlear apparatus (Figures 4.1–4.3).[4,48] Minor conformational abnormalities and other predisposing factors do not cause excessive loading of the navicular bone in most horses, resulting in normal modeling/remodeling of the navicular bone over time without the development of lameness.

In horses with severe or multiple predisposing factors, nonphysiological forces exerted on the navicular bone region begin the pathologic process that can affect the palmar/plantar fibrocartilage, dorsal articular cartilage, underlying bone, navicular bursa, podotrochlear apparatus, and DDFT.[96] Many of the pathologic changes within the navicular bone resemble those seen grossly and microscopically with osteoarthritis (OA) at other locations such as the distal tarsal and proximal interphalangeal (PIP) joints.[96,115,119] These microscopic changes include focal degeneration, cartilage erosion, subchondral bone sclerosis associated with thickening of the trabeculae, focal areas of lysis, edema, congestion, and fibrosis in the marrow spaces (Figure 4.4).[35,70,86,88,96,136]

Recent work has also indicated that the navicular bones in lame horses that lack radiographic evidence of disease can have a variety of histologic abnormalities. In this study, the presence of increased signal intensity in the spongiosa of the navicular bone with MRI was associated with the histologic findings of fat atrophy, proliferation of capillaries within the altered marrow fat, perivascular or interstitial edema, enlarged intertrabecular bone spaces, fibroplasia, and thinned trabeculae showing loss of bone.[49,69]

Figure 4.4. Cross section of the navicular bone at necropsy demonstrating cyst-like lesions within the body of the navicular bone.

Figure 4.5. Postmortem view of the navicular bone illustrating degeneration of the flexor cortex. This horse also had surface fibrillation of the DDFT.

Additional abnormalities that have been found on the flexor surface of the navicular bone in lame horses compared to age-matched controls included thinning, crevicing or loss of the fibrocartilage layer, chondrone formation, and subchondral bone necrosis (Figure 4.5).[9] In this study there was no relationship between age and the severity of the histological abnormalities in the navicular bone, but the lesions were more common in lame horses than controls.[9] Studies from both lame and non-lame horses have identified early degenerative changes on the sagittal ridge, and it is thought that degenerative changes within the navicular bone initiate at the sagittal ridge. Such early changes included thinning of fibrocartilage and subchondral bone along the flexor surface and fibrillation and disruption of the DDFT.[35,46,69]

Scanning electron microscopy studies of the distal sesamoid bone and DDFT have identified fraying of collagen fibers in the DDFT and fissuring of the fibrocartilage on the flexor surface of the navicular bone.[33,134] Damage to the fibrocartilage together with DDFT fibrillation may predispose to adhesion formation between the tendon and the bone. Other studies have identified superficial or deep sagittal or parasagittal crevices or splits of the DDFT, abrasions or fibrillation on the dorsal surface, focal fibrocartilaginous metaplasia, and focal fibroplasia (Figure 4.5).[10,96] These abnormalities were not related to age, but lesions on the dorsal aspect of the DDFT were significantly more common in lame horses than control horses.[11] In addition, true core lesions appeared to be uncommon, and there was little evidence of acute inflammatory changes within the DDFT.[10] Superficial lesions on the dorsal surface of the DDFT may occur without detectable lameness, but deep sagittal splits are usually related to lameness.[96] Abnormalities within the podotrochlear apparatus (CSL, DSIL) have also been described in horses with navicular disease, but their clinical significance is difficult to assess based on the inability to definitively distinguish between individual structures and their contribution to lameness when multiple lesions are identified.[9,84,96] Fibrocartilaginous metaplasia, collagen degeneration, and fibroplasia were the most common microscopic findings.[9,10]

The pain and lameness in horses with navicular disease/syndrome presumably comes from within the bone and/or the surrounding supporting soft tissue structures. In most cases, it probably originates from more than one site because combination injuries within the foot appear to be most likely. With significant bone degeneration, the origin of pain is probably similar to that of horses with OA. Venous drainage of marrow spaces below lesions of degenerative joint disease is thought to be sluggish, and pain is associated with dilated vessels in the subchondral spongiosa.[88] Horses with navicular syndrome have been shown to have impaired venous drainage[67,86] and have bone marrow pressure exceeding 50 mm Hg, which is significantly higher than that of control horses.[86,117] Therefore, increased intraosseous pressure associated with venous distension and hypertension may be the cause of bone pain in affected horses.

Pain from injuries to the supporting ligaments and the DDFT most likely contribute to the lameness in most cases. Significant DDFT lesions (sagittal splits and core lesions) may be very painful, similar to tendinitis at other locations. Enthesophyte formation on the proximal or distal borders of the navicular bone may represent previous tearing of the CSL attachments, but it is often difficult to determine if these abnormalities actively contribute to the pain. In addition, sensory nerve endings have been identified in the CSL, DSIL, and DDFT at its attachment to the distal phalanx.[14–16] The location where the DSIL and the dorsal aspect of the DDFT insert onto the distal phalanx has been referred to as the "intersection" and is thought to have a rich sensory innervation, particularly of substance P and neuropeptide-producing fibers, and abundant arteriovenous complexes (Figure 4.5).[14,15,119] This anatomic region may act as an initiation site for many of the more extensive tissue changes that subsequently develop in many horses with navicular disease.[119]

VetBooks.ir

Clinical Signs

Horses with navicular disease/syndrome usually have a history of progressive, chronic, unilateral, or bilateral forelimb lameness, which may have an insidious (most common) or acute onset.[35,84,115] The history may include a gradual loss of performance, stiffness, shortening of the stride, loss of action, unwillingness to turn, and increased lameness when worked on hard surfaces.[35,46] Chronic bilateral forelimb lameness is considered the norm, and navicular syndrome has been described as heel pain that blocks to a PD nerve block on both forelimbs with or without radiographic abnormalities.[100,101] However, unilateral lameness can also occur, especially with lesions that involve the flexor surface of the navicular bone and/or the DDFT. Most horses with an acute onset of unilateral lameness that blocks to the foot are not considered to have navicular disease/syndrome, and lesions in the DDFT or other problems in the foot should be suspected.

Navicular disease/syndrome is considered to be a degenerative process due to wear and tear similar to OA; therefore, middle-aged to older horses are most commonly affected. Clinical signs usually become apparent in most horses between 7 and 10 years of age, although younger horses can be affected.[35,46,100,115] Horses with developmental/congenital abnormalities such as bipartite navicular bones can often become lame as early as 2–3 years of age (Figure 4.6). Geldings are more commonly affected than mares or stallions and Quarter horses, Warmbloods, and Thoroughbreds seem more predisposed to the disease than other breeds.[35,100] The classic signalment and history for many horses with navicular disease/syndrome is a middle-aged Quarter horse gelding with a history of chronic bilateral forelimb lameness.

Although navicular disease/syndrome usually affects both front feet, the lameness may initially appear unilateral.[35,46,115] Greater than 95% incidence of asymmetrical lameness has been reported.[135] Most horses are more lame in one forelimb, both at a straight trot and when circled on a hard surface, but often demonstrate lameness on the opposite forelimb when circled with that limb on the inside. Bilateral forelimb lameness observed when circled both directions was present in 76% of the horses with less than 6 months' duration of lameness and in 52% in horses with greater than 6 months' duration of lameness in a recent study.[100] The remainder of the horses had a unilateral lameness until a PD nerve block was performed, at which time the lameness switched to the opposite forelimb.[84,100,101] However, the true severity of a unilateral lameness at a straight trot may be misinterpreted because of the concurrent lameness in the opposite forelimb. In addition, the horse may tend to point one forelimb or alternate pointing each forelimb.[115,135] Asymmetry in the extensor muscles with atrophy of the muscles associated with the lame limb can often be observed in horses with chronic lameness.[115,116,135]

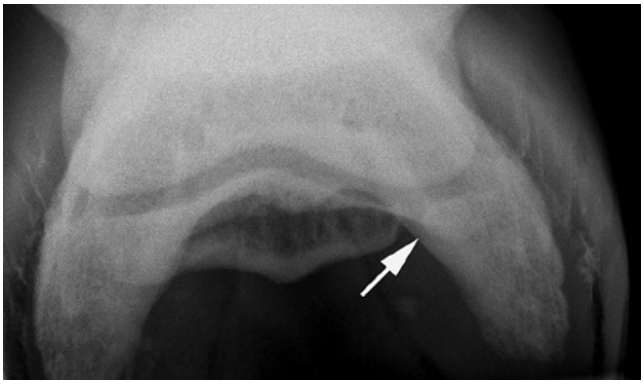

Figure 4.6. Bipartite navicular bone (arrow) as seen on a skyline radiograph in a young horse with lameness isolated to the foot.

In a recent study that compared specific sources of foot lameness verified on MRI (navicular bone lesions alone, lesions of the podotrochlear apparatus, lesions of the DDFT alone, and lesions involving navicular bone and soft tissue), there were no significant associations among groups with respect to onset of lameness, foot conformation, posture, presence of distal interphalangeal (DIP) joint effusion, hoof tester examination, flexion testing, or blocking pattern.[84] Most (73.3%) horses were lamer when lunged on a firm surface than a soft surface, and 32.7% of horses were lamer on a circle than in a straight line. Horses with podotrochlear apparatus injuries were more likely to be unilaterally lame, and horses with injury to the DDFT were more likely to exhibit lameness at the walk when turning tight turns.[84]

Various abnormalities of the hoof can be present in horses with navicular disease/syndrome. It can often be difficult to determine whether the hoof abnormalities are contributing to the disease or have developed secondary to the lameness and disuse of the foot. For example, both low, collapsed heels typical of Thoroughbreds and narrow, upright feet typical of Quarter horses can occur in horses with navicular disease/syndrome. Secondary hoof abnormalities are most likely to develop in horses with a chronic duration of lameness. Common hoof problems seen in horses with navicular disease/syndrome include low, underrun heels, contracted or collapsed heels, medial to lateral imbalances, and long toes (Figures 4.1–4.3).[4,35,47,121,135] Dorsal to palmar imbalances such as the broken-back hoof-pastern axis are also commonly seen and are considered to be a predisposing factor for development of a multitude of problems in the foot. In one study, a broken-back hoof-pastern axis occurred in 71% of the horses with navicular disease/syndrome.[135] One forefoot is often smaller, narrower, and more upright (longer heels) than the other, which is presumably from disuse atrophy. In most cases the limb with the more upright hoof conformation is the limb with the greatest lameness.[4,25,35,47,48,135] Angular limb deformities, either valgus or varus, associated with the carpus and fetlock region have also been observed in a small percentage of cases.

At exercise, most horses with navicular disease/syndrome exhibit a mild to moderate lameness (2–3 of 5) that is worse on hard surfaces.[35,84] Only occasionally is severe lameness encountered. Some clinicians feel that the severity of lameness usually increases with the duration of the lameness.[115] However, in a recent study, the mean lameness grade of horses with navicular syndrome was grade 3 for horses with less than 6 months' duration of lameness and grade 2 for horses with more than 6 months' duration of lameness.[100] The severity of

VetBooks.ir

lameness may be more related to the specific cause(s) of pain rather than the duration of the lameness.[84]

While walking or trotting, many horses tend to land toe first and may occasionally stumble.[22,96,119] At a trot, horses with bilateral lameness tend to have a stiff shuffling gait and often carry their heads and necks rigidly. This stilted gait is usually worsened when circled and has been described as the horse "trotting on eggshells." Owners often misinterpret this characteristic gait as an unwillingness to advance the limbs associated with shoulder pain. When circled in either direction on a hard surface, the lameness is usually exaggerated in the limb that is on the inside of the circle. The lameness and stilted gait is often exaggerated as the size of the circle is reduced. The horse may hold its head and neck to the outside of the circle in an effort to reduce the amount of weight carried on the inside limb. One study reported that 20% of horses that presented with no overt signs of lameness by owners displayed a bilaterally symmetrical short-stepping gait when evaluated by a veterinarian. Asymmetric forelimb lameness was easily observed when these horses were circled. This finding highlights the importance of recognizing this type of gait in horses with bilateral forelimb lameness and the necessity to evaluate these horses on different surfaces and at the lunge.[84]

Hoof tester examination is considered essential for the clinical diagnosis of navicular disease/syndrome by many clinicians. However, the reliability of this test is somewhat controversial because a negative response to hoof testers over the frog region is not uncommon in horses with navicular syndrome/disease.[35,84,100,122] In one study, only approximately 50% of the horses with lameness localized to the navicular region responded positively to hoof tester pressure over the central third of the frog.[124] In contrast, a nonfatiguable painful withdrawal to intermittent hoof tester pressure over the central and occasionally the cranial third of the frog is considered a fairly consistent feature of navicular disease/syndrome by others.[115] In addition, it is important to apply direct compressive pressure to the navicular region rather than simply applying lateral (shearing pressure) across the frog when using the hoof testers. Horses with very thick soles and hard frogs usually do not respond to hoof tester pressure. Hoof tester pain may also be present over the toe secondary to bruising from landing toe first but is usually of minor clinical significance.

Distension of the DIP joint is a nonspecific finding that may be found in normal horses as well as horses with navicular disease.[35] DIP joint distension was identified in only 4.2% of horses with various injuries to the foot that were confirmed on MRI[84] and is often detected more frequently by MRI than by clinical examination.[44,76] However, the presence of DIP effusion may be an important finding when developing a treatment plan for an individual horse. In addition, asymmetrical DIP joint effusion is usually clinically relevant and often suggests a secondary problem within the joint. Many horses with navicular disease/syndrome may react positively to a phalangeal flexion test, which often exacerbates the lameness.[115,135] However, a positive phalangeal flexion test is not specific for the navicular region and is usually not that beneficial in localizing the lameness to the foot. A positive phalangeal flexion may suggest a primary or secondary problem within the DIP joint in some horses with foot pain.

Use of a wedge block, although nonspecific, can be useful to evaluate horses with foot pain. The wedge block allows perhaps more specific manipulation of the distal limb than can be performed with flexion tests (Figure 2.111). Elevating the toe, similar to a naturally occurring negative palmar solar angle, is thought to increase the strain on the DDFT and podotrochlear apparatus and increase the pressure on the navicular bone and navicular bursa. Little work has been done to support the use of the wedge block, but in one study, toe elevation tests resulted in a sensitivity of only 55% and a specificity of only 42% for the presence of navicular pain.[122] In contrast, raising the heels is thought to decrease the strain on the DDFT and podotrochlear apparatus and decrease the pressure on the navicular bone and navicular bursa. However, it will result in increased heel pressure. One study found that heel elevation had a sensitivity of 76% and a specificity of 26% for the presence of navicular pain.[122] The observation of worsening lameness following heel elevation has also been observed in many horses with MRI-confirmed injury to the DDFT.[110]

Wedge block manipulation of the distal limb typically consists of placing the foot on the block squarely in the toe-up position. The opposite limb is usually held up in a relaxed neutral position and held for 60 seconds. The horse is then trotted off and any change in the lameness is observed and documented. The same test is then performed in the heel-up position. Because we know that many horses with "navicular disease" commonly also have injuries to the supporting soft tissues, the test can also be performed in a medial and lateral up position. With the foot placed in the lateral wedge position, the lateral aspect of the foot is placed in compression while the medial aspect of the foot is placed under tension. The authors have found horses with confirmed DIP joint disease and injuries to the collateral ligaments (CLs) of the DIP joint to show a positive response to this test.

Diagnosis

Local Anesthesia

The diagnosis of navicular disease/syndrome begins with localizing the site of lameness to the foot or more specifically to the palmar aspect of the foot using diagnostic anesthesia. Historically, a PD nerve block was thought to only desensitize the palmar aspect of the foot, but it is now known that it is relatively nonspecific and alleviates pain in the navicular bone, podotrochlear apparatus, navicular bursa, distal aspect of the DDFT, distal phalanx, middle phalanx, DIP joint, dorsal aspect of the hoof, and possibly the digital tendon sheath and PIP joint.[96,102] Therefore, a multitude of clinical problems in the foot can be desensitized with a PD block; this has been confirmed in numerous studies.[38,39,41,84,100,101]

Using a small volume of anesthetic (1.0–1.5 mL) and performing the PD block as low as possible in the heel region (axial and distal to the proximal limits of the collateral cartilages) is recommended to improve the specificity of the block to the structures within the palmar aspect of the foot.[46,96,108,109,111] Several studies have

VetBooks.ir

documented that the diffusion and distribution patterns of anesthetics are affected by volume, injection site, and time.[79,80] Some advocate that if lameness is not abolished within 10 minutes following a nerve block, the block should be deemed negative and to continue blocking.[111] It is important to be mindful of technique, volume of anesthetic used, and timing between nerve blocks. However, using good technique does not guarantee that multiple structures have not been desensitized and that the block has extended beyond what is to be expected.

The majority of horses affected with navicular disease/syndrome (80%–100%) improve substantially following a PD block and the lameness in the opposite forelimb either worsens or becomes apparent if a unilateral lameness was initially found.[99–101,115] Kinematic gait analysis has found that the mean maximal extension of the fetlock during the stance phase of the stride and the maximum flexion of the carpal joint during swing phase of the stride were significantly increased after PD blocks in horses with navicular disease.[68]

Intrasynovial anesthesia of the DIP joint and the navicular bursa can also be performed to potentially further localize the site of pain. Historically, blocking the DIP joint was thought to help distinguish between problems associated with the joint and the navicular region. However, several studies have demonstrated a lack of specificity of intrasynovial anesthesia of the DIP joint due to diffusion of anesthetic and the location of sensory nerves in close approximation to the synovial outpouchings of the DIP joint.[15,16,34,55,87,107,108] Anesthesia of the DIP joint is known to improve the lameness in a large percentage of horses diagnosed with navicular syndrome.[34,35,46,99,111,115] However, the amount of improvement in lameness following DIP joint anesthesia is often less than that following a PD block in most horses with navicular disease/syndrome. Recommended methods to improve the specificity of DIP joint anesthesia are to use no more than 5–6 mL of anesthetic and to assess the response to the block within 5–10 minutes.[96,99,107,111]

Anesthesia of the navicular bursa is probably the most specific nerve block that can be used to help localize the site of pain in horses with navicular disease/syndrome. However, it is not routinely used as the initial diagnostic block because of the need for radiographic or ultrasonographic confirmation of needle placement. A positive response to intrasynovial anesthesia into the navicular bursa may indicate problems of the navicular bursa, navicular bone, and/or navicular supporting ligaments, sole, and/or toe, or distal aspect of the DDFT.[107–109,111] Even though diffusion of local anesthetic into the navicular bursa occurs following DIP joint injection, the converse does not occur, and analgesia of the navicular bursa does not usually result in analgesia of the DIP joint.[108,111] Pain from the DIP joint can likely be excluded as a cause of lameness if analgesia of the navicular bursa improves the lameness within 10 minutes.[108,111] In addition, a positive response to intra-articular analgesia of the DIP joint together with a negative response to navicular bursa analgesia incriminates pain within the DIP joint as the cause of lameness.[111]

See Chapter 3 for further information about local anesthesia.

Radiography

Despite its limitations, radiography remains the initial diagnostic tool to assess the navicular bone in most horses with navicular disease/syndrome. However, degenerative changes within the bone can be missed because a 40% change in bone density is required before it can be identified with radiographs.[96] Therefore, the lack of abnormalities in the navicular bone does not eliminate the bone as the site of the pain and does not necessarily indicate a soft tissue problem in the foot. Several studies evaluating horses showing signs of navicular syndrome but with normal or mild radiographic abnormalities of the navicular bone have documented that the majority of these horses' navicular bones were abnormal on MRI or histological examination.[49,69,100,101] The navicular bone was considered the primary abnormality in only 33% of horses with a recent onset of lameness and in only 16% of horses with a more chronic duration of lameness.[100,101]

A complete radiographic evaluation of the navicular bone requires a minimum of lateromedial, 60° dorsoproximal to palmarodistal oblique, and palmaroproximal to palmarodistal oblique (skyline) high-quality views.[35,37,50,115] Additional radiographs such as the 60° dorsoproximal to palmarodistal oblique view of the distal phalanx and the weight-bearing dorsopalmar view are often included to completely evaluate all bony structures in the foot. Adding a shallow angle (35°) palmaroproximal to palmarodistal oblique projection has been recommended to improve the accuracy of identifying flexor cortex lysis.[64] This is supported by the fact that the majority of flexor cortex lesions occur in the mid to distal aspect of the flexor surface.[9,49] Careful attention to foot preparation (packing the frog), limb position, and centering and directing the X-ray beam according to the hoof capsule conformation is important to avoid artifacts and inaccurate image interpretation.[37,50] For example, slight obliquity to a lateral medial projection will result in a poorly defined sagittal ridge, misinterpretation of the true flexor cortex thickness and uniformity of opacity of the flexor cortex, poor demarcation between the endosteal surface of the flexor cortex navicular bone and the trabecular bone, poor representation of the proximal to distal shape of the flexor aspect, and poor definition of the articular margins of the navicular bone.[37]

There are a number of radiographic abnormalities to the navicular bone that have been described; some are considered incidental and may or may not be pathologic, and some correlate strongly with lameness. Those seen more commonly in lame horses include the following:

1. Enthesophytes at the proximomedial and proximolateral aspect of the bone. Small enthesophytes can be seen in sound horses, but large enthesophytes are usually associated with lameness.
2. Proximal or distal extension of the flexor border of the bone. This change in shape is indicative of stress at the insertion of the CSLs and origin of the DSIL.
3. Fragments at the distal border of the bone. These fragments are usually located at the distal medial and lateral angles of the bone and can be associated with lameness. Their presence may be due to ectopic

VetBooks.ir

mineralization in the DSIL, fracture directly off the distal border of the navicular or fracture of enthesophyte formation at the origin of the DSIL.
4. Numerous (>7) large and variably shaped distal border radiolucent zones.
5. Discrete radiolucent areas in the spongiosa with or without detectable communication with the flexor cortex.
6. New bone at the sagittal ridge.
7. Increased thickness of the flexor cortex.
8. Sclerosis of the spongiosa.
9. A bipartite bone.[37]

Additional abnormalities that are considered important include flexor cortex defects or erosions, loss of corticomedullary distinction, and mineralization of the supporting ligaments of the navicular bone or the DDFT.[37,65,122,130]

The radiographic abnormalities that appear to be the most reliable indicators of navicular disease/syndrome are cyst-like lesions within the medullary cavity (Figures 4.7 and 4.8), flexor cortex lesions, and sclerosis of the spongiosa with loss of demarcation of the flexor cortex and medulla (Figures 4.9 and 4.10).[35,37,130] Flexor cortex defects were seen in less than 1% of normal horses; they represent lysis of subchondral bone and are linked to fibrocartilage degeneration and damage to the DDFT (Figure 4.11).[65,130] Sclerosis was present in up to 80% of horses with navicular syndrome but in less than 16% of normal horses.[65]

Less reliable radiographic indicators include enthesophytes at the proximal or distal border of the bone, elongation of the flexor border of the bone, distal border fragments, and enlarged synovial invaginations. All of these abnormalities of the navicular bone can be present in non-lame horses and by themselves may not constitute radiographic evidence of navicular disease.[130] However, distal border fragments appear to be recognized more frequently with digital radiography and are thought to be associated with navicular disease (Figure 4.12).[7,8,37] These fragments may represent a fracture, enthesophyte, or dystrophic mineralization within the DSIL.[7] See Chapter 4 for further information on radiography of the navicular bone.

Ultrasonography

Ultrasound is an economical and readily available diagnostic technique that can be used to help diagnose potential soft tissue injuries within the foot in horses with navicular disease. However, the keratinized hoof wall, frog, and sole all limit contact with the ultrasound probe and prevent good images from being obtained.[19,96] With experience, ultrasound can be used to assess the flexor surface of the navicular bone, navicular bursa, podotrochlear apparatus, and distal part of the DDFT; evaluation of the dorsal pouch of the DIP joint and CL of the DIP joint phalanx should also be performed.[19,56] The most common abnormalities identified using ultrasound

Figure 4.8. Multiple smaller cystic lesions along the distal border of the navicular bone as demonstrated on an oblique radiograph.

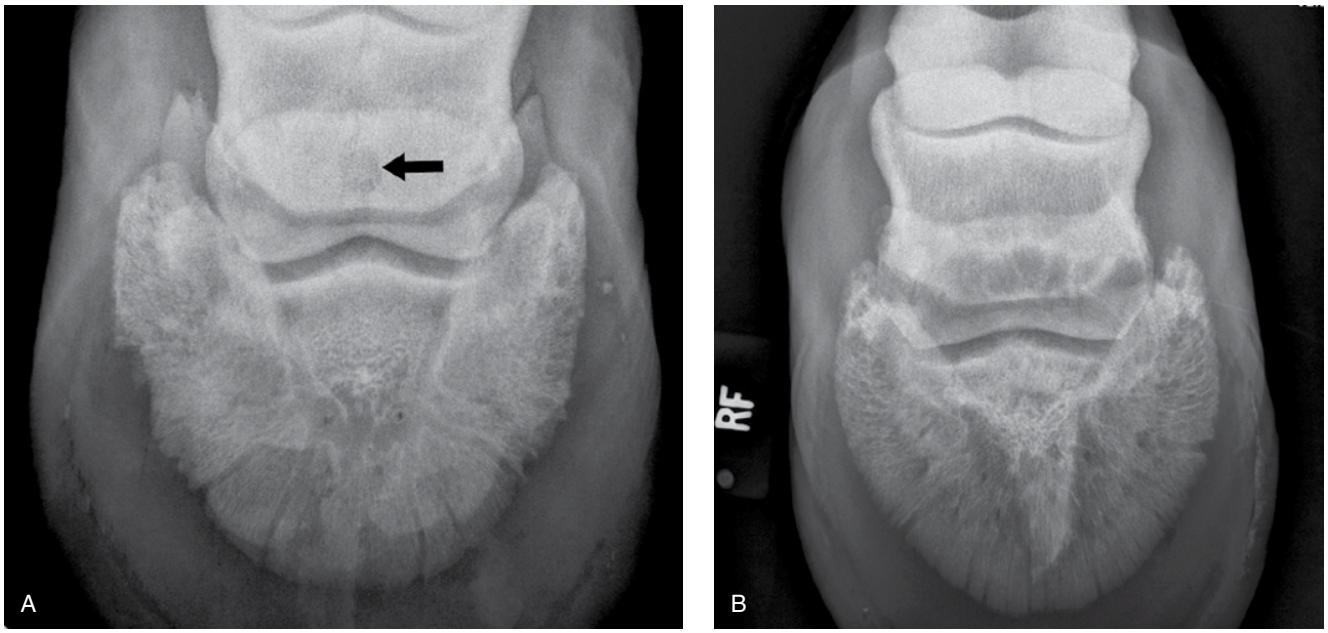

Figure 4.7. Single large cystic lesion (A; arrow) and multiple cystic lesions (B) within the navicular bone demonstrated on oblique radiographs of two different horses with signs of navicular syndrome.

VetBooks.ir

in horses with lameness isolated to the foot but with no radiographic abnormalities included changes to the DDFT (73%), effusion and synovial proliferation to the DIP joint (69%), and navicular bursitis (56%).[94] Lesions of the DDFT were most commonly found in the lateral lobe of the tendon and located just above the navicular bone in the majority of cases. These findings were similar to results of previous imaging and histopathologic studies.[10,11,20,39,42,44] Similar to radiography, the accuracy of ultrasound to document pathology within the foot has been criticized based on results of more advanced imaging such as MRI. Therefore, negative findings with ultrasound do not rule out the presence of abnormalities in the navicular region and currently is not used routinely clinically.

Figure 4.9. Multiple abnormalities within the navicular bone as seen on an oblique radiograph. Abnormalities present include remodeling along the proximal border, multiple cystic lesions along the distal border, and enthesophytes on the wings of the navicular bone.

Scintigraphy

Scintigraphy (nuclear imaging) was initially thought to be able to identify early pathologic changes within the navicular bone related to its ability to identify early alterations in bone metabolism rather than relying on anatomic changes. However, increased radiopharmaceutical uptake (IRU) has been documented to occur in only 36% of the limbs of horses with navicular disease/syndrome and in a very small percentage of limbs with soft tissue injuries within the foot.[38,40,67] Scintigraphic assessment of the foot can be helpful to identify the potential source of pain causing lameness, but false-positive results can occur, especially in horses with low-heel conformation.[38,40] Additionally, a negative scintigram of the foot does not preclude significant injuries, and scintigraphy does not provide a definitive diagnosis.[38,40,96] Results of a recent study that evaluated the diagnostic accuracy of scintigraphy in lame and poorly performing sport

Figure 4.11. Lateral radiograph of the foot in the horse in Figure 4.5. A lytic defect is present in the flexor surface of the navicular bone (arrow).

(B) A single large erosive lesion on the flexor surface of the navicular bone (arrow) in a horse with severe unilateral lameness.

VetBooks.ir

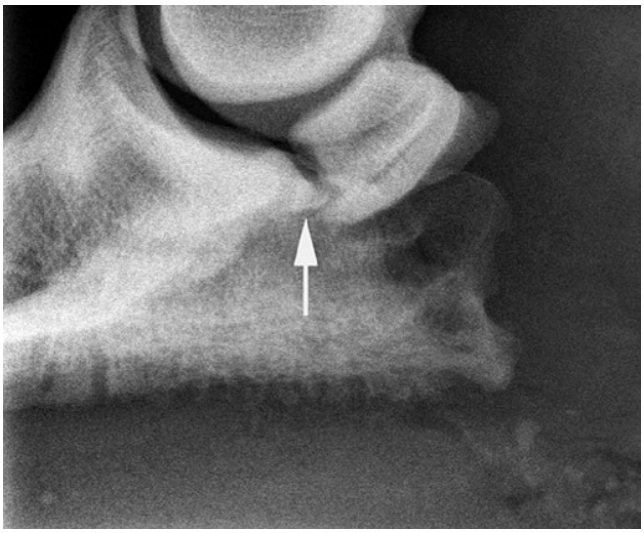

Figure 4.12. An avulsion fracture from the distal border of the navicular bone (arrow) can be seen on this lateral radiograph.

horses found an overall poor agreement between IRU and a positive diagnosis for lameness and poor performance.[93] For these reasons, and the economics of performing multiple advanced imaging techniques on the same horse, MRI is usually performed instead of scintigraphy in most horses with foot-related lameness.

Computed Tomography (CT)

CT is thought to be the best modality to detect and assess pathology within the cortex and trabeculae of the navicular bone.[91,96,118] Many osseous changes seen on CT are not radiographically evident, such as shape changes within the bone, distal border fragments, and intramedullary changes.[96,118] Soft tissue abnormalities within the foot may be detected with CT, but in general, CT is best at detecting abnormalities within bone and MRI is preferred to assess soft tissue lesions.[131] However, contrast-enhanced CT has been shown to improve the imaging of soft tissue structures within the foot and may be an alternative to using MRI.[89,91,125] Studies have suggested that the frequency of soft tissue injury identification with CT and MRI may be similar,[19,125] and using contrast-enhanced CT has been shown to compare favorably to MRI for identification of DDFT lesions within the foot.[90,92] Additional advantages to using CT include decreased anesthesia time since CT scans are very fast. The use of CT could facilitate an earlier and more accurate diagnosis of navicular bone pathology in horses but may not be able to detect the many concurrent soft tissue abnormalities that are often present in horses with foot pain.[96] However, new advances in CT technology such as the equine positron emission tomography (PET) CT may further enhance the ability of CT to document soft tissue pathology within the foot and elsewhere.[89,91] See Chapter 3 for further information on musculoskeletal CT imaging.

Magnetic Resonance Imaging (MRI)

MRI has become increasingly available in recent years and is currently the preferred diagnostic technique to assess most horses with navicular disease/syndrome.[20,39,41,43,44,78,100,101] The different sequences permit accurate evaluation of soft tissues, cartilage, and bone within the digit in near anatomic detail. The MRI technique can be performed in both the standing (low-field) and recumbent (high-field) patient, but better-quality images are thought to be obtained with high-field units. The ability to image and appreciate pathologic changes to articular cartilage and subtle soft tissue and bone abnormalities is thought to be superior with high-field vs. low-field MRI.[3]

Numerous pathologic entities have been identified with MRI in horses with navicular disease/syndrome, and many horses appear to have multiple abnormalities present within the same foot.[38,39,44,78,101] The most common abnormalities found on MRI involve the navicular bone, CSL, DSIL, DDFT, navicular bursa, CL of the DIP joint, and the DIP joint.[38,39,42,44,78,100,101] Several studies have documented that the DDFT and podotrochlear apparatus can be abnormal in horses with foot pain (Figure 4.13).[39,43,44,78,100,101] Injury to the DDFT, with a reported prevalence of 30%–64% in horses with foot lameness, is thought to be the most common soft tissue injury causing lameness in the horse's foot.[106] However, the frequency of occurrence of other soft tissue lesions such as those of the CSLs and the CL of the DIP joint differs among studies.[39,43,44,100,101] This may represent differences in the population of horses of the different studies or possibly differences in the interpretation of the MRI. From a clinical viewpoint, one difficulty with interpreting the results of MRI is determining what the primary abnormality may be when multiple lesions are found. However, this may be less important if we now assume that multiple abnormalities within the foot most likely contribute to the overall pain in horses with navicular disease/syndrome. See Chapter 3 for further information on MRI.

Treatment

Multiple factors are involved when deciding on a treatment protocol for horses with navicular disease/syndrome. In most cases the treatment must be tailor-made for each individual horse based on the severity of lameness, intended use of the horse, wishes of the owner, results of diagnostics (or lack of diagnostics such as MRI), hoof conformation, previous treatments, and most likely diagnosis.

Realistically, horses with advanced radiographic abnormalities in the navicular bone will be problematic regardless of the treatments employed. Historically, horses with minimal radiographic abnormalities of the navicular bone were thought to respond to therapy better than those with radiographic abnormalities.[115] However, this generalization is debatable because horses with DDFT injuries with or without navicular bone abnormalities tend to do poorly regardless of treatment.[41,96,106] In addition, developing a treatment protocol for horses without radiographic abnormalities and without performing an MRI can be challenging because a definitive diagnosis is difficult to make in these horses. The ability to develop a more precise treatment protocol is considered one of the benefits of performing an MRI in horses with foot pain. Using MRI to create an

VetBooks.ir

individually tailored treatment regimen is thought to promote a more positive outcome in many equine cases.[3]

A variety of treatment options are available for horses with navicular disease/syndrome with the goal of managing the disease. One of the most important treatments is corrective trimming and shoeing.[96,115,120] Other nonsurgical treatments include rest and controlled exercise, nonsteroidal anti-inflammatory drugs (NSAIDs), bisphosphonates such as tiludronate and clodronate, intrasynovial medications, and medications aimed at preventing secondary OA of the DIP joint. Surgical treatments include palmar/plantar digital neurectomy, inferior check ligament desmotomy, and endoscopy of the navicular bursa. A brief overview of these treatments is discussed below. See Chapters 8 and 11 for more information.

Rest and Controlled Exercise

In the past, prolonged rest has not been recommended for most horses with navicular disease because the lameness often returns shortly after the horse resumes exercise.[73] However, significant soft tissue injuries within the foot such as DDFT or CSL lesions may warrant a more extended rest and rehabilitation period, similar to that recommended for horses with tendinitis elsewhere in the limb. However, many of the lesions within the DDFT appear to be degenerative and not inflammatory and do not generally respond to rest alone. Nevertheless, a short period of rest is usually recommended for most horses with navicular disease/syndrome to help reduce the soft tissue inflammation and allow the horse to acclimate to corrective trimming and shoeing.[115] This is substantiated by MRI findings that concurrent soft tissue and bone pathology most likely contribute to the pain in many horses with palmar foot pain.[39–41,43,44,78] Although the rest period may vary for individual cases, the author usually recommends no work until at least the first shoeing change in most horses. A decision is usually made regarding further exercise and continued treatment at the first shoeing change based on the response to treatment.

Corrective Trimming and Shoeing

Corrective trimming and shoeing are the basis for managing the majority of horses with navicular syndrome/disease.[4,25,96,120] Many horses respond favorably to shoeing alone without requiring further medical or surgical therapy. Improvement in clinical signs within 3 months of initiation of treatment has been reported with 86% of the horses remaining free of lameness for 1 year.[120,121] The goals of trimming and shoeing are to (1) restore normal foot balance; (2) correct foot problems such as shearing of the quarters and heels, underrun heels, and heel contraction; (3) reduce biomechanical forces on the navicular region; (4) ease break-over at the toe; (5) support the heels and prevent heel descent during loading; and (6) protect the injured areas of the foot.[25,115]

Multiple types of shoes have been used for horses with heel pain, and one single type of shoe cannot be used in every horse. For instance, a horse with the low-heel, long-toe conformation may benefit from an elevated heel shoe, whereas a horse with a narrow upright foot may actually benefit from heel removal and placement of a flat natural balance or egg-bar shoe. When the heels are long, they tend to grow forward, decreasing heel support and contributing to dorsopalmar hoof imbalance (Figure 4.14).[25] In general, foot preparation or trimming is more important than the type of shoe used in most horses with navicular disease/syndrome. A well-made shoe placed on an improperly trimmed foot serves little purpose. The heels should be trimmed to the widest aspect of the frog and the toes shortened as much as possible to shift weight-bearing to the back of the foot.[4,25] See Chapters 8 and 11 for more information on foot trimming and shoeing.

VetBooks.ir

Much information to aid trimming and shoeing of horses with navicular disease/syndrome can often be obtained from lateral and weight-bearing dorsopalmar radiographs (Figure 11.31). Medial to lateral and dorsopalmar hoof balance, toe length in relation to the distal phalanx, heel height, sole depth, and solar angle of the distal phalanx are all very important pieces of information that should be used during the shoeing process (Figure 11.2).

Several different types of steel or aluminum shoes are thought to be effective in treating horses with heel pain. These include the Tennessee navicular shoe, rolled or rockered toed shoes, egg-bar shoes, natural balance shoes, equine digital support system (EDSS), onion shoes, and full-bar support shoes (Figures 4.15 and 4.16).[4,25,73,96,120] Rolling, rockering, or squaring the toe of

Figure 4.14. Lateral view of a foot with excessive heel growth resulting in the weight-bearing surface of the heels being shifted further forward within the foot (arrow).

Figure 4.15. Using egg-bar shoes is a common shoeing technique to treat horses with navicular disease/syndrome.

Figure 4.16. Heel elevation may be helpful in treating select horses with navicular disease/syndrome (A) and not in others (B). The horse in (A) was shod with wedge pads and dental impression material and improved after shoeing. The horse in (B) was shod with elevated heel shoes despite having a very upright hoof conformation on the LF, which likely contributed to the dorsal hoof wall concavity (arrow) and continued lameness.

VetBooks.ir

any of these shoes enhances break-over, thus reducing the stress on the DDFT. The goals of any of these shoes should be to ease break-over, support the heels, and reduce the forces acting on the navicular bone by the DDFT.

Heel elevation has been shown to decrease tension in the DDFT, reduce pressure applied to the navicular bone, reduce the load to the forelimbs, and reduce the stresses on the hoof capsule (Figure 4.16).[96,98,102,132] The heels are supported for a greater proportion of the stride, and the wedge tends to increase the weight transferred through the heels. A recent study that quantified the pressure distribution across the palmar surface of the navicular bone documented that the maximum pressures exerted by the DDFT corresponded to the areas of known navicular pathology.[128] However, raising the heels by 5° and 10° only redistributed the pressures on the navicular bone, suggesting that raising the heels may not be that beneficial in horses with navicular syndrome.[128] Some clinicians feel that elevated heel shoes offer mixed results and should only be used temporarily especially in horses with DDF tendinopathy.[106] However, heel elevation alone or when combined with phenylbutazone has been shown quantitatively (using a force plate) to improve lameness in clinical cases of horses with navicular syndrome.[102] The disadvantages of raising the heels with the use of pads in horses with underrun heels may cause further collapse of the poorly supported heels, and heel growth appears to be reduced with wedge pads.[25]

Egg-bar shoes and natural balance shoes have not been shown to reduce the forces on the navicular bone as effectively as heel elevation.[96] However, egg-bar shoes increase the length of the toe–heel axis causing the center of pressure to shift caudally.[98] Egg-bar shoes are usually recommended in cases where the hoof capsule is unstable due to shearing or in horses with severely underrun or collapsed heels. The egg-bar shoe increases the surface area of contact and the stability of the hoof. The shoe should be applied so it is clearly visible at the quarters and extends far enough palmarly to cover the heels.[115,120,121] Natural balance shoes, by their design, reduce break-over and if combined with heel elevation also reduce the forces acting on the navicular bone. See Chapters 8 and 11 for more information on corrective trimming and shoeing.

A minimum 2- to 3-week adaptation period is often necessary to achieve pain relief with any type of shoeing.[96,102] In most cases improvement in clinical signs after corrective trimming and shoeing should be evident within 6 weeks but may depend on the severity of the initial lameness and the specific structures affected. Severe hoof imbalances may require several shoeing intervals to achieve a normal hoof conformation, and, in some cases, the underrun heels may persist indefinitely. Additionally, not all horses respond in the same manner to a particular shoeing type, and we as veterinarians should remain flexible in using a different type of shoe if a clinical response is not obtained.

Nonsteroidal Anti-inflammatory Drugs

The use of NSAIDs is a common adjunctive treatment for horses with navicular disease/syndrome. Flunixin meglumine, phenylbutazone, and firocoxib are used most commonly, and all should be effective in reducing inflammation and lameness. Horses with navicular disease that were treated with 1.1 mg/kg of flunixin meglumine or 4.4 mg/kg phenylbutazone once daily for 4 days showed significant reduction in lameness scores for 24 hours after the last dose compared with baseline and horses treated with saline.[52] The clinical responses between flunixin meglumine and phenylbutazone were similar and suggest that once-daily dosing of NSAIDs should be effective to control pain in the majority of these horses.

NSAIDs are often used for pain relief if the horse is severely lame or if the horse needs to continue working through the initial treatment period. Phenylbutazone is usually used most frequently because it is less expensive than flunixin meglumine. It is usually given at a dose of 4.4 mg/kg PO once daily for 7–10 days as the initial treatment. This appears to effectively break the pain cycle and allows for adjustment to corrective trimming and shoeing.[96] NSAIDs may be used intermittently thereafter if they are permitted for the athletic activity of the horse.

Intrasynovial Medication

Injecting medications into the DIP joint or navicular bursa is often used as an adjunctive treatment for horses with navicular disease/syndrome.[3,25,27,75,102,127] Injection of medications into the digital flexor tendon sheath (DFTS) may also benefit some horses with more proximal lesions of the DDFT that are documented with MRI.[106] Deciding when to treat horses with navicular disease/syndrome intrasynovially and with what medication(s) to use is strictly empirical based on many clinical and diagnostic findings. The types of medications used are similar to those used to treat OA/synovitis/capsulitis in joints at other locations, such as corticosteroids alone, corticosteroids combined with hyaluronan (HA), polysulfated glycosaminoglycans (PSGAGs), or other biologic therapies.

Horses with navicular disease are thought to benefit from intra-articular treatment of the DIP joint by reducing the inflammatory response both within the joint and within the navicular region.[18,85] Studies have demonstrated that methylprednisolone acetate (MPA) or triamcinolone (TA) can diffuse between the DIP joint and navicular bursa after intra-articular or intrabursal injection.[18,85] Other studies have documented the benefit of intrabursal injections in providing substantial but temporary relief of pain in many horses with navicular disease.[27,75,127] The benefit of DIP joint injections is less well documented, but anecdotally it is considered effective in many horses.[4,25] One study did not find a significant reduction in lameness after treating the DIP joint with TA compared to corrective shoeing alone although the overall severity of lameness was further reduced following treatment.[102] However, many clinicians use intrasynovial treatment of the DIP joint as part of the initial treatment regimen, together with corrective trimming and shoeing and phenylbutazone for most horses with navicular disease/syndrome.

In many horses, especially if advanced imaging cannot be performed, there is a stepwise progression of

VetBooks.ir

treatment options based on the clinical response. The decision to use intrasynovial treatment is often made at the first or second shoeing interval and is usually based on the clinical improvement in lameness. In most cases, treatment of the DIP joint is performed before treatment of the bursa because it is easier to perform and has fewer potential complications. However, horses with radiographic abnormalities confined to the flexor surface of the navicular bone would most likely respond better to treatment of the navicular bursa than the DIP joint. Intrasynovial medication strategies including whether to use anti-inflammatories vs. biologics may be greatly improved if a complete diagnostic picture of the foot abnormalities can be determined with the help of MRI.[3]

Both TA (5–10 mg) and MPA (20–60 mg) may be used for intrasynovial treatment, but MPA is usually reserved for use in the navicular bursa rather than the DIP joint. In most cases the corticosteroid is combined with HA, and amikacin is included when injecting the navicular bursa.[25,27,75] An immediate improvement in lameness is often seen in the majority of cases after intrabursal treatment.[27,75,127] In the most recent study, 75% of treated horses returned to their intended use for a mean of 9.6 months.[75] Horses treated within 6 months of becoming lame were more likely to return to performance. Intrabursal injections appear to reduce the clinical signs of navicular disease in most horses for several months, but repeated injections may be necessary and potentially predispose to rupture of the DDFT in some horses. In general, horses with multiple abnormalities within the foot and those with chronic adhesions from the navicular bone to the DDFT do not respond well to intrabursal treatment.[75]

Polysulfated Glycosaminoglycans

PSGAGs have been used in horses with navicular disease/syndrome based on the assumption that the etiology may be similar to that of OA. One double-blinded clinical trial documented a benefit of 500 mg of PSGAG IM at 4-day intervals for eight treatments compared with saline controls.[24] In addition, PSGAG given weekly or every other week IM was thought to benefit western performance horses with chronic navicular problems.[25] PSGAG may be injected intrasynovially into the DIP joint or navicular bursa, similar to corticosteroids, but no studies have documented the benefit of this in horses with navicular disease. Therefore, intrasynovial PSGAG treatment is not commonly used in horses with navicular disease.

Bisphosphonates: Tiludronate or Clodronate

Bisphosphonates, such as tiludronate and clodronate, are drugs that have been suggested as a treatment for horses with navicular disease because of their ability to promote osteoclast-mediated bone resorption. Areas of increased bone resorption and formation are often typical of lesions within a diseased navicular bone and areas of OA, and clinicians believe that reducing bone turnover in these conditions may have beneficial clinical effects. A multicenter, double-blind, placebo-controlled clinical trial using clodronate in horses with navicular syndrome found that 75% of treated horses improved at least one grade of lameness at day 56 compared with 3% in the placebo group.[53] At day 180, 65% of horses were still considered to have an improvement in their lameness.[53] An additional study has also suggested that a single dose of clodronate reduced lameness in horses with navicular syndrome without producing detectable effects on bone turnover markers.[77] Clodronate is an FDA-approved bisphosphonate licensed for treatment of navicular syndrome in horses (Osphos®, Dechra Veterinary Products, Overland Park, KS). Current recommendations for Osphos administration are 1.8 mg/kg by IM injection with a maximum dose of 900 mg per horse (e.g. 900-mg dose standard for a 500-kg animal); recommendations to divide the dose between three sites are also given (Osphos). Tiludronate is currently not licensed for use in the United States but is labeled for use in other countries for horses with navicular disease, bone spavin, and fetlock suspensory ligament enthesopathies. The drug is currently recommended at a dose of 1 mg/kg IV over 30 minutes as a single treatment instead of 10 daily treatments.

Tiludronate has been used either systemically (1 or 0.1 mg/kg IV) or locally (0.1–0.2 mg/kg) using intravenous regional limb perfusion (IVRLP).[29,103,129] In one clinical trial of 73 horses, tiludronate (0.1 mg/kg) given IV once daily for 10 days resulted in clinical improvement of lameness, and horses returned to a normal level of activity 2–6 months' posttreatment.[29] Another study reported that systemic tiludronate (1 mg/kg IV) appeared to be beneficial in horses with navicular syndrome but no horses became sound.[129] Using tiludronate locally with IVRLP (0.1 and 0.2 mg/kg) was reported to provide no further improvement in lameness over therapeutic shoeing and injection of the DIP joint.[103] Further studies are necessary to determine the true efficacy of these drugs in treating horses with navicular disease/syndrome. See Chapter 8 for more information on bisphosphonates.

Surgical Treatments

Palmar Digital Neurectomy

PD neurectomy remains the most commonly performed surgical technique to manage horses with navicular disease/syndrome. It is usually performed as a last resort after other treatment options have failed. It should be done in conjunction with corrective hoof trimming and shoeing to reduce abnormal forces on the foot, thus slowing the progression of the degenerative changes associated with the navicular syndrome.[4,115] A PD nerve block should always be performed before the surgery to document how much clinical improvement can be expected following the neurectomy.

Horses with suspected or confirmed abnormalities of the DDFT at the level of the navicular bone are usually not good candidates for a neurectomy because of an increased risk of rupture of the DDFT. However, an increased risk of DDFT rupture post neurectomy has not been documented, but a recent study recommended that horses with core or linear lesions of the DDFT should not undergo a PD neurectomy as these horses experience residual lameness or recurrent lameness aftersurgery.[58] The decision of whether to perform a

VetBooks.ir

neurectomy is often based on the severity of lameness, age and intended use of the horse, known abnormalities based on imaging results, responses to previous treatments, and the wishes of the owner.

Various methods of PD neurectomy have been described, and all have been developed to ensure complete desensitization, prevent painful neuroma formation, and prevent axonal regrowth, which may result in reinnervation.[26,58,63,74] Choosing which surgical technique to perform is often a personal preference of the veterinarian as several studies have failed to determine the ideal PD neurectomy technique. The pull-through or stripping technique is recommended by the author, and the clinical results appear to be very good.[26,74] The advantages of the pull-through approach are that no special equipment is needed, it can be easily performed in the standing or recumbent horse, and the end of the transected nerve is not located within the incision. Regardless of the technique used for a PD neurectomy, a clean and atraumatic surgery and diligent postoperative care will minimize complications.[26,63,74] Limited activity for 30–60 days and careful bandaging of the limbs for at least 3–4 weeks are thought to reduce the inflammatory response created by the surgery and reduce scar tissue formation around the nerve stumps.

The prognosis of horses following a PD neurectomy appears to be very good initially but becomes less favorable as time progresses. In a study of 57 horses, 74% of the horses were sound at 1 year, but this decreased to 63% after the second year.[63] In a study of horses that underwent the pull-through neurectomy technique, 88% were free of lameness at 1 year.[74] Survival analysis that was used to assess the time to recurrence of lameness indicated that the mean survival with no lameness after surgery was estimated at 4.14 ± 0.33 years (median, 5 years).[74] A more recent study reported that 92% of horses responded positively to surgery and were able to return to previous athletic use for a medial of 20 months.[58] The most significant complications after a neurectomy include rupture of the DDFT, regrowth of the nerves resulting in recurrence of the lameness, and severe infection within the foot that goes unnoticed.

Inferior Check Ligament Desmotomy

Inferior check ligament desmotomy has been used in selected cases of horses with navicular syndrome in which dorsal palmar hoof imbalance (either broken-forward or broken-backward axis) appears to be a major contributing factor. In one study, four horses with navicular syndrome that were treated with an inferior check ligament desmotomy all returned to full use, and the surgery made it possible to align the hoof-pastern axis after surgery.[124] This surgery seems to be most useful in horses with an upright heel conformation and a broken-forward hoof-pastern axis, as is sometimes seen in Quarter horses with mismatched front feet. More recently the procedure has been used in horses with chronic DDF tendinopathy to supposedly reduce the tension on the DDFT, comparable with the superior check ligament desmotomy procedure that is performed in horses with SDF tendinitis.[62,106] The desmotomy is thought to reduce the strain on the DDFT, lengthen the musculotendinous unit of the DDFT, and minimize the compressive forces on the navicular bone.[62,106] The goal is to promote tendon healing while simultaneously reducing pain and lameness. Further clinical cases will need to be assessed to determine the effectiveness of this procedure.

Endoscopy/Bursoscopy

Endoscopy of the navicular bursa has become the preferred surgical treatment of horses with infections or wounds that enter the navicular bursa. Endoscopy of the bursa may also be performed as both a diagnostic and treatment tool in a select group of horses with navicular disease using a modified surgical approach.[113,114] Horses with known or suspected abnormalities on the flexor surface of the navicular bone (flexor cortex erosions) and those with DDFT lesions (dorsal abrasions) at the level of the navicular bone are the ideal candidates for navicular endoscopy (Figure 4.17). In a study of 114 horses that had navicular endoscopy, 92 horses had injuries within the bursa, and 98% of the injuries involved the DDFT.[113] Sixty-one percent of horses returned to work sound with only 42% returning to their previous level of performance. As would be suspected, horses with extensive DDFT lesions and those with combination injuries of the DDFT and navicular bone identified with MRI had worse outcomes. Although endoscopy of the navicular bursa should be considered as a treatment option for selected horses, the overall outcome of horses may not be that different than horses managed conservatively with rest and rehabilitation.[21,106] Careful case selection may improve the advantage of surgery over conservative management, but in general the popularity of using bursoscopy to treat horses with DDF tendinopathy is less than it was a few years ago.[106] Advanced imaging with CT or MRI is usually necessary prior to endoscopy to optimize the potential benefit of surgery.

Prognosis

The prognosis of horses with navicular disease/syndrome is difficult to predict because of the numerous bone and soft tissue abnormalities that can occur concurrently. Radiographs alone are not adequate to completely assess the pathology within the foot and therefore cannot be used alone to determine the prognosis unless the abnormalities are advanced. It is also known that the absence of radiographic abnormalities of the navicular bone does not indicate the lack of bone pathology.[101] The combination of bone and soft tissue lesions is usually present in most horses, which can greatly alter the prognosis.[39,44,101] In addition, most abnormalities are degenerative in nature and worsen with time and continued use of the horse. In general horses with combination injuries to the DDFT and navicular bone tend to have worse outcomes with many remaining persistently lame.[44,106]

In most instances, the numerous treatment protocols are probably more appropriately termed management strategies because the disease/syndrome is unlikely to resolve completely. In general, clinical resolution may occur in 40%–50% of the horses with navicular disease/syndrome, but the optimal treatment and prognosis will

VetBooks.ir

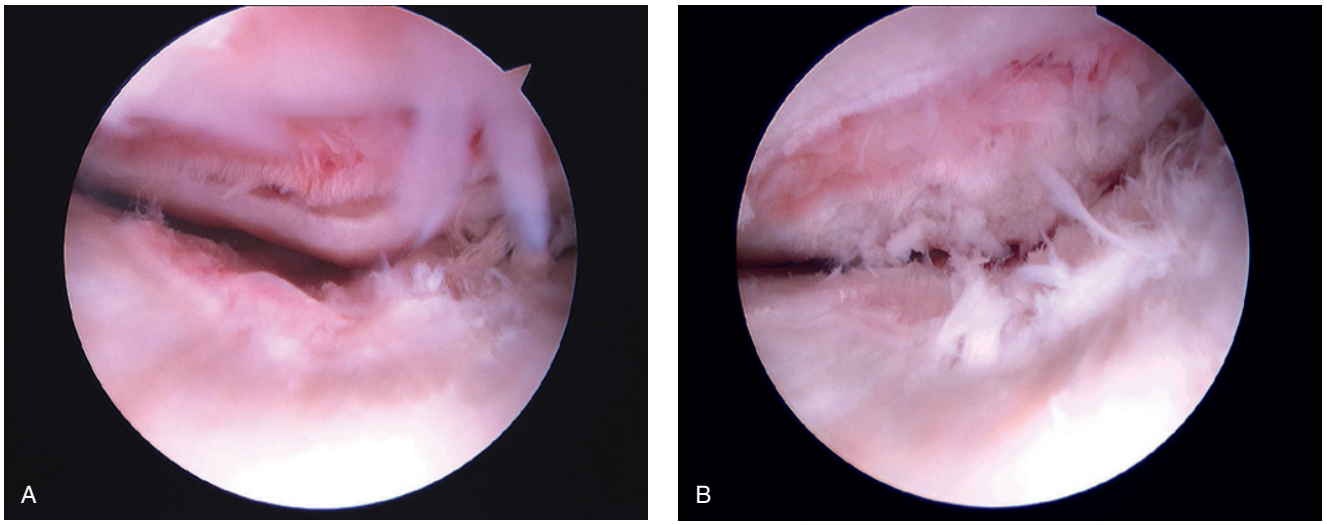

Figure 4.17. Endoscopic view of the flexor cortex lesion on the navicular bone (A) and the fibrillation of the DDFT (A and B) that was present in the horse in Figures 4.11 and 4.13. The navicular bone is at the top of the image and the DDFT is on the bottom.

differ depending on the specific pathologies that may be present.[3,39,41,44,96] For instance, horses with major radiographic abnormalities most likely will have a worse prognosis than horses with no radiographic changes and minor soft tissue pathology. Horses with navicular bone pathology demonstrated on radiographs or MRI together with concurrent DDFT lesions will also tend to have a poor prognosis. In general, horses with primary soft tissue injuries are thought to have a guarded prognosis for return to full athletic function with injuries of the DDFT being the most problematic.[21,106] Horses with significant lesions in the navicular bone per se or combination bone and soft tissue injuries usually have a poor prognosis for performance.[39,41,44,96,106] Due to the diversity of underlying problems associated with the disease, the key to controlling navicular disease/syndrome is most likely prevention.[4,96] Good foot care, proper trimming and shoeing, maintaining correct dorsopalmar hoof balance, and preventing overextension of the palmar aspect of the foot cannot be overemphasized due to the biomechanical nature of the disease.

FRACTURES OF THE NAVICULAR (DISTAL SESAMOID) BONE

Fractures of the navicular bone are an uncommon cause of lameness in horses.[54,72,116] They have been reported in many breeds and in horses with varied use.[5,72] Complete fracture can occur after acute trauma or secondary to severe bone demineralization due to navicular disease or osteomyelitis from sepsis. [5,72,95] Avulsion fractures usually occur along the distal border of the navicular bone and are thought to be associated with navicular disease,[7,8,37] although this is not universally accepted.[137] The forefeet appear to be at a greater risk for fracture than the hindfeet.[5,59,72] In one report, 22 of 25 fractures of the navicular bone were in the forelimbs,[59] and in another, 15 of 17 were in the forelimbs.[72]

Fractures of the navicular bone have been classified as avulsion fractures/fragments, simple complete fractures (transverse or oblique), comminuted complete fractures,

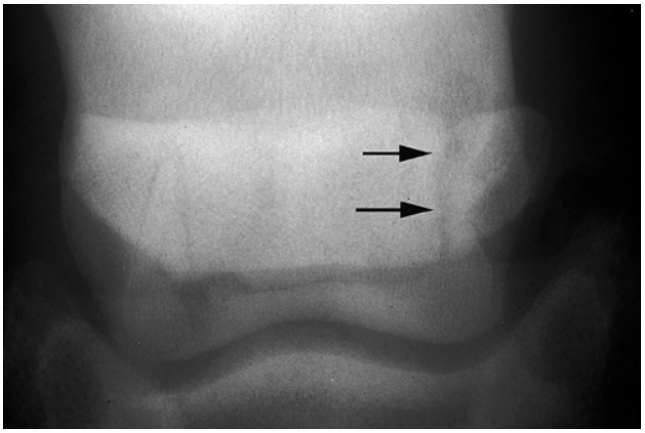

Figure 4.18. A wing fracture of the navicular bone (arrows) as seen on the oblique radiograph of the foot.

and congenital bipartite navicular bones.[37] The latter is not considered a true fracture but can be confused with a chronic fracture based on its radiographic appearance. Avulsion fractures/fragments usually involve the distal border of the navicular bone in the forefeet and are frequently associated with other radiographic signs of navicular syndrome.[8,37] These fracture fragments vary in shape, are usually small (0.2–1.2 cm in size), and occur more commonly in lame horses than clinically normal horses (Figure 4.12).[7,8,37] Simple complete fractures may be vertical, slightly oblique, or transverse.[37,66] The vertical and slightly oblique fractures usually occur medial or lateral but fairly close to the central eminence (sagittal ridge) of the navicular bone. Generally, these fractures are not displaced, but they are usually slightly separated so an obvious fracture line exists on the radiograph (Figure 4.18). Comminuted complete fractures are even more uncommon than simple complete fractures (Figure 4.19).[5] In one report only 3 of 18 horses with complete navicular bone fractures were comminuted.[5] Rupture of the distal sesamoidean (impar) ligament or DDFT may accompany these fractures.[60,116]

VetBooks.ir

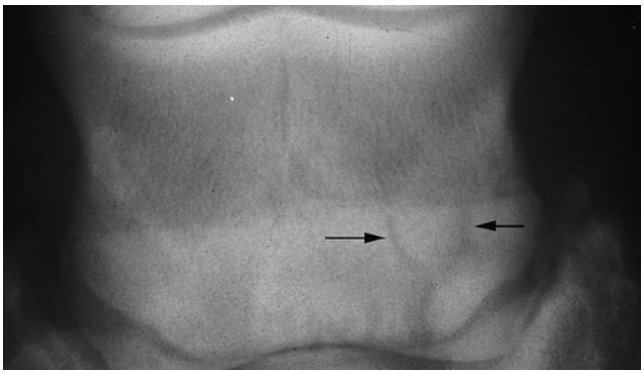

Figure 4.19. A comminuted Y-shaped fracture of the navicular bone (arrows).

Etiology

Acute trauma (concussion) to the foot is the most likely cause of most simple and comminuted complete navicular bone fractures. However, severe navicular bone osteolysis associated with navicular disease or sepsis may predispose to pathologic fractures. Avulsion fractures are most likely due to pathologic changes occurring within the navicular bone associated with navicular disease but may also be trauma induced.

Clinical Signs

The severity of lameness and clinical signs in horses with avulsion fractures are similar to those in horses with navicular disease. However, there may be a history of sudden worsening of the lameness in a single limb that responded to rest. Horses with complete navicular bone fractures typically have a history of an acute severe lameness in a single limb that improves with time. One retrospective study found that most horses were severely lame at presentation and that the less lame horses were evaluated at a mean time of 90 days after the onset of lameness (range, 30–150 days).[72] In another study, the mean duration of lameness before presentation was 4.3 months.[5]

Most horses have a painful response to hoof testers across the frog region and have effusion within the DIP joint. An increased digital pulse may be present in the acute stage, similar to horses with P3 fractures, but this is rare in more chronic cases. Horses with significant hindlimb lameness (grade 2–3 out of 5) and clinical signs referable to the navicular region should be suspected of having a navicular bone fracture. A PD nerve block should improve the lameness in most cases although anesthesia at a more proximal level (abaxial sesamoid nerve block) may be required. In some horses,[72] the reason for this is uncertain since the PD block is thought to desensitize most if not all of the foot including the DIP joint. However, the fracture may cause articular pain or pain within the DDFT that is not completely eliminated by a PD nerve block. Intra-articular anesthesia of the DIP joint usually eliminates the lameness associated with navicular bone fractures.[116]

Diagnosis

Radiographic examination of the foot is required to confirm the diagnosis. Careful packing of the frog is necessary to avoid confusing the lines from the lateral sulci of the frog that cross the navicular region with a fracture. If the line extends beyond (above or below) the navicular bone, it is usually not a fracture. When in doubt, it is best to retake the radiograph at a slightly different angle. Complete simple fractures are typically located in the sagittal plane medial or lateral to the midline (parasagittal).[37,95] Most complete fractures are best identified on the skyline or 60° oblique views of the navicular bone and should be present on multiple views (Figures 4.18 and 4.19). The fracture line should begin and end at the edges of the navicular bone and is usually easily visible, especially in chronic fractures. Navicular bone fractures need to be differentiated from congenital bipartite or tripartite separation.[37,72] Bipartite navicular bones are usually symmetric with smooth edges and have a wide radiolucent region (Figure 4.6).[4,37] They are often bilateral so the opposite navicular region can be imaged to confirm the diagnosis.

Avulsion fractures can be difficult to identify on radiographs and close scrutiny is often required. They can often be best seen on the 60° oblique view of the navicular bone but may also be present at the distal aspect of the navicular bone on a lateromedial view (Figure 4.12) or within the medullary cavity of the navicular bone on the skyline view.[8,37] There is some question as to whether these osseous fragments represent true avulsion fractures of the navicular bone or are ectopic mineralization of the DSIL or a fracture of an enthesophyte at the origin of the DISL.[37]

Treatment

There is no known specific treatment for avulsion fractures of the navicular bone. Horses are treated similar to those with navicular syndrome (see navicular disease/syndrome above) but may benefit from heel elevation (provided the heels are not already too long) to relieve tension on the DSIL and DDFT. Horses with complete navicular bone fractures are usually treated nonsurgically by confinement alone, confinement and corrective shoeing (usually with heel elevation), or external coaptation aimed at reducing hoof expansion.[5,54,72]

In one study, horses were treated with 12° of heel elevation by using 4 3° wedge pads and a flat shoe.[123] The large amount of heel elevation was thought to be an important aspect of treatment, but it is likely that more moderate levels of heel elevation (3°–6°) may also be beneficial. Regardless of the amount of heel elevation used, the horse should be reshod monthly and gradually returned to normal foot angles over a 4- to 6-month period. A minimum of 4–6 months of stall rest has been recommended because these fractures are very slow to heal.[4,72,116] One study found that a minimum of 6 months of stall rest was necessary before there was resolution of clinical signs.[72]

Surgical repair of simple complete navicular bone fractures using a single cortical bone screw placed in lag fashion has been reported.[81] Intraoperative imaging (fluoroscopy, radiography, or CT) and a specially developed aiming device is necessary to implant the screw precisely along the transverse axis of the navicular bone.[54] This technique was reported to be successful in 4 of 5 horses, and all fractures healed without excessive

VetBooks.ir

callus.[81] Computer-assisted surgery systems may provide further advantages in screw placement in the future.[54]

Palmar or plantar digital neurectomy can also be performed to relieve pain in cases that have not responded to conservative treatment.[5,72] The navicular bone is very slow to heal, and these fractures are invariably associated with damage to the impar ligament, DDFT, and DIP joint.[5,60] Chronic lameness may result from poor fracture healing and adhesions that develop between the DDFT and the navicular bone.[72] Follow-up radiography on 17 horses with complete navicular bone fractures revealed increases in the width of the fracture gap for up to 4 months after injury.[72] A noncalcified fibrous union can still be evident years after the fracture occurred, although some may heal completely (Figure 4.20).[4,116] Failure of an osseous union may be due to a combination of the soft tissue attachments and loading forces continually distracting the fracture fragments. Also the navicular bone is located between two synovial spaces, and synovial fluid may also inhibit healing. If a neurectomy is performed, prolonged rest afterward should be considered to permit the fracture to heal and prevent further damage to the surrounding soft tissue structures.[116]

Prognosis

The prognosis is considered guarded to poor for horses with complete navicular bone fractures to return to athletic performance. In general, horses with fractures in the hindlimb are considered to have a better chance to return to performance than those affected in the forelimbs. In one report 3 of 6 horses treated by stall rest alone or stall rest and external coaptation, and 2 of 4 horses treated with stall rest and corrective shoeing returned to their intended use.[72] Also, only 1 of 5 horses that underwent neurectomy returned to its intended use.[72] In another report 3 of 7 horses treated with rest alone returned to performance and 4 remained lame. Of the 6 horses that were treated with a neurectomy, 2 were sound for light riding, 2 were sound for only 1 year, and 2 remained lame.[5] In the study that used a 12° elevated heel shoe together with confinement, 4 of 4 horses became serviceably sound for riding, and 2 of 4 returned to competition.[123] Although the horses were sound for use, complete radiographic healing did not occur in any case in this study.[123] Important clinical aspects of navicular bone fractures that can be summarized from these clinical studies include the following:

1. Heel elevation should be an important aspect of treatment.
2. Four to 6 months of confinement may be necessary.
3. Complete fracture healing is unlikely to occur.
4. A PD neurectomy will minimize the lameness but does not guarantee a sound horse.

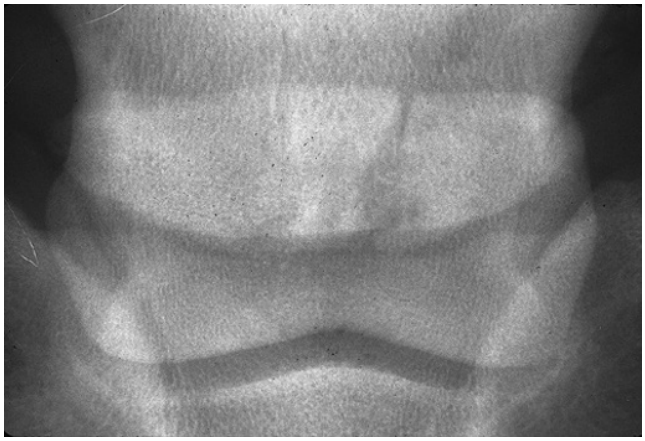

Figure 4.20. This oblique radiograph of the navicular bone was taken 23 months after the fracture occurred.

SOFT TISSUE INJURIES IN THE FOOT (DDFT AND PODOTROCHLEAR APPARATUS)

Multiple bone and soft tissue structures within the foot are desensitized with a PD nerve block.[111] Historically, radiography has been used to help differentiate between bone and soft tissue injuries, but the lack of radiographic abnormalities within the navicular bone does not indicate the lack of pathology.[2,84,101] In addition, radiographic scores of the navicular bone do not accurately predict navicular bone pathology.[84] Soft tissue injuries of the foot have always been suspected in horses with foot pain without radiographic abnormalities, and advances in ultrasound, CT, and MRI techniques have enabled improved recognition of these potential problems.[19,20,38,39,41–45,56,84,90,91,125,131] These imaging modalities have helped determine that it is common for soft tissue and bony abnormalities to coexist in many lame horses with foot problems, and multiple abnormalities are often present. For instance, several MRI studies have documented the association between DDFT lesions and navicular bone pathology, although primary tendinitis of the DDFT and other primary soft tissue injuries do occur.[39,41,42,44,84,105,112]

Soft tissue structures within the foot that can be desensitized with a PD block include the heel bulbs, digital cushion, navicular bursa, collateral cartilages of the distal phalanx, podotrochlear apparatus (DSIL, and CSLs of the navicular bone), DDFT (may only partially improve with a PD block), and CLs of the DIP joint.[35,42,44,84,111] Soft tissue abnormalities of the podotrochlear apparatus and the DDFT are most closely associated with navicular syndrome in horses and are therefore discussed below. Injuries to the CLs of the DIP joint are covered in the section on the DIP joint later in this chapter.

Etiology

The DDFT is the most commonly affected soft tissue structure in the foot and injuries may occur alone, in conjunction with navicular bone pathology, or as one component of a complex of multiple soft tissue injuries in the foot.[38,39,41–44,84,104–106] The DDFT is bilobed within the foot, and lesions can occur in either lobe anywhere along its length, from the level of the PIP joint distally to its attachment on P3.[104] Retrospective studies have indicated a prevalence of 30%–64% in horses with foot lameness with no or equivocal radiographic abnormalities of the foot.[106] Four primary lesion types in the distal portion of the DDFT have been identified: core lesions,

VetBooks.ir

dorsal border lesions, sagittal plane and oblique splits, and insertional lesions.[105,106] Abnormalities have been identified at the DDFT insertion to the distal phalanx (least common), the level of the navicular bone or CSLs (most common), more proximally in the pastern, or a combination of sites.[38,39,41–44,78] The most common location is at the level of the navicular bone and CSLs and can be true core lesions, sagittal splits, or dorsal abrasions (Figure 4.13).[10,11,39,44] DDFT lesions can occur in a single or multiple locations and can extend variable distances up or down the tendon (Figure 4.21). Abnormalities of the DDFT at the level of the proximal phalanx are more typical of true core lesions within the tendon.[39]

Abnormalities of the podotrochlear apparatus are often present in association with abnormalities of the navicular bone, especially involving the proximal or distal borders and the medulla.[39,44] Acute-onset or repetitive trauma is considered the most likely cause of most soft tissue injuries within the foot.[35,36] Concurrent abnormalities of the podotrochlear apparatus and navicular bone suggest that similar biomechanical forces and repetitive trauma to the palmar aspect of the foot likely contribute to both types of injuries.[39] However, primary injuries to the podotrochlear apparatus (CSL + DSIL) do occur.[84]

Horses that jump or have a low-heel hoof conformation may be at risk for injuries to the DDFT.[36,105] Western performance horses, especially reining and cutting horses, are also considered at risk because of the work that they are required to perform. Chronic repetitive trauma to the DDFT is often the most likely cause although single-event traumatic "tearing" of the DDFT causing a true tendinitis may also occur. Based on MRI studies, this type of lesion is most likely to occur more proximal in the foot at the level of the proximal phalanx.[39] Exceptions to this may be true ruptures of the DDFT, but the location of where these ruptures occur has not been documented. In many cases, however, it would seem likely that previous chronic abnormalities of the DDFT would predispose to complete failure. In addition, chronic DDFT injuries are not always isolated to a single site (Figure 4.21), and there is evidence to suggest that DDFT lesions may be a degenerative process due to vascular compromise rather than an inflammatory process from trauma.[11]

Clinical Signs

In general, horses that have primary soft tissue injuries in the foot are more likely to have a history on an acute onset of lameness and be unilaterally lame compared with horses with navicular disease. Horses with multiple foot problems and those with concurrent navicular pathology and soft tissue injuries are less likely to conform to this generalization. In addition, horses with flexor cortex erosive lesions of the navicular bone are often unilaterally lame. The majority of horses will improve with a PD nerve block, but the lameness will not be completely abolished in many horses with lesions of the DDFT.[36,42] More specific clinical information has been obtained from horses with injuries to the DDFT and CL of the DIP (see section of DIP joint) than from horses with injuries to the podotrochlear apparatus. The clinical signs of horses with abnormalities of the podotrochlear apparatus may resemble those with navicular disease because these injuries often occur concurrently with navicular bone pathology.[39] A large clinical study indicated that horses with primary DDFT lesions were more likely to exhibit pain on turning than horses with other types of lesions within the foot and that horses with navicular pathology combined with injuries to the podotrochlear apparatus (±DDFT lesion) were more likely to be unilaterally lame.[84]

The clinical signs may vary, depending on whether the DDFT lesion is primary or associated with navicular

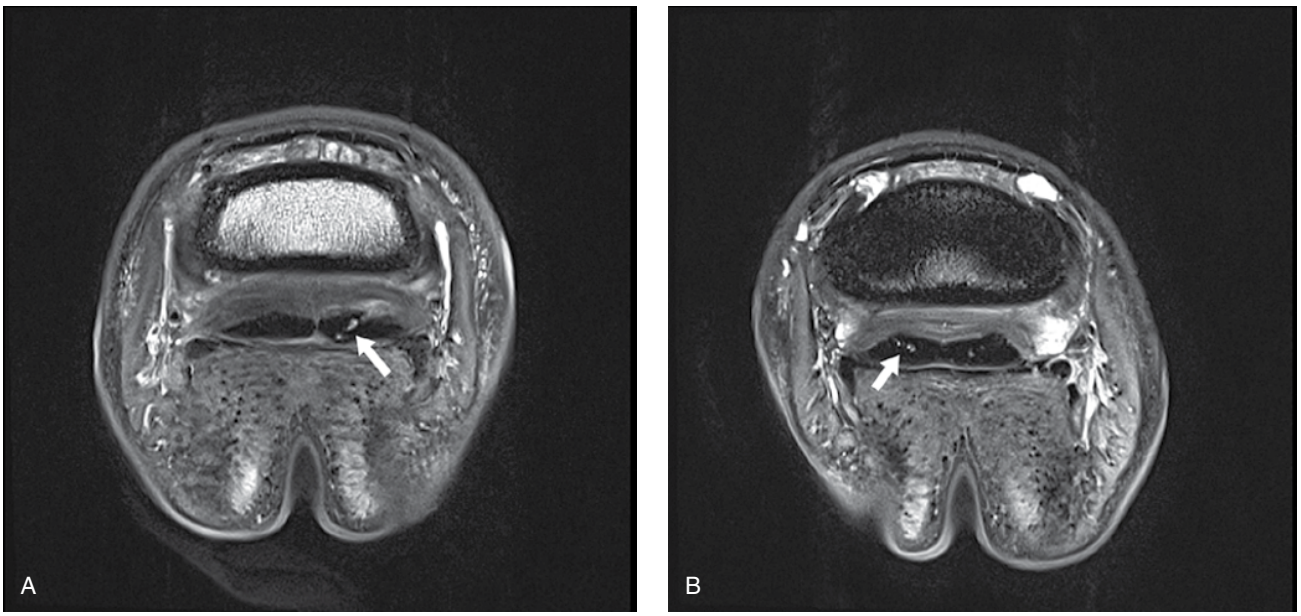

Figure 4.21. MRI images demonstrating a single large DDFT lesion (A; arrow) and multiple smaller DDFT lesions (B; arrow) at different locations along the DDFT in the same horse.

VetBooks.ir

pathology. However, there is often a history of an acute onset of moderate to severe lameness that may improve with rest and worsen with exercise.[35,36] There may be a history of activity that caused excessive hyperextension of the foot such as working in soft ground and/or jumping. The lameness may be unilateral and may worsen in a circle or when exercised on soft ground. Occasionally, pain may be elicited with deep palpation of the DDFT between the collateral cartilages of the heels. Hoof tester pain is variable but may be present if a DDFT lesion and navicular pathology are present concurrently. Phalangeal flexion may cause a positive response but is often variable. Increasing tension on the DDFT with the navicular wedge test may accentuate the lameness.[35,36]

The lameness is not reliably abolished with a PD nerve block in horses with DDFT lesions.[36,42] Horses often improve but in one study only 24% of those with DDF tendinitis responded completely to a PD nerve block.[42] The lameness should respond to basisesamoid block and many improve after IA anesthesia of the DIP joint. Anesthesia of the DIP joint was more effective in alleviating the lameness in horses with DDFT lesions than was the PD block in one study.[42] This finding differs from the clinical experience of the author. However, the response to perineural anesthesia may depend on the location of the lesion(s) and whether concurrent problems exist in the foot.

Diagnosis

A definitive diagnosis of a soft tissue injury of the foot is best determined with MRI in either the recumbent or standing patient.[38,39,41–44,78,105,106] Tendon damage within the DDFT is often seen as focal signal increase on both the T1- and T2-weighted sequences and swelling of the affected lobe in the acute stages of the disease. There is good correlation between MRI appearance of DDFT lesions and their pathological classification into core lesions, sagittal splits, insertional lesions, and dorsal surface erosions (Figures 4.21 and 4.22).[104,106] See Chapter 4 for more information on MRI evaluation of DDFT lesions.

Horses with primary DDF tendinitis often have minimal to no radiographic abnormalities. This is not the case with concurrent DDFT injuries. Ectopic mineralization may be seen in some horses with DDFT lesions but may not be correlated with tendinitis of the DDFT (Figure 4.23).[36] Enthesophytes involving the podotrochlear apparatus attachments to the navicular bone and other radiographic abnormalities of the navicular bone may suggest damage to these structures but do not provide a definitive diagnosis. Likewise, erosive lesions of the flexor surface of the navicular bone are most likely associated with dorsal abrasions of the DDFT, but navicular bursal endoscopy or MRI is usually needed for a definitive diagnosis (Figure 4.24). Not all of these erosive lesions can be identified with radiography and may require standing low-field or high-field MRI for documentation.[112] Histological examination of a few of these horses documented fibril formation and fibrocartilaginous metaplasia of the adjacent DDFT.[112]

Ultrasound can aid the diagnosis of some injuries to the DDFT and podotrochlear apparatus but is most useful to help document injuries to the CL of the DIP

Figure 4.22. A core lesion within lobe of the DDFT above the level of the navicular bone (arrow) can be seen in this PD axial MR image. *Source*: Courtesy of Dr. Natasha Werpy.

VetBooks.ir

joint.[36,45,56] Ultrasound can be performed either between the heel bulbs or through the frog after it has been softened by soaking. However, documenting the lesion may be difficult depending on its location and the skill of the operator. Certain aspects of both the DDFT and podotrochlear apparatus are inaccessible with ultrasound, suggesting that negative findings do not rule out the presence of a lesion.[56] Because of these limitations, ultrasound is currently being used to aid in the treatment of specific lesions within the DDFT that have been identified with other imaging modalities. Similar to MRI, contrast-enhanced CT can also be used to document abnormalities in the DDFT within the hoof capsule but can only be performed under general anesthesia.[89–92,131] See Chapter 3 for further information on the use of diagnostic imaging modalities within the foot.

Treatment

The most important aspects of treatment of soft tissue injuries of the foot are rest, rehabilitation, and corrective foot care.[57,104–106] Foot imbalances that may have contributed to their occurrence such as low heels, long toes, mediolateral imbalance, reverse angle of the distal phalanx, etc. should be corrected if possible. Horses with injuries to the podotrochlear apparatus are usually treated similarly to horses with navicular disease. Systemic and intrasynovial (DIP joint or navicular bursa) anti-inflammatory therapies are usually performed especially in horses with combination bone and soft tissue injuries.

Types of shoes that may benefit horses with DDFT injuries include egg-bar shoes, reverse shoes, and onion shoes, all fitted with a rolled toe.[106] The goal of shoeing is to prevent heel descent during loading in soft ground and promote early break-over at the toe.[106] Raised heel shoes may offer mixed results as they may paradoxically exacerbate lameness and may induce contracture of the DDFT during tendon healing.[106] Clinically, however, many horses with DDFT lesions initially appear more comfortable when placed in elevated heel shoes.

Rest and rehabilitation are usually performed over a minimum of 6 months and may be necessary for even longer depending on the lesion severity. The duration of rehabilitation is usually dependent on many variables including DDFT lesion type, location and size, concurrent hoof abnormalities, use of the horse, and wishes of the owner. In general, horses treated with an extended period of rest and rehabilitation are thought be able to return to use for a longer duration than horses without rest.[57,106] Even though rest and rehabilitation are important aspects of treatment, the prognosis with this therapy alone has not been considered favorable.[36,105,106] Adjunct treatment approaches for these injuries are discussed below.

Additional treatment options for horses with DDFT lesions often depend on the location of the lesion, but the overall prognosis remains poor. Dorsal border lesions at the level of the navicular bone may benefit from endoscopy of the navicular bursa and debridement of any torn tendon fibers.[113,114] Intralesional treatment of the DDFT injury and/or treatment of the navicular bursa with biologics or anti-inflammatories can be performed at the time of surgery or subsequent to surgery. Although navicular bursoscopy with tendon debridement may be indicated in select cases, its potential benefit over conservative treatment has been questioned.[106] Other surgical options in horses with DDFT injuries include desmotomy of the inferior check ligament to reduce the strain on the DDFT during healing and PD neurectomy if other therapies have failed to improve the lameness.[106]

Intralesional treatment of DDFT lesions with biologics at other locations may be performed with CT, MRI, or ultrasound guidance but may require the horse to be anesthetized.[3,90,91] A technique to inject the insertion of the DDFT at the level of P3 using radiographic guidance has also been described.[1] Intrabursal or intrasynovial injection of medications (biologics or anti-inflammatories) without navicular bursoscopy can also be performed. Corticosteroids alone or combined with HA may be used to reduce the inflammation and pain, or biological compounds such as stem cells or platelet-rich plasma may be used to hopefully promote tendon healing. Regional IV perfusion of stem cells has also been used in select horses with DDFT injuries, but the efficacy of this treatment is unknown. See Chapter 8 for more detailed information on these treatment modalities.

Prognosis

In general, horses with primary or secondary DDFT injuries within the foot have a poor prognosis for return to performance.[21,44,57,106] The injury is often a career-ending with less than one-third of affected horses being able to return to performance.[106] DDFT injuries are often negatively associated with prognosis for a variety of reasons and can be difficult and expensive to treat. In one study of primary DDFT injuries, only 25% of horses returned to their previous level of activity within 18 months. However, the prognosis was dependent on lesion type with dorsal border lesions having a better prognosis than core or parasagittal split lesions. Thirty-five percent of horses with dorsal border lesions returned to their original level of activity.[21,106] Additionally, core lesion size was reported to affect prognosis with lesions with a cross-sectional area of >20% of the affected lobe or a total length of >35 mm corresponding to horses that remained lame after treatment.[106,126] Therefore, the overall prognosis of DDFT injuries is often dependent on lesion size, type, location, and severity and the presence of concurrent abnormalities within the navicular bone or other soft tissues (primary vs. secondary). Several studies have documented that horses with multiple injuries within the bone and soft tissues of the foot have difficulty returning to performance.[21,36,44,57,106]

COFFIN JOINT AND DISTAL PHALANX

Gary M. Baxter

VetBooks.ir

OSTEOARTHRITIS (OA) OF THE DISTAL INTERPHALANGEAL (DIP) JOINT

Osteoarthritis (OA) of the distal interphalangeal (DIP) joint, or "low ringbone," is a common cause of forelimb lameness in horses. It can be a primary cause of lameness, but more commonly, it occurs concurrently with other lameness conditions of the foot. Synovitis/capsulitis of the DIP joint is considered to be a less severe form of OA that may occur in some horses in the early stages of the disease process. Although advanced low ringbone can be associated with dorsal exostosis of the extensor process of P3, contributing to an enlargement at the coronary band and pyramidal distortion of the hoof, this occurs uncommonly.[5] Distortion of the hoof leading to pyramidal disease or buttress foot is most likely associated with large extensor process fractures of the distal phalanx.[15]

Etiology

Primary OA of the DIP joint can be due to acute or repetitive trauma to the joint comparable to any articulation in the horse. Horses with a broken pastern axis (forward or backward) and other types of hoof imbalances appear particularly prone to repetitive trauma to the DIP joint and development of OA. Acute or repetitive trauma may cause tearing of the joint capsule (capsulitis) and/or direct damage to the articular cartilage and subchondral bone. Excessive strain of the attachments of the long or common digital extensor tendon to the extensor process may also occur and contribute to periostitis and enthesophyte formation along the dorsal aspect of the joint.[5] Primary OA of the DIP joint not associated with trauma, conformational defects, or developmental abnormalities of the joint has also been reported.[50] This condition was characterized as a chronic condition with a slow onset of cartilage degeneration and reactive changes within the DIP joint of a single front limb. The diagnosis of this condition was challenging with radiographs alone, and low-field standing MRI was necessary to make the diagnosis.[50]

Secondary OA can occur from other lameness conditions that involve the DIP joint, either directly or indirectly. These include navicular disease, complete navicular bone fractures, articular fractures of the distal phalanx, subchondral cystic lesions (SCLs) of the distal phalanx, osteochondral fragmentation within the joint, and desmitis of the collateral ligaments (CLs) of the DIP joint.[5,18,19,21,47] These abnormalities are thought to directly or indirectly cause pathology to the DIP joint, which leads to the development of OA over time. Prevention of DIP joint OA is often an important aspect of treatment for many of these conditions. See the discussion of each of these conditions in this chapter for more information.

Clinical Signs

Effusion of the DIP joint is usually present in most horses with OA or synovitis/capsulitis of the DIP joint (Figure 4.25). However, effusion can be present in normal horses, so this finding is not always indicative of problems within the DIP joint.[17] However, sound horses usually have less DIP joint effusion that lame horses and the effusion is often symmetrical from right to left. Most times significant effusion of the DIP joint can be seen as a slight bulging just above the coronary band. The fluid can usually be balloted from medial to lateral along the dorsal midline of the joint. With chronic or advanced disease, the joint capsule may become thickened, resulting in a firm swelling just above the dorsal aspect of the coronary band. Digital pressure over the swelling may elicit a painful response.[5] The joint may be painful to flexion and rotation, but this is uncommon unless the OA is advanced or secondary to another problem in the joint. Lameness is variable and often depends on the severity of the disease, whether it is primary or secondary, and whether one or both limbs are affected.[17] The lameness is often worse on hard ground, when circled, and after distal limb or phalangeal flexion.

Lameness associated with the DIP joint is often improved and sometimes alleviated completely with a PD nerve block.[16,55] However, anesthesia at the base of the sesamoid bones or a pastern ring block may be required for complete resolution of the lameness. Intra-articular (IA) anesthesia of the DIP joint is not specific for problems within the joint, but using a small volume of anesthetic (6 mL or less) and observing for a change in lameness very soon after the injection (within 10 minutes)

Figure 4.25. Effusion within the DIP joint can be seen and palpated as swelling just above the coronary band (arrow).

VetBooks.ir

can improve the specificity of the block for the joint.[17,55] Most horses with DIP joint pain improve rapidly and substantially after IA anesthesia. If the lameness only partially improves but persists after 10 minutes, the DIP joint is not likely the primary site of the pain. In addition, a positive response to an IA block combined with a negative response to navicular bursa anesthesia often incriminates the joint as the primary problem area.[55] See Chapter 2 for more details related to perineural and intrasynovial anesthesia.

Diagnosis

A definitive diagnosis of OA of the DIP joint can often be obtained with radiography of the foot. However, horses with synovitis/capsulitis or early OA of the DIP joint may have no radiographic abnormalities. A complete radiographic study of the foot should be performed to rule out other potential problems because DIP joint OA may be secondary to other conditions and anesthesia of the DIP joint is not always specific for the joint.

Oblique views of the DIP joint can aid in detecting periarticular new bone formation of the distal aspect of the middle phalanx (Figure 4.26).[17,39] Close inspection of the extensor process, palmar/plantar aspect of distal P2, and dorsoproximal aspect of the navicular bone for osteophyte and enthesophyte formation is important. Joint space congruity and the shape of the proximal surface of the distal phalanx should be assessed carefully. Joint space narrowing is difficult to assess because limb positioning is known to affect joint space width.[10] In general, the radiographic abnormalities surrounding the DIP joint should not be overinterpreted because there is much variation in the shape of the extensor process among horses and enthesophytes may not be associated with lameness (Figure 4.27).[17,47] In contrast, the presence of any radiographic abnormalities of the DIP joint was associated with a poor response to treatment in one study.[16]

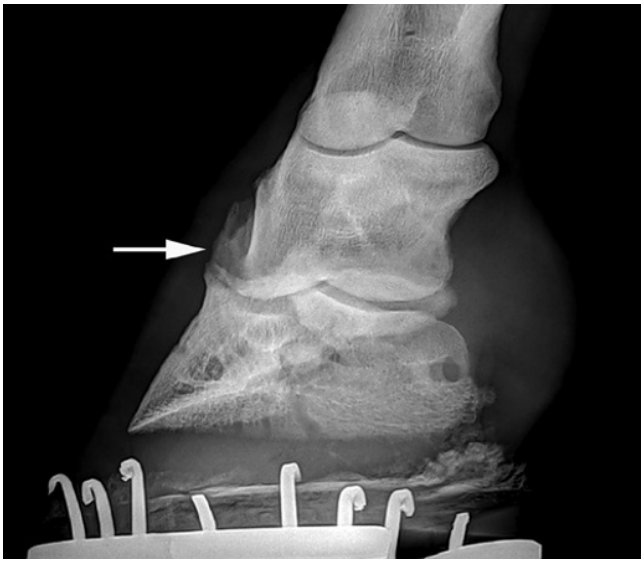

Figure 4.26. Oblique radiographs of the DIP joint are important to document abnormalities. The bony proliferation (arrow) and narrowing of the DIP joint seen on this oblique radiograph were not apparent on other views of the joint.

Figure 4.27. The calcification of the extensor tendon seen on this lateral radiograph was not clinically significant in this horse following removal of an extensor process fracture.

Additional diagnostics that may be used to confirm the diagnosis of a problem within the DIP joint, particularly if the radiographs are nondiagnostic, include ultrasound, MRI, and diagnostic arthroscopy. Ultrasound can be helpful to document problems within the CLs of the DIP joint proximal to the hoof wall and thickness of the dorsal joint capsule.[12,19] MRI is the most comprehensive advanced imaging modality that can detect articular cartilage, subchondral bone, and soft tissue abnormalities of the DIP joint if present.[18,20,21,26] Arthroscopy may be used to document articular cartilage or subchondral bone damage, but much of the joint surface of the DIP joint is not visible. Since many horses with DIP OA will have other abnormalities within the foot, MRI is usually the next imaging modality recommended after radiography.

Treatment

Horses with primary OA or synovitis/capsulitis of the DIP joint are usually treated with a combination of IA medication and corrective shoeing. Predisposing factors such as mediolateral and dorsopalmar hoof imbalances should be corrected to reduce repetitive trauma to the joint. Shortening the toe and moving the break-over further palmarly often helps these horses, and using a rim pad may alleviate concussion to the joint.[5] Direct medication of the DIP joint is usually more effective than systemic medications to reduce the inflammatory response within the joint. The type(s) of medication chosen may depend on the severity and duration of the lameness and the severity of the radiographic abnormalities. Corticosteroids alone or corticosteroids combined with hyaluronan are used most frequently. Chondroprotective agents such as autogenous serum or PSGAGs may also be used if desired.

Typically, the author recommends a combination of hyaluronan and triamcinolone (TA). However, one study reported that horses treated with three weekly injections of the DIP joint with PSGAG had a 67% successful outcome, compared with 46% of those receiving MPA alone.[35] In addition, a significantly better result was obtained in

VetBooks.ir

dressage horses than in jumping horses (eventing and show jumping).[35] This study and the clinical observations of the author support the rationale for treating horses with DIP joint pain with IA medication although horses that block completely with DIP joint anesthesia usually respond the best to this treatment. Repeat IA injections may be required, depending on the severity of the abnormalities within the joint and the response to treatment.

Treatment of horses with secondary OA of the DIP joint usually focuses on the underlying contributing problem. Treatment of the primary condition is usually beneficial to prevent worsening of the problems within the DIP joint. For instance, extensor process fractures of the distal phalanx should be removed in most cases, and other articular distal phalanx fractures should be stabilized with corrective shoeing or internal fixation if necessary. SCLs should be debrided if possible, and horses with known trauma to the articular cartilage, subchondral bone, or CLs of the DIP joint should be treated appropriately until healing has occurred. Horses with navicular disease should be shod appropriately to minimize progression of the DIP joint OA. Many of these horses may also benefit from IA medication, depending on the underlying problem. For instance, horses with navicular disease usually benefit from IA treatment of the DIP joint by reducing the inflammatory response, both within the joint and within the navicular region.[45] A recent study documented that a clinically effective concentration of MPA or TA diffused between the DIP joint and navicular bursa after IA or intrabursal injection.[45]

Prognosis

Horses with synovitis/capsulitis of the DIP joint usually have a very good prognosis to return to performance if the predisposing hoof imbalances can be corrected and maintained. Recurrence is possible but is often related to relapses in the hoof imbalances. However, one study indicated a less optimistic prognosis with only 30% of horses responding to treatment.[16] The prognosis of horses with primary or secondary OA of the DIP joint is usually related to the severity of the radiographic or MRI abnormalities.[17,18] Horses with advanced OA often respond less to any form of treatment, or the lameness recurs more quickly. Horses with mild to moderate OA have a good to guarded prognosis to return to performance. Horses with secondary OA of the DIP joint have a variable prognosis depending on the underlying problem. However, the development of radiographic signs of OA within the DIP joint does not preclude athletic performance. For instance, several racehorses with type II fractures of the distal phalanx returned to racing despite radiographic evidence of OA within the DIP joint.[47] Some feel that the radiographic abnormalities within the DIP are overinterpreted as to their influence on lameness. Correlations between MRI abnormalities and the prognosis of horses with DIP OA have not been reported to the author's knowledge.

FRACTURES OF THE DISTAL PHALANX (P3, COFFIN BONE)

Fractures of the distal phalanx are an uncommon cause of lameness compared to the numerous other conditions that affect the horse's foot.[5,56] An older report identified 65 cases of P3 fractures in 20,638 cases admitted to a hospital.[56] These fractures can occur in any foot but most commonly affect the lateral aspect of the left forelimb and the medial aspect of the right forelimb in racehorses.[5,47] Type I and II "wing" fractures are most common and the majority of these fractures enter the DIP joint.[47,56] In one report of P3 fractures in Thoroughbred and Standardbred racehorses, 71 of 74 fractures were wing fractures (types I and II), and the majority of these fractures were articular.[47] Although all breeds and classes of horses can be affected, there appears to be a higher incidence observed in racing breeds.[5,47,56]

Although fractures of P3 can assume a variety of configurations, these fractures can be classified into seven types (Figure 4.28).[6] Type I fractures are nonarticular oblique palmar/plantar process (wing) fractures (Figure 4.29). Type II fractures are articular oblique

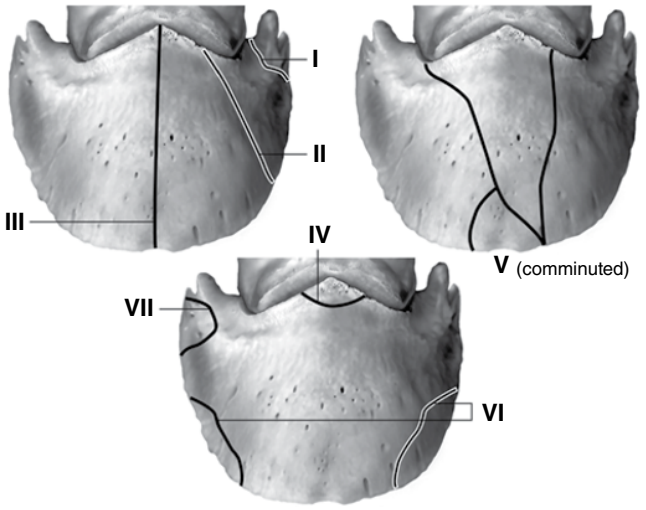

Figure 4.28. Classification of P3 fractures in horses. *Source:* Reprinted with permission from Dr. Alicia Bertone, Equine Fracture Repair, Nixon AL, ed. Reproduced with permission of John Wiley & Sons.

Figure 4.29. Type I fracture of the wing of P3. This fracture is nonarticular, but it may be difficult to document this. This particular fracture is larger than most type I fractures and may be a type II articular fracture.

VetBooks.ir

palmar or plantar process (wing) fractures (Figure 4.30) and are by far the most common type.[47,56] Type III fractures are sagittal articular fractures that roughly divide the distal phalanx into two separate halves (Figure 4.31). These fractures are uncommon and represent 3%–4% of fractures of the distal phalanx[30,47,56] and tend to occur more commonly in the hindlimb than the forelimb. Type IV fractures are articular fractures involving the extensor process. They occur most frequently in the forelimbs and can be bilateral (Figure 4.32).[11,15,30] Type V fractures are comminuted articular or nonarticular fractures and can be a variety of configurations (Figure 4.33). Type VI fractures are nonarticular solar margin fractures of the distal phalanx (Figure 4.34).[29] Type VII fractures are nonarticular fractures of the palmar or plantar process of the distal phalanx in foals (Figure 10.55). These fractures begin and end at the solar margin and are usually triangular or oblong in shape.[30,32] Initially they were thought to represent osseous bodies, but histologic findings were consistent with a fracture.[32] Frontal fractures of P3 (fracture line runs lateral to medial and splits the bone into dorsal and palmar/plantar halves) occur but are extremely rare.[1]

Figure 4.30. Type II articular "wing" fracture. This is the most common type of P3 fracture.

Etiology

Single-event trauma appears to be the predominant cause of P3 fractures. However, repetitive trauma leading the stress-related bone injury is likely the cause in racehorses.[47] Scintigraphic abnormalities of P3 have been identified in racehorses before radiographic evidence of a fracture was present.[34,47] This suggests that P3 fractures are similar to other "stress"- or "fatigue"-type fractures that occur in racehorses. Acute trauma is often the cause in nonracehorses, especially in those that involve the hindlimb.[3,6,49] Type III sagittal articular fractures usually result from direct trauma to the hoof from kicking a solid object.[56] Type VI solar margin fractures may be related to the shape and location of the solar margin within the hoof and the tremendous forces the distal phalanx undergoes during weight-bearing and work. These fractures may also occur concurrently with laminitis and pedal osteitis due to resorption of the apex of P3.[5] Type VII fractures in foals are thought to occur from compression either on the solar or dorsal cortex of the distal phalanx during weight-bearing or from tension forces generated by the DDFT and may be related to hoof conformation.[22,32] They are exclusively in the front feet, and in one study, 74% of foals radiographed had palmar process fractures.[23] Excessive trimming of the heels, sole, and frog in foals does not appear to affect the occurrence of type VII fractures in foals although these fractures appear to be associated with hoof conformation.[23] Occasionally, P3 may be fractured as a result of penetration of a foreign body through the sole. A large sidebone may also serve to predispose to type I or II fracture in the forelimb due to its lever arm effect on the palmar process (Figure 4.35).[56] An MRI study of horses

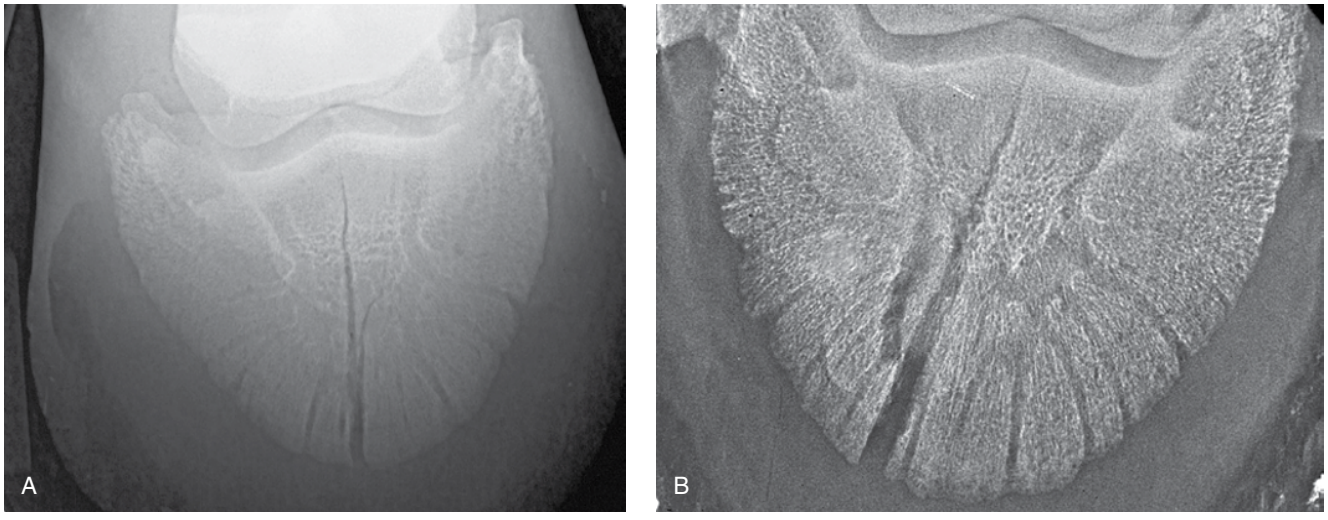

Figure 4.31. Acute (A) vs. more chronic (B) Type III sagittal fractures in two different horses. The fracture essentially splits the bone into two pieces, and the fracture gap usually widens with chronicity (B).

VetBooks.ir

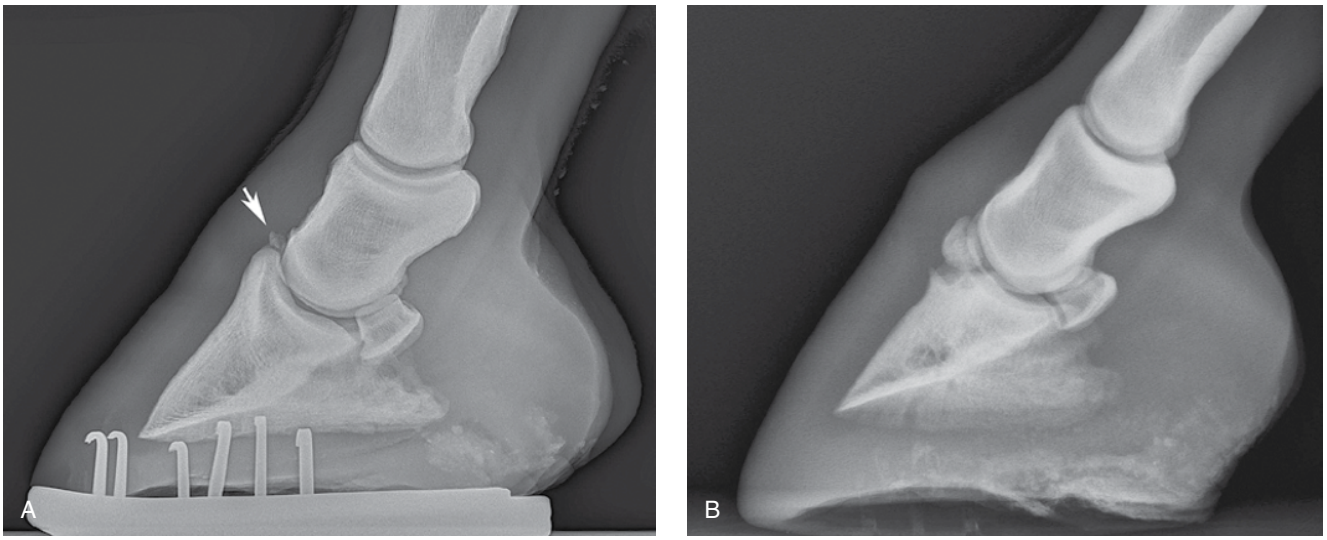

Figure 4.32. Small (A) and large (B) type IV P3 fractures involving the extensor process.

Figure 4.34. Type VI fractures are also referred to as solar margin fractures of P3 (arrow).

with ossified ungual cartilages and a P3 facture found that all fractures occurred at the base of the ossified cartilage suggesting a biomechanical cause or focal stress point from cycling.[57] The fractures involved only one of the lateral processes and were articular.

Type IV extensor process fractures may occur due to excessive tension on the common digital extensor tendon, resulting in an avulsion fracture. Overextension of the DIP joint may cause contact of the extensor process with the middle phalanx, and trauma to the dorsal aspect of the foot has also been proposed as a cause.[30,62] The development of a separate center of ossification or an osteochondrosis lesion of the extensor process may also occur.[30,56,62] Supporting a theory of a developmental lesion is the fact that lesions are often bilateral, occur in relatively young horses, and can be observed radiographically as an incidental finding in horses that are clinically normal (Figure 4.32).[9,15,30]

Clinical Signs

Generally the clinical signs are similar during the acute phases for all types of P3 fractures. A history of an acute onset of a moderate to severe lameness (grade 4–5 out of 5) is common.[5,6] In some cases the lameness will worsen within the first 24 hours after injury, presumably due to increased pressure within the hoof capsule secondary to inflammation and swelling. Exceptions to this are solar margin fractures, type VII fractures in foals,

VetBooks.ir

Figure 4.35. Type II articular fracture that was associated with a large sidebone of P3.

and developmental type IV fractures of the extensor process. Horses with these types of P3 fractures are usually only mild to moderately lame, and the lameness must be differentiated from the many other potential problems within the foot.[5,6] In all cases, if the fracture is chronic, the signs of lameness are usually diminished.

With acute fractures, an increased digital pulse may be palpable, and heat in the affected foot may be appreciated. With articular fractures DIP joint effusion is often palpable dorsal and proximal to the coronary band. Swelling and edema may also be present above the hoof wall in the pastern region. Hoof tester examination usually reveals pain over the sole region, and focal pressure over the fracture site usually induces a marked painful response. However, a negative hoof tester response does not rule out the presence of a P3 fracture, especially in chronic cases.[5] Perineural anesthesia of the PD digital nerves or IA anesthesia of the DIP joint may aid in localizing the lameness to the foot region. In general, regional anesthesia is usually unnecessary to diagnose type II and III fractures because the clinical signs are sufficient to localize the pain to the foot region. However, regional anesthesia is often necessary in horses with chronic P3 fractures and those that do not cause severe lameness.

Horses with large chronic extensor process fractures may have enlargement of the dorsal aspect of the coronary band and abnormal growth of the dorsal hoof wall. As the hoof grows, it develops a "V" or triangular shape called a buttress foot.[9,15] The abnormal hoof shape eventually will extend from the coronary band to the ground surface. Smaller type IV fractures rarely cause deformity of the dorsal hoof wall, but effusion of the DIP joint is common.

Diagnosis

Radiographic examination (30° dorsopalmar/plantar, 65° dorsoproximal to palmarodistal, lateral, and both obliques) is used to confirm the diagnosis and document the type and location of the fracture (see Chapter 3 for more details on radiographic views). In some cases it may be necessary to take special views of the palmar/plantar processes to identify the fracture. Solar margin fractures are most easily identified on the 60° dorsoproximal to palmarodistal projection using a radiographic technique with approximately one-half the exposure needed to evaluate the navicular bone.[30] Extensor process fractures are usually identified on the lateromedial view.

Most P3 fractures are readily apparent on routine radiographic projections. However, nondisplaced or stress-related fractures in racehorses may not be apparent on the initial radiographic examination because of insufficient time for resorption of the bone along the fracture line or because the cast-like effect of the hoof wall may prevent fracture displacement.[30,34] In these cases, radiographs should be repeated in 1–2 weeks, or nuclear scintigraphy, CT, or MRI can be used to help identify radiographically occult fractures of P3.[5,37,47] In one report, CT found an incomplete oblique fracture of the palmar process that was not evident radiographically 25 days after the injury.[37] CT can also be used in horses with comminuted P3 fractures to help determine the exact fracture configuration (Figure 4.33) and has become the standard to accurately determine fracture configuration.

Treatment

Options for treating horses with P3 fractures include confinement alone, confinement with corrective shoeing or foot casts, lag screw fixation (types II and III), and surgical removal of the fracture/fragment (type IV only). The decision often depends on the age and intended use of the horse, specific characteristics of the fracture, and financial constraints of the owner. In general, the majority of horses with P3 fractures are treated with confinement and corrective shoeing aimed at immobilizing the fracture and preventing expansion of the hoof wall (Figure 4.36). A foot cast or foot rim cast can serve the same purpose as the shoe and is preferred by some veterinarians. A recent study has questioned the need for immobilizing the foot because outcome did not appear to be influenced by whether the foot was immobilized in a series of 223 horses with P3 fractures.[49]

Types of shoes that may be used include a bar shoe with clips (Figure 4.36), a continuous rim-type shoe, or the Klimesh contiguous clip shoe.[1,5] All of these approaches appear to effectively prevent expansion of the hoof wall during weight-bearing, thus stabilizing the fracture. Regional anesthesia of the foot often aids application of the shoe and many horses walk more comfortably shortly after the foot is immobilized.

VetBooks.ir

In most cases the foot should remain in one of these shoes for 6–8 months, with the shoe reset every 4–6 weeks. Once clinical improvement has occurred, a less restrictive type of shoe (bar shoe only or bar shoe with quarter clips) may be used. Horse should not be worked for approximately 8–10 months, and in some cases, 1 year of rest may be necessary for clinical improvement.[5] Many P3 fractures are very slow to heal and may never develop radiographic bone union, but complete osseous union does not appear to be essential for horses to return to athletic activity.[49] In addition horses do not need to be shod with bar shoes and clips for the remainder of their athletic careers.[44]

Specific treatment of each type of P3 fracture is given below and included in Table 4.1.

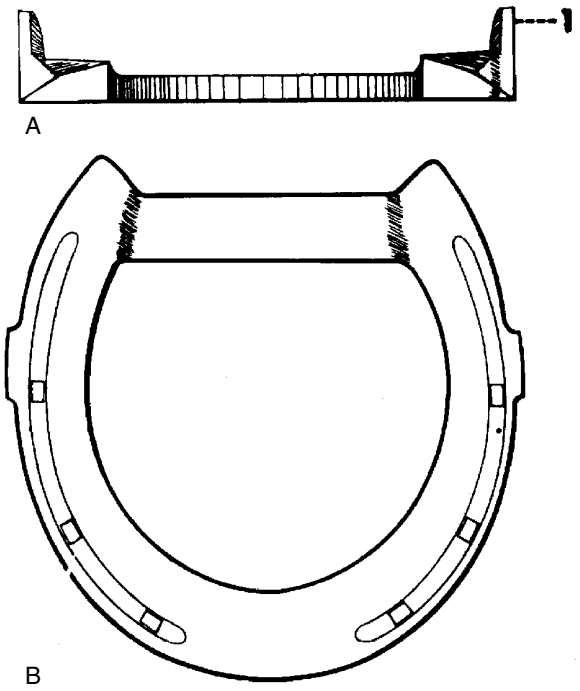

Figure 4.36. Full-bar shoe that can be used to treat horses with distal phalanx fractures. (A) Rear view of shoe showing quarter clips. (B) Ground surface view of the shoe showing full-bar and quarter clips welded to the shoe.

Type I

This nonarticular fracture is best treated with confinement and methods to prevent hoof expansion (shoe or foot cast). However, it may also respond to confinement and rest alone.

Type II

Foals less than 6 months of age should be treated with stall confinement.[60] Treatment that restricts the expansion of the hoof is usually unnecessary and may result in severe hoof contraction. Foals should be confined for 6–8 weeks, and their exercise should be restricted until bony union of the fracture is observed radiographically. Adult horses can be treated with confinement and methods to restrict hoof expansion or surgically by placing a lag screw. However, most type II fractures are treated nonsurgically because screw placement can be very difficult with this fracture type.[47] Surgery is usually only considered in horses with large wing fractures.

Type III

This is an unusual fracture in foals and adult horses and can be treated similarly to a type II fracture. These fractures tend to cause more severe lameness than type II fractures, and foot immobilization is often important to improve weight-bearing on the affected limb to prevent contralateral limb laminitis.

Table 4.1. Types of distal phalanx fractures.

Fracture type	Location	Articular	Recommended treatment	Prognosis
I	Palmar/plantar process	No	Confinement±shoeing (foot cast instead of shoe)	Very good to excellent
II	Oblique fractures of palmar/plantar process ("wing" fractures)	Yes	Confinement±shoeing (foot cast instead of shoe) Lag screw repair of large type II fractures	Fair to good
III	Midsagittal fracture	Yes	Confinement±shoeing (foot cast instead of shoe) Best candidate for lag screw repair	Unpredictable; Usually guarded
IV	Extensor process (variable size)	Yes	Removal in most cases regardless of size: arthroscopy/arthrotomy	Small: excellent Large: good
V	Comminuted	Yes or no	Confinement+shoeing (foot cast instead of shoe) Removal if secondary to infection	Dependent on fracture configuration
VI	Solar margin	No	Confinement+protective shoeing (wide-web shoes or shoes with full or rim pads)	Very good
VII	Palmar/plantar process; begins and ends at solar margin	No	Primarily in foals Confinement alone; no shoeing	Very good to excellent

VetBooks.ir

Acute type III fractures in adult horses are usually the best candidates for surgical repair using lag screw fixation (Figure 4.37).[3,6,24] Fractures of greater than a few days duration may fill with granulation/fibrous tissue, making it difficult to reduce the fracture. However, if conservative methods are not considered satisfactory, it is feasible to undertake screw fixation several weeks after the injury, even though the opportunity for interfragmentary compression is minimized.[25]

The correct site for screw placement is midway between the articular surface and solar canal through a hole in the side of the hoof wall.[24] Screw placement for type III fractures is usually less difficult than for type II fractures because the bone is essentially divided in half and there is less risk of splitting the fracture when the screw is tightened.[6,24] The major risks with this procedure are infection developing around the implant, the inability to compress the fracture, incorrect screw placement leading to continued lameness, and overriding of the fracture fragments during compression. The primary advantages are less risk of secondary OA developing in the DIP joint and faster healing of the fracture due to surgical compression.

Complete fracture healing can be expected in 6–12 months and the screw may have to be removed if lameness persists or infection around the implant is evident.[3,5,24] A computer-assisted surgery (CAS) technique has been developed to improve accurate screw insertion into sagittal P3 fractures.[2] This technique resulted in greater precision of screw length and placement compared with the conventional technique and may enable placement of two screws for improved compression. Improved accuracy of screw placement can also be accomplished by utilizing CT guidance intraoperatively.[24] Using larger diameter screws (6.5 or 5.5 mm) has been shown to increase axial compression and reduce the fracture gap of P3 fractures when compared with 4.5-mm screws in two separate *in vitro* studies.[31,33] Typically, 4.5-mm screws have been used because of the small space for screw insertion.

Figure 4.37. Lag screw repair of a type III P3 fracture. The screw must be placed through a hole within the hoof wall.

Type IV

Surgical removal of the fracture/fragment is usually the preferred treatment for type IV P3 fractures.[9,11,15,38] Acute extensor process fractures are rare in horses and are the best candidates for lag screw fixation, but this is rarely performed (Figure 4.38).[5,36] Conservative treatment with prolonged stall rest is often unsuccessful because the extensor process fracture does not heal and horses remain lame.[15,46] However, most large type IV fractures are chronic, and lag screw repair of these fractures is generally not recommended. Surgical removal of the extensor process fractures/fragments with arthroscopy or a dorsal arthrotomy is usually the treatment of choice (Figure 4.27). Arthroscopy using a dorsal approach is the preferred technique for removal of small extensor process fractures.[9,11] Large extensor process fractures (greater than 1 cm) have also been successfully removed with arthroscopy by using a motorized burr to help remove the fragment.[9,15,38] These fractures usually involve a large part of the extensor process (>25% of the joint surface) and can be challenging to remove (Figure 4.39).[9] The convalescence time after removing large fragments is generally longer than after removing smaller fragments.

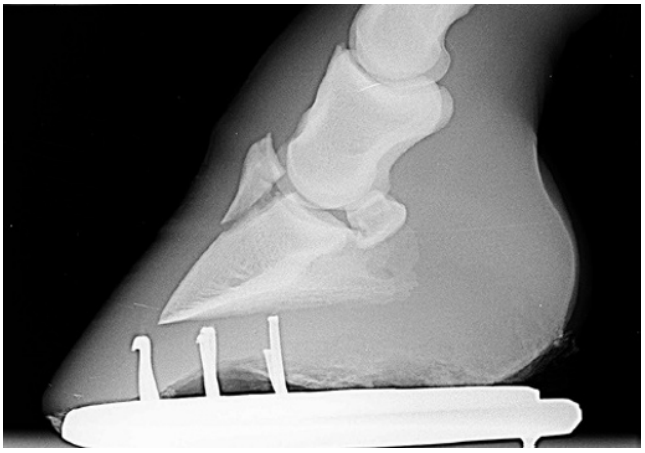

Figure 4.38. A large type IV P3 fracture that may warrant lag screw repair.

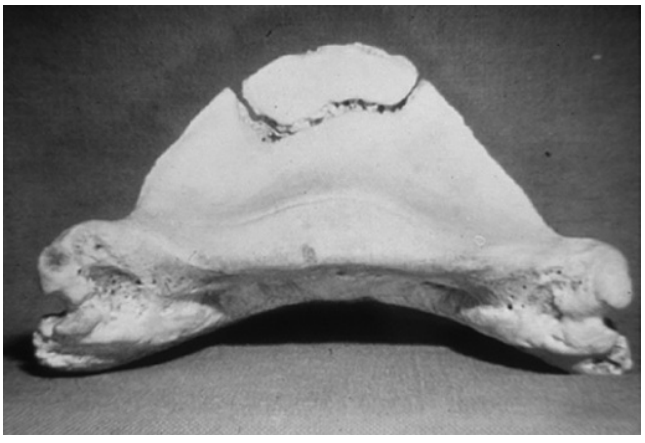

Figure 4.39. Dried bone specimen of a distal phalanx with a fracture of the extensor process. Note the width of the extensor process fragment.

VetBooks.ir

Type V

This fracture may be articular or nonarticular but regardless is best treated with confinement and methods to prevent hoof expansion (shoe or foot cast; see above for details). Confinement alone is usually not recommended for these fractures unless the fracture only involves the apex of P3.

Type VI

Treatment of solar margin fractures depends on whether the condition is primary or secondary to a chronic foot disorder (e.g. laminitis, osteitis, or infection). However, primary causes of solar margin fractures are usually treated with corrective shoeing (wide-web shoes, shoes and full pads, or shoes with rim pads) and stall or paddock rest for several months.[29] Strict immobilization with bar shoes and quarter clips is not necessary. Prolonged rest appears to be required for the best fracture healing, but this often depends on the size of the fracture. If the cause is secondary, then treatment is directed at the underlying cause initially, followed by management of the solar margin fracture.[29]

Type VII

Affected foals with this fracture are usually treated satisfactorily with confinement alone for 6–8 weeks. Exercise should be restricted until radiographic evidence of bony union is evident, which is usually observed at about 8 weeks after the diagnosis.[22,62] Application of restrictive external coaptation (e.g. bar shoe or acrylic) to the hoof is not recommended because of the severe heel contraction that can occur and the potential for the hoof to slough.

OA of the DIP joint is a common sequela to articular P3 fractures. All racehorses with articular wing fractures that had follow-up radiographs had evidence of OA on the radiographs.[47] However, this did not preclude horses from racing, and the authors warned to not overinterpret radiographic abnormalities within the DIP joint. Nonetheless, secondary abnormalities within the DIP joint subsequent to articular fractures may limit future athletic endeavors.[5] Secondary OA of the DIP joint appears to be more likely to develop with type III fractures than type II P3 fractures. If lameness persists, a neurectomy of the PD nerves may permit horses to resume athletic activity. In racehorses with primarily type II fractures, 18% had a PD neurectomy performed, which completely resolved the residual lameness and permitted them to race.[47]

Prognosis

In general, horses with hindlimb P3 fractures have a better prognosis than those in the forelimb, and the prognosis for nonarticular P3 fractures (types I, V, VI, and VII) is usually very good for all ages of horses if sufficient rest is given.[5,55] One recent study of 223 horses reported a 91% return to expected level of activity for horses with type I P3 fractures and 80% for horses with type VI fractures.[49] Foals with type VII P3 fractures usually have an excellent prognosis for return to performance, and fracture healing is expected in about 8 weeks.[32,60]

A range from 50% to 70% return to soundness has been reported for horses with type II wing fractures treated conservatively [44,49,56] However, a much better success rate has been reported in Standardbred racehorses with 81% returning to training and 63% racing.[43] However, 89% that returned to training without a bar shoe refractured at the same site, and 60% of horses returning to training with a bar shoe raced successfully.[43] This is in contrast to nonracehorses, of which 69% returned to their previous level of use and did not wear a bar shoe when they returned to training.[44]

The prognosis for small extensor process fractures treated by arthroscopic removal is generally considered to be very good to excellent. However, a recent study reported that only 46% of horses undergoing arthroscopic debridement of extensor process fragmentation remained sound after 4 years.[11] Removal of chronic large extensor process fragments also results in a good prognosis; 8 of 14 cases returned to their intended use in one report[15] and 14 or 17 in another.[9] The prognosis for large extensor process fractures treated by internal fixation also appears reasonably good in the small number of cases reported.[36,46]

The type of P3 fracture with the most variable prognosis is type III fractures. It remains unknown if affected horses have an improved prognosis with lag screw fixation compared with confinement and corrective shoeing.[3] Variable success of surgical treatment has been reported.[3,24] In one study all fractures healed, but only 2 of 4 horses returned to athletic activity and surgery did not reduce the convalescence time required. An older study using internal fixation reported that 11 of 11 horses older than 3 years of age became sound, and the most recent study that utilized CT guidance reported that 4 of 5 horses with sagittal/parasagittal fractures became sound.[24] In contrast, conservative management of horses with type III fractures was reported to have a 74% success rate for horses returning to their intended use.[49] Regardless of the treatment used, horses with type III fractures have a worse prognosis to return to performance than the other types of P3 fractures, and refracture of the bone is more likely to occur.[46]

SUBCHONDRAL CYSTIC LESIONS OF THE DISTAL PHALANX (P3)

SCLs of the distal phalanx are uncommon and can affect a wide variety of horse breeds of all ages.[4,60] Affected horses are usually intermittently lame, and the forelimbs are more frequently affected than the hindlimbs. Verschooten reported on 15 cases of SCLs involving the distal phalanx, 14 of which were located in the forelimb.[60] In another study 27 of 28 cases involved the forelimbs.[27] Most SCLs communicate with the joint surface,[28,59] although communication with the adjacent joint space can be variable.[60]

Etiology

Regardless of their location, the cause of most SCLs in the horse is considered to be either trauma or developmental.[4,48] Damage to the subchondral bone in the stifle has been shown to cause SCLs of the medial femoral condyle, and SCLs can occur at sites of previous IA

VetBooks.ir

fractures.[48] Damage to the cartilage and subchondral bone is thought to permit passage of joint fluid through the opening, resulting in resorption of the subchondral bone.[4,60] Alternatively, a developmental osteochondrosis lesion predisposes to the lesion because SCLs are often found in young horses and are frequently bilateral.[4,5] See Chapter 10 for more information about SCLs and osteochondrosis.

Clinical Signs

A history of an acute onset of lameness may be present, but more often the lameness is chronic and intermittent. The lameness may subside with rest and recur with exercise, and the severity can be variable. There are often no palpable abnormalities (including hoof tester examination), but effusion within the DIP joint may be present. The digital pulse rate may be elevated and the phalangeal flexion test is usually positive.[27] A PD nerve block improves the lameness in most cases. Intrasynovial anesthesia of the DIP joint also eliminates the lameness, especially if the SCL communicates with the joint.[28,60]

Diagnosis

Radiography is necessary for a definitive diagnosis of an SCL of the distal phalanx. The SCLs are variable in size and are usually identified within the body of the distal phalanx (Figure 4.40). The majority of SCLs communicate with the joint.[28,59] In one study, 18 of 27 SCLs were located centrally in the distal phalanx, and communication with the DIP joint was observed in all cases.[27] In a more recent study, all 11 horses had SCLs that were IA.[59]

Treatment

Recommended treatments of SCLs of the distal phalanx have included (1) confinement followed by increasing exercise, (2) IA medications, (3) transcortical drilling, (4) extra-articular surgical curettage, and (5) arthroscopic debridement.[28,58–60]

Most horses respond only transiently to IA medications, and debridement through hoof wall windows has been complicated by recurrent abscessation and lameness. A dorsal arthroscopic approach for IA debridement recently has been described in 11 horses.[59] This technique is performed with the DIP joint extended and distracted to permit access to the SCL.[59] Because of the morbidity associated with extra-articular debridement techniques, arthroscopic debridement should be considered the treatment of choice.[38,59] However, some SCLs in the distal phalanx may be inaccessible with the arthroscope.[28]

Prognosis

Variable results have been reported with extra-articular debridement of these lesions, and these techniques are often complicated by infection and continued lameness.[28] However, there are reports of successful debridement of SCLs through the hoof,[60] and 1 horse treated with an autogenous bone graft returned to race training after 6 months.[58] Ten of eleven (91%) horses treated with arthroscopic debridement of a distal phalanx SCL returned to athletic soundness.[59] All of these horses were treated between 16 and 33 months of age, so results may vary depending on the age at diagnosis.[59] However, arthroscopic debridement of SCLs of the distal phalanx should provide a superior outcome in any age horse compared with extra-articular approaches.

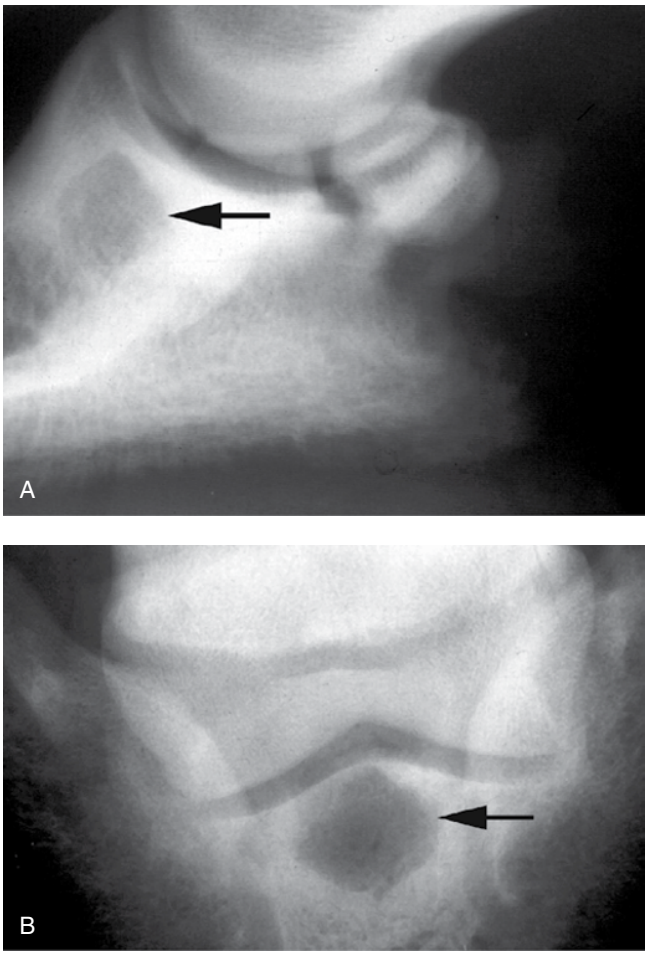

Figure 4.40. Lateral (A) and dorsopalmar (B) radiographs of a horse with SCL of P3 (arrows).

COLLATERAL LIGAMENT INJURIES OF THE DISTAL PHALANX

Desmitis of the CLs of the DIP joint is one of several soft tissue injuries that can occur within the foot. Lesions of the CL of the DIP joint were the second most common soft tissue injury in one MRI study, and they can occur alone or together with other injuries.[18–21] The medial CL of the forelimb is the most common site of injury, and although uncommon, they can also occur in the hindlimb.[19,26] These lesions may have concurrent osseous damage to the distal phalanx at the ligament insertion site (Figure 4.41).[12,13] Horses with extensively ossified collateral cartilages are also thought to be more prone to injuries of the CLs of the DIP joint.[21]

Etiology

Asymmetrical foot placement or foot imbalances may cause sliding and rotation of the distal phalanx relative

VetBooks.ir

to the middle phalanx, contributing to injuries to the CL of the DIP joint. This can occur as the result of an acute injury or from repetitive-type trauma. However, lesions within the CL of the DIP joint have recently been reported to be a primary degenerative process rather than inflammatory.[20] Histology revealed extensive fibrocartilaginous metaplasia and development of multiple intercommunicating fissures within the degenerate collagen in severe lesions.[20] This was thought to explain the poor response to conservative treatment in many horses with desmitis of the CL of the DIP joint. There are no known predisposing factors, but a recent study of 52 lame horses reported a correlation between a reduced palmar angle of the foot detected with radiography and alterations in the CLs of the DIP joint with MRI.[14]

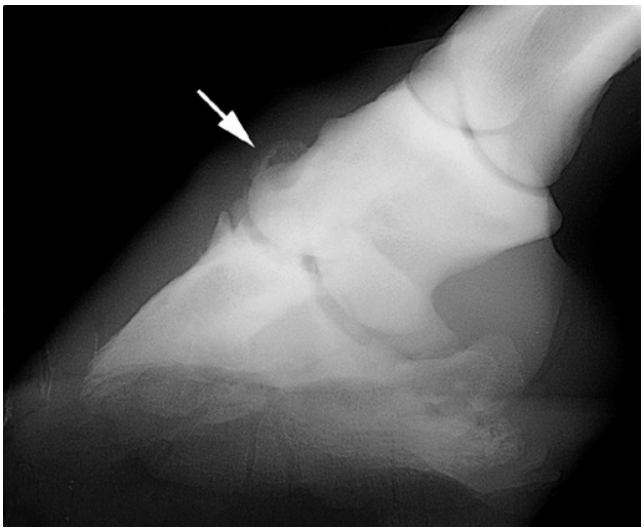

Figure 4.41. Bony proliferation on the dorsolateral aspect of P2 visible on this oblique radiograph (arrow) may be suggestive of a chronic injury to the CL of the DIP joint.

Clinical Signs

In general, horses that have primary soft tissue injuries in the foot such as injuries to the CLs of the DIP joint are more likely to have a history of an acute onset of lameness and be unilaterally lame compared with horses with injuries to the navicular region. There are often few localizing clinical signs in horses with injuries to the CL of the DIP joint.19, 26 Horses often have a history of a chronic forelimb lameness of variable severity that is worse in the circle. Palpable swelling and pain of the CL at its proximal attachment to the middle phalanx may be present above the coronary band in severe cases. However, this is uncommon and effusion of the DIP joint is also not a consistent clinical finding. Most horses (87% in one study) improve with a PD nerve block but may not be completely sound until a more proximal block is performed.19 Only 40% of horses improved with IA anesthesia of the DIP joint in one study.19

Diagnosis

A definitive diagnosis of an injury to the CL of the DIP joint is best determined with MRI in either the recumbent or standing patient. Lesions within the CL of the DIP joint are identified by the alteration in size and signal intensity (Figure 4.42). In addition, some horses may have abnormal mineralization and fluid within the distal phalanx at the insertion of the ligament[18] (see Chapter 3 for more information on MRI). Ultrasound may also be helpful, but certain aspects of the CL of the DIP joint are inaccessible with ultrasound, suggesting

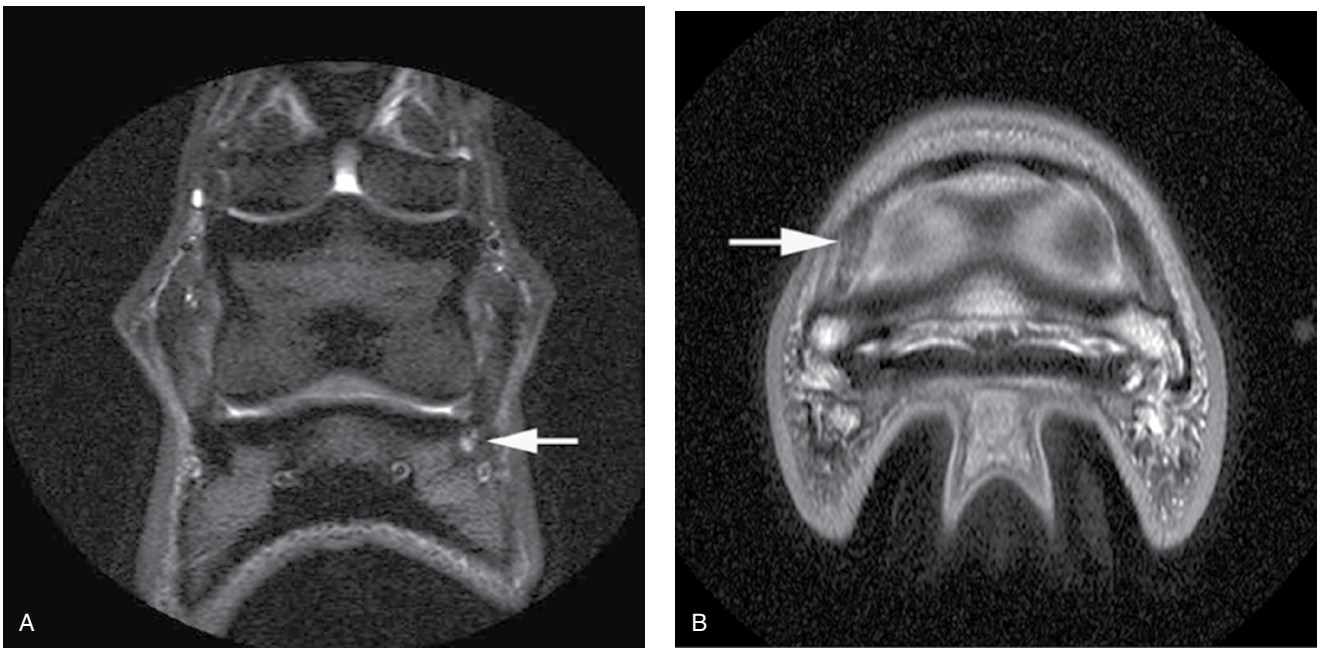

Figure 4.42. Frontal STIR (A) and PD axial (B) MR images of the foot of a 12-year-old Quarter horse with abnormalities within the medial collateral ligament of the DIP joint (arrows).

VetBooks.ir

that negative findings do not rule out the presence of a lesion.[19] Although concurrent osseous damage at the origin and insertion sites of the ligaments can be present in approximately 50% of these horses, scintigraphy is usually not recommended as an additional diagnostic tool because MRI can usually provide more specific information about the injury.

Treatment

The most important aspects of treating any soft tissue injury of the foot are rest, rehabilitation, and corrective foot care.[26,54] Foot imbalances that may have contributed to their occurrence such as low heels, long toes, mediolateral imbalance, reverse angle of the distal phalanx, etc. should be corrected if possible. For example, one study that correlated radiographic findings with MRI abnormalities found that a reduced palmar angle of the foot was correlated with alterations in the CLs of the DIP joint. Horses should be shod to decrease tension on the side of the injury by increasing the width to the branch of the shoe on the affected side and beveling the shoe on the opposite (unaffected side). Rest and rehabilitation and corrective shoeing are usually performed over a minimum of 6–8 months. Additional treatments for desmopathy of the CL of the DIP joint include extracorporeal shockwave therapy, application of a half-limb or foot cast, and medication of the DIP joint.[26] However, one large study found no benefit of using extracorporeal shockwave therapy or radial pressure wave therapy on outcome.[13] Ultrasound-guided intralesional therapy with stem cells, platelet-rich plasma, and other biological products may also be used, especially if the injury is accessible above the hoof wall (see Chapter 8 for more detailed information on these treatment modalities).

Prognosis

The reported prognosis for horses with desmopathy of the CL of the DIP joint is variable. One study reported that only 29% of horses treated with rest and rehabilitation returned to athletic function,[19] while another study indicated that 60% of treated horses (12 of 20) returned to their previous level of exercise.[26] Another study that followed horses for 2 years after presentation determined that only 27% of horses with CL injury alone and 34% of horses with CL-related osseous injury returned to their previous performance.[13] Horses with multiple soft tissue and osseous injuries within the hoof capsule did substantially worse. In general, these horses have a poor prognosis for future performance.

OSSIFICATION OF THE COLLATERAL CARTILAGES OF THE DISTAL PHALANX (SIDEBONE)

Ossification of the collateral cartilages of the distal phalanx is relatively common in certain breeds of horses, including most larger breeds such as Warmblood horses, draft horses, Finnhorses, and Brazilian jumpers.[40,51–53,61] The forefeet appear to be more commonly involved than the hindfeet, and the clinical significance of the condition remains questionable.[61] Female horses appear to be more susceptible to development of this condition, and the lateral cartilage often shows more ossification than the medial cartilage.[51] The ossification can begin at the base of the cartilage or originate as a separate area in the center of the cartilage.[8,40] In Brazilian jumpers, 7% of the horses had no ossification, 86% had ossification beginning at the base, and 7% had a separate center of ossification.[40] In either case, the palmar/plantar aspect of the cartilage is likely to be spared from the ossification process.[51]

In a radiographic study of 462 Finnhorses, 80% had evidence of sidebones, and large sidebones or separate centers of ossification were significantly more common in females than males.[53] Ossification of the cartilages in the forefeet was present in 93% of Brazilian jumpers.[40] Ten percent of Warmblood horses and 80% of draft horses had ossification of the cartilages of the distal phalanx, and the ossification was more extensive in draft horses than in Warmblood horses.[61] The lateral and medial cartilages were ossified equally in draft horses, but the lateral cartilages were more commonly involved in Warmbloods. In this same study it was concluded that ossification of the cartilage had no clinical significance.[61]

Etiology

The specific cause(s) of sidebones is(are) not clear.[53] It has been suggested that the tendency to develop sidebones is partly hereditary in certain horse breeds in Australia, Finland, and Sweden.[53,61] Hoof concussion causing trauma to the cartilage, poor conformation (particularly base narrow), and poor trimming and shoeing have also been proposed as inciting causes. One study documenting the incidence of sidebones in Finnhorses found that very few horses were base narrow and most horses were base wide and toed out.[53] Another study concluded that ossification of the cartilages was neither the cause nor the result of conformational adaptations of the front feet.[52] It has also been suggested that prolonged exercise and/or racing may have some preventative influence on ossification of the collateral cartilages. The amount of weight placed on the foot may also be contributory because primarily larger-breed horses develop sidebone.

Clinical Signs

Lameness resulting from sidebones is considered rare, and the clinical significance of radiographic apparent ossification is questioned.[5] One study found no correlation between the extent of ossification of the collateral cartilages and the onset of lameness.[61] Furthermore, despite the development of large sidebones in many Finnhorses, most horses performed satisfactorily without lameness.[53] However, large sidebones have been seen in horses associated with type I or II distal phalanx fractures by the author and were thought to contribute to the fracture and chronic lameness (Figures 4.35 and 4.43). A recent MRI study of horses with ossified ungual cartilages and a P3 facture found that all fractures occurred at the base of the ossified cartilage extending into the distal phalanx suggesting a biomechanical cause or focal stress point from cycling. However, these fractures were nonarticular and nondisplaced, but the ligaments and soft tissues adjacent to the ossified ungular cartilages were abnormal.[57]

In a scintigraphic study, a radiographically identified separate center of ossification could be detected with scintigraphy in 12 of 17 feet.[21,41,42] The authors suggested

VetBooks.ir

Figure 4.43. Standing dorsopalmar radiograph demonstrating a large uniaxial sidebone that was thought to contribute to lameness in this horse.

that scintigraphy may be useful to determine the clinical significance of ossification of the cartilages, prompting further clinical investigation such as uniaxial PD nerve block or advanced imaging.[41] However, another study by the same authors found considerable variation in the radiographic, scintigraphic, and MRI appearance of the palmar processes of the distal phalanx.[42] The study concluded that further investigation was needed to determine the clinical significance of the MRI abnormalities within the palmar processes. Currently, the clinical relevance of ossification of the collateral cartilages has not been documented but should be considered when clinical abnormalities associated with sidebones are found in lame horses.[5,21,42]

Sidebones may be visually apparent as an enlargement of the lateral and medial dimensions of the pastern region if the ossification is extensive. If the ossification involves the proximal extent of the cartilage, palpation may reveal an obvious firmness to the cartilage. Rarely is pain elicited with digital pressure. If present, the enlarged sidebone may contribute to the lameness or may be associated with a secondary fracture of the distal phalanx. A fractured sidebone reportedly causes more acute signs of lameness.[5] However, sidebones may accompany other lameness conditions of the palmar heel region (e.g. navicular syndrome) and may be mistaken for the cause. On the other hand, pain in the palmar heel region may originate from the axial projections of the ungual cartilages that extend toward the midline and have an abundant sensory nerve supply.[7]

Diagnosis

Radiographic examination of the foot usually reveals the extent of the ossification of the cartilage or cartilages (Figure 4.43). Occasionally a sidebone may appear fractured; however, the radiolucent defect must be differentiated from the junction between a separate ossification center and that part of the cartilage that is ossifying from the palmar process of the distal phalanx.[5,51] A fracture in the ossified cartilage can occur but is rare.

Documenting that sidebone is the cause of lameness in horses can be difficult. Asymmetrical swelling of pastern region, pain on palpation of the collateral cartilage, and improvement of the lameness with a uniaxial PD nerve block are suggestive of a problem in this region. However, the mere presence of an ossified cartilage without any other radiographic abnormalities is not diagnostic. The clinical relevance of these findings should be further documented with scintigraphy and/or MRI.[41,42]

Treatment

If sidebone is suspected as the cause of lameness, conservative treatment with rest, topical 1% diclofenac sodium cream (Surpass®), and oral administration of NSAIDs is recommended initially. External compression of the site together with cold-water therapy may also be beneficial. Any contributing foot problems such as foot imbalances should be addressed. Surgical removal of suspected fractured sidebones is not recommended. If lameness persists and sidebone is considered the cause of the lameness, a PD neurectomy can be performed but is usually unnecessary. Horses with sidebone and a secondary distal phalanx fracture are treated with corrective shoeing and confinement similar to a horse with a distal phalanx fracture alone (see type I and II P3 fractures).

Prognosis

The prognosis is difficult to predict because this condition is thought to rarely contribute to overt lameness.

SOLE BRUISES, CORNS, AND SUBSOLAR ABSCESSES

A bruise results from the rupture of blood vessels in the dermis (corium or sensitive tissue) beneath the sole, frog, or hoof wall. With time the hemorrhage spreads into the deep layers of the epidermis and becomes visible as the hoof grows. Accordingly, the discoloration associated with a sole bruise is most often seen several weeks after injury, whereas the same injury occurring in the hoof wall may take months before it becomes apparent.[27] Logically, bruises are most visible when the hemorrhage is superficial and the hoof is nonpigmented. It is likely the pain associated with the injury is due to the inflammatory response as well as the increased subsolar pressure.[31] If the bruised site becomes infected, a subsolar abscess is likely to develop.

A corn is a bruise that involves the tissues of the sole at the angle formed by the wall and the bar (Figure 4.44).[31] This site is often referred to as the seat of the corn. Corns occur most frequently on the inner angle of the front feet and are rarely found in the hindfeet.[31]

Etiology

Trauma to the sole is the cause of most sole bruising. However, sole bruising at the toe region may be secondary to an underlying condition such as chronic laminitis and flexural deformities.[27] Horses with flat feet, thin soles, and soft soles appear to be predisposed to sole bruising.[9] Also, horses that are barefoot, have their hooves trimmed too short, or have the sole protruding below the hoof wall appear more likely to develop sole bruising. Horses housed in muddy pens in freezing conditions, whether shod or not, often bruise their soles when the lumpy mud freezes hard.[31] Flat-footed horses that have repeated concussion to the sole adjacent to the white line because the sole contacts the inner aspect of the shoe may also develop sole bruises.[3] Any form of shoeing that concentrates weight-bearing on the sole is likely to cause bruising.

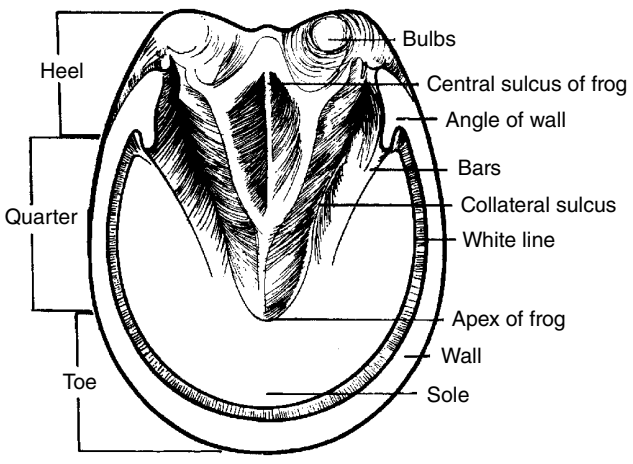

Figure 4.44. Normal forefoot showing anatomic structures.

Corns usually are caused by pressure from horseshoes or when a stone becomes wedged between the shoe and sole. They are rare among horses that are not shod. When shoes are left on too long, the heel may overgrow the shoe, causing selective pressure on the sole at the angle of the wall and the bar leading to a corn. Additionally, bending the inside branch of the shoe toward the frog to prevent pulling or stepping off the shoe can result in direct pressure to the sole, leading to bruising.[31] The application of a shoe that is one-half to one full size too small for the foot also increases the pressure on the sole area at the angle of the heels.[31] Heel calks usually enhance this effect.

Abscesses within the foot can develop from a variety of causes but are usually associated with bacteria entering a defect in the sole–wall junction, penetrating injuries into the foot, or occur secondary to another problem within the hoof (i.e. laminitis, keratoma, necrosis of the collateral cartilage, etc.). For example, "quittor" is the term used to describe necrosis and infection of the collateral cartilage of the distal phalanx characterized by multiple fistulous draining tracts proximal to the coronary band,[15,31] and "gravel" is the layman's term used to describe drainage proximal to the coronary band associated with ascending infection along the white line.[22,31]

Clinical Signs

The clinical signs associated with sole bruising or corns are often similar and variable. Most sole bruises occur at the toe or quarter regions and corns occur at the angle of the wall and bar. Occasionally the frog can be bruised as well.[25] The horse may show varying degrees of lameness (usually mild to moderate) depending upon the severity and type of the bruise or corn. The characteristics of the lameness and foot placement vary according to the location of the bruise or corn. If the bruise is acute or infected, the hoof may appear warmer and an increased digital pulse is often present.[25,31] Hoof testers often identify a focal site of pain unless the lesion is underneath the shoe at the white line. Perineural anesthesia may be required in some cases to exclude other sources of pain causing lameness.

Horses with foot abscesses are typically very lame and often non-weight bearing. Increased heat is often palpable in the foot and distal limb and an increased digital pulse is commonly found. Hoof tester pain is typically severe, and in some cases digital pressure at the site of the abscess causes a painful response. Increased swelling at the coronary band (especially at one heel bulb) may be present if the abscess has migrated up along the hoof wall. For example, ascending infection of the white line occurs when an opening at the sole–wall

VetBooks.ir

junction that permits infection to invade the laminae, which follows the path of least resistance to break open and drain at the coronary band. However, the condition may go undiagnosed until drainage at the coronary band is observed. Signs of lameness may also vary depending on the severity and location of the infection.

Diagnosis

A tentative diagnosis can often be made based on the history and clinical signs. If pain is localized to the foot but there are no obvious external abnormalities, the shoe should be removed and the sole explored by removing the exfoliating (flaky) sole with a hoof knife. Acute sole bruises may not be readily apparent because the hemorrhage has not migrated far enough distally. Chronic bruises are usually visible as a stippled reddened region.[31] In some cases the discoloration may be bluish, especially if a sole abscess is developing. Sole abscesses may have a small defect in the sole where the abscess is trying to break through the sole. Alternatively, a large-bore needle can be inserted through the soft sole to confirm the presence of purulent material beneath (Figure 4.45). Removing a small area of sole around this defect may also reveal purulent material, confirming a subsolar abscess. Hoof tester pressure at the site usually causes purulent material to exit the sole defect. Focal swellings at the coronary band (dorsally and at the heels bulbs) may suggest ascending infections along the white line even when no defects can be detected on the solar surface of the foot. In these cases, a definitive diagnosis often is not made until the abscess breaks out at the coronary band.

Acute sole bruises may not be evident radiographically unless a serum pocket or abscess has developed. Many subsolar abscesses may be seen radiographically as a gas pocket within the sole (Figure 4.46). However, many are not visible, depending on the radiographic projections, and the lack of radiographic abnormalities does not rule out an abscess. Chronic sole bruising may be associated with demineralization, increased vascular channels, and irregularity of the solar margin of the distal phalanx.[27] Chronic abscessation may be due to an underlying condition such as laminitis or keratoma and may contribute to osteolysis of the distal phalanx and sequestrum formation.

Figure 4.45. This horse was non-weight-bearing lame with no evidence of a hoof abscess or fracture. Focal pain was detected near the lateral heel and insertion of a 16-gauge needle confirmed the suspicion of an abscess.

Figure 4.46. This horse with a type II P3 fracture became acutely lame 2 months after diagnosis. A dorsopalmar radiograph demonstrated a fluid pocket (arrow) consistent with an abscess.

Treatment

Many bruises often resolve without treatment if the source of the trauma is removed. The horse should be rested from heavy work, especially if the soles are abnormally thin. When possible, the environment should be changed so that the horse is not worked on rough ground. If the horse must be used, the sole can be protected with a full pad applied under the shoe. The pad should be placed to avoid pressure to the bruised site. Wide-web shoes may also be beneficial to relieve pressure on the sole. Light paring of the sole overlying the bruise often relieves the pressure and makes the horse more comfortable.[25]

Drainage is the key to treating suppurative bruises and other subsolar abscesses. A small amount of sole overlying the abscess should be removed to permit ventral drainage. Removing a large amount of sole should be avoided because this is usually not necessary for drainage and prolongs the healing time. The foot can then be soaked in antiseptic solution if desired, and the foot bandaged. Once the abscess has resolved, the sole can be protected with protective boots or shoes until the defect has completely keratinized. If an ascending infection of the white line is suspected but cannot be confirmed (no drainage at the coronary band), soaking or poulticing the foot may draw the infection to the surface. When the abscess comes to a "head" just proximal to the coronary band, drainage can be established by lancing the abscess.[3,25,31]

VetBooks.ir

In cases in which shoeing contributes to the bruising, removal of the shoe may be all that is necessary. The horse should be rested and should not be reshod until symptoms disappear. If the horse must be used, the wall and bar in the region of the corn should be removed to prevent pressure by the shoe. A complete support shoe can be applied to allow the frog to absorb the concussion that would normally be distributed to the corn area. Another option is to apply a wide-web shoe that has been concaved out at the damaged region to decrease the pressure on the bruised site. To prevent shoes from causing corns, the heels of the shoes should extend well back on the buttresses and should fit full on the wall at the quarters and heels.[31]

Prognosis

The prognosis is usually very good for horses suffering from a single traumatic episode and in those with good foot conformation. The prognosis is reduced in horses with poor hoof conformation that are continually worked on hard ground because recurrence is common. Many of these cases develop chronic sole bruising, which eventually may lead to chronic abnormalities within the distal phalanx. Horses with routine foot abscesses also have a very good prognosis, provided the infection does not involve deeper structures in the foot. It should always be remembered that subsolar abscesses may be associated with other conditions of the foot such as keratomas, infection of the collateral cartilages, chronic laminitis, and septic pedal osteitis (PO) (Figure 4.47).

SEPTIC PEDAL OSTEITIS

Septic PO refers to bacterial infection within the distal phalanx. It can occur as an extension of a subsolar abscess, secondary to penetrating injuries or from hematogenous spread in foals. Radiographically the condition usually appears as a focal or diffuse radiolucency of the bone (osteolysis).[6,9] The distal phalanx does not have a medullary cavity, so inflammation/infection of this bone is referred to as osteitis rather than osteomyelitis.[11]

Figure 4.47. This horse had what was thought to be a routine abscess at the toe (arrow), but a lateral radiograph revealed chronic laminitis.

Etiology

Environmental microbes gain access to the distal phalanx either by direct introduction of bacteria by deep penetrating injuries, extension of infection from the soft tissues of the foot into the distal phalanx, or from hematogenous sources in foals.[23,31] Septic PO in foals should be considered as a potential site for hematogenous spread of infection associated with the septic arthritis/joint ill syndrome.[24] One study found that 8 of 22 foals with septic PO had multiple other foci of infection and none of the foals had a history of a penetrating wound or subsolar abscess.[23] Other causes of septic PO in adult horses include chronic severe laminitis, subsolar abscesses (most common), solar margin fractures, deep hoof wall cracks, avulsion hoof injuries, and penetrating wounds of the foot.[6,11,19] A sequestrum may develop in the distal phalanx as the osseous infection progresses.[6,16] In a review of 63 horses treated for septic PO, subsolar abscesses were the most common cause (56%) followed by solar margin fractures (25%) and penetrating wounds (13%).[19]

Clinical Signs

Septic PO occurs most commonly in the forelimbs in adult horses and in the hindlimbs in foals.[6,23] The forelimbs were affected twice as commonly as the hindlimbs in one study,[7] and 11 of 18 cases involved the forelimbs in another study.[6] The severity of lameness in horses with septic PO is usually severe (in one study over 50% of the horses were grade 4 of 5 lame), and the lameness may be chronic (average duration of lameness prior to presentation in one study was 18.5 days).[6,19] Increased hoof temperature and prominent digital pulses are common in the affected limb. Hoof tester exam may be beneficial to localize the site of pain as well as to promote abscess drainage in some cases. Perineural anesthesia of the PD nerves may not eliminate the lameness in all horses with septic PO. No or minimal response to PD nerve block was seen in 5 of 5 cases of septic PO, and all 5 cases improved after an abaxial sesamoid nerve block.[6]

Diagnosis

Radiographic signs suggestive of septic PO are usually straightforward and are consistent with areas of bone infection (Figure 4.48). CT examination of the foot can often provide more detailed information but is usually unnecessary to make a diagnosis. Generally, there is a loss of trabecular detail (osteolysis) with indistinct margins fading into the surrounding bone.[31] Sequestra may develop but marginal sclerosis is rarely observed in these cases (Figure 4.49).[19] Radiographic examination of 18 horses diagnosed with septic PO revealed discrete osteolysis at the margins of the distal phalanx (13 of 18 cases), gas density adjacent to the bone on 2 different radiographic projections (15 of 15 cases), focal (9 cases) or diffuse (3 cases) decrease in bone density, generalized roughening of the solar margin of the distal phalanx (7 of 18 cases), and widening of the vascular channels (13 of 18 cases).[6] Sequestra were identified in 4 horses.[6] In foals with septic PO, evidence of localized lysis or focal loss of bone density was observed

VetBooks.ir

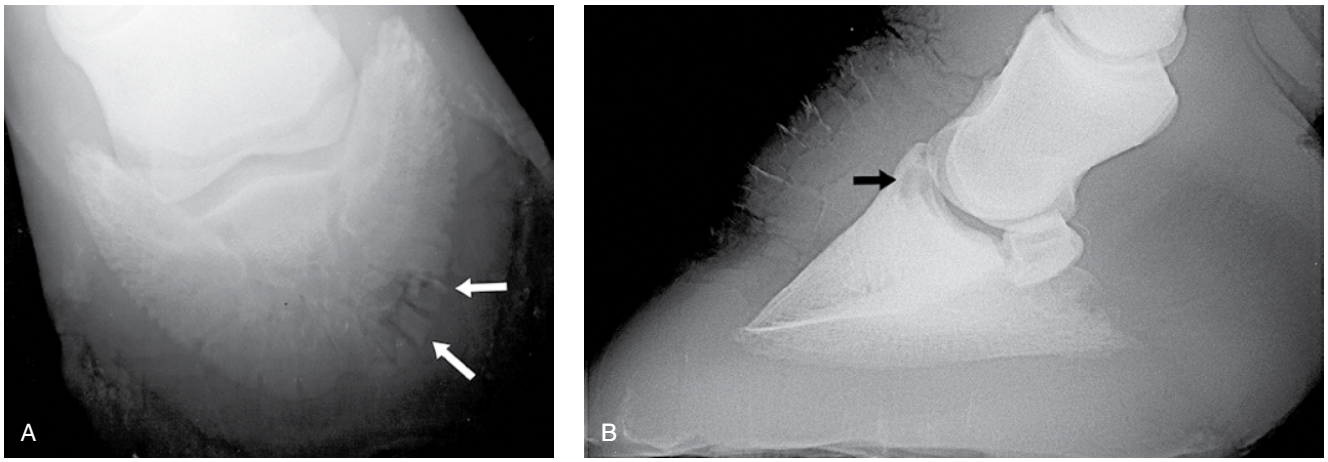

Figure 4.48. Dorsopalmar (A) and lateral radiographs (B) of the feet in two adult horses with severe lameness due to infection of the distal phalanx. Osteolysis of the solar surface (A; arrow) and extensor process (B; arrow) of the distal phalanx is evident consistent with infection.

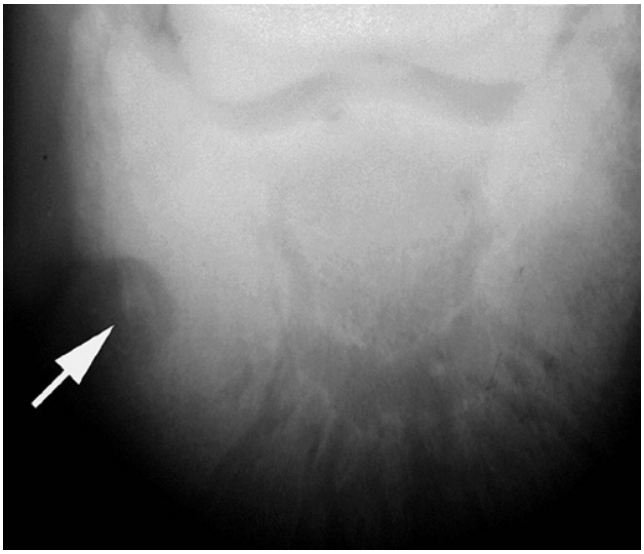

Figure 4.49. Dorsopalmar radiograph of a horse with a chronic draining tract from the solar surface of the foot. Lysis and a sequestrum can be seen along the solar surface of P3 (arrow).

Figure 4.50. The sequestrum in image 4.49 was removed through the solar surface of the foot.

at the toe (14 of 22 cases), extensor process (5 of 22 cases), or the palmar/plantar process (3 of 22 cases) of the distal phalanx.[23]

Treatment

Treatment of septic PO usually involves systemic and local antimicrobials (regional limb perfusion) and surgical debridement of the infected bone.[6,7,9,11,23] Surgical debridement may not be indicated in all cases depending on the location within the bone (i.e. extensor process in foals).[23] Debridement can be performed with the horse standing if the solar surface of the distal phalanx is involved (Figure 4.50). However, general anesthesia is often necessary to permit accurate location of the lesion, especially if a draining tract is not present, and for thorough debridement. In most cases the site of infection is approached through the draining tract, which is usually located on the sole. The abnormal bone is debrided and a sample submitted for culture and sensitivity. Regional IV limb perfusions can be repeated as needed after surgery to help treat the infection (see Chapter 12 on musculoskeletal emergencies for more details). One study reported that up to 24% of the distal phalanx could be removed without long-term adverse effects.[11]

Prognosis

The prognosis for horses with septic PO appears very good to excellent if the infection can be controlled.[7,31]

VetBooks.ir

Of 33 cases of septic PO in which follow-up was available, all 33 horses returned to their intended use.[19] In other studies, 7 of 9 horses returned to their intended use,[11] and 13 of 18 had a favorable outcome despite a high incidence of sequestra and fractures.[6] Foals with septic PO also have a good prognosis; 86% of the foals survived, 16 of 22 foals reached racing age, and 11 of these raced.[23,24]

PENETRATING INJURIES OF THE FOOT

Penetrating injuries of the foot are commonly seen in equine practice. The injury is often sustained by the horse stepping on (bottom of the foot) or contacting (coronary band, heel bulbs, and pastern region) a sharp object. Although any deep penetrating injury to the foot can potentially be serious, those that penetrate the central third of the frog, the coronary band, and the heel bulbs are at greatest risk to involve deeper vital structures. Structures at risk with injuries to the central third of the frog include the navicular bursa, navicular bone, DDFT, or distal phalanx. Coronary band injuries may involve the DIP joint, distal phalanx, and collateral cartilages of the distal phalanx. Injuries to the heel bulb region are most likely to damage the digital flexor tendon sheath, DDFT, or palmar/plantar aspect of the DIP joint. Injuries elsewhere on the bottom of the foot most likely only damage the digital cushion or the solar surface of the distal phalanx and are usually less problematic. Early identification of the involvement of a deeper vital structure and aggressive medical and surgical treatment greatly affect the outcome of horses with these injuries.[2,3,9,29] See Chapter 12 for further information about treating septic synovial structures.

Clinical Signs

The clinical signs caused by penetrating injuries may vary depending on the depth (superficial vs. deep), location (sole vs. coronary band), and duration (acute vs. chronic) of the injury.[3] In general, the more superficial the injury, the less severe the clinical signs. Horses with minor injuries to the sole that may remain asymptomatic for several days until a subsolar abscess develops are the exception. These types of injuries penetrate the cornified layer of the sole into the digital cushion but do not cause clinical signs unless an abscess develops. Deep injuries that penetrate completely through the hoof wall and contact a bone, tendon, or synovial cavity typically cause severe and acute lameness. Also, horses with wounds in the frog region that involve vital structures usually become rapidly symptomatic.

Affected horses often point the foot and resist contacting the heel (walk on the toe) when walked.[3,32] Palpation of the hoof in any horse with a penetrating injury may reveal increased heat, and a prominent digital pulse can usually be palpated.[2] Careful examination of the sole (visual, hoof tester, and probing) and coronary band is important. It has been stated that any penetrating wound of the foot deeper than 1 cm should be considered serious (Figure 4.51). The approximate reported depths of a perpendicular penetration before vital structures become involved were 1 cm for the sole, 1.5 cm for the frog, and 1.2 cm for the hoof wall.[3]

Figure 4.51. This horse had a history of stepping on a farriery nail with its hindfoot 24 hours previously. Exploration of the tract revealed that it had penetrated through the digital cushion to the solar surface of the third phalanx.

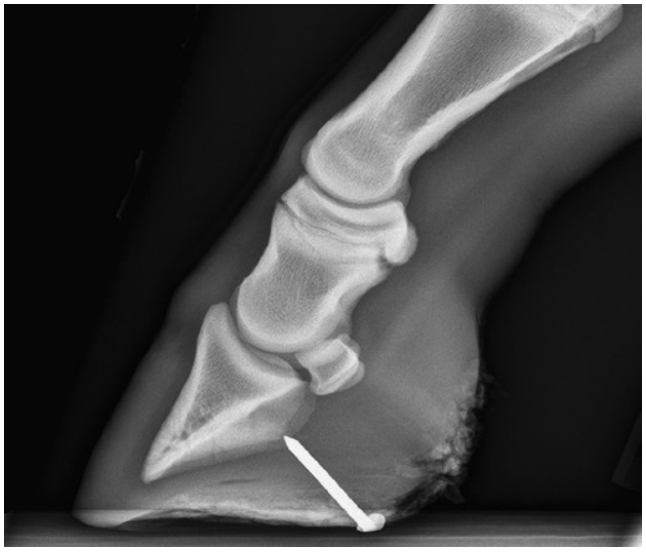

Figure 4.52. Taking radiographs of the foot prior to removing the foreign body can help identify the direction and depth of the puncture.

If a foreign body such as a nail is present in the bottom of the foot, it is ideal to take a radiograph to determine the exact depth and direction of the nail's path before removing it (Figure 4.52).[1,29] However, this is not always possible, and care should be taken to avoid deeper penetration of the nail during the process. If a wound is not obvious, careful application of hoof testers may help identify focal pain, which may indicate the site of penetration. Once a focal site of pain is found in the sole or frog, it is explored with a hoof knife. If the injury is acute (before infection) and involves the sole, a crack or small hole may be the only abnormality found.[3] In most cases, puncture wounds of the sole appear black at

VetBooks.ir

the entry site. With more chronic penetrating injuries, small areas of granulation tissue may be evident on the sole (Figure 4.53).

Wounds that penetrate the frog can be particularly difficult to locate because the softer and more elastic tissues of the frog tend to collapse and fill in the tract. Careful removal of the frog is often required to visualize the entry site. Probing of the tract can help identify both the depth and direction of the injury. A radiograph can be taken with the probe placed into the tract to further verify its location (Figure 4.51). If infection is present, gentle pressure with the thumbs or hoof testers around the entry hole may cause purulent exudate to exit the tract.[3] Perineural anesthesia is usually not needed to localize the site of lameness but is very beneficial to facilitate close examination of the injury site and removal of the frog or sole if needed.

Palpation of the coronary band for heat, pain, and swelling may also be helpful to identify the location of a penetrating wound to this region. A penetrating wound of the coronary band can be overlooked if the hair is long or if local swelling and wound drainage are not present. Once identified, wounds at the coronary band should be carefully probed and explored because they may contain foreign material such as wood.

Heat, pain, and swelling of one heel bulb are often seen with migration of a subsolar abscess. Effusion of the digital tendon sheath or DIP joint may suggest infectious synovitis.[1,14,29] Synovial fluid analysis can usually be used to confirm the diagnosis. An increased white blood cell count (more than 30,000) with neutrophilia, a pH below 6.9, and an increased protein (more than 4.0 g/dL) are highly suggestive of a septic process.[1,3,29]

Diagnosis

Additional diagnostics that can be performed to confirm the location and depth of a penetrating injury include distension of a synovial cavity with saline to detect leakage from the wound, plain radiographs, radiographs with a metallic probe inserted in the wound, contrast radiography (fistulogram), or ultrasound.[1,29] Plain radiographs may reveal the presence of gas that can be seen with a subsolar abscess or penetration of a synovial cavity. Concurrent fractures and osteolysis due to infection may also be visible. Placement of a metallic probe confirms depth and direction of the injury (Figure 4.51), and contrast radiography often confirms penetration of a synovial cavity (Figure 4.54). Ultrasound may be helpful to document injuries to the DDFT and involvement of the digital flexor tendon sheath. Cross-sectional imaging (CT and MRI) can also be very helpful to confirm both the location and the presence of infection especially when other diagnostics are equivocal (Figure 4.55).

Treatment

Treatment of superficial penetrating wounds that do not involve vital structures (bone, tendon, or synovial cavities) is generally uncomplicated. Treatment is aimed at providing adequate drainage, removing infected and necrotic tissue, and protecting the site from further contamination.[25,31] The majority of cases can be treated in the standing sedated horse using the help of perineural anesthesia. Drainage is established by removing a small amount of adjacent sole or frog with a sharp hoof knife (loop hoof knives work well) and/or a hoof groover. Underlying necrotic/infected tissue should be removed with a standard curette, hoof curette, or nail hole curette.[31] An antiseptic dressing is applied and the foot is protected to minimize further contamination. More extensive superficial infections may require periodic flushing or soaking of the foot together with bandaging and foot protection.

Figure 4.53. Chronic penetrating injuries to the foot may be identified by small areas of granulation tissue on the sole (white arrow).

Figure 4.54. Contrast radiography can be helpful to document synovial involvement in horses with chronic penetrating injuries of the frog and sole. The puncture in this horse had completely healed, but the horse developed an abscess just above the heel bulb. Contrast injected into the abscess communicated with the navicular bursa.

VetBooks.ir

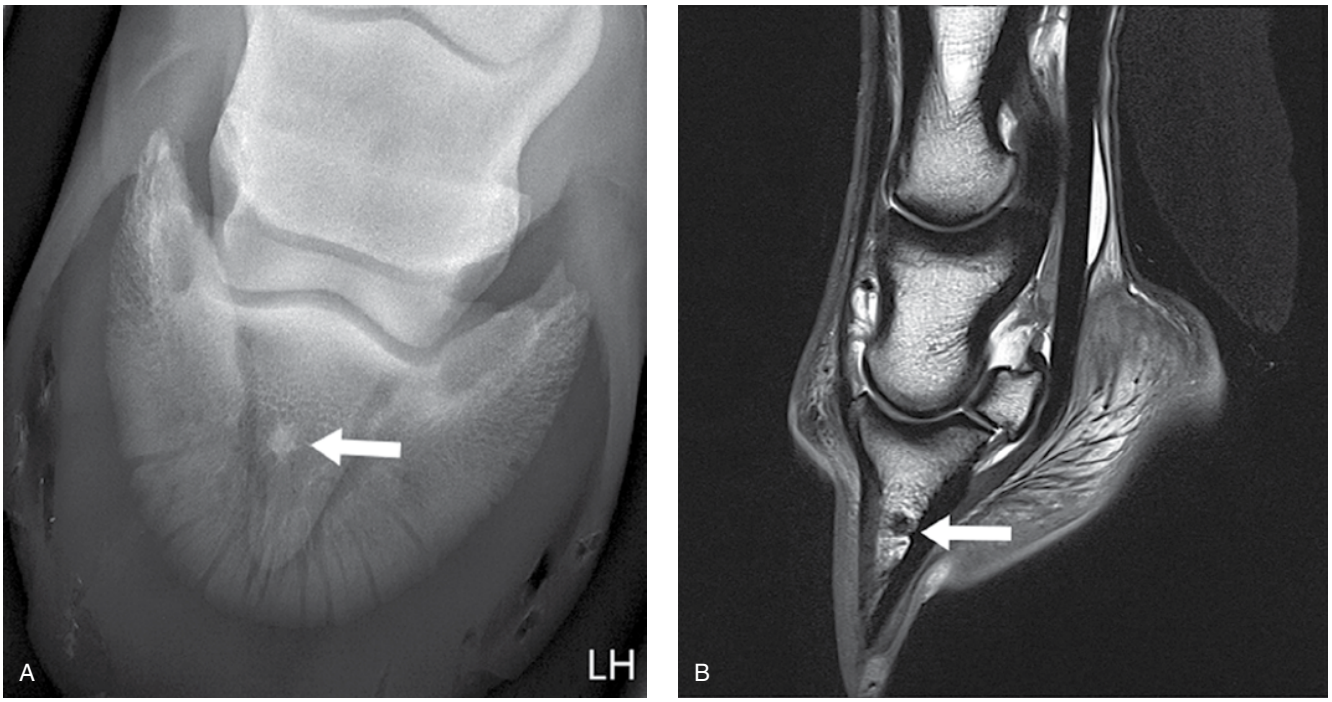

Figure 4.55. Dorsopalmar radiograph of the distal phalanx of a lame horse revealed a focal radiodense area in the center of the distal phalanx (left; arrow) that was confirmed with MRI (right; arrow). The lesion was later identified as a well-circumscribed P3 sequestrum.

Penetrating injuries that involve bone, tendon, or synovial cavities require more aggressive treatment depending on the deeper structure that is involved. Typical treatments include both systemic (IV) and local (IV regional perfusion and intrasynovial) antimicrobials, NSAIDs, local debridement of the wound, and lavage, endoscopy, or arthroscopy if a synovial cavity is involved. Wound debridement may be performed in the standing patient, but it usually best performed with the horse under general anesthesia. Lavage, endoscopy, or arthroscopy of a synovial cavity usually requires general anesthesia. Wounds that penetrate the distal phalanx should be enlarged and the distal phalanx curetted if possible as further progression of the infection into the bone is not uncommon (Figure 4.56). Soaking the foot to lavage deep wounds of the foot is generally not recommended. Involvement of the navicular bursa is best treated with endoscopy or lavage and local debridement of the defect in the frog.[1,2,33] See the section on musculoskeletal emergencies in Chapter 12 for further information.

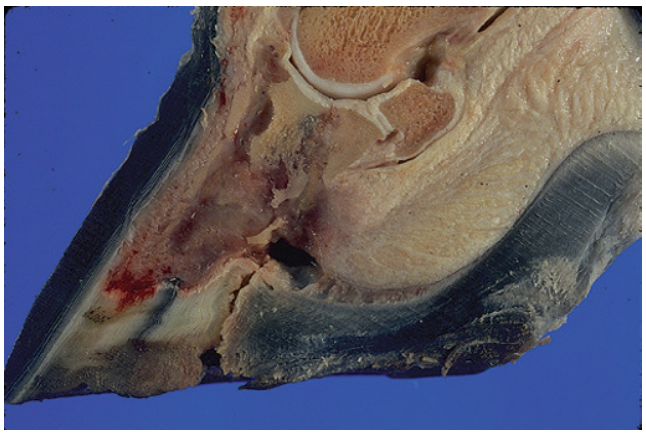

Figure 4.56. Sagittal section of P3 in a horse that sustained a puncture wound to the solar surface of P3. Subsequent infection of P3 contributed to a pathologic fracture of the bone and involvement of the DIP joint.

Prognosis

Horses with penetrating injuries that do not involve bone, tendon, or a synovial cavity typically do very well.[18] Horses with penetrating injuries outside the frog or frog sulci and centrally located in the foot also do well. A recent study reported that 91% of horses with penetrating injuries of the foot without synovial involvement and treated conservatively returned to their previous level of soundness.[18] In another study of 50 horses with deep puncture wounds of the foot, 95% of horses with injuries outside the frog or frog sulci regained full athletic soundness.[32] Horses with synovial involvement following solar foot penetration have a poor prognosis (36% and 29% in two recent studies) for return to preinjury athletic function.[10,18] In general, prompt treatment of any penetrating injury to the foot regardless of the structure(s) involved improves the chance of a successful outcome.[2,18]

KERATOMA

Keratoma is an uncommon condition of the hoof that is characterized by keratin-containing tissue growing between the hoof wall and the distal phalanx. Although the term implies a neoplastic process, histologic

VetBooks.ir

examination reveals abundant keratin, squamous epithelial cells, occasionally granulation tissue, and inflammatory cells.[13,20] The growth usually begins near the coronary band, but it may extend to the solar surface anywhere along the white line.[31] A visible deviation of the coronary band and/or hoof wall is often present, and the most commonly affected areas of the foot are the toe and quarter.[20] Occasionally a keratoma may be located at a focal site between the coronary band and sole. Lameness and the radiographic changes are thought to arise from the growth of the keratoma and the subsequent pressure that is applied to the sensitive lamina and distal phalanx.[20] Keratomas have been observed in horses ranging from 2 to 20 years of age and should be differentiated from other growths that can occur in the hoof such as squamous cell carcinoma, canker, and melanoma.[20,31] In addition, multiple keratomas may be present in the same foot, but this is uncommon.[8,17]

Etiology

Trauma and chronic irritation in the form of sole abscesses or direct hoof injuries are the cause in the majority of cases.[20,31] However, a keratoma can develop without a history of previous injury, and the initiating cause often cannot be determined.[17,31]

Clinical Signs

A history of a slow onset of intermittent lameness is common. The lameness is often seen before the distortion at the coronary band and hoof wall becomes obvious. Moderate to severe lameness is commonly observed at presentation.[17,20,31] The coronary band and hoof wall may or may not be abnormally shaped, and close examination of the foot may be required to identify any abnormality. In some cases a fistulous tract may develop in the sole or hoof wall, mimicking a subsolar abscess.[5,16] Common clinical signs of keratomas in one retrospective study were lameness and the presence of a subsolar abscess.[5] Hoof tester examination often elicits a painful response when pressure is applied over the lesion. Although perineural anesthesia of the PD nerves at or below the level of the collateral cartilages often improves the lameness, a basisesamoid or abaxial sesamoid block may be required to completely eliminate the lameness.

Diagnosis

A definitive diagnosis of keratoma is usually made based on the characteristic radiographic features. A discrete semicircular defect in the distal phalanx is often seen (Figure 4.57).[5,31] However, the absence of a discrete radiolucency cannot be used to rule out the presence of a keratoma.[17,20] The radiographic signs of a keratoma can usually be differentiated from lysis due to infection because of the smooth borders and lack of a sclerotic margin. Ultrasonographic imaging of a keratoma has been reported, and a hypoechoic, well-delineated soft tissue mass between the hoof wall and the articulation of the distal and middle phalanges was seen.[30] However, cross-sectional imaging (CT or MRI) is currently the preferred technique to both definitively diagnose and accurately localize keratomas within the hoof wall

Figure 4.57. Dorsopalmar radiograph of P3 demonstrating a smooth margined lytic defect within the bone that is characteristic of a keratoma. *Source*: Courtesy of Dr. Scott Katzman.

(Figure 4.58).[12,17] The use of CT to accurately localize keratomas was recently reported to minimize the amount of hoof wall that needed to be removed and reduced postoperative complications in operated horses.[17]

Treatment

Treatment usually involves complete surgical removal of the abnormal growth. In one study only 42% of horses treated without surgery (12 horses) returned to performance compared to 83% that were treated with surgery (23 horses).[4] Incomplete removal of the keratoma is thought to result in recurrence of the growth.[17,20,31] Surgery may be performed with the patient under general anesthesia or while the patient is standing using regional anesthesia and sedation.

Partial hoof wall resection directly over the location of the keratoma is the preferred technique. Using CT to localize the keratoma preoperatively was recently shown to improve the accuracy of hoof wall removal and facilitate complete removal.[17] Windows within the hoof wall can be made with a motorized burr, a cast cutting saw, oscillating saw, or an osteotome (Figure 4.59). Alternatively, the hole in the hoof wall can be made with a large Galt trephine. Multiple trephinations can be performed to adequately expose the lesion. The major advantage to this approach is the relative lack of disruption of the hoof wall.[16,17] Regardless of the technique, the overall goal of surgery should be to remove as little hoof wall as possible to facilitate complete removal of the keratoma.[5,16,17]

Prognosis

The prognosis is generally very good for return to performance if the abnormal tissue is completely removed.[4,5,12,17] Using cross-sectional imaging (CT or MRI) is thought to facilitate more accurate localization of the keratoma, enabling a smaller hoof wall resection and an improved prognosis.[12,17] Postoperative complications may be decreased by creating smaller hoof defects, filling the defects with antimicrobial-impregnated polymethylmethacrylate, and placing a shoe early in the postoperative period.[12] In one large study, 25 of 26 horses returned to their previous exercise level,[5] and the most recent study indicated that 28 of 31 horses returned to their previous activity level.[17] Complications occurred in only 4 of 31 (13%) horses.[17] Adequate stabilization of the hoof defect and complete removal of the lesion are important for a successful outcome.[5,12,17]

AVULSION INJURIES OF THE HOOF

Avulsion injuries of the foot region are relatively uncommon in horses but can be very serious and difficult to manage. The injuries can be categorized as complete (when the tissue is totally removed) or partial or incomplete (when the tissue remains intact on at least one border).[26,31] These injuries may involve the hoof wall, coronary band, pastern region, sole, and structures deep to the hoof capsule (e.g. distal phalanx, digital cushion, laminae, synovial cavities). In general, the seriousness of the injury is related to the depth of the avulsion and the amount of tissue that is removed. However, even with significant loss of germinal tissue, the foot has the capacity to heal, although slower than other tissues, with complete reformation of hoof wall structures if treated properly for a long enough period.[26,27,31] The foot region has limited ability for wound contraction; therefore, the wound heals primarily by epithelialization and reformation of the corium.[28,31] These processes require a healthy bed of granulation tissue and a stable, clean environment to prevent permanent hoof defects.

Complete or incomplete avulsion injuries of the coronary region may result in deformities and/or permanent hoof wall defects if not treated properly (Figure 4.60). However, if treated promptly and correctly, the majority heal without problems.[21,28,31] In addition, partial loss of the distal phalanx, digital cushion, or collateral cartilages does not appear to reduce the prognosis of affected

VetBooks.ir

Figure 4.60. Abnormal coronary band and hoof growth associated with a previous injury to the medial aspect of the coronary band.

horses for future soundness. However, secondary infection of deeper hoof tissues usually reduces the chances of a complete recovery. The time required for healing depends on the size and extent of the avulsion injury and the method of treatment. Generally, 3–5 months are needed for second intention healing of complete avulsion injuries, compared with 3–4 weeks for incomplete avulsions that are surgically repaired.[21,28]

Etiology

Incomplete avulsion of the hoof wall of the heel can be caused by vertical tears of the hoof wall, kicking or stepping on sharp objects, continued foot imbalance, and improper shoe removal in which nails are torn out of the heel and quarter regions.[28,31] Other avulsion injuries of the foot and pastern are usually caused by lacerations from sharp objects. The horse either steps on or kicks at a sharp object, or the foot becomes entrapped, resulting in the avulsion. These are commonly seen as heel bulb lacerations that often involve the hoof.

Clinical Signs and Diagnosis

The degree of lameness usually varies with the duration, extent, and location of the avulsion injury. Moderate lameness is usually seen with an acute superficial injury that does not involve deeper structures. More extensive avulsion injuries usually cause severe lameness. Gentle manipulation of the foot and phalanges can provide important information regarding the status of support structures. Involvement of deeper structures such as the DIP joint, navicular bursa, and the digital tendon sheath should be identified.[3]

For chronic avulsion injuries, varying degrees of lameness may be present. If the wound heals without problems, lameness usually subsides with time. However, if lameness and purulent exudate persist, further diagnostics such as probing the wound with a sterile probe, radiography, contrast radiography, and ultrasonography should be performed to determine the cause of the continued drainage and lameness.[3] A chronic nonhealing wound with drainage usually suggests continued infection of deeper structures or involvement of a synovial cavity.

Treatment

Incomplete Avulsion (Coronary Band Not Involved)

Incomplete avulsions of the hoof wall at the heel and quarter without involvement of the coronary band are usually best removed.[28] Attempts to salvage the hoof wall are often unrewarding and contribute to continued lameness and infection beneath the avulsed hoof wall (Figure 4.61). Removal also prevents the wall from being snagged and continually traumatized, which is often very painful.[3]

The hoof wall can be removed with the horse standing for limited involvement or under general anesthesia for larger lesions. Sharp hoof knives, nippers, and a handheld electric drill (Dremel tool) to burr the hoof wall at its attachments may be used for removal.[28,31] The dorsal attachment of the unaffected hoof wall should be beveled flush to the wound so there is little tendency for it to be snagged, resulting in further separation. The wound should be bandaged and protected from contamination and trauma until the exposed tissues become keratinized. A full-support shoe can be used to provide hoof wall stability and to reduce weight-bearing on the hoof defect by "floating" the involved heel.

Incomplete Avulsion (Coronary Band Involved)

Incomplete avulsion injuries of the coronary band alone or the coronary band and hoof wall are best managed by suturing the wound whenever possible. Reapposition of the coronary band is important to prevent future hoof deformities.[26,27] Often the hoof wall cannot be salvaged and will require removal, but the coronary band should be reconstructed in any way possible (Figure 4.62). Lacerations of the coronary band without loss of hoof wall should be sutured primarily and immobilized in a foot cast (Figure 4.63). Avulsion injuries that affect the coronary band and a small portion of the hoof wall can also be sutured and immobilized. The hoof wall adjacent to the defect can be thinned with a hoof rasp, and the separated piece of hoof wall can be thinned with a motorized burr to permit suturing.[28,31]

When the avulsion injury extends from the solar surface proximally through the coronary band, the majority of the hoof wall can be removed to within 1 cm of the coronary region, and the coronary band and soft tissues sutured if possible. Alternatively, the hoof wall can be included in the closure by thinning the walls adjacent to the defect with a Dremel tool. Regardless of the technique, accurate approximation of the coronary band is important. If left untreated, these incomplete avulsion injuries of the coronary band often remain elevated, eventually producing a horny spur at the distal extremity of the avulsion, while the remaining underlying tissue heals by scarring and epithelialization.[26,28,31] Invariably these avulsions protrude above the skin and hoof wall surface, making them susceptible to further trauma and painful to palpation. If the avulsed tissue is just removed, a permanent hoof wall defect will often develop (Figure 4.60).

Complete Avulsion

With complete avulsion injuries of the hoof, there is usually no tissue to appose and the wound and hoof defect heal by second intention (Figure 4.64). The initial

VetBooks.ir

Figure 4.61. Before (A) and after removal (B) of an incomplete hoof avulsion of the medial quarter of the hindfoot.

Figure 4.62. Before (A) and after (B) reconstruction of an incomplete hoof avulsion that involved the coronary band, sole, and frog. Realignment of the coronary band should be performed whenever possible.

VetBooks.ir

Figure 4.63. A sharp laceration of the coronary band (A) was debrided and closed primarily (B) to prevent aberrant hoof wall growth.

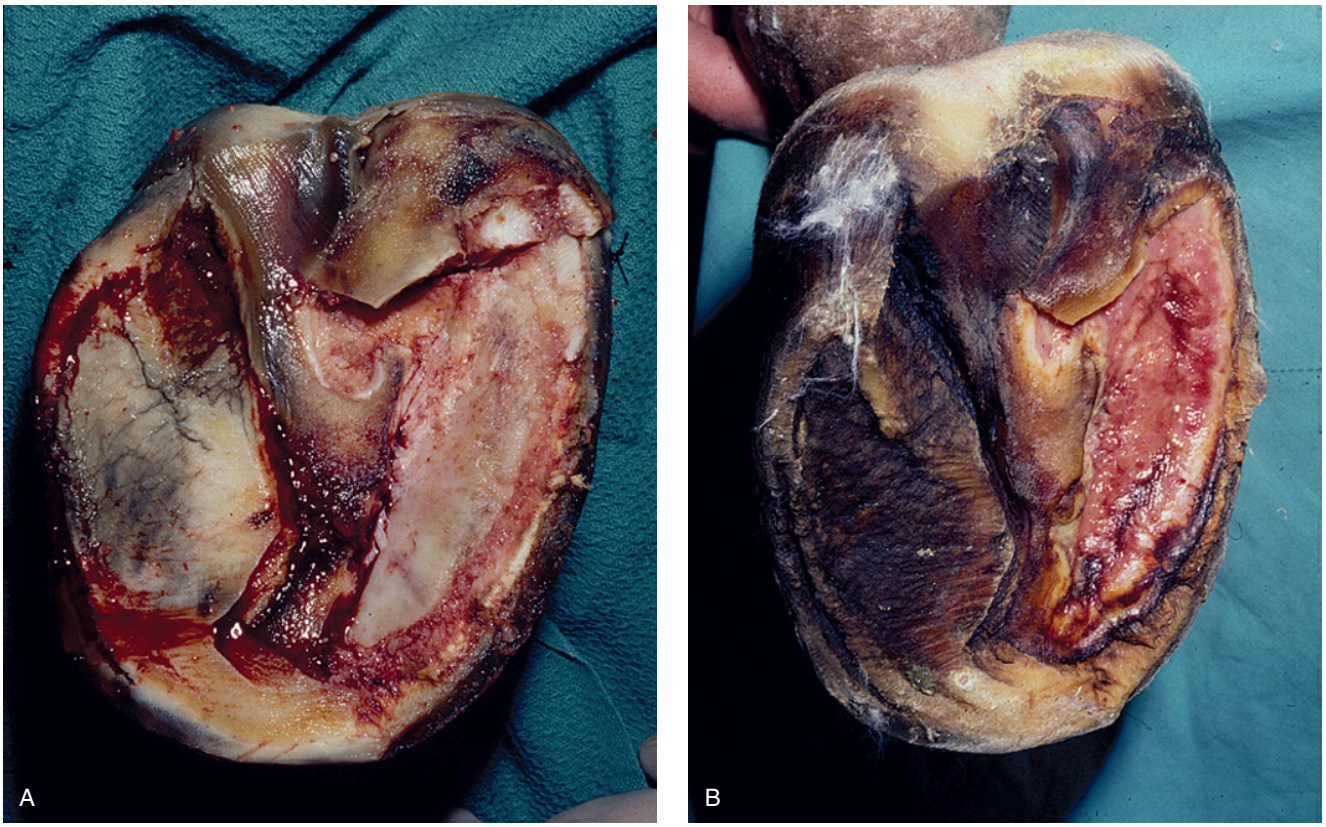

Figure 4.64. Complete avulsion of the sole with exposure of the solar aspect of P3 (A) and the same defect after it has filled with granulation tissue (B).

clinical picture is usually that of a hemorrhagic wound with obvious tissue loss.[26] The depth of the defect and potential involvement of other structures should be determined prior to treatment because their involvement affects both the type of treatment recommended and the prognosis. The practical treatment of these wounds in terms of bandaging, the use of systemic and local antimicrobials, and local wound care follow the same guidelines used to treat other limb wounds in horses.[26] Many of these wounds can be bandaged initially to control

VetBooks.ir

hemorrhage and permit repeated lavage and debridement of the wound. However, immobilization with a foot cast is often very beneficial in the long-term management of these injuries. Casts are usually left in place for 3–4 weeks and may need to be reapplied depending on the size and location of the avulsion. Wound stability is thought to improve the chances of complete reformation of the hoof wall.[31]

Hoof avulsions heal by similar processes to other open wounds, but healing is often protracted because wound contraction is limited in the foot. Wounds must heal be epithelialization and reformation of the corium, which often requires 3–5 months, depending on the size of the defect.[28] There are several types of germinal epithelial tissues in the foot (skin, limbic, coronary, parietal, and solar), and all can contribute to epithelialization of the defect.[26,27] The structure and quality of the hoof that forms is related to the type of epidermis that migrates over the surface of the wound.[26] Epithelial cells that migrate aberrantly can lead to hoof deformities.[26,27]

For instance, if epidermis from the parietal integument grows into the space formerly occupied by the coronary band, the wall generated in that location will not resemble wall generated from the coronary integument. If epidermis from the hoof migrates proximally to the coronary band, a horny spur will form in the pastern region.[26] One of the goals of treating complete hoof avulsion injuries is to prevent aberrant migration of epithelial cells and hoof wall deformities (Figure 4.60).

Prognosis

Generally, incomplete avulsion injuries of the hoof wall alone and/or including the coronary band have a very good functional and cosmetic outcome if they are sutured.[21,28,31] The prognosis for deeper avulsion injuries is often difficult to predict until complete healing has occurred. Complications such as fracture of the distal phalanx, osteomyelitis, septic arthritis, and OA of a damaged DIP or PIP joint obviously reduce the prognosis for a sound horse. Chronic hoof deformities are one of the most common sequelae of hoof avulsion injuries but do not always cause a clinical problem.[27]

LAMINITIS

James Belknap, Andy Parks, and Katy Dern

VetBooks.ir

OVERVIEW

The disease generally termed "laminitis" likely exists solely due to the unique mechanical demands placed upon the equine epidermal cell in the digital lamellae, namely, the suspension of the distal phalanx (and thus the entire weight of the horse) within the hoof wall. These lamellar epidermal cells are not only responsible for adhesion of the hoof wall to the underlying connective tissue of the basement membrane and dermis/corium (which attaches to the distal phalanx); it is now clear that the cells must maintain their cellular structural integrity (i.e. "stiffness") to resist the distracting forces normally placed upon them in their function of suspending the distal phalanx—and therefore the entire musculoskeletal system—of the horse. Although dysadhesion of the epidermal lamellae from the dermal lamellae (leading to lamellar separation) was traditionally described as the primary cause of lamellar failure, stretching of the epidermal lamellae through loss of structural integrity of the lamellar epidermal cells is now realized to be a central component to lamellar failure. When either the structural integrity of the epidermal cells or the adhesion of these cells to the underlying dermis is compromised, the resulting loss of structural strength of the digital lamellae, combined with the forces on the distal limb, leads to a displacement of the distal phalanx. Three types of displacement of the distal phalanx are described: (1) symmetrical distal displacement in which the entire distal phalanx displaces distally, (2) asymmetrical distal displacement in which the medial (most common) or lateral aspect of the distal phalanx displaces distally, and (3) dorsal rotation in which the dorsodistal tip of the distal phalanx displaces in palmarodistal direction away from the hoof wall (discussed in detail later in the chapter). Throughout this discussion, the term palmar used for the forelimbs is intended to be inclusive of plantar for the hindlimbs.

The term laminitis has been used to describe all clinical presentations of equids in which structural failure of the lamellae occurs. As laminitis occurs as a sequela to other diseases, the types of laminitis are categorized according to the general predisposing disease states associated with lamellar failure: systemic sepsis/endotoxemia (sepsis-related laminitis [SRL]), systemic endocrinopathies (endocrinopathic laminitis), or a disease or injury to one limb that necessitates preferential weight-bearing on the opposite limb (supporting limb laminitis [SLL]). Although the predisposing disease states are readily recognized, there has been a great deal of controversy for decades regarding the specific pathophysiologic mechanisms leading to lamellar failure in each type of laminitis, and, as therapies for diseases are based on the pathophysiology known for that disease, disagreement about the cascade of events leading to lamellar failure has led to confusion regarding therapeutic regimens for the disease. The somewhat recent establishment of the three primary types of laminitis has led to more rapid advancements in our understanding of systemic and local pathophysiologic mechanisms through the more accurate description of clinical cases and through the establishment of experimental models for all three types of laminitis. Concomitant with our increased understanding of the pathophysiology of the different types of laminitis, effective management and treatment tools are now being discovered.

This chapter will review the relevant anatomy, our current understanding of pathophysiologic mechanisms occurring in the different types of laminitis, the clinical presentations of the animals, and finally, a discussion of current diagnostic and therapeutic procedures for the different types of laminitis.

RELEVANT ANATOMY

The distal phalanx of the equine digit is surrounded by the hoof, consisting—similar to the skin—of the deeper dermal tissues and more superficial epidermal tissues. The dermal tissue surrounds and attaches to the outer cortex of the distal phalanx through components of the extracellular matrix (e.g. collagen fibers). In addition to providing important structural functions through the connective tissue attachments to the distal phalanx, the dermal tissue also contains all of the vasculature and innervation of the hoof. The dermis of the hoof wall consists of the sublamellar dermis (also described in the literature as "deep dermis," which attaches to the distal phalanx axially and continues abaxially as the dermal lamellae [containing the microvasculature upon which the epidermal lamellae depend for nutrition]). Importantly, the deep dermis also extends on the palmar/ground surface of the distal phalanx, providing the vasculature and innervation upon which the solar epidermis is dependent.

Similar to the skin, the epidermal component of the hoof consists of both keratinized nonviable components externally and live epidermal cells internally. The outer hoof wall, consisting of the stratum externum and stratum medium, provides both protection to the digit and a critical support function due to fact that, through the lamellar attachments to the distal phalanx, the hoof wall bears the majority of weight of the horse normally via the hoof wall's contact with the ground. The epidermal lamellae, part of the stratum internum of the hoof wall, extend vertically from the coronary groove of the proximal hoof wall distad to merge with the sole; they are placed around the periphery of the distal phalanx, interdigitating with the same number of dermal lamellae. There are approximately 550–600 primary epidermal lamellae, each of which consists of a keratinized, acellular core (continuous with the keratinized hoof wall portion of the stratum internum). Approximately 150–200 secondary epidermal lamellae emanate from each primary epidermal lamella, interdigitating with secondary dermal lamellae. The secondary epidermal lamellae are made up of two types of live epithelial cells, basal

VetBooks.ir

epithelial cells interfacing with the lamellar dermis, and parabasal epithelial cells on the interior of each secondary epidermal lamella. These cells appear to function similarly to skin epithelial cells, with basal epithelial cells attaching to the matrix fibers of the underlying basement membrane (continuous with the matrix fibers of the dermal lamellae) primarily via the same protein complexes present in the basal epithelial layer in the skin: hemidesmosomes. The lamellar epithelial cells also have an intricate cytoskeleton, likely providing the same "stiffness" to the lamellar cells as is reported in epithelial cells in other species. In lamellar failure in laminitis, it is likely that dysregulation of epithelial cytoskeletal dynamics leads to lamellar stretching of the epidermal lamellae, whereas dysregulation of hemidesmosome complexes (attached to the intermediate filament aspect of the cytoskeleton) appears to lead to dysadhesion of the lamellar basal epithelial cells from the basement membrane and therefore to separation of the epidermal and dermal lamellae.

PATHOGENESIS: PATHOPHYSIOLOGIC CONSIDERATIONS

The delineation of the three general types of laminitis has allowed more focused investigations into systemic and local lamellar events occurring in these different types of the disease. Additionally, the availability of state-of-the-art research tools to assess lamellar events has allowed rapid advancement of knowledge over the last decade. Finally, although we have had models of SRL for several decades, we have only recently developed experimental models of endocrinopathic laminitis and SLL.

Experimental models for SRL include both carbohydrate overload models and the black walnut extract model. These models were developed in order to closely emulate the clinical cases of laminitis caused by either consumption of excessive carbohydrate or of black walnut shavings (used for bedding). The first CHO overload model established included the gastric administration of a mixture of corn starch and wood flour (commonly termed the starch gruel model).[34,35] Today, this starch gruel model has largely been replaced by the oligofructose model in which a gastric bolus of oligofructose in solution is administered.[21,22,53] Whereas the black walnut extract model was useful for examining early events in the disease process,[7,47] the fact that most animals did not progress to structural lamellar failure somewhat decreased the clinical relevance of (and interest in) the model.[7] Using these models, a profound inflammatory response was detailed in the lamellar tissue (much greater than other tissues in the body).[7,46,47] Interestingly, similar inflammatory events were discovered as occur in organ injury in human sepsis, including the extravasation of leukocytes into the lamellar tissue[26,28,29] and the marked increased expression of inflammatory mediators/enzymes in the lamellar tissue including cytokines,[46] chemokine,[27,30] and cyclooxygenase (COX)-2.[46,70] Although lamellar ischemia due to decreased blood flow has been purported as the cause for lamellar failure in SRL, conflicting results are present in the literature, primarily due to the lack of a technique to accurately assess lamellar perfusion. In recent investigations in which a microdialysis probe is inserted into the lamellar tissue to assess lamellar events in the oligofructose model, lamellar perfusion does not appear to change, whereas metabolite changes suggest a similar dysfunction of mitochondrial respiration as reported in models of human sepsis.[51] Due to histologic evidence of lamellar stretching and dysadhesion in the oligofructose model of SRL, and electron microscopic evidence of cytoskeletal and hemidesmosome disarray,[32,43] it is likely that dysregulation of both cytoskeletal dynamics and adhesion dynamics is playing a role in lamellar failure in SRL. Although earlier reports proposed that matrix breakdown by matrix metalloproteases (MMPs) may play an important role in lamellar failure,[31,42,52,59] the lack of presence of activated forms of MMPs of interest[48] and the lack of efficacy of potent a protease inhibitor as a treatment for laminitis in the oligofructose model decrease the likelihood of proteases playing the central event in lamellar failure (Underwood and Pollitt, unpublished data). Finally, the same lamellar growth factor-related signaling (possibly through the proinflammatory cytokine IL-6)[16] as discussed with endocrinopathic laminitis has been documented to occur in the carbohydrate models of SRL (Belknap laboratory, unpublished data) and may play an important role in lamellar epithelial cell dysregulation and lamellar failure.

In endocrinopathic laminitis, including both metabolic syndrome and pituitary pars intermedia dysfunction (PPID), both clinical and experimental studies indicate that hyperinsulinemia (commonly termed insulin dysregulation) is the primary factor inducing lamellar failure. In a study of horses diagnosed with PPID, laminitis only occurred in those animals with hyperinsulinemia.[39] In equine metabolic syndrome (EMS), the term "insulin resistance" has been taken from the human medical literature on metabolic syndrome in which obesity leads to a poorer systemic response to insulin, most likely due to inflammatory mediators released from the excessive adipose tissue. In EMS, this obesity-related systemic inflammation has not been conclusively demonstrated; it appears that the main risk factor for laminitis may be a propensity toward hyperinsulinemia upon ingestion of carbohydrate independent of actual insulin resistance. The role hyperinsulinemia plays in lamellar failure is well supported by the most commonly used experimental model for endocrinopathic laminitis, the euglycemic hyperinsulinemic clamp (EHC) model. In this model, elevated blood insulin levels (in the presence of normal blood glucose concentrations) lead to the same histologic changes to the lamellae as observed in clinical cases of endocrinopathic laminitis.[39,43] In regard to the cause of lamellar failure due to hyperinsulinemia, it has recently been reported that the lamellar epithelial cells in the EHC model of endocrinopathic laminitis undergo the same growth factor-related signaling shown to disrupt normal cytoskeletal and adhesion dynamics in cancer biology when epithelial cells transform into cancer cells (termed epithelial-to-mesenchymal transition).[44] In both clinical cases of endocrinopathic laminitis and in the EHC model, the lamellae do not commonly undergo the dramatic dysadhesion/separation of the lamellar basal epidermal cells from the underlying dermal lamellae that commonly leads to rapid structural failure in SRL. Instead, lamellar stretching plays a more prominent role,[43] likely due to

VetBooks.ir

loss of rigidity due to cytoskeletal dysregulation/collapse secondary to aberrant epithelial cell signaling. Whereas these lamellar changes take place over 48 hours in the EHC model (likely due to the supraphysiologic blood insulin concentrations maintained),[43] the changes can occur gradually over months to years in the clinical patient.

In SLL, a recently introduced model in which a shoe with a V-shaped insert on one limb causes excessive weight-bearing on the other limb has started to shed light on the events preceding lamellar failure. This establishment of a model for SLL was critical due to the fact that clinical cases of SLL are characterized by a rapid onset of severe lamellar injury/separation, making it difficult to assess early changes in the disease process. Whereas the first study using this model suggested an increase in lamellar hypoxia in SLL due to increased concentrations of a protein induced by hypoxia,[33] a more recent study using the same SLL model in which microdialysis probes were placed in the lamellae more clearly indicated a decrease in lamellar blood flow starting approximately 48 hours after the onset of preferential weight-bearing (A. van Eps, unpublished data). On histology of lamellar samples harvested at 96 hours of preferential weight-bearing, both lamellar stretching and dysadhesion were present (Belknap and van Eps, unpublished data). As the decreased blood flow is likely due to physical factors such as a lack of movement,[23] it is unlikely that pharmacologic vasodilation will be effective in preventing or treating SLL. The breakdown in lamellar epithelial structure in SLL may not only be due to the direct effects of hypoxia on cell metabolism; we have also recently established that the same growth factor-related signaling as discussed above is occurring in the lamellar epithelial cells in the SLL model; this is most likely stimulated by factors activated due to hypoxia (Belknap and van Eps, unpublished data). Thus, in all three types of laminitis, the induction of this same growth factor-related signaling may lead to lamellar failure through disruption of epithelial cell cytoskeletal dynamics and adhesion to the underlying matrix.

PATHOGENESIS: STRUCTURAL CONSIDERATIONS OF THE EQUINE DIGIT

The stresses on the lamellae are related to the stresses borne by the two anatomical structures to which the lamellae attach, the hoof wall and the distal phalanx. Different stresses occur due to both weight-bearing and locomotion. The three primary forces affecting the lamellae include:

1. The downward force of the horse's weight through the distal phalanx
2. The torque (or moment) around the distal interphalangeal (DIP) joint created by the ground reaction force (the force exerted by the ground on the digit; also termed extensor moment)
3. The tension of the deep digital flexor tendon (DDFT) exerted on the caudal aspect of the distal phalanx (also termed the flexor moment; Figure 4.65)

It has been demonstrated in a horse with healthy feet that the sole of the foot can support the weight of the limb (i.e. counteracting the downward force on the distal phalanx from the horse's weight), but it is unknown how the forces associated with weight-bearing are distributed from the sole to the distal phalanx. More specifically, the question is how much of the weight borne by the sole is directly transferred to the distal phalanx and how much is redirected through the lamellae to the distal phalanx. The following discussion assumes that there is some direct support of the distal phalanx by the sole, but this remains unproven. In the horse shod with standard shoeing that is standing on a firm flat surface, all the stress of weight-bearing is borne by the lamellae because the only relationship between the foot and the ground surface is through the part of the foot contacting the shoe, the distal hoof wall. On the assumption that significant weight is transferred directly from the sole to the distal phalanx, then a decrease in solar support of the distal phalanx will be exacerbated by the elevation of the sole off the ground surface due to the thickness of the shoe; in the unshod foot, the character of the ground surface would therefore affect the amount of stress

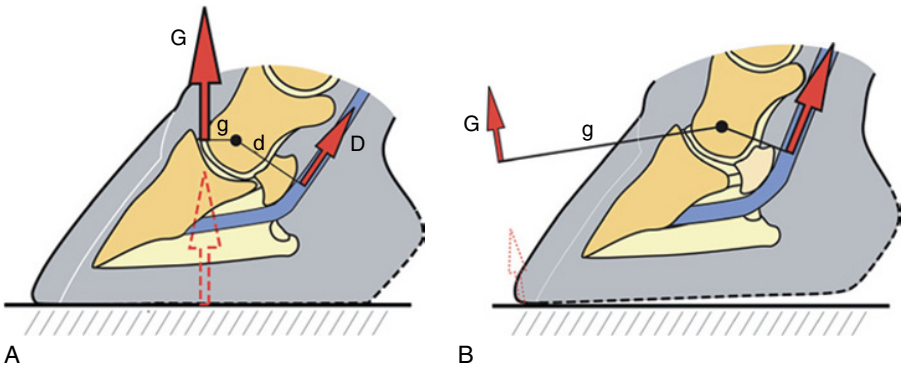

Figure 4.65. (A) At rest, the foot is stable with respect to the ground. The ground reaction force is approximately vertical, and positioned approximately in the center of the foot, slightly in front of the center of rotation of the distal interphalangeal joint. The product of the magnitude of the GRF (G, large red arrow) and the length of its moment arm (g) is the extensor moment, which is opposed by the flexor moment, which is the product of the force in the deep digital flexor tendon (D, small red arrow) multiplied by the length of its moment arm (d). (B) At break-over, the position of the foot is dynamic, and the magnitude of the ground reaction force (G, small red arrow) is decreased as the horse moves off the leg, but the length of the moment arm (g) is increased because the GRF is positioned at the toe. To cause the foot to move from the stable position at rest to the dynamic state, the flexor moment exceeds the extensor moment.

VetBooks.ir

borne by the lamellae. On a hard surface (including artificial surfaces commonly used in stables), only the distal hoof wall and adjacent sole contact the ground. This results in a similar great degree of stress on the lamellae similar to the foot with standard shoes. This is due to the combined effects of concentration of stress through the hoof wall to the lamellae and the lack of support of the distal surface of the distal phalanx. In both of these instances, the distal phalanx can be thought of as being suspended within the foot by the lamellar attachments to the hoof wall. When placed on a softer surface such as sand (or possibly an elastic flooring material), the entire solar surface can be engaged to directly support the distal phalanx in addition to being suspended by the lamellar attachments to the hoof wall. This helps to distribute the digital support through both anatomic structures and thus decrease the stress on the lamellae.[37] As is discussed later, addition of putty to the solar surface in the shod horse has the same end result.

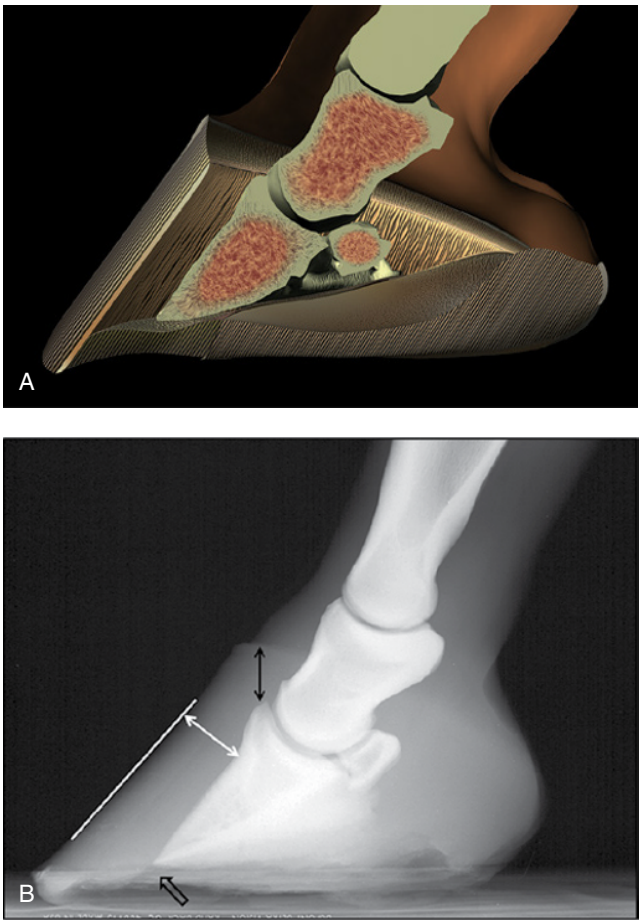
At rest, the center of weight-bearing is approximately at the center of the ground surface of the foot. During the majority of locomotion, the stresses associated with weight-bearing are also centered on the ground surface of the foot. However, during the breakover stage of the stride, ground reaction forces are localized to the toe of the foot, resulting in an increase in the length of the moment arm (and hence the torque or moment; see Figure 4.65) and thus the stress on the dorsal lamellae.

In a healthy horse, the strength of the lamellae greatly exceeds the stresses applied, thereby allowing the distal phalanx to be retained in its normal position. However, in horses with laminitis, the lamellar attachments to the distal phalanx are compromised, as discussed above. Partial loss of the lamellar integrity due to epithelial cell stretching and loss of cellular attachments to underlying connective tissue causes the remaining intact lamellae to endure the entire load of weight-bearing and locomotion, so the remaining lamellae are potentially exposed to a cycle of excessive mechanical stress leading to further stretching and dysadhesion or, possibly, tearing and subsequent failure of suspension of the distal phalanx.

The pattern of displacement of the distal phalanx within the hoof capsule varies between horses and sometimes between an individual horse's feet. The distal phalanx may displace evenly around the circumference of the hoof wall, resulting in distal displacement or sinking (Figure 4.66).

Alternatively, the distal phalanx may displace unevenly in relation to the hoof wall. A unilateral distal displacement results in either medial or lateral displacement or sinking of the distal phalanx (Figure 4.67). Although this type of asymmetric displacement is more uncommon than the dorsal rotational types of distal phalangeal displacement, it is important to assess for this because it is a devastating displacement that requires specific foot care.

The most common pattern of asymmetric displacement, usually termed rotation of the distal phalanx, occurs when the dorsal distal margin of the distal phalanx moves distally and the dorsal parietal surface of distal phalanx diverges from the dorsal surface of the hoof wall, with the distal aspect of the parietal surface of the phalanx being further displaced from the dorsal hoof wall than the proximal aspect. Rotation is categorized as:



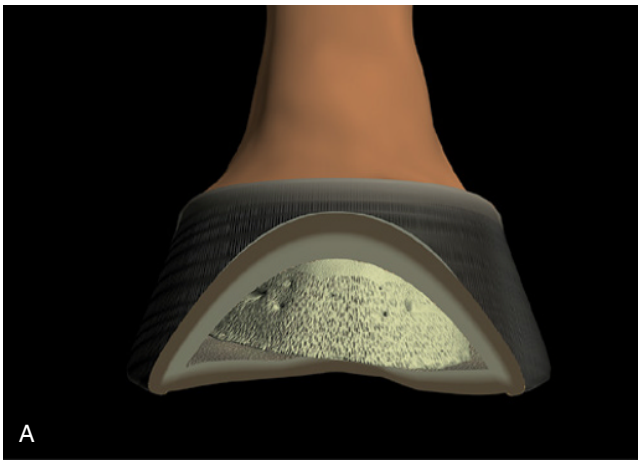


Figure 4.66. In symmetrical distal displacement, the distal phalanx descends within the hoof capsule (A). Therefore, the distal phalanx retains its alignment with the more proximal phalanges and the hoof capsule (B), but the distance between the parietal surface of the distal phalanx and the hoof wall (white arrow) and the distance between the proximal extensor process and the proximal border of hoof wall (black double arrow) increase, and the distance between the distal phalanx and the sole and ground decreases (open arrow).

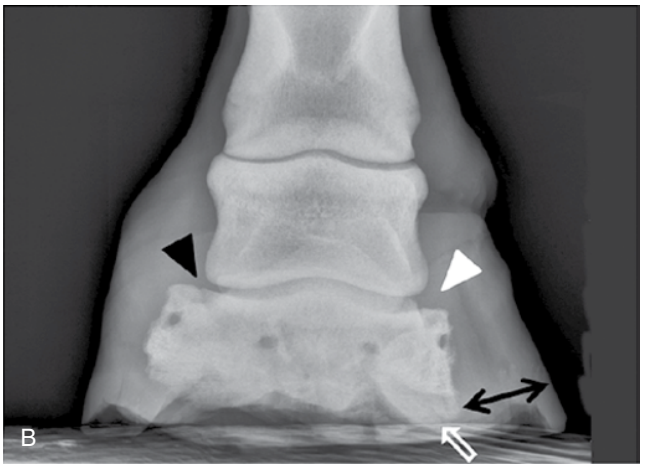
1. Capsular rotation (Figure 4.68): Divergence of the parietal surface of the distal phalanx from the dorsal hoof wall (with or without flexion of the DIP joint)
2. Phalangeal rotation (Figure 4.68): Palmar rotation of the distal phalanx (flexion of the DIP joint with or without capsular rotation) in relation to the axis of the phalanges

In most horses, the pattern of displacement is a combination of distal displacement and rotation of the distal phalanx, although one pattern is usually dominant.

In horses with acute lamellar failure (most common in SRL and SLL), the forces upon the hoof wall may rapidly exceed the support provided by the remaining intact interdigitating dermal and epidermal lamellae. This results in tearing of these remaining lamellae and displacement of the distal phalanx. The potential space

VetBooks.ir



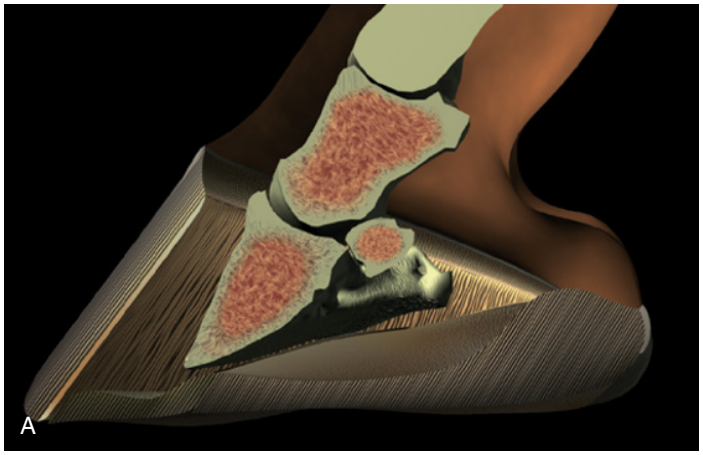


Figure 4.67. In medial or lateral asymmetrical displacement (A), one side of the distal phalanx descends (white open arrow in B). The distance between the wall and the distal phalanx increases (black double arrow), and the distance between the distal phalanx and the sole and ground decreases on the affected side (white open arrow). Additionally, the DIP joint becomes asymmetrical when viewed on a dorsopalmar radiograph; the joint space is increased on the affected side (white arrowhead) and decreased on the unaffected side (black arrowhead).

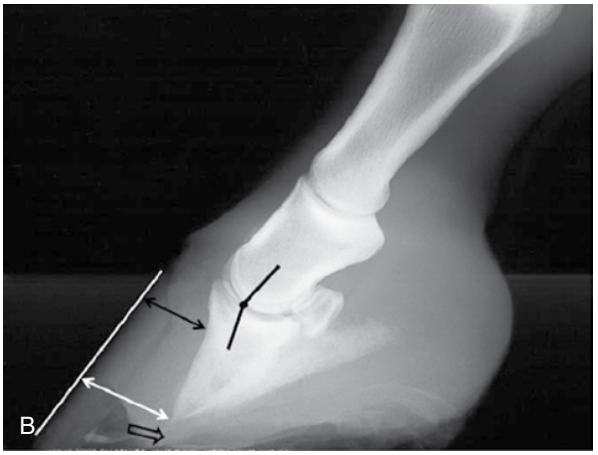

Figure 4.68. (A and B) In horses with early chronic laminitis, the surface of the hoof wall is unchanged, but the distal phalanx rotates about the DIP joint (the joint flexes, black lines in B); consequently, the normal alignment of distal phalanx with the other phalanges is changed (phalangeal rotation). Additionally, the distance between the dorsal distal parietal surface of the distal phalanx and hoof capsule increases (white double arrow) while it remains close to normal proximally (black double arrow), i.e. there is divergence of the surfaces (capsular rotation). Also, the distance between the dorsal margin of the distal phalanx and the sole and ground is decreased (open arrow).

left between the hoof wall and the displaced distal phalanx is likely to fill with blood and necrotic tissue (this area on radiographs may appear radiolucent for a short time after displacement).

After separation of the lamellae, some germinal epithelial cells remain on the deep surface of the separated epidermal lamellae, and some remain attached to the surface of the dermal lamellae. Similar to wound healing in other tissues, remaining viable germinal epithelial cells proliferate. However, the underlying damaged dermis is unable to exert normal control of epithelial proliferation.[60,71] Therefore, remaining epithelial cells undergo aberrant proliferation in the space created by displacement of the distal phalanx, resulting in a lamellar wedge of disorganized epithelial tissue, the apex of which is proximal and the broader base distal (Figure 4.69). This wedge most likely impedes the ability of the clinician and farrier to realign the distal phalanx with the dorsal hoof wall.

THE CLINICAL PRESENTATION: THE HORSE AT RISK OF LAMINITIS

As we can now place most laminitis cases into one of the three types of the disease, we realize that the clinical presentation can differ greatly not only between animals but also between the different types of laminitis. Classically, the literature has attempted to fit the laminitic horse into one of three categories: developmental, acute, or chronic laminitis. The developmental/prodromal stage was defined as the stage prior to the horse exhibiting clinical signs (i.e. the septic horse not exhibiting digital signs); the acute stage has been defined as the animal exhibiting clinical signs of digital pathology but no radiographic signs of displacement of the distal phalanx; and the chronic stage describing the animal in which displacement of the distal phalanx is present on radiographs. The authors do not find these categories useful for two

VetBooks.ir

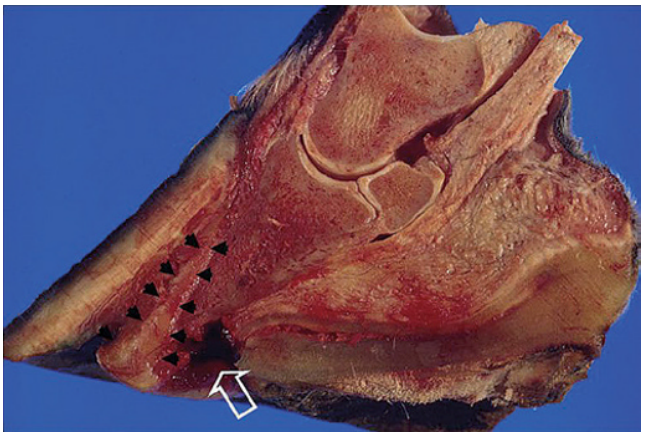

Figure 4.69. A sagittal section of the hoof wall of a horse with capsular rotation of the distal phalanx. Note the lamellar wedge (black arrows) of epithelial tissue that forms from remaining lamellar epithelial cells following displacement of the distal phalanx. Also note the penetration of the sole by the dorsodistal tip of the distal phalanx immediately dorsal to the apex of the frog (white arrow).

reasons: they do not accurately describe the range of clinical cases (not all patients with sepsis are actually in the developmental stage of SRL), and, furthermore, they do not lend themselves to treatment recommendations. Rather than these categorizations, it is best to describe the initial period as an "at-risk" period instead of a prodromal or developmental period. In addition to defining the animal at risk for the different types of laminitis (for prophylactic management of the animal), it may be best to define the acute and chronic stages in a temporal sense, with the acute stage being the first 3–4 weeks after signs of laminitis first occur (regardless of the placement of the distal phalanx) and the chronic stage being the animal treated from 4 weeks to years later.

The equid at risk of SRL is an animal suffering from an infection (e.g. enterocolitis, pneumonia, acute endometritis) or from a compromised viscus (e.g. volvulus of the large colon) that results in the animal exhibiting systemic signs of sepsis/endotoxemia (e.g. fever, injected mucous membranes, tachycardia). Although SRL research has demonstrated that lamellar inflammatory events begin long before the animal exhibits clinical signs of laminitis,[28,47] it has also been documented in both the clinical and research setting that effective intervention with digital hypothermia (discussed later) even early into the onset of clinical lameness can protect the lamellae from structural failure.[18,25] Thus, it is critical to detect these animals at risk of SRL for initiation of prophylactic therapy. Most animals with SRL will exhibit signs of laminitis prior to lamellar failure/displacement of the distal phalanx, including throbbing digital pulses, increased hoof warmth, response to hoof testers, and lameness especially exacerbated on tight turns. Again, in the authors' experience, this is likely the last possible time point to initiate therapy to avoid lamellar failure, as, once the animals are exhibiting severe lameness (i.e. Obel grade 3–4 laminitis), severe lamellar injury and displacement of the distal phalanx are commonly already present. In the interest of identifying patients early in the disease process, it is important to understand that although the forelimbs are usually most severely affected in SRL, it is also the subcategory of laminitis in which patients stand the greatest risk of having all four limbs affected. Whereas, with only forelimb involvement, the animal places its forelimbs and hindlimbs farther forward than normal (to get weight off forelimbs and place more weight on hindlimbs), the animal with involvement of all four limbs may place the forelimbs forward and the hindlimbs further caudad than normal (appearing "camped out").

The equid at risk of endocrinopathic laminitis is now realized to not always be as straightforward to identify as those at risk of the other types of laminitis. The two primary types of endocrinopathies putting the horse at risk of endocrinopathic laminitis, EMS and PPID, can have disparate presentations. For EMS, similar to the human component of metabolic syndrome, obesity is a major risk factor. Additionally, and also in parallel with findings in human medicine, genetics are recently being ascribed a larger role in EMS. This interplay between obesity and genetics is most clearly demonstrated by overweight animals that never exhibit signs of EMS-associated laminitis (EMSAL). Conversely, there are cases of athletic animals with only a moderately elevated body condition score (e.g. show jumpers) that develop EMSAL. Similar to EMS, it has recently been reported that not all animals diagnosed with PPID are at risk of laminitis, only those with insulin dysregulation.[39] Thus, diagnostic testing needs to be combined with physical signs to establish those animals at risk of endocrinopathic laminitis. Animals with pasture-associated laminitis (animals that develop laminitis when exposed to lush pasture) are included in EMSAL; these animals may exhibit the classic signs of laminitis (i.e. digital pulses, hoof warmth) after a short period of time on pasture or may undergo an insidious displacement of the distal phalanx that may go unnoticed for extended periods of time. These animals may exhibit no clinical signs of foot pathology while a gradual displacement of the distal phalanx is occurring (likely over months to years). Thus, in the authors' experience, the first sign of foot disease detected by the owner or trainer may be lameness from solar bruising due to the pressure of a moderately to severely displaced distal phalanx on the solar tissue. For this reason, it has been suggested to obtain radiographic films of the forelimb digits once a year to detect any changes in the relationship of the distal phalanx to the hoof wall (see chapter on imaging component).

The equid at risk of SLL is the animal preferentially bearing weight on one limb due to injury/disease to the contralateral limb causing pain or inability to place weight on that limb. This can occur due to fracture, synovial sepsis, nerve injury leading to paresis, or even long-term subsolar sepsis. Although SLL usually occurs in the animal with severe unilateral lameness, it can occur in the animal with moderate lameness. In a survey of equine surgeons in private and university practices, they reported that the most common cause of lameness in the contralateral limb in SLL cases was sepsis of synovial structures.[73] Similar to endocrinopathic cases, there is not a defined developmental period, as SLL may develop any time from 2 to 3 days to over 60 days of preferential weight-bearing on one limb. The animal at risk of SLL may exhibit signs of the disease within a few days of becoming lame on the opposite limb, although signs of laminitis commonly occur after the animal has been exhibiting lameness on the opposite limb for several weeks. Once signs of laminitis occur, the SLL is

VetBooks.ir

commonly characterized by a rapidly progressing catastrophic failure of the lamellae (with extensive separation of the dermal and epidermal lamellae), resulting in rapid displacement of the distal phalanx. Earlier signs of a milder lameness may not be apparent due to the lameness already present on the opposite limb.

CLINICAL SIGNS: THE ACUTE ONSET OF LAMINITIS

The clinical signs assessed in laminitis mainly refer to the degree of lameness noted and the digital exam. The lameness varies in severity from being barely detectable to an animal that is recumbent the majority of the time secondary to digital pain. Due to this variability, Obel introduced a grading system to describe the degree of lameness (Table 4.2) more than 60 years ago. Although the Obel grading system does not describe all cases of laminitis (it appears to be primarily based on cases of SRL), it is still used to describe the degree of lameness in both the clinics and when describing time points assessed in laminitis research.

Table 4.2. Obel grades of laminitis.

Grade	Associated lameness and gait abnormalities
1	At rest the horse alternately and incessantly lifts the feet, often at intervals of a few seconds. Lameness is not evident at the walk, but a short stilted gait is noted at the trot
2	The horse moves willingly at a walk, but the gait is stilted. A foot can be lifted off the ground without difficulty
3	The horse moves very reluctantly and vigorously resists attempts to have a foot lifted off the ground
4	The horse refuses to move and will not do so unless forced

Clinical signs of SRL are most commonly observed 24–72 hours following the onset of a septic disease process. The onset of disease in endocrinopathic laminitis is extremely variable; whereas an insidious, "subclinical" displacement of the distal phalanx may take place over months to years in the horse with EMS, pasture-associated laminitis may exhibit an acute and severe onset similar to SRL. In SLL, disease progression is extremely inconsistent between animals, with clinical signs of SLL occurring within days, weeks, or months after the onset of excessive weight-bearing in the affected digit.

The clinical signs of acute laminitis are characterized by lameness, an increase in the temperature of one or more hooves, increased digital pulses, and elicitation of a painful withdrawal response to hoof testers. In EMS and sepsis, the forelimbs are most commonly affected (most likely due to more weight being borne by the forelimbs); the hindlimbs may also be involved (usually in severe septic cases). SLL occurs on the supporting forelimb or hindlimb opposite the non-weight-bearing limb. The characteristic stance of a laminitic horse with both forefeet affected is placement of the forefeet well in front of the normal position and anterior placement of the hindfeet in order to shift more weight to the hindlimbs (Figure 4.70).[37]

The characteristic gait of a laminitic horse is stiff limb movement while maintaining the same laminitic posture of both fore- and hindlimbs being placed anteriorly. Horses in which all 4 feet are affected may have a more normal stance or may appear "camped out" with

Figure 4.70. Classic stance of a horse with laminitis with the forelimbs placed abnormally far forward and weight shifted toward the hindlimbs. *Source*: Courtesy of L. Brandstetter.

VetBooks.ir

forelimbs placed more anterior than normal and hindlimbs placed more posterior than normal. Similarly, their gait may be more normal in appearance than the animal with only forelimb involvement. Importantly, patients with distal displacement of the third phalanx in all four limbs are usually intensely resistant to movement and more commonly recumbent due to severe pain. It is at times difficult to determine whether the forelimbs or both forelimbs and hindlimbs are affected; short-lived anesthesia (using lidocaine) of the forefeet with abaxial sesamoid nerve blocks helps determine whether any lameness exists in the hindfeet or if any abnormality noted in hindlimb gait is merely compensation for the painful forelimbs.

Increased hoof temperature and the strength of digital pulses must be interpreted in the context of the lameness and other systemic symptoms, because it is not unusual for an increase in hoof temperature to be transient, and the interpretation of digital pulses is highly subjective. Application of hoof testers is useful to confirm the presence of pain around the dorsal margins of the sole in cases with mild lameness in which laminitis is suspected. The clinician can also use hoof testers to detect unilateral (more accurately described as uniaxial) pain (medial vs. lateral pain) in unilateral distal displacement. Less commonly, hoof testers can be used to detect heel pain in some chronically affected horses with secondary heel contracture. The veterinarian must keep in mind differential diagnoses such as sole bruising that, in the early stages, can present similarly with digital pulses and bilateral pain in response to hoof testers.

Horses with chronic laminitis have different degrees of hoof capsule deformation and lameness. Changes to the hoof capsule vary with the duration of the disease and type of displacement and may be visible in both the wall and the sole. In the case of a patient with chronic laminitis and rotation, the wall is unchanged in the immediate period after displacement of the distal phalanx, but commonly assumes a dorsally concave appearance as the disease progresses due to disparate growth between the toes and the heels (slower growth in the toe region) and the presence of a lamellar wedge. This disparate growth is also reflected in abnormal growth rings, which are more widely spaced in the heel than the toe (Figure 4.71). The sole dorsal to the apex of the frog may be soft and flattened (or convex) due to downward pressure on the sole from the dorsodistal aspect of the displaced distal phalanx secondary to either rotation or distal displacement. The flat, soft character of the sole may lead to bruising around its dorsal margin. The white line may be wider than normal, frequently with elongated keratinized lamellae, and show evidence of prior bruising/hemorrhage. In cases of distal displacement of the third phalanx, there may be a palpable (and sometimes visible) groove at the junction of the skin of the pastern and the coronary band. The lameness in the long-standing chronic case is commonly only from excessive sole pressure by the displaced distal phalanx, with minimal lamellar pain present due to healing of the lamellae (i.e. the lamellae are stable and therefore pain-free even if abnormal morphologically). The most common exception to this is the horse with recurrent laminitis due to either PPID or EMS, in which bouts of lamellar injury/instability commonly recur.

Figure 4.71. This foot from a horse with chronic laminitis demonstrates abnormal hoof growth with wider growth rings at the heel where there is more growth (small arrows) and converging to narrowly placed rings at the toe (large arrow) where minimal hoof growth is occurring. *Source*: Courtesy of Dr. Gary Baxter.

Diagnosis

The diagnosis of laminitis may be obvious in acute severe cases due to the history, characteristic stance, and digital exam. The diagnosis may be much more difficult in chronic mild cases, especially in older horses that may have bilateral distal limb arthropathies contributing to the lameness. In the acute case with severe lameness of the forelimbs, one author (JKB) performs an abaxial sesamoid nerve block with lidocaine in order to:

1. Enable the clinician to rapidly obtain good quality radiographs without undue stress to the horse
2. Enable thorough examination of the solar surface
3. Assess for involvement of the hindlimbs (by limited walking of the horse around the stall in each direction)
4. Enable the application of therapeutic shoes or pads to the affected limbs

It is important to note that lidocaine is the local anesthetic of choice for this perineural anesthesia as its short duration of action will ensure that the patient will not put excessive stress on already tenuous lamellar attachments.

In the chronic, mild case, it is best to initially block the digit with a palmar digital (PD) nerve block, which blocks solar pain due to a displaced distal phalanx,[65,66] a common cause of pain in the chronic case of laminitis. Although it has recently been established that the PD nerve (not the dorsal branch) provides the majority of the innervation to the lamellae in normal horses,[58] the PD block does not appear to block a lameness due to dorsal lamellar pain in most laminitic horses. The reason for this disparity may be that lamellar pain in laminitic horses is likely due to lamellar instability, which

VetBooks.ir

commonly results in a severe pain that may not block out with local analgesia. Thus, if the PD nerve block abolishes the lameness on the affected digit, it is likely that the pain may be due to solar pain primarily and that the lamellae are stable.

In the horse with suspected chronic laminitis in which it is unknown whether the lameness is due to laminitis or other musculoskeletal issues, it is important to perform distal limb flexion prior to nerve blocks; if the horse is severely lame, the response to flexion can be assessed at a walk. A response to flexion usually indicates the presence of an arthropathy unrelated to laminitis, the most common of which is arthropathy of the proximal interphalangeal joint.

To delineate lamellar pain from proximal interphalangeal joint pain in the horse that does not respond to a PD nerve block, the clinician can assess any remaining pain emanating from the foot by performing a modified ring block immediately proximal to the coronary band to block the dorsal branches of the PD nerve. When attempting to rule out the other common cause of bilateral forelimb lameness, namely, navicular syndrome/palmar heel pain (cases with severe degeneration of the navicular bone can mimic the lameness of a moderately severe case of chronic laminitis), the history, presentation, and radiographs are valuable in addition to the response to nerve blocks. Because PD nerve anesthesia can block both palmar heel pain and solar pain and likely a great deal of lamellar pain,[58] radiographs should be used to help differentiate between them. As with any type of severe musculoskeletal pathology, the lameness may not block out entirely with local perineural anesthesia in some severely painful cases.

Radiography

Radiography is not only critical as a diagnostic tool to determine the presence of the disease but is also critical to monitor progress of the disease and guide treatment. Radiographs should be taken at the first sign of acute laminitis to serve as a baseline for subsequent radiographic comparisons and determine if radiographic changes suggestive of previous laminitis are present. The most important views are the lateral and the dorsopalmar/plantar projections (Figures 4.67, 4.72, and 4.73). For both of these projections, it is important that the foot is placed on a block and that the X-ray beam is centered as close as possible to the solar margin of the distal phalanx (approximately 1.5 cm proximal to the surface of the block).

Early radiographic signs suggestive of distal displacement of the distal phalanx include: 1) increased dorsal hoof wall thickness (e.g. widening of the distance between the dorsal surface of the hoof wall and the parietal surface of the distal phalanx)[14] and 2) increased vertical distance from the proximal aspect of the extensor process to the firm proximal border of the hoof wall located immediately distal to coronary band (sometimes termed the founder surface of the hoof capsule). It is important to ensure that the lateral radiographic view is a true lateral; rotation of the axis of the foot by more than 10° causes the degree of rotation to be underestimated.[40]

A radiopaque object or paste can be applied to the mid-dorsal hoof wall and should end at the level of the coronary band to help identify it (Figure 4.72). The distance between the dorsal surface of the hoof capsule and the parietal surface of the distal phalanx is best measured as the shortest distance between the two immediately distal to the base of the extensor process (in Figure 4.72b) to limit the effect of any rotation on the measurement. This measurement is most valuable when pre-disease radiographs are available and then it is a relatively reliable indicator of displacement in horses in which the distal phalanx has undergone distal displacement. In normal horses (approximately 450 kg), the distance should be less than 18–20 mm (reported means of 14.6–16.3 mm). With digital radiographs it is possible to identify two layers of the hoof wall, the outer being more radiodense than the inner layer. In horses with distal displacement, the inner layer increases in thickness, while the outer layer is unaffected, at least initially. Therefore, an increase in the ratio of the inner layer to the entire thickness of the wall should also increase with distal displacement and is independent of the size of the horse. The normal ratio is approximately 40%.[36]

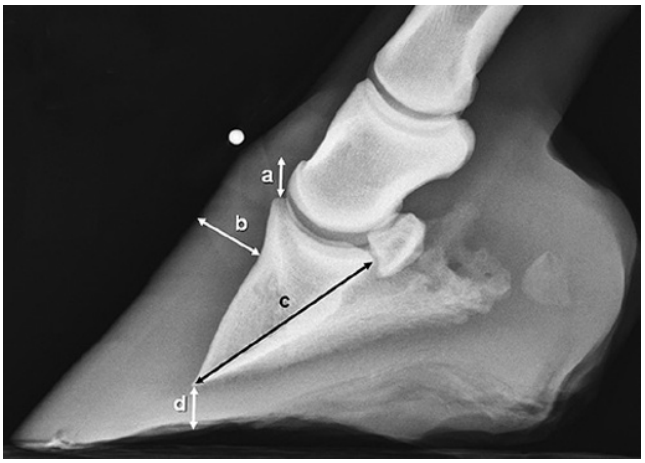

Figure 4.72. Several measurements obtained from lateral radiographs of the digit can be used to assess horses with distal displacement of the distal phalanx. a = distance from the proximal extensor process to the proximal aspect of the hoof wall (immediately distal to coronary band), b = the distance from the dorsal parietal surface of the distal phalanx to the dorsal surface of the hoof capsule, b/c = the ratio of the distance from the dorsal parietal surface of the distal phalanx to the dorsal surface of the hoof capsule (b) to the length of the palmar cortex of the distal phalanx (c), and d = the distance from the dorsodistal tip of the distal phalanx to the ground surface of the sole.

Additionally, an accurate measurement of the dorsal hoof wall thickness that takes into account the magnification and the size of the foot is the ratio between this dorsal measurement and the palmar cortical length of the distal phalanx measured from the dorsodistal tip of the bone to its articulation with the navicular bone (in Figure 4.72c). This ratio, which should be less than 28% in the normal horse, indicates possible distal displacement from 28% to 32% and indicates likely displacement if greater than 32%. The vertical distance from the extensor process to the firm proximal border of the hoof wall is also well used and is –2 to 10 mm in normal horses, depending on size (Figure 4.72a).[14] Due to the variability of this distance (–2 to 10 mm) in normal horses, it is most valuable to compare this

VetBooks.ir

measurement to pre-disease baseline radiographs to accurately assess any changes in the individual horse. Unilateral distal displacement can only be reliably assessed on a dorsopalmar/dorsoplantar projection (Figure 4.67).

Palmar/plantar rotation of the distal phalanx away from the dorsal hoof wall resulting in an angle greater than 5° confirms the diagnosis of laminitis due to capsular rotation (normal horses can have angles less than 4°). Two types of rotation can be assessed. Capsular rotation, the degree of rotation between the dorsal hoof wall and the parietal surface of the distal phalanx (α in Figure 4.73), is best reserved for assessment in the acute stage because the measurements can be difficult to interpret in horses with chronic laminitis due to deformation of the hoof wall. The angle of solar margin of the distal phalanx to the ground surface (β in Figure 4.73) is more useful in horses with chronic laminitis because it will remain unaffected by dorsal hoof wall deformation. Serial radiographs should be taken to monitor the progression of the disease and determine the success of selected treatments. Digital venography in the standing horse has been developed as a prognostic aid to assess the vasculature of the digit. A venogram in which there is no filling of contrast of the lamellar vessels, the circumflex area, and the terminal arch is reported to indicate an extremely poor prognosis for recovery.[63]

Treatment

The goal in the treatment of the acute laminitis case is to stabilize the digit in the short term regardless of the degree of displacement. In the authors' opinion, if the clinician can attain stabilization of the digital lamellae for approximately 3 weeks, distal phalangeal displacement can be addressed with other techniques including corrective shoeing and possibly deep digital flexor tenotomy in nonresponsive cases. In regard to foot support, the veterinarian must be willing to try a variety of techniques (discussed below) in an attempt to find the type of digital support that the animal responds to favorably.

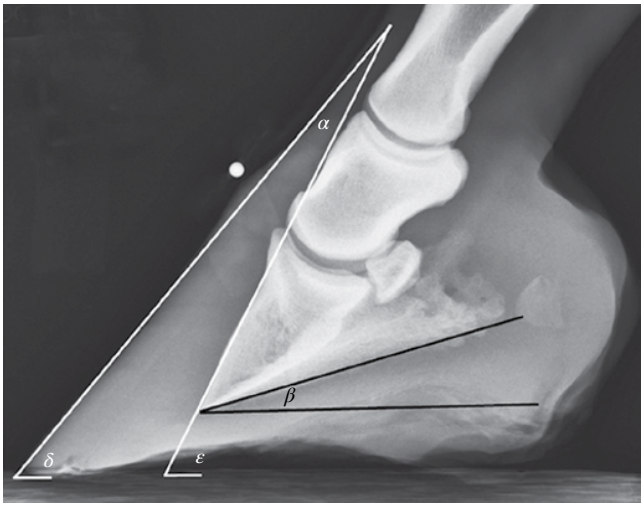

Figure 4.73. For assessment of rotation of the distal phalanx, the clinician can assess the degree of capsular rotation (angle α) at the intersection of the dorsal capsular and dorsal phalangeal lines or can measure the difference between the dorsal angles δ and ε. The relationship of the solar margin of the distal phalanx to the ground surface of the foot can be assessed by measuring angle β.

Anti-inflammatory Therapy

Anti-inflammatory therapy has endured as a central component of laminitis pharmacotherapy over the years. As discussed above, there is compelling evidence to use nonsteroidal anti-inflammatory drugs (NSAIDs) due to marked inflammatory events occurring both prior to and at the onset of lameness in the laminitic horse. Therefore, aggressive, prudent use of NSAIDs is indicated in the horse known to be at risk of laminitis (i.e. colitis, grain overload, etc.) until approximately 48–72 hours after the animal is no longer showing clinical signs of systemic inflammation/toxemia.

In addition to blocking COX enzyme activity, high doses of NSAIDs recently have been found in other species to block inflammatory pathways including some controlling basic inflammatory gene expression, some of which are upregulated in the early stages of laminitis.[9] COX-2 has recently been shown to be an important mediator in the synapses of sensory neurons; therefore, COX-2 inhibition is likely to not only decrease lamellar inflammation but also decrease central pain sensation. Due to the gastrointestinal (GI) and renal toxicity caused by NSAIDs, close attention must be paid to the animal's history (i.e. a history of gastric/colon ulcers or renal disease), the animal's hydration status, and laboratory work in the critical case to assess renal function.

The four main NSAIDs available to the equine clinician are three nonselective COX-1/COX-2 inhibitors (flunixin meglumine, phenylbutazone [PBZ], and ketoprofen) and one COX-2 selective NSAID (firocoxib). There is some question whether, during treatment with a COX-2 selective NSAID in the peracute phase of laminitis, the vascular inflammation/injury occurring in the lamellae may place the digit at risk of the same vascular accidents (thrombosis leading to myocardial infarction and stroke) that have resulted with the use of COX-2 selective drugs in humans. Thus, until proven otherwise, it may be best to use a nonselective drug in the peracute stage and consider firocoxib in the chronic, long-term case in which the drug's decreased incidence of side effects is more important. Meloxicam is available in countries other than the United States and may be of value due to slight COX-2 selectivity (approximately two- to threefold), which appears to make it a very safe option due to a low incidence of side effects and possibly fewer chances of unwanted vascular events.[10]

In the horse still demonstrating signs of systemic illness with a possible ongoing bacterial toxemia (i.e. colitis), flunixin meglumine is indicated due to its increased efficacy against endotoxemia. In the animal that has a stable hydration status and no indication of renal compromise or intestinal ulceration, the use of high-dose (1.1 mg/kg IV TID) flunixin may be indicated for up to 3–5 days; the authors decrease the dosage after 3 days if the source of bacterial toxemia appears to be resolving. If the lameness does not improve with flunixin, it is indicated to either add other types of analgesics (see constant rate infusion [CRI] below) or possibly lower the flunixin dosage by half and add 4.4 mg/kg PBZ SID.

VetBooks.ir

In the animal demonstrating renal compromise or clinical signs of GI ulceration, ketoprofen is indicated due to its reported efficacy in ameliorating both endotoxin effects and lameness[4,57] and a markedly increased margin of safety when compared with flunixin or PBZ.[49] Due to the poor response when the drug is only administered BID and the incredible safety of the drug, the BID dosage of ketoprofen can be administered QID (2.2 mg/kg IV QID). Since a "peak and trough" analgesic effect between ketoprofen dosages has been observed in some animals, it may be prudent to administer 2.2 mg/kg PBZ SID in order to have a more consistent NSAID effect.

Analgesia in the chronic case most commonly consists of PBZ therapy, with long-term doses usually in the range of 2.2–4.4 mg/kg/day to avoid complications. An important reason for PBZ's higher incidence of toxicity when compared with the other NSAIDs (almost every reported case of NSAID-related right dorsal colon ulceration has been due to PBZ) is that the drug has a longer half-life and accumulates in the tissues to a much greater degree than either flunixin or ketoprofen. One way to avoid toxicity in animals on long-term PBZ therapy is to cease administration of the drug for 24 hours once every 5–7 days to allow clearance of PBZ from the system. If the animals are too painful to be without an NSAID for 24 hours, either ketoprofen or flunixin may be given without interfering with the clearance of PBZ. Firocoxib has the advantage of once-a-day treatment and is much more protective against GI concerns than PBZ; however, in the authors' opinion, it commonly does not provide an adequate amount of analgesia in many laminitis cases.

Pentoxifylline is reported to be anti-inflammatory due to its "anti-TNF" effect[3]; preliminary results from a study using the carbohydrate model indicate a decreased incidence of lamellar failure in animals with pentoxifylline therapy initiated at the time of intragastric administration of carbohydrate.[17] It is unknown whether the efficacy is due to inhibition of inflammatory signaling, inhibition of matrix metalloproteases, or any hemorrheologic effect (not likely as requires prolonged therapy to achieve this effect in other species). Although digital hypothermia ("cryotherapy") has been demonstrated to protect the lamellae from structural failure when instituted at multiple time point in models of SRL (discussed below),[18,20,24,25] it has a variable effect on inhibition of inflammatory signaling depending on when it has been instituted.[15,16,20] Hypothermia has an inhibitory effect on a broad array of inflammatory molecules (multiple cytokines and chemokines, adhesion molecules, COX-2) if initiated prior to the administration of a carbohydrate overload,[24] but a much more focused effect (primarily IL-6 and COX-2) when initiated later in the disease process (onset of sepsis),[16] and, when instituted at the onset of lameness, no consistent anti-inflammatory effect (although still protective against lamellar failure).[15] Although intravenous lidocaine infusion, similar to that used for treatment of ileus in the equine patient, has been proposed as a treatment to decrease inflammatory signaling in laminitis, no anti-inflammatory and actually some proinflammatory properties of constant rate intravenous lidocaine infusion were reported in a laminitis model.[72]

Therapy Regarding Matrix Metalloprotease Inhibition

Although many practitioners have used tetracyclines in laminitis cases based on the drugs' reported MMP inhibitory properties, preliminary data from an equine study indicate that doxycycline is a poor inhibitor of equine MMPs of interest (MMP-2 and MMP-9) and oxytetracycline inhibits MMPs *in vitro* but was ineffective in treating the disease in a model of laminitis.[33] Additionally, further studies have decreased the interest in MMPs as a therapeutic target including (1) a study demonstrating that MMP-2 and MMP-9 were neither in an active state in lamellar extracts from clinical cases of laminitis[48] and (2) the inability to block lamellar pathology with marimastat—a potent broad-spectrum MMP inhibitor—in using an experimental model of laminitis (Underwood and Pollitt, personal communication).

Drugs Affecting Blood Flow

The majority of drugs that have been introduced for treatment of possible decreased lamellar blood flow have been demonstrated to be ineffective in increasing lamellar blood flow in the horse (i.e. isoxsuprine, pentoxifylline, and nitroglycerin paste). The only drug demonstrated to increase digital blood flow is the phenothiazine tranquilizer acepromazine, which only increases flow for a short period of time (approximately 30 minutes) when administered intramuscularly.[45]

Anticoagulant Therapy

Although there are data supporting the role of platelets in SRL,[2] there is no consensus on the use of any therapies to address this area. There are confounding data from retrospective clinical studies on the efficacy of heparin as a prophylaxis in horses at risk of laminitis.[8,13] Furthermore, experimental treatment with heparin 24 hours after carbohydrate overload (CHO) administration did not ameliorate signs of laminitis or lamellar lesions.[50] One problem with previous heparin studies is that unfractionated heparin was used, which induces autoagglutination of equine red blood cells and becomes lodged in capillaries (including lamellar capillaries); this event may further compromise affected lamellar capillaries in laminitis. Low molecular weight heaparin (LMWH) may be a valuable alternative because it does not cause equine RBC autoagglutination and has recently been reported to reduce the incidence and severity of laminitis in postoperative colic cases.[61] Unfortunately, no further studies have been published on LMWH in laminitis in the past decade.

Analgesic Therapy

The mainstay of analgesic therapy in laminitis cases is still the use of NSAIDs. Whereas PBZ is still the NSAID providing the greatest analgesia in the laminitic horse exhibiting digital pain, flunixin meglumine or COX-2 selective NSAIDs (e.g. firocoxib) may be used if there are ongoing systemic concerns in which the other NSAIDs may either be more effective or less harmful (i.e. concomitant renal disease or GI ulceration, ongoing endotoxemia).

VetBooks.ir

Due to the common inability to control digital pain with a safe dosing of NSAIDs, CRI of analgesic drugs has been used to supplement NSAID therapy in decreasing the level of pain suffered by hospitalized laminitis patients. The use of "Pentafusion" (combination of ketamine, morphine, lidocaine, detomidine, and acepromazine; Eric Abrahamsen, BEVA Proceedings, 2005) has been described for use in severely painful cases of laminitis. The CRI is a valuable addition to laminitis therapy because it takes some of the humane concerns away from the owner and veterinarian treating an animal in severe pain. Some of these drugs also affect GI motility; therefore, the animals must be monitored closely for large intestinal motility/impaction. Additionally, the animals may become unstable or overly sedate if the CRI rate is excessive. For a more focused approach, an epidural can be considered for analgesia in hindlimb laminitis.

Therapy to Limit Structural Failure of the Lamellae

The obvious overarching goal of therapies for the horse at risk of or suffering from laminitis is limiting the structural failure of the lamellae. The only therapy to consistently inhibit—or limit—lamellar structural failure in both the research and clinical setting is digital hypothermia (also termed cryotherapy).[19,25,41] Although original work demonstrating efficacy of hypothermia maintained the horses' forelimbs in an ice/water slurry to the level of the carpus,[20] more recent work has demonstrated that immersion of the foot up to the level of the pastern region is adequate to keep the hoof temperature less than 10 °C.[18] Although many clinicians use 5-L intravenous fluid bags taped to the limbs to maintain the digits in the ice slurry, commercial alternatives exist (e.g. Ice Spa Pro, Soft-Ride, Inc.). Continuous hypothermia in this manner has been demonstrated to protect the lamellae from structural failure even when hypothermia is not initiated until the onset of lameness.[25] Although most experimental studies demonstrating efficacy of digital hypothermia have been performed in models of SRL, the same protective effect was recently demonstrated to occur when hypothermia was assessed in EHC model of endocrinopathic laminitis (Belknap and van Eps, unpublished data). In the clinical setting, digital hypothermia is most commonly used as a prophylactic therapy in the septic equid at risk of laminitis. In a multicenter retrospective clinical study of the use of digital hypothermia as a prophylactic therapy against laminitis in 130 equine enterocolitis cases, horses treated with digital hypothermia were ten times less likely to develop laminitis than those not treated with hypothermia.[41] In that study, there was a trend for a worse prognosis if hypothermia were used intermittently than if not used at all (S. Holcombe, personal communication), indicating that it is very important that the digits need to be continuously maintained in the hypothermic state. Although it varies between animals, ice usually needs to be replenished every 1–2 hours to maintain the hypothermic state. Many practitioners only maintain the front digits in ice due to the increased incidence of laminitis in the forelimbs; however, it is best to maintain all four limbs in ice if possible. Although no studies have been performed to ascertain the optimal time period to maintain the digits in the ice slurry, most clinicians maintain animals at risk of SRL in ice for 24–48 hours past the abatement of clinical signs of sepsis.

Hoof Care in the Treatment of Acute and Early Chronic Laminitis

In the acute and early chronic laminitis case, it is likely that lamellar instability remains a prominent factor. Ideally, in horses with severe acute and early chronic laminitis, the force of the horse's weight on the feet should be reduced. To this end, slings have been used to enforce partial weight-bearing, but availability and inadequate tolerance by the horse frequently result in failure of this effort. Therefore, many treatment measures are aimed directly at the foot. The two main objectives of hoof care are to redistribute the force of weight-bearing away from the hoof wall and to decrease the extensor moment about the DIP joint.

Several measures of varying efficacy attempt to redirect weight-bearing away from the wall by recruiting the frog, bars, and all or part of the sole to bear weight. However, as discussed in Chapter 8, it must be remembered that the physiological role of the sole in weight-bearing is not fully understood. The amount of the ground surface that can be recruited to bear weight is highly variable between horses. In general, once the distal phalanx has displaced, pressure over the sole under the displaced distal phalanx increases discomfort. Thus, the clinician must weigh the benefits of possibly decreasing lamellar stress by applying solar support with the risk of causing excessive solar pressure and worsening the pain (and possibly the pathologic process). Before considering other measures, the clinician must decide whether to leave shoes on the feet if the horse is shod. Shoes on firm surfaces concentrate stress around the perimeter of the foot (e.g. the hoof wall and lamellae), and therefore removing them will likely be beneficial by removing this effect. Removing shoes also makes other therapeutic measures more feasible, including recruiting other parts of the ground surface of the foot for weight-bearing and modifying break-over. The potential disadvantage of removing shoes in horses with laminitis is that the removal process itself may cause additional trauma to the lamellae.

The simplest way to recruit the sole, frog, and bars for weight-bearing is to place the horse on bedding material that readily conforms to the shape of the foot. In this regard, sand is significantly better than shavings. Peat has also been used. Deep deformable substrates also permit the horse to adjust the angle of its foot to optimize comfort. However, the deep deformable substrates are not selective in how pressure is applied to the ground surface of the foot. Various devices and materials have been placed under the frog, sole, and bars to recruit varying amounts of weight-bearing. These include rolled gauze, Lilly pads, silicone putty, Styrofoam insulation board (usually 2-inch board), closed cell foam (1.5 inches thick, 4 lbs/ft^3 density), and commercial pad systems such as the Soft-Ride boots (Soft-Ride, Inc., Vermillion, OH). The closed cell foam has the advantages of not crushing like Styrofoam does, and it can be cut to bevel the ground surface to move the break-over palmarad. The softer materials may offer the additional

VetBooks.ir

advantage of softening impact during locomotion. Rigid materials may transfer weight-bearing more effectively but are discouraged because they are more likely to cause focal pressure under the margin of the distal phalanx and pain and should therefore be generally avoided or only used with caution.

The moment or torque about the DIP joint at rest can be decreased by elevating the heels. This decreases the tension in the DDFT and therefore the tension in the dorsal lamellae. This is more likely to benefit horses that have or are about to develop capsular rotation and is unlikely to help (and may hurt) those that have or are prone to distal displacement. The arm of the extensor moment at break-over can be shortened by moving the point of break-over palmar to the dorsal margin of the toe (Chapter 8). This may be done by rasping the ground surface of the hoof wall while being careful to preserve the integrity of the white line or incorporating it into a supporting device. Commercial plastic cuff and pad combinations conveniently combine a wedged heel and eased break-over (i.e. the NANRIC Ultimate, NANRIC Co., Lawrenceburg, KY).

Treatment must be titrated to the severity of the disease. Currently it is not routinely possible to assess the degree of injury to the lamellae, so the severity of the disease for each type of displacement is usually determined by clinical parameters such as heart rate, the severity of the lameness, response to treatment, and radiographic changes. In the early stages of therapy, the intensity of therapy initiated depends on the severity of clinical signs (i.e. not all horses need all of the measures described). However, in the horse that has undergone treatment and appears to be improving, it is advisable to gradually discontinue treatments, withdrawing one treatment measure at a time followed by 2–3 days of observation. In more mildly affected horses, treatment may be discontinued over 1–2 weeks. However, in severely affected horses, the treatment should be tapered off over 6–8 weeks as the treatment switches to that for the chronic laminitic patient.

Treatment of Active and Stable Chronic Laminitis

The objectives for maintaining stability of the distal phalanx and pain control are similar to that of the acute and early laminitic horse. An additional goal is to restore the relationship between the hoof capsule and the distal phalanx. The management varies with the type of displacement, severity of lameness, the way in which the horse moves, and stability of the distal phalanx. The treatment of dorsal capsular rotation, symmetrical distal displacement, and asymmetrical displacement are considered separately.

Hoof Care in the Treatment of Horses with Rotation

The challenge of treating horses with rotation, usually both capsular and phalangeal, is to realign the phalangeal axis while simultaneously realigning the hoof wall with the parietal surface of the distal phalanx (while also controlling pain). Complications are common and must be managed as they occur. The mainstay of treatment is hoof care, but various surgical techniques may be required.

Trimming and shoeing of the foot should be planned based on radiographic observations.[54,62] Dorsopalmar and mediolateral radiographs should both be taken (as described earlier) prior to shoeing. The guiding principles are as follows:

1. Realign the phalangeal axis by trimming
2. Preserve the thickness of the sole
3. Move the break-over in a palmar/plantar direction
4. Reduce the tension in the DDFT
5. Recruit weight-bearing by the ground surface of the foot depending on tolerance and type of shoeing to be used

The trim should aim to restore the angle that the solar margin of the distal phalanx forms with the ground to between 0° and 5° (in severe cases, it may be preferable to aim for 5° vs. 0°). At the same time, the sole depth should be preserved to at least 15 mm wherever possible. In horses in which the dorsal sole is greater than 15 mm in depth, the trim is along a single plane from the dorsal margin of the sole all the way to the heels (Figure 4.74A). However, in most horses with rotation, the depth of the dorsal sole is significantly less than 15 mm due to the distally displaced dorsodistal aspect of the distal phalanx.

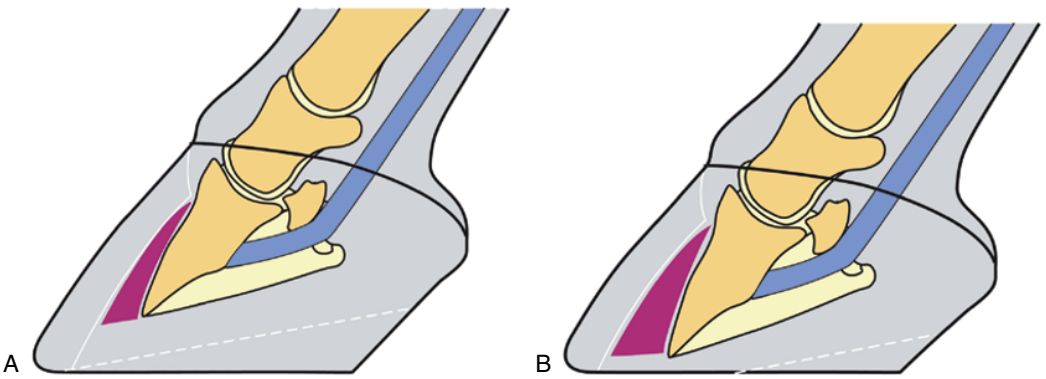

Figure 4.74. (A) When the depth of the sole exceeds approximately 15 mm across the sole, the alignment of the distal phalanx with the solar surface of the foot can be achieved by trimming the entire ground surface of the foot on a single plane (dashed line). (B) When the dorsal sole is less than 15 mm, which is common in horses with rotation, the goal is to preserve the dorsal sole, yet still realign the distal phalanx for shoeing. The palmar ground surface is trimmed (dashed line) on a different plane to the dorsal half (which is not trimmed).

VetBooks.ir

To attempt to realign the distal phalanx with the ground surface with the sole by trimming, the ground surface of the foot to one plane would inevitably decrease the thickness of the dorsal sole further. Therefore, only that portion of the foot with greater than 15 mm sole depth is trimmed, which is usually the palmar 50%–70% of the sole (Figure 4.74B). This results in two separate planes for the dorsal and palmar portions of the foot (Figure 4.74B). Depending on the shoeing technique to be employed, the dorsal plane of the foot may be brought into line with the palmar plane at the time of shoeing, usually by filling the gap with a synthetic polymer. The plane for trimming can be identified on the radiograph by drawing a line parallel to and 15 mm distal to the solar margin of the distal phalanx (Figure 4.72).

Some horses, particularly those with mild rotation and sufficient sole depth, may be managed with trimming and maintaining them on a soft ground substrate without shoeing.

Once the foot has been trimmed, the clinician must decide whether or not to shoe the horse, and if so, which type of shoe to use and how to attach it. The shoe may be attached to the foot with nails, directly with glue, with glue and a cuff, or, in some instances, with cast material (i.e. the wooden shoe). The type of shoe and the manner in which it is attached vary with duration and severity of diseases and clinician experience and preference. For less severely affected horses, most frequently, shoes are nailed to the foot in the traditional manner. However, when nailing the shoe in place is considered too painful or there is insufficient hoof wall to which to nail, a less traumatic technique using a combination of adhesives, casting tape, and screws may be used. When selecting a shoe, it is important to remember that there are several underlying principles and numerous ways of achieving them. The underlying principles or goals of shoeing include:

1. Moving the center of pressure
2. Changing the area of distribution of force
3. Decreasing the shock of impact
4. Enhancing ease of movement
5. Protecting parts of the foot

Enhancing ease of movement involves decreasing the moment arm about the DIP joint and smoothing out break-over. This is most beneficial in the dorsopalmar plane, in which the objective is accomplished by rolling the toe, setting the shoe back, squaring the toe, or using an open toe shoe. However, to a lesser extent, break-over in a medial or lateral direction can be eased by the use of rails, rounding the medial and lateral branches of the shoe, or using a Steward clog (wooden shoe) with beveled sides.

For horses with rotation, the center of pressure may be moved in a palmar direction in relation to the center of the ground surface of the foot and toward the center of rotation of the DIP joint by using extensions, by recruiting more ground surface to bear weight on the palmar ground surface, or by elevating the heels. In doing so, weight-bearing can be moved away from the most affected laminae.

Increasing the area of distribution of weight across part or all of ground surface of the foot is theoretically performed to transfer weight-bearing from affected lamellae to the sole, bars, and frog to decrease stress in the affected lamellae. However, the role of the sole in weight-bearing to spare weight-bearing by the wall has been questioned (see therapeutic shoeing in Chapter 8). Regardless of the theoretical considerations, some horses appear to benefit greatly from sole support. Support of the ground surface of the foot is most readily accomplished with the use of synthetic polymers such as polymerized silicone (two-part putties such as the impression material [Equine Digit Support System (EDSS), Penrose, CO] or advanced cushion support [NANRIC, Lawrenceburg, KY]) or polyurethane ("pour-in pads") in the space between the branches of the shoe. However, support of the ground surface is also still approached by more traditional means such as pads and heart-bar shoes.

Several shoe types have been used to address these goals including regular keg shoes, egg-bar shoes, reverse shoes, heart-bar shoes, four-point rail shoes, and wooden shoes/clogs. Each deserves consideration to examine how it accomplishes the goals and to discuss its advantages and limitations.

The keg shoe must be modified to be effective in the treatment of active and stable chronic laminitis. Break-over in the dorsopalmar plane can be eased by forging the toe of the shoe to square and roll it and setting the shoe back. Easing break-over in the medial and lateral directions can be achieved to a limited extent by rounding/beveling the outside rims of the branches of the shoe. Heel elevation can be added as needed by using a shoe with a built-in wedge or using a wedge pad, frequently a wedge rim pad. The wedge rim pad allows incorporation of as much of the ground surface of the foot as needed for weight-bearing using a synthetic polymer in the concavity of the foot between the branches of the shoe (and rim pads).

The egg-bar shoe (Figure 4.75) is probably the most common shoe used because it is readily available and many farriers and veterinarians are familiar with its use in other circumstances. It can be modified in all the same ways as the keg shoe, and it has the added benefit of the

Figure 4.75. Egg-bar shoe.

VetBooks.ir

bar that extends in a palmar direction. The palmarly extended nature of the bar causes it to act as a mild wedge when the horse stands on a soft surface by acting like a "snowshoe" and inhibiting sinking of the heel. This decreases tension in the DDFT and hence theoretically decreases the tension placed on the dorsal lamellae.

The reverse shoe combines the advantages of the egg-bar shoe with an open toe. The open toe theoretically offers superior easement of break-over in the dorsopalmar plane when compared with a closed toe shoe. However, the open toe also has the potential disadvantages of concentrating stress at the dorsal margin of the branches and not protecting the toe in horses with dorsal solar concerns such as solar prolapse dorsal to the frog. While this shoe currently appears to have fallen out of favor, it may offer a simple solution, particularly when used in horses in which access is needed to the dorsal aspect of the sole.

The heart-bar shoe (Figure 4.76) has been the traditional mainstay in the treatment of horses with laminitis.[12] The heart bar is a V-shaped piece of bar stock that has been welded between the branches of the shoe to cover the frog. Alternatively, the heart bar may be forged into the shoe, either by hand or during manufacture. As such, it can be modified in the same manner as the keg shoe. The original rationale behind employing this shoe is that it recruits weight-bearing by the frog and hence decreases weight-bearing by the lamellae. An alternative explanation for the effectiveness of this shoe is that it increases the ground surface area of the shoe in the palmar half of the foot and hence either acts as a mild wedge or at least decreases the descent of the heels into a soft substrate.

The overall principles involved in trimming and setting the shoe are similar to those of the keg shoe. However, care must be taken to ensure that there is not undue pressure from the heart bar on the frog that would result in bruising and increase lameness. Because of this concern, many farriers leave a small space between the frog and heart bar and apply a synthetic polymer underneath the heart bar; synthetic polymer can also be placed alongside the heart bar between the branches of the shoe. The heart bar may also be used in conjunction with an open toe or egg-bar shoe.

The four-point rail shoe is based on the pattern of an open-heeled shoe.[62] The toe of the shoe is squared, aggressively rolled, and broadened. Additionally, narrow wedges, called rails, are applied to the axial side of the ground surface of each branch to raise the heels. Thus, this shoe by design incorporates both ease of break-over at the toe and elevation of the heel. The use of the rails applied to the axial side of the branch of the shoe also provides improved medial and lateral break-over compared with other designs of shoe used for laminitis.

While the shoe may be hand forged or modified (Figure 4.77), the majority of those used are one of two commercially available designs: the Aluminum Four-Point

VetBooks.ir

Rail Shoe and the EDSS (Figure 4.78). The Aluminum Four-Point Rail Shoe is manufactured to incorporate all the features of the four-point rail shoe in a single unit, with incorporation of the rail into the shoe (NANRIC Co., Lawrenceburg, KY). The EDSS is marketed in the form of a kit (Figure 4.78) (Equine Digit Support System, Inc. Penrose, CO). The kit includes a flat shoe with the break-over previously described and a range of rails of different heights that can be attached to the ground surface of the shoe. Additionally, the kit contains pads, frog-shaped inserts, and silicone putty.

The advantage of the Aluminum Four-Point Rail Shoe is simplicity of construction and application; recruitment of the sole, frog, and bars to bear weight is achieved with a synthetic polymer. The disadvantage of this shoe compared with the EDSS is that the rails are of fixed height (although they can be ground down as needed) and cannot be readily adjusted once the shoe is on the foot. The advantages of the EDSS are that the rails can be applied after the shoe is on the foot and the height of the rails can be selected/adjusted. The kit is designed to recruit weight-bearing by applying a pad between the shoe and foot in conjunction with silicone putty placed between the pad and foot; plastic frog inserts can be screwed to the ground surface of the pad. Alternatively, the shoe and rails can be used with a synthetic polymer placed in the concavity of the foot and between the branches of the shoe instead of the pad and frog insert.

The Steward clog/wooden shoe (Figure 4.79) as originally described is cut from 0.75-inch plywood to correspond to the size of the foot, with a squared toe and a 45° bevel all around its perimeter so that the ground surface is smaller than the foot surface.[67] The thickness of the shoe may be increased by the addition of an additional three-quarters inch of plywood or rubber similarly beveled and added to the ground surface of the shoe. The shoe is set back from the toe so that the dorsal margin of the shoe is approximately 1.5 inches dorsal to the apex of the frog. Silicone putty may be applied between the palmar aspect of the hoof and the shoe and the shoe is attached with screws. Usually, an adhesive or a 2-inch roll of casting tape is applied over the screw heads and distal wall to improve stability. Furthermore, the shoe is open to almost infinite customization, more common forms of which include adding a wedge or recessing the dorsal solar surface for horses with solar prolapse. This shoe is simple to make and apply. By varying its customization, it can achieve all of the goals previously outlined. It is likely that the properties of the wood itself offer some advantages in relation to comfort during weight-bearing. In addition, it has been postulated that the thickness of the shoe may have at least two other advantages: (1) it permits greater adjustability for the point of and curvature of break-over, and (2) it has been postulated that the height may elevate the forelimbs sufficiently to transfer weight to the hindlimbs. Although the shoe is primarily used on forelimbs, Steward has used a shorter variety of the clog on hindlimbs (Mike Steward, personal communication).

Figure 4.78. (A) The Equine Digital Support System is a kit that provides a convenient way to adjust the break-over, support the ground surface of the foot, and elevate the heels. (B) As an alternative to using all the components of the kit, ground support may also be provided with polymerized silicone.

VetBooks.ir

The Sigafoos Series II shoe (Figure 4.80) is a kit that is composed of a cuff bonded to a rim that is attached to an aluminum plate that covers the ground surface of the foot (Sound Horse Technologies LLC, Unionville, PA). The aluminum plates may be flat or wedged and have a urethane bonding surface to which additional wedges may be bonded. This shoe can be highly customized to achieve the principal objectives. The attachment of the shoe with a cuff is atraumatic compared with nailing a shoe on, and placement of the acrylic on the outside of the wall causes less harm to the wall than when the acrylic is placed on the ground surface of the wall. Because the cuffed shoes follow the perimeter of the hoof capsule, they may require more extensive modification to set the toe back compared with other methods of shoe application.

The choice of shoe for each case is in large part personal preference based on cost, experience, and availability. It is important to emphasize principles over technique. There are several complications common to various shoeing techniques. Where weight-bearing has been relieved at the toe and concentrated at the quarters, the wall at the quarters is likely to become thinner and less resilient. Additionally, prolonged heel elevation frequently leads to heel contraction. Finally, prolonged attachment of the shoe with acrylics leads to deterioration in the mechanical properties of the wall, particularly if it is applied to the ground surface of the wall.

The application of the general shoeing principles must be titrated to the specific symptoms of the individual horse. The less damaged the lamellae, the less aggressively eased break-over, ground support, and heel elevation are required. Improving the ease of break-over benefits any horse with laminitis. The amount of area across the ground surface of the foot that should be used to distribute weight-bearing is subjective. Pressure should be limited where compression of the underlying dermis may occur between the sole and an unstable or displaced distal phalanx. Otherwise, the comfort of the horse and the perceived instability of the distal phalanx are the best indicators. The requirement for (and degree of) heel elevation is in part similarly determined by the discomfort of the animal, but also by the way the horse lands. Adjusting the heel height so that the horse lands slightly heel first is likely to result in the greatest comfort and stability of the distal phalanx.

Figure 4.80. Sigafoos Series II shoe.

The treatment time scale is highly variable and based on the severity of the original disease, recurrence of the disease, and the development of complications. However, some generalizations can be made. A more severely affected horse that is amenable to treatment and improves in an uncomplicated manner is usually shod somewhere between 3 and 6 weeks after the onset of the acute disease with eased break-over, ground surface support, and heel elevation as needed. It is desirable to remove heel elevation as soon as possible after the horse is comfortable landing with a flat foot to limit contraction of the heels, usually between 3 and 6 months. Sole support may be removed, usually in a gradual manner, between 4 and 8 months. The most successful cases may return to near normal shoeing or barefoot trimming between 8 and 12 months. Obviously, less severely affected horses that do not develop complications should recover correspondingly quicker. Horses that suffer recurrent acute episodes or develop complications may take much longer to respond or never respond satisfactorily.

Treatment of Chronic Laminitis with Distal Displacement

Horses that suffer distal displacement present different challenges from those with dorsal rotation. First, treatment directed at the acute and early chronic disease frequently lasts considerably longer than that for horses with rotation. Easement of break-over and ground surface support are both potentially beneficial and achieved in the same manner as previously described. However, there is no rationale or perceived benefit to elevating the heels; this commonly makes these horses worse. The wooden shoe/clog has gained a great deal of popularity in the treatment of distal displacement in the forelimbs.

Treatment of Chronic Laminitis with Unilateral Distal Displacement (Medial or Lateral Rotation)

The transition between the hoof care used to treat horses with acute and early chronic disease to that of stable chronic laminitis due to unilateral displacement is more blurred than in the previous scenarios because there is much less experience in treating this condition and complications, particularly separation of the coronary band, are common. However, in line with the overall objective to redirect the load away from the most damaged area of the lamellae, the logical approach is to attempt to redirect the load to the opposite side of the foot in conjunction with ground surface support.[55] This can be accomplished by either placing a 4- to 8-mm extension (concentrating ground support on the extended side; Figure 4.81) or placing a thin wedge on the side of the foot opposite the displacement or changing the weight-bearing area under the foot asymmetrically. Of these treatments, the wedge is the most aggressive and does not appear to be necessary and as such is best avoided. Therefore, starting with an extension or modifying ground surface support is suggested. The application of a wedge to the unaffected side of the foot appears counterintuitive if only the radiographic

VetBooks.ir

position of the distal phalanx within the hoof capsule is considered because it is natural to try and restore the alignment of the DIP joint. However, consideration of the stresses within the lamellae suggests that restoring the symmetry of the DIP joint is likely to be counterproductive. Unilateral distal displacement frequently occurs with some rotation, in which circumstances heel elevation may also be warranted. While this technique has been beneficial in some horses, more experience is required before firm recommendations are possible.

Figure 4.81. This horse has medial asymmetrical distal displacement, evidenced by disparate growth of the medial and lateral walls. A wooden shoe has been positioned to act as a lateral extension to increase weight-bearing by the healthier lateral side of the foot to decrease pain from compression of the sole and tension in the lamellae medially. *Source*: Courtesy Dr. Stephen O'Grady.

Casting and Splinting

Casting the distal limb is beneficial in horses with acute and early chronic laminitis but is particularly valuable in the treatment of chronic cases with unilateral complications such as subsolar abscessation (Figure 4.82). Half-limb casts, half-limb casts with transfixation pins, and open soled half-limb casts have been used.[6] However, foot or pastern casts may also provide some stability to the lamellae.[11] If fit snugly at the proximal end of the metacarpus, the half-limb casts potentially offer some weight sparing by the digit. However, transfixation pin casts are likely to provide dramatically greater load sparing by the foot. Additionally, by decreasing movement within the distal limb, casts may decrease the pain as the horse moves around a stall. Open soled casts offer the advantage that the ground surface of the foot can be inspected and treated while the foot is in the cast and that load bearing by the ground surface of the foot may be more selectively applied using synthetic polymers. If casts are only placed on one limb, it is important to place some type of support on the contralateral limb to both support the foot (which is usually also affected with chronic laminitis) and equalize the height of the two limbs. Splints offer some of the advantages of immobilization, but offer no relief from load bearing.

Deep Digital Flexor Tenotomy

Tenotomy of the DDFT abolishes or greatly reduces or abolishes the flexor moment about the DIP joint. The direct result is that the center of pressure should move in a palmar direction to a point directly distal to the center of rotation of the DIP joint. The benefits are that it decreases the tension within the dorsal lamellae and compression on the dorsal sole, thus allowing realignment of the distal phalanx with the ground without exacerbating the deleterious forces on the dorsal lamellae and sole (Figure 4.82B and C). This is usually accompanied by decreased pain and increased sole growth dorsally. The disadvantages are that the toe of the foot may become elevated from the ground as the horse rocks back or ambulates and that mild to moderate subluxation may occur in the DIP joint

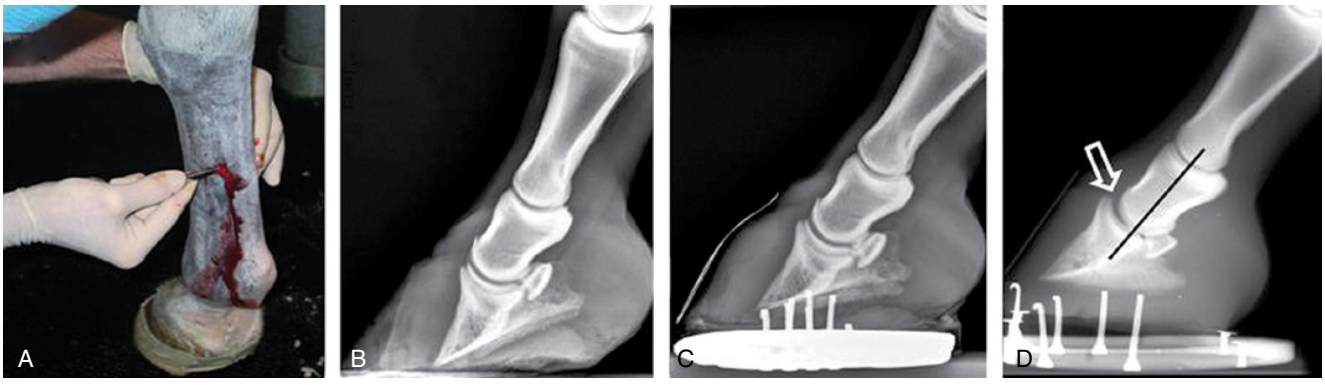

Figure 4.82. Tenotomy of the DDFT is most commonly performed standing at the mid-cannon region using a guarded bistoury (A). The tenotomy allows realignment of the rotated distal phalanx (B) with the ground surface (note realignment of the foot in C after 6 weeks). Subluxation of the DIP can occur following the procedure (D), characterized by dorsal displacement of the extensor process of the distal phalanx away from middle phalanx (arrow) and by caudal displacement of the distal articular surface of the middle phalanx so that a line bisecting the middle and proximal phalanges does not bisect the middle of the articular surface of the distal phalanx (black line).

VetBooks.ir

(Figure 4.82D). Based on these responses, the surgery is primarily indicated in horses with:

1. Early chronic laminitis that continues to rotate despite all other measures taken
2. Intractable pain originating from the dorsal sole and wall despite stabilization and shoeing
3. Secondary flexural deformities

It does not appear to consistently benefit horses with distal displacement and rarely if ever benefits the horse with unilateral distal displacement of the distal phalanx.

The surgery may be performed in the mid-metacarpal region (Figure 4.82A) or in the midpastern region.[1,69] The surgery is easier to perform in the mid-metacarpal region. Additionally, should a second tenotomy be necessary, it is preferable to perform the proximal one first because adhesions may limit the effectiveness of the second surgery in the metacarpal region if the first surgery was performed in the pastern. Tenotomy in the midpastern appears to provide greater mobility of the foot about the DIP joint, but may also cause more instability of the joint.

The tendon may be cut immediately before or after corrective trimming and shoeing is performed (it is probably best to perform the surgery first to address possible DIP subluxation following DDFT). Because tissue repair at the tenotomy site occurs fairly rapidly and will inhibit any further realignment, it is imperative to obtain the best realignment of the distal phalanx with the ground and phalanges as soon as possible after surgery (i.e. within hours to days). To counter the disadvantages of the surgery, it is advisable to perform radiographs while shoeing immediately following tenotomy of the DDFT to assess both the adequacy of the realignment of the distal phalanx to the ground surface and, importantly, the degree of subluxation of the DIP joint (indicated by both dorsal displacement of the extensor process of the distal phalanx away from the middle phalanx [arrow, Figure 4.82D] and by palmar displacement of distal articular surface of the middle phalanx in relationship to the articular surface of the distal phalanx [line, Figure 4.82D]). Application of increasing degrees of heel elevation can be assessed radiographically until the subluxation is resolved. If radiographic assessment is not available post-tenotomy, the horse should be shod with mild heel extension and elevation (approximately 3°).

Drainage and Debridement

Digital sepsis is a well-recognized complication associated with laminitis. Drainage may occur at the coronary band or through the dorsal sole. In most horses, the infection is confined to the soft tissues of the hoof, but, occasionally, the infection may involve the distal phalanx. If the hoof capsule of the sole is removed, the solar dermis usually prolapses, and the prolapsed tissue is extremely sensitive to pressure (Figure 4.83). Therefore, when subsolar sepsis is present, it is advisable to create an avenue for drainage through the distal wall rather than the sole whenever possible. If solar drainage is performed, very small portals should be made at the opposite sides of the affected area for drainage and to allow insertion of a catheter or teat cannula for lavage with saturated Epsom salts (in contrast to removing excessive sole; Figure 4.83).

Sepsis of the distal phalanx can be difficult to both diagnose and treat. It is difficult to diagnose because the radiographic changes in the distal phalanx associated with sepsis closely resemble those associated with prolonged inflammation, and therefore, septic and nonseptic inflammation is very hard to distinguish. In the majority of subsolar sepsis cases, the sepsis does not involve the bone. However, direct contact of bone after inserting a probe in a draining track conclusively identifies exposure of the bone to sepsis and is highly suggestive of septic osteitis (combined with radiographs indicative of severe focal lysis at point of probe contact).

In the authors' experience, septic osteitis of the distal phalanx is much more refractory to treatment in horses with laminitis than in horses in which the sepsis occurred for another reason. Additionally, surgery, usually consisting of curettage of the suspect bone, exposes the surface of the distal phalanx in a horse that did not have septic osteitis and increases the likelihood that the horse will develop septic osteitis. Therefore, infection should be treated as superficial unless drainage can be directly linked to the bone or prolonged treatment fails to resolve it and septic osteitis is the best explanation for the con-

Figure 4.83. Painful granulation tissue (arrow) covered with fibrin exists due to prolapse of the dermis secondary to displacement of the distal phalanx and excessive trimming of the sole. Removal of the sole from the foot in horses with chronic laminitis should be minimized to avoid this painful complication.

VetBooks.ir

tinued drainage. In the severely underrun subsolar abscess, one author (JKB) lavages the foot with saturated Epsom salts delivered through a catheter or teat cannula through small portals either in the distal hoof wall (preferred) or sole. If there is moderate to severe capsular rotation also present in the affected foot, a deep digital flexor tenotomy with "derotation" of the distal phalanx is also indicated to improve healing and decrease the chance of recurrence by decreasing the pressure on the affected dorsodistal aspect of the distal phalanx and the adjacent subsolar/solar tissue.

HOOF WALL RESECTIONS

Full dorsal hoof wall resections were at one time widely advocated to decrease the pressure of the wall on the coronary band, debride necrotic material, and encourage the realignment of the distal phalanx.[12] They accomplish these goals to some degree, including enhancing growth of new wall at the coronary band and increasing the likelihood that the newly formed wall will conform to the parietal surface of the distal phalanx. However, resecting the dorsal wall removes any support that the dorsal wall supplied to the distal phalanx, increases the vertical stresses in the wall at the margins of the resection, and causes further instability by removing circumferential tension that spans the dorsal hoof capsule connecting quarter to quarter. Consequently, the remaining dorsal quarters are more likely to become distracted from the underlying tissues. Therefore, more limited/partial hoof wall resections are more commonly performed than total dorsal hoof wall resections to minimize the loss of support to the distal phalanx and stability of the adjacent wall observed in more extensive resections. They are currently most commonly performed to debride necrotic tissues and remove the lamellar "wedge" to encourage new hoof wall growth to follow the contour of the distal phalanx.

CORONARY BAND GROOVING AND RESECTION

Coronary band grooving is designed to take pressure off the coronary band to increase the rate of new hoof wall growth (Figure 4.84).[64] It also creates a discontinuity between older, more distal hoof wall and the newer proximal wall so that the distal wall is less likely to distract the new hoof away from the distal phalanx. The groove is created in the dorsal hoof wall at the level of the base of the extensor process and extends through the full thickness of the stratum medium of the wall from one toe–quarter junction to the other. A modification of this technique involves creation of the groove as described above and then removing all of the stratum medium proximal to the groove to the level of the coronet. In the authors' experience, results with this technique are highly variable.

Resection of the cornified layer of hoof at the coronary band is probably most frequently performed when the hoof wall has separated from the coronary band. In these circumstances, it is done to decrease the chafing by the separated—and therefore somewhat mobile—hoof wall that damages underlying viable germinal tissue and enhance drainage of exudate that has accumulated under the separated tissues. It is advisable to bevel the proximal margin of the remaining hoof wall so that it is thinnest proximally (immediately distal to the coronary band) to minimize the pressure ridge that develops and impinges the underlying dermis of the coronary band and proximal lamellae. The indications and optimal timing for this procedure have not been determined.

Figure 4.84. Grooving of the proximal dorsal hoof wall immediately distal to the coronary band to encourage dorsal hoof wall growth and mechanically dissociate new hoof wall growth from the older distal wall.

Prognosis

There are numerous reasons why treatment of horses with laminitis is unsuccessful, but the three most important reasons are the severity of the original pathology, type of displacement, and severity of the clinical signs.[5,38,55,56] These factors are likely to determine the continued course of the disease and the development of complications. The prognosis following displacement is always considered guarded to poor.

Regarding the different types of displacement, rotation is considered to have a more favorable prognosis than either symmetrical or asymmetrical distal displacement. Increased experience with the treatment of asymmetrical distal displacement suggests that the prognosis for this condition is better than that with symmetrical displacement so long as separation at the coronary band has not occurred. Two radiographic criteria have been documented to determine prognosis: the degree of rotation and the distance from the proximal margin of the extensor process of the distal phalanx to the firm proximal margin of the hoof capsule (immediately distal to the coronet, distance also termed the "founder distance").[14,68] Capsular rotation greater than 11.5° predicted poor survival and capsular rotation less than 5.5° predicted return to performance. A coronet-to-extensor-process distance of greater than 15.2 mm is indicative of poor survival. Both of these reports are dated, and with recent advances in the treatment of this disease, their prognostic value should be reassessed. Additionally, the thickness of the sole and the angle that the solar margin of the distal

VetBooks.ir

phalanx subtends with the ground may be beneficial in assessing the prognosis for success; thinner soles and greater angles of the solar margin of the distal phalanx are anecdotally associated with decreased prognosis. Finally, financial constraints of the owner and the failure of the owners to follow recommendations, particularly advice regarding exercise and maintaining appointments, are likely to decrease the success of treatment.

THE PASTERN

Ashlee E. Watts and Gary M. Baxter

VetBooks.ir

The proximal interphalangeal (PIP) joint or pastern joint is a diarthrodial joint, which is formed from the distal aspect of the proximal phalanx (P1) and the proximal aspect of the middle phalanx (P2). The pastern region is bounded dorsally by the common or long digital extensor tendon together with the dorsal branches of the suspensory ligament. Palmar/plantar support structures of the pastern region are formed by the distal sesamoidean ligaments (DSLs) (straight, oblique, cruciate, and short), superficial digital flexor tendon (SDFT), deep digital flexor tendon (DDFT), and proximal and distal digital annular ligaments within the digital flexor tendon sheath (DFTS). The medial and lateral collateral ligaments provide support in the sagittal plane.

Abnormalities such as dorsal swelling or bony enlargement in the pastern region are often obvious due to minimal soft tissue in the area. The severity of lameness from the pastern region ranges from subtle to severe depending on the injury. Generally, injuries such as fractures that involve the PIP joint or tendinitis within the DFTS cause obvious lameness, whereas lameness due to early osteoarthritis (OA) of the PIP joint or strains of the DSLs may be mild. Pain and lameness in the pastern region is often exacerbated by distal limb flexion or lunging the horse with the affected limb on the inside of the circle.

Complete analgesia of the pastern region by perineural analgesia is variable. Occasionally, horses will have complete analgesia after a palmar digital (PD) nerve block,[9] most will not have complete analgesia until a basisesamoid or abaxial nerve block has been performed, and still others may require a low four-point nerve block. When blocking the pastern region, horses with suspected stress fractures of P1 should not be blocked to avoid further displacement of the fracture.

Radiography is important for the initial characterization of the injury. Ultrasonographic evaluation of the pastern is an integral part of characterizing the extent of any soft tissue injury. Additionally, nuclear scintigraphy, computed tomography (CT), magnetic resonance imaging (MRI), or tenoscopy of the DFTS may all be important to provide additional information necessary for a complete and accurate diagnosis and prognosis.

Differential diagnoses for disorders of the pastern region include PIP joint OA, osteochondrosis (OC), fractures, bone bruises, luxation/subluxation of the PIP joint, infection, lacerations, and soft tissue injuries; however, the types of injuries are often breed or use specific. For the purposes of this discussion, conditions of the pastern will include bone and joint abnormalities of P1 and P2 and the PIP joint and soft tissue injuries of the palmar/plantar aspect of the pastern including the DSLs, digital annular ligaments, distal branches of the SDFT, and the DDFT within the distal aspect of the DFTS.

OSTEOARTHRITIS (OA) OF THE PIP JOINT (HIGH RINGBONE)

The term "high ringbone" is often used synonymously with OA of the PIP joint and "low ringbone" with OA of the distal interphalangeal joint. Most cases of ringbone present with both joint and periarticular pathology.[43] OA or degenerative joint disease of the PIP joint is an important and common cause of lameness in virtually all breeds and ages of horses.[56] Older horses appear to be at greater risk and the forelimbs are more frequently affected than the hindlimbs. Secondary OA from P2 fractures (particularly palmar/plantar eminence fractures) or OC occurs more commonly in the hindlimbs.[31,71]

Etiology

Chronic repetitive trauma of the PIP joint and surrounding structures is thought to be the most common cause of PIP joint OA. Inherent conformational traits and the type of work the horse performs may also contribute to problems in the PIP joint. For example, horses that are base narrow and toe out are thought to be predisposed to OA on the lateral side of the joint, whereas horses that are base wide and toe in are believed to be predisposed to injury on the medial side of the joint. Pasterns that are overly upright may also result in increased concussion to the PIP joint

Figure 4.85. An upright pastern conformation predisposes to pastern OA.

VetBooks.ir

(Figure 4.85). Poor conformation may predispose to pulling/tearing of the soft tissues surrounding the joint or to incongruences within the joint surfaces. In addition, western performance horses that are required to start and stop suddenly or twist and turn abruptly appear to be prone to PIP joint damage.

Trauma to the periarticular soft tissues and the PIP joint may be repetitive or occur as a single, high-energy event that does not cause a fracture or joint luxation. Because the PIP joint is considered a low-motion/high-load joint, the articular cartilage and subchondral bone are placed under a greater workload, making these structures more susceptible to injury from nonphysiologic loading.[50] Overloading the PIP may cause direct articular cartilage damage and/or subchondral bone bruising that may contribute to the development of subchondral cystic lesions (SCLs) (Figure 4.86) or OA. Trauma may also cause injury of the periosteal attachments of the extensor tendons, ligaments, and joint capsule, resulting in periostitis and new bone formation. In addition, these injuries may cause joint instability or subluxation leading to secondary cartilage damage and OA. The OA may also result from an imbalance between repetitive microtrauma sustained during athletic performance and the adaptive repair mechanism of the skeletal tissue.[50] Whether primary synovitis/capsulitis is a distinct entity involving the PIP joint is uncertain,[43] but it is less commonly recognized than with other joints in the horse. Lame horses that block to intra-articular (IA) anesthesia of the PIP joint that do not have radiographic abnormalities may have PIP joint synovitis/capsulitis, subchondral bone bruising, or other unrecognized bone or cartilage damage that can only be recognized with advanced imaging such as CT or MRI (Figure 4.87). When bone bruising does not involve the subchondral bone, it can be expected to heal without long-term consequences with rest alone (Figure 4.88).

OA of the PIP joint may develop secondarily to a number of abnormalities within the joint. These include OC, unrecognized palmar/plantar eminence fractures of P2, traumatic blows or lacerations, septic arthritis, and selective weight-bearing in young horses.[16,23,71] OA of the PIP joint secondary to OC is usually seen most frequently in the hindlimbs of horses less than 3 years of age, and more than one joint can often be affected.[71] Single eminence fractures of P2 also occur most commonly in the hindlimb and can be the cause of chronic hindlimb lameness if unrecognized at the initial injury. Direct blows to the pastern region and lacerations at the margin of the PIP joint or involving the collateral ligaments may contribute to OA of the PIP joint. Infectious arthritis is often associated with an existing laceration or puncture wound that involves the PIP joint but may also develop after a wound has completely healed.

Clinical Signs

Focal or diffuse enlargement of the pastern region may be evident visually as well as on palpation (Figure 4.89). Palpable heat and pain with firm digital pressure may be appreciated. The affected pastern region may feel larger, particularly the dorsolateral and dorsomedial surfaces, than the contralateral joint. In most

Figure 4.86. Dorsoplantar radiograph of a trauma-induced SCL of the distal aspect of P1 (arrow) that was not apparent radiographically until 3 months after the original injury.

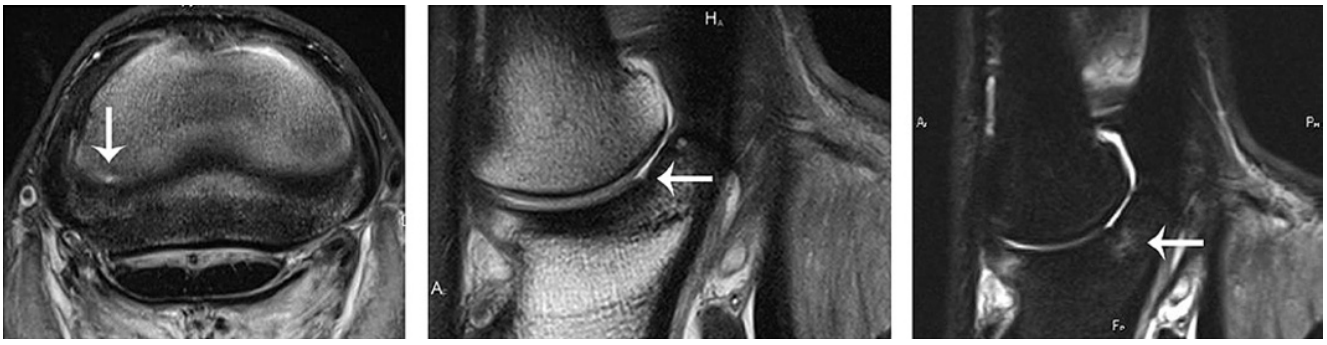

Figure 4.87. Proton density-weighted (left and center) and STIR (right) MR images from a horse with moderate to severe lameness of 1 month's duration that blocked to the pastern joint. There were no radiographic abnormalities. There is an articular cartilage defect (arrow left and center) and fluid signal intensity/bone marrow lesion in the subchondral bone (arrow right). The lameness did not improve with stall rest. The lameness persisted and the joint developed radiographically apparent signs of OA after 3 months of stall rest and it was treated with a pastern arthrodesis.

VetBooks.ir

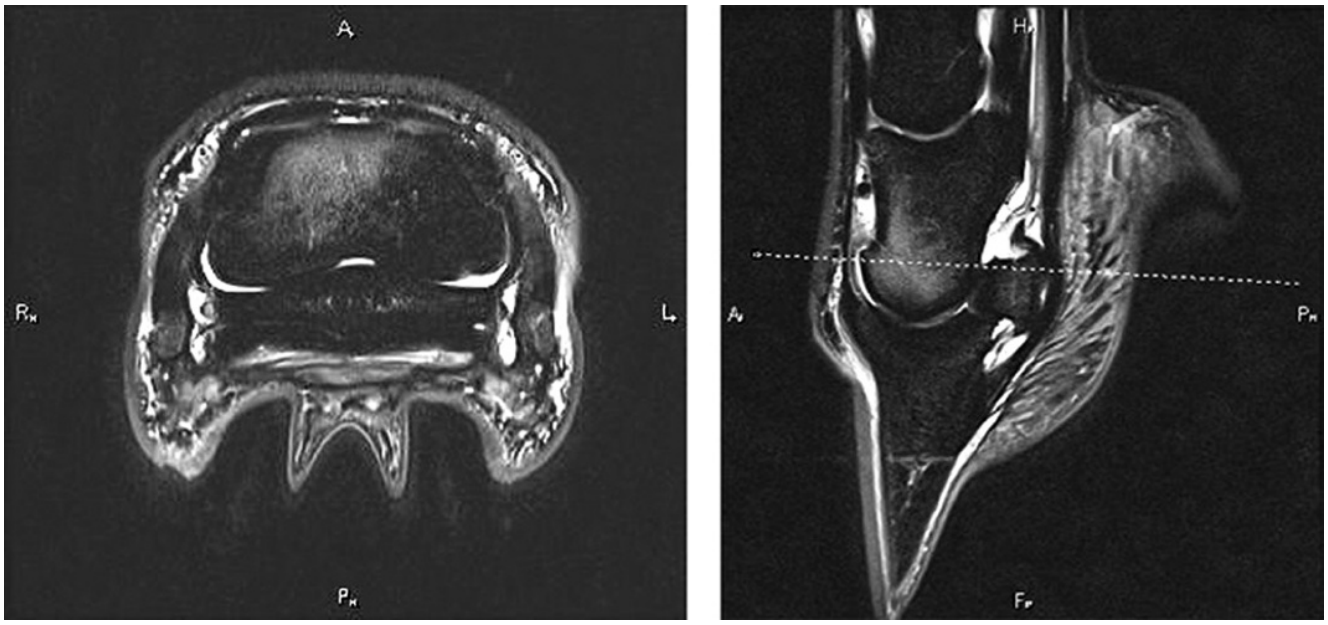

Figure 4.88. Transverse and sagittal STIR MR images with a large bone bruise of the dorsodistal P2. Because this lesion does not involve the subchondral bone, it healed without long-term consequences with rest alone.

Figure 4.89. Typical enlargement of the pastern that may be visible in horses with OA of the PIP joint. This was a 9-year-old Warmblood show jumper that was presented for pastern arthrodesis.

horses there is pain on flexion and rotation of the pastern region, unless the joint has undergone ankylosis. Obvious enlargement of the pastern and/or varus deformity of the phalanges may be present in horses with advanced disease. Horses with mild or early disease may have no visual or palpable abnormalities in the pastern region.

Lameness severity is variable depending on the severity of the disease. When there is radiographically apparent OA, the severity of lameness often correlates with the severity of the OA within the PIP joint, especially when there is joint space narrowing. The lameness is usually exacerbated at a trot, at exercise on an uneven surface (e.g. slope), or by circling at a trot. Except in early cases where there is focal medial injury, increased lameness is usually seen when the affected limb is on the inside of the circle. In some cases during foot flight, an exaggerated extension of the toe may be seen prior to foot placement.[68]

Pastern joint-associated lameness should not improve with a PD nerve block if performed very low in the pastern (just above collateral cartilages) with a small volume of anesthetic (1.5 mL).[62] However, some PD nerve blocks may desensitize the PIP joint. Most horses improve with a basisesamoid or high PD nerve block but may not become completely sound, especially if the disease process is severe. Response to IA analgesia varies depending on the injury, but improvement of lameness by 50% or more usually implicates the PIP joint as the site of the problem. The authors prefer the palmar/plantar approach to block and inject the PIP joint when there is dorsal bony proliferation, which can make the dorsal approaches more difficult.[45]

Diagnosis

A tentative diagnosis of OA of the PIP joint is often made based on physical examination findings combined with the responses to local anesthesia and radiographs. The most common radiographic findings in a study performed on 196 horses (262 joints) with chronic OA of the PIP joint were (1) joint space narrowing or collapse, (2) osteophyte formation, (3) subchondral bone sclerosis, (4) periosteal/periarticular bony proliferation, (5) deformity/collapse of the joint space, and (6) subchondral lysis (Figure 4.90).[15] Other radiographic features that may be identified include SCLs (Figure 4.86) or OC lesions,[71] and chronic eminence fractures of P2.

VetBooks.ir

Figure 4.90. Lateral radiograph of the pastern demonstrating periosteal reaction and small osteophytes on the dorsal aspect of the joint indicative of mild to moderate OA within the joint. Dorsopalmar radiograph of the same pastern demonstrating enthesophytes, subchondral lysis, and asymmetrical joint space collapse indicative of severe OA within the joint. This horse would not be expected to do well with medical therapy.

Periarticular new bone growth associated with lacerations may be limited to the site of trauma unless the joint was invaded and/or infectious arthritis is present. Infectious arthritis of the PIP joint often causes severe periosteal/periarticular bony proliferation, osteophyte formation, and subchondral lysis seen on radiographs. Older horses with trauma-induced OA or young horses with OC should have radiographs of the contralateral PIP joint performed because these disease conditions are often bilateral.

In early acute cases, there may be minimal to no palpable changes of the pastern region, and even radiographic examination may not reveal abnormalities. In these cases where pastern injury is still suspected, MRI[49,79] and/or ultrasound exam can be performed. MRI findings in cases of OA of the PIP joint include the same radiographic findings of osteophytes, joint space narrowing, subchondral lysis, periosteal proliferation with enhanced ability to detect subchondral bone changes (lysis, sclerosis), bone marrow lesions, SCLs, articular cartilage lesions, and joint effusion (Figure 4.87). Alternatively, repeat radiographic examination can be performed in 1–2 months because evidence of periostitis (periarticular new bone) and peripheral osteophyte formation may be present at that time.

Treatment

Conservative Management

The decision regarding treatment of horses with OA of the PIP joint depends on the severity of the disease, degree of lameness, age and intended use of the horse, and the owner's expectations and financial constraints. Horses with severe lameness and advanced radiographic abnormalities are usually not good candidates for nonsurgical treatments. It is important to note that the most important radiographic finding in grading the severity of OA of the PIP joint is joint space narrowing, especially when narrowing is asymmetrical (Figure 4.90). Horses with quite severe accumulation of periarticular bone but normal joint space width would be more likely to respond to conservative therapy than horses with joint space collapse, despite both groups having so-called severe radiographic changes (Figure 4.91). Horses with mild to moderate radiographic abnormalities of the PIP joint may respond well to conservative treatment, depending on the horse's intended use. Horses with a single traumatic injury to the pastern, such as those with an MRI diagnosis of a bone marrow lesion, may respond well to rest with complete healing and no long-term evidence of joint disease or OA (Figure 4.89), while others with bone marrow lesions may develop OA in the following months (Figure 4.88). There are numerous treatment options and the decision on how to treat horses with OA of the PIP joint is often made on a case-by-case basis.

Conservative management of PIP OA may involve periods of rest, systemic and/or IA anti-inflammatory therapy, trimming and shoeing, and a change in the horse's career. See Chapter 8 for more specific details on these treatment modalities. In acute traumatic cases, stall confinement and rest from exercise are important to prevent further trauma, reduce inflammation, and permit healing to occur.[16,68] Rest periods may extend from weeks to months depending on the severity and type of the injury and the response to treatment. Confinement and rest is rarely effective in horses with chronic OA of the PIP joint.

VetBooks.ir

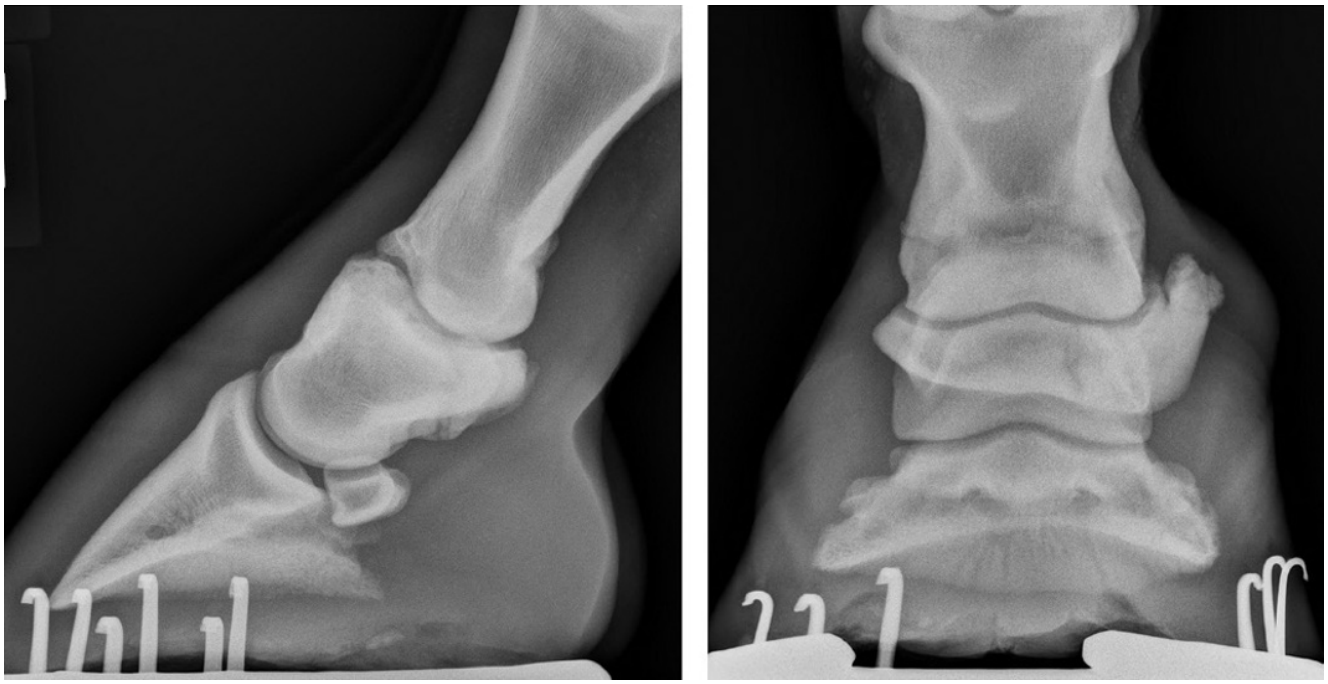

Figure 4.91. Lateral and dorsopalmar radiographs of the pastern with severe periarticular bone dorsally and medially but not joint space narrowing. Radiographs of the contralateral limb were nearly identical. This horse had minimal to no hindlimb lameness and was maintained in full work (reining) for 2 years after these radiographs were made. Recheck radiographs 2 years later were largely unchanged and there continued to be minimal lameness.

Often oral NSAIDs are combined with IA medication (steroid ± hyaluronan [HA]) of the PIP joint in horses with chronic OA to reduce the signs of lameness and improve the effectiveness of both treatments. A combination of a steroid (e.g. triamcinolone or methylprednisolone acetate) and HA can also be used IA in horses with acute disease to reduce inflammation and slow the progression of the disease. Intramuscularly or IA polysulfated glycosaminoglycans (PSGAGs), IV HA, and oral nutraceutical supplements are also commonly used.

There is some debate as to whether corrective shoeing can benefit horses with PIP joint problems. Changing heel height appears to have much more effect on altering flexion and biomechanical forces of the DIP joint than the PIP joint. In addition, raising the heel decreases the strain on the DDFT but increases strain on the SDFT and the suspensory ligament.[34] Therefore, adjusting heel height may not be beneficial in horses with PIP joint problems. However, the hoof-pastern axis should be corrected if abnormal because either a broken-forward or broken-back hoof-pastern axis can contribute to problems within the PIP joint. In general, the feet should be trimmed and balanced, and shoes applied that minimize break-over forces and provide good lateral and medial support. See Chapters 8 and 12 for more information on corrective shoeing.

Surgical Treatment

Surgical treatment for OA of the PIP joint consists of arthrodesis, which is aimed at eliminating motion within the joint, thereby decreasing pain and lameness. Natural ankylosis of the PIP joint may occur, but it is often a long, painful process with variable results. Surgical arthrodesis is generally considered a better solution with more consistent results. Numerous surgical techniques have been proposed over the years to promote arthrodesis of the PIP joint.[6,8,21,23,28,31,37,41,59,66,67,74]

The basic principles of surgical arthrodesis include removal of the remaining articular cartilage; internal fixation of P1 and P2 with screws, plates, or a combination of plates and screws; compression across the joint surface; accurate alignment of the phalanges; and variable periods of external immobilization with a half-limb cast. The authors prefer a single dorsally applied 4.5-mm, narrow, 3-hole LCP with two 5.5-mm transarticular screws in most horses (Figure 4.92). In very large horses two plates with transarticular screws may enhance stability. This technique of a dorsal plate with transarticular screws is thought to improve the comfort level of horses in the immediate postoperative period and requires casting for only 2 weeks postoperatively to optimize surgical wound healing.[31] Cancellous bone grafting is usually unnecessary, but forage or osteostixis of the subchondral bone around the joint may promote faster arthrodesis, especially in older horses that have very dense sclerotic bone. Bilateral forelimb or bilateral hindlimb arthrodesis may also be performed successfully.

Following a routine arthrodesis, the cast is removed after 2 weeks, which is adequate time for the surgical wound to heal.[31] When minimally invasive procedures can be used on moderately to severely affected OA joints, horses can be placed in a bandage only after surgery.[74] Arthrodesis for phalangeal fractures usually require a longer period of external immobilization. Postoperative stall confinement is recommended for a total of 8–12 weeks with introduction of hand-walking exercise during this time. For the second 2–3 postoperative months, horses are either small paddock confined or

VetBooks.ir

the amount of in-hand exercise is increased, dependent on horse temperament and available facilities. Although some horses may be ready to return to performance by 6 months, up to a year of convalescence may be required for others. The implants do not typically need to be removed.

Prognosis

After arthrodesis of the PIP joint, approximately 89%–95% of horses with hindlimb and 70%–85% of horses with forelimb lameness should return to their intended use, and 85% will return to athletic soundness.[31,37,41,59] Complications that may prevent horses from becoming athletically sound include implant infection, excessive bony proliferation that impinges on the DIP joint, exostosis of the extensor process of the distal phalanx, and soft tissue "irritation" associated with the implants (screws protruding from the palmar/plantar aspect of P1 and P2).

OSTEOCHONDROSIS (OC) OF THE PIP JOINT

OC of the PIP joint is identified less commonly than other joints in the horse. However, both osteochondral fragmentation and SCLs can be seen in the PIP joint.[19,20,52,60,70,71] Osteochondral fragments tend to occur dorsally (usually from the distal aspect of P1) or palmarly/plantarly (midline from the eminences of P2; Figure 4.93). SCLs due to OC are usually seen on the

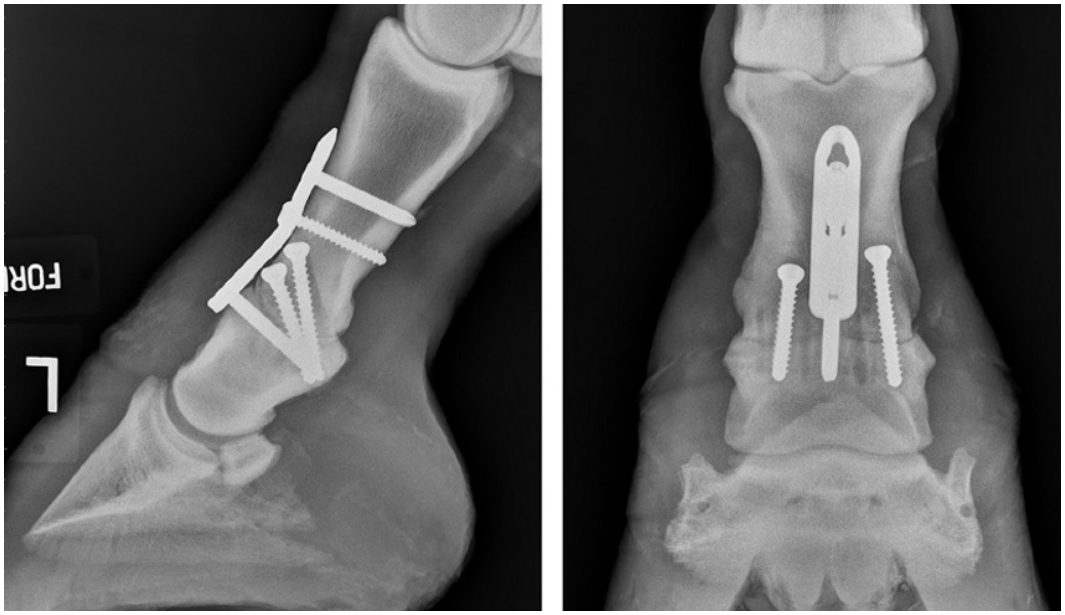

Figure 4.92. Lateral radiograph of the pastern following placement of a 3-hole LCP with two transarticular 5.5-mm screws for arthrodesis of the PIP joint.

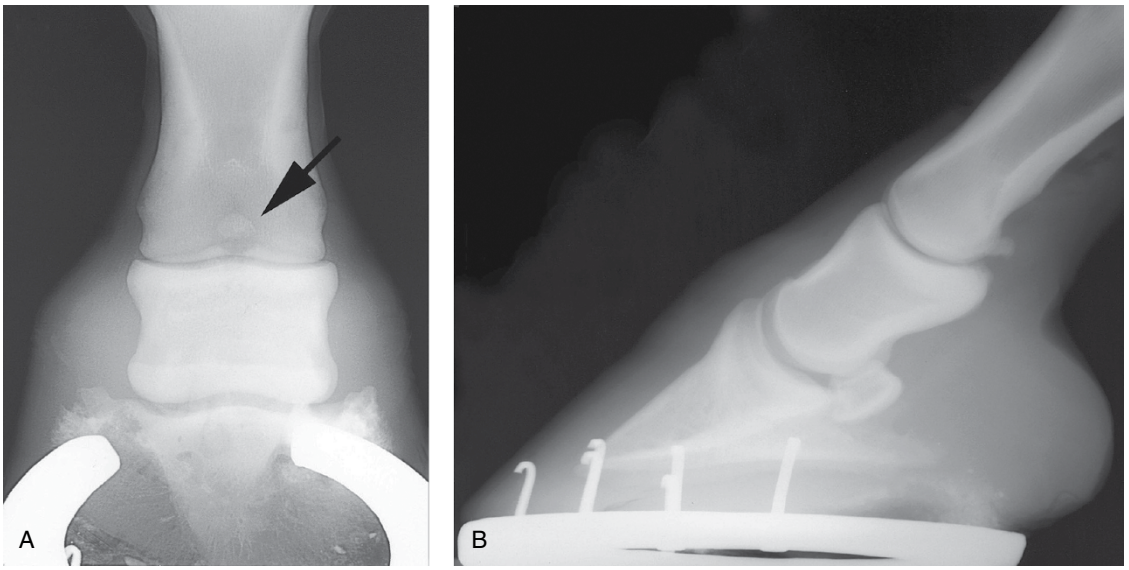

Figure 4.93. Dorsopalmar (A) and lateral (B) radiographs of a horse with palmar fragmentation of the PIP joint (arrow). The fragment was removed with arthroscopy.

VetBooks.ir

distal aspect of P1 but do occur rarely in the proximal aspect of P2 (Figure 4.94). SCLs due to OA occur with equal frequency in distal P1 and proximal P2. Malformation of the condyles of the distal aspect of P1 without fragmentation has also been recognized by the author and may represent another form of OC that leads to early OA within the PIP joint.

Etiology

The cause of OC within the PIP joint is assumed to be due to similar factors that cause the condition in other locations within the horse. However, traumatic fragmentation and articular cartilage or subchondral bone damage leading to SCLs can also occur within the PIP joint, and it may be difficult to differentiate between developmental and traumatic causes. Developmental lesions tend to occur in younger horses, whereas trauma can occur in any age horse. In addition, more severe clinical signs related to the PIP joint may be identified associated with trauma vs. OC.

Clinical Signs

As stated above, developmental lesions tend to occur in young horses and may cause variable signs of lameness, even within the same horse on a different day. Physical examination findings are similar to other problems within the PIP joint and include no abnormalities, enlargement of the pastern, pain with flexion and manipulation of the pastern region, and positive response to flexion tests. Horses with SCLs of the distal aspect of P1 tend to be more lame than those with osteochondral fragmentation. SCLs are also more common in the hindlimb than in the forelimb.[71] Due to the variable lameness that may be associated with OC in the PIP joint, it is important to identify the true source of lameness using diagnostic anesthesia in many cases.

Diagnosis

The diagnosis is confirmed with radiographs of the pastern region. Osteochondral fragmentation can usually be seen on both lateral and dorsopalmar/plantar views (Figure 4.93), whereas SCLs are often only visible on the dorsopalmar/plantar radiographic projection (Figure 4.94) or only with cross-sectional imaging such as CT or MRI (Figure 4.95). Some lesions, particularly osteochondral fragmentations, may be incidental findings on radiographs. Most SCLs that involve the distal condyle of P1 are clinically significant and often lead to lameness and OA. Radiography of the opposite PIP joint should be performed because OC lesions can be bilateral, similar to other locations.

Treatment

The treatment of choice for osteochondral fragments within the PIP joint that cause clinical problems is arthroscopic removal. Both the dorsal and palmar/plantar pouches of the PIP joint are accessible with the arthroscope, but the surgery can be difficult.[44,52] An arthrotomy can be performed but is associated with more soft tissue damage and increased likelihood of OA developing within the joint. SCLs of distal P1 (Figure 4.95) are often clinically significant and can be managed conservatively or surgically, depending on the severity of lameness. Surgical management includes trans-cyst screw application, transcortical cyst debridement, corticosteroid injection, or pastern arthrodesis (Figure 4.96). Conservative management with NSAIDs and IA medication usually resolves the lameness temporarily, but recurrence is common. Therefore, most horses with SCLs and PIP joint OA are best treated surgically.

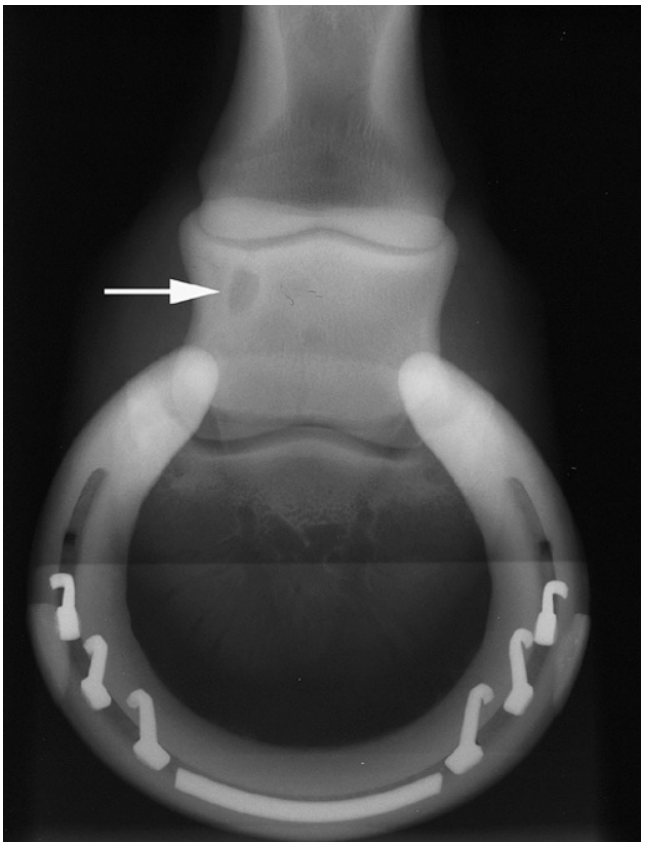

Figure 4.94. Dorsoplantar radiograph of a young horse demonstrating an SCL of the proximal aspect of P2 (arrow). This abnormality was not considered to be the cause of the lameness in this horse.

Prognosis

The prognosis following removal of OC fragmentation is usually very good, and many horses can perform athletically. The prognosis for SCLs of distal P1 after trans-cyst screw placement or transcortical debridement has not yet been reported in the literature, but if it is similar to SCLs in other locations, it will be good. SCLs of distal P1 typically do well following arthrodesis, and these horses can be used as athletes.

LUXATION/SUBLUXATION OF THE PROXIMAL INTERPHALANGEAL (PIP) JOINT

Luxation of the PIP joint is uncommon and can occur in the medial/lateral or palmar/plantar direction. Medial/lateral luxation is usually seen after severe injury to one

VetBooks.ir

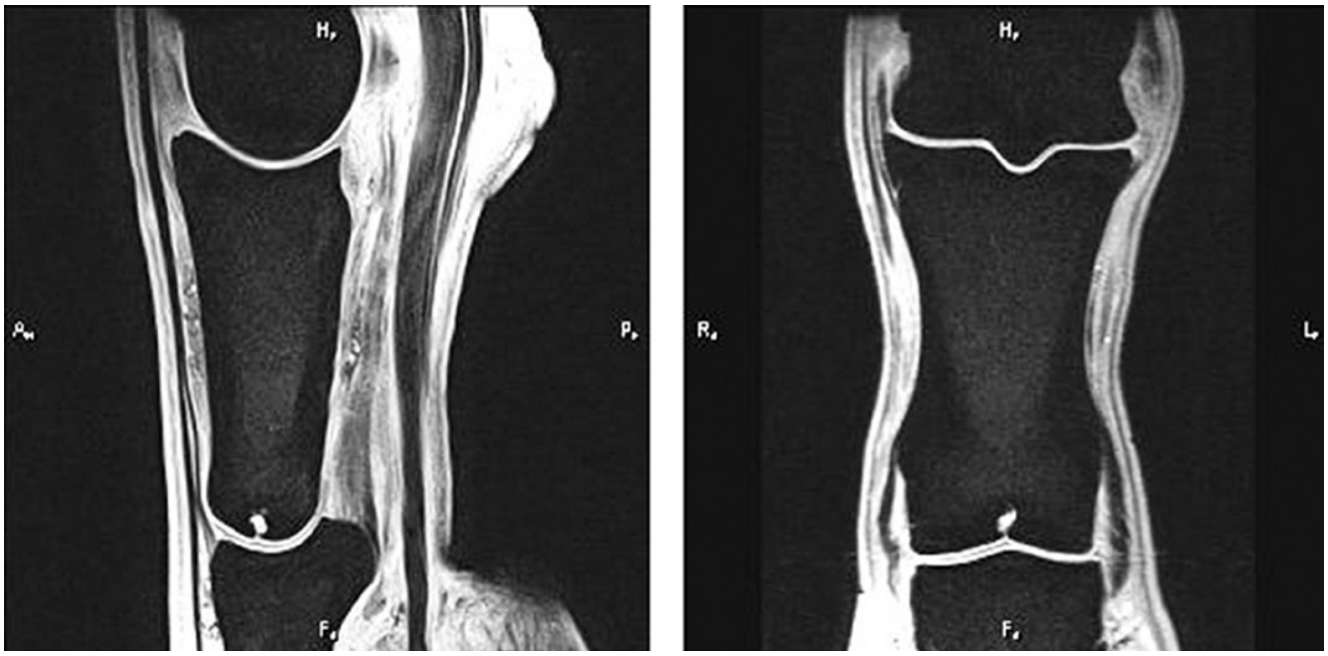

Figure 4.95. Sagittal (left) and dorsal (right) FLASH MRI images of the same horse in Figure 4.12. There is a subchondral cyst-like lesion of the distal aspect of P1 in the left hindlimb. Radiographically apparent lysis was not noted until after discovery of the cyst-like lesion on MRI.

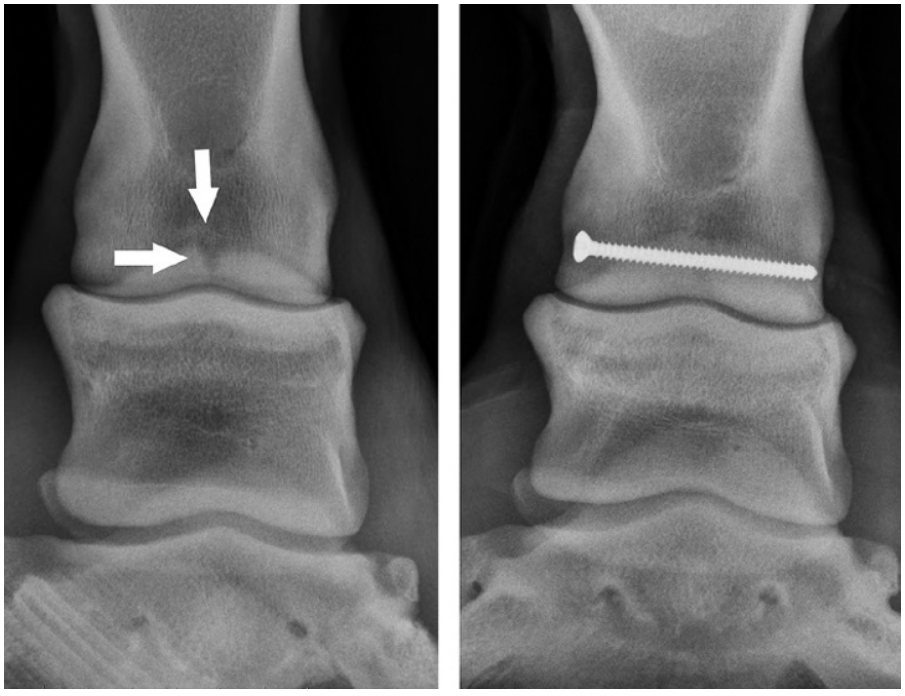

Figure 4.96. Preoperative (left) and postoperative radiographs (right) from a 4-year-old Warmblood mare treated with a transcortical screw for a subchondral cyst-like lesion in distal P1. This is the same horse shown in Figure 4.95.

of the collateral ligaments from external trauma and may be open or closed. Palmar/plantar luxation is usually seen following a severe, traumatic soft tissue injury, such as complete tearing of the straight DSL, branches of the SDFT, or a combination of these injuries, and usually only results in subluxation (Figure 4.97).[73] Luxation in the medial/lateral and palmar/plantar direction nearly always involves a single limb.

Subluxations of the PIP joint occur most commonly in a dorsal direction. The terms dorsal and palmar/plantar refer to the subluxation of the proximal phalanx relative to the position of the middle phalanx. Dorsal subluxations of the PIP joint are most common in young horses and may be secondary to flexural deformities and other developmental orthopedic diseases (Figure 4.98) as well as secondary to severe suspensory ligament injury and

VetBooks.ir

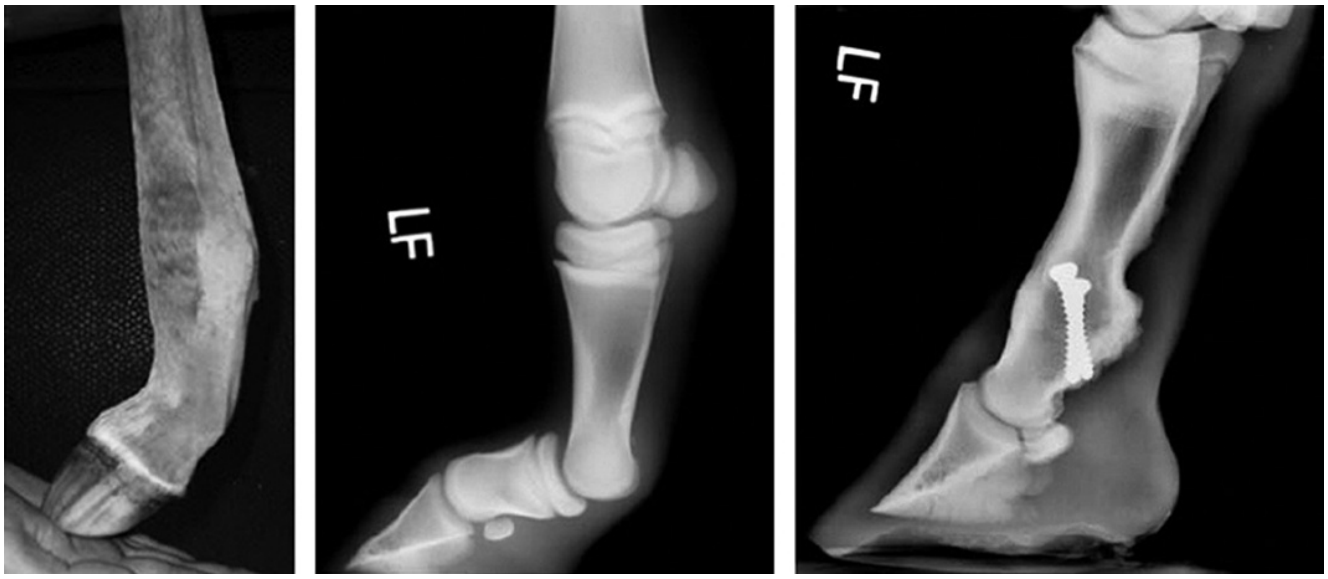

Figure 4.97. Subluxation of the pastern due to avulsion of the SDFT insertions and the straight distal sesamoidean ligament insertion that occurred at 1 month of age and was treated by pastern arthrodesis. *Source*: With permission EVE 2007.

hyperextension of the metacarpo(tarso)phalangeal joint. Although considered to be uncommon, subluxation/luxation of the PIP joint represented 21% of horses that underwent a PIP joint arthrodesis in a one report.[31]

Etiology

Lateral/medial luxations or subluxations are often caused by severe trauma resulting in joint capsule and ligamentous tearing (e.g. distal limb caught in something and the horse struggles and/or falls) or lacerations that transect the collateral ligament. Palmar/plantar subluxation/luxation generally occurs from acute trauma resulting in overextension of the PIP joint and tearing of the soft tissue support structures (joint capsule, straight DSL, and the insertion of the SDFT). Bilateral palmar/plantar eminence fractures of P2 may cause the same effect due to complete loss of the palmar/plantar supporting soft tissues. Palmar/plantar subluxation can also be seen in foals and weanlings that have jumped from heights and in foals with flexor tendon laxity that overexert themselves during free exercise.[26,73] Loss of the ligamentous support of the palmar/plantar aspect of the PIP joint results in subluxation/luxation and severe lameness.[8]

Dorsal subluxations are thought to be secondary to flexural deformities or limb contracture and may be seen in foals/weanlings that are rapidly growing with an upright conformation (Figure 4.98). A form of DDFT contracture was responsible for dorsal subluxation of the pastern in the pelvic limbs of three horses.[63] Dorsal subluxation may also be seen in horses after traumatic disruption of the suspensory apparatus and arthrodesis of the fetlock joint, or progressive, severe suspensory desmitis.[8]

Figure 4.98. A young horse with bilateral dorsal subluxation of the PIP joints. Dorsal swellings over both rear pastern joints can be seen.

Clinical Signs

The clinical signs associated with complete medial/lateral luxation due to tearing of the collateral ligament are usually obvious. These horses are often non-weight bearing or lame at the walk and have swelling of the pastern associated with the ligament injury, and a limb deformity may be present. Instability and pain may be identified with rotation or medial/lateral movement of the phalanges. In acute cases, heat, pain, and swelling of the pastern region are usually evident.

VetBooks.ir

Horses with palmar/plantar subluxation/luxation are also often very lame in the acute stage. The lameness may subside over time, but most will remain lame at the walk and the dorsal surface of the pastern will appear concave (dished out) rather than straight or convex as would occur with dorsal subluxation. In chronic cases the heel bulbs may contact the ground, and excessive hyperextension of the pastern and sinking of the fetlock is noted when the horse is walked.

Dorsal subluxation can occur without any identifiable structural abnormalities of the pastern or metacarpal/metatarsal soft tissue structures. This occurs primarily in the hindlimbs in young horses and lameness is usually absent or mild. A dorsal swelling in the pastern region may be evident when the affected limb is unweighted. This type of subluxation is often dynamic in nature and usually resolves during full weight-bearing of the PIP joint. An audible clicking sound often accompanies the reduction of the joint. When the pelvic limbs are involved, the condition is often associated with an upright conformation (straighter than normal hocks and stifle angles).[63]

With persistent dorsal subluxation of the PIP joint, an obvious swelling over the dorsal aspect of the pastern region is often evident, and the fetlock may appear slightly more extended (dropped) as compared to the contralateral unaffected limb. The dorsal swelling may appear similar to that associated with high ringbone, but on closer observation an abnormal alignment between P1 and P2 is found. However, with chronicity, both clinical and radiographic abnormalities consistent with OA of the PIP joint may develop. Lameness is variable and inconsistent in these cases and often depends on the secondary changes that develop within the joint.

Diagnosis

A tentative diagnosis can usually be made from the history and physical examination of the horse. Radiographs should be taken to confirm the diagnosis and identify concurrent abnormalities such as fractures or OA. Stress films may be needed to confirm medial/lateral subluxation because the phalanges can often remain in correct anatomic alignment unless pulled medially or laterally (Figure 4.99). Dorsal and palmar/plantar subluxations/luxations are usually obvious on standing lateral to medial views of the pastern.

Treatment

The treatment of choice for medial/lateral and palmar/plantar subluxations/luxations of the PIP joint is arthrodesis of the joint. External coaptation with a cast or Kimzey splint (Kimzey Leg Saver Splint; Kimzey, Inc., Woodland, CA) may be successful in adult horses managed acutely, but instability of the PIP joint may preclude successful realignment. Unlike medial/lateral luxations of the fetlock joint, similar luxations of the PIP joint do not respond well to casting alone and often develop secondary OA and persistent lameness. Conservative treatment of palmar/plantar subluxations/luxations is usually unsuccessful, and surgical arthrodesis is often the only option to realign the phalanges. Chronic palmar/plantar subluxations/luxations can lead to fibrosis of the PIP joint in an abnormal position, making surgical realignment difficult. Dorsal subluxations may also be treated with arthrodesis if they fail to respond to other methods of treatment. In most cases the subluxation is best treated surgically before excessive scar tissue has developed to permit more accurate and easier alignment of the joint. Horses with dorsal luxation of the PIP joint with secondary OA are also best treated with arthrodesis. See the section on OA of the PIP joint for more information on arthrodesis.

Figure 4.99. Dorsoplantar stress radiograph demonstrating complete rupture of a collateral ligament of the PIP joint. Arthrodesis of the joint is the recommended treatment.

Horses with intermittent dorsal subluxation with no apparent lameness may be treated conservatively. Horses with bilateral upright hindlimb conformation and dorsal subluxation often respond to anti-inflammatory medication and a controlled exercise program. Horses with intermittent dorsal subluxation of the pelvic limb associated with excessive tension of DDFT have been treated successfully with transection of the medial head of the DDFT.[63] The approach was between the DDFT and the suspensory ligament at the level of the proximal third of the third metatarsal bone, and a 2.5-cm segment of the tendon was removed. Alternatively, surgical transection of the accessory ligament of the DDFT may be of benefit.

Prognosis

Although there are few reports on long-term follow-up, the prognosis is good for survival and fair to good

VetBooks.ir

for return to use in horses with luxations/subluxations treated early by arthrodesis in which good reduction and stabilization of the PIP joint was achieved.[1,26,31,41,67] Convalescence is similar to that of other conditions that require a PIP joint arthrodesis, and up to a year may be required before the horse may return to performance. Three cases of bilateral acquired pelvic limb intermittent dorsal subluxation treated by tendonectomy of the medial head of the DDFT responded favorably to the treatment and the subluxation resolved between 1 and 7 days postoperatively.[63] The authors have no experience with this particular surgical technique.

FRACTURES OF THE MIDDLE (SECOND) PHALANX (P2)

Fractures of P2 occur most commonly in the hindlimbs of middle-aged western performance horses used for cutting, roping, barrel racing, pole bending, and reining.[8,10,42] However, these fractures may occur in any horse during lunging, turnout, after kicks or falls, or any form of single-event trauma. Fractures of P2 can also be seen in foals and usually involve the proximal physis, resulting in subluxation of the PIP joint.[12] Although the fracture is common in Quarter horses, any breed can be affected. Based on retrospective studies, the Quarter horse represents approximately 50% of the breeds affected, Western stock is the most common activity contributing to the injury, and the hindlimbs are affected approximately three times more frequently than the forelimbs.[8,10,42]

A variety of fracture types involving P2 have been reported, including osteochondral (chip) fractures, palmar/plantar eminence fractures, axial fractures, and comminuted fractures.[5,8,10,29,31,35,41,46,52,60,70,72] Osteochondral fractures and axial fractures are rare, whereas eminence and comminuted fractures occur commonly. Thoroughbred and Standardbred racehorses and hunter/jumper horses appear to be at increased risk for osteochondral fractures involving the PIP joint.[70] The fracture can either be located dorsally (most common) or on the palmar/plantar aspect lateral or medial to the midline.[46,52,60] Palmar/plantar fractures do not typically involve the attachments of the DSL or the branches of SDFT. Some of these osteochondral fragments may be seen in young horses and may be developmental in origin.[52] Occasionally, multiple fragments may occur on the proximal palmar/plantar aspect of P2 that appear to be avulsion fractures. Despite the size of the fragments, the development of secondary OA appears slow, but removal is usually recommended.

Radiographic examination of the opposite PIP joint should be done because palmar/plantar fractures have been reported to occur bilaterally.[46] Osteochondral fractures of P2 involving the DIP joint are uncommon and may be caused by use-related trauma or direct trauma from a penetrating injury.[70,72] Palmar/plantar eminence fractures involving the PIP joint occur frequently. They can either be uniaxial (involving one eminence; Figure 4.100) or biaxial (involving both eminences; Figure 4.101). Uniaxial eminence fractures do not result in subluxation of the PIP joint, whereas biaxial fractures can contribute to subluxation or complete luxation of the joint (Figure 4.102).

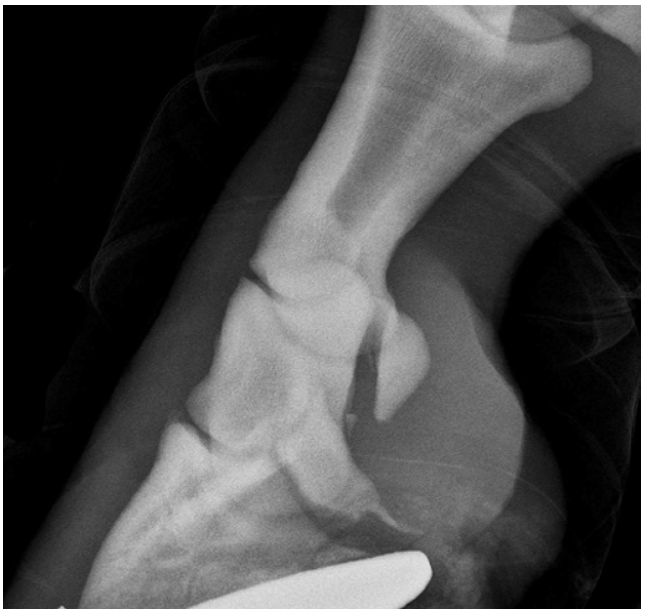

Figure 4.100. Oblique radiograph of the pastern region demonstrating a medial plantar eminence fracture of P2. This horse presented for a hindlimb lameness of 2 weeks' duration.

Figure 4.101. Lateral radiograph of the pastern demonstrating biaxial eminence fractures of P2. Internal fixation is required for these types of fractures to prevent palmar/plantar luxation of P1.

Simple axial fractures of P2 occur rarely.[63] A misdiagnosis of this fracture can easily be made if the central sulcus of the frog is prominent and it is filled inadequately with packing material prior to the radiographic exam. The fracture should be visible on at least two radiographic views to make a definitive diagnosis. This type of fracture may progress to a comminuted fracture under appropriate biomechanical factors.

VetBooks.ir

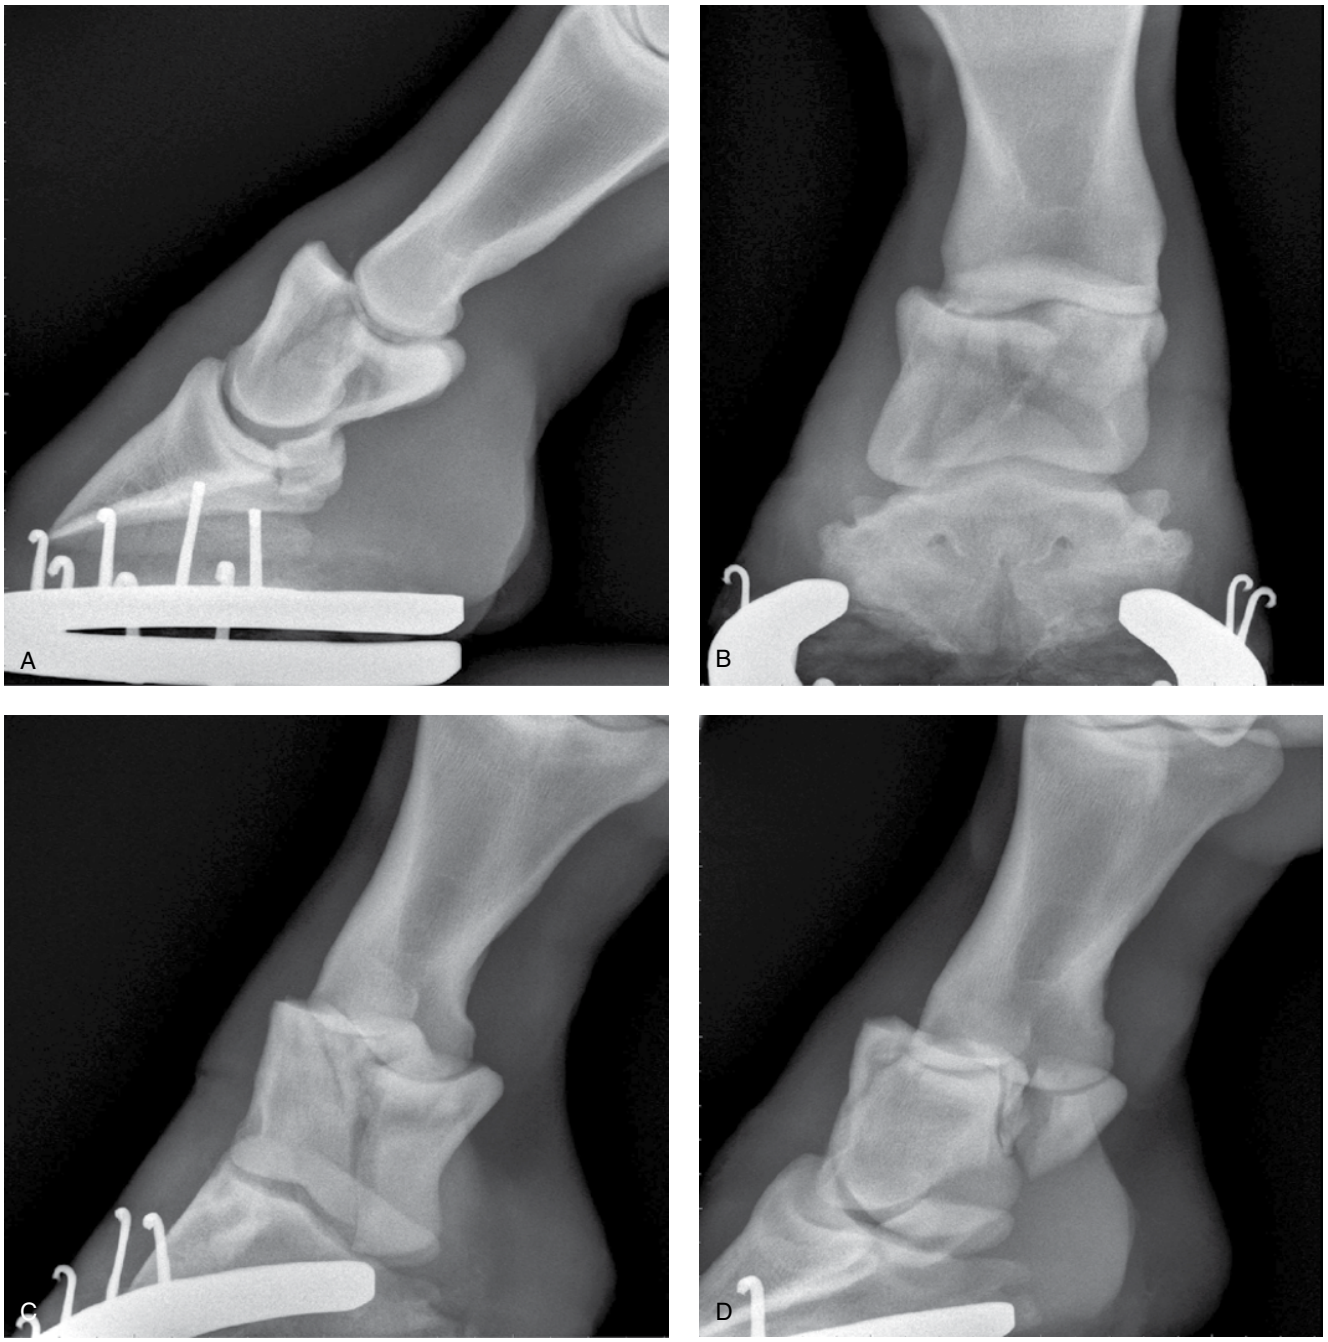

Figure 4.102. Lateral (A), dorsoplantar (B), and two oblique (C and D) radiographic projections of a horse with a comminuted P2 fracture. Multiple fracture lines are commonly seen, and most comminuted fractures involve both the PIP and the DIP joint surfaces.

Comminuted fractures are the most common fracture involving P2. They nearly always involve the PIP joint (uniarticular) but often extend distally into the DIP joint (biarticular). A variety of fracture configurations are possible, but typically multiple fracture lines oriented in several directions are visible on radiographs. In addition, it is not uncommon for these fractures to resemble a "bag of ice" due to the multiple fracture fragments. Although comminuted P2 fractures result in marked instability of the pastern region, they are rarely open. Proper immobilization of comminuted P2 fractures prior to transport to a surgical facility is highly recommended.

Etiology

Osteochondral fractures may occur from use, direct trauma to the bone (e.g. a penetrating wound), or avulsion of soft tissue attachments (palmar/plantar aspect), or they may be developmental associated with OC. Palmar/plantar eminence fractures may occur from compression and rotation that is associated with sudden stops and short turns. They may also occur during PIP joint overextension, which results in excessive tension of the SDFT and straight DSL, causing an avulsion of the eminence(s).

VetBooks.ir

The cause of simple axial fractures is unknown but may be associated with repetitive trauma. Comminuted fractures are thought to result from external trauma or a combination of compression and torsion (twisting) forces that occur with sudden stops, starts, and short turns. Most comminuted P2 fractures are thought to occur as a single-event injury, but a history of lameness in the affected limb may precede the fracture in some horses. Horses shod with heel calks are believed to be more prone to comminuted P2 fractures because the calks grip the ground, preventing the normal rotation of the foot and phalanges when the horse rapidly changes directions. These fractures may also occur in horses during light work or unrestrained paddock/pasture exercise due to sudden excessive forces (compression and torsion) placed on the limb ("bad step"). Horses turned out for exercise after long-term confinement have also been reported to be at risk for comminuted P2 fractures.

Clinical Signs

The clinical signs associated with P2 fractures that do not disrupt the weight-bearing capabilities of P2 (osteochondral fragments, single eminence, and simple axial fractures) can be variable. Some horses may have a history of an acute onset of lameness, while others may present for a chronic forelimb or hindlimb lameness. In most horses, exercise increases the severity of the lameness. Swelling of the pastern is not a reliable finding, but fetlock/phalangeal flexion and rotation of the pastern region often elicit a painful response. Crepitation or instability is generally not appreciated with uniaxial P2 eminence fractures. Circling at a trot usually exacerbates the lameness. Diagnostic anesthesia with either a basisesamoid nerve block or intrasynovial anesthesia is often required to localize the lameness to the PIP joint region. However, diagnostic anesthesia is contraindicated with other types of P2 fractures because of the risk of fracture displacement when the horse bears weight on the anesthetized digit.

Horses with comminuted or biaxial P2 eminence fractures often have a history of acute onset of severe lameness. Some owners may report that a loud "pop" was heard just prior to the onset of severe lameness. Horses are usually very lame and painful to manipulation of the pastern, and crepitus may be felt but is not a consistent finding. The pastern may also appear to be unstable during manipulation, and swelling may be present just above the coronary band in horses with comminuted fractures (due to effusion of the DIP joint). With biaxial eminence fractures the swelling is less evident and may not be apparent.

Diagnosis

A definitive diagnosis requires a complete radiographic examination. At least four views are recommended: dorsopalmar (DP), lateromedial (LM), dorsolateral to palmaromedial oblique (DLPMO), and dorsomedial to palmarolateral oblique (DMPLO). Osteochondral fractures are usually easily diagnosed with the routine radiographic views. Additional views may be necessary with comminuted fractures so that the fracture location and configuration can be accurately appreciated. Identification of whether the fracture lines extend into the DIP joint and whether there is an intact "strut" of bone that extends between the PIP and DIP is very important information for comminuted fractures. The fracture configuration has considerable bearing on the treatment method selected as well as the prognosis for future soundness.

Cross-sectional imaging like CT of comminuted P2 fractures is especially helpful in defining the fracture configuration[57] (Figure 4.103). In general, the degree of comminution and DIP joint involvement is underestimated on radiographs compared to CT. The authors routinely use CT for comminuted P2 fractures that aids in prognostication and in reconstruction of the DIP joint.

Treatment

Osteochondral Fractures

Fracture fragments associated with the PIP joint that contribute to lameness are best removed with arthroscopy.[52,70,72] Both dorsal and palmar/plantar fragments can be removed with arthroscopy, although the maneuverability of the instrumentation is somewhat limited in the dorsal joint pouch due to the extensor tendon attachment immediately distal to the joint.[60] The palmar/plantar recess

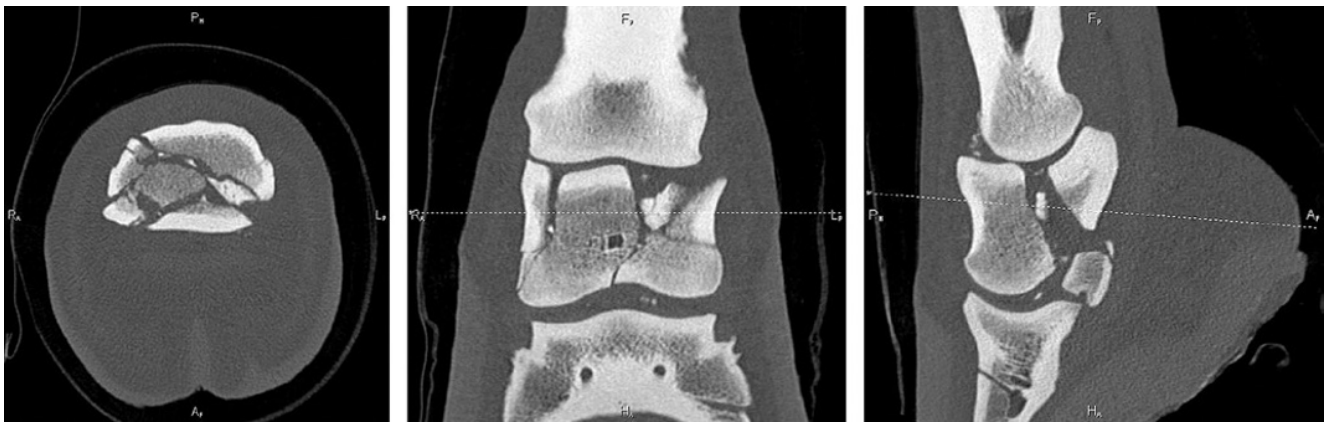

Figure 4.103. CT images of a comminuted P2 fracture that demonstrate the numerous fracture fragments that are present in different orientations. This fracture was repaired with two dorsally applied bone plates and pastern arthrodesis.

VetBooks.ir

of the PIP joint is larger, which makes surgical manipulation somewhat easier, but it is still difficult.[52] Osteochondral fractures involving the DIP joint are also best managed by arthroscopy if possible.

Eminence Fractures

Uniaxial or biaxial eminence fractures of P2 that involve the PIP joint are best treated by arthrodesis of the PIP joint followed by cast application.[42]

Although casting alone has been reported as an acceptable method of treatment in horses with uniaxial eminence fractures, it should be reserved for those cases in which pasture or breeding soundness is desired and economic constraints dictate this approach. The fractures rarely heal back to the parent bone with casting alone, and secondary OA of the PIP joint leading to chronic lameness is common.

Horses with biaxial eminence fractures will develop a palmar/plantar subluxation of the PIP joint when casted due to weight-bearing forces pushing P1 distally. If internal fixation of biaxial P2 fractures is not elected, then transfixation pin casts or another type of external fixator is recommended over casting alone to maintain phalangeal alignment. With either casting alone or transfixation pin casts, the initial cost may be less to the owner, but the costs of repeat casting, prolonged confinement, complications, etc. are often not that much less or may be more than what the cost of internal fixation would have been. Therefore, internal fixation of eminence fractures is the preferred method of treatment.

Comminuted P2 Fractures

There are varying degrees of comminution associated with nearly all P2 fractures, which can greatly affect treatment. In general, horses with comminuted P2 fractures should be reconstructed and repaired with some type of internal fixation (bone plating) if at all possible. Horses with an intact strut of bone spanning from the PIP to the DIP joints are ideal candidates for internal fixation. Horses without an intact bony strut yet have large enough bony fragments for screw fixation also often benefit from internal fixation. Horses with highly comminuted P2 fractures (so-called bag of ice) that do not have fracture fragments large enough to engage screws are best treated with transfixation pin casts or another type of external fixator.[29,35,47,48] Casting alone can also be used for these highly comminuted fractures, but fracture collapse would be an expected complication.

The use of casts, transfixation pin casts, or an external fixator is usually reserved for horses with severely comminuted P2 fractures that cannot be adequately reduced or stabilized by internal fixation and for which euthanasia is not an option. Economic constraints may also enter into the decision regarding when to use these options, although with the prolonged treatment period, the difference in cost is often negligible. Pasture soundness for breeding purposes or use as a pet is all that can be expected from horses treated with casts with or without transfixation pins. Traction to the phalanges using wires placed through the hoof wall, especially in the hindlimb, helps reduce the fracture fragments. A lower limb cast that incorporates the hoof is mandatory. Some comminuted P2 fractures may be treated successfully using this approach, but cast application for a minimum of 8 weeks is usually required.

Prognosis

The prognosis of horses with osteochondral fractures treated by arthrotomy or arthroscopy appears to be very good for return to full serviceability.[46,52,60,70,72] In one study 4 of 5 cases with osteochondral fragments (3 involved the PIP joint and 2 involved the DIP joint) treated by arthrotomy returned to their intended use.[70] There are only a few reports of using arthroscopy to remove these fragments, but it is the preferred approach with most horses returning to performance.

The prognosis for uniaxial or biaxial palmar/plantar eminence fractures treated by arthrodesis also appears to be very good for return to performance and should be considered similar to that expected for PIP joint arthrodesis used to treat OA of the joint.[42] The use of single or double bone plating is considered mandatory for biaxial eminence fractures and will most likely improve the prognosis of these horses returning to function.[12,42]

Horses with comminuted fractures that only involve the PIP joint usually have a good prognosis to return to athletic performance, provided they are treated with internal fixation. The prognosis for horses with biarticular comminuted P2 fractures is much reduced because the limiting factor in many cases is related to the health of the DIP joint. Older literature has stated that horses with comminuted biarticular P2 fractures have a 50% survival rate and slightly greater than a 10% chance of returning to athletic performance with casting alone.[8] This remains true today and emphasizes that horses with comminuted P2 fractures treated without internal fixation are very unlikely to be athletically sound.

Internal fixation with bone plates increases both survival and return to athletic function in horses with comminuted P2 fractures. In one report 7 of 8 horses with forelimb involvement were alive 2 years after injury, and 4 of 7 horses were being ridden. Of the two horses with hindlimb involvement, one was being ridden and one was lost to follow-up.[10] In another report, 2 of 3 mature horses with comminuted fractures that involved the forelimbs returned to athletic performance, and 2 of 3 foals with physeal fractures also performed.[12]

The prognosis of these horses is often dictated by the amount of fracture displacement at the DIP joint and the ability to reduce this displacement at the time of surgery. Horses with fractures of the hindlimb are also thought to have an improved prognosis over those affecting the forelimb. In general, horses with biarticular comminuted P2 fractures should be considered to have a 40–50% chance of returning to performance after internal fixation, provided complications do not occur.

FRACTURES OF THE PROXIMAL (FIRST) PHALANX (P1)

Fractures of the proximal phalanx (P1) occur frequently and can be broadly categorized into noncomminuted and comminuted fractures. Osteochondral fragmentations of the proximal dorsal or palmar/plantar

VetBooks.ir

aspects of P1 are types of noncomminuted fractures and are discussed in the fetlock section. Fracture configurations (excluding osteochondral fragmentation) range from small fissures that enter the metacarpophalangeal/metatarsophalangeal [MCP/MTP] joint to highly comminuted fractures ("bag of ice") that affect both cortices and the proximal and distal joint surfaces. Stress or fatigue-type fractures that may not be identified on routine radiographs may also occur in performance horses. Most P1 fractures are closed, although 8 of 64 comminuted fractures were open at the time of presentation and an additional 4 had extensive bruising with serous fluid oozing through intact skin in a retrospective review.[32]

Noncomminuted P1 fractures have been classified into several types:

1. Midsagittal or sagittal fractures: Exist primarily in the sagittal plane and begin at the proximal articular surface
   a. Short (extend less than 30 mm in length distally; Figure 4.104A)
   b. Long (extend more than 30 mm in length distally; Figure 4.104B)
   c. Complete (exit the lateral cortex or span both joint surfaces; Figure 4.105)
2. Dorsal frontal fractures: Begin at the MCP/MTP joint in the frontal plane and extend to the dorsal cortex or distally toward the PIP joint; can be incomplete or complete (Figure 4.106)
   a. Distal joint fractures: Involve the PIP joint
   b. Palmar/plantar eminence fractures: Involve the MTP/MCP joint (Figure 4.107)
   c. Physeal fractures: Usually Salter–Harris type II
   d. Oblique or transverse diaphyseal fractures

Comminuted P1 fractures can range from fairly simple three-piece fractures to the bag of ice type of injury (Figures 4.108 and 4.109). However, a variety of configurations of comminuted P1 fractures is possible. For treatment purposes, they are divided into fractures that have an intact cortex (strut) of P1 from the proximal to distal joint surfaces (moderately comminuted) and fractures that do not have an intact bone strut (severely comminuted).[32,40] Less common types of P1 fractures include proximal medial collateral ligament avulsion fractures, dorsal nonarticular fractures, and stress or fatigue fractures. Stress- or fatigue-type fractures may precede sagittal or comminuted P1 fractures and occur almost exclusively in performance horses. Medial collateral ligament avulsion fractures are discussed in the fetlock section.

Sagittal P1 fractures occur most commonly and may be present in the contralateral limb in a small percentage of the cases.[17,38,69] Sagittal and other types of noncomminuted P1 fractures are primarily seen in racing Thoroughbreds and Standardbreds but can also occur in other types of performance horses. They often affect the hindlimbs in Standardbreds and the forelimbs in

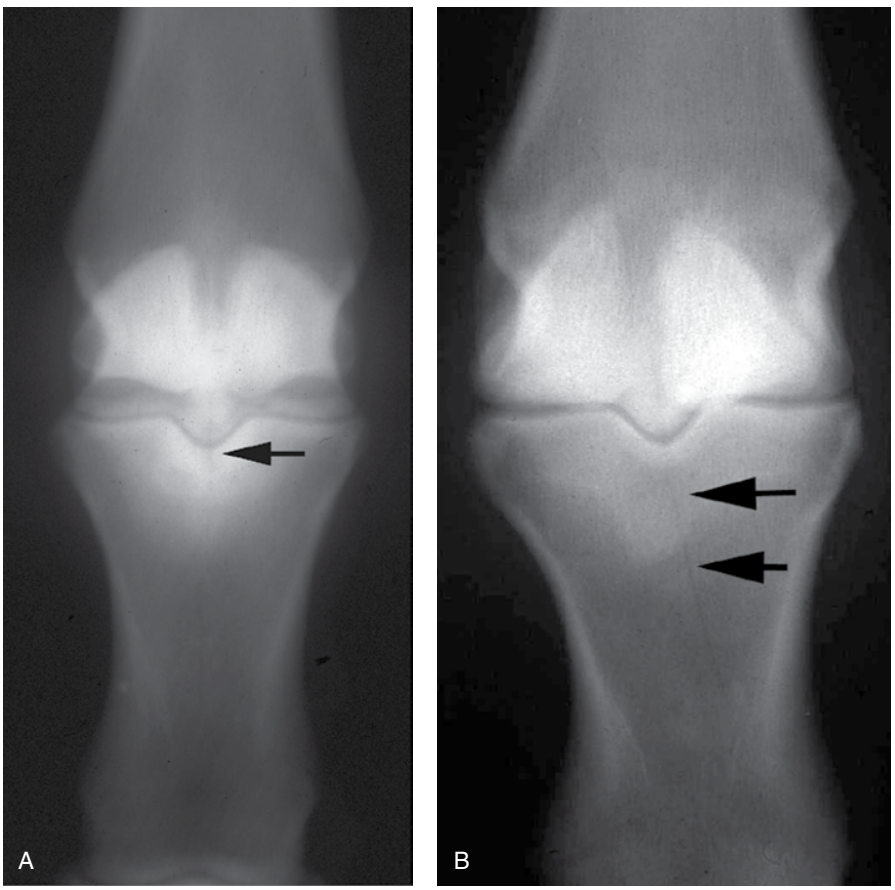

Figure 4.104. Dorsopalmar radiographs of the pastern region revealing short (A) and long (B) incomplete sagittal fractures of P1 (arrows). The fracture in (B) was repaired with two lag screws through stab incisions (Figure 4.110).

VetBooks.ir

Thoroughbreds.[17,27,38,69] Dorsal frontal fractures are relatively rare but usually occur in the hindlimb.[3] Comminuted P1 fractures also occur commonly in racing Thoroughbreds and Standardbreds. In a recent report, 72% of horses with comminuted P1 fractures sustained the injury during racing or race training.[32] However, comminuted P1 fractures may occur in other types of performance horses (especially western performance or polo) and may occur in any horse at pasture or at exercise from a single traumatic event.[32,38] In one report 27% of the horses sustained a comminuted fracture while at pasture, and a smaller percentage developed the fracture while being used for showing or pleasure riding.[38] In a more recent report, 28% of all comminuted P1 fractures were from nonracing causes.[32]

Etiology

It appears that a combination of longitudinal compression in conjunction with asynchronous lateral to medial rotation of P1 or twisting of P1 in relation to the metacarpus/metatarsus may be the cause of some fractures. During normal weight-bearing, the convex sagittal ridge of the distal end of the third metacarpal or metatarsal bone fits into the concave groove in the proximal surface of P1. If this alignment is not perfect, the convex sagittal ridge may act as a wedge to create the fracture. Also, during limb flexion, there is a lateral to medial rotation of P1 around its long axis. If the rotary movement is accelerated, as would occur if the foot slips, a P1 fracture may result. In most cases, a combination of axial weight-bearing and torsional forces usually contributes to P1 fractures.

Nearly all midsagittal fractures begin at the concave groove of the proximal aspect of P1 and tend to be

Figure 4.106. (A) Oblique view of an incomplete dorsal fracture of P1. (B) Lateral view of a complete dorsal fracture of P1 that exits the dorsal cortex. *Source:* Courtesy of Dr. Julie Dechant.

VetBooks.ir

Figure 4.107. Lateral radiograph of the fetlock demonstrating a fracture of the palmar eminence of P1. This fracture was an acute injury and was repaired by lag screw fixation. Smaller, chronic fractures are more common in this location and are often removed if they are problematic.

oriented lateral to the midline in the forelimb. This may be due to a smaller lateral articular surface of P1 in the forelimb compared with the hindlimb.[17] The consequent position of the center of the sagittal groove lateral to the midline may dictate that fractures propagate down that side of the bone in the forelimb. In contrast, sagittal fractures that extend distal or medial to the midline are approximately twice as common in the hindlimbs as in the forelimbs.[17] The relationship between the slope of the proximal and distal articulations of P1 may also account for the different fracture configurations between the fore- and hindlimb.[17]

Parasagittal P1 fractures in the athletic horse may occur as part of a chronic pathological process characterized as bone maladaptation or fatigue-type fractures. In support of maladaptation etiopathogenesis, P1 fractures can occur during normal events without unusual trauma, at a consistent and site a specific location along dorsoproximal P1 with repeatable configurations and with prodromal signs such as periostitis. These so-called fatigue fractures are usually only seen in performance horses and often represent an area of bone weakness related to stress remodeling. As microdamage accumulates from repetitive loading of P1, the bone weakens or "fatigues," predisposing to fracture. This same scenario can occur in multiple locations in performance horses (humerus, metacarpus, tibia, pelvis, etc.). Radiographically silent short incomplete parasagittal P1 fractures have been seen on MRI and scintigraphy,[51,53] and these may precede the development of a radiographic apparent sagittal P1 fracture or may predispose to a comminuted fracture. Stress fractures tend to occur most commonly in the midsagittal groove at the proximal aspect of the bone, the same area where most P1 fractures originate.

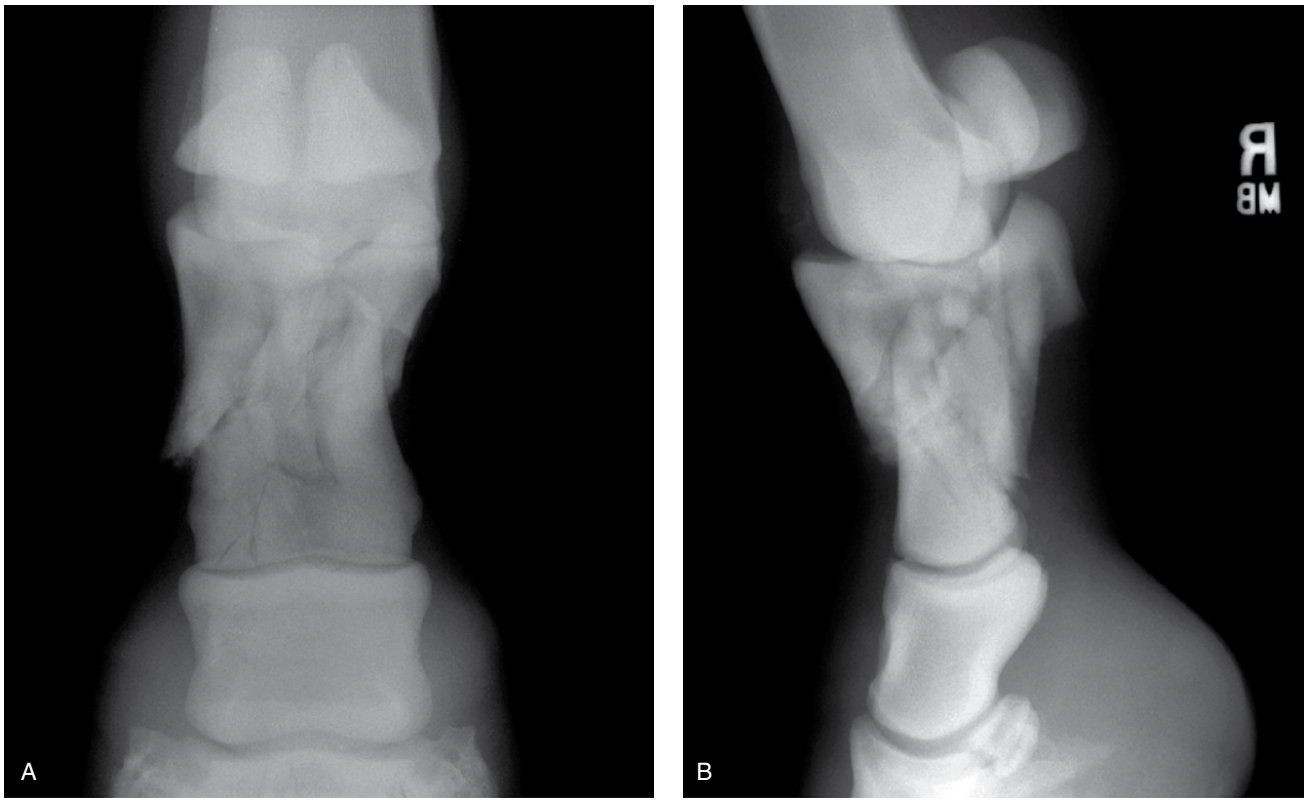

Figure 4.108. Lateral (A) and dorsopalmar (B) radiographs of a horse with a severely comminuted fracture of P1. Internal fixation is not possible with these types of fractures, and transfixation pin casts or external fixators are usually used to attempt salvage of these horses.

VetBooks.ir

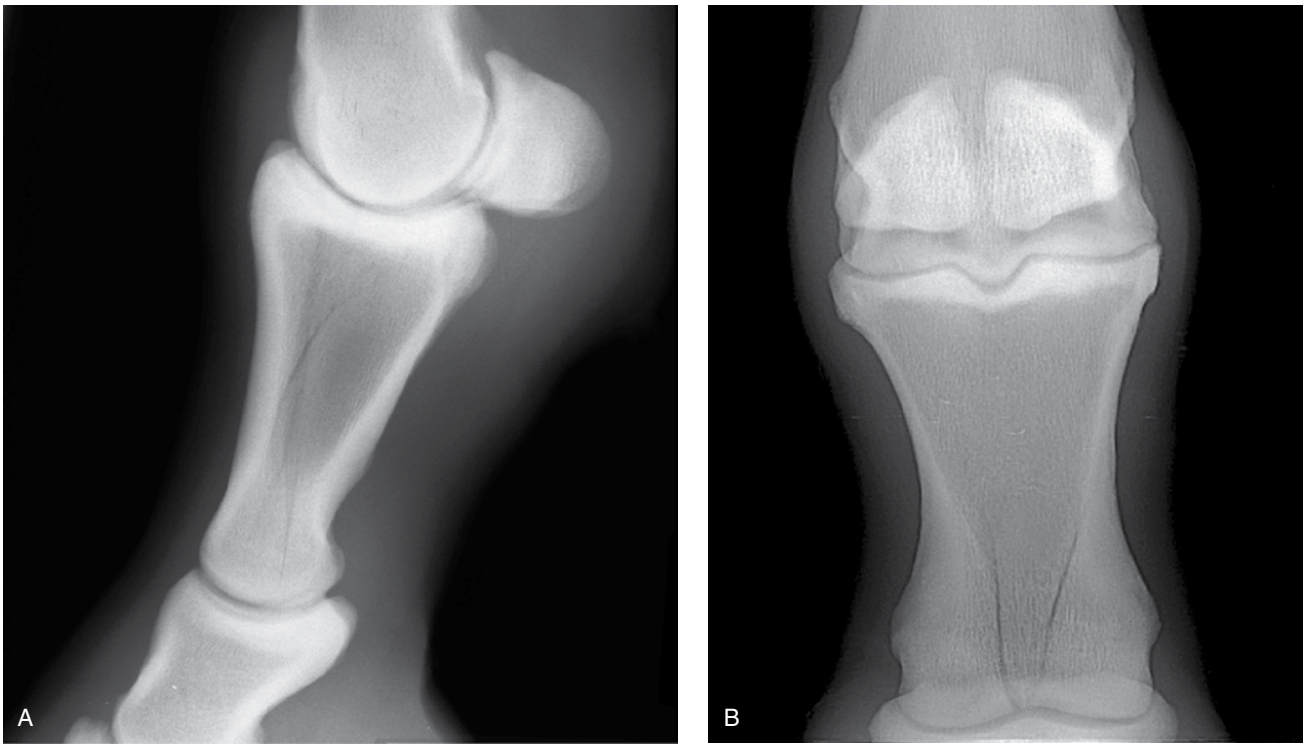

Figure 4.109. Lateral (A) and dorsoplantar radiographs (B) of a nondisplaced, moderately comminuted P1 fracture that was repaired with multiple lag screws placed through stab incisions.

Clinical Signs

The clinical signs associated with P1 fractures are variable and depend on the fracture type and degree of fracture propagation. In most cases there is usually a history of an acute onset of lameness. Horses with incomplete sagittal fractures may demonstrate moderate pain and lameness initially, but it may be of a short duration. However, fetlock effusion is usually present, and a painful response is often elicited with flexion and rotation of the phalanges.[69] Horses with complete sagittal fractures are usually quite lame (grade 3–4 of 5), and fetlock effusion and swelling of the pastern region is usually apparent. Horses with comminuted fractures are usually non-weight bearing and may show signs of physical distress such as sweating. The pastern region is often obviously swollen, and crepitus and instability is palpable.

Adequate external immobilization of the fracture in these horses is mandatory if they are being transported for surgical repair. Perineural anesthesia is usually unnecessary to make the diagnosis, but some horses with short sagittal P1 fractures may present for a routine lameness evaluation. Perineural anesthesia is contraindicated if any type of P1 fracture is suspected because it will increase the risk of fracture propagation.[32] Guidelines for transporting horses with comminuted P1 fractures can be found in Chapter 12.

Diagnosis

Radiographs are required to characterize the type of P1 fracture and dictate the appropriate treatment. The radiographic examination should include at least four views: DP, LM, DLPMO, and DMPLO. Additional views at varying angles may be necessary to accurately document the fracture configuration with comminuted fractures as well as the presence or absence of joint involvement.

Midsagittal fractures are often readily apparent on the DP view, but some short, incomplete fractures may be difficult to see radiographically. In addition, multiple fracture lines on a single radiographic view do not always indicate more than one fracture because of the spiral nature of these fractures. This occurs because the fracture lines are not completely superimposed on the radiographic view.

Some P1 fractures may also be misdiagnosed as the nutrient foramen, especially in Standardbreds.[36] In horses with comminuted P1 fractures, the presence or absence of an intact bony strut that spans from the MCP/MTP to the PIP joints is one of the most important radiographic features. In addition, the degree of fracture displacement, the presence of comminution at the joint surfaces, and whether the fracture involves the PIP joint are all important radiographic features that may affect treatment. Similar to comminuted P2 fractures, CT can be very beneficial to more accurately assess the degree of comminution of P1 fractures and to aid in preoperative planning for surgery.

Treatment

Noncomminuted P1 Fractures

The decision on how to treat horses with noncomminuted fractures usually depends on the fracture type, fracture location and length, degree of displacement, and intended use of the horse. Treatment options include confinement with bandaging, confinement with a distal limb cast, internal fixation with lag screws and/or bone plates, external skeletal fixation alone, or internal fixation combined with external skeletal fixation.

VetBooks.ir

In general, most noncomminuted P1 fractures involve an articular surface (MCP/MTP and/or PIP joint) and are best treated with internal fixation using lag screws placed through stab incisions. Horses with displaced fractures that are not treated with internal fixation have a reduced chance of returning to performance.

Short, incomplete sagittal fractures can be treated conservatively with pressure bandaging and stall rest,[17] but most are treated with lag screw fixation.[27,32,33] Fracture propagation is a risk of treating short incomplete sagittal fractures conservatively, and this occurred in 3 of 85 racehorses in one study.[17] These fractures heal with a periosteal callus over the dorsal aspect of the fracture site, which does not appear to limit function. If the fracture has not healed after 3 months, lag screw fixation is recommended. However, a recent study found an improved prognosis in nonracehorses with short, incomplete sagittal fractures that were treated with lag screws.[33] Horses treated conservatively remained lame, only 1 of 4 horses had radiographic evidence of fracture healing, and 2 of 4 horses had catastrophic propagation of the fracture. In addition, another study indicated that all incomplete sagittal fractures greater than 15 mm should be treated surgically.[69]

Horses with long (greater than 30 mm) sagittal incomplete fractures that are to be used for racing should be treated with lag screw fixation placed through stab incisions followed by external coaptation (Figures 4.104B and 4.110). Two to three screws placed 20 mm apart are generally used depending on the length of the fracture. The most proximal screw should be placed within 5 mm of the most distal point of the sagittal groove in P1. Radiographic or fluoroscopic monitoring is recommended to ensure that the MCP/MTP joint is not entered and to document fracture compression. If a cast is used postoperatively, it is generally removed after 10–14 days. Others prefer bandage support only for recovery from anesthesia.

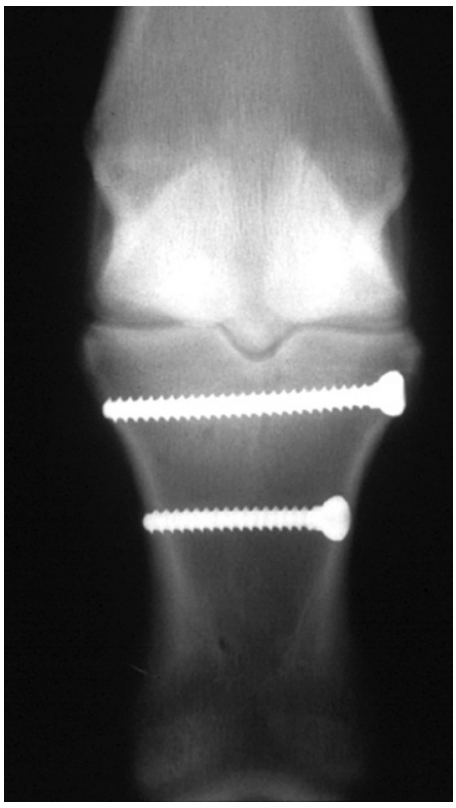

Figure 4.110. Dorsopalmar radiograph of the midsagittal incomplete P1 fracture illustrated in Figure 4.104B that was treated with two 4.5-mm lag screws placed through stab incisions.

Complete sagittal fractures that extend distally from the MCP/MTP joint to involve the PIP joint or that exit the lateral cortex are best treated by internal fixation and coaptation. These fractures are often displaced and can generally be better reduced with open approaches to P1 followed by lag screw stabilization. Plate fixation may also be used, depending on the fracture configuration. However, lag screw fixation through stab incisions similar to incomplete sagittal fractures may be sufficient, depending on the degree of displacement. A distal limb cast is usually recommended after surgery for 2–4 weeks, depending on the security of the fixation.

Bandaging and/or external coaptation has been used alone in cases in which breeding soundness is the objective or if there are economic constraints. In general, horses that are treated conservatively require about 4 months to become free of pain and lameness. They often develop considerable exostosis at the fracture site and secondary OA of the MCP/MTP joint, which may cause lameness when they resume work.[17,39]

Dorsal frontal incomplete or complete nondisplaced P1 fractures can be treated by rest and bandaging or by internal fixation using lag screws, depending on the fracture size. Needles placed into the MCP/MTP joint during the repair may help determine the proper placement of the screws. Arthroscopic examination of the fetlock joint should be considered to visualize the dorsal articular margin and debride damaged cartilage if needed. A cast or bandage may be used postoperatively. Complete dorsal fractures that extend into the PIP joint are best treated by lag screw fixation using an open approach or through stab incisions and external coaptation.[11] Needles placed in the MCP/MTP and PIP joint help guide the placement of 3–4 screws. A half-limb cast is recommended after surgery and is generally removed in 3 weeks. Fracture healing and return to training can be expected earlier following surgical treatment than with nonsurgical treatment of these fractures.

Distal articular fractures occur almost exclusively in the hindlimbs and appear to be more common in foals.[39] The acute fracture is generally best treated by lag screw fixation and external coaptation. If the fracture is chronic, secondary OA of the PIP joint is likely and arthrodesis of the PIP joint is recommended.

Physeal fractures are usually Salter–Harris type II fractures and are most common in weanlings.[11,39] Minimally displaced fractures are generally best treated conservatively with stall confinement and bandage support. In one report (four cases), all of these fractures healed with a moderate degree of malunion, but P1 remodeled so that a normal hoof-pastern axis was maintained.[39] If the fracture causes limb deformity and cannot be reduced, internal fixation may be required. If the PIP joint becomes subluxated as a result of the injury, arthrodesis of the PIP joint is recommended to realign the phalanges.

VetBooks.ir

Oblique or transverse fractures are uncommon and do not affect the physis or articular margins. Stabilization of the fracture with lag screws placed through stab incisions has been described.[39] Minimally displaced fractures may heal with external coaptation. Displaced fractures usually require open reduction and internal fixation with bone plates.

Comminuted Fractures

The objective for treatment of most horses with comminuted P1 fractures is usually to preserve the horse for breeding purposes or pasture soundness.[32] Even horses with only moderately comminuted P1 fractures that are repaired surgically rarely return to racing. In one report, zero of 33 Thoroughbred racehorses and 4 of 28 Standardbred racehorses returned to racing after surgery.[32] The goals of surgery are usually to restore the articular congruity of the joint/joints involved and to stabilize the fracture to maintain bone length. Methods for treatment of comminuted P1 fractures include:

a. External coaptation alone
b. External skeletal fixation alone (transfixation pin casts or Nunamaker skeletal fixator)
c. Lag screw fixation through stab incisions ± external skeletal transfixation (Figure 4.111)
d. Open reduction with lag screws and external coaptation
e. Open reduction with plates and screws and external coaptation
f. Reduction combined with transfixation pin casts (Figure 4.112)

Selection of the specific treatment method often depends on the fracture configuration, intended use of the horse, economic constraints, and preference of the surgeon. If internal fixation is considered, the implants should permit reapposition of the joint surfaces and provide longitudinal stability of P1. Internal fixation is usually recommended in horses with moderately comminuted P1 fractures that permit fracture realignment (Figure 4.111). With severely comminuted fractures, accurate fracture repair and longitudinal stability is sometimes impossible.

Horses with an intact cortex (strut of intact fractured P1 that extends from the proximal to distal joint surfaces) should be repaired with internal fixation. These horses have a much greater chance of surviving than horses without an intact strut of bone. In one study, 92% of horses with moderately comminuted P1 fractures treated with internal fixation had a successful outcome, whereas horses with severely comminuted P1 fractures had a much lower survival rate.[32] The intact strut of bone provides longitudinal stability to the fracture site as well as a solid piece of bone to which fracture fragments can be lagged.

External skeletal fixation is usually the treatment of choice to repair severely comminuted P1 fractures that lack an intact bony strut (Figure 4.112) and for those fractures that are open or have a severely compromised blood supply.[29,35,47,48] External fixation techniques reduce the risk of fracture collapse by using transcortical pins placed in the mid to distal portion of the third metacarpus/metatarsus, bypassing weight-bearing load through the fracture. Most horses should walk comfortably after surgery. Pin loosening, bone sequestration,

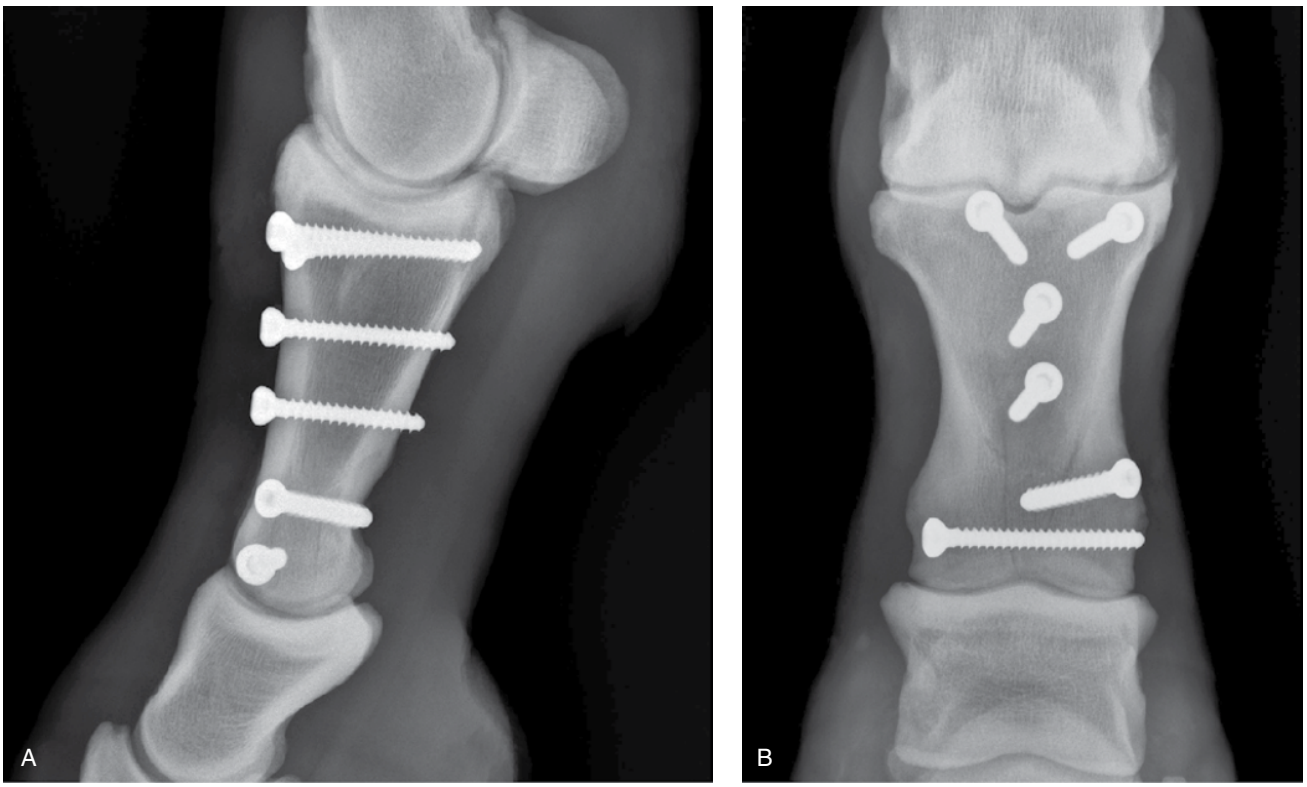

Figure 4.111. Lateral (A) and dorsoplantar (B) radiographs that were repaired with multiple lag screws placed through stab incisions.

VetBooks.ir

Figure 4.112. Dorsopalmar and lateral radiographs post-op and 3 months later at the time of hospital discharge of a severely comminuted P1 fracture treated with limited internal fixation and a transfixation pin cast.

and iatrogenic metacarpal/metatarsal fractures through the pin tracts are complications of using transfixation pin casts.[29,35] The addition of internal fixation is sometimes also used with external fixation to improve joint alignment and reduce longitudinal fracture collapse.

Casting alone can be used to treat some horses with comminuted P1 fractures, but it is less than optimal. Case selection is important and the fracture should be minimally comminuted and relatively stable to prevent axial collapse of the fracture.[39] Complications associated with using a cast alone to treat severely comminuted and unstable P1 fractures include (1) axial collapse of the fracture, potentially leading to an open fracture, (2) supporting limb laminitis, (3) excessive callus formation and OA of the MCP/MTP and PIP joints, (4) shortening of the pastern region, and (5) partial ankylosis of the MCP/MTP joint.[17,32] Because of these numerous complications, external coaptation alone is not recommended for treatment of horses with severely comminuted P1 fractures. In addition, casting or external skeletal fixation is not recommended for horses with moderately comminuted P1 fractures because of the very good success with internal fixation of these fractures.[32]

Prognosis

Noncomminuted Fractures

The prognosis for performance with noncomminuted fractures of P1 often depends on the configuration of the fracture, duration of the fracture until treatment, method of treatment, and breed and intended use of the horse.[11,17,27,69] In one study in racehorses, a significantly lower percentage of horses returned to racing following repair of complete sagittal fractures that extended into the PIP joint (46%) than following repair of short incomplete sagittal fractures (71%), long incomplete sagittal (66%), or complete sagittal fractures that extended to the lateral cortex (71%). The time from fracture to repair did not affect the outcome. Additionally the median number of races and the median fastest race times before and after surgery were not significantly different.[27] In another study with Standardbred racehorses, 89% of the horses returned to racing, but at significantly decreased performance levels.[69] In another study in young Thoroughbred racehorses, 70% of the horses treated conservatively with short, incomplete sagittal fractures raced, and 65% of the horses with long, incomplete sagittal fractures treated conservatively raced.[17] Horses with dorsal frontal fractures treated by lag screw fixation also appear to have favorable prognosis to return to performance.[11,39]

Comminuted Fractures

Horses with open or closed severely comminuted fractures that do not permit reconstruction of the fragments remain difficult to treat and have only a fair prognosis for survival, regardless of the treatment approach used. Moderately comminuted P1 fractures (those with an intact bony strut) can usually be repaired with internal fixation, and a 92% successful outcome has been reported.[32] Reasons for euthanasia of horses with comminuted P1 fractures include economic constraints, fracture collapse, iatrogenic metacarpal/metatarsal fractures, contralateral limb laminitis, and infection of the fracture site.[29,32,35]

DESMITIS OF THE DISTAL SESAMOIDEAN LIGAMENTS (DSLS)

There are three DSLs: the straight (superficial), paired oblique (middle), and paired cruciate (deep) (Figure 1.11). All of the ligaments originate from the base of the proximal sesamoid bones and intersesamoidean ligament. The straight ligament attaches distally to the proximopalmar/plantar aspect of P2, and the paired oblique ligaments attach to a triangular region on the middle and distal third of P1. The paired cruciate ligaments attach distally to the contralateral eminence of the proximal extremity of P1. There are also paired short ligaments that attach at the proximal articular margins of the MCP/MTP joint but are not considered to be part of the DSL complex. See Chapter 1 for further information regarding the anatomy of the DSLs.

VetBooks.ir

Desmitis of the oblique, straight, and cruciate DSLs occurs in all types of performance horses with injury to the oblique DSL being most common.[58] Horses that jump (e.g. event horses, show jumpers, field and show hunters, steeplechasers, and timber racehorses) and race and Quarter horses used for western performance such as reining, cutting, and barrel racing appear to be particularly prone to these injuries. However, injuries to these ligaments may not be the sole cause of lameness in many horses.[30,65]

The medial branch of the oblique DSL is more commonly injured than the lateral branch in some studies although others report equal medial and lateral frequency, and the hindlimbs are more often affected than the forelimbs.[30,58,65] When the straight DSL is injured, it is most often in the distal one-third of the ligament.[65] Injuries to the DSLs can be the primary injury or can be part of a complex of lesions, all of which contribute to some part of the current lameness. Horses with a valgus or varus limb conformation or long, sloping pasterns may be at increased risk for DSL injury.

Etiology

The DSLs are a functional continuation of the more proximally located suspensory ligament and are an important part of the suspensory apparatus that provides resistance to extension of the MCP/MTP joint during the stance phase. Hyperextension of the MCP/MCT joint can result in supraphysiologic strains in the suspensory apparatus, which may lead to injury to the DSLs. Although the DSLs in total provide this functional counter-resistance to extension, each ligament has a separate function that may account for the specific injuries that occur to these structures.

The straight DSL is the only unpaired ligament and is thought to contribute to sagittal stabilization of the MCP/MTP and PIP joints. The straight DSL would most likely be injured during hyperextension, but surprisingly, injury to this ligament is less common than to the oblique DSL.[58,61] The paired oblique DSLs are thought to play a prominent role in the limitation of rotation and abaxial movements of the MCP/MTP joint. Injuries to the oblique DSLs usually occur unilaterally, probably as a result of asymmetric loading caused by abnormal conformation, lateral/medial foot imbalances, a misstep, or poor footing. Injuries to the oblique DSL are more common than those to the straight or cruciate DSLs, although concurrent injuries to the straight and oblique DSLs have been reported.[58]

Clinical Signs

Horses with acute desmitis often present with a sudden onset of lameness. Mild swelling of the palmar/plantar surface of the pastern region may be present as a result of digital sheath effusion. The effusion is most commonly seen in acute cases (less than 3 weeks' duration), but soft tissue swelling is usually not apparent in most cases. Heat and pain with digital pressure may also be palpable in acute injuries.

Horses with chronic injuries may have a more insidious onset of lameness. Obvious heat, pain, and swelling are rarely present, and the location of the lameness often must be localized with perineural anesthesia. Sometimes there will be pain on deep palpation of the ligament. The lameness is usually mild to moderate in severity, positive to fetlock or phalangeal flexion, and worsened when the affected limb is in the inside of the circle. Palpation of the DSLs is best performed with the foot held off the ground and the MCP/MTP joint flexed so the flexor tendons are relaxed.

Swelling of a DSL must be differentiated from swelling of the medial or lateral branch of the SDFT, which is also located in the midpastern region. Passive fetlock and phalangeal flexion are commonly painful, and direct digital pressure over the swollen region of the DSL for 30 seconds may increase the signs of lameness.

Although the clinical findings may indicate a problem in the palmar/plantar pastern region, perineural anesthesia should be performed to rule out concurrent involvement of the foot. Perineural anesthesia of the PD nerve at the base of the sesamoid bone (basisesamoid block) should improve the lameness in most cases as will intrathecal block of the DFTS.[30] However, an abaxial sesamoid or low four-point block may be necessary if the ligament injury is located proximally in the pastern.[4] In addition, other concurrent problems should be closely evaluated because a recent report suggested that lesions of the DSLs found on MRI were the sole cause of lameness in only 2 of 58 horses.[65] It should be kept in mind that most horses with obvious DSL injury on ultrasound exam would not have received an MRI by the authors. See Chapter 2 for more information on perineural anesthesia.

Diagnosis

Diagnostics that may help document an abnormality to one of the DSLs include radiography, ultrasound, and MRI. Radiographic abnormalities that may suggest a previous or concurrent injury of a DSL include enthesophyte formation, avulsion fractures/fragments, and dystrophic mineralization within one of the DSLs. Enthesophyte formation at the attachment of the oblique DSL at the palmar/plantar aspect of P1 is a relatively common finding and may be incidental (Figure 4.113). Enthesophyte formation at the proximal aspect of P1 and at the base of the proximal sesamoid bone is also believed to be evidence of injury to the cruciate or short DSL.

Fractures/fragments of the base of the proximal sesamoid bone can involve the DSLs.[4] Fragments from either the dorsal aspect of the base of the proximal sesamoid bone or proximal palmar/plantar articular margin of P1 typically involve the short DSL.[55] Bone fragments have also been observed on the nonarticular proximal extremity of P1 and at the base of the sesamoid bones.[4] These fracture fragments may involve the oblique, cruciate, or short DSLs.[4,55] Dystrophic mineralization associated with the DSLs may also be present radiographically, usually at the base of the sesamoid bones. It is important to differentiate dystrophic mineralization from avulsion fractures at the base of the sesamoid bones because fracture fragments can and should be removed, whereas there is usually no treatment for mineralization.[4]

Sonographic evidence of acute desmitis of the DSLs is manifested by a diffuse increase in ligament size, fiber

VetBooks.ir

Figure 4.113. Enthesophytes on the palmar lateral cortex of P1 can be seen on this DLPMO radiograph of the pastern. The clinical significance of these lesions is questionable but may suggest a previous injury at the insertion site of one of the DSLs or far less commonly the insertion of the distal digital annular ligament (DDAL). This horse was sound and radiographs were taken as part of a prepurchase examination.

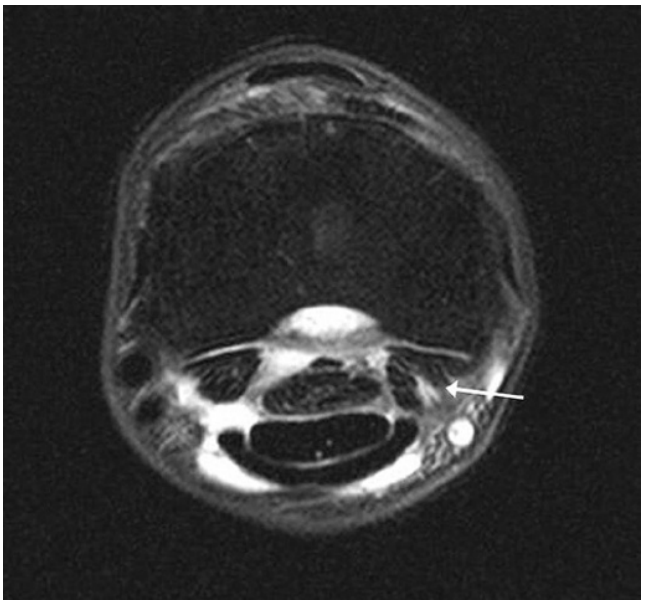

Figure 4.114. Transverse proton density MRI image showing high signal intensity (arrow) in the lateral branch of the oblique DSL in the pastern region.

disruption, discrete core lesions, and periligamentous fluid surrounding the affected ligament.[13,55] The anechoic space between the ligament and the SDFT is often reduced in size with desmitis of the oblique DSL. Chronic sonographic changes may include varying degrees of the acute abnormalities within the ligament, hyperechoic areas consistent with dense scar tissue formation, and dystrophic mineralization.[13,55] Periosteal proliferation in areas of ligament attachments may appear as irregular contours on the bone surface. Basilar sesamoid avulsion fragments, desmitis of the ipsilateral branch of the suspensory ligament in the same limb, and fragments off the proximopalmar/plantar aspect of P1 may occur concurrently in more chronic cases. Ultrasonographic identification of cruciate DSL injuries is difficult due to the location of these ligaments and therefore may be underdiagnosed.

Ultrasonography of the palmar/plantar pastern region is difficult to perform and requires experience to become proficient. There are numerous soft tissue structures that must be ruled out as potential problems. Therefore, only obvious abnormalities within the DSLs may be recognized. In a recent study to describe the normal appearance of the DSLs using MRI, 80% of the lesions found with MRI were not detected with ultrasonography.[65] Although ultrasound can be useful to diagnose problems in the DSLs, lack of ultrasound abnormalities does not rule out a problem within the DSLs. Currently, MRI is the best diagnostic tool to make a definitive diagnosis (Figure 4.114).[58,61] See Chapter 3 for additional information on MRI.

Treatment

In general, injuries to the DSLs are treated very similarly to other soft tissue problems such as tendinitis. In acute cases, confinement, cold therapy, pressure/support wraps, and administration of NSAIDs are recommended. Cold therapy in the form of an ice/water slurry applied for 30 minutes twice a day during the acute inflammatory phase is beneficial. Pressure/support bandages can be applied in between the cold treatments and maintained for 2–3 weeks or as needed. NSAIDs can be administered for up to 2–3 weeks' post-injury. Feet and hoof-pastern axis imbalances should be corrected if possible.

Once a definitive diagnosis has been made, a 6-month rest and rehabilitation program is currently recommended.[58,61] This usually involves a short period of stall confinement depending on the severity of the injury (3–6 weeks), followed by increasing periods of hand-walking and controlled exercise. Hand-walking exercise usually begins with 5 minutes once or twice a day, 3–5 days a week, and then increases 4–5 minutes/week. Clinical evaluation should be performed at 4–6 weeks, and if the horse has improved, controlled exercise can be increased.

If abnormalities were apparent on ultrasound, reevaluation is recommended 2–3 months post-injury. Further controlled or free exercise recommendations are made depending on the ultrasound findings. In one study of 27 horses with DSL injuries, 76% of the horses successfully resumed performance following a 6-month controlled exercise program.[58]

Adjunctive treatments that may be used in addition to the rehabilitation protocol include extracorporeal shockwave, ligament splitting, injection of the DFTS

VetBooks.ir

with corticosteroids and HA,[58] and intralesional treatment of the damaged ligament with stem cells or platelet-rich plasma (PRP). Nonarticular base sesamoid fragments that may be associated with DSL avulsion injuries should be removed using a "keyhole" surgical approach through the DFTS.[4] With this approach, fragments are localized with needles and removed using arthroscopic rongeurs. Nine of 10 surgically treated horses returned to their intended use.[4]

Prognosis

The prognosis for horses with DSL injuries to return to performance has historically been considered to be guarded because of the high probability of re-injury. However, more recent studies have indicated a much better prognosis. Seventy-six percent, 66%, and 90% of horses with DSL injuries or avulsion fractures of the proximal sesamoid bones returned to performance following treatment.[4,58,61] However, recurrence of DSL desmitis is always a possibility, similar to other soft tissue injuries. In addition, concurrent musculoskeletal problems such as PIP joint OA, navicular syndrome, and suspensory desmitis often reduce the prognosis for full recovery.

DESMITIS OF DIGITAL ANNULAR LIGAMENTS

Within the pastern region there are two superficial ligaments that form a retinaculum for the flexor tendons: the proximal digital annular ligament (PDAL), which inserts medially and laterally on the proximal and distal tubercles of P1, and the distal digital annular ligament (DDAL), which runs from the medial and lateral borders of distal P1 to the palmar/plantar aspect of P3 (Figure 1.11). Primary injury to both the PDAL and the DDAL can be a cause of lameness in the horse.[7,22]

Etiology

Similar to injury to other ligaments, there is often an initial small injury that leads to inflammation, fibrosis, and loss of elasticity, which leads to functional shortening of the ligament and constriction over the flexor tendons. Continued athletic use then causes additional injury to the previously damaged and functionally shortened ligament leading to recurrent inflammation, fibrosis and loss of elasticity, and further functional shortening. The permanent fibrosis and resultant constriction over the flexor tendons is likely why horses generally do not respond to rest and medical therapy.

Clinical Signs

Affected horses have a mild to moderate and consistent lameness and minimal to no external signs. Horses may be positive to flexion of the distal limb.

Diagnosis

A palmar (plantar) digital nerve block or intrathecal DFTS block will greatly improve the lameness associated with injuries to the PDAL and DDAL.

Ultrasound of the PDAL is easily performed and the normal dorsal to palmar/plantar thickness of the ligament is 2 mm.[22] Desmitis of the PDAL is seen as a thickened ligament with heterogeneous echogenicity. Due to location within the foot, distal to the DFTS, it is difficult to thoroughly assess the DDAL with ultrasound. High-field MRI is the preferred technique for diagnosis of injury to the DDAL (Figure 4.115). The thickness of the normal DDAL is also 2 mm. When injured, the thickness can increase up to 10 times the normal thickness.[7]

Figure 4.115. Transverse and sagittal PD-weighted images showing thickening and mixed signal intensity DDAL. The dotted line on the sagittal image represents transverse slice location.

VetBooks.ir

Treatment

Surgical transection of the PDAL and DDAL is the treatment of choice. In one report, five of seven horses with DDAL injury that had surgical transection of the DDAL were able to return to performance, two of which had failed to respond to rest and medical therapy.[7]

Prognosis

The prognosis for return to work after surgical transection of the DDAL appears to be good, although only one report is currently available.[7]

SDFT AND DDFT ABNORMALITIES

In general, injuries in the pastern region to the SDFT occur most frequently in the forelimbs. Chronic DFTS effusion seems to be more common in the hindlimbs, and injuries to the DDFT within the DFTS occur most frequently in the hindlimbs; however, in horses that jump, DDFT injury within the DFTS was more common in the forelimbs.[2,64] Injuries to the DDFT that are associated with navicular syndrome are covered under the foot section. Injuries involving the SDFT most commonly involve the branches of the SDFT located outside the DFTS.[13] The SDFT branches at the level of the MCP/MTP joint, giving rise to medial and lateral branches that insert on the palmar/plantar eminences of P2.[75] Abnormal conformation such as a long pastern or an underrun heel may predispose the horse to injury of the SDFT branch. Injuries to the DDFT within the pastern are nearly always within the DFTS, often cause effusion of the sheath, and may contribute to chronic tenosynovitis of the DFTS (Figure 4.116). In two different studies of horses with DFTS tenosynovitis, injuries to the DDFT were found in 44 of 76 horses[64] and 101/130 horses.[2]

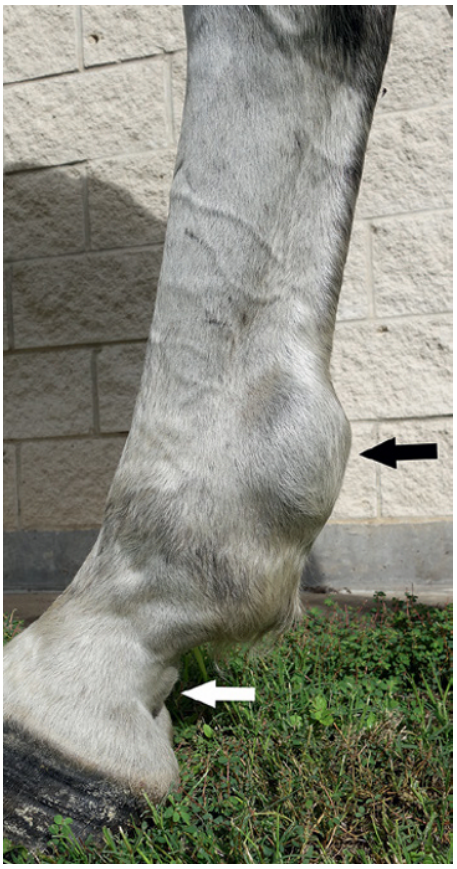

Figure 4.116. This horse was 4/5 lame in the left hindlimb and had severe effusion of the digital flexor tendon sheath and chronic DDFT injury. Arrows demonstrate the largest outpouchings of synovial effusion proximolateral and medial (black) and plantarodistal (white). Lesions of the DDFT within the tendon sheath appear to be more common in the hindlimbs than the forelimbs.

Etiology

Injuries to the SDFT in the forelimbs are usually associated with hyperextension of the MCP joint, resulting in nonphysiologic stretching and overload of the SDFT.[54] These injuries occur commonly in racehorses, but why some horses get SDFT injuries in the pastern compared to the metacarpal region is unknown. The cause of DDFT injuries within the tendon sheath is unknown, but hyperextension of the MCP/MTP joint and overstretching of the tendon are also likely.[2] It seems as though both SDFT and DDFT injuries in the pastern region occurs more frequently as a result from a single traumatic event as compared to flexor tendon injuries at the level of the metacarpus (tarsus).

Clinical Signs

SDFT Branch Injuries

Lameness usually occurs at the onset of injury with focal heat, swelling, and sensitivity noted on palpation. However, careful palpation and comparison of the medial to lateral branches are important to detect differences in size, heat, and pain because these injuries can be easily missed. Generally, swelling develops within 3–4 days and is usually uniaxial on the limb. The medial SDFT branch appears to be more frequently injured than the lateral branch, and avulsion fractures of P1 at the insertion of the SDFT branch occur infrequently. Some SDFT injuries and damage to the manica flexoria may occur within the DFTS and result in tendon sheath effusion.[14,64]

DDFT

Deep digital flexor tendinitis occurs in a variety of horses and typically presents as an acute-onset, unilateral moderate to severe lameness that is persistent.[54] Heat, pain, and swelling of the DDFT itself are usually not palpable because the damage is often located within the DFTS, which can be quite effusive (Figure 4.116). Lameness is often worse on a soft surface and generally improves with perineural anesthesia of the palmar/plantar nerves at the level of the proximal sesamoid bones. Distension of the DFTS often occurs in conjunction with the injury, and many horses present with chronic tenosynovitis of the DFTS of undetermined cause. The use of MRI and/or diagnostic tenoscopy in addition to ultrasound has increased the frequency of a definitive diagnosis of DDFT injury[2,64,78] (Figure 4.117). If the DFTS is distended, intrasynovial anesthesia of the sheath is the preferred method to confirm the location of the lameness.

VetBooks.ir

Figure 4.117. Ultrasound images (left) and contrast tenogram (right) demonstrating a lateral marginal lesion of the DDFT within the tendon sheath at the level of the proximal sesamoid bones (left; arrows).

Diagnosis

Ultrasonography is currently the most commonly used method to diagnose tendon injury and can be used in the pastern for branch lesions of the SDFT, core lesions of the SDFT, and some abnormalities of the DDFT. However, ultrasonographic examination in the pastern region may result in false-negative results.[2,14,64] This is especially true for the DDFT, where surface and longitudinal lesions are more common than core lesions and more difficult to visualize with ultrasound.[14,77,78] It is important to note that the DDFT becomes bilobed at the level of the pastern. Each lobe should be similar in size and shape. A lesion may involve one or both lobes and is typically characterized by enlargement and alteration of the tendon with or without a hypoechoic region (Figure 4.118), making it more difficult to visualize with ultrasound. Dystrophic mineralization may be seen with chronic injuries (Figure 4.119).[76]

In cases that have been blocked to the DFTS or with nonspecific signs of chronic tenosynovitis of the DFTS, diagnostics beyond ultrasound should be considered.[77,78] An MRI examination is superior to an ultrasound examination to characterize the location, type, and severity of damage to both the SDFT and DDFT within the pastern (Figure 4.120). When MRI is not available, a contrast tenogram may be useful to define marginal tears of the DDFT as well as tears of the manica flexoria with improved positive and negative predictive values over

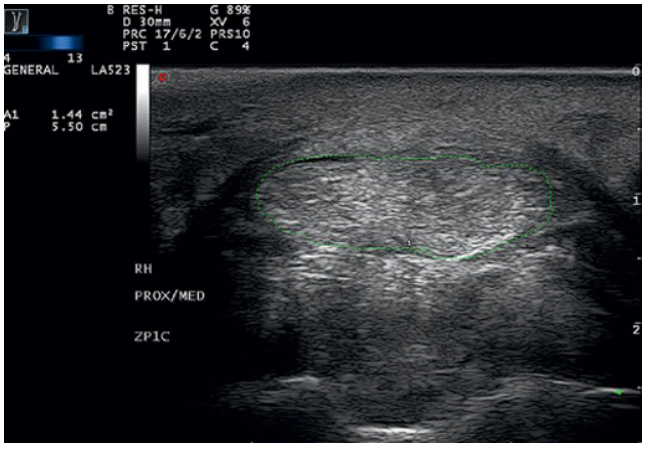

Figure 4.118. There is enlargement and mixed echogenicity of the lateral lobe of the DDFT.

ultrasound.[18,24,25] Five- to 7-mL contrast is injected with or without 10-mL local anesthetic, the horse is walked 4–5 strides to distribute contrast, and then a lateral to medial radiograph is made.

Tenoscopy of the DFTS is a definitive diagnostic tool to document intrathecal lesions of both SDFT and DDFT that may not be visible with ultrasound. An added benefit of tenoscopy is the ability to debride

VetBooks.ir

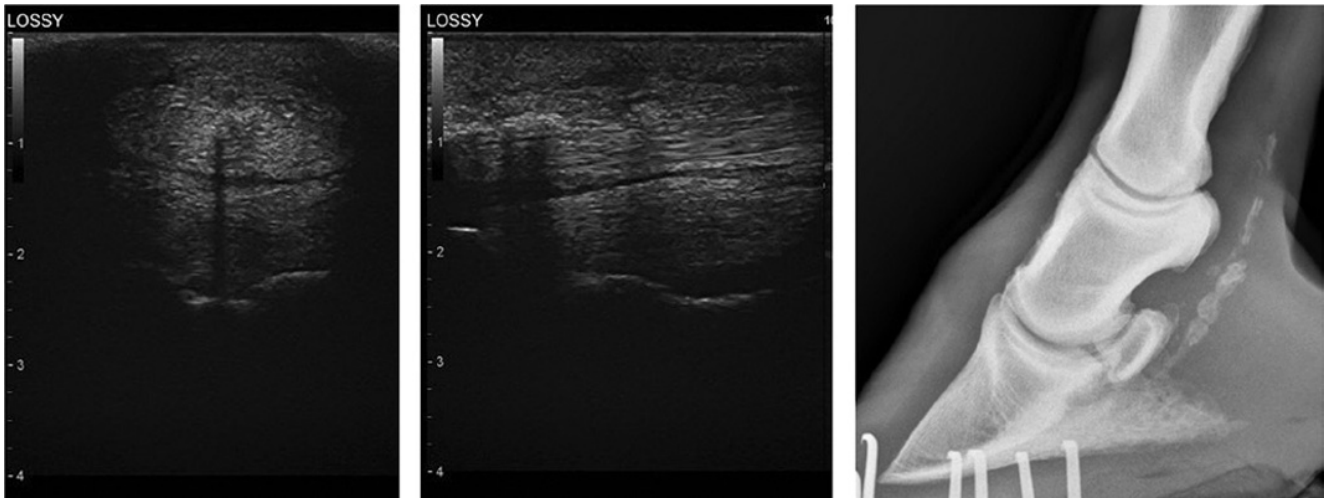

Figure 4.119. There is dystrophic mineralization of the DDFT visible on both the ultrasound and radiographic images of this horse.

VetBooks.ir

marginal tears, especially those with extruded fibers or adhesions, and tears in the manica flexoria.[14,64,77,78] If the lameness is confirmed to the DFTS and effusion is present, tenoscopy is strongly recommended, especially if the ultrasound findings are equivocal.[14,77] This is especially true if the DFTS has been treated by intrathecal administration of anti-inflammatory drugs with lack of resolution or rapid recurrence of lameness.

Treatment

Treatment depends on the location, type, and severity of the lesion. Branch lesions of the SDFT are usually treated with a controlled rehabilitation program similar to any bowed tendon injury; however, 6–12 months is typically needed. If the SDFT lesion is within the DFTS or if DFTS effusion is present, surgical exploration via tenoscopy is often helpful to further diagnose the specific problem and debride the damaged tendon.[77,78] Lesions of the DDFT at the level of the pastern or fetlock canal are often within the DFTS, and tenoscopy is often beneficial because these lesions are often difficult to diagnose and treat.[2,64,77,78] An annular ligament desmotomy may be performed at the time of surgery if considered appropriate.[2,77] When there is distension of the DFTS and ultrasound does not reveal tendon injury, medication of the DFTS with corticosteroids, HA, or interlukin-1 receptor antagonist protein (IRAP) can be performed. If there is lack of lameness resolution or recurrence of lameness, additional diagnostics such as tenoscopy should be pursued. Intralesional injection of regenerative products such as PRP or stem cells directly into the damaged tendon can also be performed. See Chapter 8 for more details on these treatments.

Prognosis

In general, soft tissue injures of the SDFT and DDFT in the pastern region can be difficult to diagnose and tend to have a worse prognosis than SDFT and DDFT injuries in the metacarpal or metatarsal region. Horses with SDFT branch injuries in the pastern region are thought to have a poorer prognosis to return to racing than SDFT injuries in the metacarpal region, with more frequent recurrence of injury. Following tenoscopic debridement, surface lesions of the DDFT within the DFTS result in only 38%–42% of horses returning to previous level of performance.[2,64] Without tenoscopic debridement of surface DDFT lesions, especially when there are extruded fibers, the prognosis appears to be poor. In one study, 10 of 17 horses with longitudinal tears of the DDFT returned to their previous level of work.[77] In another study of 76 horses with chronic DFTS tenosynovitis, sheath distension was eliminated in 33% and improved in 69% of the horses.[64] In the same study, 68% of the horses were sound, and 54% returned to their preoperative level of performance.[64]
