THE FETLOCK

Matt Brokken and Alicia Bertone

OSTEOCHONDRAL FRACTURES AND FRAGMENTATION OF THE PROXIMAL PHALANX

Osteochondral fractures of the proximal aspect of the first phalanx (P1) can occur in any horse used for performance but are particularly common in horses that exercise at speed. Most fractures of this type involve the dorsal articular surface of proximal P1 in the forelimb, medial or lateral to sagittal midline. The left forelimb and medial aspect of the joint are affected more often. Chip fractures from the dorsodistal aspect of the third metacarpal/metatarsal (MC/MT) bone also occur but are less common.

Other less frequently occurring fractures of P1 include fractures of the lateral and medial eminences of the proximopalmar (or proximoplantar) surfaces and avulsion fractures of the midproximal palmar articular margins just below the sesamoid bone. In addition, there are fragments associated with the palmar or plantar proximal aspect of P1 that may be traumatic or developmental in origin.

Etiology

Dorsoproximal P1 "chip" fractures are caused by concussion and overextension of the fetlock joint. Typically, similar to osteochondral fractures of the dorsal aspect of the carpus, these fractures occur toward the end of the race in racehorses. From the appearance of the fractures, it seems that excessive overextension of the fetlock joint is probably involved. Overextension places stress on the dorsoproximal aspect of P1 as it is pressed against the distal third metacarpal bone. Limb fatigue is a factor in overextension of the fetlock joint, noted at the end of races when the back of the fetlock may contact the ground (running down). The fracture most frequently occurs medial to midline most likely due to the fact that the medial aspect of proximal P1 is more prominent and extends slightly more proximal than its lateral counterpart.

Fractures of the proximopalmar (or proximoplantar) eminence are also a result of trauma (most likely torsional) and may be associated with complete or partial tearing of the collateral ligament of the fetlock joint with possible subluxation/luxation.[43]

The cause of proximal palmar/plantar P1 fragments is debatable. In most horses, the belief is that they are developmental.[36] Axial fragments are classified as type I and are articular. Type I fragments can be associated with lameness at speed with clinical signs similar to dorsoproximal P1 fractures. Type II fragments are located abaxially and typically have minimal articular component; however, they can be a source of performance-limiting lameness.

Clinical Signs

Synovitis of the fetlock joint indicated by distension of the palmar/plantar pouch (between the suspensory ligament [SL] and the palmar or plantar surface of the cannon bone) is commonly found. Horses in race training often present with a history of lameness, which increases after exercise, and a workout or a race may cause the horse to be markedly lame. After prolonged rest, the horse may seem to be sound, only to go lame again when returned to training. Horses with fractures of the palmar/plantar eminence of proximal P1 will typically have an easily observable lameness (normally lame at the walk) along with varying degrees of swelling/edema associated with the fetlock region.

Some horses, particularly with chronic chip fractures, have only a small amount of swelling or lameness to indicate that there is a chip fracture. There may be fibrous enlargement on the dorsal surface of the fetlock joint that is easily palpated. It is difficult to produce pain in the affected region by digital pressure, but some heat may be detected over the dorsal surface of the joint. Flexion of the affected fetlock often elicits pain, and a fetlock flexion test usually exacerbates the lameness. If the examiner is unsure of this response, it should be compared with the opposite fetlock.

In most cases it is not necessary to use local anesthesia to identify chip fractures within the fetlock. If the examiner is suspicious that the fetlock is involved, radiographs should be taken. However, if confusion exists regarding the contribution of the fetlock to the lameness, either intrasynovial anesthesia of the fetlock (preferred) or a low four-point nerve block (proximal to the fetlock) can be performed. Diagnostic analgesia is recommended for some fragments of the palmar/plantar aspect of proximal P1 to determine their clinical significance.

Diagnosis

A definitive diagnosis is best made with radiographic examination. A minimum of four views (five views including the flexed lateral) should be obtained. Oblique radiographs should be taken to determine whether the chip is on the medial or lateral side of the midline (Figure 4.121). For palmar/plantar fragments, oblique radiographs raised ~20° from horizontal can be helpful in limiting the superimposition of the sesamoids on proximal P1 (Figure 4.122). However, it is important to note that the downward oblique projections may make detection of dorsal P1 fractures more difficult. It is important to radiograph the contralateral fetlock, because bilateral fractures are not uncommon, and clinical signs may not appear until the horse is back in training.[1,24,28,49,108] Ultrasonography also may be used to diagnose chip fractures of the dorsal aspect of P1 and concurrent proliferative synovitis of the fetlock synovial pad if present. Acute proximal eminence fractures can be difficult to appreciate on the lateral and dorsopalmar/plantar radiographic views and are best detected on oblique projections (Figure 4.123).

Treatment

Arthroscopic removal of small chip fractures in the dorsal or palmar/plantar aspect of the joint is the treatment of choice for the greatest chance of a quick return to full performance.[24,49,56,108] Arthroscopic evaluation permits removal of multiple fragments, visualization of the entire joint, and surgical treatment of lesions that may not have been identified on radiographs (Figure 4.124). Lesions commonly seen in association with P1 chip fracture include proliferative synovitis of the dorsal metacarpal synovial pad (32% of which had chip fractures) and cartilage erosion of the metacarpal

VetBooks.ir

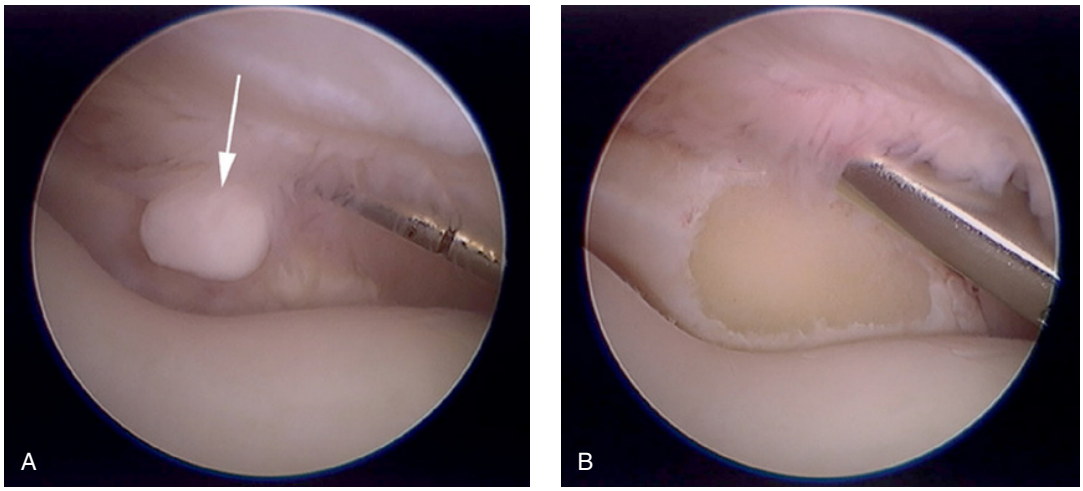

Figure 4.124. Arthroscopic images of a small dorsoproximal P1 fragment before (A; arrow) and after (B) fragment removal.

condyle.[28,49] It is recognized that some small nondisplaced fractures can be treated successfully with adequate rest for 120 days. If training continues, these fragments often displace and cause adjacent articular cartilage erosion. Two to four months of rest and controlled exercise is recommended before the horse is returned to a regular exercise/training program. This somewhat depends on the degree of joint damage and cartilage debridement. In some horses, small frontal fractures of the dorsal margin of proximal P1 are identified. These fractures can heal with conservative management but if lameness persists, some have advocated compression of the fracture with small screws (2.7 or 3.5 mm).[106]

Fractures of the palmar/plantar eminence can be treated conservatively, but due to the soft tissue attachments, there typically will be a large degree of osseous remodeling around the fracture due to movement. Osteoarthritis (OA) of the fetlock joint typically results in varying degrees. If the fragment is large enough, internal fixation with lag screw(s) may allow for a faster return to function and may lessen the development of OA. Removal of smaller fragments is also an option. Typically, these horses are in a rest and rehabilitation program at least 4–6 months to allow time for the bone and adjacent soft tissues to heal. The benefit of removing palmar/plantar fragments to improve performance has been questioned based on a study that indicated there was no difference in racing speed, career earnings, or lifetime starts between Standardbred racehorses with the fracture and those without.[19]

Prognosis

The prognosis is usually good to excellent for treatment of proximal dorsal chip fractures, but it is somewhat dependent on the size and number of chip fractures, their duration, whether or not corticosteroids have been injected, amount of concomitant articular cartilage damage, and degree of OA. Several reports indicate that the prognosis for return to athletic performance, including racing performance, is good to excellent (approximately 80%) with arthroscopic surgery to remove the fragment.[19,20] The presence of other fetlock lesions noted at arthroscopy decreased the prognosis in racing Thoroughbreds, but success was still good (greater than 70% return to racing).[24,49,56,108]

Small acute, nondisplaced fetlock chip fractures usually have a good prognosis with conservative treatment. Arthroscopic surgical removal may still be elected in these cases because the convalescence is shorter after surgical removal (often under 30 days) than for the bone to heal (90–120 days) and the risk of fracture displacement or refracture is eliminated. Factors that lower the prognosis include extreme large size of the fragment, chronicity, degree of synovitis/capsulitis, and amount of OA present. Standardbred racehorses often have chronic joint changes associated with dorsal P1 fractures. In general, racehorses that develop dorsal P1 fractures have reduced lifetime earnings compared with racehorses that do not develop these fractures.[59]

The prognosis for proximal palmar/plantar fractures that require compression screw fixation depends on the degree of initial trauma at the time of fracture. Often this is not fully appreciated until the radiographs are taken 3–4 months after surgery. The prognosis after removal of smaller proximal palmar fractures is considered to be very good, although the benefit of removal has been questioned in Standardbred racehorses.[19,20]

FRACTURES OF THE PROXIMAL SESAMOID BONES

Fractures of the proximal sesamoid bones are common injuries in racing Thoroughbreds, Standardbreds, and Quarter horses.[6,15,18,54,67,78,79,83,84,86,92] These fractures take various forms including apical, abaxial (articular and nonarticular), midbody, basilar (articular and nonarticular), sagittal, and comminuted. Combinations of fracture types such as apical/abaxial fractures may also occur. The forelimbs are most frequently affected in the Thoroughbred (right forelimb) and Quarter horse, whereas the hindlimbs are more frequently affected in the Standardbred (left hindlimb). Most of these fractures distract as a result of the pull of the SL proximally and the distal sesamoidean ligaments (DSLs) distally.

VetBooks.ir

Severe fractures involving the sesamoid bones and metacarpophalangeal/metatarsophalangeal joints are one of the most common types of fatal musculoskeletal injuries in racing Thoroughbreds and Quarter horses.[7,46,68,77] In a recent study in Thoroughbred racehorses, fractures of the proximal sesamoid bones represented 55% of all catastrophic fractures, while the most common noncatastrophic fractures involved the carpus and first phalanx.[91]

Fractures of the apical portion of the sesamoid bone are the most common, comprising more than 88% of sesamoid fractures. In Thoroughbred racehorses 2 years or older, 64% involve hindlimbs and 36% forelimbs.[78] Sesamoid fractures are most common (53.4%) in 2-year-olds, and then 3-year-olds (23%).[78,79] Apical fractures are frequently articular, singular, rarely comminuted and usually involve less than one-third of the bone (Figure 4.125). Apical fractures occur most frequently in the lateral sesamoid bone of the left hindlimb (42.8% of fractures) compared with the right hindlimb (36.6%) in Standardbreds, whereas a more equal distribution is observed in Thoroughbreds.

Basilar fractures are less common (6% of sesamoid fractures in Standardbreds). They represent an avulsion fracture associated with the DSLs and may be comminuted. These fractures are more common in the Thoroughbred than in the Standardbred and can be small articular, transverse articular, or nonarticular (Figure 4.126).[15,84,92]

Abaxial fractures are uncommon in Standardbreds (3%), and more common in Thoroughbreds and Quarter horses.[84,92] These fractures can either be articular or nonarticular and can be difficult to diagnose and may require an additional tangential projection on the radiographic examination to identify their exact location, or they can be identified on the dorsopalmar/plantar projection.[8,66]

Midbody transverse sesamoid fractures are seen most frequently in Thoroughbreds, older Standardbreds (mean age 6.5 years), and young foals under 2 months

Figure 4.126. DP radiograph of a Thoroughbred racehorse with a thin fracture of the base of the proximal sesamoid (arrow). Also note the other degenerative changes present in the fetlock (marked sclerosis of the palmar condyles of the distal third metacarpal bone, remodeling of the fetlock joint space; primarily on the side of the base sesamoid fragment).

VetBooks.ir

of age.[18,32,44,74] Fractures roughly separate the bone into equal portions and invariably enter the fetlock joint (Figure 4.127). Due to the distractive forces of the SL proximally and the DSLs distally, most of these tend to separate. Infrequently, they remain in apposition, but may separate at a later time. If both sesamoid bones are fractured, they usually become distracted and the suspensory support apparatus is lost.

Etiology

The cause of most proximal sesamoid bone fractures is excessive tensile forces related to fetlock hyperextension that maximally loads the sesamoid bones. Fetlock extension is greatest at the end of a race due to fatigue of the digital flexor muscles that support the fetlock. The bone fails when the sesamoid bone can no longer withstand the distraction forces applied to it by the SL and DSLs. The muscle fatigue factor is illustrated when young foals that are placed on pasture fracture their sesamoid bones while running to keep up with the dam.[32,44] It has also been reported that 70% of Quarter horse fatal musculoskeletal injuries occur within 10 yards of the finish line regardless of the race distance.[7]

Other factors such as poor conditioning, improper trimming and shoeing, and poor conformation create additional stresses on the sesamoids, as do training and racing schedules.[2,68] Although uncommon, direct blunt trauma such as a kick or interference or a misstep leading to unequal tension on the bone may also contribute to sesamoid fractures. The sesamoid bones also undergo marked bone resorption when the fetlock is immobilized, and pathologic fracture after cast removal has been reported in adult horses.[53]

During training these bones rapidly remodel, which initially decreases bone porosity and increases bone trabecular width and mineralizing surface, thereby enhancing the bone's ability to withstand stress.[107] The SL also increases in strength with training until it exceeds the strength of the bone, making bone failure the method of suspensory breakdown in racing or heavily training racehorses.[17] The vascular pattern of sesamoid bones may be implicated in site selection of fractures as the orientation and distribution of vessels parallel the radiographic lucencies seen in horses with sesamoiditis and correspond to the configuration of apical fracture patterns.[94]

Clinical Signs

The medial or lateral sesamoid bones, or both, may be fractured. Lameness is very pronounced in acute stages. The horse is reluctant to bear weight on the limb and will not permit the fetlock to descend to a normal position during weight-bearing. Swelling, heat, and pain are often severe in the fetlock region. Tenosynovitis or suspensory desmitis, which also may be present, may confuse the diagnosis if radiographs are not taken. The horse evidences pain when pressure is applied to the affected bone or bones. Extension of the fetlock during weight-bearing causes pain. Observation of the gait reveals that the fetlock is held rigid so that it cannot extend as much as the opposite normal fetlock. Lameness at the walk and trot may not be obvious after 1–2 weeks' rest, but joint effusion persists.

The fracture in the bone may occur in any area of the sesamoids, but proximal fractures are more common than distal fractures; proximal fractures also are more

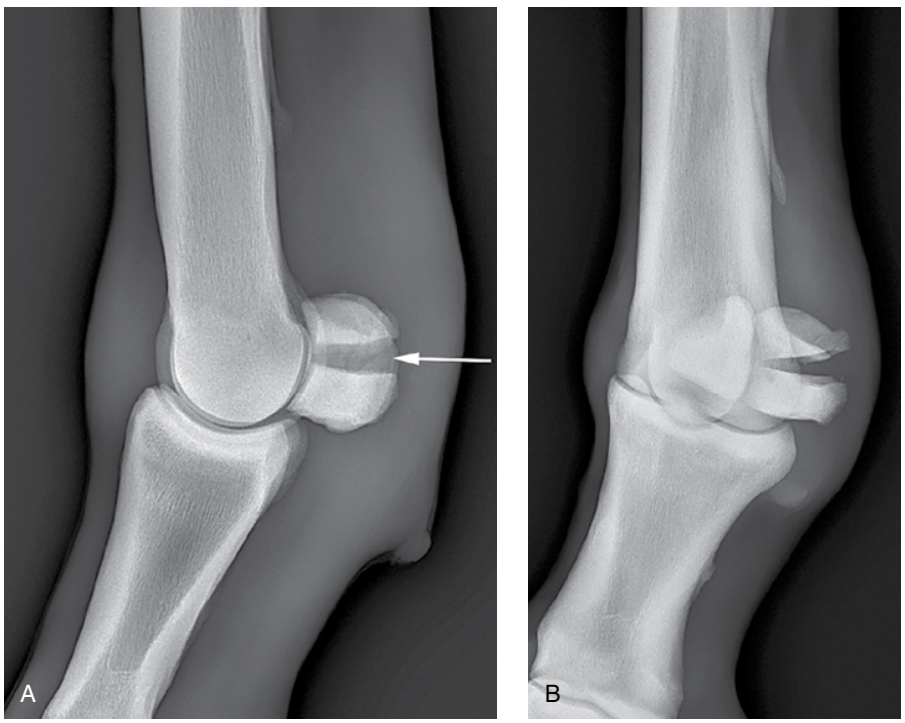

Figure 4.127. (A) Lateral and (B) oblique radiographs of a horse with a midbody sesamoid fracture (arrow).

VetBooks.ir

amenable to treatment. Desmitis of the SL and DSLs may occur concurrently with fractured sesamoids.

A history of galloping to exhaustion in an attempt to keep up with the dam is common for young foals under 2 months of age that have sustained fractures of their sesamoid bones.[32,44,74] These fractures often occur in foals that have been confined to a box stall for several days and then turned out for free exercise with the dam.

Diagnosis

Diagnosis is based on the physical examination findings described and confirmed with radiologic examination of the affected fetlock. If a fetlock joint is severely swollen and the horse shows pain when pressure is applied over the sesamoid bone(s), radiographs should be taken to rule out the possibility of fracture. Cases of tenosynovitis also should be radiographed to eliminate the possibility of fractured sesamoid bones accompanying this condition. Sesamoiditis may cause similar signs, but radiographs do not demonstrate a fracture, and joint effusion is not a prominent feature of sesamoiditis.

Standard radiographic views should include the dorsopalmar (DP), lateromedial (LM), and oblique projections. Occasionally the flexed LM may demonstrate lesions that are not detectable on the other standard projections, and estimation of reduction potential of midbody fractures can be made. The addition of the skyline projection of the abaxial surface of the sesamoid bone is helpful in some cases to identify the exact location of fractures on the abaxial surface (Figure 4.128).[66] The radiographs should be closely examined for any signs of OA associated with the fetlock and incomplete fractures that may be confused with enlarged vascular channels.

If an incomplete sesamoid bone fracture is suspected, repeat radiographs should be taken after a period of 2–4 weeks of stall rest, or nuclear scintigraphy can be performed. This permits better evaluation of the fracture line because it allows sufficient time for lysis/remodeling of the bone to occur. It should be emphasized that if these horses are allowed to exercise, they run a great risk of distracting the fracture and worsening the prognosis. Ultrasonography should be performed on all apical and abaxial fractures to identify the degree of concurrent injury to the SL.

Treatment

The treatment of sesamoid bone fractures is based on the location of the fracture and the intended use of the animal. Treatments include stall rest, cast application, surgical removal, lag screw fixation, circumferential wiring, and bone grafting.

Most fractures that are treated conservatively heal by a weak fibrous union, and the fracture line can be observed on radiographic examination for prolonged periods of time. A portion of these fractures that have apparently healed will separate at a later date and result in pain again. Generally, the conservative approach should be used for those horses that are not going to be used for performance in the future and in young foals without distraction of fracture fragments. Surgical treatment of sesamoid bone fractures in horses intended for performance is preferred for the most rapid return to performance with the least risk of future OA or sesamoid re-injury. Surgical removal or stabilization to promote earlier bony union reduces the risk of secondary OA and provides the best prognosis.

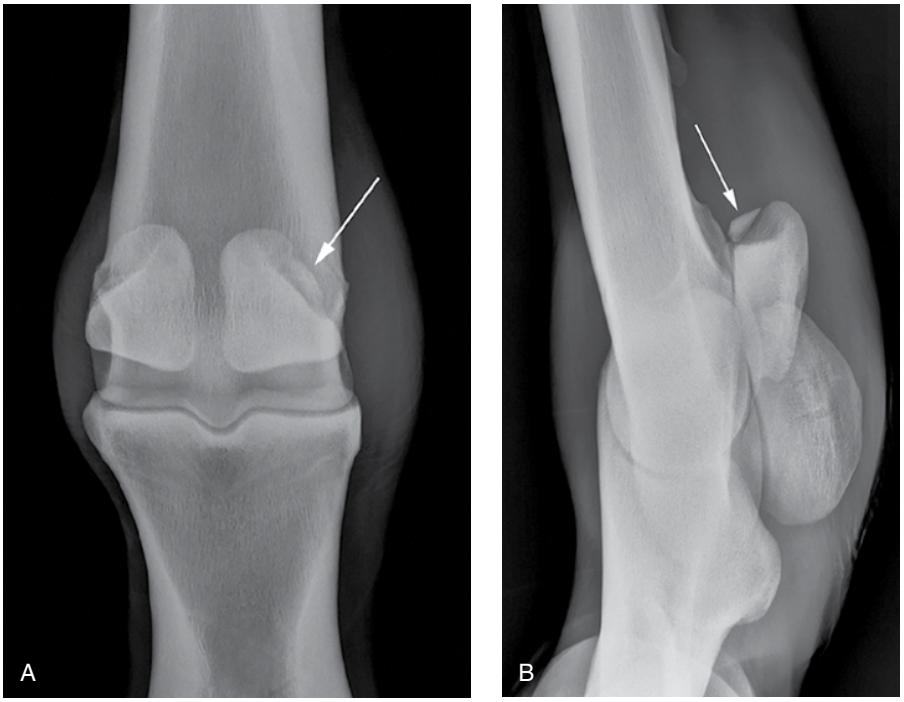

Figure 4.128. (A) DP radiograph of a horse with an abaxial sesamoid fracture (arrow). (B) Skyline projection to highlight the abaxial fragment of the sesamoid (arrow).

VetBooks.ir

Apical, articular abaxial, and basilar fractures involving less than one-third of the sesamoid bone are best treated by surgical removal of the fragment.[8,13,67,78,79,83,84,86,92] Nonarticular abaxial fractures may require removal, but horses often perform successfully without surgery. Midbody transverse fractures affecting the middle third and basilar transverse fractures of the proximal sesamoid bones have been treated successfully with lag screw fixation or circumferential wiring to provide postoperative bone compression and immobilization.[8,39,54,76,102,104,105] Lag screw fixation has been shown to have superior results in comparison with other surgical options.[18] Ideally, the fragment should be in one piece and should involve at least 30% of the bone for use of screw fixation repair. Casting is recommended after surgery because the forces to bend or cyclically fail the screw at the fracture site are high, particularly if anatomic reduction was not complete. Bone graft can be inserted into the fracture site just prior to tightening the screw. Bony union is expected within 6 months and return to training at about 9 months. The screw does not need to be removed, even if it breaks, as long as it is not infected. Approximately 44% of horses repaired with a 4.5-mm lag screw returned to race in one study.[18]

Surgery is easily performed with the horse in lateral or dorsal recumbency under general anesthesia. Surgical removal of apical sesamoid fractures smaller than one-third of the length of the bone can be performed by arthroscopy or arthrotomy through the palmar/plantar recess of the fetlock joint. Arthroscopy offers the advantage of more precise dissection and a faster return to performance for small articular fractures without suspensory involvement (3 weeks) and the ability to remove more than one fracture from a joint with minimal incisional morbidity. Lag screws are best directed from a distal to proximal direction.

For basilar fractures, the arthroscope is similarly placed in the fetlock recess, but the instrument portal must be made into the distal fetlock recess such that instruments can be placed parallel to the base of the sesamoid. Abaxial fragments that lie entirely on the basilar aspect (nonarticular) of the sesamoid bone cannot be reached by any arthroscopic approach and must be removed by incision directly over the fragment. Most of these fractures do not need to be removed and heal by fibrous union. Removal of nonarticular basilar fractures can be performed between the DSLs for smaller fragments or through the tendon sheath,[15] and using intraoperative ultrasound to help locate these fragments has been reported to be beneficial.[5]

Biaxial midbody sesamoid fractures are a common cause of breakdown in the Thoroughbred and Quarter horse racehorse.[7,46,77] Due to the fact that the suspensory apparatus is lost and distal limb vascular supply may be disrupted, management is directed toward immobilizing the fetlock joint for a sufficient time period to stabilize soft tissue damage. Treatment options include surgical arthrodesis or conservative ankylosis, although many of these horses may be humanely euthanized. A major complication to this "breakdown" injury is supporting limb laminitis in the contralateral weight-bearing limb. See the section on traumatic suspensory rupture for more information.

Fractures of the sesamoid (typically axial) that occur in conjunction with fracture(s) of the metacarpal or metatarsal condyle are serious injuries that should be identified with radiography because the prognosis for returning to racing, even with repair of the condylar fracture, is poor.[6] These fractures are usually sagittal and axial and occur due to extreme pulling on the intersesamoidean ligament when the condylar fracture displaces. These fractures suggest significant soft tissue injury to the fetlock joint and that OA is likely to ensue regardless of treatment (Figure 4.129).

Prognosis

The reported prognosis for apical sesamoid fractures is good to excellent (88% of Standardbreds[104] and 77% of Thoroughbreds[78] return to racing), for abaxial fractures is good (71% of Thoroughbreds or Quarter horse racehorses returned to racing),[86] for basilar fractures is fair (50%–60% of Thoroughbreds return to racing),[83] and for midbody fractures repaired by either lag screw fixation or circumferential wiring is fair (44%–60% return to performance).[39,54] However, repair of midbody fractures using lag screws is thought to provide a more favorable prognosis.[18] In addition, a recent study indicated that the size of apical fractures does not appear to influence the prognosis in racehorses.[47] Reports of conservative treatment options are not available for comparison, but generally it is presumed that the prognosis is guarded to poor for either basilar or midbody

Figure 4.129. Axial sesamoid fracture (arrows) in a horse with a lateral condylar fracture. *Source:* Courtesy of Dr. Wes Sutter.

VetBooks.ir

fractures that are not treated surgically. Most of these joints develop significant OA and restricted range of joint motion. If both sesamoids are fractured, the prognosis is poor due to the loss of suspensory support and only should be considered for salvage of valuable breeding stock or in horses of great sentimental value.

SESAMOIDITIS

Sesamoiditis is observed frequently in racing horses and hunters and jumpers between 2 and 5 years of age.[60–62,89] The condition is characterized by pain associated with the proximal sesamoid bones and insertions of the SL that result in lameness. The pain is thought to result from inflammation at the interface of the SL with the proximal sesamoid bones.[62,89] Concurrent SL branch disease should be suspected in these horses. A significant relationship between the presence of sesamoiditis and the subsequent development of SL injuries has been documented.[71] Evidence of sesamoiditis suggests a 5 times greater risk for developing injuries to the SL branch with the onset of training.[58] Pain, heat, and inflammation can usually be clinically detected at the insertion of the SL during the active stages of the disease process, but marked lameness and limitations on performance can also occur without any clinically detectable signs.[22,37]

Radiographs can reveal a range of changes from accelerated early remodeling response in the bones (increased size and number of vascular canals) to marked proliferation of bone along the abaxial margin of the sesamoid and increased bone density of the sesamoid. The SL and the DSLs may also be affected and show calcified areas. The increased bone production is thought to result from inflammation from tearing of the attachments of either the SL or the DSLs. Young Thoroughbreds with more severe radiographic signs of sesamoiditis are thought to be at increased risk to develop future suspensory branch injuries.[58] However, it is also possible to see radiographic changes indicating chronic sesamoiditis in sound performing horses, suggesting that some horses heal the injury and regain suspensory strength.[37]

Etiology

Any unusual strain to the fetlock region may produce sesamoiditis. Most commonly in racehorses, hunters, and jumpers, it can affect any type of horse. It is caused by increased stress to the attachment of the SL to the sesamoid bones. Injury to the DSLs may also occur at their attachment to the basilar portion of the sesamoid bones.

The sesamoid bones have a substantial intraosseous blood supply that enters the midportion of the bone through multiple abaxial channels that correspond to the channels that enlarge in sesamoiditis, indicating bone remodeling. This may represent the initiation of the remodeling response to bone stress of training, or it may reflect an increase in blood flow due to inflammation and injury to the SL, or both.[94] The sesamoid bones undergo intense remodeling in response to training,[107] and the progression of radiographic changes correlates to bone response to remodeling and injury.

Interestingly, several studies have categorized the radiographic changes in sesamoid bones of young (2- and 3-year-old) racehorses and discovered that many horses have increased size and number of vascular channels without lameness.[37,38] Yearling Thoroughbreds with more than two irregular vascular channels had a decrease in number of race starts and earnings at 2 and 3 years of age.[85] This supports the idea that remodeling is a normal response to training and that only if the stresses exceed, the bones' capability to strengthen would microfracture and bone damage occur. Although radiographic vascular changes of bone remodeling were not associated with sesamoid fracture, the vascular structures course along known lines of fracture in adult racehorses. The sesamoid bones have an extensive sensory nerve supply that may explain bone pain associated with trabecular bone injury.[26,27] Concurrent suspensory branch injury may also contribute to the palpable pain and lameness in affected horses.[34,58,71]

Clinical Signs

Symptoms of this condition are similar to those caused by fracture of the sesamoid bone. In the early stage, minimal swelling is observed, but increased heat may be felt over the abaxial surface of the sesamoid bone(s). As the disease progresses, visible enlargement of the soft tissues overlying the palmar/plantar surface of the fetlock can be seen as fibrosis of/around the injured SL becomes apparent. On palpation, pain withdrawal can usually be elicited by placing pressure over the abaxial surface of the sesamoid bones. In more advanced cases, pain may be elicited by applying pressure over the branches of the SL. The horse will also likely be positive to distal limb flexion.

At exercise, the lameness varies considerably and depends on the acuteness of the injury and its degree. In general, the lameness is most evident during the first part of exercise and is more exaggerated when the horse is exercised on hard surfaces. Perineural and/or intrasynovial anesthesia is used infrequently to diagnose this condition. Horses respond to a low four-point nerve block, but not to an intra-articular fetlock block, locating the lameness to the periarticular structures.

Diagnosis

The radiologic changes of true sesamoiditis have been described as bony changes on the abaxial surface or basilar region, increased number and irregularity of the vascular channels, and increased coarseness and mottling of the bone trabeculation (Figure 4.130). In acute cases, radiographs may have to be taken approximately 3 weeks after onset of the condition to determine whether bony changes will occur on the sesamoid bones. The condition may also occur with tenosynovitis, fracture of the sesamoid bones, and injury to the SL from which it must be differentiated. Careful radiographic interpretations of the mottled trabecular pattern seen in the proximal sesamoid bone are necessary to differentiate a fracture. Incomplete fracture can be differentiated from these coarse vascular canals because the fracture usually extends to the abaxial surface and the vascular canals do not. In addition, fracture lines frequently run at different angles than the vascular channels.

VetBooks.ir

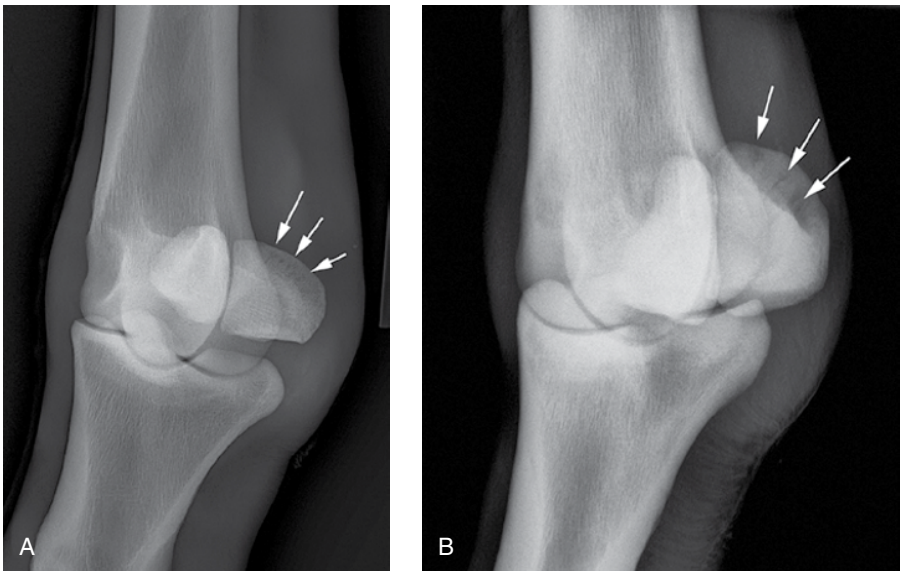

Figure 4.130. Radiographs of the fetlock in two different horses demonstrating mild sesamoiditis (A) and moderate sesamoiditis (B) with increased number of the vascular channels in the lateral proximal sesamoid bone (arrows).

Nuclear scintigraphy typically indicates increased radiopharmaceutical uptake (IRU) in the region of the sesamoid bones, but the uptake is usually less than what would occur with a fracture. Ultrasound of the SL and DSLs may be useful, but many horses may have no abnormalities in the ligaments in the acute phase. However, subclinical SL branch change has been reported in Thoroughbred yearlings with evidence of sesamoiditis suggesting that ultrasound examination should be performed in all affected horses.[71]

Treatment

If heat, pain, and swelling are detected at the bone or suspensory insertion, then efforts should be made to reduce the inflammation. Both topical and systemic anti-inflammatory medications may be used. Rest from performance until soundness at the trot is achieved followed by slow increasing duration and intensity of exercise allows the bone to continue to remodel and strengthen. Importantly, the exercise must be kept below the level that would reinjure the bone. Similar to other SL injuries, convalescence is long (6–8 months), and injury often recurs when horses return to full work. In chronic stages, blistering and ESWT have been used but with equivocal success. Young Thoroughbred horses with suspensory branch injuries and concurrent sesamoid inflammation treated with PRP at the junction between the bone and the ligament were more likely to start at least one race during their 2-year-old racing year than horses treated with saline; but this benefit did not extend into their 3- and 4-year-old racing years.[34]

Prognosis

The prognosis for return to full athletic performance free of lameness is guarded to unfavorable, depending upon the amount of periosteal reaction and new bone growth that occurs on the sesamoid bones and the extent of concurrent injury to the SL and the DSLs. In yearling racehorses, enlarged vascular canals identified on radiographs have been associated with fewer race starts and reduced earnings compared with horses with normal vascular canals.[85] Young racehorses with abnormal sesamoid bones should also be monitored closely for future adjacent SL branch injuries that may occur.[34,71]

AXIAL OSTEITIS/OSTEOMYELITIS OF THE PROXIMAL SESAMOID BONES

Etiology

Osteitis/osteomyelitis of the axial border of the proximal sesamoid bones is an uncommon cause of lameness in horses. The cause remains unknown and speculative with vascular, infectious, and traumatic etiologies implicated.[51] The condition is specifically associated with the intersesamoidean ligament within the apical to midbody axial margins of the sesamoid.[51] The condition has occurred in horses with septic tenosynovitis of the digital sheath, septic bacterial arthritis of the fetlock, and secondary to an *Aspergillus* fungal fetlock infection.[80,103] In another report, the clinical signs and radiographic lesions were suggestive of sepsis, although histology of lesions revealed infarction and necrosis as well as osteoporosis and chronic inflammation in the intersesamoidean ligament.[16]

Clinical Signs and Diagnosis

Horses typically present with a consistent lameness that may be severe (often lame at the walk). In one report, lameness ranged from 2 to 5 out of 5 (mean 4 out of 5).[103] In another report of 12 Friesian horses, all lesions were in the hindlimb, and lameness was acute and severe.[16] Radiographs usually reveal bone lysis at the attachment of the intersesamoidean ligament primarily at the midbody and apical regions with varying degrees of joint effusion (Figure 4.131A).[51] A single or

VetBooks.ir

both sesamoids may be affected. Some lesions appear cystic, whereas others appear to erode the axial border more diffusely.

Treatment and Prognosis

Ultrasonography along with advanced imaging (CT and/or MRI) of the fetlock can assist with determining the surface location of the lytic areas and assist with the decision for surgery (Figure 4.131B).[51] Small lesions that are internal or only open toward the intersesamoidean ligament may be best treated conservatively. Most lytic lesions have surgical access to the area from the palmar/plantar fetlock joint and/or digital sheath using arthroscopy. Abnormal bone and ligament should be debrided if present, and samples are submitted for culture and sensitivity. Debridement can make horses more lame due to the disruption of the thick, fibrous intersesamoidean ligament. Cast or splint application may help improve the horses' comfort level while healing. Regional limb perfusion with an antimicrobial offers the advantage of perfusion of multiple affected sites including the fetlock joint, tendon sheath, and sesamoid bones.[80] Prolonged administration of antimicrobials should be based on accurate culture and sensitivity results.

The prognosis for return to performance is considered guarded to poor, although horses may become pasture sound or return to less strenuous activities.[51,103]

OSTEOARTHRITIS OF THE METACARPOPHALANGEAL/METATARSOPHALANGEAL JOINT

Traumatic arthritis includes a diverse collection of pathologic and clinical states that develop after single or repetitive episodes of trauma and may include synovitis (inflammation of the synovial membrane), capsulitis (inflammation of the fibrous joint capsule), cartilage injury/damage, subchondral bone injury, or intra-articular fractures.[9–11,57] Any type of traumatic joint injury can progress to OA within the fetlock.

Etiology

Soft tissue injury to the joint commonly occurs in horses in full work and represents an overuse of the joint or a single-event injury. Joint injury can also occur as a sporadic event due to trauma. In young horses just put into training, fetlock joint soreness and joint effusion can develop and can usually be managed with a modified exercise plan and medication. Abnormal limb conformation may also predispose horses to joint soreness and eventually OA of the fetlock. Bone fatigue and subchondral damage are also known to occur in racing Thoroughbreds and predispose to the development of OA.[3,4] See section on palmar/plantar osteochondral disease (POD) later in this chapter.

Clinical Signs

In mild cases, joint inflammation occurs without lameness and is noted as joint soreness on flexion and joint effusion in a young, recently worked or maximally performing horse. Swelling of the palmar/plantar joint pouches is usually noted first, followed by dorsal pouch effusion with more chronic effusion. Cases that involve a capsulitis of the fetlock, particularly the dorsal fetlock, often have palpable heat and a more severe response to flexion. If exercise is sustained, lameness may ensue and is frequently bilateral. In moderate cases, joint soreness and effusion persist and lameness worsens with exercise. In severe cases of injury or advanced joint degeneration, lameness can be severe, and obvious joint enlargement and decreased range of motion can ensue.

VetBooks.ir

Diagnosis

Clinical examination provides a high degree of suspicion that OA of the fetlock is the cause of lameness. Both radiographs and nerve blocks or a fetlock joint block can help localize and define the fetlock OA. Radiographs can help diagnose an underlying cause in many cases, such as intra-articular osteochondral fragments (either as part of osteochondrosis or as an intra-articular fracture), subchondral cystic lesions (SCLs), subchondral bone erosion, osteophytosis, or joint space narrowing (Figure 4.132). Typically, digital nerve blocks do not block fetlock OA, but a low four-point block significantly improves the lameness.[9–11] However, there have been reports of horses with marked cartilage injury in the fetlock joint improving with a palmar digital nerve block.[25] Direct intra-articular anesthesia of the fetlock offers additional diagnostic benefits of achieving complete resolution of lameness, access to a joint fluid sample for analysis, and a direct portal for simultaneous treatment. If the joint fluid appears hemorrhagic or cloudy, an immediate synovial fluid analysis and culture should be performed to rule out a septic process.

In the past, horses that responded to a direct block to the joint but did not respond to rest or medical therapy were candidates for arthroscopic surgery. Now, the use of advanced imaging (CT or MRI) provides a more accurate identification of the pathology and determination of whether a horse is a candidate for arthroscopic surgery or medical therapy (Figure 4.133). This is especially true for horses with subchondral bone and articular cartilage damage. Both CT and MRI are considered to be superior to digital radiography to detect subchondral bone pathology in the metacarpophalangeal joint.[63,64]

Figure 4.133. Sagittal proton density MR image depicting marked cartilage damage of the distal third metacarpal bone (arrows) along with marked sclerosis of the adjacent subchondral and medullary bone (arrowheads).

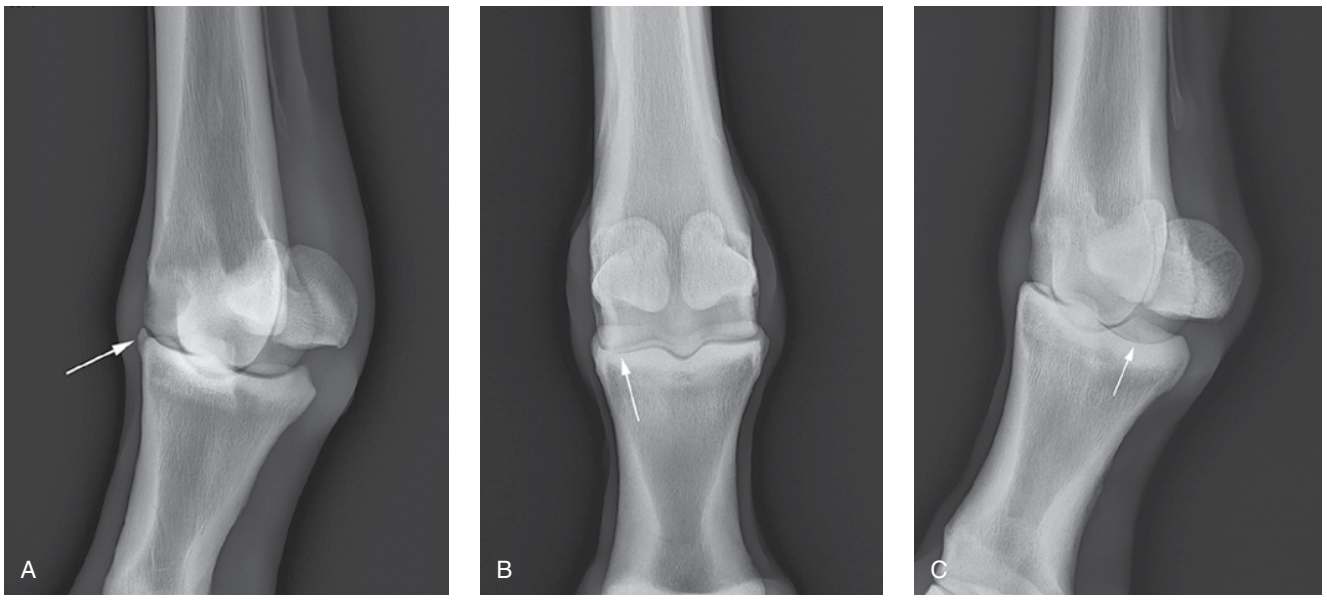

Figure 4.132. DLPMO radiograph of the fetlock (A) of a horse with a large periarticular osteophyte on the dorsomedial aspect of proximal P1 (arrow). DP (B) and oblique (C) radiographs of another horse with severe narrowing of the medial aspect of the fetlock joint (arrow) due to marked cartilage loss. The joint narrowing can also be seen on the oblique projection (C; arrow). Note that there are minimal other radiographic signs of OA in this horse other than subchondral bone sclerosis in proximal P1 (B and C).

VetBooks.ir

Treatment

Management of fetlock OA should address any primary problem and potentially include the following: rest, physical therapy, bandages, shoeing changes, and systemic and intra-articular joint medications. Arthroscopic surgery is recommended in horses that have concurrent predisposing conditions such as osteochondrosis or osteochondral damage/fragmentation. Performance horses that are lame from fetlock joint soreness should be rested until lameness resolves, frequently a minimum of 30 days. Return to work should be gradual and can be supplemented with systemic joint medications and shoeing alterations to promote breakover of the foot and an easy landing (rim pads, remove caulks and toe grabs, etc.). Use of athletic bandages to provide support to the fetlock joint during work can be very helpful and pressure bandages after workouts prevent swelling. Many jumping and racehorses are routinely treated with icing and wrapping of the fetlocks after workouts. If the fetlock effusion becomes chronic in nature with no active bone injury, many of these horses benefit from a low level of controlled exercise.

Joint medications can be effective for horses with OA of the fetlock. These include systemic nonsteroidal medications to reduce pain and inflammation, systemic polysulfated glycosaminoglycans (PSGAGs) to manage cartilage health, systemic hyaluronan to reduce synovitis and promote cartilage health, and intra-articular use of these and similar products and/or steroids for maximal relief of pain and inflammation.[9–11] Biologic therapies, such as autologous conditioned serum and stem cells, have also been promoted for intra-articular treatment of OA. These medications are frequently used after surgery or in OA without a surgical indication. Many show horses, particularly jumping and racehorses, have chronic soreness and early degenerative changes in the fetlock joints. Many of these horses are maintained on intramuscular injection of PSGAGs and intravenous (IV) hyaluronan throughout the show or race season.

The importance of regular and regulated exercise is critical to managing horses with fetlock OA. Confining horses with primary OA often worsens their stiffness and discomfort. Regular exercise and turnout provides the greatest longevity with this condition.

Prognosis

Early recognition and management of traumatic OA of the fetlock are key to keeping the joint in good health and continuing training in racehorses. Once degenerative changes in the joint are visible on radiographs, the prognosis is still fair with management if the horse is sound enough to perform with treatment. Many horses are maintained in full work while their fetlock OA is being managed. Once horses are no longer sound with the medical management listed, an extended period of rest may permit them to return to training, usually at a reduced expectation. Many top equine athletes can continue to perform at some level of activity with fetlock OA.

PALMAR/PLANTAR OSTEOCHONDRAL DISEASE

The palmar/plantar MC/MT condyle of the racehorse is thought to receive greater than twice the amount of stress compared with the dorsal surface of the bone at racing speeds. These excessive forces make this area vulnerable to bone necrosis and cartilage injury.[75] With these lesions, the subchondral bone of the palmar condyle is unable to carry out one of its important functions to support the overlying cartilage, which has been implicated as a major component in the development of OA (Figures 7.22–7.24).[72] A well-documented sequela of these repetitive high impact injuries is palmar/plantar osteochondral disease (POD), particularly in Thoroughbred racehorses. POD is thought to be due to repetitive overloading and impact of the distal MC/MT III bones, resulting in performance-limiting lameness with progression to permanent OA in severe cases.

Etiology

Repetitive overloading to the palmar/plantar aspect of the third MC/MT condyles at training and racing speeds contributes to focal areas of fatigue to the subchondral bone at the articulation of the palmar/plantar MC/MT III condyles with the proximal sesamoid bones. As a result, the bone remodels in an attempt to enhance its ability to handle the stress and load.[10,41] With continued stress, microtrauma occurs due to the decreased compliance of the sclerotic bone, resulting in edema and hemorrhage in these regions usually accompanied with microfractures.[3,50,52] The subchondral bone damage is thought to cause lameness and loss of training days primarily in Thoroughbred racehorses. Periods of rest are useful to allow for bone healing between months of training but have also been shown to result in subchondral bone resorption and eventual collapse of the overlying articular surface adjacent to the subchondral bone lesions with eventual articular cartilage degeneration.[3] The pathology is reportedly worse in the medial condyle of the forelimbs and lateral condyle in the hindlimbs.[70] Parasagittal microcracks and condylar fractures have a similar etiology to POD and therefore have been reported to occur simultaneously within the same limb, but are thought of as separate clinical entities.[31,45] Severe cases of POD often result in career-ending lameness and significant OA.

Clinical Signs

The primary clinical sign of POD is performance-limiting lameness localized to the fetlock region in racehorses. Metacarpophalangeal/metatarsophalangeal joint effusion is an uncommon finding with POD. The most common baseline lameness grade is 2/5 with approximately 60% of cases of diagnosed POD being positive to flexion of the fetlock joint.[95] Perineural anesthesia of the palmar/plantar metacarpal nerves is more useful in these cases as intra-articular anesthesia yields inconsistent results due to the pathology originating within the subchondral bone.[95] The lameness can present as bilateral or as an abnormal action in the limbs suggestive of quadrilateral disease.[4]

Diagnosis

Diagnosis of POD can be difficult with radiographs alone. However, due to the cost of nuclear scintigraphy and MRI, Davis et al. in 2017 described the common

VetBooks.ir

radiographic features of POD as focal radiopacities and/or radiolucencies in the palmar/plantar MC/MT III condyles along with flattening of the condyle and osteophytosis (Figure 4.134).[29] They reported a significant improvement in sensitivity and specificity of diagnosis of POD with plain radiographs following education of reviewers on the common radiographic features of POD. The authors concluded that radiography is useful in later stages of disease but other imaging modalities are required for early diagnosis of POD.[29] Nuclear scintigraphy has been reported as a useful diagnostic tool for POD. In 2011, Trope et al. demonstrated that increased IRU of the palmar/plantar MC/MT III condyles was the most common finding in the fetlock of Thoroughbred racehorses and was associated with fewer starts and less money earned than controls.[93] The patterns of IRU with nuclear scintigraphy are consistent with POD lesions diagnosed on postmortem examination; however, there has been no correlation with the degree of uptake and prognosis for return to racing.[4] The use of MRI has allowed for improved understanding of the relationship between pathology and prognosis in cases of POD. In 2012, Powell described the appearance of POD lesions with standing low-field MRI as regions of focal hyperintensity along the margin of the joint surrounded by hypointense regions on STIR/T2* sequences. Abnormalities were not detected radiographically in these horses.[73]

On *postmortem* evaluation, lesions can range grossly from discoloration of the subchondral bone with minimal to no cartilage erosion to severe subchondral bone discoloration and associated cartilage damage (Figure 7.47).[4] Histologically, common findings include microfractures of the trabecular bone with thickening and sclerosis of the adjacent bone, areas of osteocyte necrosis and eventual collapse, and degeneration of the overlying articular cartilage.[3]

Treatment

Treatment options are limited and range from rest, which allows for bone remodeling in the early stages of the POD, to systemic and intra-articular anti-inflammatory therapies. A period of 60- to 120-day small paddock turnout to allow for appropriate subchondral bone remodeling was recommended by Tull et al., with 95% of horses diagnosed with POD returning to racing.[95] If progression of the disease continues, pain control is difficult and typically unrewarding in the majority of cases.

Prognosis

Lameness associated with the early stages of POD can resolve with appropriate rest from training allowing the bone time to remodel and heal. As lesions progress and cartilage damage occurs, progression to severe OA occurs, resulting in career-ending lameness.

FETLOCK SUBCHONDRAL CYSTIC LESIONS (SCLS)

Fetlock subchondral bone cysts (SCLs) occur most commonly on the weight-bearing surface of the MC/MT condyle and less commonly on the weight-bearing surface of proximal P1. Cystic lesions of the distal metacarpus/tarsus that open into the fetlock joint can occur in young horses and are possibly considered part of the developmental osteochondrosis syndrome.[12]

Etiology

Some SCLs in the fetlock and other articular locations are considered part of the developmental orthopedic disease complex that occur during growth and the conversion of cartilage to bone. However, some are thought to

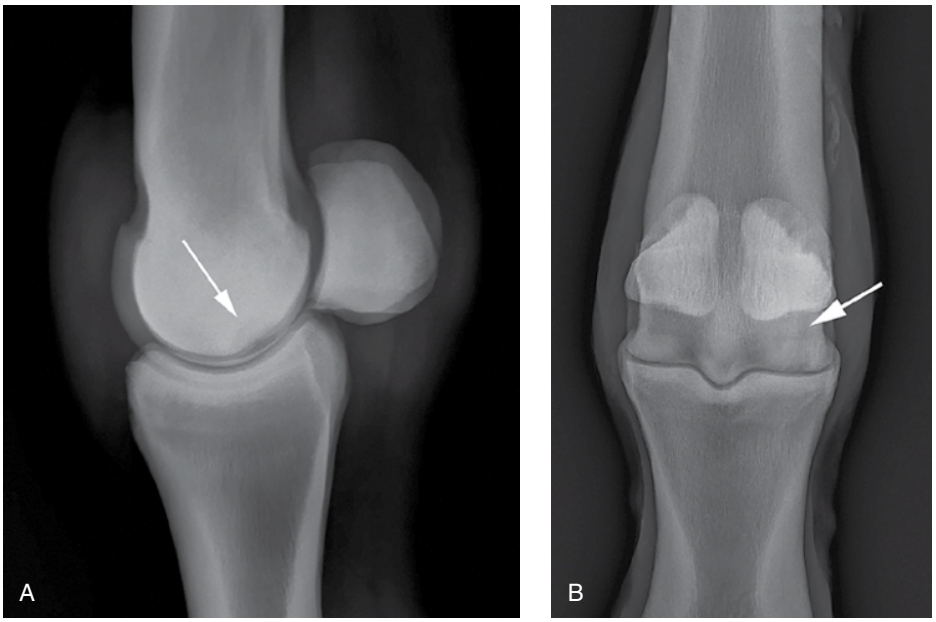

Figure 4.134. Flexed lateral (A) and dorsopalmar (B) radiographs of two different fetlock joints demonstrating radiolucent defects and severe sclerosis of the palmar condyles of the distal third metacarpal bone (arrows).

VetBooks.ir

be associated with subchondral bone trauma and are more common in adult horses. Injury to the articular cartilage and underlying subchondral bone from high impact may allow synovial fluid to enter the fissure and increase intraosseous pressure, contributing to cyst development. Typically, the lameness and joint inflammation in these horses improve as the cyst matures.

Clinical Signs

The average age of horses with clinical signs in one study was 18 months, although the SCL may develop prior to the onset of clinical signs.[42] Proximal P1 or distal MC/MT SCLs can develop in horses of any age from trauma. Moderate lameness is often present together with pain on fetlock flexion in most cases and fetlock joint effusion in approximately 50% of the cases. However, the degree of lameness can vary considerably depending on the location and age of the SCL.

Diagnosis

The diagnosis is usually made by radiographic evaluation of the joint (Figure 4.135A). In the early development of the SCL, it may not be apparent on radiographs, and follow-up radiographic examination is recommended if clinical signs that refer to the joint persist. Nuclear scintigraphy can identify a focal area of increased uptake in the bone as the SCL is developing and for several months after it has formed. Chronic SCLs may not have significant bone turnover above the surrounding condyle and may not be detectable with scintigraphy. Advanced imaging (CT or MRI) is often helpful to document the extent of the SCL and any secondary articular pathology that may be present in horses with trauma-induced lesions.

Treatment

Surgical debridement of metacarpal SCLs by an arthroscopic approach has historically been the preferable treatment if the diagnosis is made before significant signs of OA have developed (Figure 4.135B).[42] Medical therapy with newer regenerative therapies or intra-articular PSGAGs may also be helpful depending on the location and characteristics of the SCLs. For SCLs that do not respond to conservative treatment or debridement, osteostixis by extra-articular approach or mosaic autologous osteochondral grafting can be performed.[12]

Prognosis

The prognosis for return to performance appears to be good for most horses with SCLs of the distal metacarpus/tarsus. In one report, surgical treatment of third metacarpal SCLs resulted in 80% of horses (12 of 15) returning to their intended use.[42] Follow-up radiographs to determine the degree of OA/degeneration of the joint are helpful in determining the long-term prognosis. Horses with trauma-induced SCLs typically have a more guarded prognosis for performance than those with developmental lesions regardless of their location.

TRAUMATIC RUPTURE OF THE SUSPENSORY APPARATUS

Traumatic rupture of the suspensory apparatus with or without fractures of both proximal sesamoid bones is a common cause of acute breakdown in the racing Thoroughbred and often results in humane destruction of the animal.[14,40,46,77] Proximal luxations of the sesamoid bone without fracture can also occur with trau-

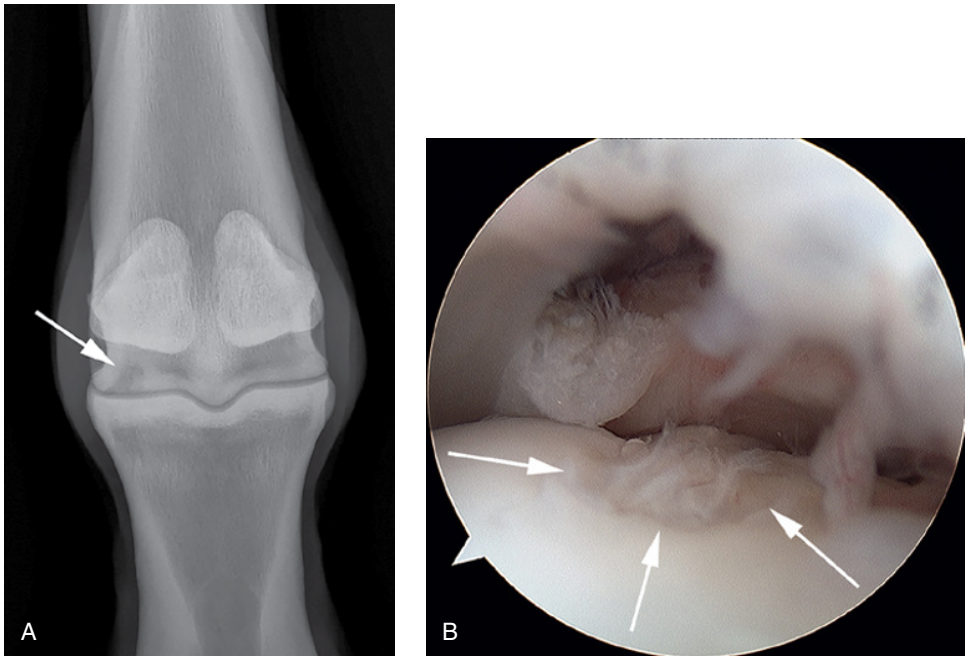

Figure 4.135. (A) DP radiograph of a horse with a subchondral cystic lesion in the medial aspect of the distal third metacarpal bone (arrow). (B) Arthroscopic image of a subchondral cystic lesion on the distal condyle of the third metacarpal bone. Note the well-defined margins of the cyst (arrows).

VetBooks.ir

matic rupture of the DSLs. Transverse or comminuted fractures of both proximal sesamoid bones allow the apical portions to be drawn proximally by the pull of the SL while the basilar fragments remain attached to the DSLs. Occasionally, open luxation of the fetlock joint can occur. Besides the severe trauma sustained by the supporting soft tissues and bone, the adjacent digital arteries are frequently damaged sufficiently to result in ischemic necrosis of the hoof. Treatment of traumatic rupture of suspensory apparatus should only be considered as a salvage procedure.

Etiology

Extreme overextension of the fetlock is the likely cause for disruption of the suspensory apparatus. Preexisting pathology of the bones or SL need not be present for this catastrophic failure to occur, but the presence of an abnormal finding in the SL on prerace inspection by a regulatory veterinarian increased the risk of SL injury 3.4-fold in future races as compared with a control population.[23] In a recent postmortem study of Thoroughbred racehorses, moderate lesions identified in the SL branches or DSLs were more likely to occur in horses that died from suspensory apparatus failure or metacarpal condylar fractures than in horses that died from nonmusculoskeletal causes.[40] Factors that increase the strain on the flexor surface of the limb would be expected to increase the risk of suspensory apparatus failure. Thoroughbred horses racing with low toe grabs or full toe grabs were 6.5 and 15.6 times more likely to incur a fatal suspensory apparatus injury than horses without toe grabs.[48] A study of Thoroughbred horses in New Zealand suggested that injuries to the suspensory apparatus were more likely in males, older horses, and horses in training without any starts, and there was no association between injury and cumulative high-speed exercise.[69]

Clinical Signs

On gross observation the affected fetlock is usually very swollen, and the horse usually bears its entire weight on the unaffected limb. The lameness is obvious, and if the animal transfers its weight to the affected limb, the fetlock will sink to the ground. Palpation often reveals the proximal displacement of either the intact sesamoid bone or the apical fractured fragments. Immediate stabilization of the limb is critical to prevent rupture of the neurovascular bundles. The blood supply to the distal limb can be estimated by palpation of a pulse, presence of distal bleeding and/or use of Doppler devices, or the IV injection of 5 g of sodium fluorescein.[90] The vascular supply is best evaluated after the horse has been treated for shock and the limb stabilized. Intense vasoconstriction initially can be interpreted as lack of blood supply.

Diagnosis

Radiographic examination usually reveals either the proximal displacement of the intact sesamoid bone or proximal displacement of the apical portions of the fractured sesamoid bones (Figure 4.136A). Associated swelling of the soft tissues is also quite evident, and preexisting degenerative lesions within the sesamoid bones and fetlock joint may also be present.[100]

VetBooks.ir

Treatment

Treatment should be considered for horses that are to be used for breeding or when there is sentimental value. Management of the horse on the racetrack is critical for success in treatment. Emergency crews must immediately restrain the horse and apply secure splints, such as a cast or the Kimzey Leg Saver® to permit transport of the horse to a facility for radiographs. Immediate immobilization of the affected limb is required to decrease the chances of further injury to the soft tissue as well as the vascular supply. Maintenance of the splint for a 4- to 5-day period prior to the selection of the final treatment permits the horse to acclimate to the immobilization and recover from the trauma and allows definition of the extent of skin necrosis and loss of vascular supply accompanying the injury. The fetlock arthrodesis procedure does not need to be performed immediately, and the soft tissue injury and permanent deficit and risk of infection must be evaluated to properly predict the outcome with surgery.

Treatments include casting, splinting, and fetlock arthrodesis (Figure 4.136B).[14,21,100] Casting and splinting are aimed at supporting and immobilizing the fetlock until soft tissues have healed sufficiently to support body weight. The use of a fetlock sling shoe can work in partial breakdown injuries. The Kimzey Leg Saver splint is not as rigid as a cast, but allows cleaning and treatment of soft tissue injuries and is designed to assist with fetlock joint support in suspensory apparatus injuries. Arthrodesis with implants and bone graft can be used to achieve a pain-free stable fusion of the fetlock joint if the soft tissues are intact and risk of infection is minimal. Supporting limb laminitis of the unaffected foot is a common sequela to this injury; therefore, the contralateral foot should be supported to distribute loading along the sole.

Casting the limb in flexion can immobilize the fetlock until healing has occurred, but may be complicated with severe pressure sores over the sesamoids that may result in septic osteomyelitis requiring euthanasia.[100] Casting is also expensive and labor intensive due to the multiple cast changes required and the prolonged duration for fusion. After 8 weeks in a cast, the limb is supported in a bulky bandage, and a special shoe is applied to elevate the heel. Other methods of supporting the limb with weight-bearing on the toe (splints) and with sling support shoes can be successful, but continual monitoring and aftercare is required for an extended duration. Of 25 cases managed conservatively, 15 survived.[82] Complications were similar to those from surgical techniques and included pressure sores, osteomyelitis, avascular necrosis, and supporting limb laminitis.[82]

Surgical arthrodesis of the fetlock should be considered in acute cases with intact skin that have not developed wounds during the initial management of the soft tissues. It is also recommended in chronic cases that fail to ankylose or in those horses that have chronic joint pain. The most popular method to achieve fetlock arthrodesis is use of a single 14-hole broad plate secured with 5.5- and 4.5-mm cortical screws spanning the dorsal surface of the metacarpus, fetlock joint, and proximal phalanx.[14,21] If the suspensory apparatus is disrupted, the palmar tension band must be reestablished or the plate will bend when loaded. The palmar tension band can be reestablished by securing dorsal 4.5-mm cortical screws into the sesamoid bones from adjacent to the plate for avulsions proximal to the sesamoid bones or of the apex of the sesamoid bones. For injuries without intact sesamoid bones or with disruption of the DSLs, a tension band wire must be placed around the palmar surface of the joint.[14]

Prognosis

The prognosis appears to be good for pasture and breeding soundness with preselection of cases. With arthrodesis, 32 of 54 horses with arthrodesis of the fetlock survived and were eventually allowed unrestricted activity.[14] The prognosis is better for horses in which fetlock arthrodesis was elected as the primary treatment rather than as a last resort and was better for horses in which fusion was elected for OA rather than rupture of the suspensory apparatus. In one report, 4 of 6 Thoroughbreds with breakdown injuries treated with fetlock arthrodesis with the locking compression plate survived.[21]

LUXATION OF THE METACARPOPHALANGEAL/METATARSOPHALANGEAL JOINT (FETLOCK LUXATION)

Lateral and medial luxation of the fetlock joint occurs uncommonly, but is a recognized syndrome that can affect all ages and breeds of horses. Usually, either the lateral or medial collateral ligament is ruptured, creating an obvious varus or valgus deformity of the fetlock region.[88,109] Occasionally, avulsion fractures associated with the insertion of these ligaments or joint capsule may occur and be noted on the radiograph proximal to the joint space. Articular fractures of the palmar/plantar eminence may also accompany the luxation.[43] Both forelimbs and hindlimbs can be affected, and the joint was open in half of 10 reported cases.[109] The diagnosis is usually quite obvious because an angular deviation of the fetlock joint is present. Occasionally the luxation will reduce spontaneously, and only a lateral or medial swelling will be noticed. Immediately after the injury, if the luxation is reduced, some horses will be minimally lame and appear sound at the walk. Re-luxation can occur if the joint is not adequately stabilized. Physical manipulation of the fetlock in these cases clarifies the suspicion of luxation. Typically, the joint re-luxates when it is flexed and abducted away from the side of injury.

Etiology

This injury frequently occurs when the horse steps in a hole or gets a foot caught between two immovable objects. The luxation results while the horse attempts to break free. Owners frequently relate the history of finding the horse caught in this situation. Occasionally horses spontaneously luxate their fetlock during high-speed activities (e.g. racing, rodeo eventing) or after running into an object.[88]

Clinical Signs

The clinical signs are usually obvious and are helpful in differentiating this injury from a fracture. However,

VetBooks.ir

fractures of the proximal phalanx can accompany the luxation. A varus (outward deviation of the cannon bone and inward deviation of the digit) or valgus (inward deviation of the cannon bone, outward deviation of the digit) angular deformity is usually present (Figure 4.137). Occasionally, the luxation will reduce spontaneously, and the remaining evidence of its occurrence will be lameness, joint instability, and asymmetrical fetlock swelling over the torn collateral ligament.

On palpation, the fetlock can usually be reduced and re-luxated without the degree of pain or evidence of crepitation associated with fracture. More frequently, the swelling that is present is less than that observed with fracture, and the swelling is located selectively over the lateral or medial surface. Although the digital vascular supply is rarely compromised, it should be carefully evaluated, particularly in open luxations.

Diagnosis

Generally, the diagnosis can be made by physical examination alone. However, radiographs should be taken to identify concurrent fractures or damage to the articular surface and subchondral bone (Figure 4.138). Radiographs are particularly important in young foals to rule out the possibility of growth plate fractures as a primary cause or a secondary contributing cause to the angular deformity.

Figure 4.137. Image of closed subluxation of the left hind fetlock prior to reduction and cast application. Note the lateral aspect of the distal third metatarsal bone (arrow).

Treatment

Treatment of simple luxation of the fetlock can be rewarding. In most cases the injury is limited to the supporting soft tissues, and after the luxation is reduced under anesthesia, good axial alignment can be maintained by casting or splinting the limb until healing occurs. Prior to applying the cast, needle drainage of the hematoma (if present) that overlies the ruptured collateral ligament provides a better fit for the cast. Although centesis of the hematoma and cast application can be performed in the standing horse, general anesthesia and lateral recumbency are preferred. Reduction of the luxation is usually not difficult. A cast is applied that incorporates the foot and extends to just below the carpus or tarsus in the adult. Casts or splints are maintained for 6 weeks with stall rest. After cast or splint removal, bandage support and limited exercise are recommended. Swelling (thickening) will be noticed over the area of collateral ligament rupture, and a cosmetic blemish will remain. Additionally, some horses may have trouble placing their heel on the ground when coming out of the cast and may need a wedge shoe for a period of time. A gradual return to exercise is recommended because re-luxation of the fetlock can occur if collateral ligament healing is incomplete.

Success can be achieved without suture of the collateral ligament, although there are several reports in the literature on open repair. To repair the ligament, the end is located after surgical incision, debrided, and sutured.[109] Alternatively, a polypropylene mesh has been substituted for the ruptured ligament.[97] Arthroscopic removal of the articular fractures should be elected if full athletic performance is a goal. This is not necessary for light riding soundness if the fragments are small and from the palmar/plantar eminence. Occasionally large avulsion

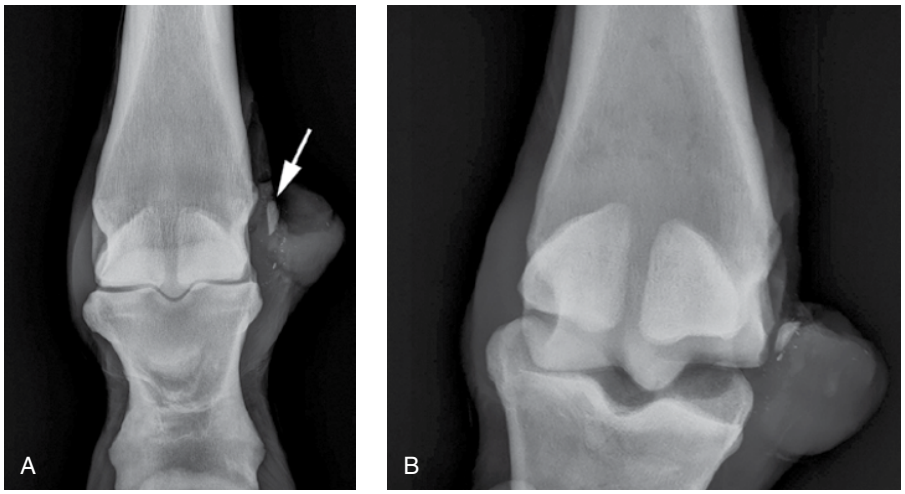

Figure 4.138. (A) Standing and (B) stressed DP radiographs of a horse with subluxation of the fetlock with fragmentation of the collateral ligament origin (arrow).

VetBooks.ir

fractures associated with the collateral ligament may warrant internal fixation to reconstruct the joint surface and improve the prognosis.

Acute open luxations can also be managed successfully.[88] However, prior to immobilization, thorough debridement of all devitalized soft tissues, bone, and cartilage should be performed. The joint should be thoroughly lavaged, and antimicrobials placed within the synovial cavity. IV regional perfusion also is warranted. If the joint is minimally contaminated and was treated immediately, a primary suture apposition of the soft tissues is recommended. A distal limb cast is then applied and removed when deemed appropriate based on the horse's progress. However, cast immobilization is usually required for 6 weeks minimum.

Prognosis

The prognosis for simple luxation of the fetlock is good for breeding soundness but guarded for athletic performance. In one report, 7 of 10 horses, some with open luxations, could be used for breeding, and 1 horse was riding sound.[109] Often the final prognosis cannot be accurately assessed until follow-up radiographs are taken at 2–3 months after injury. Immediate stabilization of the joint usually permits healing without the development of significant OA. Lack of stabilization or unrecognized luxation often results in OA in horses allowed exercise.[81]

Acute open luxations exposing the fetlock joint also respond well to early therapy as described. However, one must always be reserved in giving a good prognosis until joint infection and OA from direct trauma have been ruled out as complications. The long-term outlook for return to serviceability is often dependent on the degree of initial trauma sustained by the bone and the severity of secondary OA.

CONSTRICTION OF OR BY THE FETLOCK PALMAR/PLANTAR ANNULAR LIGAMENT

The palmar/plantar annular ligament (PAL) is a tough, fibrous, thickened, relatively inelastic part of the digital flexor tendon sheath (DFTS) strategically located to support the tendons as they course around the palmar/plantar aspect of the fetlock joint. The PAL together with the sesamoid bones provides a canal for the tendons to glide through. The PAL is lined with synovia and acts to prevent displacement of the tendon, which reduces its mechanical efficiency. Tendons within any tendon sheath and supported by an annular ligament can become enlarged from injury or infection. The chronic tendon enlargement/inflammation within the sheath can also create adjacent PAL thickening. Primary injury to the PAL can also occur, resulting in thickening (desmitis) and a subsequent reduction of the diameter of the canal.[65] Compression of the tendon and pressure within the canal subsequently restricts the free gliding function of the tendon, inducing pain and possibly ischemia to the tissues within the canal, analogous to carpal tunnel disease in people.

Constriction of or by the fetlock PAL can be a cause of lameness in performance and general-purpose riding horses. Although all breeds and uses of horses can be affected, sport horses, racehorses, Paso Fino horses, and Warmblood horses appear to be at a greater risk. In one report desmitis of the fetlock annular ligament was diagnosed mainly in sport horses and less frequently in racehorses.[98] In an unpublished report on 49 horses, Paso Fino horses and Warmblood types were overrepresented compared with the normal hospital population.[96] In another study, middle-aged to older general-purpose riding horses predominated, and PAL desmopathy occurred more frequently in the hindlimb than in the forelimbs.[65]

Etiology

Constriction of or by the fetlock annular ligament usually occurs as a result of trauma and/or infection. The injury may involve the annular ligament, primarily resulting in inflammation and thickening (desmitis) of the structure and thus producing constriction without abnormalities in other structures within the fetlock canal. Alternatively, the condition may be associated with distal superficial digital flexor tendon (SDFT) tendinitis or longitudinal tears in the deep digital flexor tendon (DDFT).[101] Due to the fact that the PAL is minimally elastic, swelling of the digital flexor tendons caused by fibrosis and associated tenosynovitis can cause the signs of constriction of the annular ligament. Inflammation and subsequent scar tissue enlargement often associated with a low flexor tendinitis ("low bowed tendon") may extend to involve the PAL, also resulting in desmitis. Adhesions may form between the SDFT and the annular ligament, further restricting motion. Tendinitis of the DDFT within the fetlock canal also enlarges the tendon within the canal and induces a tenosynovitis and produces the signs of annular ligament constriction. Wounds such as wire cuts or nail punctures can occur in the region of the palmar/plantar aspect of the fetlock, producing thickening, tenosynovitis, and constriction. One report revealed that primary desmitis of the annular ligament was the cause in 55% of the cases, tendinitis was the cause in 31%, and sepsis was the cause in 14% of the cases.[96] Synovial masses within the DFTS may also produce a constriction of the annular ligament and signs of tenosynovitis.[33]

Clinical Signs

Horses often present with a history of lameness that increases with exercise, resolves with rest, and returns when put back into performance. The most notable feature of annular ligament constriction is swelling of the palmar/plantar soft tissues of the distal limb around the fetlock and a characteristic observable proximal border of the annular ligament ("notching"). In nearly all cases, there is distension of the DFTS proximal and distal to the PAL.

The lameness is characterized by its persistence, pain on fetlock flexion, and worsening with exercise because of inflammation and increased constriction. In the most severe cases the horse is reluctant to place the heel on the ground and will accentuate the cranial phase of the stride to compensate. The continual external pressure on the tendons may produce abnormalities in the digital flexor tendons.[55]

VetBooks.ir

Perineural anesthesia, first of the foot and subsequently of the distal metacarpus or metatarsus, eliminates the lameness and locates the source of the lameness to the region of constriction. Direct anesthesia of the tendon sheath is usually not necessary, but may be performed if a fluid sample is being obtained for cytology or if the sheath is injected as a conservative treatment. However, anesthesia of the DFTS is fairly reliable for documenting painful conditions within the sheath. In horses that respond dramatically to tendon sheath anesthesia, tenoscopy of the tendon sheath is often indicated.

Diagnosis

The physical findings and the results of diagnostic anesthesia provide a presumptive diagnosis. Ultrasonography is indicated to identify the structures involved and assist with the selection of treatment. Normally the annular ligament is thin (less than 2 mm). One study found that measurement from the external skin surface to the internal annular ligament surface was the most reproducible index of annular ligament thickening.[65] Lesions identified at ultrasound vary and can include core tendon lesions or longitudinal tearing of the DDFT and SDFT, fibrosis, tenosynovitis and synovial proliferation, adhesions, and thickening of the annular ligament.[30,65,96] Subcutaneous fibrosis associated with PAL is common and should be differentiated from true thickening of the annular ligament itself.[65]

Radiographic evaluation of the fetlock region should always be performed to evaluate possible osseous involvement, particularly of the sesamoids. In lesions associated with wounds or of traumatic origin, osteomyelitis or sequestrum of the sesamoid bones can be present concurrently with PAL constriction. This finding necessitates additional treatment and decreases the prognosis for soundness or elimination of infection. In one study of 38 cases of annular ligament constriction, 6 horses had proximal sesamoid bone abnormality, and 12 horses had bone enthesophytes at the attachment of the annular ligament (insertional desmopathy).[87]

Treatment

Treatment of affected horses is often dependent on the stage of the disease, concurrent abnormalities, and intended use of the horse. Options usually include conservative medical therapy or desmopathy of the PAL with or without tenoscopy.[65] Adjunctive surgical procedures to simultaneously treat tendinitis, tendon core lesions, adhesions, and synovial proliferation are indicated if the underlying conditions exist. Conservative therapy is usually reserved for horses in the early stage of the disease or those with primary PAL desmitis and usually consists of oral and topical anti-inflammatories, intrasynovial treatment of the DFTS, controlled exercise, and bandaging the limb. The most commonly used surgical options for transection of the PAL is either a percutaneous approach or transection of the PAL concurrently at the time of tenoscopy. Tenoscopy of the DFTS is currently the preferred method to address synovial masses and tendon lesions and perform the annular ligament transection (Figure 4.139). Tenoscopy offers the advantage of visualization of the sheath and synovium and the tendons partially. Resection of adhesions, proliferative synovium, and tendon splitting can be performed as desired.[33,101] If tenoscopy is not an option, then a percutaneous approach either above or in the middle of the PAL can be performed. The PAL is transected either with curved scissors or a curved blunt-tipped bistoury. Although many feel that surgical transection is the ideal treatment, in one study of 71 horses with PAL injuries, the type of treatment did not appear to influence the outcome.[65]

Prognosis

Horses with PAL desmopathy alone that was not accompanied by abnormalities in the tendon (bowed tendon) had a good prognosis following surgical transection (84% returned to performance).[35,99] Other studies have reported a range of 50%–87% of horses with desmitis of the PAL returning to athletic function.[55,65] If SDF tendinitis is present, the tendinitis rather than the constriction appears to limit the performance. In one study, of the 13 horses with SDF tendinitis together with

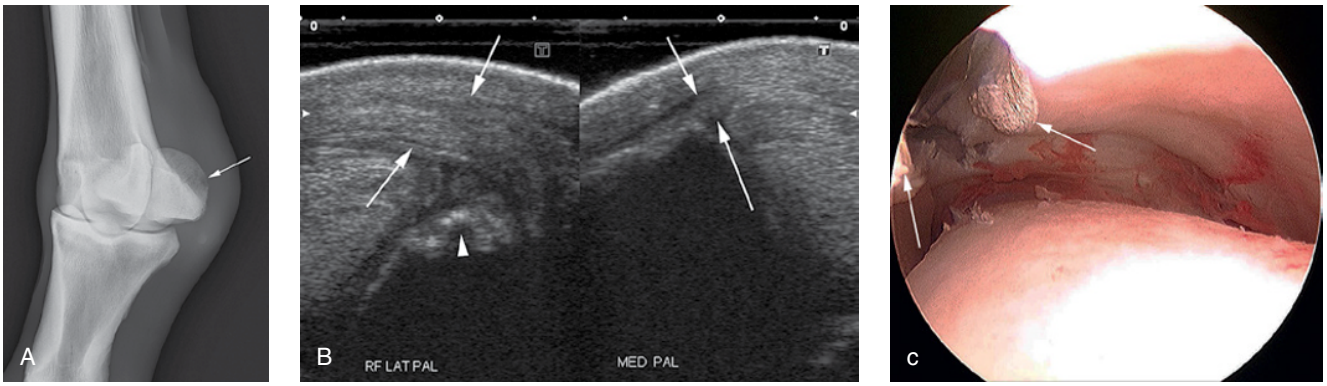

Figure 4.139. This horse sustained a wound previously over the lateral sesamoid bone of the fetlock. (A) DLPMO radiograph depicting the focal lucency in the lateral proximal sesamoid (arrow) with osseous reaction distally in the sesamoid. (B) Ultrasound examination of the fetlock demonstrating marked thickening of the lateral aspect of the PAL compared with the medial aspect (arrows). There is also irregularity of the lateral aspect of the proximal sesamoid (arrowhead). (C) Tenoscopic image after transection of the markedly thickened palmar annular ligament (arrows).

VetBooks.ir

annular ligament desmitis treated by annular ligament resection, only 38% became sound.[96] Of horses with longitudinal tears of the DDFT, 58% became sound.[101] Of 25 horses with synovial masses and adhesions, 72% became sound.[33] Some horses with primary desmitis can become sound with rest alone.[55] Bilateral PAL thickening, concurrent limb injuries, subcutaneous fibrosis, and lesions within the DFTS all have a negative effect on prognosis.[65]

BUCKED SHIN COMPLEX AND STRESS FRACTURES OF THE DORSAL THIRD METACARPUS

Bucked shins and stress fractures of the dorsal surface of the third metacarpal bone constitute a spectrum of diseases that are observed in young (2–3 years of age) fast gaited horses. Although the greatest incidence is observed in young racing Thoroughbreds, it also affects young Quarter horses and occasionally racing Standardbreds (Figure 4.140). The hindlimbs are much less commonly involved. Overall, the incidence of bucked shins and stress fractures has decreased significantly in the last 10 years, most likely due to changes in training methods.

Figure 4.140. A racing Quarter horse with the classical metacarpal profile of a dorsal cortical stress fracture.

Etiology

Different subdivisions of this disease are described later; however, it appears that all clinical syndromes have a common pathogenesis.

In young horses put in training, the metacarpal bone is exposed to new stresses. In younger horses (2-year-olds), the metacarpal bone is less stiff, and therefore, greater strains are measured on the dorsal cortex during high-speed exercise than in older horses. This high-strain environment may lead to cyclic fatigue of the bone and subsequent bone pain (bucked shins, sore shins).[94] Dorsal metacarpal strain is even greater in the lead limb (the left limb in racing in the United States), correlating with the most common location of dorsal cortical stress fractures.[28]

During normal maturation of the third metacarpus, horses aged 1–2 years resorb primary osteons and have a greater amount of resorption cavities and incompletely filled secondary osteons than older horses. This bone structure is more susceptible to fatigue microdamage resulting from training because of higher bone porosity, fewer completed secondary osteons, and a lower proportion of circumferentially oriented collagen fibers.[133] In racing Quarter horses put in training, the bone density of the medial and lateral dorsal metacarpus significantly decreased during the first 62 days of training and then significantly increased from day 104 to day 244 of training.[52,90] Horses experienced fewer bone-related injuries when they had greater cortical mass in the lateral aspect of the third metacarpus at the commencement of training.[90] The changing shape of the metacarpal bone during maturation[93] and training[29,122] is consistent with lower strains during high-speed exercise in older horses.

The thickening of the dorsal cortex, including diffuse dorsal periosteal new bone seen particularly in horses in training, is likely a natural response to these demands on the bone to withstand stress without developing microfractures or dorsal cortical fractures (Figure 4.141). This has been further confirmed by experimental exercise conditions that induced marked modeling and remodeling of the dorsal cortex, particularly subperiosteal bone formation at the midshaft of the third metacarpal bone. Additionally, horses completing the full training program had greater mineral bone content despite a lighter body weight.[83] Foals significantly increase metacarpal bone mineral density with age, and lack of exercise retards the normal bone development.[25]

In summary, in horses in race training, high strains can induce cyclic fatigue of bone, resulting in microdamage or ultimate bone failure. The body responds with bone modeling and remodeling, but microfracture damage may develop and cause pain. Historically, the majority (more than 80%) of 2-year-old racing Thoroughbreds[6] and many racing Quarter horses[52] demonstrated dorsal cortical pain with an estimated 12% that went on to develop acute failure or dorsal cortical fracture, usually within 6 months to 1 year of showing dorsal cortical pain.[93] Transformational clinical and experimental studies performed during the 1990s evaluating bone modeling and remodeling in Thoroughbred racehorses demonstrated that galloping long distances increased the likelihood of bucked shins by 36.4%, while breezing short distances reduced the likelihood of bucked shins

VetBooks.ir

by 98.6%.[16,94] These studies also found that slow-speed exercise produced tensile strains on the dorsal cortex of the metacarpus, whereas high-speed exercise produced compressive stains on the dorsal cortex. Since that time, the incidence of bucked shins has dramatically decreased, as most Thoroughbred horses are now trained shorter distances, at higher speeds. The incidence of fatigue failure of the metacarpal dorsal cortex continues to be greater in Thoroughbreds than Standardbreds. This was not attributed to inherent differences in the mechanical properties of the bone, but rather gait differences and resultant bone stresses during training and racing.[95]

Clinical Signs

Early dorsal metacarpal disease is usually observed in young Thoroughbred racehorses (2–3 years old) as they begin intense race training and occasionally in older horses that have not been strenuously trained or raced as 2-year-olds. The disease has an acute onset and is most obvious after intense exercise. Horses can be described as having a short, choppy gait; however, overt lameness is usually not present. Additionally, any gait deficits often resolve after short periods of rest. A visible convex swelling overlying the surface of the affected portion of the cannon bone is common. On palpation, the dorsal cortex of the third metacarpal bone is acutely painful to pressure or concussion. Frequently the horse will withdraw the limb in response to pain. Radiographs taken at this time are usually negative; however, fractures are occasionally observed as well as a minimal amount of superficial cortical osteolysis.

Subacute to chronic dorsal metacarpal disease invariably develops as a result of acute disease that is unresponsive to therapy or has gone unrecognized. It is most frequently seen in horses 2–4 years of age.[86] Only mild degrees of gait deficit may be noticed at exercise. On palpation, varying degrees of pain may be elicited, but a more obvious enlargement is palpable on the dorsomedial cortex (Figure 4.140). The pain response is typically more profound after strenuous exercise, and the left limb is usually more severely affected. Periosteal new bone formation is usually observed on radiographic examination (Figures 4.140 and 4.141).

Dorsal metacarpal bone failure or stress fractures usually occur in the dorsolateral cortex, although fractures can occur in the dorsal or dorsomedial cortex. It is usually observed in older horses, 3–5 years of age, that have a history of bucked shins. As with dorsal metacarpal disease, the lameness may not be prominent while the horse is rested. However, it is usually prominent after strenuous exercise. On palpation, a rather discrete painful area can be palpated on the dorsolateral, or less commonly dorsomedial, surface of the left third metacarpal (cannon) bone at the junction of its middle and distal third. Only rarely is the right third metacarpal bone involved. Radiographs usually point to a cortical fracture on the dorsolateral surface (Figure 4.142).

Diagnosis

A tentative diagnosis of bucked shins or a dorsal cortical stress fracture can be made from the clinical findings and the age relationship. Little information is derived from local direct infiltration anesthesia of the painful area because it provides only partial relief in the lameness. Median and ulnar nerve perineural anesthesia or proximal metacarpal regional anesthesia with a ring block is required for total relief of pain, but this is rarely indicated.

Radiographs can assist with the diagnosis of dorsal cortical stress fracture. A series of four radiographic views should be taken: dorsopalmar (DP), lateromedial (LM), dorsolateral to palmaromedial oblique (DLPMO), and dorsomedial to palmarolateral oblique (DMPLO). The DLPMO and the LM best identify the dorsal medial bone proliferation, and the DMPLO and LM best identify the dorsolateral cortical fractures. Horses continuing to train and race with sore shins can be screened for the development of fractures with radiographs. Some fracture lines can be difficult to see; serial oblique radiographs can be helpful.

It is rare to see radiographic abnormalities in acute dorsal metacarpal disease. In subacute dorsal metacarpal disease, periosteal new bone formation (of reduced density compared to underlying cortex) and surface cortical bone resorption may be observed. In chronic disease, a thickening of the dorsomedial cortex with associated periosteal new bone formation is seen. Occasionally an endosteal response may be observed in the advanced cases. Dorsal cortical fractures have a characteristic radiographic appearance and usually enter the cortex distally and progress proximad at a

VetBooks.ir

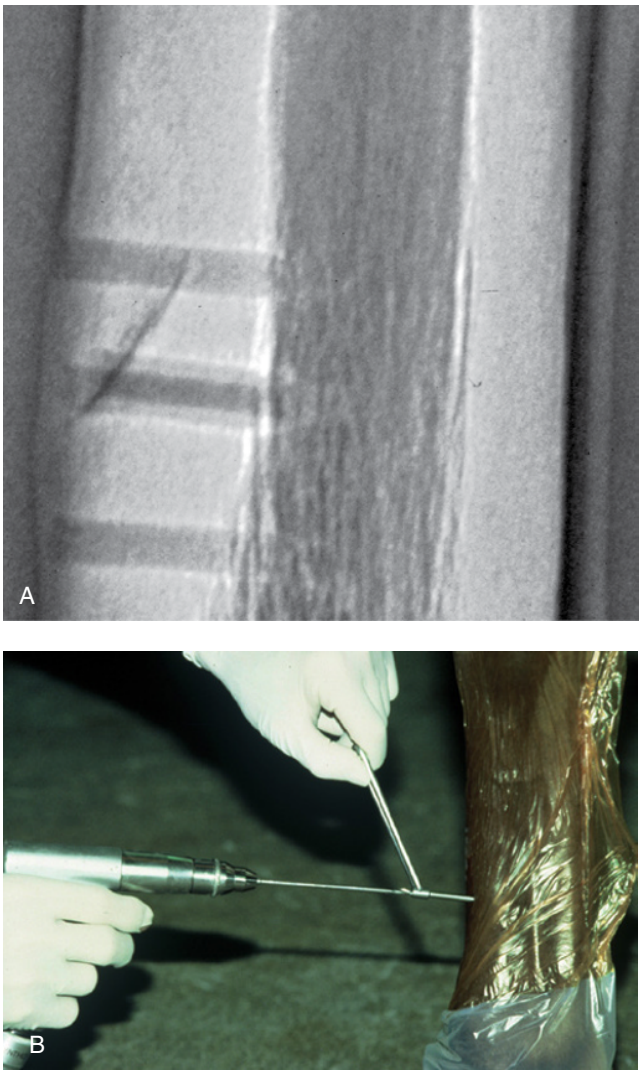

Figure 4.142. Radiograph of a dorsal cortical fracture treated with osteostixis procedure (A) that was performed standing (B).

35–45° angle. On occasion, dorsal cortical fractures can enter the cortex proximally and course distally.

Most frequently the fracture appears in radiographs as a straight or slightly concave fracture line (tongue fracture) (Figure 4.142). Occasionally, the fracture line exits the proximal (or distal) cortex such that a saucer fracture is produced. Rarely, the fracture continues to enter the medullary canal. Multiple fractures may emanate from the distal site of the cortical entry (often termed "fissure fractures"). Periosteal callus is often present at the site of fracture and is a function of the chronicity of the disease. Endosteal proliferation is observed occasionally in fractures that are completely through the cortex. Repeated radiographs at 7- to 10-day intervals may be necessary to identify a fracture that is suspected but not observed on initial radiographic examination.

Nuclear scintigraphy can provide information about the stage of disease in horses showing dorsal cortical pain or in those with undiagnosed forelimb pain. The sensitivity of this technique to identify bone metabolism and turnover is high, and it allows detection of abnormalities in horses in the acute–subacute stages that are still in training. Racehorses may have bone scintigrams performed to determine whether training should continue or to identify focal uptake indicative of impending fracture. In a review of 121 bone scintigrams of racing Thoroughbreds with clinical history of dorsal metacarpal disease, horses without fractures (bucked shins) had a mild to moderate diffuse uptake of radioisotope, unlike the focal intense uptake typical of dorsal cortical fracture. Chronic fractures are less focal and intense because of surrounding bone remodeling; however, they still appear relatively focal compared to early disease.

Standing robotic cone-beam computed tomography (CT) might be useful in defining difficult-to-see fractures. Use of quantitative CT to measure bone mineral density and three-dimensional morphologic changes in the metacarpus may provide improvements in identifying risk factors or imminence of fracture.

Treatment

There is no specific medical treatment for dorsal metacarpal disease, necessitating that horses be laid up or put on a convalescent exercise program to provide time for the early acute changes to subside. Many horses with acute bucked shins can continue to train after 5–10 days of rest and anti-inflammatory analgesics. Hand walking, ponying, cold water hosing, and bandaging should continue until the dorsal cortex can be palpated without eliciting pain. Speed and distance are introduced slowly, with constant monitoring of dorsal cortical pain. Initially, daily galloping distance is reduced to 50%. An overall modification of the training program with less galloping miles and more short-distance breezing may be necessary. The overall goal is to gradually increase the stress to the dorsal surface of the metacarpal bone at such a rate such that this surface can model according to compressive demands without producing structural damage.

Subacute and chronic dorsal metacarpal disease can be the most difficult to treat. After an exacerbation, many of these horses may not be suitable for the modified training regimen described above, and pain immediately returns with any sustained galloping. These horses may have marked periosteal new bone formation. More prolonged rest is usually necessary for bone remodeling of this new periosteal bone and remodeling of fatigued bone. The time required is usually 110 days.

Dorsal cortical fractures in young horses may resolve with the conservative approach outlined above for subacute or chronic bucked shins. Convalescent periods may extend from 4 to 6 months because fracture healing is slow at this site. In either case, serial radiographic studies should be performed at least every 30–45 days to assess the bone healing.

Several surgical procedures have been recommended for treatment of dorsal cortical metacarpal fractures, including placement of a unicortical screw in lag fashion, placement of a neutral unicortical positional screw, and dorsal cortical drilling or osteostixis (Figures 4.142B and 4.143). Transcortical screws are not recommended due to the expected differences in strain between the palmar and dorsal cortices, risk of fracture, and risk of damage to the suspensory ligament (SL). Placement of a dorsal unicortical screw in lag fashion can be technically

VetBooks.ir

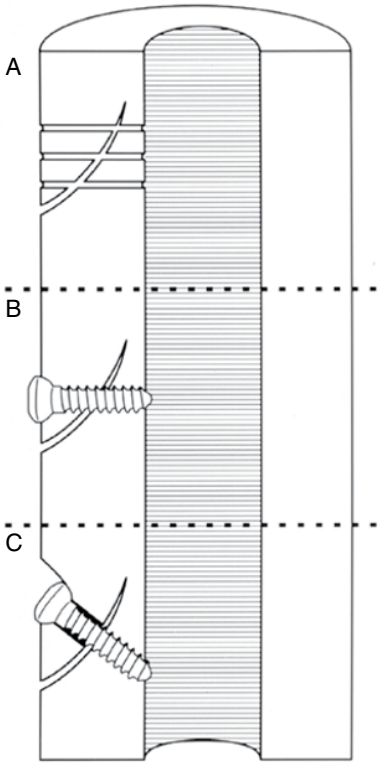

Figure 4.143. (A) Dorsal cortical drilling (osteostixis) of a dorsal metacarpal stress fracture. (B) Positional unicortical screw placement. (C) Unicortical screw placement in lag fashion.

difficult due to the short depth of the cortex (about 22 mm) and need for radiographic control, but provides the best fracture stability. Placement of a neutral dorsal unicortical screw to help stabilize the fracture, combined with dorsal cortical drilling, is often elected to provide added stability over dorsal cortical drilling alone. For screw fixation, cortical bone screws (4.5 or 3.5 mm) are used.

Many surgeons currently recommend removal of the screw after a sufficient time of healing (2 months). Many horses have and will race successfully with the dorsal cortical screw in place. However, reoccurrence of dorsal cortical pain may occur (regardless of the presence of a screw), and the screw will be presumed to be the cause. If any fracture occurs in this horse in the future, such as condylar fracture or complete metacarpal failure, the screw may be considered a cause. Screws can be easily placed and removed standing.[23,27,57,129] Many surgeons prefer standing fracture fixation to avoid risk of catastrophic fracture during recovery from general anesthesia. Fractures can be repaired standing with sedation and perineural anesthesia using radiographic guidance.

Postoperative management includes stall rest and bandaging for 2 weeks, followed by 6 weeks of stall rest with hand walking. Screw removal is usually performed at 8 weeks, followed by an additional 2 weeks of hand walking. Tack walking and light jogging can be introduced 2 weeks after screw removal; however, more intense race training should not commence until 4 months postoperatively. Greater than 95% of horses can return to racing in approximately 8 months.[27]

Osteostixis can be performed under general anesthesia or in the standing horse (Figure 4.142B). Holes (5–7) are made with a small drill bit (2.0–2.5 mm) in a diamond pattern through the dorsal cortex into the marrow cavity. This procedure can be combined with unicortical screw application. Success for return to racing is similar (greater than 80%) to that recently reported for screw fixation, and a quicker return to racing (4–6 months) has been reported.[57] Clustered drill holes act as a stress concentrator and significantly decrease the stress required for metacarpal failure in cadaver limbs, but catastrophic failure through the drill holes is not a reported complication of the procedure *in vivo*.[129,130]

Other adjunctive treatments have been recommended with or without surgical treatment, including electrical stimulation at the fracture, extracorporeal shockwave therapy, injection of osteogenic substances (sodium oleate), intralesional injection of steroids, thermocautery (pin firing), chemical vesication (blistering), needle drainage of the hematoma, and cryotherapy (point freezing). These treatments have met with varying degrees of success, and no controlled studies have been performed. In all cases, no matter what the treatment, an adequate period of rest combined with a controlled exercise program is required.

In one study of Thoroughbred racehorses, distinct training strategies were used at various stables, and the allocation of exercise to breezing (15 m/s), galloping (11 m/s), and jogging (5 m/s) was associated with lack of bucked shins for 1 year (survival of bucked shin syndrome). Survival was significantly reduced by allocation of exercise to breezing and increased by allocation to galloping. It was recommended that to reduce the incidence of bucked shins, trainers should allocate more training effort to regular short-distance breezing and less to long-distance galloping.[16]

Prognosis

The prognosis is good to excellent for return to racing with surgical treatment of dorsal cortical fractures; reports range from 80% to 98%. However, this underestimates the loss of racing days of horses with sore shins that remain in training and recurrence of pain or fracture once subacute or chronic disease occurs. The impact of this syndrome, particularly in 2-year-olds, is evidenced by the observation that if 2-year-old racing Thoroughbreds were not permitted to race for 6 weeks if sore shins are palpated prerace, significant improvements in predictable finishes occurred.[55] Adjustment of training regimens may assist with prevention, and training on grass, wood fiber, or softer surfaces without toe grabs is recommended.

Other Stress Fractures of the Third Metacarpal/ Metatarsal Bone

Although dorsal cortical stress fractures are by far the most common location of stress fracture in horses, particularly racehorses, other sites and variations within the metacarpus can occur. Dorsal cortical fractures may extend more proximal than the site of exit from the cortex, and fissure lines can sometimes be identified, most typically in the proximal metacarpus on other views. If a fracture line is noted on the craniocaudal view, a spiraling

VetBooks.ir

fracture or nondisplaced complete metacarpal fracture should be suspected. Fractures may be limited to the dorsal cortex and respond to lag screw fixation. Detailed radiographic investigation should be performed to define the fracture and determine whether confinement to an overhead wire, casting, or surgery and compression of the fracture with screws is recommended.[102,132,138] Similar fractures can occur in the metatarsus of the hindlimb.[102]

Unicortical fractures of the distal palmar/plantar condyle have been reported with increasing frequency due to more sensitive diagnostic imaging techniques; nuclear scintigraphy, the 125° dorsoproximal to dorsodistal view, CT, and magnetic resonance imaging (MRI) can be used for identification. Treatment can involve rest for 3–4 months or lag screw fixation across the palmar aspect of the condyles. Horses have a good prognosis for return to racing.[68,106]

Primarily in racing Standardbreds, longitudinal stress fractures or focal intense radioactive areas of uptake on nuclear scintigraphy can occur in the proximal palmar/plantar aspect of the third metacarpus/metatarsus and is a recognized syndrome. Physical findings are very subtle, but lameness can be blocked to the proximal metacarpus and scintigraphy is diagnostic. Most horses have abnormal radiographs, although high detail film and several projections may be needed to see the fracture. Rest resulted in a 64% return to the previous level of performance.[78,103] Internal screw fixation[118] and surgical drilling[145] also resulted in success. Dorsomedial articular fractures of the third metacarpal bone also can occur in racing Standardbreds. Lameness is abolished with intracarpal anesthesia. Periosteal new bone production can be seen on radiographs near the distal aspect of the fracture. All seven horses in one study healed and returned to soundness (one with internal fixation).[117]

FRACTURES OF THE CONDYLES OF THE THIRD METACARPAL/METATARSAL BONES (CONDYLAR FRACTURES, LONGITUDINAL ARTICULAR FRACTURES)

Fractures of the condyles of the third metacarpal and metatarsal bones occur most frequently in racing Thoroughbreds, less frequently in Standardbreds, and occasionally in Quarter horses and Polo ponies; they comprise a subset of catastrophic breakdowns on racetracks.[8,96,97] Fractures usually occur at high speeds. Males are overrepresented (59% in one study and 75% in another), and the distribution of fractures is approximately one-third incomplete nondisplaced, one-third complete nondisplaced, and one-third complete displaced (Figure 4.144).[147] Fractures affect the lateral condyle more commonly. Fractures in the lateral condyle usually propagate toward the lateral cortex, whereas fractures in the medial condyle tend to spiral proximally with the dorsal fracturing line moving medial or develop a transverse component in the mid-diaphysis causing a "Y" fracture configuration. For these reasons, medial condylar fractures should be considered to be at a higher risk for catastrophic failure and treated appropriately. In a study of 145 condylar fractures in mostly Thoroughbreds, forelimbs (81%) and lateral condyles (85%) were more frequently involved. The right and left forelimbs were approximately equally involved. Most fractures (59%) were initiated in the middle of the condyle and extended a mean of 75 mm proximally to exit the cortex. Axial fractures and medial condylar fractures tend to be longer. Articular comminution can occur, usually at the palmar/plantar articular margin, and was identified in 15% of fractures. The more axial fractures were more likely to have articular comminution (23%). Eight of 145 fractures evaluated spiraled proximally. Concurrent lesions included proximal phalanx eminence fractures, sesamoid fractures, and sesamoiditis.[147]

In another study of 233 condylar fractures, Thoroughbreds were overrepresented, and Standardbreds underrepresented based on the hospital population. Standardbreds had more metatarsal condylar fractures. Medial metatarsal condylar fractures had a 25% chance of suffering a mid-diaphyseal fracture ("Y" fracture). In this study, the distribution of Thoroughbred condylar fractures was 66% forelimb, with approximately 50% complete. Seventy-nine percent of Thoroughbreds with incomplete lateral condylar fractures (77% treated surgically) returned to racing, whereas a significantly lower percentage (33%) of complete lateral condylar fractures returned to racing (all treated surgically). Eighty percent

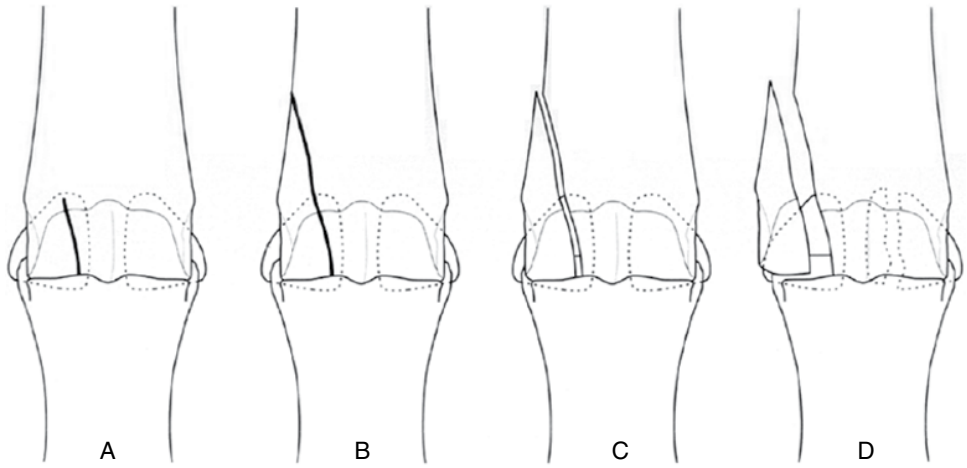

Figure 4.144. Condylar fractures. (A) Incomplete. (B) Complete nondisplaced. (C) Complete separated. (D) Complete displaced.

VetBooks.ir

of Standardbreds (6 of 7 treated surgically) raced after treatment. In summary, return to racing in Thoroughbreds was significantly reduced with complete fractures, forelimb fractures, evidence of sesamoid fracture, or female sex (presumed retired for breeding).[8] Complete condylar fractures tend to be longer (mean 85 mm) than incomplete fractures (mean 57 mm).[112] Axial sesamoid fractures are associated with displaced lateral condylar fractures that disrupt the collateral ligament and avulse the intersesamoidean ligament complex.[6]

Another report of 124 condylar fractures in Thoroughbreds corroborates the above findings of the more recent reports. It was noted that 90% of condylar fractures occurred in 2- and 3-year-olds and that most were acquired during training between April and October. In this report, 17% of displaced lateral condylar fractures returned to racing.[45] The variation in successful return to racing of displaced condylar fractures may be related to the duration of fracture prior to surgery. Destruction of the articular surface occurs quickly following a displaced fracture; therefore, immediate immobilization and repair are critical to a successful outcome.[111]

Condylar fractures of the hindlimb are more common in Standardbreds and are more likely to be medial and to not exit the cortex. These fractures can propagate proximally or progress to a complete "Y" fracture, even with stall confinement.[110,111]

Etiology

The etiology includes trauma from high compressive loads, asynchronous longitudinal rotation of the cannon bone, and exercise on uneven surfaces. The risk of fatal condylar fracture in Thoroughbred racehorses is 7 times and 17 times more likely if horses are shod with low or regular toe grabs, respectively.[66] The toe grab changes the hoof angle and presumably places more stress on the suspensory apparatus and plants the foot more securely. This likely alters the compressive and rotatory forces on the distal metacarpus.

Recent structural studies of the distal condyle of unexercised and exercised horses have demonstrated that the normal mineralized articular cartilage tends to cleave in the sagittal plane and that the main subchondral bone trabeculae are arranged in columns and run in the sagittal direction with fewer mediolateral connections. Blood vessel canals lie inside these sagittally oriented structures. The sagittal column orientation provides maximum strength and protection in the sagittal plane in which the joint rotates but offers minimal resistance to fracture propagation in this plane. The anatomical course of condylar fractures of the third metacarpal bone can be explained by the anisotropic structural arrangement of the mineralized tissues.[18] In horses in race training, densification (sclerosis) of the subchondral bone of the palmar/plantar surface of the condyles was identified by CT techniques,[114] and this correlated with linear defects in the mineralized cartilage and subchondral bone in the same region with intense surrounding bone remodeling.[115] Microcracks in the subchondral bone of the metacarpus may coalesce and represent a preexisting pathology in horses with catastrophic fracture.[87,97]

In a histopathologic study on North American racehorses, similar palmar condylar cartilage fibrillation with underlying bone sclerosis and areas of bone necrosis were noted. Evidence of active bone remodeling was present around the sclerotic zones with osteocyte necrosis apparent as prominence of subchondral vessels and osteoclastic activity. Fragmentation lines indicating matrix fragility and microfractures were apparent. This area of the condyle was grossly flattened.[92] Similar microdamage including microfractures in regions of osteoporosis and thinning of the zone of calcified cartilage was seen histologically in the bone of lateral condylar fractures obtained from fatal injuries.[134] In an experimental study with controlled training exercise, bone density, particularly in this palmar condyle region, was significantly greater in horses with high intensity exercise.[113] In summary, the palmar condyle is the site of maximum loading in racing, and the bone responds by increasing density (sclerosis). Bone fatigue failure occurs and, due to the normal columnar arrangement of the bone trabeculae, propagates acute failure in the configuration seen in condylar fractures (Figure 4.145).

Clinical Signs

The clinical signs may vary from a mild lameness that is exacerbated by exercise with little heat or swelling present with nondisplaced, incomplete fractures to severe lameness with heat, pain, and swelling in the acute, displaced fracture. The incomplete, nondisplaced fractures are often so subtle that they are missed on physical examination, but may be detected by radiographs, nuclear scintigraphy, or CT. However, fetlock joint effusion is usually present because fractures originate at the articular surface. This is best seen in the palmar or plantar recess of the fetlock joint capsule. The external swelling of the lateral side of the large metacarpal or metatarsal bone depends on the degree of separation of the proximal end of the fragment and is readily palpated in displaced fractures. More swelling is observed with greater separation of the fracture fragment. The degree of pain associated with the palpation and the amount of heat that is felt depends on the acuteness of the fracture. Fracture movement and crepitation also may be detected.

Increased lameness can be observed in a horse after it has been exercised and when the horse is circled to the affected side. Flexion and rotation of the fetlock usually result in sufficient pain to cause withdrawal of the limb. In the acute, displaced fracture, crepitation may be felt with rotation of the fetlock. Increased lameness can be observed when flexion tests are used in cases in which there is a fissure fracture. Preferably, if a fracture is suspected based on history, clinical signs, and joint effusion, radiographs should be immediately taken without further lameness examination or joint manipulations to decrease the risk of propagating the fracture or worsening the articular cartilage injury.

Diagnosis

It is advisable to take radiographs if a condylar fracture is suspected. Perineural and intrasynovial anesthesia should be considered only after it is confirmed that a

VetBooks.ir

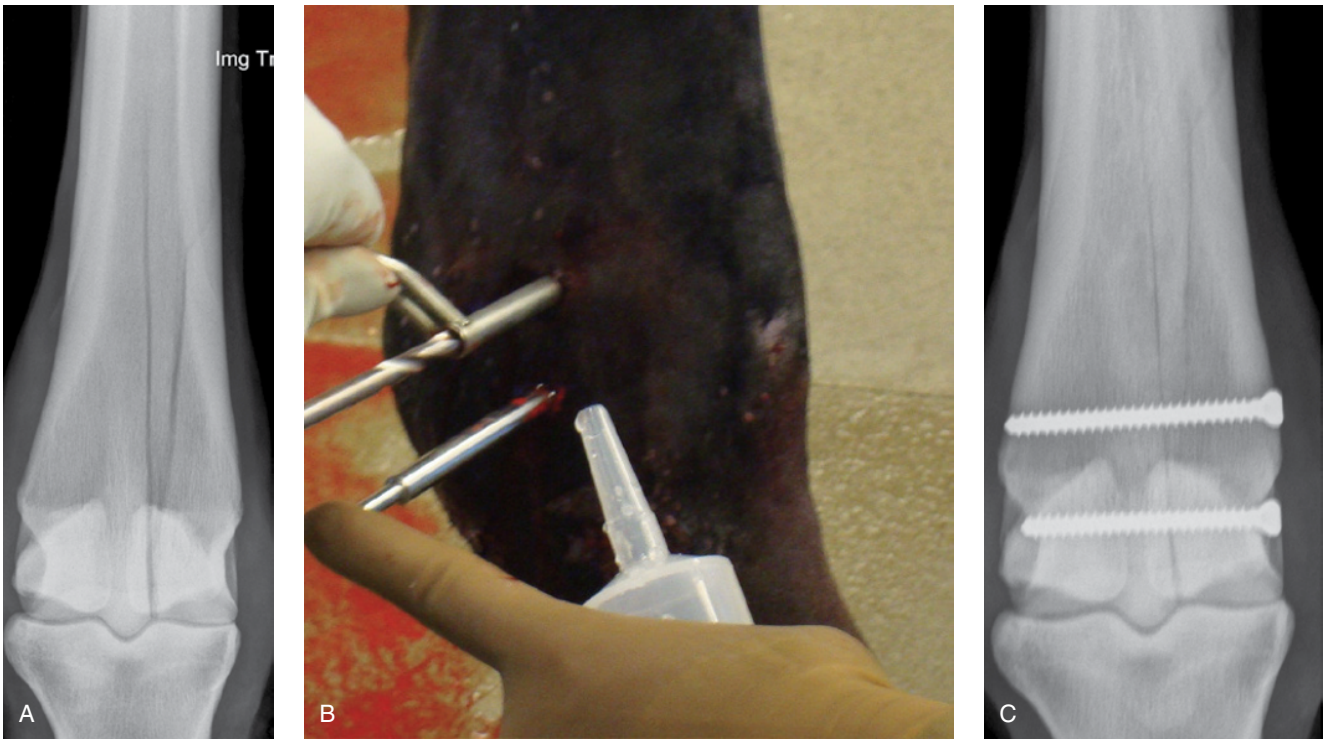

Figure 4.145. Radiograph of a spiraling medial condylar fracture in a racing Standardbred (A) repaired standing (B) with two parallel 5.5-mm cortical bone screws. At 4 weeks postoperatively, the compression at the screws is apparent and bone healing is progressing (C).

fracture is not present. A small percentage of these fissure fractures are difficult to identify radiographically, so it is important to closely scrutinize the radiographs.

Diagnosis is made with a standard series radiographic examination (DP, LM, DLPMO, and DMPLO). Additionally, a flexed DP view should be obtained to highlight the palmar/plantar surface of the condyles and evaluate the fracture line for comminution. Long cassettes are recommended so that the fetlock joint as well as the proximal cannon bone can be included in the study (Figure 4.145). Close evaluations of the study should follow to rule out the possibility of other injuries. Lesions that have been associated with condylar fractures include osteochondral fractures of the proximal phalanx (P1), fractures of the proximal sesamoid bone, osteoarthritis (OA) of the fetlock, palmar and plantar osteochondral lesions of the distal third metacarpal or metatarsal bone, SL desmitis,[73] and longitudinal fractures of the metatarsus. These associated lesions may be significant regarding the recommendation of treatment and the prognosis. Standing robotic cone-beam CT and nuclear scintigraphy can also be used to locate bone damage prior to fracture or to identify a fracture that is difficult to detect radiographically.

Treatment

The recommended treatment of most condylar fractures is internal fixation with transcortical screws placed in lag fashion for return to full athletic performance and health of the fetlock joint (Figures 4.145 and 4.146).[126] Incomplete, nondisplaced fractures can be treated conservatively with successful return to racing, and surgery is not always required. The advantages of screw fixation include the original fracture that will not become further displaced, shorter convalescence, a reduced incidence of refracture at the same site, and decreased risk of posttraumatic OA within the fetlock.

Horses with incomplete fractures that are treated with cast or support bandages should be confined to box stalls and observed closely for 2–3 weeks for any signs of increased pain and possible displacement. Bandages should be reset at least every other day for limb inspection. For conservative management of nondisplaced fractures, stall rest for 2 months followed by 30 days of hand walking and then 30 days of light turnout is recommended. Fractures in young horses can heal by 90 days, but the most articular edge of the fracture often requires additional time. Horses put in training at 90 days are at risk of articular osteolysis upon return to training.

Internal fixation should be used in all complete condylar fractures (nondisplaced and displaced) in horses intended for athletic performance (Figures 4.145 and 4.146). Immediate diagnosis and immobilization of the limb are critical preoperatively to enhance success. Surgery should be performed quickly but need not be performed on an emergency basis. The horse can be safely transported and permitted to recover from the incident if the limb is immobilized in a cast or complete commercial splint.

For surgery, the horse is positioned in lateral recumbency under general anesthesia with the affected limb up. Lag screws can be placed through stab incisions in the skin. The location and spacing of the screws can be preplanned by measurements made on the radiographs or preferably by using intraoperative fluoroscopic imaging. Regardless, the first screw is always placed in

VetBooks.ir

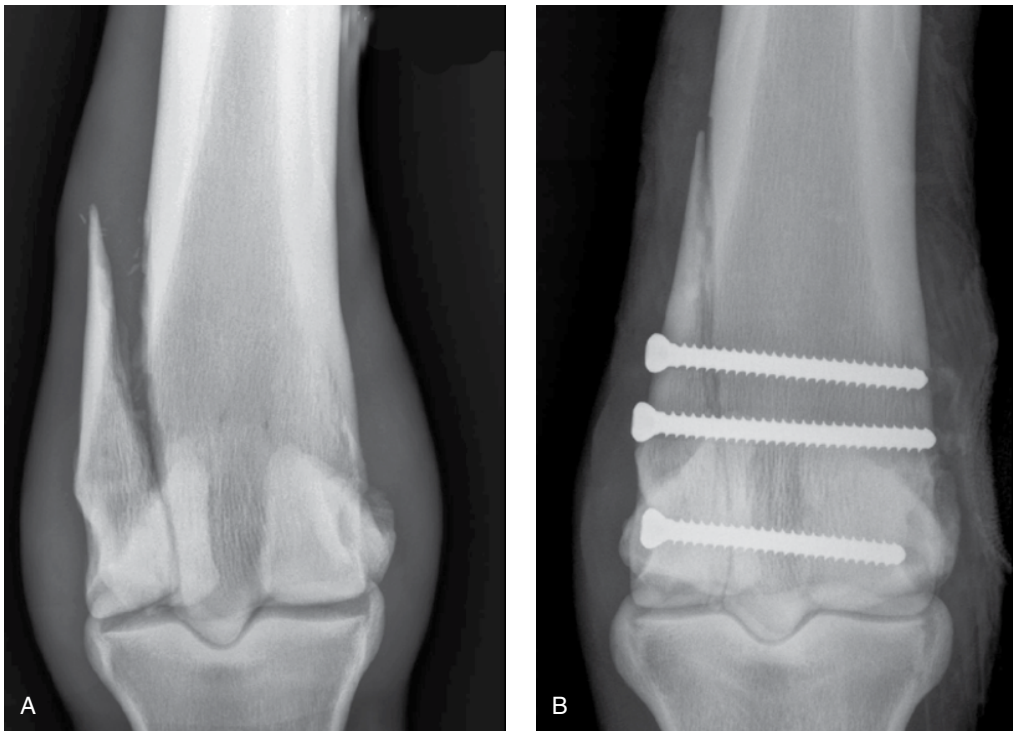

Figure 4.146. Craniocaudal radiograph of a displaced lateral condylar fracture in a racing Thoroughbred (A) repaired with three 5.5-mm cortical bone screws (B).

the supracondylar fossa, and subsequent screws are placed approximately 20 mm proximal to the first one. Most lateral condylar fractures can be repaired with two screws. Ideal screw placement is parallel to the joint with the first screw in the supracondylar fossa, engagement of both cortices without depositing bone material in the opposing collateral ligament, and compression of the fracture so the fracture line is eliminated or barely identifiable on the immediate postoperative radiograph. Increased duration and displacement of the fracture reduce the success in obtaining the latter result. Fractures are usually repaired with 4.5- or 5.5-mm cortical bone screws, although some success using headless titanium compression screws has been reported.[47,105] CT should be performed prior to starting the surgery to understand the fracture propagation if there is any question about the presence of a spiraling component to the fracture. This may affect the decision to use a bone plate in addition to screws and screw placement.

Displaced fractures can be compressed with Association for the Study of Internal Fixation (ASIF) bone clamps prior to drilling to stabilize the fracture and initiate compression or can be held in reduction by a Steinmann pin placed in the glide hole. Reduction of displaced condylar fractures can be a challenge, particularly in the cranial to caudal direction that may not be apparent on craniocaudal radiographs taken at surgery. Arthroscopic evaluation of the articular alignment should be used in all displaced fractures. Arthroscopic inspection of the dorsal articular surface often reveals a 1- to 2-mm step in the cranial direction of the fractured component. Arthroscopy also allows debridement of other bone fragments such as P1 eminence fractures or comminution of the palmar fracture line. Articular damage also can be assessed, which may affect prognosis in displaced fractures, particularly those of more chronic duration (days to weeks).

In displaced fractures, an open incision extending the full length of the fracture, use of multiple bone clamps, and initial focus on the reduction of the most proximal portion of the fracture may help maximize reduction. Screws (4.5- or 5.5-mm cortical bone screws) are tightened distal to proximal and retightened to maximize compression.

Medial condylar fractures, especially in the hindlimbs, are at risk of catastrophic failure if they propagate proximally and either spiral or develop a Y component middiaphysis.[3] Lateral condylar fractures can uncommonly spiral proximally. These fractures can be treated with multiple screws placed in lag fashion,[119,126,144] although plating techniques are likely the most reliable fixation method.[53] Locking compression plates (LCPs) can be applied using a minimally invasive approach to reduce incisional complications. Lag screw fixation can be performed with the horse standing to reduce the risk of catastrophic breakdown on recovery from anesthesia (Figure 4.145).

Casting is usually not performed for recovery. A full-limb cast has been recommended for long spiraled fracture repairs, but not all surgeons use this because there is a risk of complications in recovery.[110] Horses are usually comfortable on the limb immediately after repair and walk in the stall without gait deficit when on low doses of phenylbutazone. Continued lameness postoperatively is a red flag for problems and radiographs should be obtained.

VetBooks.ir

Postoperative exercise should be limited for at least 3 months. Stall rest confinement is recommended for this period, and after 2 months hand-walking exercise can begin. Follow-up radiographs should be taken 3 months postoperatively, and if the healing is progressing normally, the horse can be turned out into a small paddock for an additional month. The training schedule depends on the type of fracture but could begin as early as 4 months or as late as 6 months. In one study horses were more likely to race if the fracture line could no longer be identified at the 2- to 4-month radiographs.[146]

Screws are generally not removed after healing has occurred unless residual lameness results that can be directly attributed to their presence. In a review of 233 cases of condylar fractures, most repaired by interfragmentary compression, screws were only removed in 20 of the cases, and there appeared to be no consistent difference in the performance between this group and the group with screws in place.[8] This study noted that horses with screws placed closer to the joint had a lower return to racing. Subchondral sclerosis was proposed as a cause for this pain. In general, removal of screws is not routinely performed for condylar fractures except if screws are placed in the diaphysis such as in medial condylar fractures of the metatarsus or spiraling fractures. Screw removal is easily performed under general anesthesia; the location of the screws can be confirmed with marker needles and radiographs. In most cases the screws can be removed through small stab incisions alone. Bone plates are always removed in horses intended for athletic pursuits following surgery. Standing plate removal can usually be performed 3 months following surgery, provided the fracture has healed well. Stall rest for an additional 30 days is required after plate or screw removal, followed by stall rest with hand walking for an additional 30 days.

Prognosis

The general prognosis for athletic performance and returning to racing is excellent for nondisplaced incomplete fractures, whether treated conservatively (82% and 87% in two reports)[8,146] or following internal fixation (74% and 79% in two reports) for forelimb fractures,[8,146] and 93% for metatarsal fractures in one report.[8] Prognosis for athletic performance and return to racing is fair for complete displaced and nondisplaced fractures following internal fixation (58% in one report).[146] In two other reports, 33% of complete fractures (displaced and nondisplaced)[8] and 19% of displaced fractures[45] returned to racing. Rapid immobilization and repair of displaced fractures probably can dramatically affect outcome. In cases of complete displaced fractures or when there has been a delay in diagnosis and treatment and/or improper immobilization has been selected, a guarded to poor prognosis can be expected.[112] Only 12 of 38 cases in one report were able to return to racing.[112] This prognosis is altered because of increased damage to the articular surface that is likely to result in OA of the fetlock. The prognosis for return to racing is considered poor for comminuted fractures or subchondral bone lesions in the palmar or plantar surface of the distal end of the cannon bone.[112]

FRACTURES OF THE THIRD METACARPAL/METATARSAL (CANNON) BONE

Fractures of the third metacarpal/metatarsal (cannon) bone occur commonly in all ages, but more commonly in young horses, and all breeds of horses. The metacarpus/metatarsus is particularly susceptible to fracture because of the distal location and because little soft tissue covers the bone to help absorb impact energy in blunt trauma.[120]

Although fractures of the cannon bone can assume a variety of configurations, ranging from a simple fissure to severe comminution, younger horses seem to sustain simpler fractures than adults, possibly because of more elastic and less brittle and shatter-prone bone. Frequently, distal fractures that involve the growth plate, or rarely persistent proximal physes, in young animals are Salter type II fractures (Figure 10.7).[79] Because of the minimal soft tissue covering, the fractures are commonly open or become open soon after the injury occurs. More than half of referred metacarpal/metatarsal fractures are open.[84] Concurrent fractures of the small metacarpal bones are common. Stress fractures of the metacarpus and metatarsus in racehorses that can progress to acute and complete failure of the bone are discussed earlier in this chapter. Once catastrophic failure occurs, fractures are treated as discussed below.

Etiology

External trauma in any form can cause fracture of the cannon bone, e.g. kicks and falls. When foals are affected, the dam has often stepped on the limb, causing a fracture. Propagation of stress fractures or propagation of forces through screw or transfixation pin holes can result in similar complete cannon bone failure.

Clinical Signs and Diagnosis

Complete yet nondisplaced fractures of the cannon bone secondary to direct trauma can occur and may be difficult to initially diagnose (Figure 4.147). The lameness may be nonspecific and variable. Heat, swelling of the soft tissues overlying the fracture, and pain on deep digital palpation are usually present. A wound at the site of impact is also often present. Diagnosis may be delayed if soft tissue injury is evident because the lameness may be attributed to this cause. As lameness persists or worsens, radiographs are often taken and may reveal fracture lines. If the horse is turned out, invariably complete bone failure occurs. If stall confinement is maintained, the diagnosis is often made at the second radiograph when periosteal reaction is noted at sites of cortical exit and bone resorption of the fracture line widens the fractures.

In complete bone failure, the diagnosis of fracture of the cannon bone is obvious (Figure 4.148). In all cases, these fractures should be immediately supported and then radiographed to identify the type (simple vs. comminuted) and location in relation to joint surfaces. The limb should not be manipulated excessively during the physical exam because this may lead to penetration of bone fragments through the skin. If treatment is to be considered or further diagnosis is to be obtained, a cast

VetBooks.ir

or PVC full-limb splint should be immediately secured to the limb without moving the horse.[13]

Treatment

The selection of treatment of cannon bone fractures depends on the type of fracture (open vs. closed, simple vs. comminuted), location of the fracture (articular vs. nonarticular, proximal vs. distal), animal's age and intended use, presence of wounds, vascular compromise, and economics.

The preferred treatment for most cannon bone fractures is internal fixation with one or two DCPs (Figures 4.148 and 4.149) or LCPs. LCPs are ideal for minimally invasive plate fixation extending the length of the bone.[64] Individual lag screw fixation can also be combined with plates where appropriate. Metacarpophalangeal arthrodesis may be necessary in fractures with distal comminution.[19] Severe fractures may heal with transfixation pins and external fixators or casts. These methods are more successful in foals with rapid healing and low body weight. In adult horses, these severe fractures have a guarded prognosis, but use of external coaptation, plating in the face of open wounds and vascular compromise, or sequential procedures have been successful in rare instances.[14,64,76]

Stall rest should be anticipated for 4 months in foals and 6 months in adults, although hand walking can begin as soon as fracture callus bridges the fracture and other complications of implant failure have not occurred or have arrested. In general, horses that are to be used in athletic competition should have their plates removed in stages, 2–3 months apart. After plate removal, stall rest is continued for an additional 2 months and then exercise is slowly initiated.

Prognosis

The prognosis for successful treatment of third metacarpal and metatarsal bone fractures depends on multiple factors. In general, transverse, slightly oblique, and slightly comminuted fractures in the mid-cannon bone region in foals under 7 months of age have a good to excellent prognosis with internal fixation. Older horses with similar fractures have a more guarded prognosis due to their size and the risk of supporting limb laminitis, but in general have a fair to good prognosis. Older horses with open, comminuted, or articular fractures have a guarded to poor prognosis for recovery. Unfortunately, older horses have a greater risk of comminuted open fractures that involve the nutrient foramen.[84]

METACARPAL/METATARSAL EXOSTOSIS (SPLINTS)

Exostoses of the second and fourth metacarpal/metatarsal bones, or "splints," are a condition most commonly diagnosed in young, immature horses but can be seen in older horses. The condition is thought to be associated with direct trauma causing subperiosteal hemorrhage and periosteal bone proliferation or instability between the second and fourth metacarpal/metatarsal (MC/MT) bones and the third MC/MT bone (Figure 4.150). Inflammation or tearing of the interosseous ligament can occur during training, especially in musculoskeletally immature horses. Splints are most commonly seen in the proximal half of the bones and metacarpal II is most commonly affected. Conformation abnormalities such as offset carpi, improper hoof care, and mineral imbalances may exacerbate the condition.[108]

The second and fourth MC/MT bones are commonly called splint bones. Each is attached intimately to the respective third MC/MT bone by an interosseous ligament. The splint bones articulate with the carpometacarpal joint or tarsometatarsal joint and are exposed to loads on weight-bearing. The interosseous ligament consists of dense fibrous tissue that can tear with the strains applied during independent motion of the splint bones and the cannon bone. Initially, inflammatory periostitis and desmitis develop. Subsequently, new periosteal bone is produced, creating the characteristic profile of a splint (Figure 4.150).

The terminology used to identify the condition is variable. A true splint refers to a sprain or tear of the interosseous ligament. Blind splint refers to an inflammatory process of the interosseous ligament that is difficult to detect on physical examination because the swelling occurs on the axial (inner) side of the splint, between the small metacarpal bone and the SL. Osteolysis between the second and third metacarpal bones may be observed on radiographic examination. Periostitis of the splint bones results from superficial trauma to the periosteum, which, in turn, causes a proliferative periostitis. Although a residual blemish remains, the horse is usually not lame. A knee splint is the enlargement of the proximal portion of the splint bone that may lead to OA within the carpometacarpal joint.

VetBooks.ir

(B) Postoperative view demonstrating fracture repair with two broad dynamic compression plates on the dorsolateral and dorsomedial sides of the metatarsus. Additional screws were placed in lag fashion from outside the plates to secure the butterfly fragments.

Etiology

The enlargement of the splint bones associated with this disease results from proliferation of fibrous tissue and osteoperiostitis. The causes are tearing of the interosseous ligament that binds a small metacarpal bone to the large metacarpal/metatarsal bone, external trauma, and healing of a transverse or longitudinal fracture. If the inflammation associated with the periosteum is sufficient, over time it will result in ossification (proliferative exostosis) of the splint bone. The size of the splint usually depends on the degree of inflammation and the surface area involved. In any case, the splint usually assumes an elongated form, lying parallel to the small metacarpal bone.

The second metacarpal bone is more frequently involved because of the difference in its articulation with the carpus. The second metacarpal bone is entirely articular, and its articulation is flatter than that of the fourth metacarpal bone. *Ex vivo* biomechanical evaluation of the second metacarpal bone has shown that it plays a significant role in torsional stability of the carpus.[121] It is proposed that excessive loading can lead to tearing of the interosseous ligament in the region that is most frequently affected. Metacarpal fusion progresses normally with aging, and 78% of all horses 2 years old and older had two or more sites of fusion. The rate of metacarpal fusion/horse/year appeared to be at least 10 times higher than the rate of painful exostoses causing fusion, indicating that this process occurs subclinically in most horses.[75]

Imbalanced nutrition or overnutrition in young horses has also been implicated in the development of splints.[108] Imbalances and deficiencies in calcium and phosphorus have been associated with an increased incidence of splints. However, no well-documented studies have proven this to be true. In many cases horses that are suspected of having a calcium and phosphorus imbalance also grow rapidly. It may be that their increased weight causes sufficient compressive forces so that splints develop as a result of this, rather than the imbalance. In general, young horses that are poorly conformed, overweight, and overexercised have a greater chance of tearing the interosseous ligament before metacarpal fusion is complete.

Clinical Signs

The condition is most common in young horses undergoing heavy training, but cases occasionally occur in older, mature horses. Heat, pain, and swelling

VetBooks.ir

over the affected region are usually present in active splints. Splints most commonly occur about 3 inches below the carpal joint (Figure 4.150). One large swelling or a number of smaller enlargements may occur along the length of the splint bone at its junction with the third MC/MT bone. Horses have variable lameness but generally worsen with work and seem to be worse on hard ground. In mild cases no lameness may be evident at the walk, but lameness is exhibited during the trot. Palpation of the axial aspect of the splint is useful to determine if there is obvious impingement of the SL.

New bone growth that occurs near the carpal joint may cause carpal OA (knee splints). Extensive new bone formation on a splint bone may also encroach on the SL and cause chronic lameness unless it is removed. Growths of this kind can be determined by palpation, radiographs, and ultrasound examination. After the original inflammation subsides, the enlargements usually become smaller but firmer as a result of the ossification. The reduction in swelling is usually the result of resolution of fibrous tissue, rather than a decrease in size of the actual bone formation. In the early stages, the greatest bulk of the swelling is from inflammation, and this normally resolves to a much smaller size. Some cases of splints may not cause lameness.

Diagnosis

The obvious signs lead to a diagnosis when the affected limb is examined carefully. Heat, pain, and swelling over the regions mentioned, plus lameness, are enough to make the diagnosis. Diagnostic analgesia may be required to prove that the splint is a true cause of lameness. The diagnosis should be confirmed with a radiograph (Figure 4.151) as fractures of the splint bone can be confused with splints. Ultrasonographic examination can demonstrate concomitant injury to the suspensory and possible ligament impingement. In some cases, nuclear scintigraphy may be needed to confirm a blind splint. New bone growth resulting from trauma may occur on the third metacarpal or third metatarsal bones, close to the splint bone, and may be mistaken for splints. Palpation and radiographs, however, show that these swellings are dorsal to the junction with the splint bones. This type of new bone growth is most often caused by interference.

VetBooks.ir

Treatment

Treatment for splints includes anti-inflammatory agents and rest for the acute phase and occasionally surgery in the more chronic stages. Counterirritation is still practiced for the chronic phases but is of unknown significance. Other treatments include extracorporeal shockwave therapy, icing, topical diclofenac liposomal cream (Surpass), acupuncture, and massage.

Inflammation and swelling are the hallmark of this disease in the acute phase. The administration of nonsteroidal anti-inflammatory drugs (NSAIDs) coupled with the application of hypothermia and pressure/support wraps appears to be most beneficial to decrease the heat, pain, and swelling. Hypothermia can be attained with ice or ice/water packs or whirlpool boots. They should be applied for 30 minutes, 2–3 times a day for at least 2–3 days. Some recommend hand massage for 10 minutes after each treatment, after which a support bandage is applied. Affected horses should be confined to a stall for at least 30–45 days, and hand-walking exercise for 15–20 minutes twice a day should be begun after the acute inflammation subsides.[108]

Figure 4.150. Visible enlargement of the medial splint area just distal to the carpus typical of horses with "splints." *Source*: Courtesy of Dr. Gary Baxter.

Intralesional corticosteroid can reduce inflammation and may help prevent excessive bone growth. Corticosteroid therapy should be accompanied by counterpressure bandage. In this case the horse is generally rested longer than 30 days and should not resume training as rapidly as when counterirritation is used. However, the swelling may be considerably less. It is also true that splints will heal without therapy, provided adequate rest is given.[108] If the splint results from interference, splint or shin boots (guards) may help prevent further trauma. If the horse interferes because of improper trimming and shoeing, this should be corrected.

If the proliferative bone is excessive, surgery may be indicated in a very small percentage of the cases (Figure 4.151). Surgery to remove exostoses for medical or cosmetic reasons has resulted in fair to good success. In one study, 15 exostoses removed for cosmetics or lameness resulted in minimal recurrence of the bone proliferation.[5] In a larger study of 95 Standardbreds, the splint bones were amputated to remove excessive bone callus. In horses with proximal splint bone removal in which the proximal portion was stabilized with screws or bone plates, horses were still limited in performance at 12 weeks. Horses in which a subperiosteal removal of the exostosis was performed were sound 12 weeks postoperatively.[141] It is recommended to retain the splint bone lever arm by reflecting the periosteum to prevent

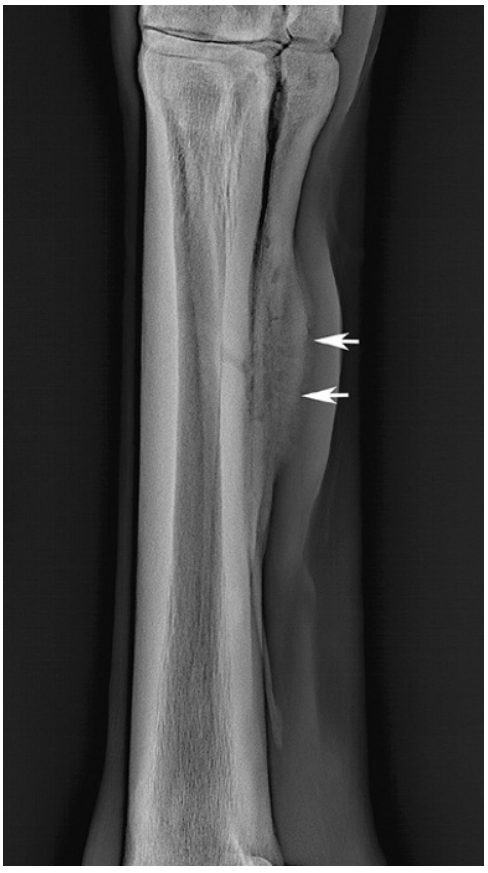

Figure 4.151. This large exostosis of the medial splint (arrows) was contributing to lameness and was removed surgically. Just the exostosis was removed and the underlying splint bone was left intact.

VetBooks.ir

formation of excessive new bone and associated irritation of the SL. In some cases, it is necessary to surgically remove a bony exostosis that interferes with the action of the SL or the carpal joint or one that is so large that the opposite foot hits it repeatedly. These require care in dissection of the proximal structures, including ligaments of the palmar carpal support. If the bone growth has been caused by trauma from interference, the surgery will not be successful unless corrective shoeing or use of splint boots will stop the interference.

Prognosis

Prognosis is good to excellent for soundness except for those in which the exostosis is large and encroaches on the SL or the carpal joint. Chronic recurring lameness can occur in horses that are not rested long enough, which can be 5–6 months. Surgery to remove the excess bone callus can successfully alleviate lameness, and recurrence does not occur in most cases. Surgery may speed up the return to athletic soundness and improve the cosmetic blemish.

FRACTURES OF THE SMALL METACARPAL AND METATARSAL (SPLINT) BONES

Fractures of the small metacarpal and metatarsal bones (splint bones) can occur anywhere along their length, but they are most commonly located at the distal third.[3,17,31,32,35,136] In most cases fractures located at the distal third are simple fractures (Figure 4.152), in contrast to fractures of the middle and proximal portion, which are often complicated by comminution, osteomyelitis, and bone sequestration (Figure 4.153).[10,31,58,101]

Fractures of the distal part of a small metacarpal or metatarsal bone usually occur in older horses (5–7 years of age) and only rarely occur in horses under 2 years of age.[17] This is thought to occur as a result of decreased pliability in the interosseous ligament and more strenuous training programs in older horses.[17] In contrast, younger horses tend to sustain damage to the interosseous ligament supporting the small metacarpal bones, resulting in the condition referred to as splints. The forelimbs are more frequently involved than the hindlimbs; the fourth metacarpal bone in the left forelimb is affected more commonly than the hindlimb.[17,136] The relationship between SL desmitis, sesamoiditis, and fetlock OA is more than casual. It appears that the enlarged fibrotic SL decreases the absorptive capacity of the fetlock and creates a space-occupying mass that may lead to fracture of the small metacarpal/metatarsal bones followed by further displacement of the fracture fragment.

Fractures of the proximal half of the small metacarpal or metatarsal bone are often comminuted. Open fractures can often be complicated by osteomyelitis with or without sequestrum formation. Fractures of the proximal lateral splint bones are usually a result of direct trauma (Figure 4.153).[10,58,101]

Figure 4.152. Fractures of the distal splint bones such as this rarely heal and are usually removed.

Figure 4.153. Proximal fractures of the fourth metatarsal bone are often comminuted and open and are due to traumatic injuries. *Source*: Courtesy of Dr. Gary Baxter.

VetBooks.ir

Etiology

Fractures of the distal part of the small metacarpal or metatarsal bone result from external and internal trauma. External trauma can result from a kick from another horse, interference, direct blows from hitting another object, or traumatic wounds. Internal trauma occurs from increased axial compression forces on these bones during races or from pressure from the SL or increased tension from the fascial attachments. It is conjectured that the increased incidence of left fourth metacarpal bone and right second metacarpal bone fractures observed in Thoroughbreds may be the result of increased weight-bearing on the bones when they are racing in a counterclockwise direction. In contrast, the SL and supporting fascia may put these bones under tension sufficient to cause fracture in the hindlimbs.[3,17,31,32,35,136] Because there is an increase in incidence of left second metatarsal bone and right fourth metatarsal bone, which is the tension side of the hindlimb in horses that run counterclockwise, it is logical to assume that tension created by the bowstring effect of the SL or increased tension developed by the internal fascia may lead to fracture.

It is difficult to decide whether the incidence of SL desmitis is a result of distal splint bone fractures that may cause irritation to this structure, or, conversely, that the swollen SL becomes space occupying enough to cause these fractures. Whatever the case, a higher incidence of SL desmitis is noted in the forelimb in association with distal splint bone fractures.[3,17,31,32,35,136]

More complicated fractures of the proximal part of the small metacarpal or metatarsal bones result from direct trauma, either from interference or direct blows to the surface. These fractures are often open initially, which frequently results in osteomyelitis or septic arthritis of the carpometacarpal or tarsometatarsal joint. In some cases there is not a break in the skin initially, but the comminuted fractures become sequestered and result in recurrent draining tracts. Fractures of the second metacarpal bone of racehorses also have been associated with excessive torsional forces that may occur in the starting gate.

Clinical Signs

On visual observation, swelling is usually a prominent feature of proximal splint fractures, but it may or may not be present with distal splint fractures. In general, the degree of swelling associated with the distal splint fracture depends on the acuteness of the fracture. The more acute the fracture, the more the swelling. Associated swelling in the SL may also be observed.

In the acute case, in both instances, horses frequently point their foot. Trotting exercises may or may not cause lameness, but this is totally dependent on the acuteness and type of fracture that has resulted. Circling or fast work may be required to cause sufficient lameness to be observed.

On palpation, heat, pain, and swelling are obvious features of acute fractures, and in some cases draining tracts are also present. The pain and heat decrease with time. However, because callus formation is a frequent sequela to the nonsurgically treated fracture, the fracture site will become enlarged over time (Figure 4.154).

Figure 4.154. This lateral radiograph was taken 3 months after occurrence of a fourth metatarsal fracture. A large callus had developed and there is minimal bridging of the fracture line. *Source*: Courtesy of Dr. Gary Baxter.

In cases in which only mild pain is evidenced with palpation, yet the horse is quite lame, the limiting features of this horse resuming performance may be associated with SL desmitis.[3,17,31,32,35,136] To gain a full appreciation of the involvement of the small metacarpal or metatarsal bone, the limb is flexed so the full extent of this bone can be palpated. A thorough physical examination of the SL should follow.

Diagnosis

A persistent swelling over the affected splint bone, exhibiting heat and pain when pressure is applied, should lead one to suspect a fractured splint bone. Some fractured splint bones closely resemble the disease called splints. Some such fractures heal, but the bony swelling is confused with "splints." Radiographs are necessary for a positive diagnosis of a fractured splint bone and to differentiate between a fracture of the splint bone and splints or soft tissue injury. Direct infiltration of local anesthesia of the fractured small metacarpal or metatarsal bone may be used in cases in which a concomitant SL

VetBooks.ir

desmitis is present. This helps to define the contribution of the fractured splint to the lameness. This is particularly important in cases in which minimal pain is elicited on deep palpation of the bone, but the horse is quite lame.

Radiographs should be taken in all cases to identify the fracture, its limits, and whether sequestration and osteomyelitis exist in association with a complicated fracture. The proximal fractures may extend toward or into the carpometacarpal or tarsometatarsal joint (Figure 4.155).

Treatment

Small Distal Fractures

Small distal fractures of the splint bones are traditionally treated by removing the distal fragment, but this approach is not universally recommended.[35,136] Up to two-thirds of the length of the splint can be removed without untoward sequelae; however, distal splint fractures can heal spontaneously and are not usually a continued cause of lameness. Nonunion distal splint fractures are frequently not the cause of lameness, and evaluation of the concomitant suspensory desmitis is warranted. In conclusion, surgical removal of these distal splint fractures is often not necessary, but may be performed, particularly for persistent fractures. At least 70% of horses with distal splint fractures have suspensory desmitis, which is generally agreed to be the cause of continued lameness.[136]

Figure 4.155. A dorsomedial to palmarolateral oblique radiograph of the carpus showing an oblique articular fracture of the second metacarpal bone.

Closed Nonarticular and Nondistracted Proximal Comminuted Fractures

Closed nonarticular and nondistracted proximal comminuted fractures of the splint bones may heal successfully with 2–4 months of rest. In hindlimb lateral metatarsal fractures, the horses will be minimally lame and training can continue after the acute inflammation is resolved (approximately 30 days). Surgery may become necessary if:

1. Draining tracts develop.
2. Lameness and pain associated with the fracture are moderate to marked.
3. Exuberant bony callus impinges on the SL.
4. Infection is present.
5. A nonunion or sequestra is developing on follow-up radiographs.
6. A faster recovery and return to performance is desired.

If surgery is required, it should be performed aseptically with the horse placed in lateral or dorsal recumbency.

Two surgical approaches have been successful: removal of the fractured fragments only or removal of the fracture and distal splint bone. If the fracture is in the proximal third, any contiguous piece of bone present should remain to stabilize the proximal component. In closed fractures in which more than two-thirds of the splint bone is to be removed, a small bone plate is recommended to stabilize the remaining proximal fragment.[17,101] If the proximal fragment is not anchored, excessive movement of this fragment may occur and result in interosseous desmitis, degenerative OA of the carpometacarpal or tarsometatarsal joints, or avulsion of the proximal fragment. Screw fixation is less frequently successful. The small metacarpal bones are more predisposed to avulsion after proximal fractures than the metatarsal bones because of the major attachments of the collateral ligaments.

Open Distal and Middle Fractures

Open distal and middle fractures of the splint bone often lead to draining tracts or sequestra, so it is recommended to treat these surgically with open removal of the fracture with or without the distal splint (Figure 4.156). The distal splint bone is left if it seems to provide some stability to the proximal fragment.

Open Proximal Fractures

Open proximal fractures of the splint bones can be more difficult to treat due to draining tracts, sequestra, septic arthritis, and unstable proximal fragments. Several treatment options are available including medical management, fracture debridement, internal fixation,[101] and complete removal if it involves the fourth metatarsal bone[10] (Figure 4.157).

VetBooks.ir

Figure 4.156. Chronic middle splint fracture with secondary drainage and periosteal reaction that is best treated with surgical debridement and removal of the distal fragment.

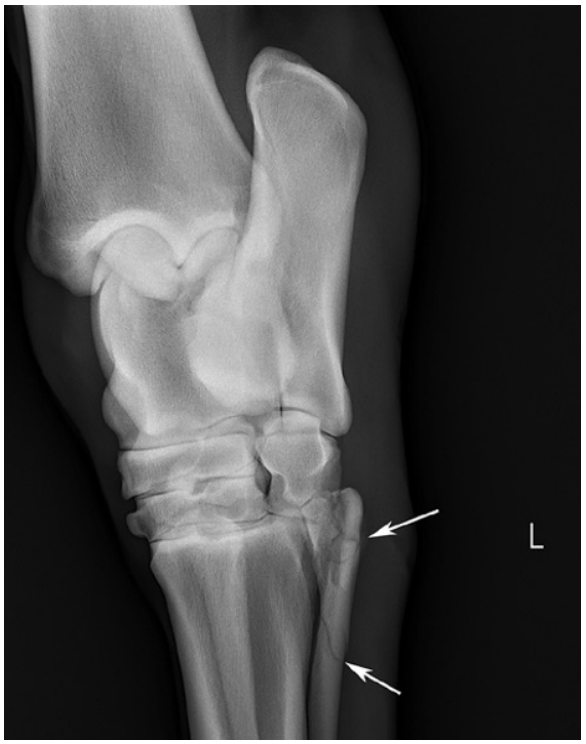

Figure 4.157. Open, articular, comminuted proximal fourth metatarsal fracture (arrow) that was initially debrided and treated conservatively. Infection persisted and the entire fourth metatarsus was removed.

Conservative treatment with local lavage, systemic antimicrobial therapy, and local antimicrobial therapy using regional limb perfusion with or without intra-articular injections can be successful. A recent study found that 11/12 horses with open proximal fractures responded favorably to medical treatment.[63]

Surgical treatment can involve simple debridement of the wound with removal of any loose bone fragments. If there is any concern about intra-articular communication, the joint should be sampled and lavaged during surgery. These procedures can be performed under standing sedation and local anesthesia or can be performed under general anesthesia. A drain can be placed to facilitate drainage postoperatively. Sequestrum formation may occur and require further surgical intervention at a later date. Cancellous bone grafts are useful for treating nonunion fractures in this area.

If more than two-thirds of the splint bone is removed and it appears unstable and active infection is not present, a small bone plate can be secured to the proximal portion of the splint and the cannon bone using 3.5-mm screws. If the fourth metatarsal bone is involved, bone plates may be abandoned for complete removal of the splint bone. If placement of a plate is felt to result in implant infection, the proximal portion can just be left and, if luxation occurs, can be addressed at that time. This may give adequate time for the wound to clean up and decrease the chance of infecting the repair.

For an optimal cosmetic end result, bandages are maintained postoperatively. The horse should be maintained in a stall for at least a total of 6 weeks. Hand-walking exercise can begin at about the second week after surgery, and free exercise can begin after 6 weeks. Training is usually initiated after 2–3 months of rest and is totally dependent on the degree of soft tissue damage associated with the fracture site.

Prognosis

For distal splint bone fractures, the prognosis for return to performance depends on the severity of suspensory desmitis, not on the radiographic healing of the fracture.[17] In a retrospective study of 34 cases of distal splint fractures without SL desmitis, 75.3% of the horses returned to previous levels of performance, and only 50% of the horses with SL desmitis accompanied by the fractured splint resumed to previous levels of performance.[65] In another series with an increased percentage of SL desmitis, only 25% of the horses returned to previous levels of performance.[17]

The prognosis for comminuted closed splint bone fractures is good to excellent with or without surgery, par-

VetBooks.ir

ticularly if the horse is used for performances other than racing.[17] The prognosis for open comminuted splint bone fractures is good to excellent with surgery if approximately one-third of the proximal splint remains. The prognosis for open comminuted fractures of the proximal splint is more guarded, and about 60% return to performance without lameness. These cases can be complicated by sequestration, osteomyelitis, and infectious arthritis.

ENOSTOSIS-LIKE LESIONS

Enostosis-like lesions (ELLs) have been identified in the third metacarpal and metatarsal bones on nuclear scintigraphic examinations.[1,9] Lesions are identified as areas of focal, moderate to intense increased radiopharmaceutical uptake (IRU) in the medullary cavity (Figure 4.158). Radiography of the affected bone may reveal areas of increased radiodensity in the medullary cavity, often near the nutrient foramen. ELLs in the metacarpal/metatarsal bones may or may not be associated with lameness. Other causes of lameness should be ruled out first. Treatment consists of stall or small paddock turnout for 3 months. Prognosis is generally good for return to athleticism; however, horses with more than one ELL appear to have a decreased prognosis.[1]

SUSPENSORY LIGAMENT DESMITIS

The SL is predominantly a strong, tendinous band containing variable amounts of muscular tissue (2–11%).[39,42] It originates from the palmar carpal ligament and the proximal palmar surface of the third metacarpal bone in the forelimb and descends between the second and fourth metacarpal bones. In the hindlimb, the SL originates primarily from the proximoplantar aspect of the third metatarsal bone. An accessory ligament originating from the plantar fourth tarsal bone also joins the SL. In the distal metacarpus/metatarsus it divides into two branches that insert on the proximal sesamoid bones. The extensor branches pass obliquely dorsad to join the common digital extensor tendon in the proximal phalangeal region. The suspensory apparatus is continued distally as the straight, oblique, cruciate, and short distal sesamoidean ligaments. The SL phylogenetically represents the median interosseous muscle and is also known as the interosseous muscle or proximal (superior) sesamoidean ligament.[36,37,39,42]

The percentage of muscle in each region has been identified; Standardbreds had 40% more muscle in their SL than Thoroughbreds, and it has been suggested that this may be associated with biomechanical differences in gait between the two breeds or genetic factors. *In vitro* strength testing of the suspensory apparatus in training and resting horses suggests that there is an increase of strength with training. The absolute load to failure in a single load-to-failure compression test was higher in horses that had been in racehorse training, and failure in the trained group was usually by fracture of a proximal sesamoid bone. In the untrained group, the SL failed.[22]

Injuries to the SL can be divided into three areas:

1. Lesions restricted to the proximal one-third (proximal suspensory desmitis [PSD])
2. Lesions in the middle one-third, sometimes extending into the proximal third (body lesions)
3. Lesions in the medial and/or lateral branch (branch lesions)

PSD, or inflammation of the origin of the SL, is the most common cause of soft tissue injury to the limbs, comprising approximately 30% of tendon/ligament injuries[143] and approximately 60% of soft tissue injuries that localize to the proximal metacarpus/metatarsus (MC/MT).[22] PSD occurs most commonly in sport horses, such as event horses, jumpers, dressage horses, and racehorses. The hindlimbs are more frequently affected than forelimbs and have a lower success rate of returning to performance after rest and convalescence: 69% for hindlimbs vs. 80% for forelimbs.[22] Overall, lameness associated with the origin of the SL occurs in about 5% of horses (36 of 1,094 horses and 31 of 638 horses) with a forelimb lameness.[36,37,39,42]

Injury can be exclusively within the ligament, involve tearing of the Sharpey fibers at the origin of the SL, or be associated with avulsion fracture(s) of the origin of the SL that involves the proximal MC/MT. High PSD and acute tearing of Sharpey fibers may present with similar signs as those described for blind splints and desmitis of the carpal (distal) check ligament. In chronic cases of tearing of the origin of the SL, radiographic evidence of bone resorption and surrounding sclerosis is often present. With avulsion fracture of the origin of the SL, either the lateral or medial branch may be involved in one or both limbs and will likely be noted on radiographs or seen as a displaced piece of bone on ultrasound (Figure 4.159). This lameness most frequently

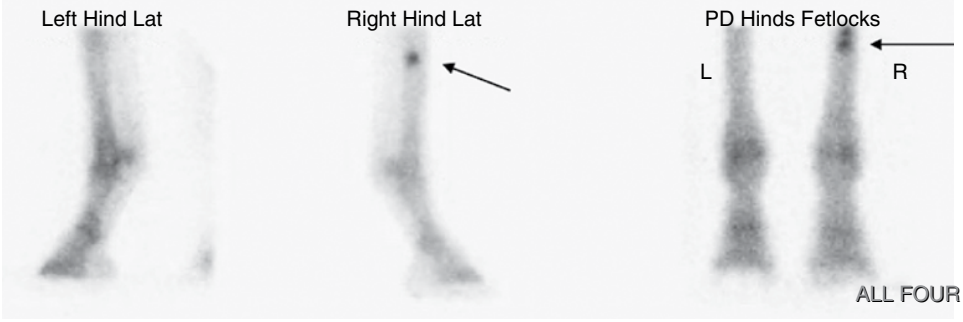

Figure 4.158. Lateral and dorsopalmar nuclear scintigraphic images of the metacarpal regions in a horse with right front lameness. There is a focal, intense area of increased radiopharmaceutical uptake in the proximal medullary cavity of the right front limb (arrows) consistent with an enostosis-like lesion (ELL).

VetBooks.ir

occurs in Standardbreds, hunters and jumpers, and polo ponies, but other breeds are affected as well.[137]

Injury to the body of the SL is less common and occurs most frequently in racehorses, specifically Standardbred racehorses. The body of the ligament also is usually involved in cases of degenerative suspensory ligament desmitis (DSLD).[56] In general, lesions of the body of the suspensory have a more guarded prognosis for return to full athletic work than proximal injury or injury of the branches of the suspensory.[143]

Injury to the SL branches occurs most commonly in Standardbred racehorses or jumping horses. "Bowing" or "springing" of the distal ends of the splint bones and fracture of the distal splint bones is associated with desmitis of the branches of the suspensory. This finding is considered a result of the enlargement of the branches physically forcing the ends of the splint bones abaxially. This predisposes the splint bones to fail or fracture at their thinnest point. These fractures do not heal spontaneously because the splint bones are under tension. Lameness is often due to the suspensory problem and not the fracture.

Etiology

The SL is primarily made up of dense white fibrous connective tissue. Proximally, the body of the SL separates and attaches into two palmar depressions just distal to the carpometacarpal or tarsometatarsal joints (Figure 4.160). Overloading of the SL may cause trauma to any portion of the ligament, but origin injuries are seen more commonly in sport horses. Hyperextension of the carpus/tarsus in conjunction with severe overextension of the fetlock joint has been proposed to cause proximal lesions. In general, the more severe the trauma, the more severe the ligamentous lesion. Working horses in deep, soft arenas or in eventing where there is excessive rotational movement of the limbs may increase the risk of injuries. Lesions in the body or branches of the suspensory also occur in sport horses worked in soft ground. Therefore, soft tissue injuries, including suspensory injuries, occur more frequently in Europe where horses race and train on turf. Lesions within the branches are also associated with fetlock lameness and suggest that high rotary motion of the fetlock may predispose to suspensory branch injury as may occur in racehorses and animals with dropped fetlock conformation.

Clinical Signs

Most horses with PSD present with a history of intermittent lameness of several days' or week's duration that is exacerbated by resumed exercise. The onset may be acute or insidious. Generally, heat and swelling are palpable on the proximal aspect of the limb only in acute cases. In chronic intermittent cases, physical findings are less obvious or may not be present to assist with a diagnosis. However, slight proximal swelling may be felt on the medial side between the SL and deep digital flexor

VetBooks.ir

tendon (DDFT) in some cases.[36–39,41] Additionally, firm digital pressure overlying the proximal SL in these cases usually elicits a nonfatiguable painful response (Figure 4.161). The lameness is generally mild to moderate (1 to 2+ out of 5) at a trot and may be more obvious when the horse is circled at a trot with the affected limb on the outside of the circle. Horses with hindlimb PSD can exhibit moderate to severe hindlimb lameness. Lower limb flexion exacerbates the lameness in 50% of horses with forelimb suspensory problems, and hock flexion exacerbates the lameness in 85% of horses with hindlimb suspensory pain.[39]

Figure 4.161. Location for digital palpation of the origin of the suspensory ligament in the forelimb. The origin is easier to palpate in the forelimb than in the hindlimb.

Horses with tearing of the Sharpey fibers at the origin of the SL or avulsion fractures most frequently present with a history of acute onset of moderate to severe lameness. Horses sustaining a fracture of the origin of the SL often have attained racing speeds in their workouts. Digital pressure at the origin of the suspensory may induce a painful response and exacerbate the lameness (Figure 4.161).

Horses with injury to the body or branches of the SL usually have visible and palpable swelling and signs of acute inflammation at the site of injury. In more insidious onset cases, the enlarged ligament has less inflammation and is firmer on palpation. Pain on digital pressure and a positive response to fetlock flexion are common in affected horses.

Diagnostic Analgesia

Proximal suspensory injury can be challenging to accurately diagnosis and requires a combination of diagnostic analgesia and diagnostic imaging. Diagnostic ultrasonography, nuclear scintigraphy, CT, and MRI can all be used following lameness evaluation and diagnostic analgesia to confirm and characterize SL pathology (Figure 4.162).[22,41,44,72,143]

Diagnostic analgesia is necessary to localize the lameness to the proximal suspensory. There are many different approaches to diagnostic analgesia of the proximal suspensory. The authors prefer anesthesia of the lateral palmar nerve or lateral plantar nerve. This technique may be more specific and also requires less volume of

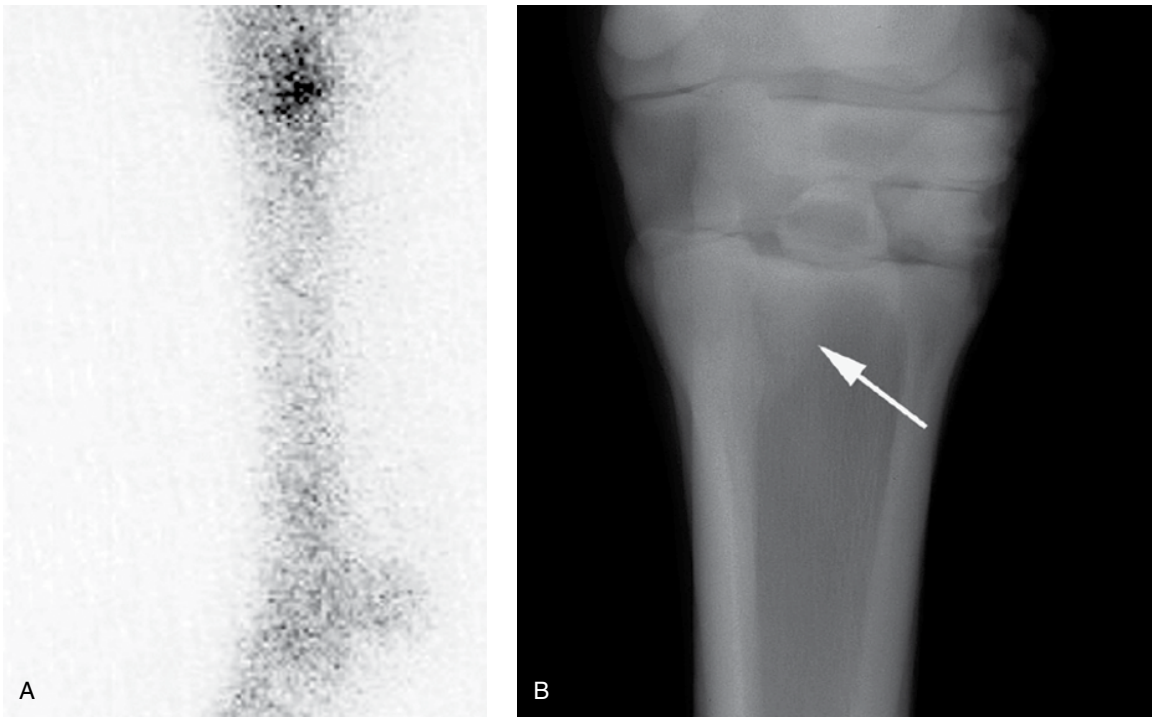

Figure 4.162. Nuclear scintigraphy can identify bone injury at the origin of the suspensory ligament (A). Radiographic lesions such as sclerosis (arrow) can be subtle (B) and usually only identified on the craniocaudal view due to the overlap with the splint bones on the lateral view.

VetBooks.ir

local anesthesia; therefore, the risk of diffusion is lessened, and interference with subsequent ultrasonography is decreased. Alternatively, direct infiltration of the origin of the SL or a high four-point block with anesthesia of the palmar/plantar nerves and palmar/plantar metacarpal/metatarsal nerves can be performed.

In the forelimb, perineural anesthesia of the lateral palmar nerve usually improves forelimb lameness and can be performed just below the accessory carpal bone from the palmar or lateral aspect of the limb or on the medial aspect of the accessory carpal bone. In a minority of horses, the ulnar nerve needs to be blocked to completely abolish the lameness. Diffusion of local anesthesia into the middle carpal joint following anesthesia of the proximal suspensory region has been reported.[89] Diffusion occurs most commonly with anesthesia of the medial and lateral palmar nerves with needle insertion just axial to the splint bones and can be minimized by anesthesia of the lateral palmar nerve performed just below the accessory carpal bone. Additionally, anesthesia of the lateral palmar nerve can lead to penetration of the carpal sheath.[46] Inadvertent anesthesia of the middle carpal joint and carpal sheath needs to be considered during the diagnostic process of a horse with suspected PSD. It should also be noted that low four-point block may cause partial improvement in lameness associated with PSD due to proximal diffusion of local anesthesia.[88]

In the hindlimb, the desensitization of the deep branch of the lateral plantar nerve is the preferred nerve block. This block can be performed just distal to the head of the lateral splint bone with the needle directed axial to the splint (Figures 2.156 and 2.157). As in the forelimb, diffusion of local anesthesia or direct penetration into the tarsometatarsal joint or tarsal sheath can occur, especially when the direct infiltration of the origin of the SL or both the medial and lateral plantar nerves is blocked. It is often worthwhile to perform intra-articular anesthesia of the tarsometatarsal joint on a separate occasion to confirm diagnosis of PSD.

In the forelimbs, desmitis of the distal accessory ligament of the deep digital flexor tendon (ALDDFT) must also be considered.[22] In one study, lameness due to lesions created in the flexor tendons or proximal SL with collagenase injection was not reliably abolished until the ulnar block was added.[69] Similar results were obtained with hindlimb blocks.[61,70]

Diagnostic Imaging

Ultrasonographic examination, radiographic examination, nuclear scintigraphy, MRI, and to some degree, CT, particularly contrast CT, are the current methods for determining the damage within the origin of the SL.[22,36,43,72,143,148] Ultrasonography is by far the most commonly used modality as it is accessible and relatively simple to perform. That being said, lesions in the proximal SL are often subtle and difficult to detect, especially considering interference by both splint bones (particularly in the hindlimb) and the variability in hyperchogenicity due to differences in the amount of muscle present. The entire SL should be imaged in transverse and longitudinal planes. Ultrasonographic abnormalities of the SL that are often identified include enlargement of the ligament (linear width and circumference), poor definition of margins, central or peripheral areas of hypoechogenicity, diffuse reduction in echogenicity, hyperechogenic foci, and irregularity of the plantar cortex of the third metatarsal bone (enthesophyte formation or avulsion fracture).[36,37] Normally, the SL is the most echodense structure in the palmar or plantar MC/MT.[37,143] Comparison to the contralateral limb should be performed, but the disease condition can be bilateral in 18% of horses,[37] so standardized normal comparisons should also be used. Repeat ultrasonographic exams can be performed every 60 days to evaluate response to treatment. Although ultrasonography is the most commonly used diagnostic tool, lack of ultrasonographic abnormalities in the proximal SL does not necessarily rule out a problem. MRI of horses should be considered in horses with lameness localized to the proximal SL with diagnostic analgesia but without ultrasonographic abnormalities. Increased signal intensity and enlargement or alteration in shape of the origin have been seen on MRI in horses with PSD, despite normal ultrasonographic exams.[22,38]

Radiographic examination may be negative for acute high SL desmitis and tearing of Sharpey fibers. However, bone sclerosis of the proximal plantar metatarsal bone, alteration of the plantar subcortical trabecular pattern, and enthesophyte formation were noted in 23 of 47 horses diagnosed with hindlimb PSD (Figure 4.162).[39] Additionally, radiography can be used to rule out causes of lameness attributable to the carpal or tarsal joints. CT can be used to better define this proliferation.[72] Early bone resorption can occur at the origin of the heads of the SL. Avulsion fracture associated with the origin of the SL can also be observed on radiographic examination.

Nuclear scintigraphy can diagnose cases with bone involvement or remodeling, but in horses with confirmed origin of suspensory lesions has been shown to be less sensitive than expected and cannot reliably diagnose the condition.[41] CT can identify enthesophytes that surround the ligament that are not well delineated on radiographs.

Desmitis of the body and branches of the suspensory can be diagnosed with a combination of ultrasonography and radiography. Radiographs should be included to identify the concomitant bone abnormalities such as distal splint bone fractures and proximal sesamoid bone fractures. Ultrasonography commonly identifies enlargement and hypoechoic areas within the body or branches of the ligament.

Treatment

Treatment for horses with a structural abnormality on ultrasound and/or radiography consists of a convalescence program of confinement and slow return to exercise. Immediate medical management, including anti-inflammatories, hydrotherapy, and bandaging, is recommended to reduce any swelling that may occur and to support the fetlock. If a lesion is present on ultrasound, initially, stall rest for 2 months followed by repeat ultrasound is recommended. Hand walking for 15 minutes twice daily for the first 4 weeks and for 20 minutes twice daily for the last 4 weeks can be performed if the horse is sound at the walk, the origin lesion is not greater than 50% of the cross-sectional area

VetBooks.ir

(CSA), and straight hindlimb conformation is not present in a hindlimb injury. Trotting can begin after 8 weeks if the lesion is reasonably improved on ultrasound and the horse is sound at the trot in hand. A slow and controlled (saddle) or rein lunging exercise program can continue until 16 weeks, when another ultrasound is performed. If soundness persists and the lesion appears healed on the 16-week ultrasound exams, the horse's exercise can increase. Total healing time is 8 months and return to full competitive performance may not be possible for 1 year.

Recurrence of injury is greater in horses that have been inadequately rested and for abnormalities within the hindlimbs. Balancing the foot, shoeing with egg-bar shoes, and using sport fetlock support bandages can improve the flexor surface support. A more prolonged convalescent period is required if pain returns after exercise has begun. Use of oral glycosaminoglycans, systemic polysulfated glycosaminoglycans, and systemic hyaluronic acid may have benefit, although unproven. Use of internal blisters, intralesional steroids, and mineralizing agents is contraindicated.

Regenerative medicine therapies consisting of ultrasound-guided injection of bone marrow aspirate concentrate (BMAC), autologous mesenchymal stem cells (MSCs), or autologous platelet concentrates have shown efficacy.[4,137] In one study of suspensory desmitis of the body, autologous platelet concentrate injection in Standardbred racehorses resulted in all nine cases returning to racing with good performance, equal to peers in money earned.[137] Surgical splitting,[60] ultrasound-guided desmotomy and fasciotomy,[61] and shockwave therapy[62,77] have also been described for PSD injury that has significant lesions on ultrasound or that does not respond as expected to confinement and medical management. Improvement in most horses occurs over 6 months of treatment. Neurectomy of the deep branch of the lateral plantar nerve with concurrent fasciotomy has a reported success of 77.8% of horses with PSD alone. However, in this study, all horses with concomitant straight hock conformation and/or hyperextension of the fetlock remained lame and horses with concurrent OA of the distal tarsal joints were reported to have a significantly worse prognosis following surgery (44.2%).[41] However, the surgery may be particularly useful in horses with compressive damage to the lateral plantar nerve, which can cause persistent lameness.[135]

In suspensory desmitis of the branches, treatment of concomitant disease of the fetlock, support bandaging, and a modified training program permits many horses to continue performing. Intralesional orthobiologic therapies described previously are also frequently performed. Surgical removal of the distal splint fractures is controversial and may not address the primary cause of lameness.

Horses with a dropped fetlock conformation have lost suspensory support to the limb and are at high risk of re-injury or complete SL breakdown. Use of support bandages and heel extension shoes, such as an egg bar, are recommended. Many of these horses are retired. In addition, horses with DSLD often have a bilaterally dropped fetlock conformation as part of the presenting clinical picture, suggesting severe damage to the SL.

Prognosis

The prognosis for acute forelimb PSD is good (greater than 80%) for return to full work in sport horses with forelimb PSD following 3–6 months of rest and controlled exercise.[22,100] For hindlimb lameness, the prognosis is significantly worse with only 14%–69% of horses returned to full athletic function without detectable lameness.[22,38] The wide variety of outcome with hindlimb PSD may be related to the greater range and tendency for more severe lesions, concomitant neuropathy and compartment syndrome, and conformational issues that predispose the SL to greater stresses, such as dropped fetlocks and straight hocks. Recently, it was reported that neurectomy of deep branch of the lateral plantar nerve resulted in an 80% return to performance for hindlimb PSD.[135] Osteostixis of the proximal metatarsus at the origin of the PSD in hindlimbs has also been reported.[61] The presence of upright hindlimb (straight hock) conformation is overrepresented in horses with hindlimb suspensory injury and may predispose the ligament to injury and recurrence—hence, the poor success rate for permanent resolution of lameness. Another proposed reason for the poor prognosis associated with hindlimb PSD is the development of a "compartmental syndrome" resulting from the limited space available between the prominent splint bones into which the inflamed SL can expand.[39]

Recurrence of PSD also relates to use. In one study, dressage and show jumping horses had the highest recurrence rate of PSD, 37% and 46%, respectively, compared with racehorses (27%), show hunters (19%), and field hunters (18%).[26] In addition, the larger the SL lesion, the greater the chance of recurrence. Generally, the recurrence of PSD after 1 year following successful treatment is low, but when it does occur, the prognosis is guarded for return to performance. The prognosis is also reduced when PSD is associated with other lesions such as tendinitis of the SDFT and DDFT or desmitis of the superior check ligament.[42]

The prognosis for avulsion fracture associated with the origin of the SL appears good for uneventful recovery to full work after 3–6 months of rest and controlled exercise. Horses with evidence of exostoses developing around the splint bones, but in association with PSD, may benefit from bone debridement after CT.[72]

Degenerative Suspensory Ligament Desmitis (DSLD)

DSLD is a debilitating disorder thought to be limited to the SL of Peruvian Pasos, Peruvian Paso crosses, Arabians, American Saddlebreds, Quarter horses, Thoroughbreds, and some European breeds. It primarily affects the body and proximal aspects of the ligament and is often bilateral. Both forelimbs or both hindlimbs can be involved, and frequently the disorder leads to persistent incurable lameness requiring euthanasia. Many horses have excessive fetlock extension (dropping) on presentation, and horses with hindlimb involvement often have the combination of straight hocks and fetlock hyperextension (Figure 4.163). Affected horses often have palpable enlargement and pain of the SL. The diagnosis is usually made based on patient signalment and history, clinical examination, and ultrasonographic abnormalities within the affected SL. Treatment is

VetBooks.ir

Figure 4.163. Severe dropping of the fetlock together with a straight hock conformation is typical of horses with DSLD. *Source:* Courtesy of Dr. Gary Baxter.

empirical and supportive but often not effective in altering progression of the disease. Horses often remain lame or worsen, and the prognosis is poor for recovery.

The etiology of DSLD is unknown, but the disease tends to run in families, suggesting hereditary influences. A recent study suggested that the disease may be due to excessive accumulation of proteoglycans within the SL and other tissues in affected horses.[56] Histopathologic examination of horses affected with DSLD revealed increased accumulation of proteoglycans within the SL, SDFT and DDFT, patellar and nuchal ligaments, cardiovascular system, and sclerae, compared with control horses. This study indicated that the abnormalities associated with DSLD are not limited to the SL but affect many other tissues and organs with significant connective tissue. The authors suggested that DSLD is actually a systemic disorder of proteoglycan accumulation and propose the term equine systemic proteoglycan accumulation (ESPA) as a more appropriate name for the condition.[56] It should be noted that 22/28 horses in this study were Peruvian Pasos; therefore, extrapolation to other breeds must be considered with caution. It has also been proposed that DSLD in non-Peruvian Paso breeds is due to progressive exercise-induced degeneration of the SL and not associated with a proteoglycan disorder. Regardless, the disease is almost always progressive and the prognosis for athleticism is poor.

SUPERFICIAL DIGITAL FLEXOR (SDF) TENDINITIS (BOWED TENDON)

Tendinitis of the SDFT is a common injury in horses working at high speeds including Thoroughbred and Standardbred racehorses. Thoroughbred racehorses have a reported incidence of 7%–43%.[34,116] Superficial digital flexor (SDF) tendinitis can also occur in other performance horses including show jumpers, event horses, dressage horses, and Quarter Horses. Unlike SL injury, SDFT injury is almost exclusively a forelimb problem. Lesions can range from peritendinous inflammation and pain without structural damage to complete tendon rupture. Tendinitis usually results in a high degree of morbidity with prolonged periods out of work.

Classical SDF tendinitis is localized to the mid-metacarpal region in the forelimb and appears as a convex "bow" to the visual profile of the metacarpus on the side view, hence the term "bowed tendon" (Figure 4.164). Anatomically, the SDFT is the most superficial of the flexor tendons/SL, and therefore enlargement is readily visible and palpable.[80] In normal horses, the SDFT develops in size and tensile strength with training. The SDFT musculotendinous unit originates on the caudal humerus and extends to a bivalved attachment on the palmar/plantar eminences of the second phalanx. Therefore, complete disruption of the SDFT can be associated with dorsal subluxation of the distal first phalanx as well as dropping of the fetlock. In the author's experience, rupture of the SDFT is uncommon, but occurs most frequently in eventing horses and geriatric horses that run when out in pasture.

Less common locations for injuries to the SDFT are the distal MC/MT, the branches of the SDFT in the pastern region, and the proximal SDFT at the level of carpus and above, including lesions at the musculotendinous junction. Lesions in the distal cannon bone are often referred to as "low bows" and can be associated with digital sheath tenosynovitis or constriction of the annular ligament (Figure 4.165). Tendinitis of the branches of the SDFT can be difficult to diagnose because this is not a common location of injury and the classical swelling seen at other locations may not be present.

Damage to the SDFT in its proximal aspect is a syndrome that more commonly affects older (>15 years) nonracehorses. In one study, the mean age of affected horses was 18 years (range of 11–23 years), and Quarter horses (9 of 12 horses) were the predominant breed.[24] Most horses have moderate to severe lameness and positive reactions to carpal flexion, and the majority required an ulnar nerve block to alleviate the lameness (9 of 12 horses). Swelling of the proximal SDFT can be subtle and easy to miss. The prognosis for return to soundness in these aged performance horses appears to be poor.[24]

Etiology

As the forelimb contacts the ground at the gallop, the fetlock is hyperextended, and the flexor tendons are placed under very high tensile loads.[54] Tendons are elastic and can store kinetic energy upon loading that assist with propulsion and support of the large body loads in a "bungee cord" effect. In the Thoroughbred racehorse, the tendon strain (elongation) can be as

VetBooks.ir

Figure 4.164. Classic appearance of mild (A) and more severe (B) SDF tendinitis of the left forelimb. Note the convex palmar surface to the middle region of the metacarpus (arrows).

Figure 4.165. A "low bow" of the SDFT as illustrated in this image can be associated with concurrent digital tendon sheath tenosynovitis. *Source:* Courtesy of Dr. Gary Baxter.

great as 16%, putting this structure close to its physiologic limit during maximal exercise.[142] The high demands placed on the SDFT put it at risk of overstrain injury. This can occur as a single overloading but is more commonly due to repetitive trauma leading to microdamage of the collagen structure that contributes to final failure of fibrils. An age-related effect on SDF tendonitis has been proposed. The SDFT matures early (by ~2 years) with increased strength in response to exercise, after which the tendons develop patchy areas of acellularity, matrix fibrillation, and an overall limited ability to adapt and repair.[98,99] Increasing age and exercise demands can lead to subclinical tendonitis due to accumulation of microtrauma without adequate repair. Full clinical tendonitis can result if biomechanical forces are sufficient.

Clinical Signs and Diagnosis

Diagnostic advances, particularly with ultrasonography and MRI, have greatly enhanced our ability to diagnose and define the degree and extent of damage in SDFT injuries. However, a careful clinical examination can identify early focal swelling and tenderness well before a detectable lameness occurs. Intervention at this early phase can prevent structural damage to the tendon. Excellent husbandry and observant animal caretakers are keys to this early recognition.

In more significant SDFT injuries, a more diffuse enlargement, tendon thickening, and local heat with lameness after exercise occur. Severe tendon injuries are recognized clinically as horses that do not want to put the hoof flat on the ground, thereby putting tension on the flexor surface of the limb. The acute phase of SDF tendinitis can last 2–7 days, the subacute phase 1–3 weeks. Aggressive treatment of the inflammation and

VetBooks.ir

swelling is paramount to limiting the fibrosis and tendon disfiguration that can be permanent.

Chronic SDF tendinitis is manifested by fibrosis and firm swelling on the palmar or plantar (flexor) surface of the limb (Figure 4.164B). Chronic SDF tendinitis may not have heat or edema associated with the condition, yet lameness may be present. The use of diagnostic ultrasonography enables initial and reasonably accurate determination of the extent and location of the lesions.

A complete ultrasound examination extends from proximal to metacarpus/metatarsus to the heel bulbs and determines the CSA of the SDFT and the lesions at multiple locations from proximal to distal. Comparison to the contralateral side may provide a comparison and possibly identify a subclinical condition. Longitudinal scans permit the validation of structural lesions and the assessment of fiber alignment. Hypoechogenicity can be caused by fibrillar disruption and/or inflammatory processes (hemorrhage, edema, and cellular infiltration in the early stages).[107,116] Ultrasound images correlate to histologic lesions. If an SDFT injury is acute/subacute and has clinical signs of inflammation, a repeat ultrasound within 2 weeks is indicated after the inflammation has subsided. Hypoechoic areas within the SDFT can be edema fluid or hemorrhage early on after the injury and may not necessarily be fiber disruption or structural damage (Figure 4.166). If the acute signs of injury have resolved and hypoechoic areas within the SDFT persist, they likely represent fiber disruption (Figure 4.167). MRI has demonstrated an advantage over ultrasound for distinguishing fibrosis from normal tendon in chronic tendinitis.[67]

Treatment

Immediate medical treatment of SDF tendinitis is recommended to reduce or eliminate the acute swelling and inflammation as rapidly as possible to prevent fiber damage or early fibrous tissue formation. Routine physical therapy such as icing, cryotherapy, pressure wraps,

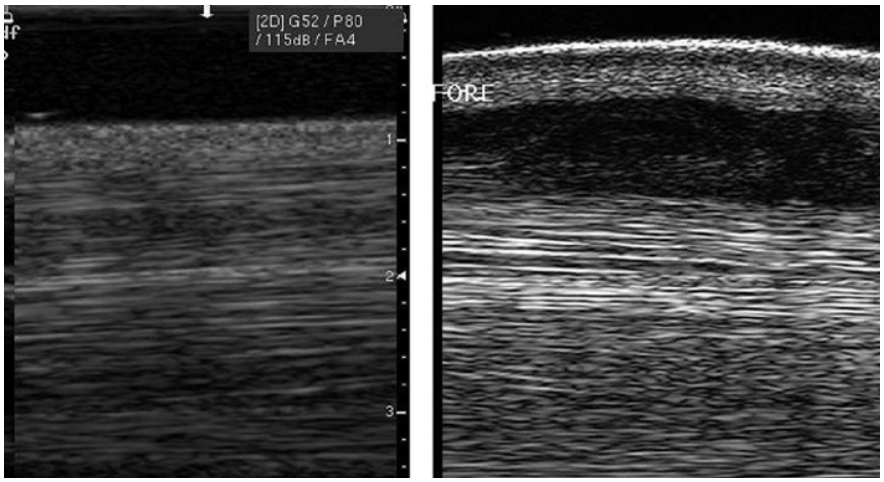

Figure 4.166. Ultrasound longitudinal sections through the midportion of a normal SDFT (left) and SDFT with acute tendinitis. Note the hypoechoic area (black) in the middle of the SDFT that usually corresponds to edema or hemorrhage in acute cases.

VetBooks.ir

and topical hyperosmotic sweats or diclofenac liposomal cream, along with systemic NSAIDs, is instituted along with rest until the ultrasound can be performed. In acute, severe injury such as rupture, a soft cast, resin cast, or Kimzey Leg Saver splint (Kimzey Welding Works, Woodland, CA) may be indicated until radiographs or ultrasound can occur. The application of topical steroids ± dimethyl sulfoxide is controversial, but can be very effective at eliminating signs of inflammation. Systemic steroids are generally not recommended because they may impair the early healing response. Local injections in or around the tendon are usually considered after the results of the ultrasound examination at 1–2 weeks, when most of the fluid accumulations (edema, blood) have resolved and the extent of fiber damage can be accurately determined.

If ultrasound examination is normal and the acute inflammation surrounding the tendon resolves within 1–2 weeks, then hand walking followed by a return to exercise in 30 days or so may be effective. A cautionary re-ultrasound prior to work is indicated to be certain the original ultrasound is still normal, or further damage did not occur upon retraining. If areas of hypoechogenicity are noted within the tendon at ultrasound, then additional treatment and rest are indicated. Lesions should be quantified and horses rested at least until follow-up ultrasounds at 60-day intervals.[82]

Many medical treatments for SDF tendinitis are used in practice. Systemic hyaluronan and polysulfated glycosaminoglycans may be used to reduce adhesions and promote extracellular matrix quality, even though they have lower levels of evidence for success; they also carry a low risk of complications.[40,49–51,54,59,60,67,71,80,82] Intra- or perilesional injection of these same drugs is used less often, and controlled experimental studies have been unable to confirm a benefit.

Several medical therapies have been developed specifically for tendon or ligament injuries. Injectable autologous biologic therapies such as bone marrow, BMAC, MSCs, acellular collagen, platelet-rich plasma (PRP), and concentrated plasma are commonly used to treat SDF tendonitis (Figures 4.168 and 4.169). Acute, subacute, or chronic tendinitis with a persistent centralized hypoechoic area can be injected intralesionally.[4] In the acute and subacute phase, patient-side products like PRP, BMAC, and allogeneic MSCs are used due to their availability. Such therapies are likely beneficial even during the acute phase as they help modulate the inflammatory process.

At this time, bone marrow or fat can be harvested for culture expansion of MSCs, which requires 2–4 weeks.[71,124] Several experimental and clinical studies have described the treatment of SDF tendonitis with adipose-derived stem cells in PRP,[30] adipose-derived stem cells,[91] and bone marrow-derived MSCs,[51,127] with improved tendon organization and decreased re-injury rates in racehorses reported. Use of ultrasound guidance for injection facilitates the injection into the lesion (Figure 4.169). Intravenous or intra-arterial regional limb perfusion using stem cells has been used clinically in some cases of extensive SDF tendinitis due to the difficulty of adequately injecting the entire lesion. Although some studies have evaluated the localization of stem cells following regional perfusion,[128,131] studies evaluating the possible benefit of this technique in horses with pathology have not been published. Although these materials may aid tendon healing, proper rehabilitation and a convalescent exercise program remain paramount to success with any treatment.

Figure 4.168. Gravitational device for the isolation of platelet-rich plasma and platelet-poor plasma.

Electromagnetic and electroshock stimulations have been proposed as treatments for tendon injury. Studies suggest that these techniques should be used with caution because they can cause physical damage to the tissue.[15] Similarly, low-level laser therapy (also called soft or cold laser therapy) has not substantiated clinical claims of benefit.

Surgical Management of SDF Tendinitis

Two surgical procedures are described for treatment of SDF tendinitis: a tendon splitting procedure and proximal accessory ligament transection on the affected forelimb (frequently both, including the unaffected limb). The surgical technique of longitudinal tendon splitting was advocated to decompress the lesion (relieve the hematoma), provide a vascularization channel to central lesions,[2,140] and consequently promote healing, particularly of core lesions in injured SDFT. In experimental and clinical studies, tendon splitting decreased the core lesion size within 8 weeks.[2,60] Importantly, tendon fibers are separated in the longitudinal plane and not transected, with this procedure, or more fiber damage could occur.

Transection of the accessory ligament (superior check) of the SDFT has been reported to drop the fetlock angle

VetBooks.ir

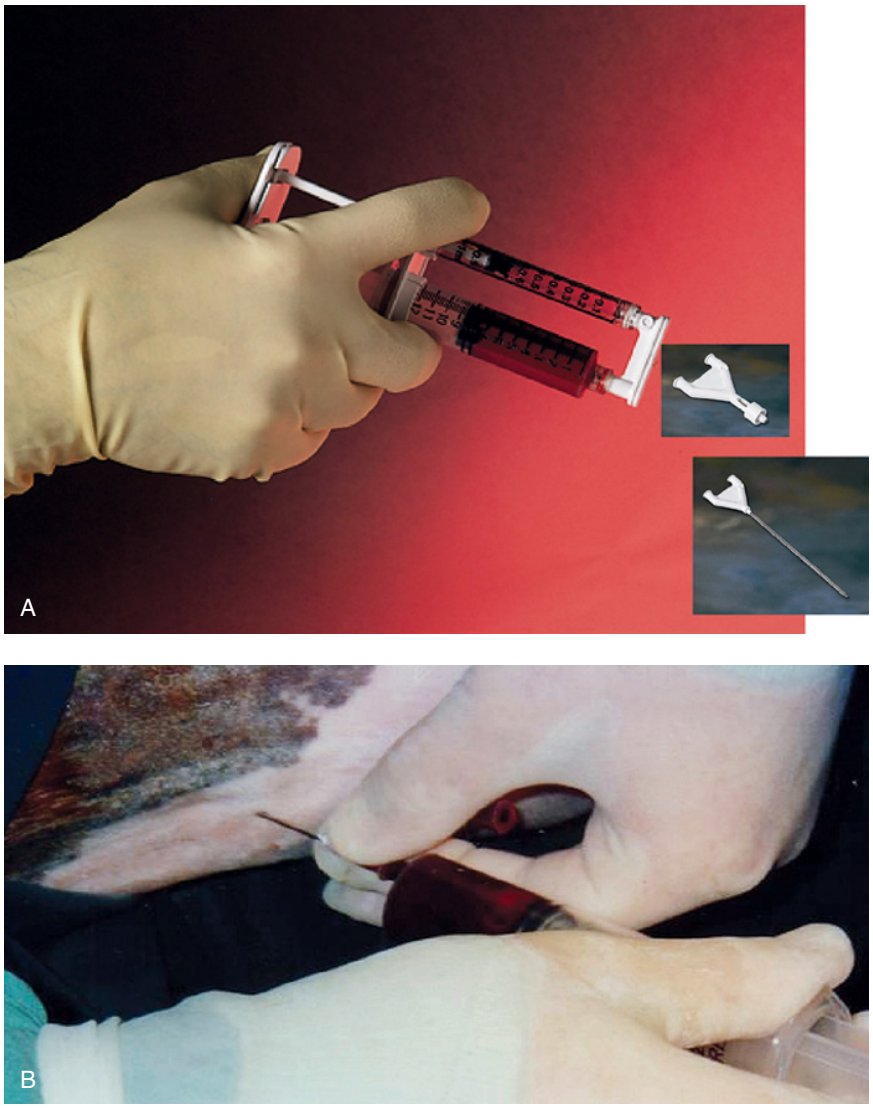

Figure 4.169. (A) A dual port injection syringe permits simultaneous injection of platelet-rich plasma (PRP) (red) and thrombin (clear) into SDFT core lesions. The thrombin serves to clot the PRP. (B) Injection of PRP into an SDFT after ultrasound identification of the site of the lesion. Small aliquots (less than 0.5 mL) of PRP can be injected 0.5 cm apart throughout the length of the lesion.

(increase hyperextension) in normal horses[123] and has been used as a successful surgical therapy for flexural deformity of the fetlock for many decades. Transection of this ligament releases the SDFT, and a gap forms at the transection site, altering the biomechanical forces on the SDFT and reducing peak loads on the SDFT at full weight-bearing.[20,123] However, an *in vitro* study has also shown that SDFT strain is increased following transection of the ALSDFT, which would be suboptimal. In a retrospective study in 62 Thoroughbreds, 92% of the horses were able to train and race after proximal check ligament surgery, and 66% started at least five races.[21] Another study in Standardbred racehorses reported that 92% of horses raced at least once after surgery and 87% raced at least five races, with most having had a bilateral procedure.[59] The evidence for efficacy of proximal check ligament surgery in treating horses with SDF tendinitis is somewhat controversial though, as a trend toward re-injury and a 5.5-fold increase in SL desmitis following surgery have been reported.[49]

Prognosis

Incidence of re-injury is an outcome measure of successful management of SDF tendinitis. Published reports of re-injury in horses treated conservatively with rest alone are 48%[116] and 56%.[124,125] Medical therapies such as hyaluronan, PSGAGs, etc. did not show a difference in re-injury rate.[40] Stem cell therapy reports a significantly reduced re-injury rate of 18%.[51,124] Surgical transection of the accessory ligament of the SDFT reports a reduced re-injury rate of 25%.[59]

Rehabilitation

The value of a carefully controlled rehabilitation program combined with regular ultrasound examination has been documented as providing the best chance for an equine athlete to return to full performance following SDFT (or SL or biceps tendon) injury.[107] Most structural lesions need a minimum of 6 months of restricted

VetBooks.ir

athletic activity to allow for the majority of healing to occur, and clinical signs of lameness should be absent after a short period of rest and before any forced exercise. Tendon rehabilitation protocols are tailored according to whether the structural damage is graded as mild, moderate, or severe. In mild structural injury, the SDF has a tendon CSA that is less than 20% greater than normal SDFT, a core lesion of 15% or less of the total tendon CSA, or a longitudinal lesion of 20% or less of the total length of the tendon. A moderate structural injury has a 20%–35% greater CSA, a core lesion of 15%–30% of the total tendon CSA, or a longitudinal lesion of 20–35% of the length of the tendon. A severe structural injury has a 35% greater CSA than normal, a core lesion greater than 30% of the total tendon CSA, and a longitudinal lesion greater than 35% of the length of the tendon.

All cases with structural injury to the tendon or suspicion of a structural injury should have an initial period of stall confinement and hand walking after acute inflammation subsides, usually a minimum of 30 days. Hand walking is generally 15 minutes twice daily from 0 to 30 days. Many mild tendinitis cases can begin riding at the walk at 30 days, but most moderate and severe injuries require at least 60 days of hand walking.

A second ultrasonographic examination is made at 30 and 90 days, and the tendon lesion compared to original scans. Repeat PRP or stem cell injections can be performed under ultrasonographic guidance every 30 days for three to four treatments. Horses without lameness and good grades of lesion can increase the rehabilitation exercise to include riding at a walk 30 minutes daily from 90 to 120 days, increasing over the next several months. After several months of walking, and in horses without lameness and improvement in ultrasound grade, horses can begin trotting under control. One method is to have horses trot under saddle only on the straight portions of the ring to avoid asymmetric loading on the limbs. The number of laps and times per day can be increased, gauged by the progress of the horse and tendon healing on ultrasound. Cantering can be added for 5 minutes every 2 weeks for 120 days for good and fair cases, whereas poor cases have a reevaluation and discussion of further treatment options. No active race or jump training should begin for at least 6 months from the injury.

Arguably, a controlled exercise program may be preferable to turnout after 60 days. This statement is supported by the results of a retrospective study of 50 Thoroughbred racehorses with SDF tendinitis.[50] The severity of the lesion and type of rehabilitation were significant. Of 16 horses kept in pasture, 2 of 8 raced. Of 28 horses kept in a controlled exercise regimen, 20 of 28 raced. Successful cases usually require 8–9 months of rest and rehabilitation to return to their previous full workload. Shortening this period or advancing too quickly often results in worsening of the tendon lesions. The premise for use of controlled exercise is to initially reduce inflammation, maintain gliding function, and improve healing.

Prevention

Based on changes seen in tendon matrix associated with development, aging, function, and exercise, it has been hypothesized that immature tendon may have a greater adaptive ability and may respond to an appropriate exercise regimen to produce a more functionally adapted tendon.[49] Recent studies suggest that foals allowed free pasture exercise develop a larger, stronger, more elastic tendon compared with those that were confined or subjected to a training program. Effects on the noncollagenous matrix appear to be responsible for these differences. In contrast, training or excess exercise may have permanent detrimental effects on the biomechanical and functional properties of the SDFT in the foal. The implication is that the determination of optimum exercise intensity and timing and the role of the noncollagenous matrix in tendon physiology in the young horse may hold the key to developing tendons that are more capable of resisting injury. Optimal conditioning of a young horse may result in improved performance and reduced tendon injury later in life.[33,125]

DEEP DIGITAL FLEXOR TENDINITIS

Strain injuries of the DDFT in the metacarpal or metatarsal region are uncommon compared with injuries of the SDFT, ALDDFT, or SL on the basis of both postmortem surveys[139] and ultrasonographic examinations.[48,109] However, many DDFT lesions are within the hoof and cannot be seen with ultrasound.

Etiology

Classic deep digital flexor (DDF) tendinitis in the distal metacarpal/tarsal area is usually traumatic in origin, but direct blunt trauma may be a more common cause than with SDF tendinitis. Excessive strain (deformation) of the tendon, usually as it passes over the fetlock, can induce inflammation or structural damage. The anatomic confluence of the digital sheath and annular ligament relatively immobilizes the DDFT at this site, possibly predisposing this area to injury. Horses that hit themselves around the fetlock region with other limbs during exercise can induce a DDF tendinitis. DDF tendinitis can be confused with SDF tendinitis and desmitis of the ALDDFT based on visual appearance (Figure 4.170).[139]

Many, if not most, DDFT abnormalities are degenerative in nature and are located in the distal phalangeal region of the forelimb. Distal injuries of the DDFT palmar/plantar to the flexor cortex of the navicular bone are a well-recognized postmortem and MRI finding and are considered part of the heel pain syndrome.[81,104]

Clinical Signs

DDF tendinitis is suspected with careful physical and lameness examination. It can be confused with distal SDF tendinitis (low bow) or desmitis of the ALDDFT on visual examination and palpation, especially if edema or hemorrhage blends the structures (Figure 4.170). Limbs should be palpated both with load on and off the limb. In unloaded limbs, the SDFT can be moved off of the DDFT, permitting better palpation. If injury of the DDFT has occurred within the digital sheath, sheath distension can also make palpation of the structures more difficult. In both SDF low bow and DDF tendinitis, a convex

VetBooks.ir

Figure 4.170. Horse with DDF tendinitis illustrating the location of many of these lesions in the distal aspect of the metacarpus (arrows). However, the swelling can appear similar to SDF tendinitis. *Source*: Courtesy of Dr. Gary Baxter.

appearance to the caudal limb just above the proximal aspect of the annular ligament occurs, suggesting a relative annular ligament constriction.

Horses with acute injury to the DDFT are usually lame. Ultrasound examination and/or MRI is used to determine the structures involved and the extent of structural damage. Contrast CT has been used to assess angiogenesis of DDF tendinitis and can be used as an alternative to MRI.[104]

In one study, classic traumatic-induced DDF tendinitis was seen in 24 cases with ultrasonographic lesions in the DDFT in the metacarpal/metatarsal region.[7] Clinical signs included a sudden onset of mild to moderate lameness associated with filling of the digital flexor tendon sheath. Intrasynovial analgesia of the DFTS consistently improved the degree of lameness in all cases. Regional four-point blocks also produced a significant improvement, but there was a less consistent response to abaxial sesamoid nerve blocks. On ultrasound examination, 20 of 24 cases had small, distinct, often circular focal hypoechoic areas within the DDFT in the distal metacarpus/metatarsus, usually within the digital sheath and proximal to the proximal sesamoid bones. These hypoechoic areas tended to be localized and extended only a short distance proximodistally (usually less than 1 cm). The lesions were considered focal rather than true "core" lesions as seen in the SDFT and could be easily missed if not carefully examined through the digital sheath. All cases had an increase in the amount of fluid in the DFTS.

Longitudinal tears of the DDFT in racehorses have been reported and can be initially thought to be DDF tendinitis. Ultrasound examination has failed to identify the tears in a significant number of horses. Most longitudinal tears occur within the sheath, and effusion should direct the clinician to further investigation of the digital tendon sheath. See the section on digital flexor tendon sheath tenosynovitis.

Treatment

Treatment of DDF tendinitis is similar to that of SDF tendinitis in terms of physical therapy, systemic medical management, and convalescence. DDF tendinitis may be treated surgically with distal accessory desmotomy for the same reasons that SDF tendinitis may be treated with proximal accessory desmotomy to relieve tension on the DDFT.[11] Literature supporting this treatment is limited, partly due to the rarity of the condition. Injuries to the DDFT within the sheath are frequently treated as a DDF tenosynovitis, in addition to treatment of the tendon injury. See the digital tenosynovitis in the fetlock section.

Prognosis

The prognosis for DDF tendinitis is guarded, depending on severity. In one study of 24 cases,[139] only 7 returned to athletic use.

DESMITIS OF THE ACCESSORY LIGAMENT OF THE DEEP DIGITAL FLEXOR TENDON (DISTAL CHECK LIGAMENT)

The ALDDFT (distal or inferior check ligament) is a direct continuation of the palmar carpal ligament and fuses to the DDFT in the proximal metacarpus.

Etiology

The ALDDFT provides stability to the hyperextended carpus in the midstance phase of the stride because it shares tensile load with the DDFT.[74] Desmitis of the ALDDFT has been reported as a fairly common forelimb injury, third behind suspensory desmitis and SDF tendinitis. This condition is reported in pleasure horses, ponies, and show jumpers; is less frequent in racehorses and event horses[37]; and may not be recognized as a serious problem initially.[85]

Clinical Signs

Lameness occurs suddenly after work and is associated with visual and palpable swelling in the proximal metacarpus of often older horses (older than 10 years) within 24 hours.[85] Ultrasound examination reveals enlargement of the diameter of the accessory ligament and hypoechoic areas indicating edema, hemorrhage, or fiber damage. Swelling in this region tends to persist and progress to a firm fibrosis. Lameness is consistent and improves with rest, but recurs with resumed exercise, similar to other soft tissue injuries to the flexor surface of the forelimb.

Treatment

Treatment of ALDDFT differs from that of SDF or DDF tendinitis in that the accessory ligament structure

VetBooks.ir

is not considered paramount to supporting the load in the working horse. Therefore, treatments may be more geared toward eliminating pain and lameness. Treatment has empirically included oral nonsteroidal medication, intralesional hyaluronan injection to reduce adhesions, and intralesional injection of steroid to reduce pain and inflammation as well as to reduce fibrosis. More recently, ALDDFT desmitis has been treated with injections of stem cells, BMAC, and PRP.

Desmotomy of the ALDDFT may relieve excessive tension on a fibrotic ALDDFT in chronic cases (greater than 3 months); in one study, only 14%–18% made a full recovery.[12] It has been suggested that desmotomy may prevent re-injury.[11] Horses that have received a desmotomy of the ALDDFT as a treatment for chronic rotation of the third phalanx can have pain at the desmotomy site when returned to full work. Similar medical treatment as described above can be effective in eliminating pain. Topical nonsteroidal and steroidal mediations can be effective.

As with all other soft tissue injuries to the flexor surface of the metacarpus/metatarsus, a controlled convalescent exercise program should be followed based on lameness and ultrasound examination at 60-day intervals.

Prognosis

The reported prognosis for resolution of pain and return to work is guarded. In one study of 27 horses, 12 (44%) resumed work within 5 months, and 10 (37%) eventually resumed full work. It is strongly recommended that controlled exercise be used, rather than pasture turnout, and that lameness is resolved long before healing is complete. The horse's return to work should be based on the results of serial ultrasonographic appearance.

CHAPTER

Lameness of the Proximal Limb

THE CARPUS

Chris Kawcak

The carpus is composed of three joints: the antebrachiocarpal (radiocarpal) joint lies between the distal radius and the proximal row of carpal bones, the middle carpal (intercarpal) joint lies between the proximal and distal row of carpal bones, and the carpometacarpal joint lies between the distal row of carpal bones and the proximal third metacarpus (Figure 5.1). The proximal row of carpal bones is composed of the radiocarpal bone, intermediate carpal bone, ulnar carpal bone, and accessory carpal bone. The distal row of carpal bones is composed of the second, third, and fourth carpal bones, and occasionally the first carpal bone. These bones have been shown to move independently through strong intercarpal ligaments that help to dissipate the axial stress through the carpus.

Although the antebrachiocarpal joint is usually isolated from the other carpal joints, one report has documented a communication to the middle carpal and carpometacarpal joints.[37] The middle carpal and carpometacarpal joints communicate routinely, and on occasion the antebrachial carpal joint and the carpal sheath can communicate.[103] Of clinical significance is the fact that the carpometacarpal joint has distal palmar outpouchings that extend distally to the axial side of the second and fourth metacarpal bones. This area interdigitates with the proximal suspensory ligament; therefore, infusion of anesthetic into this area may inadvertently lead to anesthesia of the carpometacarpal and middle carpal joints. Conversely, injection of the middle carpal joint may lead to inadvertent desensitization of the proximal suspensory ligament area.[38]

Disease within the carpus often results from stress-induced fatigue damage that leads to osteochondral damage at consistent sites, especially in racehorses. Carpal disease can also result from acute damage that can lead to osteochondral damage at inconsistent sites or damage to the soft tissues, which typically occurs in nonracehorses and as acute traumatic incidences in all horses. Because of the consistency of stress-induced damage within racehorses, clinicians are more likely to give a reliable prognosis based on large retrospective studies of these problems. However, acute lesions in unusual sites are often difficult to completely characterize and treat, and it is difficult to give an accurate prognosis. In addition, osteoarthritis (OA) is common in the carpus in all breeds and can either result from progression of obvious damage early in life or can be insidious in onset later in life.

Osteoarthritic carpi typically manifest into progressive joint space narrowing, osteophyte and enthesophyte formation, and restricted range of motion. Often there is varus deformity due to medial collapse of the joints. Regardless of the site of pain within the carpus, horses with carpal pain typically show limb abduction while moving at both the trot and the walk and consequently have a very short gait. Although synovial effusion of the carpal joints is usually indicative of primary carpal pain, a lack of effusion can occur in cases of primary subchondral bone pain. Conversely, veterinarians must also be careful of swelling in structures other than the carpal joints such as the extensor tendon sheaths and acquired bursitis lesions such as hygromas. Effusion in either structure can be mistaken for synovial effusion of the dorsal aspect of the carpal joints.

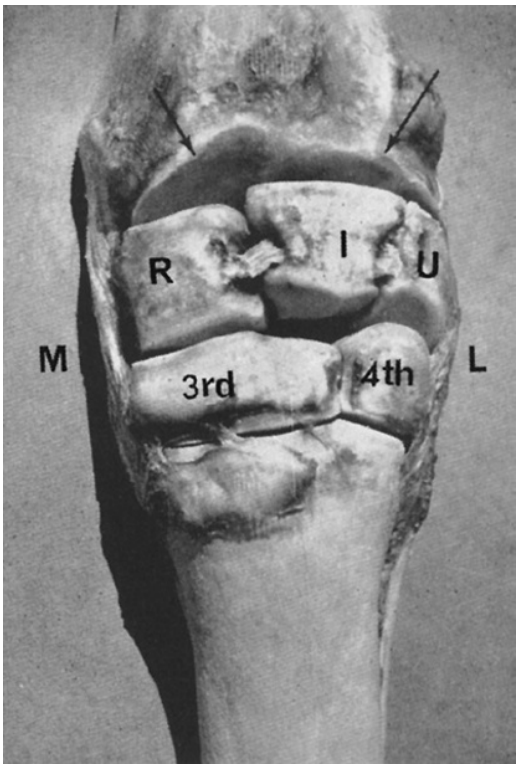

Figure 5.1. Normal left bony carpus. The joints (from proximal to distal) are the antebrachiocarpal (radiocarpal), middle carpal (intercarpal), and carpometacarpal joints. Arrows, areas where chip fractures may occur on the radius; M, medial; L, lateral; R, radial carpal bone; I, intermediate carpal bone; U, ulnar carpal bone; 3rd, third carpal bone; 4th, fourth carpal bone.

DEVELOPMENTAL ABNORMALITIES OF THE CARPUS

Developmental abnormalities of the carpus are one of the most common problems at birth in young horses. The types of developmental problems can be classified into three categories:

1. Angular limb deformities (ALD) or deviation in the frontal plane is defined by the joint and/or bone at the center of the deviation and further defined by the placement of the distal limb in reference to that center.[13] For instance, in the carpus, the distal limb is medial to the carpus in foals that have carpal varus, and the distal limb is lateral to the carpus in those that have carpal valgus. It should be noted that most foals are born slightly carpal valgus because there is greater musculature on the lateral aspect of the distal radius compared with the medial, thus providing increased tension across the carpus on the lateral side of the limb. However, with birth and growth, this usually self-resolves to a normally straight limb.
2. Flexural deformities are defined as deviations in the sagittal plane of the knee so that the joint of reference is cranial or caudal to a line drawn down the center of the limb from the lateral side.[13]
3. Rotational deformities occur when the limb distal to the point of origin rotates outward or inward from the normal axis.[13]

Angular and flexural deformities are usually pathologic in origin and often require prompt therapy. However, rotational deformities are often conformational, and the origin often occurs proximal to the carpus. In those foals in which angular and flexural deformities are deemed to be of clinical significance, prompt therapy is needed to prevent lameness and loss of future athletic performance.

A study of three breeds of French horses (Thoroughbred, trotters, and Selle Français) showed that carpal valgus was the most frequent congenital abnormality (found in 42.1% of foals) and that carpal contracture occurred in 30.8% of foals. During the study conformation became less valgus and most issues resolved by the time of weaning.[101]

Angular Limb Deformity

ALD in general are discussed in Chapter 10, but more detail is provided here on ALD of the carpus. ALD of the carpus are one of the most commonly treated problems in equine practice. However, mistakes are often made using both overconservative and overaggressive approaches to treatment. An understanding of the normal developmental patterns of the limbs is essential to avoid these mistakes.

Etiology

ALD of the carpus can result from asymmetric growth in the distal radial metaphysis, asymmetric growth of the distal radial epiphysis, incomplete ossification of the cuboidal bones or the proximal aspect of the second and fourth metacarpal bones, and/or joint laxity. ALD are typically congenital or acquired. Congenital abnormalities such as incomplete ossification of the cuboidal bones and collateral ligament laxity are not uncommon. Uterine malpositioning or stagnant movement can lead to decreased growth, which can be correlated with mare nutritional status.[77] Cuboidal bone ossification is typically complete by the time of foaling,[82] but without complete ossification, normal loading (weight-bearing) within the joints can cause progressive damage to the cartilaginous structure, predominately on the lateral side of the joints leading to progressive valgus deformity. Toxic chemicals and other possible endocrine influences have also been linked to congenital ALD.[3,39,50,83]

Some foals are born somewhat dysmature and may have joint laxity in the carpus. Constant monitoring and reassessment of these cases are necessary. Oftentimes the stress of turnout or small pen exercise is enough to strengthen those tissues and self-correct the problem. However, in these individuals, care must be taken to avoid excessive exercise, which could lead to progressive ALD. In these latter cases, progressive laxity can lead to pathologic stress levels within the carpal bones, possibly leading to carpal bone malformation. Carpal deformity should be evaluated before turnout and then again after a determined amount of time (1–2 hours). If the deformity is slightly worse after turnout, but returns to baseline throughout the day, then the amount of turnout can be adjusted to help the foal adapt and self-correct.

Foals that have acquired ALD are usually born normal, but the limb starts to deviate with time. This can

VetBooks.ir

be caused by unrecognized congenital ALD that worsens, trauma to the physis or the epiphysis, lameness on a contralateral limb, overnutrition as a foal which induces large body mass, inappropriate exercise, lack of exercise, excess exercise, or poor conformation with growth.[13] As an example, foals that have narrow chests at birth and yet straight limbs have a propensity to develop a wide chest that may lead to carpal varus in the future. In these cases it is good to examine the mare and possibly the stallion to try to determine the type of conformation that may influence the joints in the future. If trauma to the physis or epiphysis is severe enough, the growth may actually stop on that side due to damage to the physeal cartilage, sometimes leading to bone bridging across the physis.[39] Any skin abrasion over a physis should be thoroughly explored to be sure that contamination and subsequent septic physitis does not develop.

Clinical Signs and Diagnosis

The most important information that a veterinarian can give an owner about foals is that they require constant monitoring during growth. Foals can be considered to be easily deformable due to a number of factors during growth, as mentioned above, and they require at least weekly monitoring to stay ahead of rapid changes. For instance, a lameness of any cause in any limb may cause secondary ALD in other limbs. Therefore, during history taking, it is important to know how often the foal has been monitored and the changes noted by the owner since birth. The history should reveal whether these foals were normal at birth, if they were premature, the diet of the mare and foal, and when the ALD was first noticed.

The foal should be examined both statically and dynamically. It should be allowed to freely walk around so as not to induce an abnormal stance through handling (Figure 5.2). This should be done for several minutes because clinical impressions can easily change based on how the foal is standing. It is also common to examine the limb with the veterinarian standing at the foal's shoulder, looking straight down through the radius, carpus, and third metacarpus to assess ALD. In addition, because rotational deformities are common with carpal ALD, care must be taken not to overinterpret the severity. For instance, it is common to see outward rotation of the limb in addition to a carpal valgus deformity. If the foal is examined from directly in front of the foal's head, then this rotational deformity can make the ALD look worse than it really is. It is important to remember to stand directly in front of the face of the particular carpus. In the case of the previous example, the examiner must stand dorsolateral to the midline plane of the foal to accurately assess each carpus.

In some instances the author recommends that periodic photographs or videos be e-mailed for review, and in these cases it is important to remind the owner that the photographs must be taken directly in front of the face of the carpus. It is common to recommend taking several photographs starting at the very front of the foal and rotating laterally right and left in front of the knee.

During physical examination, the foal can be manually "squared up" if needed; however, that must be taken into consideration along with assessment of the foal moving around freely and standing freely. The foal should also be walked to characterize foot flight. For instance, it is not uncommon in foals with carpal varus to break over the dorsolateral aspect of the foot, in which case they may actually swing the limb out. The same is true with carpal valgus, in which the foal may swing the leg medially due to dorsomedial break-over. The conformation of the hoof can often help in determining break-over, because the site of break-over—either dorsolateral or dorsomedial—will be worn compared with the other side.

During physical examination it is important to identify the site of deformity and estimate its severity, characterizing it as mild, moderate, or severe. Some people advocate the use of a goniometer; however, classifying these into mild, moderate, and severe is sometimes just as effective. It is important to jog these foals or let them run free in a small pen to determine whether a subtle lameness is present, especially in an opposing limb, and to palpate the limbs for effusion, physeal pain, and

Figure 5.2. A foal demonstrating normal degree of carpal valgus expected after birth in the left forelimb and a moderate carpal valgus of the right forelimb. Notice that the foal is standing fairly square on its own, providing a good examination. However, the examination findings should be an assessment based on several minutes of examination and movement.

VetBooks.ir

swelling (Figure 5.3). It is also important to manipulate the limb to characterize any joint laxity. Physeal swelling in particular should be palpated for pain because septic physitis can be insidious in onset and severity.

The above physical examination techniques can only be performed if the foal is sound and standing. When the foal is recumbent, it can be observed while trying to stand. If this cannot be accomplished and if the owner has not seen the foal stand and nurse, then serum IgG concentrations in the foal should be assessed. If the foal is lying down, joint laxity must be assessed, and if there is severe ALD, it is important to assess whether this is reducible and if swelling is present anywhere on the limb. The limb should be put through a full range of motion to assess whether pain is present and to assess the full range of extension and flexion.

Diagnostic Imaging

Radiographs of the carpus should be performed to include the distal radius and proximal cannon bone for points of reference for measuring ALD. Some clinicians advocate using long film detectors to do this; however, appropriate assessment can usually be accomplished using standard detectors. It is important to remember that the growth status of the physes often cannot be accurately assessed radiographically. For instance, characterizing a physis as open or closed is difficult radiographically, since growth stops well before radiographic evidence is seen. In particular, assessment of distal radial physeal closure cannot be accurately estimated with radiographs, because it is not uncommon for the physis to remain visible even after growth has stopped.

Figure 5.3. A weanling's limb showing mild carpal varus deformity and physeal swelling on the medial aspect of the distal radius.

Both dorsopalmar and lateromedial views are necessary. On the dorsopalmar views, lines are drawn dissecting both the distal radius and the proximal third metacarpal bone; the area where the lines intersect helps to describe the location within the joint in which the deviation is occurring (Figure 5.4).[19] For instance, if the intersection occurs within the joints, then cuboidal bone malformation often is the cause of the ALD. A goniometer or digital measurement can be used on the radiograph to measure the severity of angulation. In addition, lines can be drawn through the joint surfaces and the distal radial physis, and the line or lines that deviate from perpendicular to the third metacarpal bone can be identified as the site of deviation.

Care must be taken not to overinterpret these results. It is not uncommon to have to sedate foals to acquire radiographs, and the sedated stance may not truly represent the severity of deformity. In most cases sedation can make any degree of joint laxity worsen the appearance of the radiographic findings.

In addition to measuring angles, the degree of ossification, malformation, and damage to the joint must be characterized. It is recommended that a full series of carpal radiographs be taken if initial films show any signs of damage, because subtle damage can affect the prognosis. Any foal deemed to be premature or dysmature should have a radiographic examination of both carpi and other joints such as tarsi since incomplete ossification of the cuboidal bones is not uncommon. Dorsopalmar and lateromedial views of the carpus should be obtained. A grading system has been developed called the skeletal ossification index (SOI),[1] which has been correlated with gestational age and body weight, but not with prognosis for soundness.

It is not uncommon in the physes to see metaphyseal flare, asymmetrical widening of the physes, sclerosis of the physes (which usually occurs on the concave surface), physeal widening (which usually occurs on the convex side of the deformity), epiphyseal wedging, carpal bone wedging (which primarily occurs in the third carpal bone), distal displacement of the ulnar carpal bone or the fourth metacarpal bone, and increased angulation of the head of the fourth metacarpal bone.[14,15,98] Although it is important to characterize these findings, their significance on prognosis is questionable. In addition, any osteochondral fragments, signs of physeal trauma, septic physitis, osteomyelitis, or arthritis must be taken into consideration because their presence significantly affects the prognosis. In general, most people characterize the degree of angulation as mild (5°–10°), moderate (15°–25°), or severe (more than 25°).

Treatment

Treatment of ALD of the carpus depends on the severity and type of deformity that is present. Conservative therapy is often used for most congenital causes of ALD. Sometimes, in mild cases of deformity,

VetBooks.ir

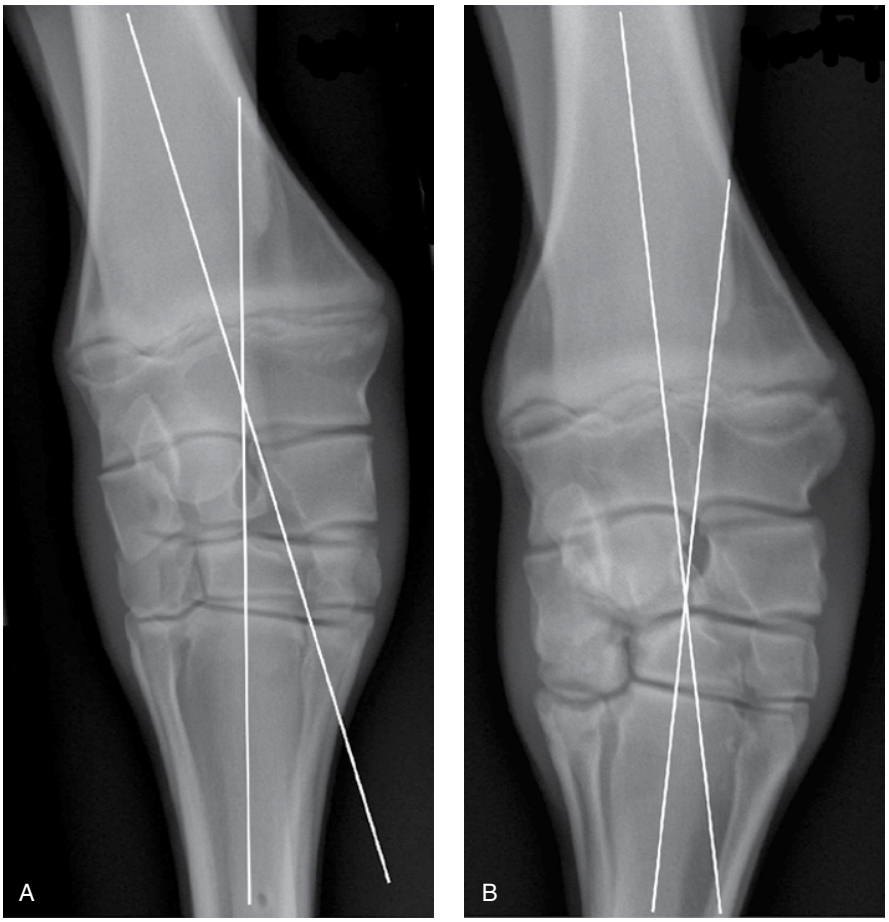

Figure 5.4. Radiographs demonstrating how lines can be used to determine the site of angulation in carpal ALD cases. (A) Distal radial epiphysis. (B) Intra-articular.

this is as simple as stall rest and proper trimming for normal break-over of the hoof. In foals with carpal valgus, the dorsomedial aspect of the foot is typically worn because the foal will break over in that location. Therefore, the dorsolateral aspect should be trimmed to achieve a normal-appearing foot. Some advocate medial hoof extensions, although there is concern that this could lead to ALD in the fetlock joint, and some advocate the use of excessive dorsolateral trimming. The author prefers to use extensions instead of excessive trimming, especially in foals that are toed out in addition to being carpal valgus. In the author's experience, prolonged use of medial or lateral extensions can lead to abnormal changes in the growth of the fetlock joint, at least until the time of distal third metacarpal physeal closure (3–4 months).

Nutritional status of the foals should also be assessed and corrected if abnormalities are detected.

If the degree of palpable joint laxity is significant, the angulation is severe, and/or there is decreased ossification of the cuboidal bones, then a tube cast or splints may be necessary to axially align the joints (Figure 5.5). A tube cast or splint is usually applied from the proximal radius distally to the level of the fetlock joint. It is important to leave the foot out so stimulation of muscle contraction of the forelimb can be continued to minimize limb weakening.

The techniques for applying tube casts and splints include a bandage alone, bandage plus PVC pipe placed on the caudal aspect of the limb, and bandage plus a cast that is either placed on the caudal aspect of the limb or a true tube cast that surrounds the limb. Care must be taken when applying splints and casts as foals are susceptible to pressure sores. Instead of PVC pipe splits, the author prefers cast material elongated over the back of the limb with similar placement to PVC pipe. Regardless of the type of application, these should be changed every 7–10 days and usually are needed for approximately 14 days. The author tries to minimize external coaptation, which weakens the limb and can cause significant sores.

Keep in mind that significant problems can result in a foal in a tube cast or in a splint, particularly slippage of the cast or the foal outgrowing the cast. Cast sores are a major problem in foals; if there is any concern about the foal's use of the limb or if heat is detected in the cast, it is best to change it at that time.[106] It is recommended that tube casts and splints be applied under general anesthesia after physically straightening the limb. The author has successfully used a customized sling and buggy system, especially in foals that have incomplete ossification of their carpal and tarsal bones.

In some cases of mild ALD, brief turnout may be helpful when the foal is thought to be strong enough.

VetBooks.ir

However, close observation is needed, especially in the first few days. It is important to observe the foal before it goes out and assess the degree of ALD. The typical recommendation is to turn the foal out for a couple of hours initially and reassess the degree of deformity when the foal comes back in. It is not uncommon to see the ALD worsen and/or the foal develop a mild flexural deformity and/or shaking in the carpal joints when it comes in from turnout. If this occurs, the foal's amount of turnout should be decreased until these signs cease. Foals usually respond quite rapidly, reaching significant or even full turnout within 7–14 days. Increased turnout may help strengthen and broaden the chest in narrow-chested foals in which carpal ALD and external limb rotation are concerns, resulting in a more normal limb conformation.

Surgical options are used when the foal either fails to respond to conservative therapy or the angulation is severe enough that it is unlikely to correct on its own. Periosteal transection has been used for decades to help correct ALD.[4,48] The rationale is that endochondral ossification is stimulated on the side in which the periosteum is transected and elevated.[4,25] In the carpus this is typically done on the concave side of the distal radial metaphysis 3 cm proximal the physis.

The efficacy of periosteal stripping has come under debate in recent years.[100,110] Although some clinicians feel that it still has merit, two studies demonstrated its lack of efficacy.[100,110] The studies show that the limb will typically correct on its own with proper foot trimming. Slone found that there was no difference between horses that underwent the procedure and those that had stall rest and appropriate hoof manipulation.[110]

Transphyseal bridging, which retards growth on the convex side of the limb, is more predictably effective than periosteal transection for correcting ALD.[40] The procedures include:

1. Placing two screws and a figure-8 wire on the convex side, in which a screw is placed proximal and distal to the physis and wire interlaced between the screws to stop the growth on that side
2. Placing a staple or plate across the physis[13]
3. Placing a transphyseal screw at an angle across the physis on the convex side

Significant growth does not slow in the distal radial physis until approximately 16 months of age; therefore, transphyseal bridges can be used out to 16–20 months of age in the carpus.[41] These bridges are most effective between 0 and 8 months of age, when the most rapid growth occurs. Bridges also can be used in severe cases younger than 6 months of age or in older cases that are nonresponsive. It has been suggested that the screw and wire technique be used in foals less than 6 months of age[128] and a transphyseal screw in those older than 6 months of age because of concern of bone bridging across the physis and overcorrection of the deformity after removal of the transphyseal screw. However, it appears that approaches are changing. The author currently will use a transphyseal screw in most cases of varus and valgus deformity. Witte et al.[128] have not seen a problem with bone bridging, and Baker et al. saw no complications when used to correct cases of carpal varus. In fact they saw no deleterious effects on sales prices or racing performances in those foals.[6] Baker et al. showed that in foals less than 2 months of age that had bilateral carpal valgus (some deemed severe up to 17°), unilateral periosteal transection had no comparable effects to the unoperated limb. This lends considerable support to the fact that at this age considerable improvement in angular deviation can occur with conservative treatment.[7]

The concern with the transphyseal screw technique is that although it is simple and quick, the effects of the screw on normal physeal physiology are not completely understood. The screw and wire technique can be used through two stab incisions and then the tissues in between undermined to place the wire to minimize scarring and potential soft tissue complications. It is not necessary to countersink the screws because that makes removal more difficult. In addition, some surgeons feel that the screws can be offset in the cranial to caudal direction to address rotational abnormalities that may originate at the carpus. In some cases, a transphyseal screw can be placed across the distal lateral radial physis in the standing yearling.[88] In nearly all cases, the screw must be removed, and this can generally be done standing or under a quick general anesthesia in more difficult foals.

In some cases a dorsomedial toe extension is preferred for foals with valgus deformity, to help further

VetBooks.ir

stimulate growth correction, although it is reserved for foals older than 3–4 months of age to avoid problems with fetlock ALD.

In addition to fixation, in severe cases in which bone bridging is thought to occur, the physis can be resected and fat graft interposed to keep the physis open.[43]

Prognosis

The prognosis is good to excellent in more than 80% of the cases.[4,14,15,40] However, Mitten et al. found that in 199 racehorses, there was no significant difference in the ability to start. Foals that had periosteal transection experienced a slight decrease in the percentage of starts, a slight decrease in the number of 2-year-old starts, and a slight decrease in the starts percentile ranking number compared with a nontreated group. Although the limbs were deemed to be straight, the investigator concluded that other factors in the carpus could have led to these reduced outcome parameters in cases treated with periosteal transection.[86] There is concern that significant ALD of the carpus could lead to subtle but permanent deformity within the carpal bones. This could theoretically lead to abnormal forces within the carpus, which is another reason to address these promptly.

Flexural Deformity

Flexural deformity, commonly known as bucked knees, is thought by some to occur in 3%–4% of foals.[13] While mild cases are typically uneventful (Figure 5.6), severe cases can result in dystocia during birth. The deformities, characterized by a disparity in length between the muscle tendon unit and bone, can be congenital or acquired. Acquired deformities occur between 1 and 6 months of age.

Figure 5.6. A foal with mild flexural deformity of the carpi that did not require treatment because it self-corrected over a few days.

Etiology

The pathogenesis of flexural deformity is unknown. Autosomal trisomy in two foals has been associated with this problem.[21] It has been hypothesized that the more common congenital occurrences are due to uterine malpositioning; poor mare nutrition; exposure of the mare to influenza, Sudan grass, locoweed, or other agents; and trauma to the limb, in which increased flexor tone and decreased extensor tone are noted.[78,79]

Acquired flexural deformity can be induced by rapid growth, overnutrition, pain in the limb, or pain in other limbs that causes overloading of that particular limb. Rapid growth is thought to induce physeal pain, and consequently some of these foals stand with their carpi flexed to relieve the pain. In addition, damage to the suspensory ligament, superficial digital flexor tendon (SDFT), or deep digital flexor tendon (DDFT), or injury to the heel or carpal pain can cause the foal to rest the limb in a flexed fashion, leading to contracture of those tissues.

It is not uncommon to see mild flexural deformity in foals that have been turned out soon after birth. In these cases it is thought that the normal exercise, especially in those foals that may be slightly dysmature, can lead to microdamage within the physes and consequently pain. This tends to improve on its own within a couple of hours of rest. In addition, rupture of the common digital extensor tendon can lead to flexural deformity; however, it is unknown whether the rupture causes the deformity or vice versa.

Clinical Signs

The degree of flexural deformity is variable and usually involves both front limbs. In mild cases it may only occur after turnout or when the foal is newborn. In these cases improvement usually occurs within days, with or without rest. In foals with significant flexural deformity, the gait is often significantly affected, and it becomes very difficult for the foal to move around. In addition, the fetlock joint may become involved in the deformity and make it difficult for the foal to rise. It is not uncommon to see skin trauma to the fetlock in these foals.

Diagnostic Imaging

Radiographs should be taken in cases that are deemed to be clinically significant. Lateromedial and dorsopalmar views are needed to assess for incomplete ossification of the bones, cuboidal bone malformation, or damage in the carpus. A complete series of radiographs should be taken if abnormalities are detected on initial views.

VetBooks.ir

Treatment

Treatment depends on the severity of the flexural deformity. In cases of acquired deformity in which rapid growth and pain is thought to play a role, the foal can be weaned to decrease the energy intake from the mare's milk or a muzzle can be applied to the foal to reduce nursing. In addition, the foal's nutrition must be reassessed, turnout can be reduced, and low levels of NSAIDs can be used to reduce the inflammation that is thought to occur in the physis. In mild cases or those that only occur with exercise, turnout can be reduced. For farm managers, it is important that they understand to observe the foals both before and after turnout to monitor whether there is improvement or worsening in the flexural deformity. This will help guide the amount of turnout each foal should have. In some mild cases, physical therapy in the form of 15 minutes of manual extension every 4–6 hours can also be used.[50]

Oxytetracycline can be administered in most cases with good results.[57,68,72] The typical protocol is 3 g oxytetracycline mixed in a 1-L bag of balanced electrolyte solution IV, once daily for 3 days. This should be given over 30 minutes to minimize any possible problems. The effects of oxytetracycline typically occur 3 days beyond the last administration.

If the deformity is severe at birth and the foal cannot stand, casts or splints can be applied immediately and changed every 24 hours. A bandage with a caudal splint is usually sufficient because the flexural deformity is in the cranial to caudal direction.[61] Again, the splint should only extend to the fetlock joint to maintain muscle strength. Foals have been shown to respond well to this.[49] Several commercially available braces can also be used. Regardless of the type of external coaptation used, close observation and monitoring are essential. Skin damage is common, and for milder cases it is often best to treat without coaptation to avoid long-term scarring.

Because of the potential of sores from casts and splints, it is not uncommon to use these for several hours a day and rotate their application. The author typically sedates or anesthetizes the foal, applies a thin bandage from the fetlock joint to the proximal radius, and molds a 4-in. cast material lengthwise from proximal to distal across the caudal aspect of the limb. Vet wrap can then be applied over this to stabilize the leg. Once this is set, it can be reused several times in daily bandage changes.

If contralateral limb lameness is present, that must be addressed to prevent and/or treat flexural deformity in the secondary limb.

Medical management of flexural deformities carries a good prognosis if the foal shows improvement within a few weeks. Carpi may buckle or shake slightly for several months; however, that appears to resolve on its own. This appears to vary with turnout and rest, which can be managed effectively.

Surgical options, while available, are of questionable efficacy. In mild cases, desmotomy of the superior check ligament and/or inferior check ligament can be done to help relax the stress in the caudal aspect of the limb. In congenital forms of flexural deformity, radiographs may indicate cuboidal bone malformation. In these cases, musculotendinous unit contracture of the SDFT, DDFT, ulnaris lateralis, flexor carpi ulnaris, and possibly the suspensory ligament can occur. Therefore, the ulnaris lateralis and flexor carpi ulnaris insertions on the accessory carpal bone may need to be severed to improve the condition.[13]

Prognosis

The prognosis is good for cases of mild flexural deformity that respond well to therapy. However, for those that fail to respond or are severe in nature, the prognosis is often poor.

MISCELLANEOUS CARPAL SWELLINGS

Extensor Carpi Radialis Tendon Damage

Etiology

Rupture or tearing of the extensor carpi radialis tendon occurs rarely in both adults and foals. Although the etiology is unknown, it has been reported in adults to occur mostly in jumpers and in horses that have exostoses on their distal radius.[23,76,115,120] This is typically traumatic in origin in foals and adults.

Clinical Signs and Diagnosis

On physical examination there is swelling of the sheath over the carpus (Figure 5.7). For those with complete rupture, overflexion of the carpus occurs as the foal or horse walks. There may or may not be extensor carpi radialis muscle atrophy, and a palpable defect is often detected within the swelling of the extensor carpi radialis tendon sheath.

Treatment

Rest is often necessary. Surgical repair of complete rupture in the acute stages in adults has been recommended, with casting for 2–4 weeks after surgery. Tenoscopy and debridement of the ruptured ends has also been advocated, along with casting for 2–4 weeks.

Prognosis

Overall, the prognosis for complete rupture of the extensor carpi radialis tendon in an adult is poor for athletic use, but guarded to good for those that have partial tears. Ruptures in foals are thought to carry a good prognosis.

Common Digital Extensor Tendon Rupture

Etiology

Usually both common digital extensor tendons are ruptured, although this can occur in a single limb. The rupture typically occurs shortly after birth. This problem has been reported to occur with other signs such as decreased endochondral ossification at other sites, decreased pectoral muscle mass, and prognathic conformation to the jaw.[84] It is overrepresented in Arabian horses, Quarter horses, and Arab-Quarter horse crosses.[84] Some have speculated that this is heritable,

VetBooks.ir

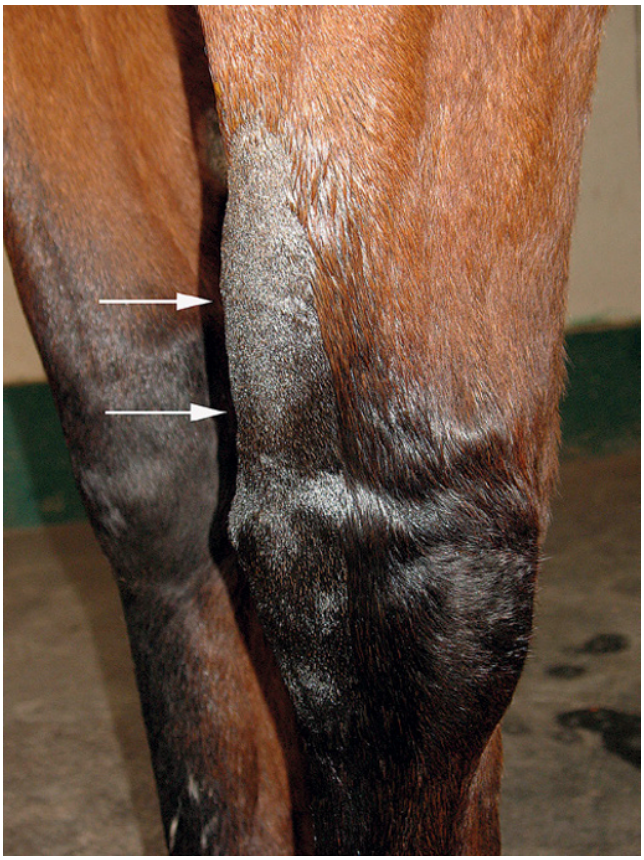

Figure 5.7. An adult horse with synovial effusion of the extensor carpi radialis tendon sheath proximal to the carpal joints (arrows). *Source*: Courtesy of Dr. Ty Wallis.

especially if other congenital defects are present. It is often uncertain as to which came first, rupture of the common digital extensor tendon or the flexural deformity. However the author has seen traumatic rupture of the common digital extensor tendons in foals that were born with severe carpal flexural deformity. Historically, these foals often demonstrate some shaking at the carpi and possible buckling. It is interesting to note that one study showed that there were histologic signs of chronic changes in the tendons in a newborn foal that had ruptured; the investigators hypothesized that the chronic changes could have occurred *in utero*.[13,132]

Clinical Signs and Diagnosis

Clinical signs include swelling on the dorsolateral aspect of the carpus, mainly in the form of effusion in the common digital extensor tendon sheath, occasional fetlock knuckling, possible palpable separation of the tendon, and variable lameness (Figure 5.8). In Meyer's report of 10 cases, 4 foals had severe flexural deformity, 3 had mild flexural deformity, and 3 had no flexural deformity. Thus, the degree of flexural deformity can be variable. These foals must be palpated because they can be easily confused with simple flexural deformities. Radiographs and ultrasound of the carpi can be performed to check for other problems and document the amount of tendon separation.

Figure 5.8. A foal showing bilateral effusion of the common digital extensor tendon sheaths due to rupture of the tendons.

Treatment and Prognosis

Treatment commonly includes stall rest with or without bandaging. Bandaging is recommended to help protect scraping of the dorsal aspect of the fetlock joint that may occur due to hyperflexion of the carpus. Primary repair of the tendons has been advocated by some clinicians,[55] although it is not necessary because the tendon ends are unlikely to heal primarily and rather adhere to the sheath. Splints or casting can be used if a persistent flexural deformity results. Fetlock joint contracture can sometimes occur, and in these cases an inferior check ligament and/or superior check ligament desmotomy can be performed.

In uncomplicated forms of rupture of the common digital extensor tendon, the prognosis is often good, although it is guarded if significant contracture is present.

DORSAL CARPAL SWELLING

Hygroma

Etiology

A hygroma is an acquired bursa on the dorsum of the carpus caused by trauma from falling, getting up and down, hitting a fence, or chronically pawing and hitting the dorsum of the carpus, such as on a feeder or water trough.[99,115,119]

VetBooks.ir

Clinical Signs and Diagnosis

Nonpainful, fluctuant, uniform soft tissue swelling occurs on the dorsal aspect of the carpus (Figure 5.9). Pressure does not induce swelling in any associated joints or tendon sheaths. Range of motion of the carpus may be reduced, but lameness is unusual. However, lameness can be severe if the hygroma is infected. Injection of radiopaque contrast agent into the hygroma confirms its extra-articular position. If a hygroma is suspected of being infected, then a fluid sample should be submitted for cytology and culture, similar to the procedures performed for septic arthritis.

Treatment

Some hygromas may resolve on their own, but in most cases drainage and injection of anti-inflammatory agents can be used; repeated injection is necessary in many horses.[115,119] Spontaneous resolution has been seen after injection of an iodine-containing contrast agent. Injection of atropine (7 mg total dose) may also help to resolve the swelling. Owners should be warned that bandaging is an essential component of treatment and that long-term chronic skin thickening may occur. Other treatments include incisional drainage, injection of irritants such as Lugol's solution, and blistering.[115,119]

Contrast radiography should be performed to ensure that the hygroma is an isolated structure. Although preoperative contrast radiographs may show no communication between a hygroma and a joint or tendon sheath, it is possible that one exists in the form of a one-way valve from the joint into the mass.[52,99] Drainage of the mass with a Penrose drain and bandaging has been used successfully for treatment of recurrent hygromas.[2] However, the author has found the effectiveness of this to be limited.

Surgical excision can be performed in horses with chronic hygroma and is best accomplished if the fluid sac is left intact and dissected from the other tissues.[113] Soft tissue and skin closure are routine, and a splint or sleeve cast can be used to prevent flexion for better healing. Prognosis for resolution of hygroma is often good, although some degree of thickening usually persists and the owner should be warned of a likely cosmetic blemish.

Figure 5.9. Chronic hygroma of the carpus. Notice the diffuse swelling isolated over the dorsum of the carpus. *Source*: Courtesy of Dr. Gary Baxter.

Synovial Hernia

A synovial hernia is a defect in a joint capsule or tendon sheath through which the synovial membrane can protrude. The condition is uncommon and rarely causes lameness, but it is a cosmetic blemish. A soft tissue mass can be palpated over a joint and often can be moved between the hernia and the underlying joint or tendon sheath. Synovial hernias can occur between the mass and either the palpable carpal joint or extensor tendon sheaths. Unlike synovial effusion, synovial hernias seem to have a larger outpouching of fluid and may disappear with joint flexion. Contrast agent injected into the hernial sac is detected in the underlying joint or tendon sheath, although a one-way valve may be present, limiting movement of contrast material. If the synovial hernia is of cosmetic concern, surgical excision can be performed, with a good prognosis for soundness provided no other joint diseases are present.[113]

Ganglion

A ganglion is a fluid-filled structure that connects to a joint or tendon sheath through a one-way tract from the joint into the mass. Unlike a synovial hernia, the mass lacks a synovial lining and often is filled with mucin. Ganglions, although common in humans, are rare in horses, and they have been reported around the stifle and the carpus.[75,99] Demonstrating a connection between a ganglion and an adjacent joint by injection of radiographic contrast agent into the mass may or may not be possible.[2]

Synovial Fistula

Synovial fistulae are communications between two synovial structures, usually a joint and tendon sheath. They have occurred between the antebrachiocarpal joint and the common digital extensor tendon, the middle carpal joint and the extensor carpi radialis tendon sheath or the common digital extensor tendon sheath, and the extensor carpi radialis tendon sheath and a carpal hygroma.[21,52,56,67] Additional joint damage is often present in association with the fistula, causing lameness referable to the area.[67] Swelling in the joint and nearby tendon sheath occurs, and fluid often moves between the structures. Radiography may reveal additional joint or tendon sheath damage, and contrast agent injected into one of the structures is visible in the other.

VetBooks.ir

Occasionally a fistula can be seen during arthroscopic surgery, but closure of the fistula requires an arthrotomy. Arthroscopic surgery for treatment of a primary problem, without repair of the fistula, has resulted in resolution of lameness without resolution of the swelling. Fistulae are typically not repaired unless a cosmetic effect is important, if the swelling itself is impeding performance, or if medical therapy fails to alleviate lameness.

INTRA-ARTICULAR FRACTURES

Although most horses with intra-articular fracture of the carpus display acute onset of clinical signs, the damage is chronic in nature, at least in racehorses, and occurs at consistent sites in the dorsal aspect of the joints. The damage is the end result of a chronic process in which stress-related subchondral bone damage occurs.[59,111] The pathogenesis of repetitive stress injury is discussed in Chapter 7. Acute fracture and fragmentation of the carpus can occur, but this is typically in unusual locations, especially in the palmar aspect of the joints, making an accurate prognosis difficult to make. Therefore, in equine athletes, and particularly racehorses, the damage occurs in predictable sites that lend themselves to more accurate prognosis with treatment.

Three types of fractures can occur within the carpal joints of the horse: osteochondral fragmentation, slab fracture, and comminuted fracture.

Osteochondral fragmentation occurs on a single articular surface and is commonly found on the radial carpal, third carpal, intermediate carpal bone, and distal radius. The fragments can be attached with fibrous tissue, loose, or free within the joint and are categorized as (1) recent and complete fragment; (2) fragment with capsule attachment; (3) chronic fragment with bone attachment, usually by fibrous tissue; or (4) fragment with extensive attachment to the bone.[13]

Regardless of the type of fragmentation, osteochondral fragmentation typically occurs at consistent locations; again, this reflects the chronic nature of the disease. Thoroughbreds and Quarter horses commonly show fragments within the radiocarpal and middle carpal joints. In Thoroughbreds, fragmentation commonly occurs off the distal aspect of the radiocarpal bone, distal lateral radius, and proximal aspect of the intermediate carpal bone. In Japan, the most common sites for fragments to occur in Thoroughbred racehorses are the distal lateral radius, proximal aspect of the third carpal bone, and distal aspect of the radiocarpal bone.[87] In racing Quarter horses, fragmentation occurs off the distal aspect of the radiocarpal bone, proximal aspect of the intermediate carpal bone, and distal lateral radius.[79] In Standardbreds, the fragmentation typically occurs in the middle carpal joint, especially on the third carpal bone (Figure 5.10).[69,93,105] It is important not to rely on these generalizations because fragmentation can occur anywhere within the carpi and the distribution may differ with different population bases.[81] Fragmentation can also occur at the palmar aspect of the antebrachial carpal and middle carpal joints.[62,127]

Slab fractures of the carpus usually occur completely through the bone (they fracture through both articular surfaces), and although they are most common in the third carpal bone, they can occur in the intermediate and radial carpal bones as well. In Thoroughbreds and Standardbreds, slab fractures commonly occur on the third carpal bone and primarily affect the radial facet. These fractures can also occur on the intermediate facet, both facets, or in a sagittal orientation.[75,105,116]

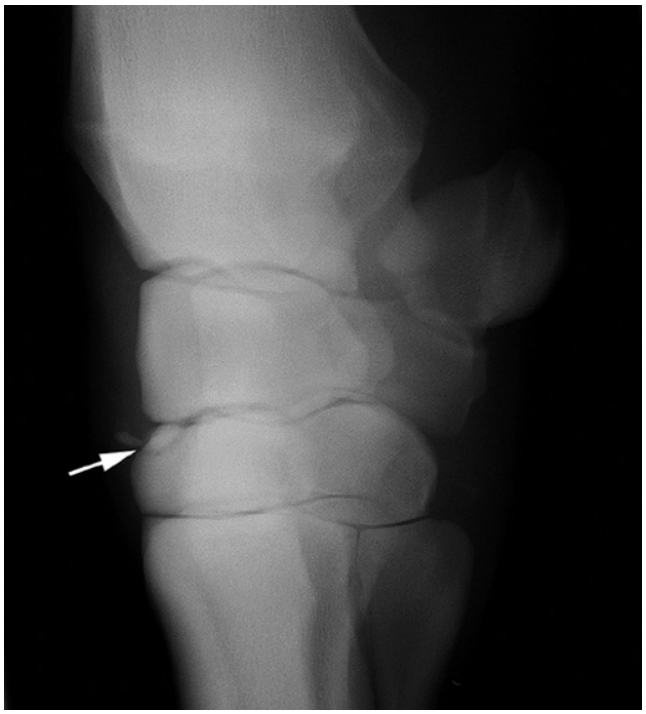

Figure 5.10. Oblique radiograph of the carpus demonstrating osteochondral fragmentation of the proximal third carpal bone (white arrow). Although this site of damage is seen more commonly in Standardbreds, this was a racing Quarter horse. *Source*: Courtesy of Dr. Gary Baxter.

Comminuted fractures of the carpus occasionally occur, and although they primarily involve the third carpal bone, they can also involve the radial carpal, intermediate carpal, and fourth carpal bones. Horses that suffer these fractures are usually axially unstable. They require emergency stabilization and usually surgery to be sound for breeding.

In addition to fragmentation and fracture of the carpus, it is not unusual to find subchondral bone lysis that leads to pain, typically in racehorses. This primarily occurs in older Standardbred racehorses due to chronic stress-induced disease within the subchondral bone.[103] This syndrome is discussed in the OA section of this chapter.

Etiology

The biomechanical forces that occur in the carpus and lead to fracture are difficult to characterize due to the large number of bones and soft tissues involved. The carpal bones are not in direct contact with their opposing surfaces during the flight phase of the gait. However, with weight-bearing and full extension, it is hypothesized that the carpal bones assume a congruent articulation with their opposing bones.[3,5] It is also hypothesized

VetBooks.ir

that this level of congruity can change with fatigue, increased speed, poor racing surface, poor trimming, possibly uncoordinated movement, and variability in racing surfaces, perhaps leading to fracture.

Subtle geometric abnormalities that may be within these joints also could predispose these horses to fracture. Considering the incidence of ALD of the carpus in young horses, it is likely that these subtle geometric abnormalities occur, causing problems at speed. This is a known occurrence in the distal third metacarpus in the fetlock joint. Pathologic studies that have been performed in an effort to determine the cause of these fractures have led to the observation that many are chronic in nature in racehorses.[111]

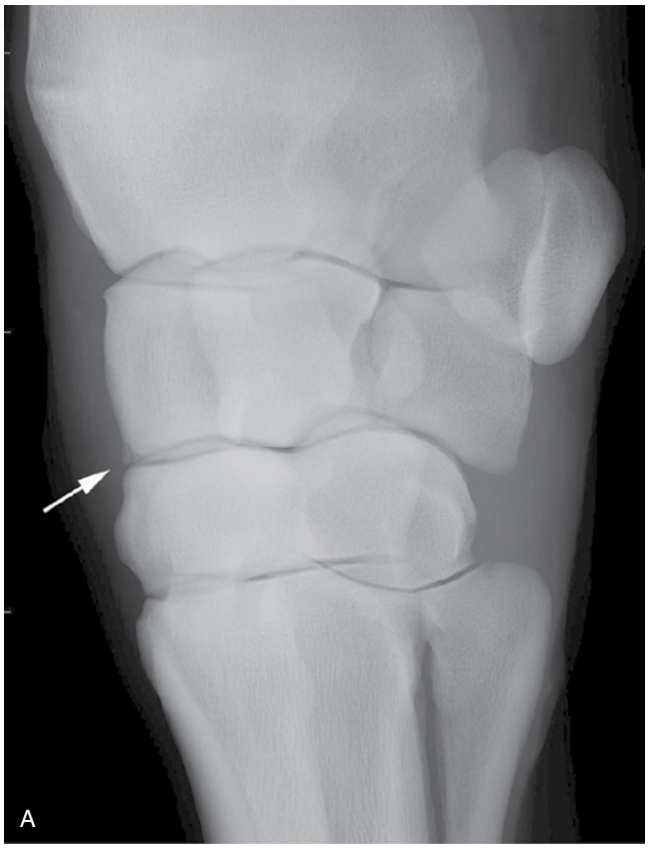
It is known that increased axial loading leads to increased dorsal compression between opposing carpal bones. Therefore, chronic high loads and the instantaneous maximum loads likely lead to disease.[94] Although these horses typically present with acute lameness and swelling, histopathologic observations have demonstrated a chronic disease process that not only leads to bone microdamage but attempts at bone remodeling and healing.[34,35,92,95,111,131] It has been shown repeatedly that intense bone modeling and remodeling occur at the sites at which osteochondral fracture occurs.[59] It is likely, then, that some of these fractures may in fact occur during the peak bone remodeling phase, which includes intense osteoclastic bone resorption. Not unlike dorsal metacarpal disease, some of these horses may be predisposed to fracture during these intense remodeling periods. Therefore, it is likely that chronic repetitive stress can lead to a chronic pathologic process that ultimately leads to bone failure and demonstration of clinical signs.

Soft tissue fatigue that can occur within the joints includes a decrease in soft tissue support of the joint capsule and the surrounding tendons and ligaments. This is compounded by the hypothesis that the hoof often impacts the ground before maximum extension occurs, thereby causing the joint to snap shut and leading to the assumption that these intensive, pinpoint stresses can occur at these sites[3,5] and may lead to damage. In addition, it has been observed that fatigue of the flexor tendons and muscles in the caudal aspect of the leg can lead to hyperextension, as has been observed in many horses at the end of the race. Because of the prevalence of damage that occurs dorsally, several investigators have hypothesized that a back-at-the-knee conformation can lead to increased incidence of disease.[3,103] However, Barr et al. showed that there was no correlation to the incidence of carpal damage when this conformation was evaluated.[9] Others have observed that most horses in Europe are "over at the knee" and therefore likely have a decreased incidence of this problem, although this has not be substantiated.[3]

Clinical Signs

Horses with fracture in the carpus can appear with various degrees of lameness, synovial effusion, soft tissue swelling, and carpal flexion during standing. If osteochondral damage is complete and enters the joint, synovitis typically results, which leads to clinical signs of joint effusion and pain. However, on rare occasions when subchondral bone damage alone occurs, synovitis leading to joint effusion may not be appreciated, and the horse may or may not be positive to carpal flexion. Horses with small osteochondral carpal fragments are often only subtly lame with mild amounts of effusion and soft tissue swelling.

The common characteristic of their movement is abduction of the forelimbs, which some have hypothesized is an attempt to minimize carpal flexion. Consequently, this decreases hoof height during flight. Horses with osteochondral damage are often positive to carpal flexion. Horses that have complete fracture such as slab fractures may have intense pain even with passive flexion. Horses with fracture or fragmentation of the palmar aspect of the joints are often significantly responsive to flexion, which reflects the extensive soft tissue damage that can occur in this area. In more chronic stages of osteochondral fracture, there may be physical limitations to the amount of flexion in the carpus, with or without pain.



Horses with comminuted fractures of the carpus are often axially unstable, and effusion may be associated with subcutaneous swelling. If the horse can tolerate it, it is a good practice to palpate the dorsal aspect of the carpal bones while flexed, because horses with osteochondral damage often demonstrate pain on palpation of certain bones. Often, fibrous thickening of the joint capsule can be appreciated if a significant amount of joint capsule is involved in the fragmentation. However, in these cases, the presence of a hygroma or extensor sheath swelling must be ruled out.

If there are obvious signs of osteochondral fracture, it is often a good idea to perform a radiographic examination prior to performing intrasynovial analgesia because with loss of pain, the horse no longer protects the limb, possibly leading to worsened damage. If a subtle lameness is present or radiographs are inconclusive, then intra-articular analgesia is often needed to confirm the site of pain. For intra-articular analgesia of the carpal joints, 5–7 mL of anesthetic is injected into the joint and the horse checked after 10 minutes and again at 30 minutes.[58] Horses that have incomplete slab fractures that have not broken into the joint may not respond significantly to intra-articular anesthesia. The same may be true of horses that suffer from subchondral bone disease of the middle carpal joint. However, in these horses, there may be subtle preexisting lameness that prompts further diagnostic imaging.

Diagnostic Imaging

A minimum of six radiographic images are needed to fully characterize the carpal joints, especially those with small fragmentation (Figure 5.11). Most of the fragments are on the very dorsal aspect of the bones; therefore, some practitioners recommend that oblique views be taken more parallel with the lateromedial view to fully characterize the damage and detect subtle lesions. Images should be evaluated for osteochondral damage that can be surgically addressed, as well as osteoarthritic changes such as osteophyte, enthesophyte, and joint space narrowing that can affect the prognosis for any surgical outcome. Not all radiographic abnormalities can be clinically significant. Simon and Dyson showed

VetBooks.ir

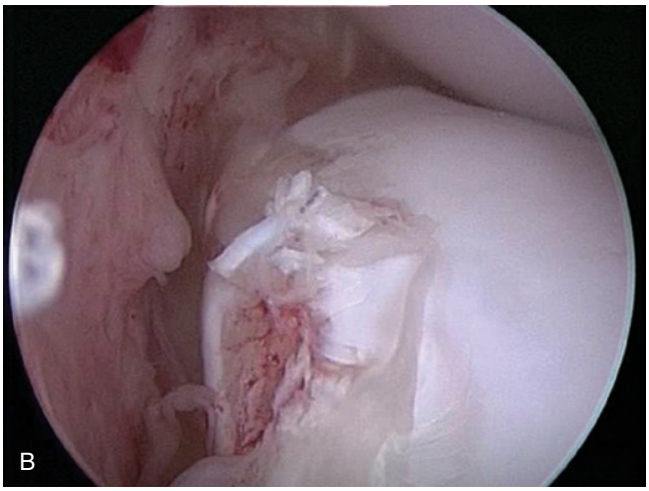


Figure 5.11. A radiographic image (A) showing a subtle fragment on the distal aspect of the radial carpal bone (arrow). The corresponding surgical image (B) is shown as well. This demonstrates how radiographs typically underestimate the severity of articular cartilage damage within the joint.

that radiographic abnormalities within the ulnar carpal bone are likely incidental findings and oftentimes may not be clinically significant.[108] At times it can be difficult to identify the clinical relevance of what may appear to be an osteophyte in the joint; however the presence of this finding along with synovial fusion and lameness often confirms an intra-articular component involved in the disease process, therefore justifying surgical exploration.

Both limbs should be radiographed, because more than 50% of all horses with osteochondral fragments have them in both carpi.[79] In addition, the third carpal skyline view is important for detecting sclerosis, lysis, and fracture and has been shown to give a good impression of third carpal bone density.[118] Some surgeons believe there is a correlation between the amount of pain and the duration and displacement of the fragment, but no objective studies have characterized this.

Mineralization in the palmar aspect of the carpal joints is often appreciated. Some clinicians have attributed this to chronic corticosteroid injection; however, there is evidence that sometimes this is due to chronic damage within the dorsal aspect of the joints that leads to maceration of the fragments and migration to the palmar aspect of the joint.[44] Sometimes significant OA and articular cartilage loss are present in these horses. In addition, in cases of comminuted osteochondral fracture of the carpus, the third carpal bone is usually involved, along with the radiocarpal and/or intermediate carpal bone. These can be difficult to characterize, and subtle changes in the angles of the radiographic images may be needed.

Slab fractures of the carpus are usually most easily seen on the standing lateromedial projection because these fractures often reduce in a flexed lateral position. However, nondisplaced fractures often require a skyline for full characterization (Figures 5.12 and 5.13). Sagittal slab fractures typically occur on the medial aspect of the radial fossa of the third carpal bone, and either a third carpal bone skyline projection or a dorsomedial to palmar lateral oblique projection is needed to see this. In addition, subchondral bone lysis within a third carpal bone may not initially be present on radiographs, which justifies the use of subsequent radiographs to diagnose this problem once the bone in that area has resorbed. Nagy and Dyson have shown that significant osteochondral remodeling occurs in the medial aspect of the carpus as demonstrated by magnetic resonance imaging (MRI). Therefore, advanced imaging techniques are sometimes needed to fully characterize the amount of bone damage at this site.[90]

Nuclear scintigraphy is beneficial, especially in racehorses, due to intense remodeling of the carpal bones. Furthermore, scintigraphy can best characterize the intense sclerosis and lysis that can result and may cause pain. A study of Standardbreds showed that increased uptake was common in the middle carpal joint, and most of this reaction was thought to be clinically significant.[33]

VetBooks.ir

In the study by Simon and Dyson, lameness related to the carpal joints was associated with increased ratio of radiopharmaceutical uptake and increased radiopharmaceutical uptake grade, both of which correlated with opacity of the third carpal bone.[108] In addition, intense uptake has been observed in 2-year-old Quarter horses that were worked on a treadmill for 6 months.[59] Therefore, it is important not to overinterpret the findings because uptake can occur in horses that are undergoing active exercise.

MRI and computed tomography have also been used to characterize subtle lesions in the carpus. Computed tomography has higher resolution and can be used to detect both subtle lesions and bone mineral density abnormalities (Figure 5.14). MRI is useful for detecting soft tissue damage and bone edema.[90] Edema in the subchondral bone has been seen in joints with damage, but its cause and consequences are unknown. Ultimately, arthroscopic surgery is usually the best diagnostic tool to characterize and treat the problem in the carpus. The exception to this may be cases in which subchondral bone pain is a primary problem without the overlying articular cartilage damage.

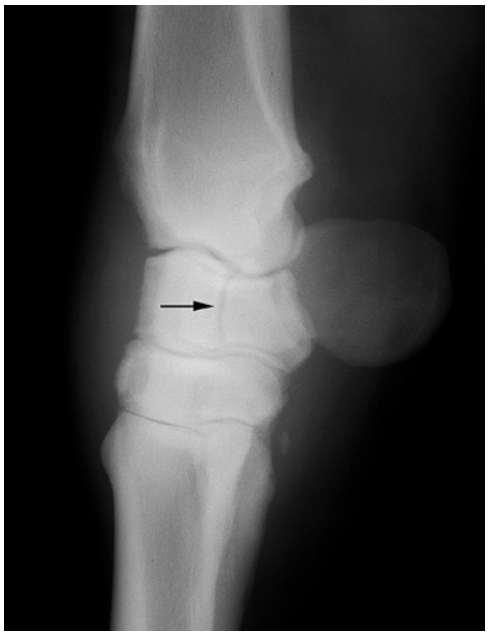

Figure 5.13. A lateral radiograph of the carpus demonstrating a slab fracture of the radial carpal bone (arrow).

Treatment

While some clinicians recommend rest for treatment of osteochondral fragmentation of the carpus, most surgeons believe that arthroscopic removal of the fragments and the resultant reduction of synovitis induced by the instability provide a more predictable outcome. Most surgeons feel that in horses that are conservatively treated, if these fragments are allowed to heal in an incongruent fashion, the fragment of bone can break away later with training, again leading to clinical signs. Arthroscopic surgery is the best method to fully characterize the disease process, treat the primary problem, and give an accurate prognosis for return to athletic use.

Degeneration of articular cartilage and bone has been graded for severity and correlated with outcome:[81]

Grade 1: Minimal fibrillation or fragmentation at the edge of the defect left by the fragment, extending no more than 5 mm from the fracture line
Grade 2: Articular cartilage degeneration extending more than 5 mm back from the defect and including up to 30% of the articular surface of that bone
Grade 3: Loss of 50% or more of the articular cartilage from the affected carpal bone
Grade 4: Significant loss of subchondral bone (usually distal radial carpal bone lesions)

After osteochondral fragments have been removed, augmentative therapy such as microfracture or various intra-articular medications can be used if the lesions are severe. There has been concern about operating horses after they have been recently injected with corticosteroids because the horses may be predisposed to postoperative synovial sepsis; however, this has not been shown to be of major concern.

Arthroscopic surgery of the carpus is typically performed to remove the fragmentation or repair the fracture. Wright

VetBooks.ir

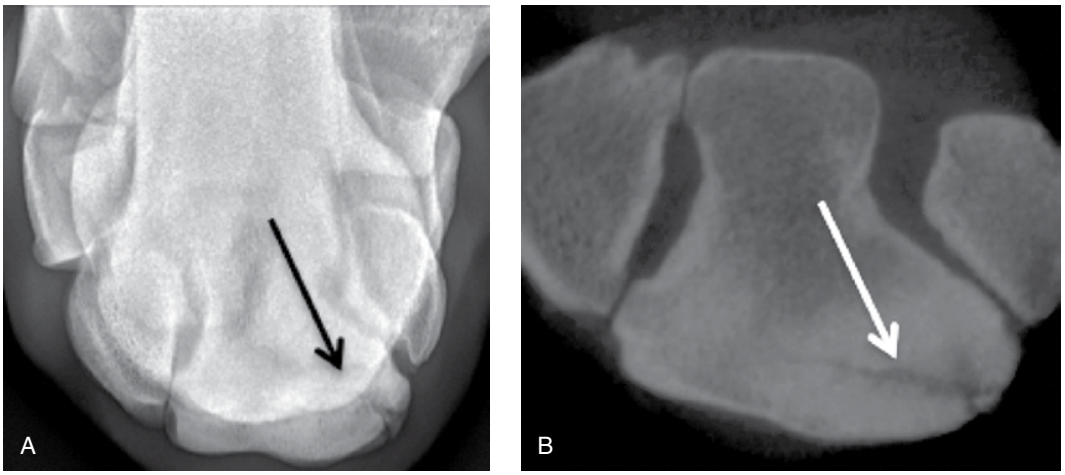

Figure 5.14. (A) Skyline radiograph of a 2-year-old Thoroughbred filly demonstrating osteochondral damage in the third carpal bone (arrow). (B) CT of the same horse that helps delineate the full extent of the fracture (arrow).

and Smith have shown the use of 2.7-mm screws to repair osteochondral fragments that are typically removed. These fragments must be of sufficient size and integrity to hold a 2.7-mm screw, and if successful, the prognosis using this repair technique is excellent.[130] For more details on arthroscopic surgery of the carpus, see McIlwraith et al.[69,81] While the majority of arthroscopic surgery is performed in the dorsal aspect of the joint, occasionally fragmentation of the palmar aspect of the joint can be removed with relatively good success.[26,62]

Slab fractures usually require internal fixation, such as lag screw fixation, to provide the best chance of achieving athletic soundness. However, thin slab fractures (less than 5 mm) can be removed because often they will not support lag screw repair. However use of smaller screws such as 2.7-mm screws may help achieve improved fracture fixation.

Although surgery may not initially be considered for horses intended for retirement or breeding, it is possible that some cases may degenerate and later become unstable or see advanced progression of OA if the fracture is not stabilized. The degree of joint surface damage, which is common with slab fractures, often dictates the prognosis of return to athletic use (Figure 5.15). Stephens et al. showed that complete displaced fractures can be repaired through internal fixation and incomplete and/or nondisplaced fractures can be treated with rest and conservative therapy.[116]

Sagittal slab fractures also are seen. In a retrospective study, 7 of 12 horses treated conservatively for sagittal fractures raced; however, most experienced surgeons believe that internal fixation is needed for the best prognosis.[36,103] Details of arthroscopic repair of slab fractures can be found in McIlwraith et al.[81] Methods to repair slab fractures vary according to surgeons. Some prefer single 4.5- or 3.5-mm cortical screws placed through the radial facet via arthroscopic guidance. Fractures through the radial and intermediate facets require two screws. A headless variable pitch screw has been used, and experimental evidence shows this to be equivalent to cortical screws for holding strength. This type of screw theoretically eliminates pain caused by a cortical screw head.[20]

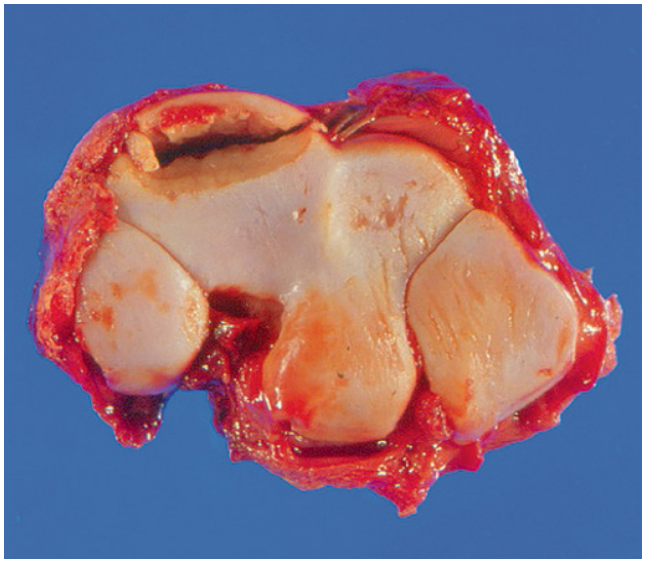

Figure 5.15. Gross image of a slab fracture of the radial facet of the third carpal bone. Notice the degeneration of articular cartilage and subchondral bone that can occur. Even with good reduction, this joint surface defect can worsen the prognosis for return to athletic function.

Comminuted fractures require internal fixation or arthrodesis to restore axial stability to the limb and give the horse a chance to become pasture sound.[16,64] The immediate stability gained from internal fixation improves the time to pain-free limb use and prevents overuse and consequent laminitis in the opposing limb. Conservative therapy with casting and/or splints results in more prolonged lameness, which can lead to cast sores within the limb and often laminitis within the opposing limb. Conservatively treated horses sometimes heal with a deviation and significant chronic pain in the limb. It is unusual for a horse to achieve athletic soundness after such an injury because the joint surface damage is often severe. Lag screw fixation can be used to stabilize individual fractures; however, in severely

VetBooks.ir

comminuted injuries, internal fixation with plates may be necessary, and partial or full arthrodesis needed.

Postoperative Care

For osteochondral fragmentation, sutures are removed at 10 days, and horses maintained in a bandage for 10 days. One common sequela to carpal bandages is the creation of sores over the accessory carpal bone and the medial distal condyle of the radius. There are several ways to prevent these, including padding on either side of the structures, creating a window in the bandage for these areas to be exposed, or using super glue or adherent drapes over the incision sites without a bandage. Most clinicians prefer bandages because the compression helps decrease postoperative swelling; however, it has been observed that super glue has worked well.

The time needed for rehabilitation depends on the amount of damage, and the intensity of postoperative rehabilitation depends on the amount of articular cartilage damage and where the damage occurred. Rehabilitation is faster for the antebrachial carpal joint than the middle carpal joint because damage in the former is less common on the weight-bearing joint surface and consequently suffers minimal stress-induced damage. In general, most surgeons recommend 2 weeks of stall rest followed by 2–4 weeks of stall rest and hand walking and then 2–4 additional weeks of turnout or swimming for problems within the antebrachial joint.[103] For mild to moderate damage within the middle carpal joint, the recommendation is 2–4 weeks of stall rest, 4 weeks of stall rest and hand walking, and 8 weeks of turnout or swimming; for severe middle carpal joint lesions or global articular cartilage damage, 4–6 months of rest are often recommended.[103] Typically horses with slab fractures require 4 weeks of stall rest, 8 weeks of stall rest and hand walking, and 2–3 months of paddock turnout. Horses should be radiographed prior to training, and rarely will the screw need to be removed.[103] For a detailed description of rehabilitation techniques, the reader is referred to Haussler and King.[46]

In addition to rehabilitation, some form of intra-articular therapy is recommended to reduce inflammation and speed healing, especially of articular cartilage. If intra-articular medication is needed, the horses can be injected at the time of suture removal or after. The author prefers interleukin-1 receptor antagonist protein (IRAP) or polysulfated glycosaminoglycan/hyaluronic acid combination (with amikacin) once weekly for 3 weeks, starting 2 weeks after surgery. Treatment with IRAP is not uncommon, especially for severe joint damage, because the growth factor content within this product can be significant and theoretically help with articular cartilage healing. Intra-articular hyaluronic acid and polysulfated glycosaminoglycan are thought to promote healing and decrease inflammation.[60] Some surgeons find intra-articular stem cell therapy to be beneficial, although a study showed minimal benefit in experimental osteochondral fragmentation. However microfracture and intra-articular stem cell therapy has been shown to have a positive effect at other sites.[80] Theoretically, the stem cells could promote release of growth factors into the joint, affecting articular cartilage healing of a defect.[60]

Some surgeons use systemic nonsteroidal anti-inflammatory medications for horses with carpal fractures, either phenylbutazone or Equioxx therapy. Local application of Surpass has also been shown to be beneficial both clinically and in experimental studies.[60] Although systemic polysulfated glycosaminoglycan and intravenous hyaluronic acid therapies generally have shown modest effects, they may help maintain horses with carpal damage. The author recommends the use of passive range of motion and swimming if significant joint capsule damage is noted at the time of surgery.[46]

Potential postoperative problems include sepsis and subcutaneous infection. Problems such as persistent effusion and osteophyte formation are usually a result of the primary disease process, although excessive debridement of the joint capsule can lead to enthesophyte formation.

Prognosis

The prognosis for osteochondral fragmentation is variable depending on the breed. For Thoroughbreds and Quarter horses, the chance of racing at the same or increased level is approximately 68%.[79,87] McIlwraith et al. found that horses with grade 1 or 2 damage were more likely to return to racing than those with grade 3 or grade 4 damage (74% vs. 54%, respectively). However, Lucus et al. found that in Standardbreds, 74% raced at least one start, although most had decreased earnings and numbers of starts.[69] For slab fractures, 65%–77% of horses raced. Martin et al. found that 68% of horses raced postsurgically, although they had significantly decreased value.[75] Stephens et al. found that 65% of Thoroughbreds raced but decreased their earnings per start and that 77% of Standardbreds raced, 100% if they had raced before.[116] The prognosis is good for riding or breeding.[65] For a more accurate summary of prognosis for arthroscopic treatment of carpal damage, the reader is referred to McIlwraith et al.[81]

ACCESSORY CARPAL BONE FRACTURE

Fracture of the accessory carpal bone can occur in any breed and primarily occurs in the frontal plane through the lateral groove of the bone (Figure 5.16). It is hypothesized that most of these fractures heal by fibrocartilaginous nonunion due to the constant pull from the flexor muscles.[10,31]

Etiology

Accessory carpal bone fractures are thought to result from external trauma; however, it is very rare to see primary skin damage over these sites. Some clinicians have hypothesized that the cause may be extreme internal forces such as asynchronous contraction of the flexor carpi ulnaris and ulnaris lateralis muscles,[5] horses landing partially flexed, leading to a bowstring effect of the flexor carpi ulnaris lateralis and flexor tendons,[71] or extreme stress induced by the bone being caught between the third metacarpal bone and the radius, because concurrent lesions have been seen in the caudal radius.[102]

VetBooks.ir

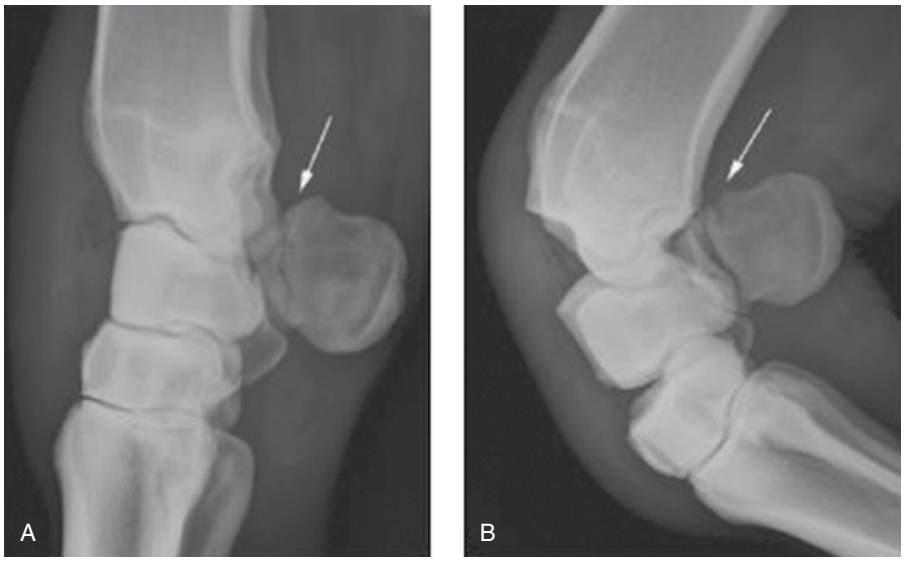

Figure 5.16. Lateromedial (A) and flexed lateromedial (B) radiographs of a fracture of the accessory carpal bone (arrows).

Clinical Signs and Diagnosis

Horses with fractured accessory carpal bone typically have acute lameness with or without dorsal carpal or carpal canal swelling. There is often palpable pain over the accessory carpal bone, crepitus is sometimes felt, and sometimes with flexion, lateral to medial instability can be palpated. Care must be taken in examining these horses because they are very painful with flexion and may stand with their carpus flexed. One frequent clinical sign is a decrease in digital pulses with flexion.[13] Radiographs are often sufficient for characterizing the fracture; however, ultrasound examination of the carpal canal can help to characterize the extent of damage. It is important that a complete set of radiographic images are obtained, especially for complete fractures of the accessory carpal bones as it has been shown that fracture fragments can displace in multiple planes and even displace within the carpal canal distally. With this in mind, it would be important to image distally to the mid metacarpus to ensure that fragments are not present in the distal aspect of the carpal canal.[85] It is important to perform a complete ultrasound examination of the carpal canal as fracture fragments can cause damage to the soft tissues of the carpal canal.[85] Ultrasound examination should be repeated during the healing process because fibrous union is common, and expansion of this fibrous response could impinge the carpal canal, leading to pain. It is thought that severely comminuted fractures could increase the chance of carpal canal involvement, but large retrospective studies are lacking.

Treatment and Prognosis

Damage to the accessory carpal bone can be treated conservatively with 3–6 months of stall rest, small fragments can be removed via arthroscopy, or lag screw fixation of larger fractures can be performed.[31] Three to six months of rest or lag screw fixation are recommended.[31] Ulnar neurectomy and arthroscopic surgery and debridement have also been recommended, but subtotal resection is no longer advocated. Small fragments involving the proximal dorsal aspect of the accessory carpal bone may involve the palmar aspect of the antebrachiocarpal joint and can be removed arthroscopically.[62] It is important to address damage to the carpal canal and remove any possible fragments that may be present and debride damaged soft tissues within that area.[85] However, because involvement of the carpal canal is often delayed until well into the healing phase, tenoscopic examination and retinacular release, if needed, also may be delayed. Periodic radiographs should follow treatment; distraction and further lysis of the fracture due to the fibrocartilaginous nonunion may be seen over time. Prognosis for healing is good.[62,85] Although return to soundness is generally good, it can be reduced if significant carpal canal involvement is evident.

CARPAL LUXATIONS

Luxation of the carpal joints is rare but can occur in any of the three joints. The medial collateral ligament is reportedly most commonly ruptured; however, the lateral collateral ligament can be affected with or without carpal bone comminution. Avulsion fractures can also occur as a result of external trauma such as foaling, jumping, falling, slipping, or from kicks.

Clinical Signs and Diagnosis

Clinically, the horses are acutely lame with swelling around the joint, and there may or may not be an ALD present, depending on the severity of damage. These luxations are rarely open; in the author's experience this occurs mostly in racehorses with catastrophic injuries to the carpus. Horses with carpal luxations may be axially unstable, and crepitus may be palpable during manual deviation of the joint (Figure 5.17). Damage to the collateral ligament can also occur on its own.[30]

VetBooks.ir

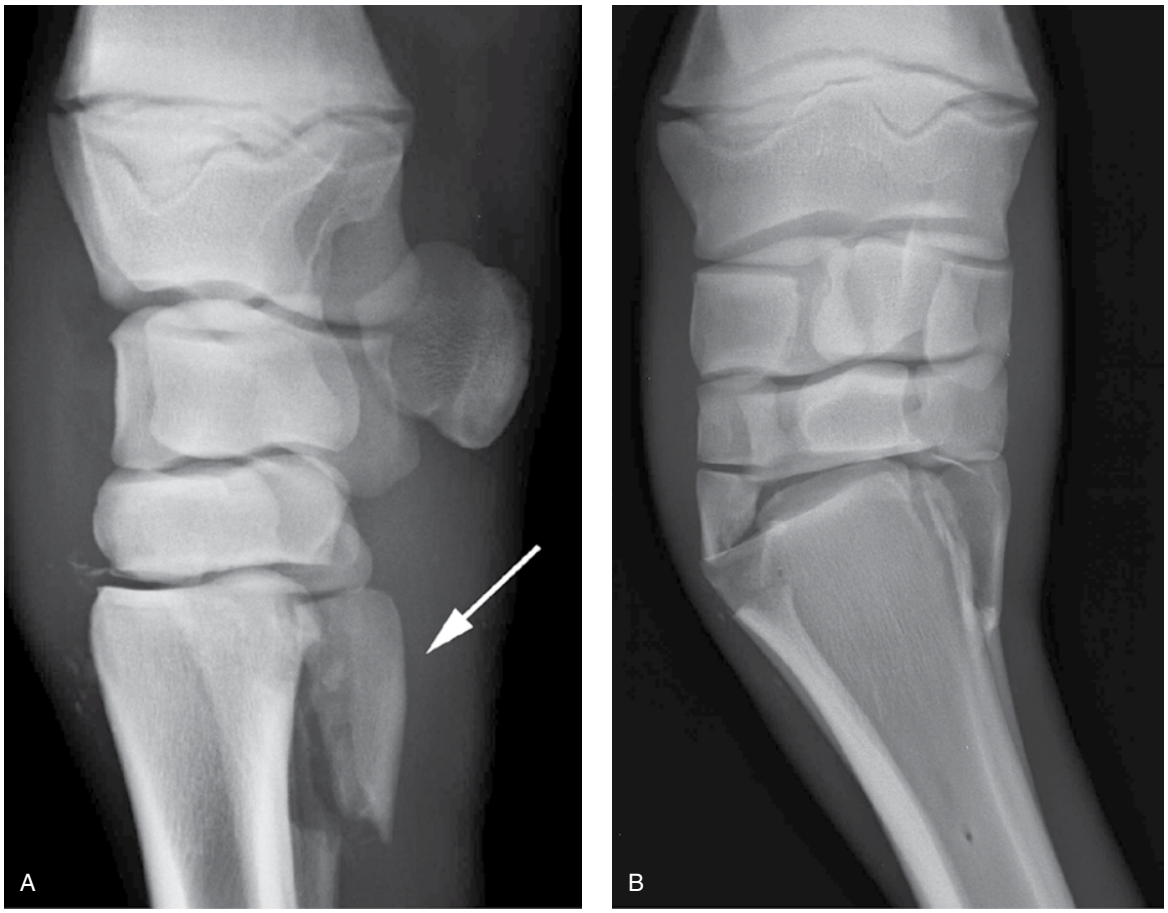

Figure 5.17. Radiographic images showing biaxial splint bone fractures (A, arrow) that led to instability and luxation of the carpus (B). *Source*: Courtesy of Dr. Gary Baxter.

Radiographs and ultrasound are often diagnostic, although in some partial tears the horse must be sedated and manual deviation of the carpus imposed to see the subluxation on radiographs (stress radiographs). In addition, dorsopalmar luxations can occur and radiographs should be assessed closely. Ultrasound is the best diagnostic method for characterizing full- and partial-thickness damage to the collateral ligaments, although with time, enthesophyte formation is usually appreciated radiographically.

Treatment and Prognosis

Treatment for complete luxations often involves placing the horse under general anesthesia to achieve reduction. Arthroscopic surgery may be helpful to debride damaged tissues if joint damage occurs. The luxation can be reduced if the carpal bones are not involved; otherwise, fractures may need to be debrided to facilitate reduction. Dorsopalmar luxations can be difficult to reduce, and sometimes manual fatiguing of the limb or surgery is needed to reduce the luxations. Once reduced, the limb can be put through rotational manipulation.

If the limb is deemed to be rotationally stable, then a tube cast can be applied from the proximal aspect of the radius to the distal third metacarpus.[13] If the limb is deemed to be rotationally unstable, a full-limb cast should be used. Foals are usually casted for approximately 4 weeks and adults for 6 weeks to allow fibrosis to occur in the collateral ligament area and joint capsule. The horse may be transferred to a bandage and/or splint for several weeks, but stall confinement for several months is necessary.

Partial or pancarpal arthrodesis may be needed to stabilize the limb for breeding and pasture soundness if multiple fractures are present (Figure 5.18).[22] However, even if the limb can be reduced adequately, chronic OA and pain may necessitate arthrodesis to control pain and prevent contralateral limb laminitis. Soft tissue lesions can be augmented with stem cells, platelet-rich plasma, or extracorporeal shockwave therapy to help stimulate healing. The prognosis is good for healing but guarded for athletic use.

SOFT TISSUE DAMAGE TO THE CARPUS

Collateral ligament injury is sometimes seen in the carpus. Although these may be difficult to diagnose acutely, improvement in ultrasound examination of these structures and the use of MRI have helped with early diagnosis. Some have described collateral ligament abnormalities in the carpus closely associated with OA;[30] so the problem is sometimes diagnosed well after OA has already been established.

VetBooks.ir

Figure 5.18. Lateral radiograph 1.5 years after the horse (Figure 5.17) underwent arthrodesis of the carpometacarpal joint using a locking plate. *Source*: Courtesy of Dr. Gary Baxter.

Injury to the intercarpal ligaments is common, especially in cases with osteochondral damage. The dorsomedial intercarpal ligament attaches to the distal radiocarpal bone in the area where osteochondral fragmentation typically occurs. Whitton et al. have shown that the dorsomedial intercarpal ligament resists dorsomedial displacement of the radiocarpal bone; therefore, it is likely that the stress at this site makes this area prone to damage.[123,125] Selway proposed that hypertrophy of this ligament could lead to disease, but Whitton et al. have shown no correlation between dorsomedial intercarpal ligament hypertrophy and osteochondral damage.[122,124,126]

The palmar intercarpal ligaments have been shown to provide considerable stability to the carpus. The medial and lateral palmar intercarpal ligaments allow abaxial translation of the carpal bones to dissipate axial forces through the carpus.[18] Whitton et al. found no correlation of tearing of the palmar intercarpal ligaments with the severity of disease other than the fact that severe tearing of these ligaments can lead to instability of the joint and hemarthrosis. Beinlich and Nixon reviewed the diagnosis and treatment of horses with avulsion fracture of the lateral palmar intercarpal ligament from the ulnar carpal bone[11,12] and found that the fragments were best demonstrated on the dorsopalmar and especially the dorsolateral palmar medial projections, which corresponded with arthroscopic findings in this group of horses. In addition, they found that arthroscopic removal of these fragments was more beneficial than rest alone, with 91% of those horses returning to their intended use.[11,12]

Enhanced diagnostic information can be achieved from MRI and CT arthrography.[45,89] On MRI, Nagy and Dyson characterized many intercarpal ligaments that cannot be identified or characterized using other imaging techniques. Gray et al. also showed that CT arthrography could be used to characterize the intercarpal ligaments and that it is an acceptable technique to diagnose lameness originating from the carpus.

OSTEOARTHRITIS

Etiology

OA is common in the carpus and can result from 1 of 2 syndromes. In young horses that are athletes, such as racehorses, stress-related bone damage—especially that which causes physical damage to the joint—can result in secondary OA; see Chapter 7 for details on stress-related bone damage. It is likely that the pathologic process that leads to this disease progresses to the point of articular cartilage damage and OA. The other form of OA occurs in horses that demonstrate insidious, progressive onset of disease regardless of their previous history. In either case, if the severity of damage can be stabilized, these horses are often clinically manageable for nonracehorse type of work. However, when the damage is progressive, it is possible that even pasture soundness is questionable.

Clinical Signs and Diagnosis

Whether the OA is due to previous injury or insidious in onset, the clinical response is similar. Horses with a previous history of disease can be monitored closely for radiographic evidence of advancing OA and treated. In insidious cases, often no problems are noticed until the limb begins to swell and lameness becomes obvious. In the latter cases, the farrier will often note that the horse begins to resent flexion and manipulation of the limb. Radiographs taken at this point often show some signs, and treatment can be helpful if started at that time.

Radiographic signs of OA may include mild osteophytes, enthesophytes, and osteochondral fragmentation early in the disease process (Figure 5.19). Subchondral bone sclerosis may be identified and mild joint space narrowing may be present. Severe changes can result from the progression of OA, leading to combinations of subchondral bone sclerosis and lysis.

Treatment and Prognosis

Some early forms of OA can be treated with rest and systemic nonsteroidal anti-inflammatory treatment. Stall confinement is rarely helpful in management of horses with carpal OA; in other species, including humans, strengthening of periarticular soft tissues is beneficial.[17] Paddock turnout seems to help these horses, although it is important to monitor their activity and limit their exposure to other horses that may stimulate excessive exercise.

VetBooks.ir

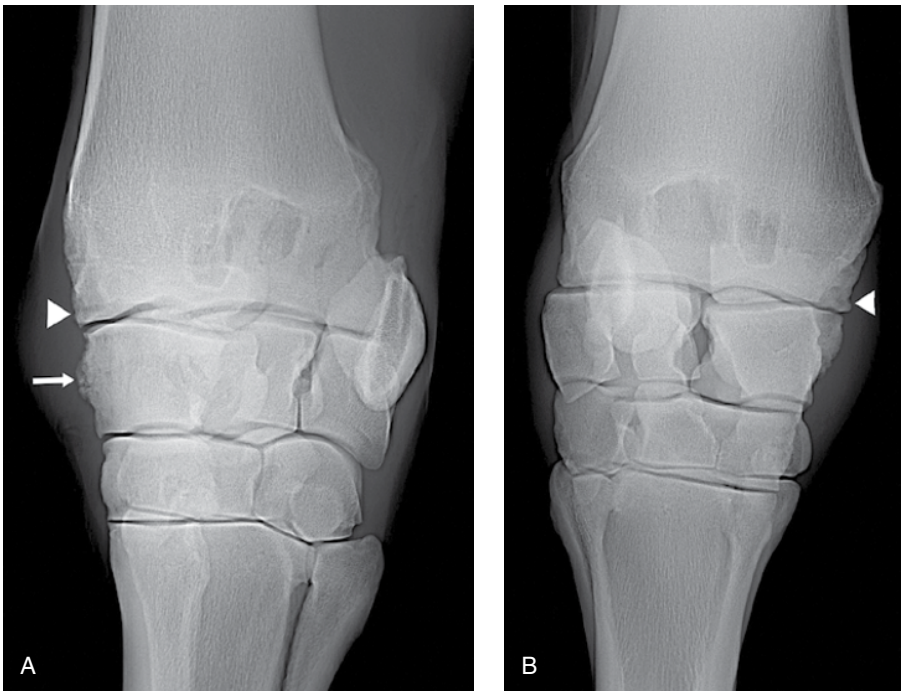

Figure 5.19. Radiographs demonstrating mild signs of osteoarthritis, including enthesophyte (A; arrow) and osteophyte (A, B; arrowheads) formation.

Surgery can be performed to remove osteochondral fragments or for augmentative therapies such as microfracture and resurfacing; however, the disease process will likely continue to progress postoperatively, and in most cases the goal of surgery is to help relieve pain and the severity of the disease.

Intra-articular medication is meant to treat the synovitis component that often leads to pain, but its efficacy for treating subchondral bone damage is questionable. Intra-articular corticosteroid and hyaluronic acid combinations may work for a short period of time but often stop working. Intra-articular hyaluronic acid and polysulfated glycosaminoglycan combinations or IRAP may be considered. In some cases, there is subjective evidence to show that intra-articular administration of stem cells may be helpful in managing horses with carpal OA. Although it is thought that only triamcinolone acetonide or betamethasone should be used in high-motion joints such as the carpus, methylprednisolone acetate may be the only thing that is effective in some cases of severe OA. Although this has been shown experimentally to result in progressive articular cartilage damage, in these cases management of pain is often considered the priority. It is sometimes difficult to determine the origin of the greatest site of pain in horses with carpal OA. In cases with severe osteophyte and enthesophyte formation and subsequent reduced range of motion, the author has occasionally used corticosteroids administered via regional limb perfusion of the carpus to help alleviate pain. Further studies are needed to evaluate the efficacy of this treatment, but in some cases it seemed to be effective.

Medial collapse of the carpal joints is not uncommon in severe cases of OA, and often dorsolateral break-over of the hoof in that limb is noticeable. This progressively worsens between trimmings; it is a subjective opinion that this can lead to worsening of pain. A mild lateral extension or a full shoe itself may help to alleviate some of this pain by slowing the dorsolateral break-over that occurs. In severe cases of OA, partial or pancarpal arthrodesis is often advocated to reduce the amount of chronic pain in the limb and prevent laminitis in the opposing limb.

CARPOMETACARPAL OSTEOARTHRITIS

OA of the carpometacarpal joint is a separate syndrome that predominantly involves mainly Quarter horses and Arabian horses.[73,96] The osteoarthritic changes manifest mostly at the articulation between the second carpal and second metacarpal bones and radiographically show osteoproliferative changes and joint space narrowing medially (Figure 5.20). Lameness is insidious in onset, but can progress rapidly. The etiology of this problem is unknown, but it has been suggested that an anatomic abnormality may exist between the second and third carpal bones.[73] Medical management of these cases can be frustrating over time because they typically become less responsive to treatment.[96] Similar to OA at other sites, medical management is worth attempting until there is concern that the lameness could contribute to opposing limb laminitis. At this point, a partial carpal arthrodesis could be performed. Partial carpal arthrodesis can be performed in one of two ways. Barber et al. evaluated a drilling technique for arthrodesis in 12 horses and found that it was considered successful in most cases.[8] However when evaluated experimentally, the same technique failed to produce consistent ankylosis in normal joints.[97] Consequently, some surgeons have advocated plate fixation to fuse the joint.

VetBooks.ir

OSTEOCHONDROSIS OF THE CARPUS

Osteochondritis dissecans has been reported in the carpal bones, although it is uncommon compared to other joints in the horse. Subchondral cystic lesions in some carpal bones are incidental and are often of questionable clinical significance. This is especially true with cysts within the second carpal bone in association with the presence of the first carpal bone and in the proximal aspect of the second metacarpal bone. However, subchondral cystic lesions in the radiocarpal bone and the distal aspect of the radius (Figure 5.21) are often clinically significant, and arthroscopic surgery and debridement are warranted if they are felt to communicate with the carpal joints. Simple drilling or transcystic screw could also be considered in these cases. Oftentimes, MRI or CT is needed to best characterize these lesions.

OSTEOCHONDROMA OF THE DISTAL RADIUS

Osteochondroma (OC) formation at the distal end of the radius is an uncommon condition causing lameness in the horse.[53,63,70,114] The growth most commonly occurs in adult horses adjacent to the physis at the caudal distal aspect of the radius.[47,112,113] Although very uncommon, the cranial aspect of the radius also can be involved.[104] Radiographically and histologically, these new bone growths appear much like those reported for hereditary multiple exostosis. However, unlike hereditary multiple exostosis, they appear as singular lesions or affect only a few other long bones, rather than numerous growing bones. Solitary OCs have been reported in two foals; the distal palmar aspect of the middle phalanx was affected in one, and in the other the calcaneus was involved.[24,32] The reader is referred to Chapter 7 for more details.

Etiology

Although a single dominant autosomal gene is responsible for the development of multiple exostosis in humans and horses,[107] the genetic implications for isolated OC remains unclear. In humans, solitary OCs are not considered to be inherited.[51] It is postulated that metaplastic cartilage foci develop in the metaphysis and distal diaphysis from abnormal growth of the periosteum. As the cartilage grows, it undergoes endochondral ossification similar to that occurring at the physis. The developing exostosis, which is continuous with the cortex of the bone and surrounded by a cartilage cap, is called an osteochondroma.

Nixon et al. have reported on a series of cases in which exostoses of the palmar aspect of the closed physis were removed arthroscopically. In these cases, although they appeared similar to OC, they were histologically different.[91]

Clinical Signs

Affected horses often present with a history of intermittent lameness that increases with exercise. An obvious

VetBooks.ir

swelling of the carpal canal sheath cranial to the ulnaris lateralis is often present and may be visible medially or laterally on the limb (Figure 5.22). In some cases the swelling can be extensive. At exercise a moderate lameness graded 1–2 out of 5 is commonly observed.[112] Palpation of the caudodistal aspect of the radius with the limb held flexed at the carpus allows the examiner to feel the bony protuberance in some cases. Deep palpation of the site is often painful, resulting in limb withdrawal from the pressure. The range of carpal flexion is usually less than normal, and considerable pain is elicited with rapid carpal flexion. A carpal flexion test usually exacerbates the lameness.

Diagnosis

Radiography is necessary to diagnose the condition and its location. In most cases the OC is located on the caudomedial aspect of the distal radius adjacent to the physis; however, smaller OCs have been observed on the caudolateral aspect of the distal radius as well. Radiographically, these lesions appear as conically shaped bony protuberances with an outer cortex and inner medullary cavity (Figure 5.23). The size of the OC and degree of ossification are variable. Ultrasonography can also be used to determine the presence of deep digital flexor tendinitis.[121] Considering in racehorses associated flexor tendon damage is present in almost all cases, ultrasonographic examination is essential.[129] Intrathecal anesthesia is occasionally needed to confirm the clinical significance of the lesions.

Treatment

Although the instillation of corticosteroids into the tendon sheath temporarily resolves the tenosynovitis, the clinical signs usually reoccur.[121] Presently surgical excision of the OC is the treatment of choice and it is curative in most cases. Although excision of the OC via an open lateral or medial approach has been described,[47,63,70] the removal using an arthroscopic technique is currently recommended.[112,113,129] Both lateral and medial endoscopic approaches have been described; the author prefers the lateral approach. The exact technique can be found in other references.[81]

Prognosis

The prognosis for surgical excision of solitary OCs is good for return to performance. In one report, follow-up on two horses after 1 and 2 years found that the horses were free of lameness and no distention of the sheath was apparent.[112] In another report, follow-up 4 months after surgery found the horse to be free of lameness and no swelling in the carpal canal.[113] No lameness has been observed in two other cases at 4- and 12-year follow-up, and the bone excision sites remained nonreactive radiographically. Nixon et al. found that all 10 horses in their series of exostoses returned to intended use, with only 1 horse requiring additional medical therapy.[91] In yet another study in 22 Thoroughbred racehorses, all horses went back to work after surgical removal and debridement of soft tissue damage.[129]

DESMITIS OF THE ACCESSORY LIGAMENT (RADIAL OR SUPERIOR CHECK LIGAMENT) OF THE SUPERFICIAL DIGITAL FLEXOR TENDON

Etiology

The accessory ligament of the superficial digital flexor tendon (AL-SDFT) is a strong fibrous band that originates from the distal caudomedial surface of the radius and joins the SDFT at that level.[42] Until recently sprain to this structure has been poorly defined, and many conditions associated with the caudal aspect of the radius and carpus were attributed to this condition including (1) lowering of the angulation of the accessory carpal bone, (2) enthesophyte formation at the distal caudomedial aspect of the radius, (3) cranial displacement of the proximal end of the radius, and (4) alterations in the antebrachiocarpal (radiocarpal) joint capsule on its dorsal surface.[42,74]

Sprain of the AL-SDFT has been more clearly defined with the improvements in ultrasound resolution and the advent of MRI.[27,28] The condition occurs most commonly in young adult horses with a high level of physical activity. In a report on 23 horses with abnormal ultrasonographic findings in the AL-SDFT, 11 of 23 were racehorses, 9 of 11 were sport horses, and the remaining were pleasure or instruction horses.[28] Presumably, extreme hyperextension of the fetlock in conjunction with hyperextension of the carpus can cause a sprain of the AL-SDFT.[66,74]

Clinical Signs

Affected horses have a history of starting races and workouts quite well but are reluctant to really sprint out. Rarely do they attain their previous performance levels.[42,74] A visible swelling of the carpal sheath is observed in some cases. At a walk, a gait impediment characterized by a lateral floating placement of the foot just before it contacts the ground may be observed. The toe and heel are placed on the ground at the same time, much like a horse walking down an incline. In a review of 30 cases, this gait alteration was most commonly observed with radiographic lesions on the caudomedial distal aspect of the radius associated with the origin of the AL-SDFT.[42] In acute cases the carpal sheath is frequently distended and variably painful to digital palpation.[42] Simultaneous trauma to the SDFT may also occur, resulting in a painful swelling.[54]

Diagnosis

In acute cases, radiographs of the caudal aspect of the distal end of the radius are usually negative. However, in chronic cases, radiographs of the distal radius may reveal enthesophytes associated with the attachment of the AL-SDFT. Interestingly, in a study in which radiographs were taken on horses with abnormal ultrasonographic findings in AL-SDFT, only 4 of 18 had an abnormal profile at the caudal distal aspect of the radius, and 14 of 18 were considered normal.[27] This underscores the value of ultrasound examination in the diagnosis of desmitis of the AL-SDFT.

Ultrasound findings associated with injury of the AL-SDFT include thickening, hypoechoic defects, and alteration in fiber pattern alignment.[27] Injury to the AL-SDFT can also be accompanied by abnormal findings involving one or more of the structures in the carpal canal such as synovial effusion within the carpal sheath, tendinitis of the SDFT, distension and thickening of the retinaculum flexorum, tenosynovitis of the sheath of the tendon of the flexor carpi radialis muscle, and/or injury to the proximal attachment of the suspensory ligament (third interosseous muscle). Characterization of this additional damage is important for determining therapy and prognosis.

Treatment

In the acute cases exhibiting carpal sheath distension, needle drainage and the injection of a corticosteroid and hyaluronic acid are recommended.[27,28] Rest in a stall for 4–6 weeks is recommended with hand-walking exercise beginning at the third week. Systemic nonsteroidal anti-inflammatory drugs may be indicated for associated problems and are administered as needed. Pressure/support wraps are applied and maintained for 2–3 weeks. Following stall rest the horse should be confined to a small run for another 6 weeks. Recheck ultrasound examination should be done at this time to assess healing. Generally, affected horses can return to performance in 4–6 months.[28] Arthroscopic examination of the carpal canal can be performed to aid in characterization of the damage and treatment if necessary, and tenoscopic release of the carpal flexor retinaculum can be performed if needed.

Prognosis

The prognosis appears to depend on the severity of the injury, the intended use of the horse, and whether the SDFT is involved. In one study, 8 of 13 sport horses were able to return to their previous level of activity, whereas only 7 of 16 racehorses returned to racing at their previous level.[29] In another report, of eight horses suffering from injury to the AL-SDFT alone, without tendinitis of the SDFT, six returned to their previous level of performance within 4–6 months.[28] Tenoscopic release of the carpal flexor retinaculum has been useful for resolving lameness in two horses.[117]

THE ANTEBRACHIUM, ELBOW, AND HUMERUS

Jeremy Hubert

FRACTURES OF THE RADIUS

In an original retrospective study of radial fracture configurations, comminuted fractures were most common (21 of 47), followed by oblique fractures (12 of 47), transverse fractures (7 of 47), and physeal fractures (7 of 47). Open fractures usually involve the medial surface of the antebrachium, where there is minimal soft tissue coverage (Figures 5.24–5.26)[72] A more recent study of 54 cases of radial fractures reported that 24% were open and comminuted, 26% were incomplete or fissure fractures, and 50% were deemed repairable as oblique (10), transverse (7), Salter–Harris type II (5), spiral (3), and combined fractures of the radius and ulna.[78] Incomplete or fissure fractures are relatively common fractures of the radius; the majority of which occurred along the longitudinal plane.[20] Other uncommon radial fractures include stress fractures and smaller articular fractures involving either the proximal or distal articulation.[52] Radial stress fractures compose a small percentage of reported stress fractures. In a recent study of stress fractures in a racing Thoroughbred population, only 4.3% of stress fractures involved the radius.[53]

Figure 5.24. A complete oblique fracture of the radius extending from the mid-diaphysis to the metaphysis. *Source*: Courtesy of Dr. Andrew Lewis.

Etiology

Radial fractures usually result from a high-impact blunt trauma such as a kick from another horse. A controlled postmortem study to evaluate fracture configurations of the radius after a simulated kick on the medial aspect of the radius resulted in the majority of the bones sustaining a fissure fracture (incomplete fracture) that ran longitudinally along the diaphysis. The next most common configuration was an oblique fracture, sometimes with a fissure component, followed by a butterfly fragment fracture.[30] The medial aspect of the bone was chosen in the postmortem study to emulate the more common finding of a kick to the medial side; a smaller retrospective study of radial fractures revealed the

Figure 5.25. A cranial to caudal view of a distal diaphyseal comminuted fracture of the radius. *Source*: Courtesy of Dr. Martin Waselau.

VetBooks.ir

majority occurred from a kick to the medial aspect of the bone (Figure 5.26).[52] Age may play a role in fracture configuration; comminuted or butterfly fragment fractures are usually noted in older horses (older than 2 years), whereas simple oblique fractures occurred in younger horses. Transverse fractures were exclusive to foals less than 6 months of age (Figure 5.27).[72]

Clinical Signs

Horses with complete displaced fractures present with a non-weight-bearing lameness, varying degrees of swelling in the antebrachium, and instability associated with the fracture site. Crepitation may be felt and pain elicited when the distal limb is manipulated. Wounds and penetration of the skin from the fracture on the distal medial side of the antebrachium are common.

Horses that present with complete or incomplete nondisplaced fractures are usually very lame but are willing to bear some weight on the limb. Instability and crepitation are not present; however, there is usually some swelling of the antebrachium, and pressure applied to the region is often painful.[7] Wounds at the site of traumatic impact are often present on the medial distal aspect of the antebrachium (Figure 5.26).

Stress fractures are difficult to identify on physical signs alone. Horses generally present with a history of an acute onset of lameness that subsides with rest and reoccurs with exercise. Horses are often mildly lame at examination and shoulder flexion may worsen the lameness. These fractures can also occur bilaterally.[52]

Diagnosis

The presence of a displaced radial fracture is confirmed on radiographic examination. Several views are often needed to evaluate the configuration and extent of the fracture. Computerized tomography (CT) may be useful to help determine the ideal internal repair method if a complex comminuted fracture is to be assessed completely.

Acute nondisplaced fractures may be difficult to diagnose initially on radiographic exam. If a nondisplaced fracture is suspected, the horse should be cross-tied in a stall to prevent it from lying down, and repeat radiographs should be taken in 2–4 days. This time period usually allows recognition of the fracture lines. Alternatively, nuclear scintigraphy can be used to assist in the diagnosis.

Stress fractures are usually best diagnosed by nuclear scintigraphy where a focal increased uptake of the radionuclide in the midshaft of the radius is usually found (Figure 5.28).[52] Confirmation with radiography can be performed at a later date. Evidence of focal endosteal or periosteal reaction indicates a healing stress fracture that will correlate with the focal area of increased uptake. Alternatively, quantitative scintigraphy can be performed.[85] This enables the clinician to assess the degree of injury if there are no initial radiographic findings as well as later during the convalescent period when the quantitative findings can be used to accurately determine a date to return to training or work.

Treatment

First Aid

Immediate immobilization of a displaced radial fracture is very important (see musculoskeletal emergencies in Chapter 12). Appropriate attention to any open wound to address contamination and to reduce further soft tissue damage is necessary. With closed displaced fractures, application of appropriate external coaptation can prevent the fracture from becoming open. A heavy layered cotton bandage is firmly applied from the hoof to as far proximal on the antebrachium as possible. Two splints, one placed lateral and one placed caudal to the limb, with the lateral splint extending from the ground to the withers and the caudal splint extending from the ground to the olecranon process, is recommended.[10,93] Nonelastic adhesive tape or 1–2 rolls of fiberglass cast material are used to affix the splints to the bandage. The portion of the lateral splint that extends proximal to the bandage should contact the brachium when the limb is in a weight-bearing position.[90] This proximal application of the lateral splint provides counterpressure to prevent the limb from abducting with weight-bearing. This approach generally stabilizes the limb enough to allow the patient to be transported for treatment without running the risk of further injury to the fracture site.

Nondisplaced Fractures

Fractures that are nondisplaced or incomplete with minimal displacement are often candidates for conservative treatment. This involves stall confinement for up to 3–4 months.[7,20] It may be necessary to attach the horse to a wire to keep the horse from laying down to initially prevent catastrophic breakdown of the fracture. Horses should be closely watched for tolerance of being tied. NSAIDs are initially administered; these can be weaned off over time. Short hand walks can be initiated after 90 days. A total of at least 6 months before a return to intended use should be considered.

Displaced Fractures

Internal fixation of complete displaced fractures of the radius is the preferred method of treatment. The use of transfixation casts is generally considered for open contaminated fractures in which the chances of successful plate fixation are poor because of the risk of infection or when there are economic constraints. The application of a full-limb cast alone for displaced fractures of the radius is not acceptable in most cases because the humeroradial joint cannot be adequately immobilized. If a cast is applied, it frequently results in increased rotational forces on and movement at the fracture site. In addition, the more proximal the fracture, the greater the chances that the cast will cause a pendulum effect to the distal limb. This causes more tissue damage and results in a failure of the fracture to heal.[27] However, cast application alone has been used to successfully treat some distal radial fractures when there are economic constraints.

A combination of a full-limb cast and Thomas splint has also been recommended for some uncomplicated midshaft radius fractures in young horses.[27,67] Bandage splints have been used to treat a few horses with complete fractures of the distal radius. In one report, two horses with complete fractures (one nondisplaced, one displaced) involving the distal half of the radius were treated successfully with a modified Robert-Jones bandage with the addition of light strong splints.[68] Healing occurred in 14–16 weeks and both horses were able to return to usefulness.

A transfixation pin cast using positive profile, centrally threaded, one-fourth-inch stainless steel pins placed transcortically in a sagittal plane at 30° to each other is best suited for fractures in the distal third of the radius (Figure 5.29).

A single-plate application on the cranial or craniolateral surface is only recommended in foals less than 250 kg that have a transverse mid-diaphyseal fracture with an intact caudal cortex (Figure 5.30).[90] In foals, it is preferential not to bridge the physes and to not engage the ulna because it could result in elbow dysplasia and arthritis due to the differential growth rate of the ulna and radius.[79] Internal fixation in adult horses for displaced fractures generally has an unfavorable prognosis. In larger foals and adults, two plates are used: one is placed as a tension band on the cranial surface, and the other is placed as a neutralization plate on the lateral or medial surface 90° to the other plate (Figure 5.31).[5] The use of a 5-mm locking compression plate (LCP) or a dynamic condylar plate (DCP) as one of the plates is recommended.[47,90] In a report of 54 radial fractures, double plating was used in all adult horses. A variety of plates were used including DCP, limited contact dynamic compression plate (LC-DCP), dynamic condylar screw (DCS), or the LCP. Although there was no correlation as to what would be the best plate, these authors believed that the use of LCP would ultimately provide a better outcome based on the improved stability shown in

biomechanical testing. Plate luting with antimicrobial-impregnated PMMA and bone graft application is advisable[90] although in a recent study there was no correlation with grafting, antibiotic-impregnated PMMA, intravenous regional limb perfusion, and survival to discharge, but there was a correlation with surgical time.[78]

Physeal Fractures

Salter–Harris type I and II fractures of the proximal physis are encountered although infrequently (Figure 5.32). They may be accompanied by a fracture of the ulna, and a degree of radial nerve trauma may be encountered. Minimally displaced fractures may be treated conservatively in select foals (Figure 5.32). Repair generally involves a single-plate fixation of the ulna with the screws at the level of the proximal physis and lower, engaging the radius. A second plate can be placed laterally with the proximal screw in the physis, although this is usually unnecessary.[90] In smaller foals, the repair can be performed by transphyseal screws, and a wire fixation instead of a lateral plate can be placed alone. There is minimal growth from the proximal physis due to the damage, and luxation of the elbow joint is unlikely. Type III fractures that are nondisplaced are rested, whereas displaced type III fractures are repaired with screws placed in lag fashion in combination with a tension band application.[72,90]

VetBooks.ir

Figure 5.32. A Salter–Harris type II fracture of the proximal radius (arrow). This foal was treated conservatively.

Prognosis

Nondisplaced complete and incomplete fractures appear to have a good prognosis with conservative treatment.[7,20,68,78] Stress fractures of the radius are expected to have a good prognosis if adequately rested, similar to reported results of tibial and humeral stress fractures.[67]

The prognosis for displaced radial fractures depends on the age and weight of the horse, its temperament, and the fracture type. Although there are a few reports of successful treatment of displaced radial fractures with internal fixation in mature horses, most adult horses have an unfavorable prognosis for survival regardless of the treatment selected.[72,78,90] In one report on 47 cases of radial fractures, successful treatment (82%) only occurred in horses younger than 2 years of age with an overall rate of 64% survival to hospital discharge.[72] In the more recent report of 54 cases, the prognosis for survival to discharge for young horses with open reduction and internal fixation (ORIF) techniques was good but the converse was true for older horses with negative correlations associated with surgical site infection (SSI) and increased surgical time (>168 minutes).[78] In one retrospective study of horses weighing more than 300 kg presenting with radial fracture, 9 of 15 were treated with internal fixation, and only 2 horses were discharged from the hospital to resume their former activities.[5] Reasons for nonsurvival included primary implant failure, infection causing implant failure, and support limb laminitis. Comminuted fractures were associated with the highest incidence of fatal complications. In the more recent study, 27 horses underwent ORIF and 15 survived to hospital discharge (56%), of which only three were adult horses. Failure in the surgically managed adult horses was a result of SSI and resultant construct failure in 13.[78]

Displaced closed simple fractures of the radius in foals have a favorable prognosis. Physeal and transverse mid-diaphyseal fractures have an excellent prognosis. In one report, 2 of 2 foals with Salter–Harris type I and II proximal physeal fractures and 6 of 7 foals with mid-diaphyseal transverse fractures were treated successfully. Treatment of proximal oblique fractures in 3 of 4 foals also had an excellent outcome.[72]

THE ELBOW

Fractures of the Ulna

Ulna fractures are a relatively common fracture in younger horses. In a retrospective study of 49 ulnar fractures, 79% occurred in horses less than 2 years of age.[92]

Ulnar fractures are classified as types I through VI (Figure 5.33). Types I and II are Salter–Harris types, fracturing through the apophysis of the olecranon tuberosity in horses that are usually less than a year old. Type I is more common in neonates, whereas type II is more common in older foals. The incidence of these fractures is reduced as this physis closes, starting around 15 months of age. Types III through VI involve the diaphysis of the olecranon (Figure 5.34). In adults the fractures often involve the articular surface and are displaced due to contracture of the triceps apparatus.[19,21,24,92] Displacement is relative to the level of fracture on the ulna; fractures distal to the level of the elbow joint have less distraction due to the ligaments between the radius and ulna.

Etiology

Direct impact or trauma is the most common cause; however, in foals, type I and II fractures can occur from excessive tensile load of the triceps apparatus. Kick injuries appear to be a common cause of ulna fractures in adults and may be associated with wounds on the lateral aspect of the elbow.

Clinical Signs

Fractures of the ulna usually result in an acute non-weight-bearing lameness with a classic dropped elbow appearance (with the carpus flexed and the horse not bearing any weight on the limb). Nondisplaced fractures may initially show the dropped elbow appearance but will show progressive weight-bearing of the limb. Varying degrees of soft tissue swelling, crepitation, and skin wounds can be apparent. Limb manipulation is resisted, and efforts to get the horse to load the leg, even with a splint in place, are unsuccessful until the triceps apparatus has been repaired.

Diagnosis

Diagnosis is based upon the appearance of the horse, limb palpation, and radiographs. Differential diagnoses may include radial or humeral fractures, radial nerve

VetBooks.ir

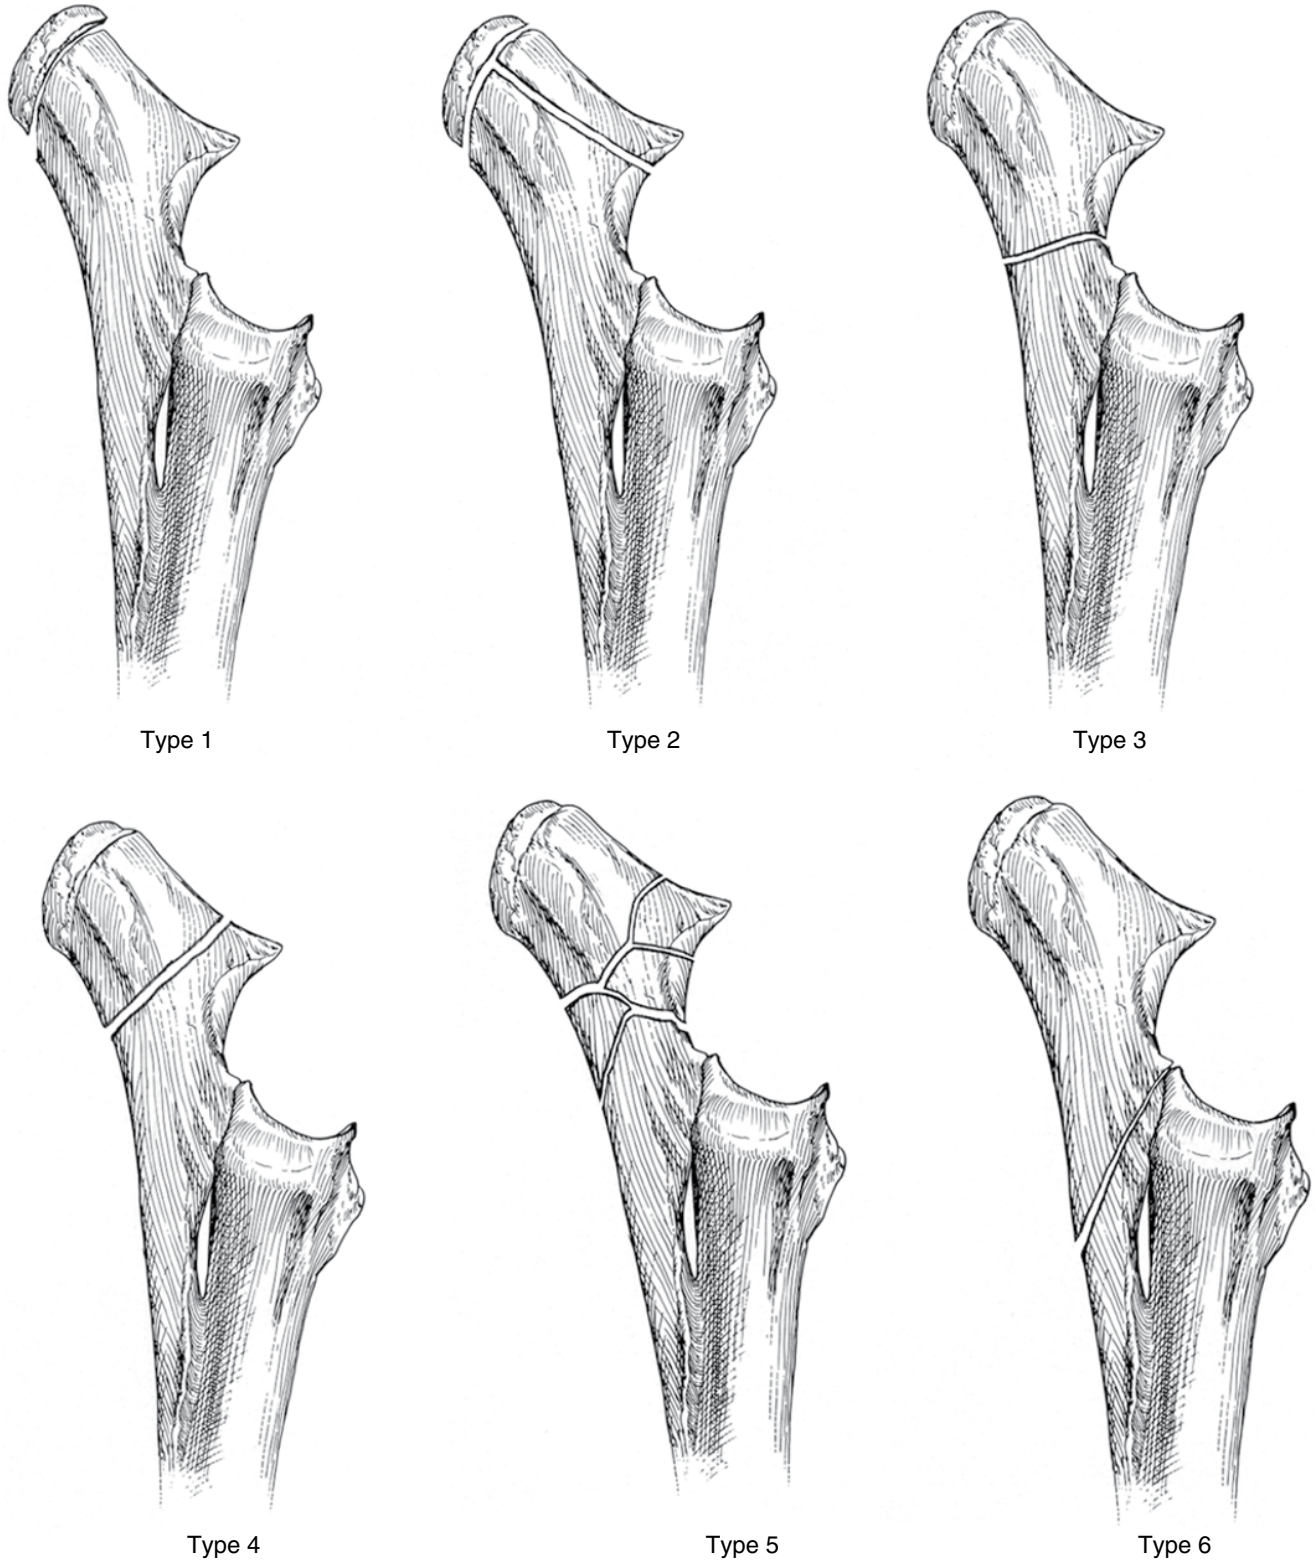

Figure 5.33. Classification of equine ulnar fractures.

paresis, or joint sepsis until a radiographic study has been performed. This should include lateral and craniocaudal views to provide the configuration of the fracture. In cases of a type I fracture in foals, it may be necessary to take a flexed view to provide distraction of the fragment to identify the fracture correctly.[69]

Treatment

Fracture cases that include nondisplaced, nonarticular ulna fractures or severely comminuted are candidates for conservative treatment (Figure 5.35). Horses with articular fractures with minimal displacement

VetBooks.ir

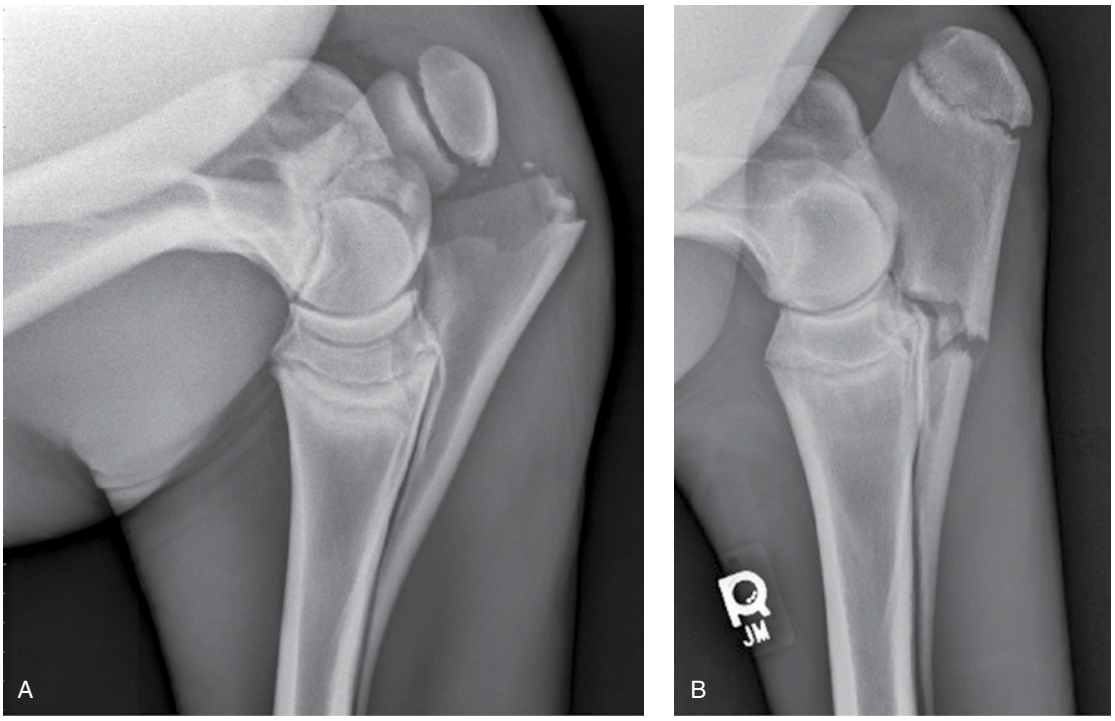

Figure 5.34. (A) Type III ulnar fracture. *Source*: Courtesy of Dr. Lori Gaschen. (B) Type VI ulnar fracture. *Source*: Courtesy of Dr. Martin Waselau.

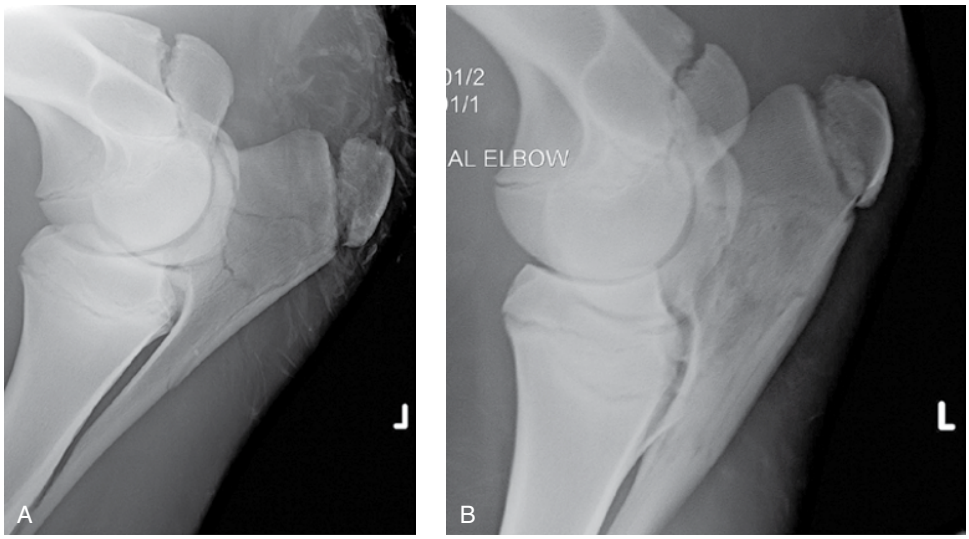

Figure 5.35. Comminuted ulna fracture in a young foal (A) that healed following conservative treatment (B).

also may be treated conservatively; however, better results are obtained with internal fixation to maintain joint congruity. Conservative treatment includes bandaging the limb with a caudal splint incorporated to the level of the proximal antebrachium (Figure 12.8). Complete stall rest is necessary, and a bandage and splint are maintained for at least 6 weeks or until a substantial improvement in the lameness is noted. NSAIDs are administered in the early stages. Repeated radiographic studies can be performed to ensure fracture healing and that progressive displacement is not occurring.[92]

Internal fixation of ulna fractures is performed in two basic manners. In young horses (younger than 6 months), the repair may be performed using a combination of screws, pins, and tension band wires, or plating (Figures 5.36 and 5.37). Distracted type I and II fractures require contouring the plate over the top of the olecranon. In younger foals a hook plate can be applied, or in even younger foals a tension band device with a pin or screw can be placed through the proximal epiphysis of the olecranon and a tension band wire applied and twisted about a screw placed caudally and distally in the ulna.[14,63]

VetBooks.ir

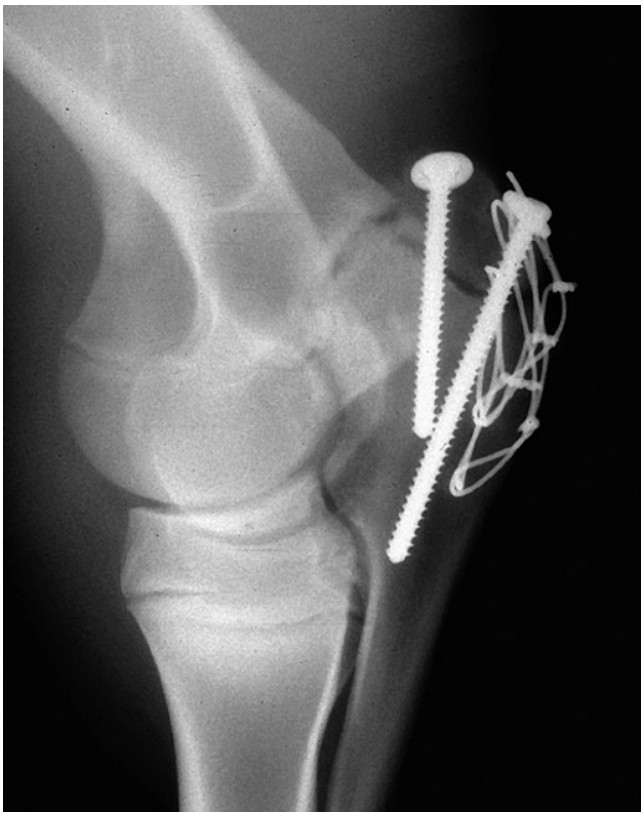

Figure 5.36. Two 4.5-mm cortical screws with washers and figure-8 wires used to create a tension band for a type I ulnar fracture. *Source*: Courtesy of Dr. Gary Baxter.

Figure 5.37. Type III ulnar fracture repaired with a narrow DCP applied to the caudal aspect of the ulna. The fracture was in an older horse; therefore, the distal screws penetrated the radius. *Source*: Courtesy of Dr. Katie Seabaugh.

In older horses, a caudal application of a plate using the tension band principle is necessary.[12,18,19,57] A controlled study of different repair types in adult cadaver limbs showed that DCP application was more biomechanically sound than pins and wires.[33] Plates are applied to the caudal aspect of the olecranon and ulna to counteract the tension of the triceps brachii muscle (Figure 5.37). The plate may be contoured over the top of the olecranon if the fracture is proximally located. Depending upon the size of the horse, a narrow or wide DCP can be applied; a broad DCP is applied in horses greater than 500 kg.[65] More recently the LCP has been used in repairs of the olecranon and may be indicated if possible.[37,47] In most adult horses the 4.5-mm-narrow LCP is likely to be adequate.

Prognosis

The prognosis for conservative management of nondisplaced fractures and nonarticular fracture types I and IV of the ulna is considered good.[92] Nondisplaced articular fractures, especially the type VI fracture, also respond well to conservative treatment. One retrospective study reported 70% of affected horses becoming sound.[92]

The prognosis for internal fixation of displaced types III, IV, V, and VI is also considered to be good.[19,21,24] Internal fixation of type I and II fractures in younger foals has a good prognosis when a hook plate is used, with 7 of 10 foals becoming athletes.[63] Type II fractures in young horses also do very well when repaired with DCP, with 16 out of 24 horses returning to athleticism.[81] In another study of pins and tension band wiring, 13 of 22 horses were reported to be athletically sound, and 18 fractures were considered to be repaired successfully.[61] In a recent prospective study using LCP in 16 horses with 18 fractures, complete fracture healing was achieved in 13 horses. Twelve fractures were type II and six type IV. Post-discharge complications of implant infection and lameness were resolved with implant removal.[37]

Luxation and Subluxation of the Elbow Joint

Subluxation or luxation of the radiohumeral joint with or without a concomitant fracture has been reported, although it is an uncommon injury.[17,42,71,73,82] Subluxation commonly occurs with rupture or partial tear of the medial collateral ligament.[76] Complete luxations often occur in conjunction with a fracture[46,82], but luxation without fracture has also been reported (Figure 5.38).[17,42]

Etiology

Severe, forceful limb abduction such as getting a leg caught in a fence is often associated with subluxations of the elbow, whereas severe falls have been reported to cause complete luxations.[17]

Clinical Signs

Swelling in the axilla of the affected side and a non-weight-bearing lameness are the commonly reported

VetBooks.ir

Figure 5.38. Luxation of the elbow joint with the humerus displaced medially. No fracture was present. *Source*: Reprinted with permission from Rubio-Martinez et al.[71]

signs for a subluxation. Palpation of the medial aspect of the joint and manipulation elicit a painful response, and limb instability may be noticeable. Signs associated with partial rupture of the medial collateral ligament may be less obvious because there is less inherent instability. Swelling may still be noticeable on the medial aspect of the joint. Joint effusion is usually noticeable laterally along with a grade 2–3 of 5 lameness. Flexion or abduction exacerbates the lameness.[76]

A complete luxation usually causes severe swelling and discomfort, with horses unable to bear weight nor extend their limb. This will not resolve until correct alignment and stabilization is established.[76]

Diagnosis

A definitive diagnosis is made with radiographic examination. Subluxation may require stressed views, and chronic cases may reveal evidence of osteoarthritis and an enthesiopathy of the medial collateral ligament. Stressed views are performed by manipulating the limb to exacerbate the subluxation, in this case by stabilizing the humerus and applying pressure to the radius in a medial or lateral direction.

Treatment

Closed reduction and conservative management has been achieved in select cases,[17,42] but more commonly, internal fixation is required because conservative management fails. Conservative management usually results in continued instability and resultant osteoarthritis.[42] Attempts to repair the collateral ligaments in complete luxations have been attempted.[71] Prosthetic collateral ligaments have been made by placing screws in the medial and lateral epicondyles of the distal humerus and the proximal tuberosities of the radius near the attachment of the collateral ligaments and wrapping surgical wire around them in a figure-8 pattern to emulate the ligament.[71]

Luxations in conjunction with an ulna fracture have been reported with no attempt to repair the collateral ligaments. The fracture was repaired with a broad DCP placed on the caudal surface of the ulna. Stability was attributed to the interdigitation of the three bones of the elbow joint.[82] With any repair attempt, significant distraction is necessary to aid the replacement of the luxation; in one case a small (1 cm) piece of the anconeal process was removed to assist in reduction.[71] Removal of the anconeal process should not affect prognosis.[2,39]

Prognosis

The prognosis for subluxation of the elbow appears to be guarded to unfavorable to return to performance, depending on the degree of injury to the medial collateral ligament.[76] Generally, a partial tear injury is expected to have a better prognosis, and some of these horses may be able to return to light work.

The prognosis for complete luxation is generally considered guarded[71,73,76]; however, there are at least two reports of repairs, and the horses were considered sound 6 and 14 months after surgery; the former horse had a concomitant ulna fracture.[17,82]

Subchondral Defects and Subchondral Cystic Lesions (SCLs) of the Elbow

Subchondral defects and subchondral cystic lesions (SCLs) of the elbow joint are uncommon, although they have been observed in a wide variety of horse breeds of all ages.[8,36,95] SCLs typically communicate with the joint, and they most commonly occur on the medial side, involving either the proximal medial radius or distal medial condyle of the humerus (Figure 5.39).[36] Although uncommon, SCLs can occur bilaterally.

Etiology

Proposed causes for subchondral defects and SCLs include osteochondrosis at a weight-bearing location in the joint and trauma. Trauma is perceived to occur by a concussive event, causing damage to the cartilage and subchondral bone plate, and the resultant pressure and presence of synovial fluid developing a cystic lesion.

Clinical Signs

Horses often present with a history of an acute onset of lameness that may wax and wane with use.[8,36] Palpation of the caudal aspect of the elbow joint capsule may reveal fluid distension and some thickening. Flexion and extension of the elbow region often elicits a painful response, and a flexion test usually exacerbates the

VetBooks.ir

lameness.[36] The size of the SCL or its location does not appear to influence the degree of lameness. Intrasynovial anesthesia eliminates the lameness in most cases.[8,36]

Diagnosis

Radiographs are required to make the diagnosis. In one study, 4 of 7 of the SCLs were located in the proximal medial radius, and 3 of 7 were located in the distal medial condyle of the humerus.[36] In another study, SCLs were located primarily in the proximal medial radius (5 of 6), and 1 of 6 was located in the distal medial condyle of the humerus.[8]

Treatment

Subchondral defects are generally treated conservatively, whereas SCLs can be treated either conservatively or surgically.[8,36,95] Both have been treated successfully with prolonged rest and NSAID administration.[36,95] Initially, rest with concurrent intrasynovial treatment of triamcinolone and hyaluronic acid may be indicated. If the lesions do not appear to be resolving or the lameness does not improve, surgical intervention may be advised. In one study of six horses with SCLs in which conservative (3 of 6) and surgical (3 of 6) treatments were compared, surgical extra-articular enucleation of the cyst provided better long-term success (determined by return to athletic function) with less evidence of osteoarthritis than conservative therapy.[8]

While extra-articular access of the cyst is the recommended surgical approach, a complete treatment via arthroscopic approach to this joint is limited due to the cyst location. Lesions located in the proximal radius are generally not amenable to an arthroscopic approach; however, lesions located in the medial or lateral humeral condyles may be accessed more easily arthroscopically. Often the lesions are visualized with the arthroscope, yet adequate debridement is difficult (Figure 5.39).[59] For a medially located lesion, the surgery is performed with the horse positioned in lateral recumbency with the affected limb down. Care is taken to identify but not disturb the neurovascular plexus, a known complication of this approach, and the humeroradial joint identified with needle placement. The relative location of the cyst is then identified radiographically; extra-articular osteostixis and/or arthroscopically guided intralesional or extra-articular steroid injection can be performed.

Prognosis

The prognosis appears to be good for conservative treatment of SCLs as long as there is no radiographic evidence of osteoarthritis. Supporting the conservative approach for the treatment of SCLs is one report in which 6 of 7 horses treated with rest and the administration of anti-inflammatory agents returned to their intended use.[36] Five of the six horses returned to intense athletic performance, four flat racing, and one barrel racing. The recommendations from this report were that nonsurgical treatment should be considered in horses without radiographic signs of osteoarthritis and that surgery could be considered as an option if the horse remains lame at the 90-day follow-up examination.

The outcome of surgery on three horses with SCLs resulted in 2 of the 3 returning to their intended use. The other horse sustained a comminuted fracture of the radius during recovery from anesthesia.[8] More recently, there is evidence that if accessible, injection of the cyst itself with triamcinolone has shown favorable results in other joints,[40,88] and there is one report of a successful elbow cyst injection.[29] Injection of the cyst with corticosteroids either via arthroscopic guidance or in an extra-articular manner is recommended if possible.

Bursitis of the Elbow (Olecranon Bursitis)

Historically shoe boil or capped elbow is regarded as a problem in draft breeds, but there are reports in a variety of horse breeds.[35,74] It may occur on one or both elbows and is a characteristic movable swelling over the point of the olecranon tuberosity, usually developing from trauma. The trauma results in a transudative fluid accumulating in the subcutaneous tissue, which becomes

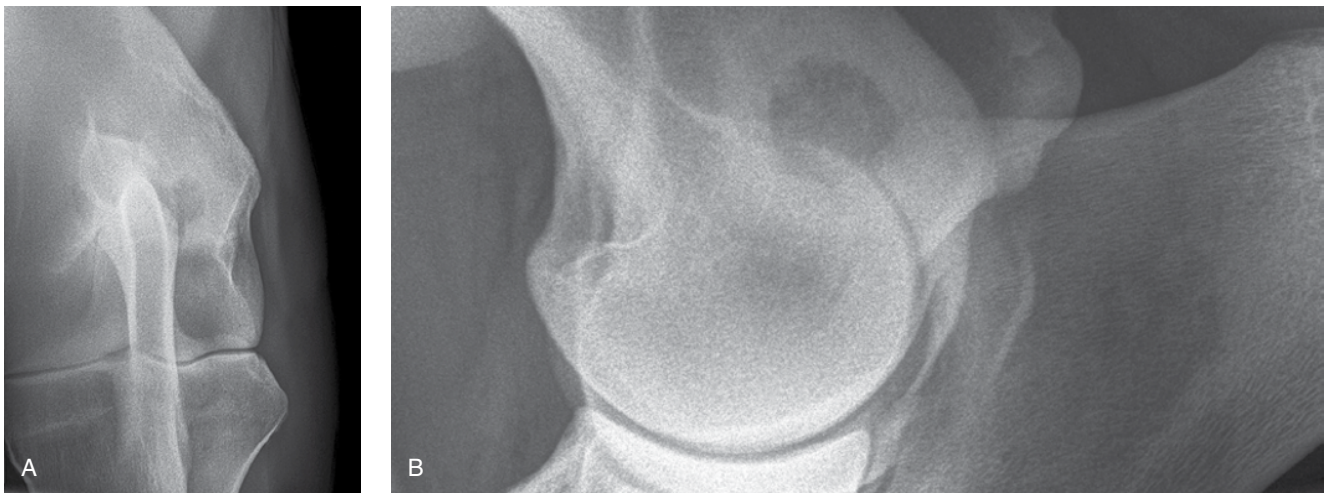

Figure 5.39. Subchondral cystic lesion located on the axial aspect of the lateral epicondyle of the radius demonstrated on cranial to caudal (A) and lateral (B) radiographic views. This cyst was observable arthroscopically. *Source*: Courtesy of Dr. Alanna Zantingh.

VetBooks.ir

encapsulated by fibrous tissue. Ultimately a synovial like membrane develops, producing fluid that is similar to joint fluid although it differs in viscosity and mucin clot.

Subsequently the chronic bursitis is characterized by the accumulation of bursal fluid and thickening of the bursal wall by fibrous tissue; fibrous bands and septa may develop in the bursal cavity, and the subcutaneous tissues around the bursa continue to thicken.[35] Bursal enlargement usually develops as a painless swelling that does not typically interfere with function unless it becomes greatly enlarged. In most cases, the acquired bursa is only a cosmetic blemish unless it becomes infected. An infected bursa is painful, causes lameness, and may break open to drain. The small true bursa that underlies the insertion of the triceps brachii muscle is rarely involved.

Etiology

Acquired bursitis is commonly caused by trauma from the shoe of the affected limb hitting the point of the elbow during motion or more commonly when the horse is lying down. American Saddlebreds and Standardbreds may hit their elbows during exercise. The bursae may become infected by a puncture or iatrogenically.[35]

Clinical Signs

The condition is characterized by a prominent, often freely movable swelling over the point of the elbow, which may contain fluid or may be composed primarily of fibrous tissue in the chronic stages. Lameness is usually not present unless the bursa is greatly enlarged or infected. Infected bursae feel warm, and firm pressure causes pain (Figure 5.40).

Figure 5.40. A chronic, infected, acquired capped elbow of the left forelimb. *Source*: Courtesy of Dr. Gary Baxter.

Diagnosis

The diagnosis can usually be made on physical findings alone. However, if the bursa appears infected, radiographs should be taken to rule out trauma or infection involving the olecranon process. If a draining tract is present, contrast material may be injected into the tract to identify its depth and course. Ultrasound can also be used to determine whether deeper structures are involved.

Treatment

In the acute stage, the condition may resolve by preventing further trauma to the region with a shoe boil roll or boot. The fluid can adjunctively be removed aseptically and corticosteroids injected after removal.[34,35] The lesion can be injected more than once. If the initiating cause is removed and the lesion is treated before extensive fibrosis occurs, it may resolve. However, in one report, 7 out of 10 horses were treated with intrabursal steroids, and none resolved.[35] Surgical intervention after lesion draining and injection is possible.[43]

There are reports of other substances such as strong 7% iodine being injected into affected bursae with varying success. Orgotein has been used, resulting in reduction but not resolution, as have short-lived radionuclides such as dysprosium-165.[35]

Surgical intervention either by placing drains or en bloc resection appears to have the greatest success.[34,35] Open drainage and application of Penrose drains and pressure bandages over periods of up to 8 weeks was successful in three horses.[87] En bloc resection is the treatment of choice for large and mature acquired olecranon bursae. Preferentially, the procedure is performed standing. Local anesthesia is administered and a curved skin incision is made over the lateral aspect. A plane of dissection is made to remove the mass in its entirety. Excess skin is removed as needed, and the skin is then closed in a tension-reducing manner such as widely placed vertical mattress sutures. A stent bandage is placed to protect the suture line and provide some compression. The horse can be maintained in cross-ties or an overhead wire until satisfactory healing is attained, usually 2–3 weeks.[35]

Prognosis

Conservative treatment of an acquired bursa to achieve acceptable cosmetic outcome is guarded. En bloc resection is regarded as a superior way to manage the lesion with good cosmesis.[34,35] In one report 5 out 6 horses resolved with primary healing after surgery.[75]

FRACTURES OF THE HUMERUS

Fractures of the humerus are relatively uncommon in horses, possibly because of the short, thick configuration of this bone and the prominent surrounding heavy musculature. The fracture can occur in horses of any age, breed, or sex, but most often affects foals less than 1 year of age, racing or race training Thoroughbreds, and horses that are used for jumping or steeplechase events.[14,55,60,96] In a study evaluating 54 horses with humeral fractures, the mean age for fracture occurrence

VetBooks.ir

was 3 years, and 28 of 54 (52%) were less than 6 months of age.[14]

Humeral fractures are classified as incomplete or complete, open or closed, simple or comminuted, and nondisplaced or displaced. Most are complete, closed, and displaced. Comminution occurs occasionally. Humeral fractures can also be classified by location: proximal humeral head (epiphysis and metaphysis in foals), greater tubercle, deltoid tuberosity, mid-diaphyseal, distal metaphyseal and epiphyseal, and distal condylar and epicondylar (Figures 5.41 and 5.42).[14,25,60,66,83,94] Most fractures are reported to involve the middle third of the diaphysis, either oblique or transverse or spiral configuration and almost never open (Figure 5.42).[11,56] A study on 54 horses with humeral fractures reported that 9 of 54 (17%) involved the physis (1 proximal and 8 distal), 8 of 54 (15%) occurred in the proximal metaphysis (4 oblique and 4 transverse), 11 of 54 (20.4%) were distal metaphyseal fractures, 26 of 54 (48%) were diaphyseal (2 short oblique, 4 transverse, 20 long oblique or spiral), and 1 of 54 was open.[14] In another study done on 22 horses with humeral fractures, 14 of 22 fractures were spiral in configuration.[96] Uncommonly foals will sustain multiple fractures involving the elbow region.[6,62] Fractures of the greater tubercle can involve either the caudal or cranial aspect[83,94] and occasionally are comminuted.[60]

Because of the large muscular attachments to the humerus, there is often considerable overriding with displaced fractures (the distal fragment being displaced

VetBooks.ir

caudad and the proximal fragment being displaced craniad). However, it is uncommon for proximal complete humeral fractures to become displaced because of the stability provided by the surrounding muscles (supraspinatus, infraspinatus, subscapularis, and deltoid), biceps tendinous insertions, and periarticular capsular attachments of the shoulder.[66] Incomplete stress fractures occur in two typical locations: the proximal caudal lateral cortex and the distal cranial medial cortex.[56]

The radial nerve courses in the musculospiral groove of the humerus and may be traumatized to varying degrees as a result of complete displaced diaphyseal or metaphyseal humeral fractures.[11,55] The damage may range from a minor neuropraxia to a complete severance of the nerve. Because of the profound effect on prognosis, it is important to evaluate the degree of nerve dysfunction early in the convalescent period.

Etiology

Humeral fractures frequently occur in foals, in weanlings secondary to falls or other impact injuries, and in racing breeds as either catastrophic failure during race falls or failure as a result of accumulated stress and microfracture.[11,56,60,96] In a study of 54 horses with humeral fractures, falls on hard surfaces or related to racing were responsible for fractures in 11 horses, kicks in 2 horses, post-anesthetic recovery in 2 horses, collisions with fences or another horse in 3 horses, and car collision in 1 horse.[14] Trauma is the cause of most fractures of the deltoid tuberosity or greater tubercle.[60]

Figure 5.43. Radial nerve paralysis, evidenced by the classic dropped elbow stance. This stance can also be seen in horses with ulna and humeral fractures, but accompanying soft tissue swelling is usually present. *Source*: Courtesy of Dr. Gary Baxter.

In an *in vitro* model, the configuration of the fracture was predictable and depended on the direction from which the insult originated. When the force was applied in a craniocaudal direction, the humerus fractured transversally; when the force was applied in lateral to medial direction, the humerus fractured obliquely.[56]

Horses sustaining stress fractures are at an increased risk to develop a complete fracture if they are not managed properly. A study of 34 Thoroughbred racehorses with humeral stress fractures found an increased risk of complete fracture in horses that returned to racing after a short 2-month lay-up period.[13] In one study that did not have any horses develop complete fractures during rehabilitation, the mean time to return to racing for horses with humeral fractures was 7.5 months.[67] Radiographic and scintigraphic reexamination allows for more accurate assessment of recovery.[85]

Clinical Signs

Horses with nondisplaced or minimally displaced proximal fractures (Salter–Harris type I epiphyseal, greater tubercle, or deltoid tuberosity) and nondisplaced midshaft fractures often present with a history of a severe lameness that improves over a 24- to 48-hour period. Moderate swelling may be present at the site of injury for a proximal fracture or over the lateral muscles for a midshaft fracture or even distal if a few days have passed. Pain is often present with pressure applied over the fracture and on limb manipulation. Radiography often provides a definitive diagnosis.

Incomplete fractures and stress fractures resulting in lameness can be most difficult to diagnose.[52,56,67,80,91] In some cases lameness and mild swelling may be adequate to lead to a tentative diagnosis of a fracture, but the definitive diagnosis often requires nuclear imaging.[67]

Horses with complete displaced fractures often present with a history of an acute onset of a severe nonweight-bearing lameness. Marked to moderate swelling of the muscles overlying the region is often seen, and the elbow is usually dropped (Figure 5.43). The dropped elbow may be due to the overriding of the fracture segments resulting in functional limb shortening or from the varying degrees of damage to the radial nerve.[14] Limb manipulation usually causes increased pain and an increased range of motion when the limb is adducted and abducted. Crepitation is often difficult to appreciate in heavily muscled horses, with the muffling effect of the swollen musculature. Limited manipulation should be done because it may result in further trauma to the radial nerve. Radiographs will identify the fracture, but evaluation of radial nerve damage is more difficult. Electromyography (EMG) of the antebrachial extensor muscles can be used after 2 weeks to evaluate radial nerve damage. In one study 4 of 40 horses treated for fractures of the humerus were destroyed because of loss of radial nerve function.[14]

Fractures of the distal epiphysis, condyles, and epicondylar region are very uncommon.[26,62,89] When they do occur, they often present with a history of marked lameness of a short duration. Swelling associated with the elbow region may be apparent, including joint effusion if the fracture is articular.

VetBooks.ir

Diagnosis

Radiography is used in most cases to confirm the fracture and define the configuration. A slightly oblique medial to lateral projection with the limb held in extension usually provides the information needed for epiphyseal and shaft fractures. In most cases the study can be done in the standing sedated horse. Foals can be restrained in lateral recumbency with the affected limb down to obtain a diagnostic lateral projection. Craniocaudal views of the distal humerus and oblique views of the proximal humerus can be obtained in most standing sedated horses and foals. Craniocaudal views of the entire proximal humerus are more difficult to obtain, and general anesthesia may be required.

Multiple radiographic views may be needed to identify fractures of the greater tubercle and deltoid tuberosity. Obtaining a cranioproximal to craniodistal oblique projection of the proximal portion of the humerus in a standing horse often highlights the long oblique fractures of the greater tubercle that are not evident on a mediolateral view.[60] In one study of deltoid tuberosity fractures, the authors noted a cranial 45° medial to caudolateral oblique view assisted in diagnosis.[28] In this study 86% of the fractures were identifiable with ultrasonography alone.

Horses with stress fractures often have a grade 3/5 lameness in the affected limb that improves quickly after the initial injury. Manipulation of the elbow and shoulder often exacerbates the lameness, yet diagnostic anesthesia is not useful.[67] A definitive diagnosis of stress injuries requires nuclear scintigraphic as well as radiographic examination. The caudodistal cortex or the caudoproximal cortices are most commonly affected, but fractures of the cranioproximal and craniodistal cortices also may occur.[4,52,67,80] Radiography may identify callus formation along the affected cortex in chronic cases. For more information on humeral stress fractures, refer to the section on Thoroughbred racehorses in Chapter 9.

Treatment

Currently three options are considered when managing a horse with a humeral fracture: nonsurgical (conservative) management with prolonged stall rest, surgical reduction followed by stabilization, and euthanasia.[11,14,55,66,80,84] Of the two treatment approaches, nonsurgical management appears to provide the best outcome compared with surgical approaches for most nonarticular incomplete or complete humeral fractures, no matter what the age of the horse (Figure 5.42).[14,96]

In one report, 7 of 10 horses treated nonsurgically were able to be ridden 5–12 months after the diagnosis was made, and only 1 of 3 surgically treated (2 rush pins, 1 lag screws) cases was considered sound for riding.[96] The ages of the horses that were treated nonsurgically ranged from 2 to 60 months (mean 21 months). In another study, conservative treatment resulted in 9 of 17 cases being considered successful; 4 became athletically sound and 5 were pasture sound.[14] The horses that were treated nonsurgically ranged in age from 1 week to 15 years (mean 3 years). Euthanasia still remains a commonly selected option. In a retrospective study done on 54 horses with humeral fractures, more horses were euthanized (44.4%) than treated with surgical (24%) or conservative (32%) management.[14] In another retrospective study, 9 of 22 humeral fracture cases were euthanized.[96]

Nonsurgical Management

Nonsurgical management has been used successfully to treat stress fractures; incomplete or complete nondisplaced or minimally displaced nonarticular fractures; minimally displaced Salter–Harris type I and II fractures of the proximal and distal physis; deltoid tuberosity fractures; complete displaced proximal and distal transverse and oblique fractures; and complete displaced diaphyseal transverse, short, and spiral oblique fractures.[14,28,56,66,96] In two reports a better outcome was obtained in foals compared with adults.[14,96] Long transverse and oblique fractures can be reasonably stable when the caudodistal aspect of the proximal fragment rests within the epicondylar groove. Shorter oblique fractures have less stability and usually require internal fixation. Contraction of the heavy musculature surrounding the humerus also helps stabilize the fracture while it heals. Of 19 cases of fracture of the deltoid tuberosity, local wound care alone resulted in a return to athletic function without lameness in 13 of the 14 available to follow-up.[28]

Nonsurgical management consists of 3–6 months' stall rest, with periodic radiographic or nuclear imaging reevaluation of the fracture for healing.[66,80] Initially, incomplete or complete nondisplaced fractures can be maintained on an overhead wire to minimize the chance of developing a complete fracture.[56,66,80]

Complications are not common but may include contralateral-limb laminitis and angular limb deformity, radial nerve damage, and nonunion.[14,96] No adverse effects attributable to shortening of the humerus, such as a shortened stride or a straightened elbow joint, were reported in successfully treated horses in these studies.

Surgical Management

Unfortunately, the current techniques of dynamic compression plating, intramedullary fixations, and cerclage bands or wires do not have sufficient strength to provide adequate stability in adult horses.[11,55,56]

Intramedullary pinning, bone plating, and ASIF or interlocking intramedullary nailing or rush pins have been used to successfully treat foals and ponies with humeral fractures.[14,15,23,66,91] Bone plates have been applied to repair nonarticular humeral fractures in foals and yearlings.[14,61,86] At present most reports describe the use of DCP or LC-DCP; there are few if any reports of the use of LCP for humeral repairs. The interlocking intramedullary pin has been used successfully in foals weighing up to 220 kg.[91] In larger foals a cranial plate is also applied to augment the reduction.

Unstable and extensive greater tubercle fractures of the proximal humerus may require removal or internal fixation with lag screws.[1,60,94] Extensive fractures of the deltoid tuberosity, although uncommon, also can involve the greater tubercle of the proximal humerus. Surgical intervention is required to reestablish cortical continuity of the bicipital groove and reestablish the tensional

VetBooks.ir

support of the tendinous insertions of the deltoid, brachiocephalicus, supraspinatus, and occasionally the infraspinatus muscles.[66] Generally all that is needed are 2–3 4.5- or 5.5-mm cortical or 6.5-mm cancellous screws placed in lag fashion that engage the transcortex.[23] This has been performed with success as a standing procedure.[54] In heavy horses a narrow DCP may be used to provide a tension band effect.[66]

Fractures of the condyles or epicondyles of the distal humerus occur infrequently in horses, but small articular fragments involving the condyles should be removed arthroscopically.[62,64] If the fragment is nonarticular, conservative therapy is considered.[26] More extensive fractures of the condyles or epicondylar region may require internal fixation with lag screws.

Prognosis

The prognosis for stress fractures, nondisplaced complete or incomplete fractures, or minimally displaced complete nonarticular fractures managed conservatively appears very good.[14,80,96]

The prognosis for complete displaced nonarticular fractures is guarded but appears better for horses managed conservatively. In one study in which conservative management was used in 17 horses, 9 (53.9%) were considered successful, 4 horses became athletically sound, and 5 horses became pasture sound; younger horses may do better.[14] In this same study, 13 horses were treated surgically with a variety of internal fixation methods; 3 of 13 horses survived and became athletically sound. The successful outcomes were all surgically treated with stacked pinning and all were young foals. In another study, conservative management was used in 10 horses, 7 of which were able to be ridden 5–12 months after the diagnosis was made.[96] The horses' ages in the successful group ranged from 2 to 60 months. Of the 3 horses treated surgically, 1 became pasture sound 10 months after surgery. The conclusion was that the best candidates for nonsurgical treatment are nonarticular humeral fractures with minimal displacement that involve the midshaft and are spiral and oblique with minimal overriding of the ends of the bone.

For fractures involving the greater tubercle and deltoid tuberosity, the prognosis appears good for conservative management of nondisplaced and surgically treated displaced greater tubercle and deltoid tuberosity fractures.[14,22,60] A recent report of 19 cases of treated conservatively resulted in 13 horses returning to athletic function with no lameness.[28] In one report, 9 out of 10 horses with greater tubercle fractures treated surgically returned to athletic use. Of these, 7 had the fragment removed and 2 had internal fixation.[60] There are few reports of epicondylar fractures, but in one case of a fracture of the epicondyle and supracondylar crest, the horse returned to athletic use after the fracture fragments were removed.[62]

NEOPLASTIC LESIONS OF THE HUMERUS

There have been several reports in the recent literature of both primary and metastatic bone tumors in the proximal humerus of the horse.[16,38,44] These lesions remind the clinician to consider neoplasia as a differential diagnosis as a cause of lameness.

Primary osteosarcoma has been diagnosed and described in an adult Quarter horse mare.[44] Chronic significant and progressive lameness was noted; discomfort was isolated by palpation to the scapulohumeral joint. Arthrocentesis was normal and diagnostic analgesia was uneventful. Radiographs revealed an aggressive bone lesion in the proximal humerus. Euthanasia was elected due to the poor prognosis and lack of improvement despite therapy. Histological examination provided a definitive diagnosis. Osteosarcoma is rarely reported in the horse and when so more frequently in the head.[49]

A primary hemangiosarcoma was diagnosed in an 11-year-old Clydesdale gelding.[16] Local palpation of the proximal humerus revealed discomfort and diagnostic analgesia was unhelpful. In this case nuclear scintigraphy was performed, resulting in significant uptake of isotope in the proximal humerus. Radiographs revealed a radiolucent area with areas of sclerosis and some irregular new bone formation. Bone biopsies were performed but considered non-diagnostic. A definitive diagnosis was made after histopathological examination of the tissue subsequent to euthanasia. Hemangiosarcoma has been reported in the horse;[41] however, in this report only one of 11 cases was reported to be involving bone in a limb.

Metastatic lesions in the bone from intestinal adenocarcinomas are unusual and reported in a horse with lameness associated with sequestrum formation and a pathologic fracture.[38] A tentative diagnosis of osteomyelitis had been provided, but postmortem histopathology provided a definitive diagnosis of metastatic adenocarcinoma with primary lesions in the colon.

PARALYSIS OF THE RADIAL NERVE

Paralysis of the radial nerve as a primary cause of lameness is an uncommon condition that results in the inability to extend the elbow, carpus, and digit. Similar dysfunction may also be observed with other conditions involving the upper forelimb; therefore, differentiation can be difficult, particularly shortly after injury occurs.

The radial nerve, often the largest branch of the brachial plexus, derives its origin chiefly from the eighth cervical and first thoracic nerve roots of the plexus. In 10% of horses the seventh cervical nerve root contributes to the radial nerve.[32] The radial nerve innervates the extensor muscles of the elbow, carpus, and digit and supplies the lateral flexor of the carpus (ulnaris lateralis). Paralysis of the radial nerve inactivates these muscles.

Etiology

In most cases, paralysis of the radial nerve is due to trauma of the shoulder region caused by hyperextension of the forelimb or extreme abduction of the shoulder.[70] Fractures of the humerus, the seventh cervical, and first thoracic vertebrae can all result in radial nerve paralysis.[50] Tumors, abscesses, and enlarged axillary lymph nodes that occur in the cranial thoracic region along the course of the nerve and tumors of the brachial plexus and radial nerve themselves may also result in radial

VetBooks.ir

nerve paralysis.[58] There have been isolated reports of radial nerve paralysis included in a generalized distal axonopathy.[31]

Prolonged lateral recumbency while under general anesthesia on an operating table or while on the ground may also produce a radial-paralysis-like syndrome in the forelimb.[48,51] Episodes of ischemia are likely to cause neuropractic conduction changes and permanent nerve changes if prolonged.[51]

Clinical Signs

The signs vary depending upon the extent or degree and location of paralysis. When the portion of the radial nerve supplying the extensors of the digit is affected, the signs are characteristic. In the acute phase the horse is unable to bear weight because of the inability to extend the elbow, carpal, and phalangeal joints. If the limb is placed under the horse and fixed in place, it can bear weight passively.[70] While the horse is standing, the shoulder is extended and the elbow is dropped (dropped elbow appearance) and extended while the carpus and digits are flexed. The muscles of the elbow and the extensors of the carpus and digit appear relaxed, and the limb appears longer than normal. The "dropped elbow" appearance is not specific for radial nerve paralysis; this appearance can be seen with many other conditions associated with the elbow, humerus, and shoulder regions (Figure 5.43). Occasionally, radial nerve paralysis is accompanied by paralysis of the entire brachial plexus. In this case, the limb shows paralysis of the flexor and extensor muscles and is unable to bear weight.

With complete radial nerve paresis, the horse is generally reluctant to move, and at a walk the limb is dragged forward passively by the action of the proximal pectoral, biceps brachii, and coracobrachialis muscles, with the dorsal surface of the hoof in contact with the ground. Due to the physical distress associated with radial nerve paralysis, some horses may sweat profusely and have an elevated pulse and respiration.[70] Milder cases of radial nerve paralysis present with varying degrees of non-weight-bearing lameness and a dropped elbow with mild flexion of the carpal, fetlock, and phalangeal joints. At a walk the lameness is often characterized by a lowered foot flight arch and a shortened cranial phase of the stride.[15]

Diagnosis

Many cases of radial paralysis are due to external trauma; therefore, the scapula, humerus, radius, and olecranon process should be examined radiographically.[58] Radial nerve paralysis must be further differentiated from rupture of the medial collateral ligament of the elbow, elbow arthritis, and myopathy of the biceps brachii, triceps brachii, anconeus, and extensor carpi radialis muscles.[70]

It previously was believed that cutaneous sensation to the craniolateral aspect of the antebrachium is lost with complete loss of nerve conduction of the radial nerve or brachial plexus and that if the sensation is present, it indicates the lesion selectively affects the motor fibers.[70] However, studies done in horses indicate there are no areas of skin innervated only by either the radial or the axillary nerves—the ulnar, median, and musculocutaneous nerves can be related to such areas.[9]

Electrophysiological studies can be helpful in characterizing the extent of nerve damage and can be used to determine selective denervation of the extensor muscles. However, because it takes approximately 7 days for the axon distal to the site of the damage to degenerate, EMG done before this time has limited usefulness.[3] Alternatively, faradic stimulation done 7 days after clinical signs develop can be used to differentiate between neuropraxia and axonotmesis or neurotmesis.[70] Radiography, ultrasonography, and laboratory analysis of muscle enzymes may be needed in some cases to make an accurate diagnosis of radial nerve paralysis.

Treatment

Treatment consists of systemic and local anti-inflammatory therapy, stall rest, application of a bandage splint, and controlled exercise. A PVC bandage splint applied to the caudal aspect of the limb from the proximal antebrachium to the fetlock will maintain the limb in extension, permitting the horse to bear weight comfortably. The splint is maintained until the horse can place the limb in extension without support. Controlled exercise can be started when clinical signs (neurologic function) begin to improve. The amount of exercise is dictated by the horses' capabilities. Electromyographic studies can be done at 4- to 6-week intervals to access return of nerve function.

Prognosis

EMG has been found to have a good prognostic value in assessing the extent of the injury in a small number of cases.[15] In most cases a guarded to poor prognosis is given,[15,45] but compression and entrapment injuries often lead to partial or complete recovery.[77] Recovery may take a few weeks in pure neuropraxia to several months or years in axonotmesis.[45,58] Reinnervation is, however, unlikely with more severe nerve damage.[15]

ACKNOWLEDGMENT

The authors thank Dr. Ted S. Stashak for his contributions to this chapter in the previous edition.

THE SHOULDER AND SCAPULA

JEREMY HUBERT

VetBooks.ir

INFLAMMATION OF THE INTERTUBERCULAR BURSA (BICIPITAL BURSITIS)

Inflammation of the intertubercular (bicipital) bursa as a primary cause of lameness is uncommon, even though the condition can occur in horses of any age, breed, or sex.[11,42,48] In 2 reports the condition was responsible for lameness in 1 of 54 and 1 of 41 horses suspected of having shoulder lameness.[40,64]

The bicipital bursa is located between the bilobed tendon of the origin of biceps brachii muscle and the tubercles at the cranioproximal aspect of the humerus. The synovial membrane of the bursa extends around the axial and abaxial limits of the tendon and onto the margins of its cranial surface. Although uncommon, communication can exist between the shoulder joint and the bicipital bursa.

Etiology

Trauma to the cranial surface of the shoulder region is believed to be the most common cause of a primary bursitis.[11,40,48,97] Other suggested causes include stretching or tearing of the bursa or biceps tendon during the cranial phase of the stride with the limb in full extension or by a fall or slip that results in flexion of the shoulder with extension of the elbow.[80,95] Inflammation of this bursa can also be caused by dislocation of the biceps brachii tendon that may be associated with congenital hypoplasia of the minor tubercle.[25,51,66] Proximal humeral subchondral bone cysts adjacent to the intertubercular groove of the bicipital bursa may cause local inflammation,[59] and such cysts have been reported to be infected.[45]

Infection either from an open or penetrating wound or from hematogenous spread to the bursa has also been reported.[40,79,97] Cases of septic bursitis concurrent with septic tendinitis and arthritis of the scapulohumeral joint or bursitis with associated tendinitis and humeral osteitis have been reported.[43,44]

Clinical Signs

A history of trauma to the shoulder region is the most common factor; the signs of lameness usually have an acute onset that is most obvious during the stance and swing phases of the stride. On physical examination swelling over the cranial aspect of the shoulder region may be evident with or without a wound being present. Generalized shoulder and pectoral muscle atrophy may be seen in more chronic cases.[40,48,97] Pressure applied over the biceps tendon and bursal region and manipulation of the shoulder region in flexion and extension usually result in a prominent painful response (Figure 5.44). The responses to pressure and limb manipulation should be compared with those found on the contralateral unaffected limb.[48]

The lameness is often obvious. At exercise, a lameness of 3–4 out of 5 is generally seen (greater if septic), with the swing and stance phases being altered. The lameness is often characterized by a shortened cranial phase of the stride, a decrease in the height of the foot flight arc, reduced carpal flexion, and a fixed shoulder appearance during movement. The horse is often reluctant to bear full weight on the affected limb while standing.[48]

Diagnosis

Radiographs of the shoulder and ultrasound examination are performed if the physical examination localizes the pain causing lameness to the bursal region. Manipulation of the elbow into hyperextension may stress the biceps brachii tendon, helping to localize the lesion.[70] However, if the localizing signs are not obvious, bursitis is confirmed by centesis and local anesthesia of the bursa. A proximal approach to the bursa is considered to be the most successful for bursal centesis.[88] This technique is further improved by extending the scapulohumeral joint. The radius is held in a plane parallel to the bearing surface, and a 9-cm 18-g spinal needle inserted parallel to the ground into the lateral portion of the intertubercular groove. This procedure was more likely to access the bursa in the standing horse (Figure 5.45).[24] However, ultrasound-guided centesis has been demonstrated to be superior for reliably accessing the bursa.[85]

Radiographs of the shoulder region are taken to identify any osseous changes in the tubercles or bicipital groove or bursa and to rule out the possibility of fractures of the supraglenoid tuberosity or proximal humerus or ossification of the biceps tendon

Figure 5.44. As the shoulder is flexed, tension is created in the tendon of the biceps brachii muscle. If the horse has bicipital bursitis or ossification of the tendon, a painful response is elicited.

VetBooks.ir

(Figures 5.46 and 5.47).[11,40,48,75,97] Generally, only mediolateral, craniomedial to caudolateral oblique, and flexed cranioproximal to craniodistal (skyline) radiographs are taken in adult horses.[48,58] A cranioproximal to craniodistal oblique view is useful when the tubercles are thought to be involved.[78] Radiographs may appear normal if the disease only involves the bursa. If a wound or draining tract is present, centesis with contrast material assesses communication with the bursa.

Ultrasound examination of the biceps tendon, bursa, and bicipital groove can be very informative, even when radiographs appear normal (Figure 5.48).[17,49,77,78] Ultrasound changes associated with bursitis have included edema or hemorrhage in the biceps tendon or bursa, disruption of the tendon architecture with peritendinous thickening, an irregular surface of the bicipital groove, and hyperechoic material in the bicipital bursa.[26,97] Infection must be ruled out if hyperechoic material is seen in the bursa.[97] Nuclear medicine may be useful in some cases to detect early infected or actively remodeling bone adjacent to the bursal region when ultrasound and radiography appear normal.[48,78]

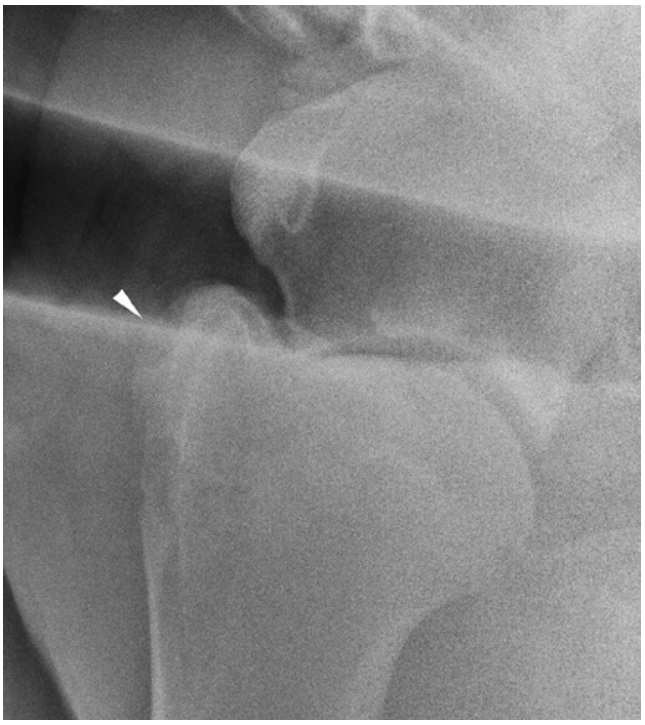

Figure 5.46. Osseous changes on the tubercles of the cranioproximal humerus (arrowhead). Infiltration of lidocaine into the bursa resolved the lameness in this case.

Treatment

Conservative Treatment

Noninfectious bursitis without radiographic evidence of a fracture or pathology on the cranioproximal aspect of the humerus may respond favorably to rest, parenteral and/or topical administration of nonsteroidal anti-inflammatory drugs (NSAIDs), and in some cases intrasynovial injection of the bursa with corticoids and hyaluronic acid (HA).[40,42,59,81]

The duration of rest generally depends on the nature of the injury, the patient's clinical response to rest, and whether or not the biceps tendon was damaged. NSAIDs

VetBooks.ir

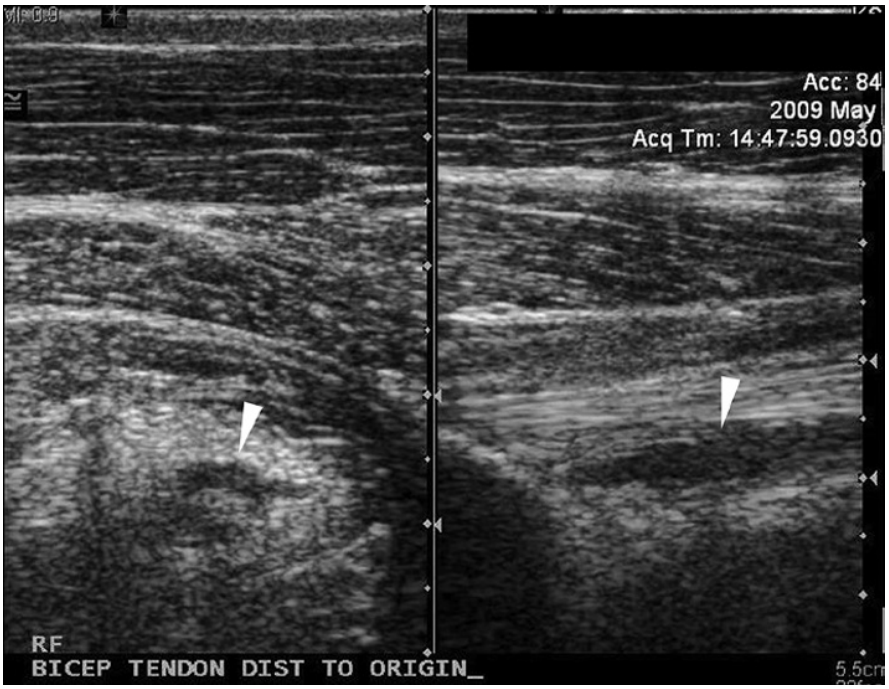

Figure 5.48. Core lesion of the medial branch of the biceps tendon just distal to the origin of the biceps brachii muscle (arrowheads).

are generally administered for 10–14 days and hand-walking exercise is begun after that. Manipulating the limb passively through a range of motion may also be helpful.[40,42,48,81] When the tendon has been injured, rest periods for up to 3 months followed by paddock rest for another 3 months may be required to allow healing of the tendon.

When the tendon has ossified, extracorporeal shock-wave therapy (ESWT) may be indicated. In humans, calcifying tendinitis is commonly treated with ESWT[46,61,82] and has been used with fair success in horses with calcifying tenopathies of the deep digital flexor tendon.[84] Additional therapy could include stem cells, IRAP, and PRP therapy, depending upon the lesion. ESWT applied to tendon lesions is still controversial; however, anecdotal reports appear to be encouraging.[18] In these horses, controlled exercise was begun as early as possible, generally after 2–3 weeks of confinement to improve range of motion and healing. The patient's clinical response and ultrasound findings should be used to determine progress in healing.

Surgical Treatment

Bursitis that results from a displaced fracture, from osseous changes associated with the proximocranial aspect of the humerus, or from sepsis generally requires surgery to resolve the problem. Incisional as well as endoscopic approaches to the intertubercular bursa have been used and described.[4,11,40,48,94] If a fracture is present, the fragment is removed, and the bed debrided and smoothed.[48] Controlled exercise as described for the conservative approach is begun at the time of suture removal in most cases.

In cases in which infection appears to be the cause, centesis of the bursa should be done to collect fluid for culture and cytology. Next, the bursa should be drained and then debrided and lavaged copiously under arthroscopic guidance followed by therapies aimed at treating infected synovial cavities[94] Controlled exercise and moving the affected limb through a passive range of motion are advocated to reduce restrictive adhesion formation.[11]

In cases where an osseous cyst is detected within the intertubercular groove of the proximal humerus, arthroscopic surgical debridement is recommended.[7,45]

Prognosis

Acute cases of nonseptic bursitis when a fracture is not the cause often respond favorably to conservative treatment.[58] Conservative therapy for more chronic cases of nonseptic bursitis appears less satisfactory.[11,40,48,97] In one report of 3 horses with chronic nonseptic bicipital bursitis that were treated surgically, all became pasture sound.[48]

Horses with chronic septic bursitis cases treated conservatively have a poor prognosis for return to performance, and surgery is usually recommended. Surgical intervention with debridement, lavage, and appropriate antimicrobial therapy and rest gives a favorable prognosis.[40,43–45,64,79,97]

A small case series described five cases of osseous cyst-like lesions in the lateral intertubercular groove of the proximal humerus that were treated successfully with corticosteroid and HA.[59] Likewise a report of endoscopic or open debridement of such lesions resulted in a favorable outcome.[7,45]

INFLAMMATION OF THE INFRASPINATUS BURSA

The infraspinatus bursa is located between the tendon of the infraspinatus muscle and the caudal eminence of the greater tubercle of the proximal humerus. The bursa

VetBooks.ir

is not visible in most horses except when inflamed or septic.[80] This is an uncommonly reported cause of lameness.

Etiology

Severe adduction of the forelimb and/or the possibility of direct trauma to this region is considered to be the cause (Figure 5.49).[80,99]

Clinical Signs

The involved forelimb may be held in an abducted position, presumably in an attempt to reduce the pressure on the infraspinatus bursa. During exercise, a moderate lameness is present with an obvious decreased cranial stride.[80,99] Adduction of the limb reportedly elicits a painful response and results in increased signs of lameness at exercise (Figure 5.50).[80] If the bursa is septic, the lameness exhibited is usually severe.[99]

Diagnosis

Ultrasonographic evaluation and comparison with the opposite limb may be required, along with ultrasound-guided centesis[85] and local analgesia, for a definitive diagnosis.[99]

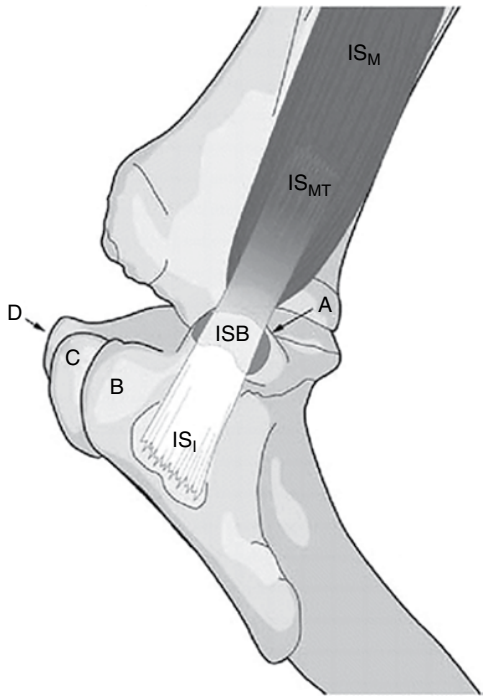

Figure 5.49. This line drawing illustrates the location of the infraspinatus bursa underlying the infraspinatus tendon. A, caudal eminence of greater tubercle (GT); B, cranial eminence of the GT; C, intermediate tubercle; D, lesser tubercle; ISM, infraspinatus muscle; ISMT, musculotendinous junction of the infraspinatus muscle; ISI, infraspinatus tendon insertion; ISB, infraspinatus bursa. *Source*: Reprinted with permission from Whitcomb et al.[99].

Treatment

In the acute stage, synoviocentesis and the administration of corticosteroids into the bursa are recommended. With sufficient stall rest (6 weeks or more) and the parenteral administration of NSAIDs, a good end result can be expected. Varying degrees of lameness may remain with chronic cases.[80] Septic involvement of the bursa requires endoscopic debridement and flushing. The initial distension of the bursa may require distension with fluid by ultrasonographic guidance to place the needle. The bursa is small and movement of instruments is restricted by the overlying muscle and infraspinatus tendon.[99]

Prognosis

In one report 3 horses returned to soundness after surgical treatment of septic infraspinatus bursitis.[99]

OSTEOCHONDROSIS (OC) OF THE SCAPULOHUMERAL (SH) JOINT OR SHOULDER

Osteochondrosis (OC) of the scapulohumeral joint or shoulder is most frequently diagnosed in weanlings and yearlings 6–12 months of age, but it has been reported in foals younger than 5 months and in horses up to 8 years old.[29,38,52,54,65,67,72–74] The incidence of the disease varies; one study reported diagnosing OC of the shoulder in 54 joints of 38 young horses radiographed for shoulder problems,[74] and in another study OC and subchondral bone cysts were observed in 6 of 29 diagnosed shoulder problems.[38] The condition is considered the most debilitating form of osteochondritis dissecans (OCD), and when it is diagnosed in older yearlings, chronic manifestation of secondary degenerative joint changes is usually present.[74]

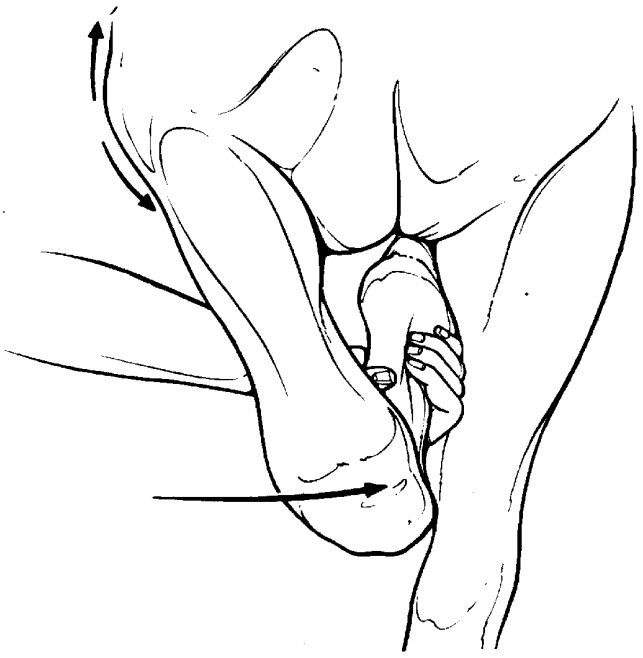

Figure 5.50. Adduction of the limb may result in a painful response in horses with infraspinatus bursitis.

VetBooks.ir

The primary cartilage lesion is located in the glenoid, humeral head, or both (most common), and the disease often affects a major part of the joint surface.[74] Regardless of the site of the lesion, secondary degenerative changes in the joint are prominent features of this disease. An exception is the solitary subchondral cystic lesions that are occasionally seen in the glenoid cavity.[38,54]

Etiology

Overnutrition, imbalanced nutrition, and a genetic predisposition to rapid growth at some stage of the development still appear to be reasonable hypotheses for most young affected horses. The secondary degenerative changes within the joint are exacerbated by the resultant instability.[74]

Occasionally, subchondral bone cysts are seen in the glenoid without cartilage changes in the humeral head, alterations of the contour of the articulations of the shoulder, or signs of secondary osteoarthritis.[38,54] Thus, it has been suggested that subchondral bone cysts may not be a manifestation of OC in the scapulohumeral (SH) joint.[40] A traumatic etiology is often suspected in such cases of subchondral bone cysts.[54]

Clinical Signs

Most horses present with a history of mild to moderate intermittent forelimb lameness with insidious onset. Atrophy of the muscles associated with the shoulder region is a common finding in chronic cases. A smaller foot with a higher heel and excessive toe wear is also commonly observed in the foot of the affected limb. Direct firm pressure with the thumb just cranial to the tendon of the infraspinatus muscle over the cranial lateral aspect of the shoulder joint may elicit a painful response, particularly in younger horses (Figure 5.51).

Exercise usually results in a moderate to severe lameness that is characterized by a shortened cranial (extension) phase of the stride and a delay in limb protraction. Stumbling may occur in some cases due to inadequate foot clearance. A prominent shoulder lift, reduced carpal flexion, and limb circumduction are often seen in the most severely affected horses. Manipulation of the affected limb in extension and flexion and abduction may cause pain and often increases the signs of lameness. Intrasynovial anesthesia is used to localize the lameness to the shoulder region; 10–15 mL of a local anesthetic should improve or eliminate the lameness in most cases.[38]

Diagnosis

Radiographs are necessary to definitively diagnose the OC lesion. The most common radiographic findings include:

1. Flattening and indentation of the caudal aspect of the humeral head
2. Alterations in the contour of the glenoid cavity with a subchondral cystic radiolucency
3. Osteophytes at the caudal and cranial aspect of the glenoid cavity (Figure 5.52)
4. Subchondral bone sclerosis

Figure 5.51. Thumb pressure applied just cranial to the infraspinatus tendon may elicit a painful response in horses with shoulder osteochondrosis.

5. Remodeling of the humeral head and glenoid cavity (Figure 5.52)[67]

Less common findings include osteophytes and subchondral bone cysts associated with the humeral head.[74] Intra-articular free bodies are uncommon, but when present they settle in the cranial and caudal cul-de-sacs of the joint.[72] Centrally located glenoid sclerosis and small glenoid cysts can easily be overlooked.[32]

The normal ultrasonographic anatomy of the SH joint has been described, and humeral head OC has been diagnosed using ultrasonography; however, the evaluation of the glenoid is difficult.[92] Nuclear scintigraphy may be used to identify subtle lesions.[32,54]

Arthroscopy may be useful to make a definitive diagnosis in cases in which the lameness is localized to the SH joint with intrasynovial anesthesia but a lesion is not identified on radiography or scintigraphy. The conclusions drawn in one retrospective study of 15 horses with subtle osteochondral lesions in the SH joint suggested that a combination of the physical examination, radiology, scintigraphy, and arthroscopy may be necessary to diagnose subtle osteochondral lesions of the SH joint.[32]

Treatment

Rest and confinement may be considered for horses with mild to moderate radiographic changes that are not intended for athletic performance.[52,67,74] Of the 17 horses treated with rest, the treatment was considered moderately successful in 7 cases.[74] In another case series of 3 horses with isolated subchondral cysts in the glenoid, HA was injected into the affected joint with

VetBooks.ir

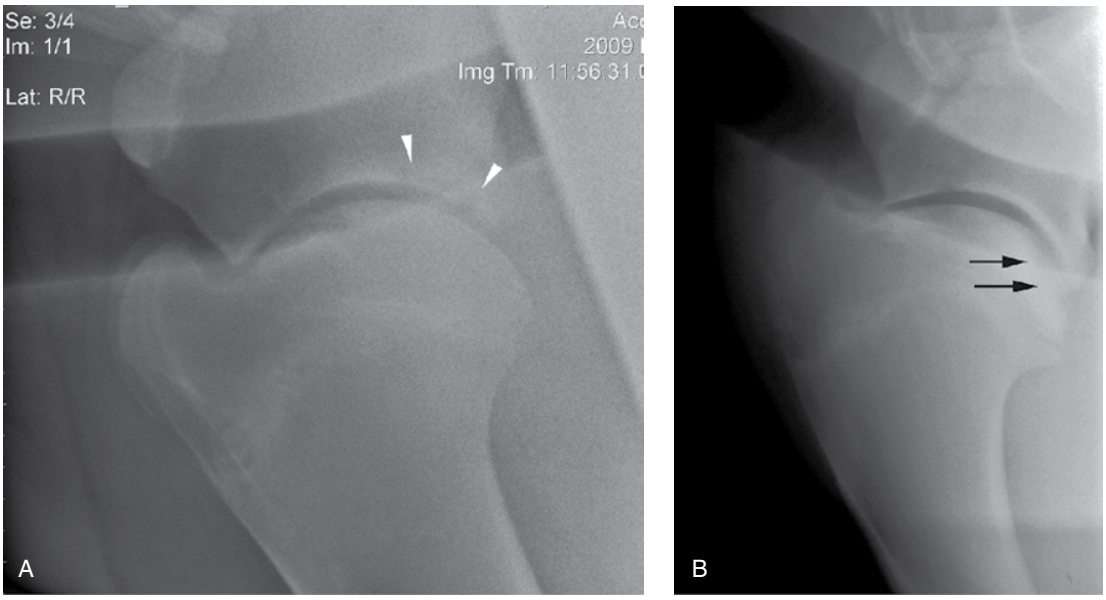

Figure 5.52. (A) An OC lesion of the caudal aspect of the glenoid cavity (arrowheads). This horse was grade 3 out of 5 lame. (B) An OC lesion on the caudal humeral head (arrows). This horse was lame at the walk and had significant muscle atrophy.

moderate success.[38] In a more recent report of 14 horses treated conservatively, 7 became sound with conservative treatment.[52]

Surgical cases should be selected carefully because of the generalized pathologic changes that are present in many cases. However, surgery benefits some horses even when secondary changes are present.[10,29] With very severe degenerative changes, the prognosis is poor and surgery is not recommended.

While arthroscopic surgery is the preferred approach for treating these lesions,[10,71] the technique is not easy, and it is particularly difficult in adult horses. In most instances the cartilaginous changes extend beyond the limits of the subchondral abnormalities seen on radiographic examination (Figure 5.53). Problems associated with arthroscopic surgery in the shoulder usually involve inadequate access to medially located lesions and debridement of large lesions.

Prognosis

Generally the prognosis with rest or surgery is considered guarded, but this is somewhat dependent on the horse's intended use and the severity of the OC lesion. Horses with mild to moderate OC have the best prognosis, and those with severe lesions usually remain lame. In one report on the outcome of arthroscopic surgery on 11 horses, 7 became athletically sound,[10] and follow-up radiographic examinations on those 7 indicated remodeling and improved contour of the glenoid and humeral head. In another study, long-term follow-up on 35 horses with OC of the shoulder treated arthroscopically found that 16 of 35 were successful.[40] A more recent study of 32 horses with shoulder OC (16 with bilateral lesions) also reported a poor outcome. In this study, the lesions were graded mild, moderate, or severe using a system that took into account lesion size and lesion severity.[52] However, there was no difference in conservative versus arthroscopic treatment.

Arthroscopic access to medially located lesions or debridement of large lesions such as this can be difficult and often results in a poor prognosis. *Source*: Courtesy of Dr. Gary Baxter.

OSTEOARTHRITIS (OA) OF THE SCAPULOHUMERAL JOINT

OA of the SH joint is a relatively uncommon condition that can affect a variety of breeds, ages, and uses of horses.[32,40] Reports found a higher incidence of OA in Shetland ponies, miniature horses, and Falabella ponies, with a possible congenital cause.[19,22,53,76]

Although the recognition and treatment of conditions associated with SH joint have improved, the diagnosis of specific problems related to this joint remain a challenge.[32] As a result, some may require extensive diagnostic imaging, including arthroscopy, to make a definitive diagnosis. Unfortunately, the delay in recognition of the

VetBooks.ir

cause may increase the likelihood of the development of secondary OA.[72,93]

Etiology

OA of the SH joint can have multiple causes. In younger horses a developmental role due to OC may be the cause, whereas in older horses trauma may be causative.[32] A radiographic study comparing Shetland ponies diagnosed with OA, skeletally mature Shetland ponies without a history of lameness, and skeletally mature horses found that ponies had a flattening (dysplasia) of the glenoid contour, which was thought to make them more susceptible to the development of OA.[19] A recent study showed that 6 of 20 ponies had radiographic evidence of dysplasia with diagnosed shoulder OA.[22] Other case reports of SH joint OA have indicated that the glenoid cavity is relatively dysplastic in Shetland ponies.[53] Other causes of OA include intra-articular fracture and injury to the joint capsule resulting in synovitis and capsulitis.

Clinical Signs

A history of trauma is relatively common. In one report, 8 of 15 horses that had subtle OC lesions in the SHJ had a history of a traumatic insult.[32] Where mild swelling may be apparent over the shoulder region in the acute case, muscle atrophy is variable and may not reflect chronicity or severity of the lameness.[38,41] Disuse atrophy of the extensor carpi radialis muscle may be apparent in the affected limb in some cases, and an upright narrow foot may also be observed in the affected limb.[32] In contrast, in another study, only a small proportion (fewer than 5%) of the cases with shoulder problems had a smaller foot on the affected limb, although a severely lame horse may have abnormal toe wear.[38,41] Deep thumb pressure applied just cranial to the tendon of the infraspinatus muscle may elicit a painful response in young and light muscled mature horses. Upper limb manipulation (flexion, extension, adduction, and abduction) may also result in a painful response.[41]

The signs of lameness are typical of shoulder lameness, and the degree depends on the severity of the problem. At a trot, the height of the foot flight and the flexion of the carpus are decreased during the swing phase of the stride compared to the contralateral limb. The cranial phase of the stride of the lame limb is often shortened, and as the lame limb is advanced, a prominent lifting of the head and neck occurs on the affected side.[41] Additionally, the horse appears to "fix" the SH joint on the affected side. The lameness grade in one study ranged from subtle and intermittent to 4 on a scale of 5.[32]

Diagnosis

Diagnostic anesthesia can assist in localizing the problem to the shoulder region.[32,38,41,85] Radiography, ultrasound, nuclear medicine, and/or arthroscopy may be required to make a definitive diagnosis of the problem.[32,38,78] Radiography, although important in evaluating abnormalities of the shoulder joint, often underestimates the full extent of the changes involving the glenoid cavity and the humeral head.[38,40] Radiographic changes identified in one report in horses with subtle lesions in the SH joint included glenoid sclerosis, focal glenoid lysis, glenoid cysts, and alteration in the humeral head contour.[32] In another report a flattening of the glenoid without changes in the contour of the humeral head was seen in Shetland ponies.[19] Other radiographic changes associated with OA include osteophyte and enthesophyte formation (Figures 5.54 and 5.55). Contrast arthrography may improve the chances of identifying a SH joint lesion.[41,72]

The normal ultrasonographic anatomy of the shoulder region has been described.[100] Although the detection of humeral head OC has been reported, its major value appears to be in identifying injury to the soft tissue support structures surrounding the SH joint.[38,78,100] Evaluation of the glenoid cavity with ultrasound also appears limited.[32] Ultrasonography has been used to diagnose the condition in Shetland ponies when radiographs were non-diagnostic and only revealed dysplasia or flattening of the glenoid cavity. Joint distension and capsulitis provide the diagnosis.[53]

Nuclear medicine may be useful to diagnose a subtle shoulder lameness with focal intense uptake of the radioisotope, most commonly in the humeral head.[31,32]

Treatment

Conservative treatment may be indicated in horses that have no radiographic lesions and that respond favorably to intrasynovial anesthesia. Treatment involves rest, controlled exercise, anti-inflammatory drugs, and relevant intra-articular therapy including corticosteroids, HA, and IRAP. Rest periods may be as short as a few weeks to 3 months.

Horses that do not respond to the conservative treatment or have radiographic or scintigraphic changes and

have responded favorably to intrasynovial anesthesia are candidates for arthroscopy.[32] Localized cartilage damage is debrided down to healthy subchondral bone, and osteochondral fragments are removed if they are loose.

There are reports of performing scapulohumeral arthrodesis in miniature horses to reduce morbidity in those with severe shoulder dysfunction.[6,89] A narrow DCP was placed across the cranial surface of the scapula, and the humerus with screws placed in lag fashion across the joint through the plate.[89] This procedure improved the horses' lameness by several grades, improving morbidity.

Prognosis

The prognosis appears favorable for horses without radiographic apparent lesions that respond favorably to intra-articular anesthesia and are treated conservatively with rest and intra-articular therapy.[40] Those with obvious radiographic evidence of OA generally do not respond well.

The prognosis for horses treated by arthroscopy appears good for subtle cartilage lesion. In the case of SH joint OA due to shoulder dysplasia in ponies, the prognosis does not appear as favorable. In a report of 20 ponies, 6 were euthanized for continuing severe lameness, and the other 14 remained lame.[22] In two other case reports, ponies remained lame despite concurrent conservative treatments.[53,76]

LUXATION OF THE SCAPULOHUMERAL (SHOULDER) JOINT

Luxation or subluxation of the SH joint is uncommon in horses. In a survey of 128 cases of suspected shoulder lameness in horses, only 2 cases had shoulder luxation.[38]

Figure 5.56. Cranial-caudal radiograph of the same miniature horse in Figure 5.55. The humerus and scapula were positioned more laterally than normal. *Source*: Courtesy of Dr. Gary Baxter.

Ponies appear to be at a greater risk for this condition.[8,23,40,60,101] The head of the humerus can displace in several directions, including cranial,[63,101] craniolateral, lateral, craniomedial, and medial (Figure 5.56).[23,40,50] When the humerus becomes luxated, it displaces proximad due to the contraction of the muscles surrounding the SH joint, and the direction of the luxation appears to depend on the direction of the inciting injury.

Of the cases presented in which the direction of the luxation was documented, lateral luxation with proximal displacement was most common.[40,60,63] Because the equine SH joint is stabilized by a ball-and-socket articulation, the tendons from surrounding muscles, and the glenohumeral ligaments within the joint capsule, it is not surprising that luxation of the joint results in considerable damage to these structures.[23,40] In one report arthroscopic examination following closed reduction of a luxated SH joint of 2-weeks' duration revealed bony and soft tissue debris, a cartilage defect, and a tear in the joint capsule.[63]

Etiology

Luxation of the SH joint generally occurs following excessive (forceful) trauma to the shoulder region such

VetBooks.ir

as may occur from a fall, while a horse is attempting to jump a fence, or as a result of a horse pulling and twisting a flexed limb while the foot is caught.[23,60,63,101] A report documented SH joint luxation in a septicemic foal with multiple joint laxity,[50] another cause was a rough recovery from general anesthesia,[69,103] and luxation of the SH joint has occurred following removal of a large supraglenoid tubercle (SGT) fragment.[12,16]

Clinical Signs

A history of trauma with an acute onset of severe lameness is common.[3,12,16,60,101] At presentation, horses typically exhibit a non-weight-bearing lameness. An abnormal stance may also be apparent with the elbow and carpus held semiflexed and the distal limb adducted or abducted, depending on the direction of the luxation. The distal limb is adducted when the humerus is luxated laterally, craniolaterally, or cranially or is slightly abducted if the humerus is luxated medially. A variable amount of swelling is present in the shoulder region, depending on the length of time since injury.

Muscle atrophy may be most prominent in chronic cases. One report found prominent muscle atrophy of the infraspinatus and supraspinatus muscles 2 weeks following luxation of the SH joint.[63] Distortion of the normal anatomic landmarks at the shoulder region may be apparent if swelling is not excessive, which may aid in determining the direction of the luxation. With lateral or cranial luxation, the greater tubercle and head of the humerus may be most prominent, and with medial displacement, the lateral lip of the glenoid cavity can be palpable.[63] Affected horses generally violently oppose upper limb manipulation.[23,60]

Diagnosis

Radiographs should be taken to confirm the diagnosis and rule out fracture. Generally an adequate study can be obtained in the standing horse, and the mediolateral view is thought to be the most informative.[38] The addition of the craniocaudal oblique projection will allow a better assessment of the direction of the luxation.[39] Stressed views may assist in diagnosis. Ultrasound examination may also be used to assess the extent of injury to the soft tissues supporting the SH joint.

Treatment

Ideally, the luxation should be corrected as soon as possible. General anesthesia is required in most cases, although there is one report of correction of a SH joint luxation using sedation in a 5-day-old foal with multiple joint laxity.[50] In foals, pulling the affected limb into extension while an assistant pushes or pulls the humeral head back into position will generally suffice. The foal may have to be stabilized with counterpressure applied the chest or axilla.

In the mature horse, the patient can be placed in lateral or dorsal recumbency. In lateral recumbency the body can be anchored to a fixed object, and a tension-creating device that is attached to the radius or pastern region to apply traction is used while the operator forces the shoulder back into position. If the horse is placed in dorsal recumbency, a hoist can be used to apply traction and the body weight is sufficient to provide counterweight.[69,101] An audible click may be heard when the humeral head reduces, after which it should be possible to freely manipulate the joint.[23,60] In acute cases, reduction may be accomplished very quickly. In more chronic cases, gradually increasing traction may be required with limb manipulation before reduction is achieved.[63] Arthroscopic examination of the SH joint following closed reduction may improve the outcome particularly if there is evidence of bony debris within the joint on radiography.[63] As such a radiograph should be taken of the SH joint after the reduction is complete.

Recovery from anesthesia should be assisted in all cases. Following recovery the horse should have strict stall rest for 2 months to allow healing of the joint capsule and surrounding soft tissue structures.[23] Anti-inflammatories and intra-articular therapies are indicated. Reoccurrence of the luxation does not appear to be a problem in the horse.[101]

Repair of a case of chronic subluxation of the SH joint in a minishetty stallion by arthrodesis has been reported.[8] The chronicity and bony changes acquired provided a recommendation for arthrodesis. Arthrodesis of the shoulder can usually be performed in miniature horses with a single broad or narrow LCP (Figure 5.57).

Prognosis

The prognosis for SH joint luxation is considered good for return to soundness following closed reduction and an adequate rest period, in cases in which there is not a complicating fracture. In one study, all 6

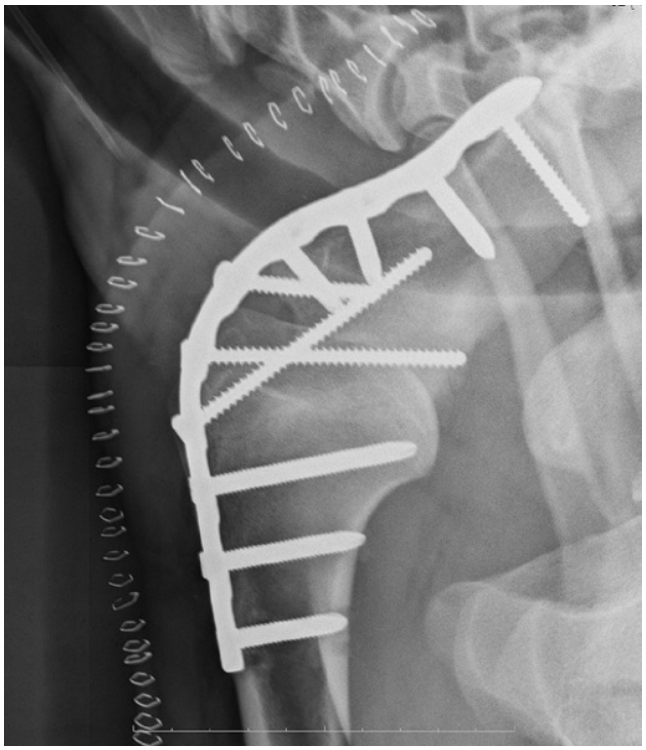

Figure 5.57. Treatment of a chronic shoulder luxation in a miniature horse with an LCP and transarticular screws.

VetBooks.ir

cases reported with SH joint luxation treated by closed reduction returned to soundness.[12,16,23,40,60,63,101,103] The prognosis for larger horses may also be good. One report of shoulder luxation in a Thoroughbred filly has been described.[63] The filly was sound for light work 8 months after closed reduction and arthroscopic examination of the joint. Long-term successful outcome was achieved in a racing Thoroughbred filly that luxated the joint during recovery from anesthesia.[69] It has been suggested that the prognosis may be improved and more accurately predicted if arthroscopy is used following closed reduction to remove any subsequent bone fragments.[23] Arthrodesis of the SH joint in a minishetty stallion with chronic subluxation resulted in a good outcome with minimal lameness at a trot 6 weeks post surgery.[8]

SUPRASCAPULAR NERVE INJURY (SWEENY)

Suprascapular nerve injury resulting in atrophy of the supraspinatus and infraspinatus muscles and shoulder joint instability can affect any age or breed of horse.[14,34] The condition was originally reported as most commonly affecting draft breeds and was believed to be associated with repeated trauma to the shoulder region from poorly fitted harness collars. With the decline in draft breeds, the condition is most commonly seen in horses as result of trauma to the shoulder region. The term "sweeny" has been defined as atrophy of the shoulder muscles in horses and is a commonly used synonym for suprascapular nerve paralysis.[14]

Etiology

Trauma to the suprascapular nerve as it passes over the cranial thin border of the scapula is believed to be the cause.[33,34,62] The suprascapular nerve originates from the sixth and seventh cervical spinal segments and passes via the brachial plexus to innervate the supraspinatus and infraspinatus muscles that overlie the scapula.[36] As the nerve reflects around the cranial edge of the scapula, it passes beneath a small but strong tendinous band. In this position the nerve appears to be most susceptible to direct trauma and compression against the underlying bone.[33–35] In horses without clinical evidence of muscle atrophy, there is also histologic evidence of chronic demyelination and remyelination at the point where the suprascapular nerve reflects over the cranial edge of the scapula. These findings suggest there may be chronic nerve compression caused by constriction of the small tendinous band resulting in subclinical neuropathy. It has been suggested that the chronic neuronal injury may make the suprascapular nerve more susceptible to acute trauma and the development of clinical signs or that spontaneous development of the condition, without a traumatic insult, may be possible.[33–35]

Clinical Signs

A history of trauma to the shoulder region is relatively common. The clinical signs vary depending on the extent of the nerve damage and the duration of the condition prior to examination. Shortly after the injury, horses often exhibit severe pain and are reluctant to bear weight on the affected limb.[35] As the pain subsides and the horse begins to bear weight, a pronounced lateral instability (excursion) of the shoulder joint (shoulder slip) during weight-bearing is observed. This sign is usually seen within 24 hours of injury and is most apparent as the horse is walked slowly toward the examiner.[35] The instability is the result of loss of the stabilizing function of the supraspinatus and infraspinatus muscles, which serve as the major lateral support for the shoulder.[62] It has been suggested that this outward excursion of the scapula during weight-bearing may cause intermittent stretching of the suprascapular nerve leading to continued trauma and perpetuation of the paralysis.[1] The acute lameness may be followed by complete recovery over a 2- to 3-month period, or denervation atrophy of the supraspinatus and infraspinatus muscles may become evident. Following injury to the nerve, muscle atrophy usually becomes apparent as early as 10–14 days after injury.[33] Once atrophy begins, the scapular spine becomes more prominent due to the loss of the muscles cranial and caudal to it (Figure 5.58).

Diagnosis

A presumptive diagnosis of suprascapular nerve injury can be made from the clinical signs and the history of trauma to the region. Radiographs of the region should be obtained to rule out a fracture or OA of the shoulder joint. Electromyographic evaluation (EMG) of the supraspinatus and infraspinatus muscles confirms selective suprascapular nerve injury.[40] For the EMG studies to be most meaningful, they should be performed a minimum of 7 days after injury. EMG findings of denervation of muscles supplied by other branches of the brachial plexus should prompt further neurologic evaluation to rule out injuries to the brachial plexus, spinal cord disease at the sixth and seventh cervical segments, and other diseases such as equine protozoal myelitis.[14,33]

Figure 5.58. Prominent atrophy of the supraspinatus muscle is evident in this horse with suprascapular nerve injury.

VetBooks.ir

Treatment

Both conservative and surgical treatments have been described for management of horses with suprascapular nerve injury.[5,15,35,68,87,102] Initial treatment in all cases is directed toward reducing inflammation in the region of the suprascapular nerve. Stall rest with the administration of NSAIDs and the topical application of cold hydrotherapy or ice packs and topical anti-inflammatories may produce a resolution of the clinical signs.

Conservative Treatment

When conservative treatment is selected, stall rest is continued until shoulder joint stability returns, followed by confinement to a pasture for an additional 2–4 months. In one study the mean time for resolution of the gait abnormality was 7.4 months, and 7 of 8 horses evaluated had a complete resolution of the joint instability.[35] The conclusions from this study were that stall rest appeared to be a viable alternative to surgery for the treatment of suprascapular nerve injury. It can be speculated that surgical decompression may result in a faster return to athletic function.

Injection of a corticosteroid into the shoulder joint may also be beneficial. In one report, 6 horses with suspected suprascapular nerve injury were treated successfully with intra-articular corticosteriods.[68] However, it is uncertain whether these horses had a true neuropraxia of the suprascapular nerve or scapulohumeral joint inflammation that caused disuse muscle atrophy, or both. Anti-inflammatory therapy is recommended. Therapeutic ultrasound has also been suggested as a treatment.[15]

Surgical Treatment

Surgical decompression of the nerve can be considered in patients that continue to exhibit signs of suprascapular nerve dysfunction for 10–12 weeks. This time frame is based on the rate of peripheral nerve regeneration (1 mm/day) and the distance from the site of nerve injury on the cranial border of the scapula to the infraspinatus muscle (7–8 cm). Using these parameters nerve function should return in 10–12 weeks.[87] In horses that show no improvement after 12 weeks or more of rest, entrapment of the suprascapular nerve by scar tissue between the overlying ligament and the cranial border of the scapula is likely. Although the time frame for reversing neurogenic muscle atrophy in large animals is not known, in humans, neurogenic muscle atrophy becomes dramatic after 4 months with loss of up to 80% of muscle fiber volume. It is generally accepted that functional reinnervation is unlikely after 12 months.[56,102] After that, irreversible changes within the muscle occur, and it is replaced by fibrous tissue.

Surgical decompression involves removing a small piece of bone from the cranial border of the scapula underlying the nerve (Figure 5.59).[87] By removing the

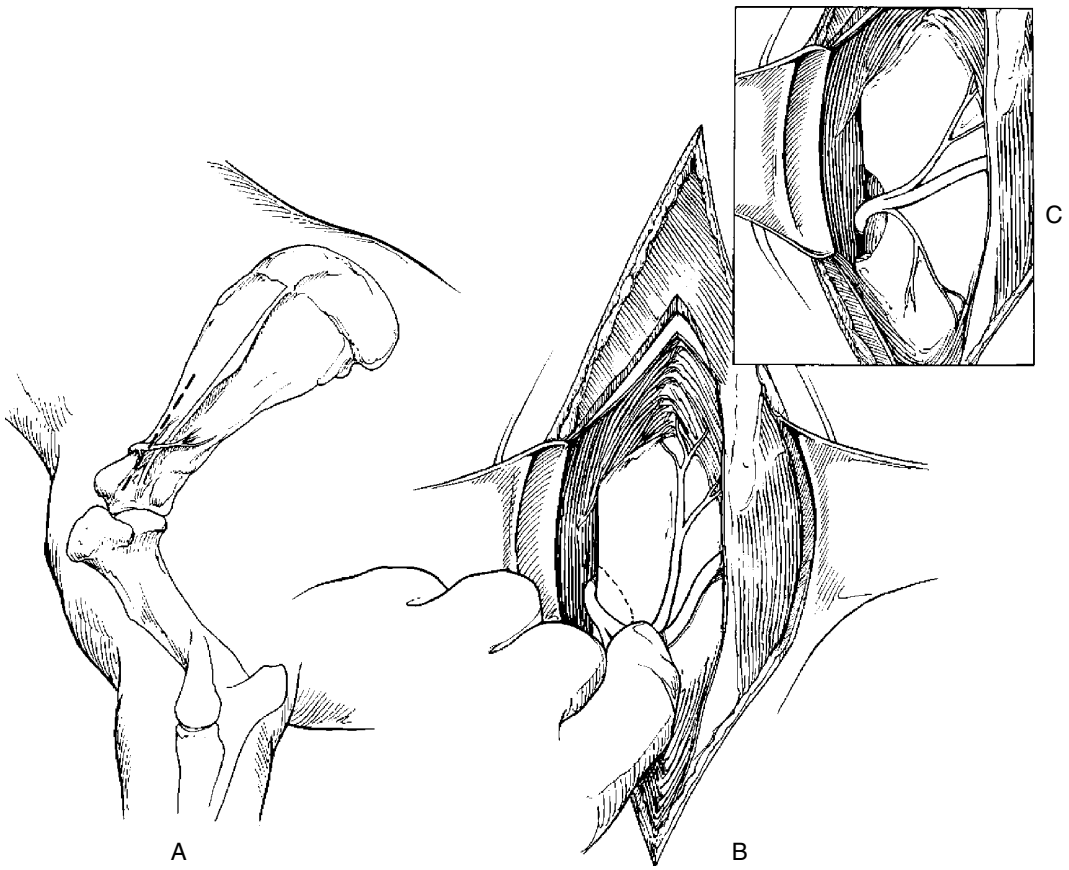

Figure 5.59. (A) Location of the skin incision (dotted line), centered over the suprascapular nerve and cranial to scapular spine. (B) The suprascapular nerve is identified, and a small crescent-shaped piece of bone is removed from the cranial border of the scapula (dotted line). (C) The bone has been removed and tendinous band resected.

VetBooks.ir

notch of bone, it is thought that the nerve is decompressed, allowing for reinnervation. Complications of the surgery include the possibility of a glenoid fracture arising from the site of the notched bone.

Prognosis

The prognosis for return to soundness in horses with suprascapular nerve injury is favorable for both conservative and surgical treatments. In one report 7 of 8 horses with suprascapular nerve injury treated conservatively were able to return to their intended use.[35] All eight initially had pronounced shoulder joint instability during weight-bearing, and joint stability returned within 3–12 months. The conclusion was that rest alone carries a good prognosis for recovery of a normal gait and return to performance; however, the recovery period may be prolonged.

A high percentage of surgically treated horses are expected to return to performance. In one report 18 of 20 horses with suprascapular nerve injury returned to soundness.[86] An important and severe complication associated with the surgery is the postoperative occurrence of fracture of the SGT and complete subluxation of the SH during anesthetic recovery.[87] Horses that develop severe atrophy of the supraspinatus and infraspinatus muscles prior to surgery may not regain normal muscle mass, and some atrophy will remain in the proximal one-third of the scapula.

FRACTURES OF THE SCAPULA

Fractures of the scapula are uncommon in horses. This is in part due to the scapula's proximal location, its close proximity to the ribs, and the large protective muscle mass overlying the region.[3] Although scapular fractures occur in all ages and breeds of horses, young (less than 4 years) intact males appear more prone to sustain the fracture.[3] Fractures of the scapula in racing Thoroughbreds and Quarter horses have been extensively described. The incidence is low at 0.39 and 0.98/1000 starters, respectively.[96] In another recent study evaluating fatal musculoskeletal injuries in racing Quarter horses, scapular fractures accounted for 8% of the injuries.[83]

Fractures of the scapula can involve the spine, SGT, body, neck, and glenoid cavity. Of these, fracture of the SGT is most common. Although simple scapular fractures are most common, comminuted fractures also occur. Bone sequestra may also develop following fractures of the scapular spine, particularly when a penetrating wound results in a comminuted fracture.[9,37] Stress fractures of the scapula have been recently described in Thoroughbred racehorses.[28] A high incidence of suprascapular nerve injury occurs following fractures of the neck of the scapula. Injury to the subscapularis nerve and brachial plexus is a rare complication associated with fractures of the scapula.

Etiology

Scapular fractures are usually caused by direct trauma or following falls during racing or jumping.[30,37] Scapular fractures resulting from racing or race falls at high speeds tend to be comminuted.[96] Penetrating wounds to the lateral shoulder region can also cause fractures of the spine of the scapula.[30,37] The California racing population reported 73 Thoroughbreds and 28 Quarter horses sustained scapular fractures while racing or training. There was a predominance of male horses and right shoulders, and the injury occurred early in their careers. Quarter horses appeared to sustain the injury more frequently.[96]

Clinical Signs

Horses frequently present with a history of trauma and signs of lameness ranging from mild to non-weight-bearing.[3,9,40] Horses with an acute fracture of the scapular spine usually exhibit focal swelling, will bear weight, and usually exhibit a mild to moderate lameness at exercise (Figure 5.60). Deep palpation over the fracture site usually elicits a painful response.

Evidence of penetrating wounds may be present. Chronic cases of scapular spine fractures may present with a draining tract or a history of the development of a recurrent draining tract as a result of a penetrating wound and sequestration of bone fragments.[9,37] Horses with fractures of the body or neck of the scapula are

Figure 5.60. Prominent swelling (arrow) located over the lateral right shoulder region of a young horse with a complete fracture of the body of the scapula. The foal was lame at the walk and carried the limb further axially than normal. *Source*: Courtesy of Dr. Gary Baxter.

VetBooks.ir

usually reluctant to bear weight initially, have difficulty advancing the affected limb, and often have swelling over the fracture site. Deep palpation and limb manipulation usually elicit a painful response.[3,20] Fractures of the scapular neck may also result in secondary suprascapular nerve injury and signs of paresis in some cases. Chronic cases of more than 3 weeks' duration usually exhibit varying degrees of atrophy of the muscles in the shoulder region and proximal antebrachium.[40] As time passes, swelling may become more apparent in the lateral shoulder region as a result of muscle atrophy, healing soft tissues, and callus formation. A swinging and support limb lameness is observed at a trot. Horses sustaining these fractures should also be assessed for other problems such as fractured ribs and intrathoracic trauma.[20]

Diagnosis

Radiographs of the region are needed for a definitive diagnosis. Medial to lateral, ventrodorsal, and oblique cranial to caudal radiographic projections reveal most fractures of the scapula. The study can be done while the horse is standing in most cases. Some fractures through the body of the scapula can be difficult to image because of the superimposition of the ribs and vertebrae over the scapula; in these cases the limb must be protracted to obtain a diagnostic film.[40] If a fracture is suspected but not observed, the horse should be confined to a stall and radiographed again 10–14 days after injury.[37] A scintigraphic exam can be performed prior to this to assist in the diagnosis. Some large, heavily muscled horses in severe pain may require general anesthesia to obtain diagnostic radiographs. Stress fractures of the scapula are diagnosed by nuclear scintigraphic exam and ultrasonography after lower limb analgesia has been performed to rule out a lower limb issue in racehorses that are acutely lame after racing.[28] Suprascapular nerve injury can be difficult to detect by physical exam alone in the non-weight-bearing limb. Electromyography (EMG) can be helpful in assessing nerve damage at least 7 days after the injury has occurred.[20]

Treatment

Conservative Treatment

Fractures of the scapular spine generally do not require surgical intervention, and most heal by bone union. On the other hand, fractures following a penetrating wound may develop bone sequestra; in these cases surgery is recommended. Some minimally displaced nonarticular fractures of the scapular body and neck or stress fractures may also be treated conservatively with a good result.[13,28,40] Providing stall rest for several months, taping the shoulder to the body wall to prevent abduction of the limb, and slinging cooperative animals have been used successfully in some cases without articular involvement.[28,37,40]

Surgical Treatment

Transverse fractures of the body and proximal neck can be surgically treated with internal fixation in young animals.[20,47,90] Stabilization is achieved with two dynamic compression (DCP) bone plates applied cranial and caudal to the scapular spine in the angle formed by the spine and the body.[20,47,90] Longitudinal fractures have been repaired using several narrow DCP placed across the fracture line staggered along the scapula.[55]

Severely comminuted fractures or fractures of the distal neck and those extending into the glenoid are very difficult to treat surgically with internal fixation. The configuration of the fracture and its close proximity to the shoulder joint do not permit application of orthopedic implants. Euthanasia is recommended in horses with extensive joint involvement and/or severe joint instability.[13]

Prognosis

The prognosis is good for fractures involving the scapular spine with or without surgery for removal of a sequestrum, and most horses can return to performance after an adequate rest period. Young horses with nonarticular simple or minimally comminuted fractures of the body and proximal neck have a good prognosis for soundness after application of internal fixation. At the 1-year follow-up of 2 horses that underwent internal fixation, complete healing and return to full function were noted.[20,47] A longitudinal fracture of the scapula in a young horse resulted in soundness at 6 months after internal fixation.[55] In adults, nondisplaced fractures of the body or neck may heal satisfactorily with conservative therapy.[40] Horses with complete fractures in the distal neck, articular fractures, and severely comminuted fractures all have a poor prognosis for return to performance.[13,37]

FRACTURES OF THE SUPRAGLENOID TUBERCLE (TUBEROSITY)

Fractures of the SGT can occur in a variety of breeds of horses and horses with a variety of uses.[15,16,27,75] They are relatively common, accounting for about 30%–50% of reported scapula fractures.[37,57] Fractures of the SGT are often simple, intra-articular, and usually affect horses less than 2 years of age.[16,57,75] In contrast, one report on STG fractures in 9 horses found 4 with comminuted fractures and 6 of the 9 were in horses 3 years or older (range 3–13 years).[37]

Anatomically, the SGT serves as the proximal attachment for the biceps brachii muscle and two glenohumeral ligaments that support the SH joint. The coracoid process, which is the medial projection of the tubercle, serves as an attachment for the coracobrachialis muscle. The SGT and the coracoid process develop from a single center of ossification and fuse with the cranial portion of the glenoid cavity and the main body of the scapula at about 10–12 months of age.[91] Because the fracture plane often courses along this growth plate, it has been suggested that this fracture may result from a separation of the physis of the SGT in young horses.[57]

Etiology

Fracture of the SGT is most frequently associated with trauma to the cranial shoulder region. Because of its superficial location, it appears that the SGT is most susceptible to injury. In two reports most horses with

VetBooks.ir

SGT fracture had a history of falling or direct trauma to the shoulder.[37,75] Overflexion of the shoulder leading to increased tension on the biceps brachii and coracobrachialis tendons that attach to the SGT has also been proposed as a mechanism for this fracture.[2] Fracture of the SGT has occurred in several horses with suprascapular nerve paralysis following surgical removal of a piece of bone from the cranial border of the scapula.[15,16]

Clinical Signs

A history of trauma resulting in severe lameness that improves rapidly is common.[16,37,75] This rapid improvement may be the reason that this fracture is not initially diagnosed in some instances and that recognition of the problem only occurs after the horse remains lame longer than expected or when muscle atrophy becomes prominent.[37,75]

In acute cases swelling is usually apparent over the point of the shoulder, and palpation generally elicits a painful response. Crepitation may also be appreciated in some cases. At a walk, the horse typically retains the ability to extend the SH joint, but the cranial phase of the stride is markedly shortened. A lameness score of 3–4 out of 5 is typical in the acute phase. As time passes, swelling over the point of the shoulder diminishes, and palpation may reveal a firm, nonpainful swelling over the point of the shoulder.[37] Movement of the tubercle can be perceived in some cases. Varying degrees of muscle atrophy are usually apparent in chronic cases.[37] Some horses may also exhibit signs of suprascapular or radial nerve paralysis. Intra-articular anesthesia of the SH joint may not improve the lameness.[37]

Diagnosis

Radiography is required to make a definitive diagnosis of the fracture (Figure 5.61). Generally, the fracture is simple or comminuted and intra-articular.[15,37,75] Calcification of the biceps tendon may also be associated with fracture of the SGT.[37] Electromyographic studies are sometimes needed to rule out neurogenic atrophy of the affected muscles.

Treatment

Several options can be considered for management of SGT fractures. The selection of the management approach depends on the nature and duration of the fracture, economics, and the expectation of performance level of the horse.

Conservative management consisting of the administration of NSAIDs and prolonged stall rest for 3–4 months followed by pasture turnout for 6–9 months may be selected in some cases. Horses with nonarticular or minimally displaced intra-articular fractures respond best to this approach and may be able to return to their intended use, depending upon the degree of OA that may develop.[16,37,75] The use of platelet-rich autologous plasma has been described as an adjunctive therapy to conservative management.[21]

Surgical management of horses with SGT fractures consists of either surgical removal of the SGT fragment or internal fixation with or without transection of the biceps brachii tendon. The goal of surgery is to prevent the development of secondary OA caused by joint incongruity.

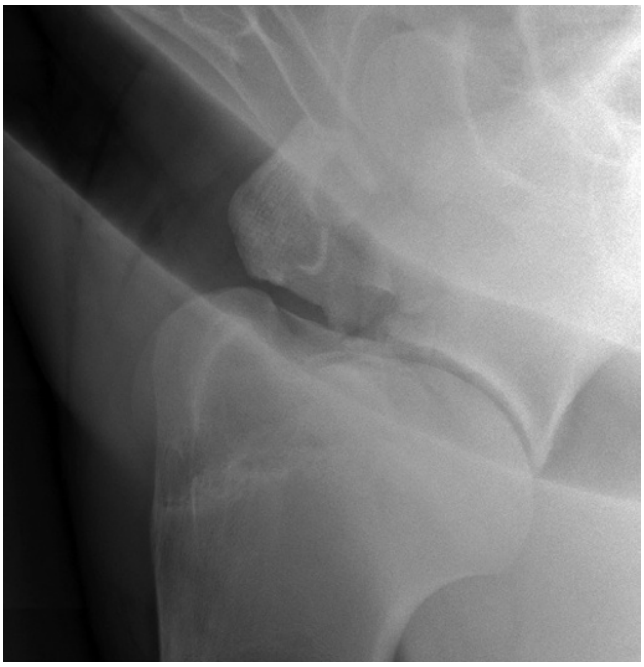

Figure 5.61. Fracture of the supraglenoid tubercle of the scapula with moderate displacement.

Removal of the fragment involves dissection of the tendinous attachments of the biceps brachii and coracobrachialis muscles of the SGT. Excising the fractured SGT decreases the pain created by fracture movement and prevents further joint damage that develops from impingement of the fragment on the articular surface of the humeral head.[9] Surgical excision of the SGT appears to be best suited for most chronic fractures and for comminuted articular fractures.[75,98] In one report, 4 of 7 horses returned to performance, including 1 racing Thoroughbred that had a successful career at a reduced performance level. Caudal luxation of the scapula can occur with excision of the fractured SGT.[15]

Several methods of internal fixation consisting of various combinations of interfragmentary compression with lag screws and tension band wires have been used. Cancellous bone screws placed in lag fashion across the fracture gap were reported to be unsuccessful in 2 horses.[57] Internal fixation using Kirschner wires in combination with cerclage wire placed in a figure-8 pattern to stabilize the fracture fragment was used successfully in one case.[57] Stab incisions made through the tendon of the biceps brachii muscle to place bone screws in a lag fashion was also used successfully in one report.[27] Bone plating of SGT fractures has also recently been advocated. Internal fixation has limited success, particularly in heavily muscled horses; the porous bone in the scapular neck does not hold screws adequately, fracture reduction is difficult, and fixation fails due to the tension exerted by the biceps brachii tendon.[2,15,16] Partial or complete transection of the biceps tendon has been advocated to eliminate the tension on the fracture fragment and prevent implant and bone failure.[2,15] Trauma and damage to the suprascapular nerve can occur due to the surgical procedures mentioned.

VetBooks.ir

Prognosis

A good prognosis for return to performance can be expected for conservative management of horses that have nonarticular fractures or minimally displaced articular fractures of the SGT.[16] The prognosis for return to athletic soundness is poor for conservative management of horses that sustain simple or comminuted displaced articular fractures, but pasture soundness is possible in some.[15,37]

The prognosis following surgical excision of the fractured SGT is better than that achieved with conservative management for return to performance in horses with displaced simple or comminuted articular fractures and for chronic articular fractures.[16,37,75,98] In one report, 4 of 7 horses treated with surgical excision of the fractured tubercle returned to performance, including one racing Thoroughbred that had a successful career at a reduced performance level.[16]

Presently the prognosis for internal fixation appears best if a combination of internal fixation and complete transection of the biceps brachii tendon is used for simple acute fractures.[2,16,27] In one report, 3 of 3 horses treated by this method were sound for their intended use.[16]

ACKNOWLEDGMENT

The authors thank Dr. Ted S. Stashak for his contributions to this chapter in the previous edition.

THE TARSUS

W. Rich Redding

VetBooks.ir

INTRODUCTION

The forelimb receives 60%–65% of the weight of the horse and rider during locomotion, while the hindlimbs are used primarily to generate forward momentum. Performance horses (other than racehorses) require a rearward shift in weight distribution, which allows more impulsion from the hind end. In particular, the disciplines of dressage, eventing, and show jumping are good examples of horses that need to work "off the forehand" and drive through the hind end during collection and propulsion. This change in weight distribution increases the incidence of hindlimb injuries seen in sport horses. The tarsus accounts for many of the hindlimb lameness conditions in performance horses, and the appropriate use of diagnostic imaging is critical to accurately diagnose the specific site of the problem.

Horses with hindlimb lameness may demonstrate little evidence of the source of lameness. In addition, it may prove difficult to examine the hindlimb due to the potential risk of injury, be it real or perceived. Many equine professionals (owners, trainers, and veterinarians) rightly or wrongly suspect the tarsus or stifle to be the most common source of lameness. However, the gait characteristics of hindlimb lameness are similar irrespective of whether the source of pain occurs in the proximal or distal limb. A careful and consistent clinical examination and the use of diagnostic analgesia can identify the most likely region that may be the cause of the lameness. Radiographic and ultrasonographic examinations are complementary and quite effective tools in the evaluation of both bone and soft tissue structures of the limb of the horse.[20,23,32,35,36,58,63,106,116,140,144,146] When these techniques are unable to define a specific cause of lameness, then more advanced diagnostic techniques such as nuclear scintigraphy, computed tomography (CT), or magnetic resonance imaging (MRI) may be required.[7,13,14,21,44,45,49,59,102,103,109,115,119,125,137] An accurate diagnosis and prognosis becomes critical to effectively address and rehabilitate injuries in these cases of lameness.

Strain-induced injury of both the soft tissues (tendons and ligaments) and bone (modeling) are the most common causes of orthopedic injury in athletic animals, either equine or human. Injuries of the structures of the tarsus are quite common and are diagnosed with a combination of clinical examination, diagnostic analgesia, and diagnostic imaging.[7,17,24,40,43,54–57] While clinical examination can often suggest the region of the tarsus as a clinical problem, intra-articular and/or regional anesthesia should be utilized to confirm and to more accurately isolate the source of lameness. If the lameness has been isolated to as specific an area of the tarsus as possible, then diagnostic imaging should be focused on this area. Once an accurate diagnosis is attained, the clinician can develop a directed treatment strategy and rehabilitation schedule for that specific problem(s). Imaging of the tarsus should begin with a thorough radiographic and sonographic examination. The complicated anatomy of this joint can significantly compromise a complete examination with these two imaging tools,[59,60,77] and the use of nuclear scintigraphy, CT, or MRI may be required to find the source of pain. Currently MRI is considered the gold standard for imaging the distal limbs of the horse but is not without risk to the horse because it requires general anesthesia. Because of the complexity of the tarsus, the examiner must develop a keen understanding of the normal anatomy and the types of injuries that typically can occur in the tarsal region to most effectively utilize diagnostic analgesia and imaging techniques.

DIAGNOSIS OF TARSAL LAMENESS

Exam and Palpation

An accurate diagnosis is critical to effectively manage injuries of the tarsus. The diagnosis of tarsal disorders of the hindlimb can be challenging. Often clinical signs are not obvious or specific to the tarsus, and lameness is thought to originate from more proximal on the limb. Careful examination of the distal limb can provide some indication of a specific problem that coexists with tarsal problems. Structures in the distal limb and tarsus should be palpated with the horse standing on the limb and with the limb raised. Application of hoof testers should be performed in acute cases to rule out the presence of pain associated with the foot before evaluating the rest of the limb. Some injuries may involve multiple structures, so it is critical to develop a complete routine examination protocol of the entire limb. Manipulation of the limb by flexion, extension, and rotation may provide some indication of joint(s) involvement. Flexion tests to accentuate lameness may be helpful to differentiate lower limb from the proximal limb involvement. However, the reciprocal apparatus of the hindlimb makes it virtually impossible to flex the lower limb and proximal limb separately. The degree of flexion of the distal limb, however, can be exaggerated beyond that of the proximal limb by holding the leg as close to the ground as possible (similar to how the farrier holds the limb) and selectively flexing the lower limb. Performing the distal limb flexion first before the proximal limb allows a comparison between the respective outcomes. Many horses with proximal limb involvement may respond markedly to both distal and proximal limb flexion. In general, flexion tests of the hindlimb have low specificity, which should emphasize the use of diagnostic analgesia to confirm the source of lameness.

Diagnostic Analgesia

Diagnostic analgesia should be utilized to isolate the source of lameness either by sequential regional

VetBooks.ir

analgesia (predominantly by eliminating the distal limb as the source of lameness) or by intra-articular analgesia of the distal hindlimb.[28,42,72] If the clinical examination indicates the tarsal region to be the source of lameness, then intra-articular analgesia can be performed without fear of blocking the lower limb. If the clinician has no indication as to the source of lameness, then regional analgesia should be performed starting with a low plantar (six-point) nerve block. Once the distal limb is eliminated as the source of lameness (negative response to the low plantar), then intra-articular analgesia of the tarsometatarsal (TMT) and distal intertarsal (DIT) joints should be performed. Communication between the DIT and TMT joints is variable. Previous studies found communication between of the DIT and TMT joints ranged from 8% to 30% and even found variability between both hocks of the same horse.[11,80] Surprisingly communication between the distal tarsal (DT) joints and the tarsocrural (TC) joint was found to occur in about 3% of horses.[18] Therefore, the author recommends that both DT joints be injected for both diagnostic and treatment purposes.

Intra-articular analgesia is thought to be more specific than perineural analgesia, but either technique may be misleading particularly with respect to DT joint disease. Inaccuracies in the diagnostic analgesia techniques can and do occur. For example, a negative response to DIT/TMT intra-articular analgesia does not preclude DT joint pain. Narrowing of the DIT joint space or periarticular new bone can impede or prohibit intraarticular injection. In addition, the response to intra-articular analgesia may be very poor or at best delayed in the presence of extensive subchondral bone damage. Isolating the source of pain to the proximal plantar region requires that analgesia of the deep branch of the lateral plantar nerve (DBLPN) or perineural analgesia of the plantar metatarsal nerves at the subtarsal site should be performed. This would indicate that proximal suspensory desmitis (PSD) may be the source of lameness. Lameness due to PSD should be substantially improved (65%–70%) following these blocks. However, a recent study showed proximal diffusion of contrast media after DBLPN creating the potential for false-positive results.[28] In addition analgesia of the DBLPN can influence DT joint pain, and intraarticular analgesia of the TMT joint can abolish lameness in some horses with PSD (8%).[38] Lameness of the proximal plantar region may occasionally improve following a low plantar (six-point) nerve block most likely due to proximal diffusion of the local anesthetic. One study evaluating analgesia of the DBLPN revealed that 37.5% of horses had contrast in the tarsal sheath (TS) and 25% had sufficient mepivacaine in the TMT joint to produce analgesia.[28] Therefore, a comparison between the respective outcomes of intra-articular and perineural analgesia may be useful in those horses without radiographic or ultrasonographic abnormalities. If necessary, a tibial nerve block may prove useful to distinguish between DT joint pain and PSD pain, as analgesia of the tibial nerve will result in analgesia of PSD without significantly influencing DT joint pain.

A wide range of conditions can cause TC joint pain in horses. Some of these conditions that affect the TC joint may not respond to intra-articular analgesia but in fact require perineural analgesia of the tibial and fibular nerves to demonstrate an improvement in lameness. In one study evaluating horses with TC joint pain, intraarticular analgesia improved lameness >50% in 12/17 limbs (70.6%), but <50% in 3/17 limbs (17.6%).[51] Some periarticular structures may need to be carefully evaluated with diagnostic imaging and require the use of more specific analgesic techniques to confirm their significance. For example intrasynovial injection of anesthetic into the TS is necessary to isolate a lateral deep digital flexor tendon (LDDFT) injury as the source of lameness. Some clinicians use a subtarsal nerve block to eliminate the proximal plantar region. However, when subtarsal injection around the plantar metatarsal nerves (with/without the plantar nerves) was evaluated utilizing contrast medium, it was found that the TS was injected in 40% of the limbs.[42] No proximal diffusion was identified when the perineural injection was place in the correct location outside the TS. Contrast medium was identified in only one TMT joint, suggesting that the likelihood of subtarsal analgesia influencing the tarsus is relatively small.

Anesthetizing the tibial and the deep and superficial peroneal nerves above the point of the hock should desensitize the entire distal portion of the limb. However, the horse may not be able to utilize the limb appropriately and may start to drag the toe of the desensitized limb. The tibial nerve is a large nerve, and some clinicians have suggested that it may take up to 45–60 minutes before enough diffusion has occurred before it provides complete analgesia. Blocking the stifle before the tibial nerve is completely desensitized may lead to a false positive (the horse seems to improve to the stifle block, but the improvement is actually more complete analgesia of the tibial nerve). In addition, local diffusion from the tibial injection site may result in resolution of lameness associated with gastrocnemius tendonitis.

There is a close anatomical association of the TMT joint and the proximal suspensory ligament (SL) and its innervations. The lateral plantar nerve gives off a deep branch approximately 3 cm proximal to the head of the Mt4 bone.[72] The DBLPN branches into medial and lateral plantar metatarsal nerves, which provides sensory and motor innervation to the proximal SL. A previous study of injecting of contrast medium into the TMT joint demonstrated significant amounts of contrast located plantar and distal to the TMT joint following injection.[28] It was hypothesized that this may result in perineural anesthesia of the plantar metatarsal nerves and the proximal aspect of the SL. Perhaps more importantly, these plantar outpouchings of the TMT joints may permit inadvertent intra-articular anesthesia of the TMT joint following diagnostic anesthesia of the proximal metatarsus similar to what occurs in the forelimb.

Because it is considerably easier and safer to inject the TMT joint, some clinicians prefer to block the TMT joint first. If there is no or only partial improvement in baseline lameness, the DIT joint should then be blocked. Lameness is often improved within 10 minutes, but due to the extensive pathology in some horses, it may take longer to see complete clinical improvement. A positive response to intra-articular analgesia of DT joint pain may be limited (<50% improvement from baseline lameness). When utilizing perineural analgesia of the peroneal and tibial nerves, it may take a minimum of

VetBooks.ir

20 minutes to influence DT joint pain. Occasionally the response is even more delayed, making it preferable not to proceed with further blocking for at least 1 hour. In addition, some horses with DT joint pain may respond better to intra-articular medication than either intra-articular or perineural analgesia.

Imaging of the Tarsus

The equine tarsus is a complex joint and can be difficult to accurately image due to the unique anatomic arrangement and the superimposition of many structures.[59,60,77] Many of the changes that develop in and around this joint with disease are chronic. Radiographs have proven to be useful to evaluate bony changes associated with the tarsus.[23,36,63,106,145] While soft tissue swelling can easily be seen on radiographs, accurately identifying the specific structures involved can be difficult. Diagnostic ultrasound (US) is a very useful imaging technique that can provide valuable information about the soft tissues of the joint, the articular cartilage, and the subchondral bone surfaces.[32,35,59,116,140,148] Diagnostic US and radiology are considered the minimum imaging techniques to be utilized when evaluating a specific anatomical region of the musculoskeletal system. For example, ligament and tendon injuries frequently occur at the bone–soft tissue interfaces or insertions onto bone (enthesis) with the earliest change often being early bone production. Both radiography and US are necessary to effectively evaluate the injury especially since US has proven to be more sensitive than radiology at identifying early periarticular remodeling and enthesis new bone formation. More information on tarsal ultrasonography can be found in Chapter 3.

Nuclear scintigraphy may prove useful when radiographic and sonographic examination fails to reveal significant clinical information about the source of the lameness.[44,49,59,102,103,119,137] More recently MRI is being utilized for tarsal imaging due to short-bore high field strength magnetic systems when other imaging modalities are inconclusive. MRI of the tarsus has been useful in the diagnosis of abnormalities that may not be apparent radiographically or ultrasonographically.[13,14,21,45,83,125] Abnormalities seen with MRI include subchondral bone injury of the talocalcaneal joint, bone bruising of the distal tibia, intertarsal ligament enthesopathy with associated bone edema, focal osteoarthritis (OA) in the plantar aspect of the DIT and talocalcaneal joints with localized loss of joint space and subchondral bone sclerosis, and soft tissue injuries of the collateral ligaments (CLs) of the TC and the proximal intertarsal (PIT) joints, as well as tendonitis of the deep digital flexor (DDF) tendon at the level of the calcaneus.

Radiography of the Tarsus

Radiography is the most accessible and commonly used imaging modality for the diagnosis of bone lesions of the tarsal bones such as osteochondrosis (OC), OA, or fractures. Radiographic interpretation of images of the tarsus must consider the complex anatomy and superimposition of these bony structures of the tarsus. Radiographic examination evaluates bone pathology by the detection of subtle differences in bone density, trabecular detail, and cortical thickness. However, a decrease in bone density of between 30% and 50% has to occur before a change is visible radiographically.

Many of the bony conditions that affect the tarsus manifest abnormal radiographic findings that are located at the dorsum of the tarsus. Pathologic abnormalities of the tarsus tend to be in specific anatomical areas, and soft tissue swelling is helpful to localize abnormalities.[2] Radiographic examination of the tarsal region is often performed to evaluate the distal tarsus joints for OA (TMT/DIT) or to diagnose the presence of OC in the TC joint. Occasionally special projections are needed to elaborate an area not clearly defined with the standard radiographic examination such as the flexed lateral or skyline of the tuber calcis (TC) (Figure 5.62). Other common abnormalities of the tarsus visible on

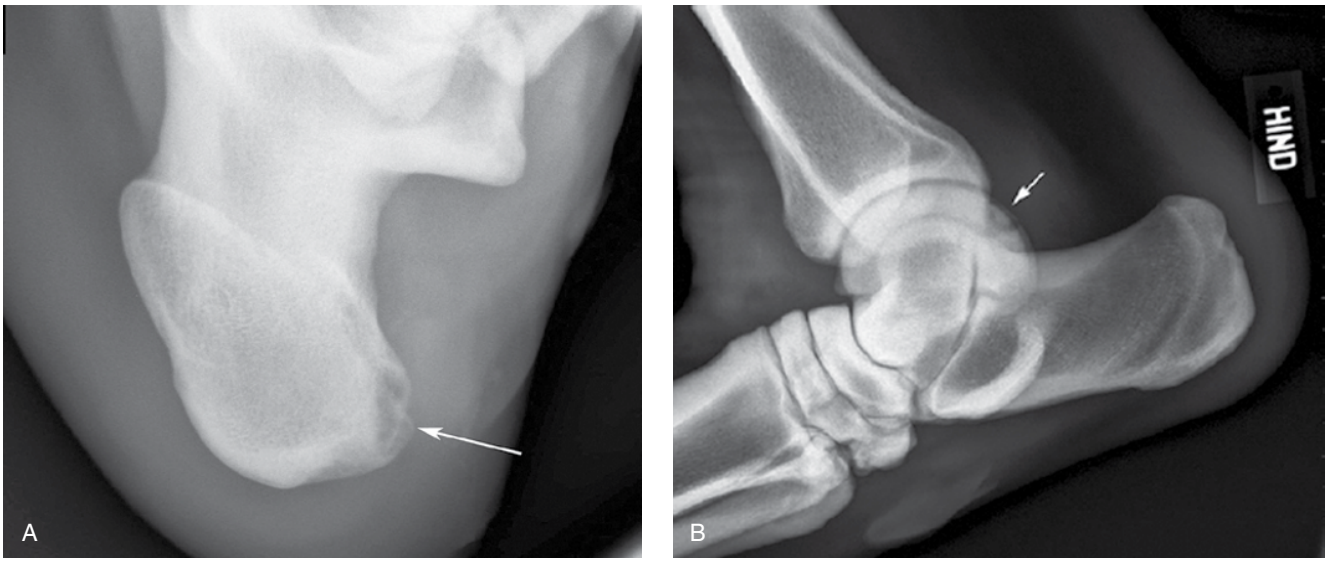

Figure 5.62. Skyline (A) radiograph that was necessary to document osteitis of the calcaneus (arrow) and flexed lateral radiograph (B) that revealed a large fracture fragment on the plantar aspect of the medial trochlear ridge of the talus (arrow) that was not visible with other views.

VetBooks.ir

radiographic exam include soft tissue swelling without bony change, fractures, and developmental disorders. The most common clinical condition requiring radiographic examination of tarsus is bone spavin. This arthritic condition of the DT joints manifests a variety of radiographic changes including osteophytes at the joint margins of the DT joints, loss of joint space, and the presence of sclerotic tarsal bones, particularly the central tarsal bone. However, joint space narrowing associated with the distal joints caused by bone spavin can be difficult to detect and are best demonstrated with radiographic projections that center the beam on the lower tarsal joints.

Another common clinical condition requiring radiographic examination of the tarsus is OC of the TC joint. The most common sites for OC in decreasing frequency of occurrence are the distal intermediate ridge of the tibia (DIRT), the lateral trochlear ridge (LTR), the medial malleolus (MM), the medial trochlear ridge (MTR), and the lateral malleolus (LM). OC of the TC joint most commonly manifests as osteochondral fragmentation, but subchondral lucencies and irregularity can also occur.

Ultrasonography of the Tarsus

Many of the structures of interest in the tarsus are superficial and lie just under the skin and subcutaneous tissue, and therefore US provides an excellent means imaging these soft tissue structures (Figure 5.63). A high-frequency (10–18 MHz) linear probe with variable focal zones is ideal and can be enhanced when a standoff works best. A scanning depth of 4–6 cm or less is appropriate for most structures. The sonographic examination of the tarsus should be methodically examined from the dorsal (extensor surface), medial, lateral, and plantar (flexor surface) aspects of the joint.[146] These areas should initially be examined with the animal weight-bearing, and because diagnostic US has the added benefit of providing real-time information, these structures should also be examined throughout their range of motion. When evaluating the dorsal and plantar aspect of the tarsus, it is important to utilize a normal range of motion with flexion and extension in an attempt to evaluate the weight-bearing and non-weight-bearing surfaces of the articular cartilage of the joint. This technique can also be utilized when evaluating the joint for OC and the position and mobility of osteochondral fragments predominantly in the dorsal and plantar aspect of the joint. Structures in close proximity that have similar sonographic density can be difficult to separate. Detailed descriptions of the US examination of the tarsus exist.[32,35,59,116,140,148]

Scintigraphic Examination of the Tarsus

Hindlimb lameness that cannot be conclusively diagnosed with radiographic and ultrasonographic examinations may be candidates for scintigraphy.[44,49,59,102,103,119,137] The bone scan technique can allow detection of subtle bone changes undetected by other diagnostic methods. DT joint pain is often associated with increased radiopharmaceutical uptake (IRU) in the DT joints compared with that seen in normal horses. Any acute onset of lameness thought due to a tarsal fracture but without radiographic evidence of a fracture is also a candidate for a bone scan. Increased radionuclide uptake does not always equate with clinical significance, emphasizing that interpretation of nuclear scintigraphic images without reference to the clinical examination and other imaging results can be potentially misleading (Figure 5.64).

Computed Tomography of the Tarsus

CT in the horse is indicated when other bone imaging technologies are inconclusive or when there is a fracture that needs more characterization. CT can provide information about a bony lesion not available with other imaging techniques.[109,115] Occasionally CT can be useful when other imaging techniques demonstrate tarsal lesions and there is a need for better interpretation (like

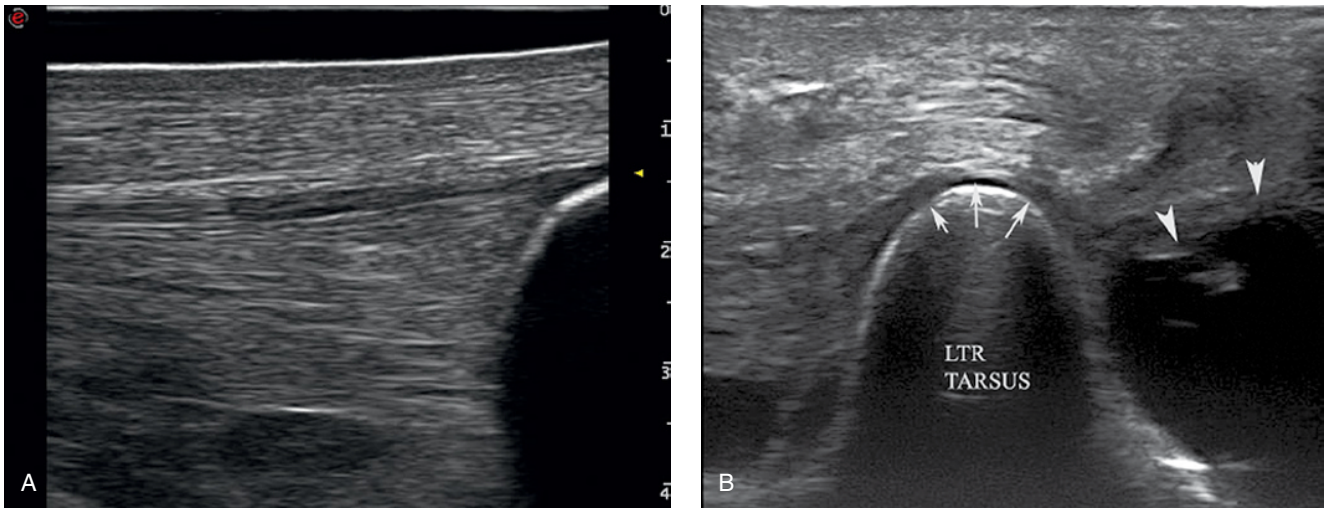

Figure 5.63. Ultrasonographic images of the normal gastrocnemius attachment to the tuber calcis (A) and the articular surface of the lateral trochlear ridge of the talus (B).

VetBooks.ir

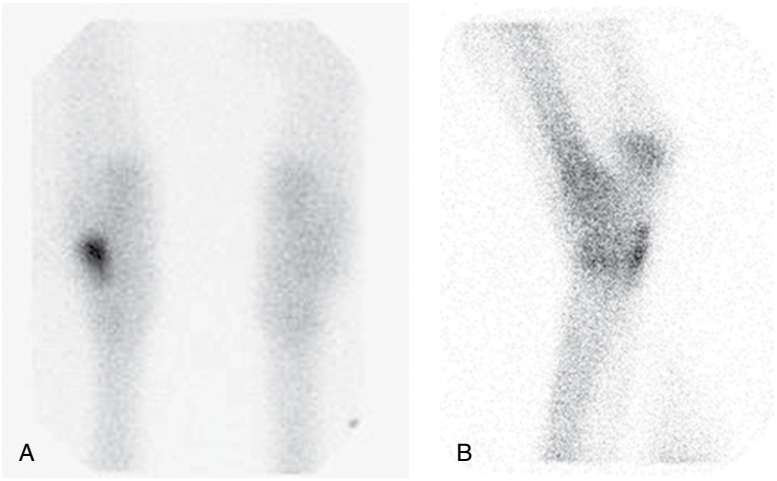

Figure 5.64. Nuclear scintigraphy can provide information about specific conditions that occur in the tarsal region that are associated with the bone modeling. Image on the left (A) is of horse with talocalcaneal OA, and the image on the right (B) corresponds to an area of calcification of the plantar ligament.

Figure 5.65. Cross-sectional imaging techniques such as CT eliminates the superimposition of the different bones that make up the tarsus. This CT demonstrates a comminuted fracture of the central tarsal bone and can be used to more accurately place screws to compress the fractures.

scintigraphy) (Figure 5.65). Subchondral cyst-like lesions, osteolytic lesions of any of the tarsal bones, degenerative changes of the DT joints, sclerosis of any of the tarsal bones (but particularly T3), and reaction around the interosseous ligaments can all be identified very clearly with CT. CT is especially helpful to determine the extent and complexity of a fracture better than radiography. Focal lesions located between the tarsal bone surfaces that are difficult or even impossible to detect with radiography and ultrasonography can be better characterized with CT.

MRI of the Tarsus

MRI can be useful for evaluation of DT pain because there is a lack of correlation between the presence and severity of radiographic changes compared with lameness in many horses (Figure 5.66). Protocols for MRI of the tarsus have been suggested, and equine tarsal MRI anatomy has been described using both low- and high-field systems.[13,14,21,45,83,125] In the normal tarsus, articular cartilage of the DT joints is very thin, which does not allow for distinction of proximal and distal cartilage layers in these joint spaces. Subchondral bone plates of the DT bones and the MTIII have homogeneous low signal intensity with a regular osteochondral junction and a smooth but undulating deep border. In competition horses that undergo high intensity training, subchondral bone thickness is greater medially in the DIT joint and laterally in the TMT joint.[21,125] This repeatable thickness pattern of subchondral bone is lost in horses with DT lameness. For instance, cadaveric tarsi from horses with histories of DT

VetBooks.ir

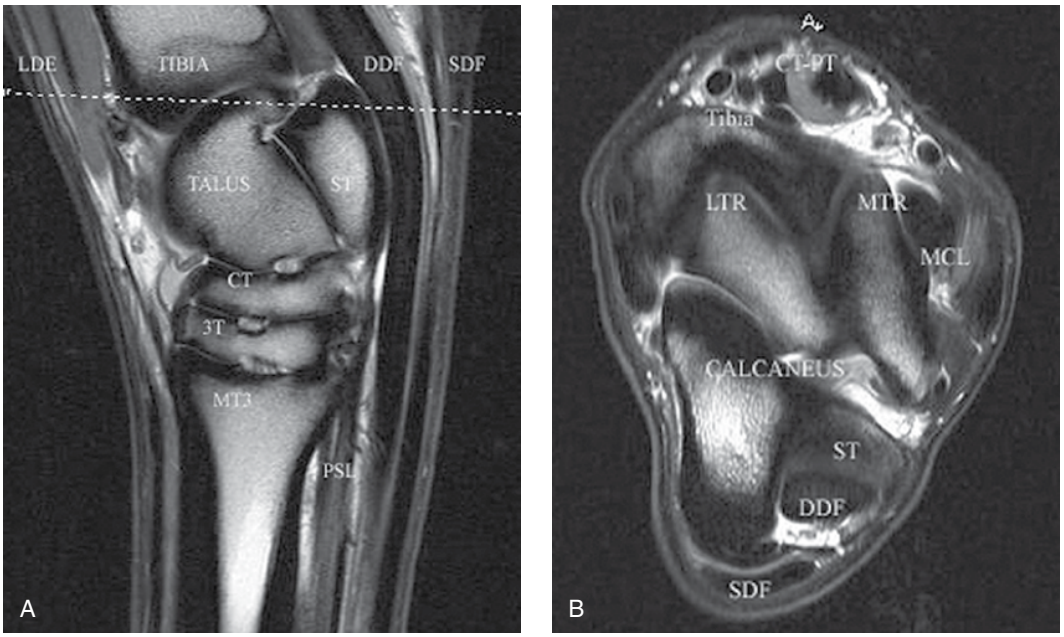

Figure 5.66. Sagittal PD (A) and transverse PD (B) MR images of the tarsus demonstrating normal soft tissue and bone anatomy. MRI is an extremely useful tool for detection of many types of pathology within the tarsus.

pain revealed variations in subchondral thickness compared with horses without histories of DT pain.

There are few reports on the incidence of MRI diagnoses in the tarsus of live horses. In one cadaver study, MRI was more sensitive and specific than radiography for detection of all types of pathology of the DT joints, including intertarsal ligament pathology, cartilage erosion, osseous cyst-like lesions, and subchondral bone irregularity. In live horses with lameness associated with the tarsal region, the presence of abnormal STIR signal hyperintensity compatible with the presence of bone bruising was reported in the central and third tarsal bones, talus, and tibia. MRI of the tarsus has also been helpful to diagnose abnormalities that are not identified with other imaging modalities. These abnormalities have included subchondral bone injury of the talocalcaneal joint, bone bruising of the distal tibia, intertarsal ligament enthesopathy with associated bone edema, focal OA in the plantar aspect of the DIT and talocalcaneal joints with localized loss of joint space and subchondral bone sclerosis, desmitis of the CLs of the TC and the PIT joints, and tendinitis of the deep digital flexor tendon (DDFT) at the level of the calcaneus.

ARTICULAR DISEASES OF THE TARSUS

Osteoarthritis (OA) of the Distal Tarsal (DT) Joints/DT Joint Pain

DT OA has been recognized as a cause of hindlimb lameness for centuries. It is frequently called bone or jack spavin or occult or blind spavin in the absence of radiographic abnormalities. Chronic cases often develop an enlargement over the medial or dorsomedial aspects of the DT joints. In addition, the term juvenile spavin has been used to describe the development of DT OA in horses less than 3 years old typically before the animal has done much work.[65] This is likely due to developmental lesions of the DT bones (i.e. OC) such as cuboidal bone hypoplasia that is seen in premature and dysmature foals that causes collapse of the central and third tarsal bones.[2,3]

Performance horses in a variety of disciplines and of all ages can develop lameness associated with the DT joints. The DIT and TMT joints are considered the joints of the hindlimbs most likely to develop OA from work-related stress (wear and tear). There are certain types of activities that may contribute to uneven or excessive loading of the lower hock joints. These include sports that require a great deal of hock flexion (dressage), stress (jumping), sudden stops or turns (western events, such as reining), or a great deal of concussion (Standardbred [STB] racing). In addition, OA of the DT joints can occur relatively frequently in mature horses that are ridden at a gallop and canter. While bone spavin is seen frequently in mature sport horses used for a variety of disciplines, it is also found as a source of lameness in young Thoroughbred (TB) and STB racehorses. Bone spavin often occurs in normally conformed horses. There are however some conformational abnormalities such as sickle hock, cow hock, or excessive straightness of the hindlimbs that may predispose to DT joint pain. These types of conformations are felt to produce greater stress in the medial aspect of the tarsal joint.

Etiology

OA of the DT joint (bone spavin) typically involves the TMT and DIT joints but occasionally may extend into the PIT and TC joint. DT OA is common in a wide variety of disciplines probably because these events cause increased torsional and shear forces on the DT joints. Many feel that excessive compression and rotation of the DT joints during training and competing create abnormal tension on the intertarsal ligaments and

VetBooks.ir

potentially excessive tension on the attachment of the major dorsal ligaments. It has long been thought that DT joint pain begins on the dorsomedial aspect of affected joints, which then progress dorsally. However, Dyson has reported that DT joint OA initially manifests radiographic and scintigraphic abnormalities on the dorsolateral aspect of the joints.[40,43]

OA of the DT joints commonly affects athletic horses during the most productive years of their lives and can limit career length.[7,17,24,43,56,57,99,100,138] The pathogenesis of spavin can be divided into three phases: (1) fibrillation of cartilage, (2) osteolysis, and (3) ankylosis. The first stage can be observed in young horses and can predominantly be found at two predilection sites on the articular cartilage of the DIT joint. The lesions can then progress further in the direction of the subchondral bone plate where osteolytic lesions may develop. In this phase, horses commonly start to show clinical signs of lameness. In some cases, the lesions may proceed further until a complete ankylosis occurs. The degree of osteolysis may significantly influence whether diagnostic anesthesia will be effective at eliminating the lameness or provide only partial improvement. Dyson[43] classifies horses with DT pain into three categories: (1) horses that respond to IA analgesia of either the DIT or TMT joints or both, but with no detectable radiological abnormality; (2) horses with predominantly periarticular osteophyte formation; and (3) horses with joint space narrowing, subchondral bone lysis, and sclerosis. However, these three categories are not necessarily considered continuums of OA of the distal tarsus. OA also has been associated with increased intramedullary pressure particularly within the cuboidal bones of the tarsal region.

In some breeds such as the Icelandic horse, there appears to be a genetic component to development of OA in the DT joints. While heritability can be difficult to prove, there has been a very obvious decrease in prevalence of bone spavin in the Royal Dutch Warmblood Studbook (KWPN) due to a strong and consistent selection process.[7] Selection was based on two main criteria: conformation and a reduction in radiographic signs of bone spavin. It has also been shown in the Dutch Warmblood that there is a strong relationship between a faulty conformation in the hock region (sickle hocks but also extremely extended hocks and abnormal outward rotation during the stance phase) and the occurrence of bone spavin. Animated gaits (such as seen with American Saddlebred and Tennessee Walking Horse) can also contribute to the development of bone spavin in these horses. For example, the rack is a fast four-beat gait during which the horse places their hindlimbs extremely far forward.

Diagnosis

The diagnosis of distal limb/tarsal disorders of the hindlimb can be challenging.[61] Frequently clinical signs are not obvious and not specific to the tarsus. Structures in the distal limb and tarsus should be palpated while standing on the limb and with the limb raised. Manipulation of the limb by flexion, extension, and rotation may provide some indication of joint(s) involvement. A moving examination should be performed at a walk and trot in a straight line and circle as well as a canter in a circle. If possible, watching the horse being ridden can be very useful and may be most effective at demonstrating the lameness that the owner/trainer has described. When the opportunity exists, the horse can be examined with a rider up and comparisons made about the gait before and after intra-articular diagnostic analgesia is performed.

Physical examination can be confusing and reveal pain and sensitivity through the back and pelvic regions. These clinical findings may give the impression that lameness originates from the topline or more proximal on the limb. Some horses with DT joint pain manifest a lower arc of the foot flight and toe dragging with wear patterns developing on its dorsal edge of the toe. In addition, some may manifest a change in foot conformation due to an alteration in how the horse loads the foot. In acute cases of moderate lameness, the application of hoof testers should be performed to rule out the presence of foot pain before evaluating the rest of the limb. Some lamenesses may involve multiple structures, so it is critical to develop a routine examination protocol that evaluates the entire horse while concentrating on the affected limb.

Joint distension is not a typical sign of OA of the DT joints, because the tarsal retinaculum over these small joints prevents its detection. However, changes in the silhouettes of the hock may develop medially. This can be due to soft tissue change such as with cunean bursitis and/or effusion of the cunean bursa. However, this change in shape is more often due to a firm bony swelling associated with more advanced stages of DT OA. Palpation of the horse may also demonstrate soreness of the epaxial muscles in the lumbar region and sometimes the caudal gluteal muscles. A compensatory forelimb lameness may also develop due to a reluctance of the horse to bear appropriate weight on its hindlimbs.

Physical examination may not reveal any obvious abnormalities. Palpating the tarsal region may reveal irregularity over the dorsomedial aspect of the tarsus, but often this is not sensitive to digital pressure. Some clinicians may perform a manipulation called Churchill's test, which is accomplished by directing digital pressure over the head of the medial splint as a reflection of DT pain. The test is considered positive when the horse abducts the limb away from the pressure. The lameness examination should begin with a flexion test of the least affected hindlimb first, because the more severely affected limb may remain lame after flexion, which can complicate the rest of the lameness exam. The disease is often bilateral, and flexing the unaffected limb may be quite positive or it may cause the hindlimb gait to even out because the pain is distributed more evenly behind. Proximal and distal limb flexion test should be performed separately. The proximal limb flexion test or spavin test is useful at accentuating lameness with tarsal joint pain in most affected horses. However, a positive response is not specific for the tarsal lameness because the reciprocal apparatus creates flexion of tarsus, stifle, and coxofemoral joints (to varying degrees) simultaneously. A stifle flexion test may be utilized to help differentiate lameness originating from the tarsus vs. the stifle. Many horses with proximal limb involvement may respond positively to both distal and proximal limb flexion.

VetBooks.ir

DT joint OA often occurs bilaterally, but occasionally it may occur unilaterally. There is often a history of gradual onset of lameness. Occasional horses with bilateral DT joint pain may not manifest overt lameness but may be thought to have a behavioral issue or a lack of performance. When lameness occurs, it may become worse when the horse is worked hard for several days and may improve with rest. Lameness tends to be worse when the horse is first started into work. Many mildly affected horses tend to warm out of the lameness after a short time. The horse may feel stiff or jerky when circled to the affected side, and it may refuse or be reluctant to go in the opposite direction or take the opposite lead. However, some horses show more lameness with the lame or lamer limb on the outside. Western performance horses (i.e. reining, roping, and cutting) or gaming horses that are required to stop aggressively can become reluctant to decelerate or perform sliding stops required for their discipline. An animal may develop a problem with the performance of discipline-specific maneuvers such as refusing to jump or to jump poorly with an increase in rails knocked down. The horse may have trouble picking up or holding a lead or may show a reluctance to turn in one direction. The development of these types of performance or behavioral issues can be consistent with the development of DT joint pain.

The way in which horses with DT joint pain manifest lameness can vary considerably. Some clinicians have reported a tendency for horses with DT joint pain to manifest a characteristic limb carriage and foot placement. This gait can be described as an axial deviation of limb during the swing phase of the stride with a rapid abaxial deviation of the limb just before contact with the ground (so-called J-step). While this limb carriage is common in horses with DT pain, it is not pathognomonic. In addition the horse with DT joint pain can have a reduced degree of flexion of the hock during the swing phase of the stride. This translates into a reduction in the height of the foot flight arc and a shortening of the cranial phase of the stride often with an associated dragging of the toe. Lameness associated with DT pain may include asymmetrical movement of the tubera coxae, shortening of the cranial phase of the stride, and sometimes a reduced extension of the fetlock during stance phase. In addition the affected limb usually lands toe first, resulting in excessive wearing of the toe. Kinematic gait measurements recorded after endotoxin-induced lameness of the DT joints were considerably different than what occurs clinically in horses with bone spavin.[79] This study reported that fetlock and tarsal joint extension decreased during stance phase, fetlock joint flexion and hoof height during swing phase increased, and vertical excursion of the tuber coxae became more asymmetrical.[79]

Diagnostic Analgesia

Flexion tests of the hindlimb have low specificity (multiple joints are flexed at the same time), which emphasizes the need to utilize diagnostic analgesia to confirm the source of lameness. Accurate placement of the intra-articular anesthesia of the TMT and/or DIT joints should be performed in many horses to confirm that the origin of the lameness is the tarsus. However, the accuracy of diagnostic analgesia may be questioned based on the potential for leakage of local anesthetic around the proximal plantar metatarsus and extension around the insertions of the cranial tibialis (CT) and peroneus tertius (PT) tendons following injection of the TMT joint. The injection of contrast media into the DT joints of the tarsus demonstrated that once the media filled the joint space, there was extension of fluid surrounding the proximal plantar metatarsus and origin of the SL in 70% of the limbs.[42] One study found that forced injection into the TMT joint caused rupture and extra-articular leakage of contrast around the head of the lateral splint.[80] Leakage was found to occur close to the area of the lateral plantar nerve and DBLPN, potentially leading to false-positive responses. In addition, the variability of communication between the TMT and DIT joints[11,42,80,121] suggests that these joints should be anesthetized separately.

The TMT joint is the easiest joint to inject and is approached plantaroproximal to the base (head) of the fourth metatarsal bone. The site for injection of the DIT joint is from the dorsomedial aspect of the limb distal to the palpable distal border of the medial branch of the tendon of the tibialis cranialis muscle (cunean tendon) and between the central, third, and combined first and second tarsal bones. In the normal horse this may be difficult to accurately palpate, making is difficult to comfortably inject this joint. Many clinicians prefer to inject the TMT joint first with 2–3 mL of mepivacaine until resistance is felt. Any more pressure increases the risk of anesthetic solution escaping the joint capsule. When communication between these two joints exists, needle placement into the DIT may allow for observing of local anesthetic dripping out of the needle. The clinician should interpret this carefully as the needle may easily enter the TMT joint if it is placed too far distally in the space between the third and second tarsal bones. When communication of these joints is found to exist, treating only the TMT joints may prove to be effective at adequately managing DT (both DIT and TMT) joint pain. That may not be the case once the pathological process progresses and begins to occlude or obstruct this communication. Interpreting the results of intra-articular analgesia of the DT joints may prove to be difficult. Intra-articular analgesia may only improve the lameness score by 50% due to moderate to advanced osteoarthritic and coexistent subchondral bone pain. Improvement is generally seen within 20 minutes, but occasionally the response is delayed. Some clinicians recommend delaying further blocks until at least 1 hour has elapsed.

Moderate to severe OA with proliferative periarticular bone can make placing a needle into a narrowed joint space difficult if not impossible. In these cases radiographic and US-guided control may be required to assist needle placement into the joint space. When intra-articular analgesia is too difficult or ineffective at eliminating lameness of the DT joints, perineural analgesia of the superficial and deep peroneal (fibular) and the tibial nerves should be utilized. Blocking of the caudal tibial and deep peroneal nerves is a reasonably accurate diagnostic method. However, other structures in addition to the DT joints are blocked, and the effect of this block may not be complete. Further, confirmation of complete

VetBooks.ir

analgesia is difficult, and desensitization of such a large portion of the limb occasionally alters the horse's movement. Perineural analgesia can be problematic and may take 30 minutes to an hour to become effective. The tibial nerve is quite large, and it may take a prolonged period of time for the analgesia to diffuse into and affect the nerve. This block is not specific for the DT joints and necessitates a methodical approach and sequential desensitization of the distal limb, proximal suspensory area (proximal plantar region), and TC joint. Once these have been performed without effectively eliminating the lameness, then a peroneal and tibial nerve block can be performed.

Perineural analgesia techniques around the tarsus can also provide inaccurate results. For instance, analgesia of the DBLPN can influence DT pain, and according to Dyson,[38] intra-articular anesthesia of the TMT joint can abolish lameness in horses with PSD (8% incidence).[38] Therefore a comparison between the respective outcomes of intra-articular and perineural anesthesia is useful. A tibial nerve block can be useful to distinguish between DT joint pain and PSD pain, as anesthesia of the tibial nerve will result in analgesia of the PSD without significantly influencing DT joint pain.

Imaging

Radiography

Radiography can be quite helpful in the diagnosis of OA of the DT joints. Radiographic examination to evaluate the DT joints should have the primary radiographic beam centered on the DT joint spaces and focused tangential to the joint spaces to best interpret changes that occur in these joints. Radiographic signs of bone spavin include (1) periarticular osteophytes ("spurs"), (2) irregularity and lucency at the intertarsal joint margin, (3) irregular width of the joint space and cysts in the subchondral bone, (4) narrowing or loss of joint space, (5) subchondral bone lysis, (6) new bone production of the distodorsal tarsus, (7) bulging of the dorsomedial contours of the central and third tarsal bones, and (8) ankylosis (Figure 5.67). The degree of lameness is not necessarily correlated with the degree or type of osteoarthritic change detected radiographically. Early radiographic changes of OA of the DT joints include periarticular osteophyte formation, subchondral lucent areas, subchondral sclerosis, periosteal new bone, and narrowing of joint spaces. Certain radiographic changes such as periarticular osteophyte formation or joint narrowing may be highlighted in the DLPMO and dorsoplantar projections.

Early cases of bone spavin have radiographic signs that occur on the dorsomedial aspect of the tarsus that progress dorsally. Some clinicians indicate the earliest radiographic signs occur on the dorsolateral aspect of the tarsus. However, not all horses with DT pain have radiographic evidence of OA. Scintigraphic examination can be a helpful diagnostic tool in these cases and may reveal subtle changes within the tarsus not detectable by radiographs. In contrast, some horses with radiographic evidence of OA are not lame. The correlation between the degree of lameness and the extent of radiological abnormalities is poor. However, even subtle radiographic lesions can support the diagnosis in the presence of appropriate clinical findings. There appears to be little association between the duration and degree of lameness, the response to intra-articular anesthesia, and radiographic findings in horses with OA of the DT joint. Some lameness clinicians believe that horses with cystic changes and subchondral bone lucencies on radiographs develop more severe lameness. In contrast, some horses with few radiographic signs are problematic in that degeneration never progresses, and they remain lame. Some horses predominantly develop periarticular changes, whereas others have abnormalities confined to the central and third tarsal bones and proximal MT3.

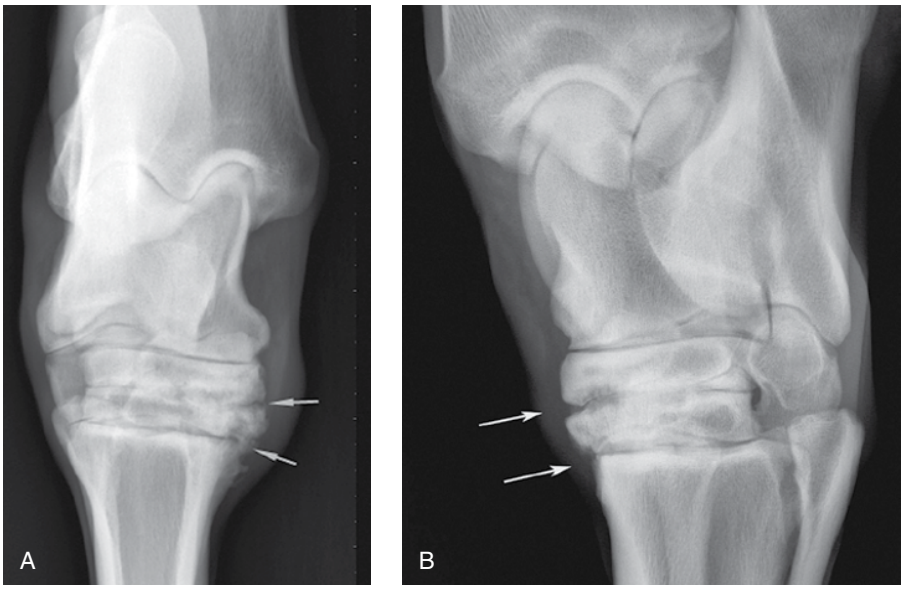

Figure 5.67. Radiographic changes of OA of the distal tarsal joints can vary considerably including periarticular osteophyte formation, subchondral lucent areas, subchondral sclerosis, periosteal new bone (A), and narrowing of joint spaces. The radiograph on the right is a horse with juvenile spavin with moderate degenerative changes of the DIT and TMT joints (B).

VetBooks.ir

Nuclear Scintigraphy

There is a repeatable pattern of RU in the DT region of normal horses, and an alteration in this pattern could provide an indication of tarsal pathology, related to altered patterns of bone remodeling. Nuclear scintigraphy is often unnecessary, but it can be helpful in difficult horses and those horses with performance problems rather than overt lameness. IRU may be focal or more diffuse, and this can vary between horses. Focal increased uptake may reflect intertarsal ligament enthesopathy rather than OA. Intense IRU may be present in the absence of radiological abnormalities, and these horses tend to respond poorly to intra-articular medication, despite a positive response to intra-articular analgesia. Horses with diffuse radiopharmaceutical uptake tended to respond to treatment better than those with focal uptake.[103] Diffuse uptake possibly indicates more generalized inflammation from use as compared to focal articular degeneration demonstrated by focal peaks of uptake. The distribution of inflammation may bear prognostic value as well. While nuclear scintigraphy can be useful adjunct to confirm DT joint modeling activity, it may also help to document other sites of involvement (Figure 5.68).

MRI

The primary indication for MRI is indicated when pain has been localized to the tarsal region using perineural analgesia or by intrasynovial analgesia, but there are no radiological or ultrasonographic abnormalities sufficient to explain the degree of lameness. However, an effusive TC joint may be a stronger indication for exploratory arthroscopy than for an MRI as the ability to surgically address the problem (if found) can be accomplished during the same anesthetic procedure. However, the most common use of MRI of the DT joints is to further evaluate horses that have pain originating from the proximal plantar region suggestive of PSD.

MRI examination of the tarsus requires that the horse be under general anesthesia. Acquiring diagnostic images of the tarsus in the horse in a low field strength magnet (usually found in standing systems) may prove to be difficult because of slower acquisition times and the inherent motion that occurs proximally on the limb. The contralateral limb would ideally be examined for comparison. See the imaging chapter on magnetic resonance imaging (MRI) for further details.

Using MRI, horses with DT pain have been found to have intertarsal ligament damage, focal cartilage damage, and localized bone pathology including cystic lesions and microfractures. It is therefore possible that DT pain incorporates a variety of different conditions, culminating in end-stage OA.

Differentiating DT Joint Pain from Proximal Plantar Region Pain

PSD of the hindlimb has become a frequently diagnosed cause of acute and chronic hindlimb lameness in mature horses that perform dressage, eventing, and general-purpose work.[38,39,82] The recent increase in the diagnosis of PSD may be due to improvement by veterinarians and equine professionals in recognizing this condition. However, lameness referable to this region is often initially assumed to originate from the DT joints. Subsequent intra-articular injection of corticosteroids into the DT joints may provide a local anti-inflammatory effect, which can minimize the pain associated with the active desmitis. This may allow the resumption of work before appropriate repair has occurred, leading to further damage to the SL. An accurate early diagnosis of PSD is critical to minimize further damage to the SL and justify aggressive and expensive treatment to salvage the horse's career. In one study of 40 horses with lameness

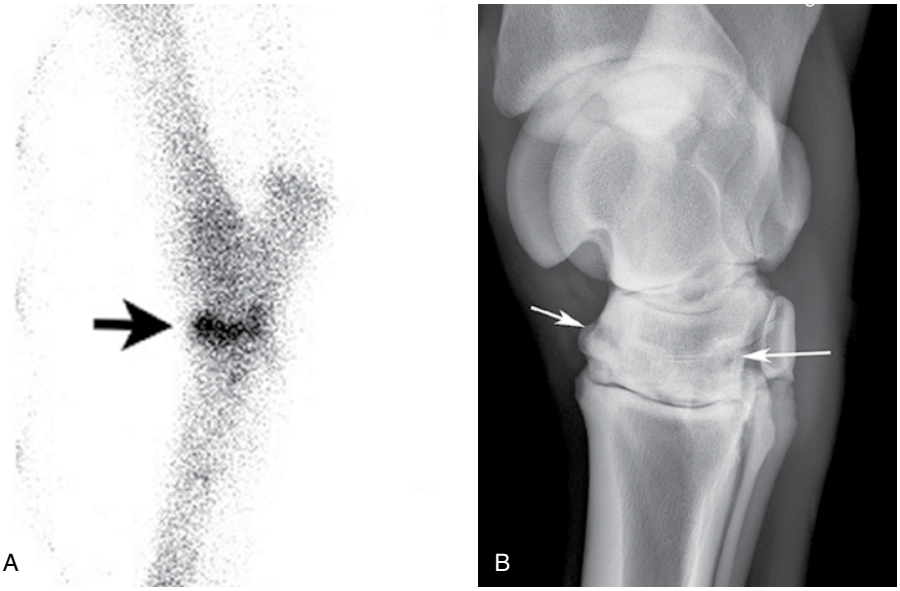

Figure 5.68. Lateral scintigram (A) and radiograph (B) of the tarsus of a horse with distal tarsal OA. There is diffuse uptake within the distal tarsal joints and joint space narrowing and lysis within the DIT joint (arrows) visible on the radiograph.

VetBooks.ir

that was eliminated by proximal plantar analgesia that underwent MRI of the region, some of the horses had OA of the DT joints, subchondral cystic lesions (SCLs) of the CT and 3T bones, intertarsal ligament pathology, and bone edema of the third and fourth tarsal bones without evidence of proximal suspensory disease.[82] Many of these horses had diagnostic analgesia of the TMT and DIT performed without significant response. The findings in this study continue to fuel questions about causes of tarsal pain and the accuracy of analgesia of the proximal metatarsal region.

Treatment of DT OA

OA of the DT joints commonly affects athletic horses during the most productive years of their lives and can limit their career potential. The goal of treatment is to provide significant, long-lasting pain relief that will permit the horse to remain comfortably in work. Horses with minimal radiographic changes of the DT joints may respond favorably to a short period of reduced activity, corrective shoeing, systemic medications (like nonsteroidal anti-inflammatory drugs [NSAIDs]), and a change in the work program. Intra-articular treatment options have included the use of corticosteroids, hyaluronan, or polysulfated glycosaminoglycans (PSGAGs).

A common strategy in the management of horses displaying mild bilateral hindlimb lameness (particularly those breeds and disciplines that are predisposed to DT lameness) is to medicate the DT joints with corticosteroids and evaluate for a response. A short-term response (less than 2–3 months) should be a concern that the primary source of pain was not effectively addressed and should be an indication to more carefully evaluate the tarsal region for other sources of lameness. The deposition of steroids into the TMT joint can have a local effect on the soft tissue structures in proximal plantar region and may suppress inflammatory changes in the proximal SL. Corticosteroids can also suppress healing by inhibiting the production of collagen, which may lead to a perpetuation/exacerbation of any injury of the proximal SL in this area. A short duration of effect for intrarticular (IA) corticosteroids could also be indicative of more advanced changes within the DT joints. Further clinical and imaging examination (potentially including MRI) of the tarsal region should be recommended.

Most clinicians recommend some form of intra-articular medication (see below) to help subdue the inflammatory changes within the DT joints. The response to therapy can often be predicted based on the extent of radiographic signs and to a certain degree on the duration of clinical signs. One study demonstrated a positive outcome following intra-articular medication in only 38% of cases with OA of the DT joints.[81] However, in that study only the TMT joint was treated in the majority of the horses, which may explain their low success rate. Another study reported that 52% of horses were able to return to their previous level of exercise, with an improvement in 70% of horses that had both the TMT and DIT joints injected.[24]

Historically it had been suggested that injection of corticosteroids (with or without hyaluronic acid [HA]) into the DT joints while maintaining the horse in work would eventually lead to ankylosis of these joints. It was felt that the presence of the corticosteroids within the joint would have a significant detrimental effect on chondrocyte metabolism and the continued work on compromised cartilage would lead to the advancement of the cartilage damage in these joints. However, clinically this does not seem to be effective, and there has been little evidence that ankyloses can be promoted by consistent intra-articular injection of corticosteroids. The current approach to managing bone spavin especially in a younger horse is to preserve the articular cartilage whenever possible.

Many factors may play a part in determining the specific treatment and management of horses with bone spavin.[64] These may include the degree of lameness, extent of radiological abnormalities, use of the horse, competition regulations, response to previous treatment, and financial constraints. Clinically horses with extensive radiological abnormalities or with scintigraphic abnormalities in the absence of radiological change seem to have a more limited response to intra-articular injections. Resting horses with bone spavin is usually not beneficial. Anti-inflammatory medications are indicated to reduce inflammation and pain in affected horses. Phenylbutazone (2.2 mg/kg, BID) can be continued for an extended period of time in most horses or given only when the horse is worked. Treatment with NSAIDs (particularly phenylbutazone) can be quite effective in some horses, and attempts should be made to find the lowest dose possible that will alleviate lameness. Long-term use of oral phenylbutazone at 1gram twice daily for a 500-kg horse is generally well tolerated. Any treatment should be combined with corrective trimming and shoeing. The inclusion of systemic treatment such as PSGAGs, pentosan, oral nutraceuticals, or any combination may also be chosen in certain cases.

Intra-articular Medications

Intra-articular medications such as corticosteroids, hyaluronan, and more recently IRAP can be utilized in joint inflammation.[43,53,81,90,130] Corticosteroids are potent anti-inflammatory agents and inhibit the inflammatory process at all levels and have been the mainstay of treatment for many years. Many horses with DT joint pain have been successfully managed throughout their athletic career with consistent (biannual to annual) intra-articular injections of corticosteroids. There are quite varying opinions about which drugs are most effective in the DT joints and for how long the clinical effects from these different drugs might last. It is not universally accepted which drug is most efficacious, what dose of any drug should be given, how frequently these injections need to occur, or if intra-articular antibiotics should be given in conjunction with the drug. The corticosteroids that are most frequently used include methylprednisolone acetate (MPA), betamethasone, and triamcinolone (TA) either alone or in combination with some form of hyaluronan products. Rest has been recommended after injection, but there is little evidence to support any prolongation of effect by doing so. In humans rest postinjection has been advocated after intra-articular medications in the belief that restriction of activity might reduce clearance of the medication and enable better penetration of intra-articular tissues.

VetBooks.ir

Depo-Medrol at a concentration of 40 mg/mL is most frequently used at 80–100 mg/joint. Use of Depo-Medrol at the 80 mg/mL concentration should be discouraged as this product has a high incidence of flare reactions. Triamcinolone can be used at 4–9 mg/joint depending on how many joints are to be injected. Most clinicians do not exceed a total body dose of 18–20 mg because of reported increased risk for laminitis, although this dose limitation seems to be a source of debate. The frequency of injection should not be more often than every 3–4 months and in most instances twice a year is sufficient. It is thought that corticosteroid injections can be repeated two or three times per year without promoting progressive radiological change. There are no controlled clinical trials assessing the relative efficacy of different corticosteroids or the use of the combination of corticosteroids and hyaluronan, although some clinicians believe that combination therapy provides a longer clinical effect. Hyaluronan alone is of questionable value.

If the PIT joint is involved, the control of synovitis is indicated to prevent, or at least retard, development of OA in the TC joint. Frequent injections of the TC (and therefore the PIT joint) should be discouraged as this is a high range motion joint and can be at risk of developing progressive OA. Some clinicians suggest that hyaluronan prolongs the anti-inflammatory effects of the corticosteroid and can counteract the negative effects of MPA; however there is no evidence to support this. There is even conflicting evidence about whether HA combination therapy with TA or betamethasone esters does in fact prolong the chondroprotective effects of the corticosteroids. Lastly, disagreement also exists with respect to whether HA should be used at all because of the limited fluid volume that can be injected into the DT joints. Chronic administration of intra-articular corticosteroid should prompt regular radiographic evaluation of cuboidal tarsal bone density to detect the degree of advancement of OA in these joints.

A recent study evaluated the concentration of MPA or its ester methylprednisolone (MP) in the DIT joint after injection of MPA into the TMT joint. Injection of 80 mg of MPA into the TMT joint allowed diffusion into the DIT joint.[130] It was thought that the MPA and/or MP may have diffused either through the tarsal canal and space between the fused first and second tarsal bones and the third tarsal bone or through the thin synovial membrane. Regardless of the mode of diffusion, molecules of MPA or MP were found to diffuse from the TMT joint into the DIT joint in a concentration that was believed to be high enough to suppress inflammation. The authors proposed that horses affected with OA of both the DIT and TMT joints that are treated by intra-articular injection of MPA can be treated by instilling MPA into the TMT joint alone. However, it is questionable whether this concentration is effective to manage DT pain. In addition, diffusion of MPA and MP needs to be evaluated in horses with clinical disease of these joints.

Autologous conditioned serum (ACS) is thought to act by blocking the receptor to the inflammatory cytokine interleukin-1 (IL-1).[53,96] Arthrex Biosystems independently patented the technique of IRAP enrichment of serum and subsequent injection of this enriched serum into joints as IRAP® and IRAPII®. The technique has been used in human orthopedics (Orthokine®) since 1998 for treatment of OA, rheumatoid arthritis, and spinal disorders. There have been no case-controlled or peer-reviewed publications published in the literature regarding the efficacy of IRAP in DT joint OA in the horse. When using IRAP/IRAPII for the DIT or TMT joint, the manufacturer recommends using 1–2 mL/joint every 14 days for three treatments. This treatment needs to be evaluated clinically and with controlled research.[53,96]

Alternatively, intra-articular injections of PSGAG (three injections given every 2 weeks) have also been used in competition and racehorses with DT joint pain.

Extracorporeal Shockwave Therapy (ESWT)

The use of extracorporeal shockwave therapy (ESWT) in horses with DT OA was first described in a series 74 predominately western performance horses (130 joints).[88] The horses had been treated medically and had either become refractory to IA treatment or the response had reached an unacceptably short duration. Horses were treated under general anesthesia and received 2000 pulses. Fifty-nine of 74 horses (80%) showed improvement in lameness of at least 1 grade 90 days after treatment, but only 13 (18%) were sound. No radiographic differences were detectable between pre- and 90-day posttreatment evaluations. The fact that ESWT stimulated no further ankylosis in the large series of horses with DT OA might cause one to more strongly consider pain relief as a significant component of the mode of action. An analgesic effect of ESWT was thought to be the cause of improvement seen in these horses.

Bisphosphonates

Bisphosphonates are thought to be the most potent inhibitors of bone resorption clinically available to human and veterinary medicine. Two bisphosphonates that are now commercially available for use in the horse are tiludronate (Tildren$_R$) and clodronate (Osphos$_R$). An intravenous form of tiludronate (Tildren$_R$) has been used in horses at 0.1 mg/kg bwt/day for 10 days and is currently licensed for the treatment of navicular disease and bone spavin. The main action of tiludronate is the inhibition of osteoclasts, which in turn inhibits bone resorption. Tiludronate slows down bone remodeling and is felt to restore a normal balance between bone resorption and bone formation. Tiludronate has also been shown to have anti-inflammatory properties by decreasing the amount of nitric oxide and cytokines released from activated macrophages, which promote the early inflammation response. A recent clinical study[62] showed that Tildren$_R$ was effective in treating bone spavin in horses particularly when utilized in association with a controlled exercise program. Horses with periarticular osteophytes and subchondral bone thickening were felt to respond better. Little work has been performed to evaluate clodronate (Osphos$_R$) in the treatment of bone spavin in horses.

Whatever protocol that is selected to treat horses with DT OA, it should be combined with corrective

VetBooks.ir

trimming and physiological shoeing (Figure 5.69). Horses with tarsal pain or bone spavin may attempt to unload the dorsal (front) aspect of the small tarsal joints by redistributing their weight. The first indicator of a DT problem may be the pattern of shoe wear. When a horse that has been wearing the hind shoes level from heel to toe begins to wear the toe excessively, it may be an indication that the horse has altered its gait in an effort to minimize extension. A second indication of a hock problem may be dragging of the toe on the affected limb(s). However this has also been described in horses that have pathology involving the stifle. Excessive toe wear may be the result of the horse trying to minimize hock flexion and carrying the hoof in a low arc of flight. Low or underrun heels affecting the health of the foot, or as a cause of lameness, are often overlooked in the hindfeet and may contribute to lameness of the distal hock joints. Underrun or collapsed heels in the hindfeet may lead to subtle bilateral lameness, which is often attributable to hock, stifle, or back pain. Low heels or short shoes allow the ground surface of the hoof at the heels to move forward, changing the conformation of the distal limb, which alters the angulation of the hock. Damage to the heels of the hindfeet is easier to improve than in the forefeet, possibly due to the anatomy and the difference of the load encountered on the hindlimbs.

Hindlimb foot management is aimed toward improving foot conformation and to facilitate break-over by shortening the toe by squaring and/or rolling the toe of the shoe if necessary. Shoes to the hindfeet are fit the same as the front where a line is drawn across the widest part of the foot and the shoe is fitted so the line is placed in the middle of the shoe.[3] In the hindfeet, the branches of the shoe will extend beyond the end of the heels. The appropriate length of the hind shoe can be determined by dropping a vertical line from the bulb of the heel to the end of the shoe. Fitting the shoe in this manner will change the conformation of the distal limb and the angulation of the hock during impact and the stance phase of the stride. To help reduce weight, wide-webbed wedged (flat) aluminum shoes are used in some show horses, but one has to be cautious when applying a wedge to low heels as this may increase pressure on these structures. A lateral trailer or a lateral extension of the shoe tends to stop excessive twisting of the limb. However, these devices may be contraindicated in horses that have to stop and turn quickly, because the extension may dig into the footing and stop the distal limb abruptly, causing abnormal torque on the distal limb joints. Common shoeing recommendations for horses with DT OA include lateral (outside) extensions or trailers, heel elevations, and rolled or squared off toes.[107]

Advanced Treatment Procedures

Surgical Arthrodesis of DIT and TMT Joints

When bone spavin becomes refractory to systemic treatment and intra-articular medications, more aggressive therapy may be warranted. The natural resolution of advanced OA (bone spavin) is ankylosis. Ankylosis can stabilize the joint sufficiently enough to minimize the pain creating lameness (Figure 5.70). However, ankylosis is unpredictable and can take some time to progress to soundness. This rarely happens without surgical intervention, and therefore surgical arthrodesis techniques have been developed to help accelerate joint fusion.[1,4,6,33,48,91,129,150,151] The optimal treatment for arthrodesis of the DT joints should be minimally invasive, create widespread necrosis of the chondrocytes and destruction of the articular cartilage matrix, cause little to no discomfort for the horse during the treatment period, lack serious complications, and be affordable.

A variety of techniques have been developed for surgical arthrodesis of the DT joints. Currently, intra-articular drilling of the joint spaces is the most widely used means to promote surgical arthrodesis. Focal mechanical destruction of the articular cartilage and subchondral bone via "three-path" technique with removal of less than 60% of the cartilage is probably the most common arthrodesis technique (Figure 5.71). Variations in technique include size of drill bit, use of bone graft, and degree of radiographic or fluoroscopic control utilized during the procedure. The drill tracts eventually heal with a bridging callus, which crosses the joint space acting to stabilizing the joint in a manner similar to spot welding of metal. One study found that of 36 horses having the three-drill tract procedure performed, 66% were able to return to their previous levels of performance.[33] An additional 14% of horses improved after surgery, but did not meet the criteria to be considered successful. In that study, no clinical, radiographic, or surgical factors were beneficial in predicting clinical outcome; however, there was a trend toward improved outcome when precise radiographic monitoring of the drilling procedure was performed at surgery.[33] The major disadvantages of this technique include expense and prolonged convalescence, which ranges from 4 to 12 months. There is also a concern that results in upper-level competition horses are less favorable. Careful

VetBooks.ir

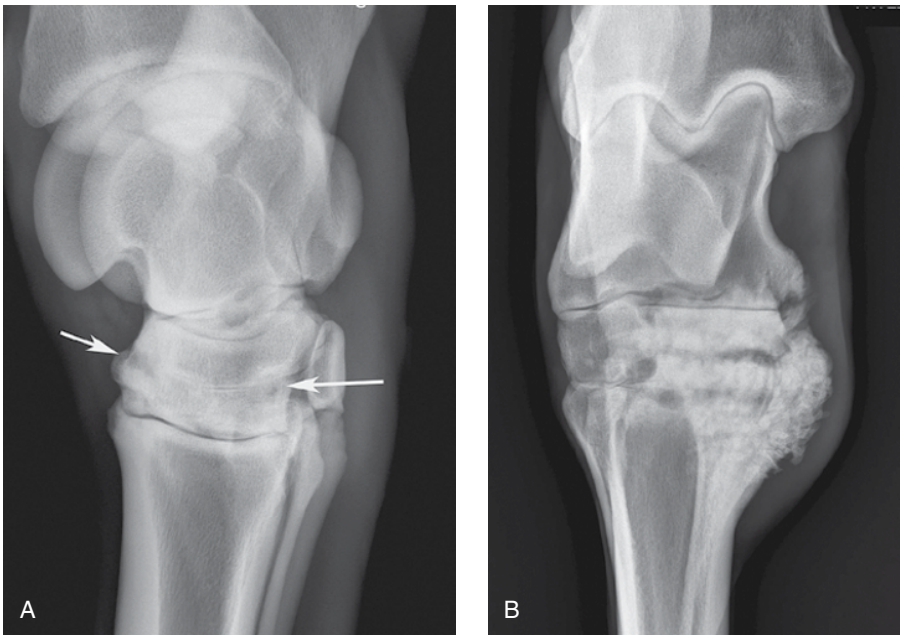

Figure 5.70. The outcome of horses that undergo natural ankylosis of the hocks is variable. The tarsus on the left (A) has nearly fused naturally and the horse is sound. The one on the right (B) is attempting to fuse secondary to an infectious process and remains consistently lame.

radiographically or fluoroscopically controlled surgical drilling of the articular cartilage is essential to maintain the drill within the joint space to allow the removal of the maximum amount of articular cartilage.

The use of internal fixation in horses with DT disease has not been shown to improve the success rate of arthrodesis beyond drilling alone. If the PIT joint is involved, the prognosis is less favorable, but it too should be drilled, because this offers the best chance of a complete recovery. Other techniques that have been utilized in addition to drilling include intramedullary decompression or fenestration of the DT bones. This has been proposed to provide rapid pain relief in some horses, but this has not been proven. Complications of IA drilling include fracture of the CT or T3 bone(s), development of OA in the PIT joint, and continued lameness despite apparent bone bridging of the DT joints. The latter may be due to micromotion between the tarsal bones and splint bones or bone on bone contact secondary to cartilage destruction from the treatment technique used.

Laser Arthrodesis

Laser-facilitated arthrodesis is another technique to promote fusion of the DT joints. This technique has been most commonly been performed using the neodymium–yttrium aluminum garnet (Nd:YAG) or 980-nm diode laser (Figure 5.72). Laser arthrodesis is thought to be effective because it destroys the articular cartilage by superheating and vaporizing synovial fluid. It has been suggested that the increased temperatures that develop within the joint result in chondrocyte death as well as a collagen shift in the intertarsal ligaments and joint capsule. Reports on horses with laser-facilitated arthrodesis suggest improvement in the successful outcome with minimal postoperative pain and decreased convalescent time compared with other methods.[67,68,130] Surgeons performing this technique suggest that horses with radiographic changes such as severe periarticular osteophyte formation or excessive mineralization of the joint capsule require a modification of the laser procedure to facilitate placement of the laser fiber into the joint. These changes may signify a less favorable prognosis after surgery.

In one study that compared three methods of laser arthrodesis, the energy applied to the DT joints did not result in generalized articular cartilage destruction when evaluated with MRI and histology.[151] Full-thickness thermal destruction of the articular cartilage extended only a few millimeters from the insertion site of the laser across the joint. It was also speculated that the laser may cause less postoperative pain due to thermal damage to nerve endings in the subchondral bone, synovium, and joint capsule, resulting in decreased pain perception in horses after treatment.[151]

Chemical-Induced Arthrodesis: Ethyl Alcohol

Ethyl alcohol is a colorless liquid that has been reported to provide clinical success in facilitated ankyloses of the DT joints. Ethyl alcohol is thought to affect chondrocytes (neurolysis and tissue destruction at the drug–tissue interface) in a manner similar to monoiodoacetate (MIA) but without the severe postinjection pain. MIA has been evaluated and utilized in the past to chemically induce arthrodesis but has fallen out of favor due to the severity of postinjection pain and the development of severe long-term complications (PIT and TC OA).[16,18,37,126] Like MIA, ethyl alcohol can be easily injected into the joints, and because of its neurolytic and nonselective protein destructive properties, it has the potential to block sensory innervation to the joint while causing necrosis of chondrocytes and hastening

VetBooks.ir

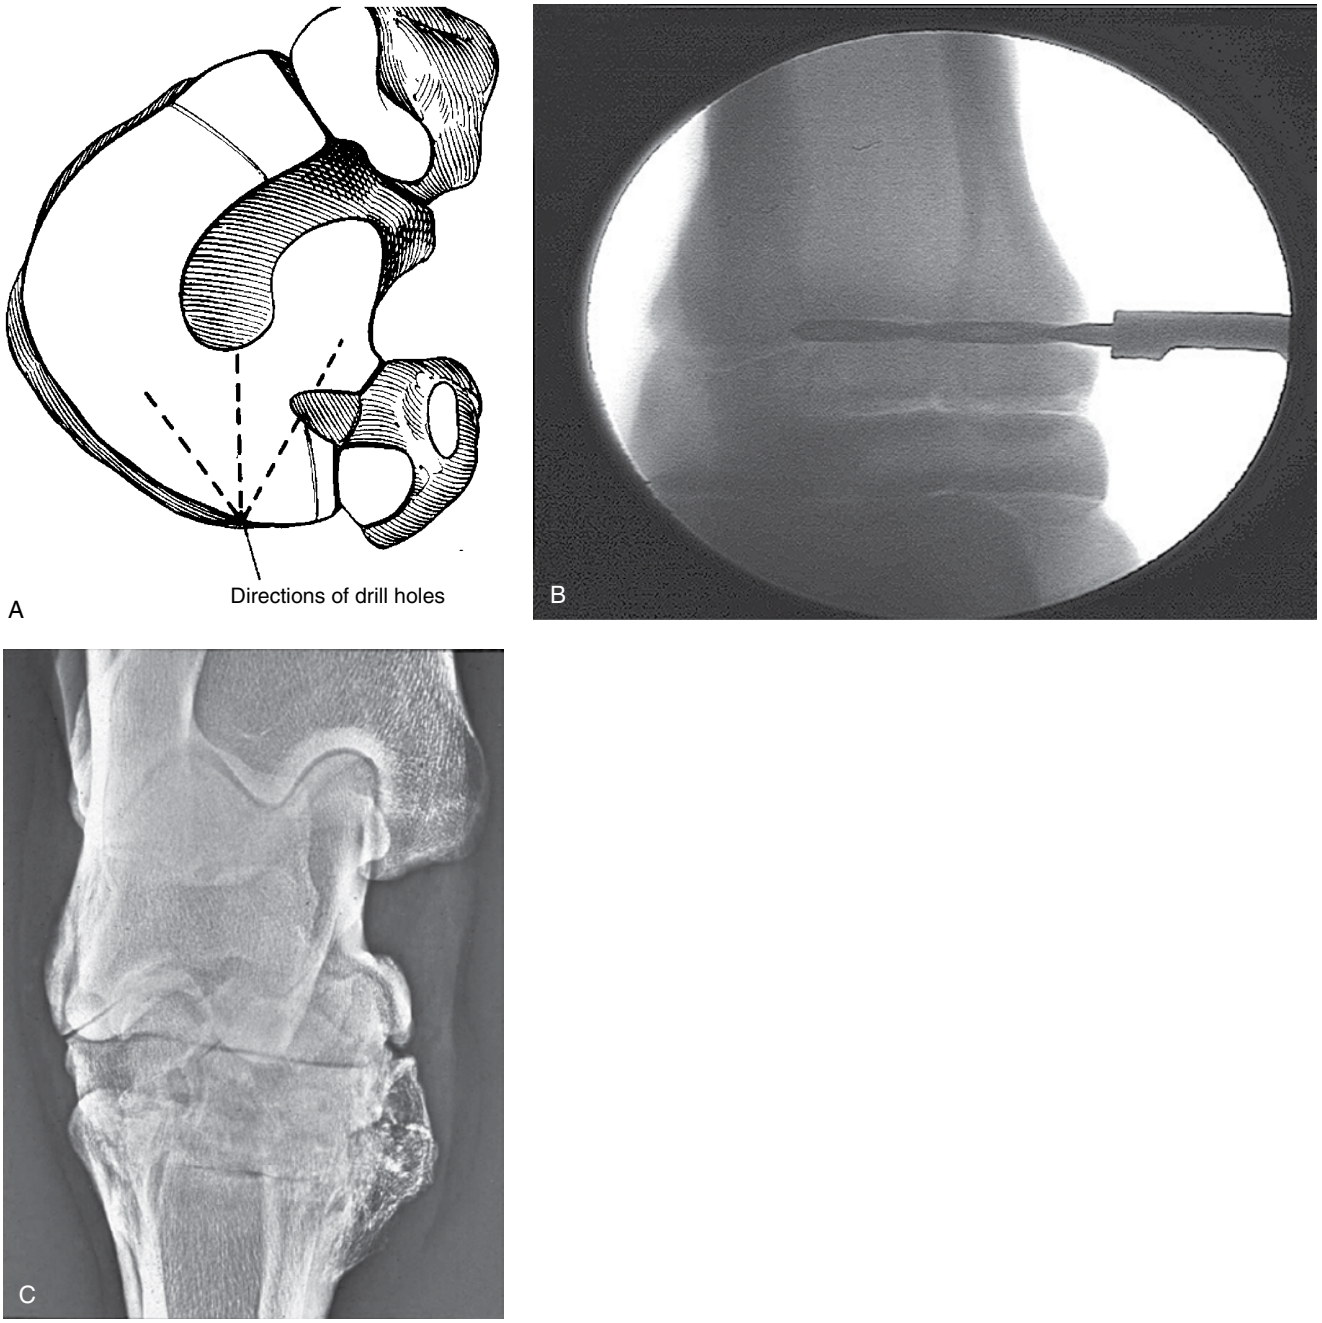

Figure 5.71. DIT joint surface of the central tarsal bone illustrating the 3-drill path technique for distal tarsal arthrodesis (A). *Source*: Courtesy of J.D. Sullins. The drill is inserted through a single hole, passed in three different directions, and can be monitored with radiography or fluoroscopy. (Image is with horse in dorsal recumbency.) (B). A significant amount of joint surface is undisturbed, which preserves stability but promotes arthrodesis of the distal two tarsal joints (C). *Source*: Courtesy of Dr. Gary Baxter.

arthrodesis. Minimal local irritation has been observed in areas of the injections (subcutaneous and intra-articular), with no long-term adverse outcomes such as skin necrosis or hair discoloration.

Administration of ethyl alcohol into the TMT joint of healthy horses appeared to facilitate arthrodesis of the joint in a pain-free manner. TMT joint fusion was achieved with either 70% or 95% ethyl alcohol in 15 of 16 horses without lameness or radiographic evidence of tarsal joint OA.[132] None of the horses were lame after injection, and joint fusion was complete by 8 months. No significant difference in lameness scores was observed between the use of 70% and 95% ethyl alcohol treatments. There was marked, generalized narrowing and extensive, multifocal bony bridging across the joint space between the third tarsal and third metatarsal bones, and the articular cartilage in areas without bony fusion was thin and discolored. The treatment appeared to cause minimal pain and suggested that ethyl alcohol may destroy the sensory innervation of the synovium, joint capsule, and subchondral bone, which permitted fusion of the joint without associated lameness.

VetBooks.ir

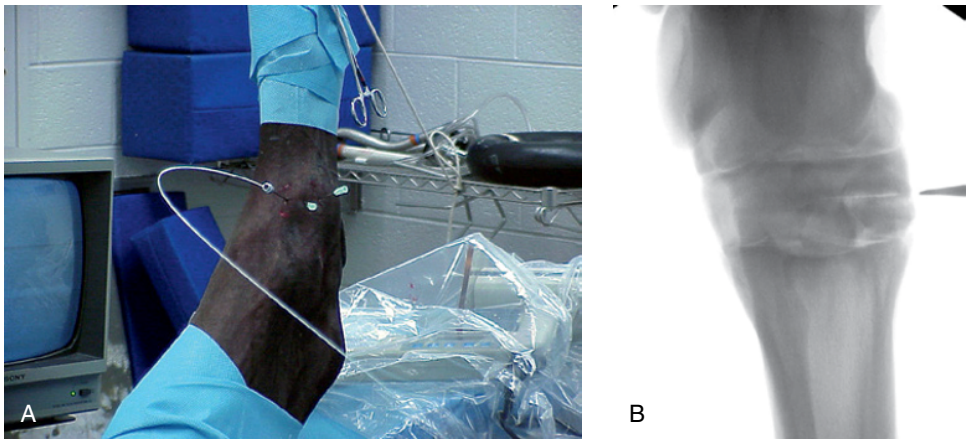

Figure 5.72. Laser arthrodesis of the tarsi is usually performed under fluoroscopic guidance with the horses in dorsal recumbency. The laser fiber is inserted through needles placed into each DIT and TMT joint (A), and the position is confirmed by fluoroscopy (C-arm) or radiographs (B).

A follow-up study using ethyl alcohol in horses with DT OA revealed a rapid reduction in lameness, such that horses could return to their intended use after injection.[25] Contrast arthrograms were performed in these horses and when no communication with the PIT or TC joint could be identified, 3 mL of 70% ethyl alcohol (prepared from 95% laboratory-grade ethyl alcohol) was injected via the needles used for the arthrographic evaluation. Lameness resolved in 18 of the 21 treated horses, but the horses did not develop the degree of joint fusion expected based on the original study in young, healthy horses. However, the horses with clinical OA had a rapid and sustained reduction in lameness such that they could be trained (i.e. brought into work) or competed within days following treatment.

CUNEAN TENECTOMY

The proposed rationale for performing cunean tenectomy is to reduce the torsional forces on the cuboidal bones of the tarsus, which presumably result from tension in the medial extension (cunean tendon) of the cranial tibial muscle.[46,55] The procedure is simple to perform in the standing horse. Clinical reports on the success rates for cunean tenectomy are lacking, but anecdotal information indicates efficacy in many horses. It seems that the clearest indication for cunean tenectomy would be in horses with chronic lameness that has failed to respond to medical treatments and is alleviated by local anesthesia of the cunean bursa. However, infiltration of the cunean bursa with local analgesia may not be specific because of the adjacent joint capsules. Efficacy of cunean tenectomy may depend on early return to exercise before scar tissue replacement becomes restrictive. Currently, cunean tenectomy is performed infrequently because it is unlikely to completely restore soundness.

Neurectomy of the Tibial and Deep Peroneal Nerves

Neurectomy of the deep fibular nerve or a partial neurectomy of the tibial nerves has been reported as a treatment for horses with bone spavin.[73] The technique has reported that approximately 60% of treated horses returned to full athletic function. The authors' conclusion was that the convalescence was shorter than following surgical arthrodesis, but that the surgery time was prolonged due to the sizable incisions that must be closed. However, with all the options present for arthrodesis and facilitated ankyloses, neurectomy of the tibial and deep peroneal nerves should be considered a salvage procedure and not a first-line approach to horses with nonresponsive OA of the DT joints.

Tarsocrural Joint Effusion/Bog Spavin

Synovitis and fluid accumulation within the TC joint is a common finding in young horses and is referred to by laypeople as "bog" spavin. Most often it is a benign nonseptic fluid of unknown cause. When distended, the TC joint protrudes into four distinct pouches. The largest and most prominent is located dorsomedially, with a smaller one dorsolaterally and two large plantar (plantaromedial and plantarolateral) pouches on each side of the joint just dorsal to the tuber calcaneus. Pressure exerted on any one of these swellings can move the fluid between the joint pockets. These fluctuant, movable swellings must be differentiated from periarticular edema (local or diffuse) with less distinct fluid pockets that is more characteristic of an extra-articular joint problem.

Injury to the TC joint can occur due to stops, quick turns, or other traumatic events that can create injury of the joint capsule. Occasionally, performance horses can develop acute TC effusion manifesting as a severe lameness (approaching that of sepsis). Synovitis and capsulitis are probably significant components of the pain creating lameness, but the cause can be elusive. In these cases, radiographic abnormalities are usually absent. Horses are treated with rest and local and systemic anti-inflammatory therapy. Response to therapy can be profound and rapid. However, structural damage such as CL sprain or nondisplaced fracture should be ruled out before using anti-inflammatories and returning the horse to work. As is often noted in horses with osteochondritis dissecans (OCD), the swelling is often not painful to palpation.

VetBooks.ir

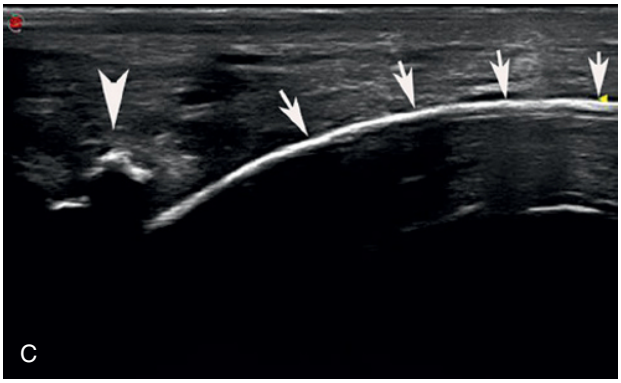
Horses presenting with TC effusion should have a complete lameness evaluation and should have radiographic and ultrasonographic examinations centered on this joint. Horses may have a "bog" that persists for years without lameness even in successfully working horses. There may or may not be significant radiographic signs of disease. As a primary condition, the term "bog" should be limited to those clinical situations in which the inciting cause of the effusion cannot be identified. Lameness can be quite variable and often depends upon the severity of the synovitis. The underlying cause for the development of effusion includes straight hindlimb conformation (through the tarsus), presumably due to continuous trauma to the articular cartilage (Figure 5.73). Subtle OC lesions can worsen with time and can precipitate synovitis/capsulitis and the potential to develop OA. Horses that have mild but clinically significant disease, especially those that require intermittent intra-articular treatment, may eventually, and usually, become more lame as the OA advances.

Many different types of pathology can produce TC effusion (bog spavin). These include OC, OA (including the TC, PIT, and DT joints), traumatic injuries (including CL injuries and capsular tearing), poor conformation, and infection. These will be discussed in more detail in subsequent sections of this chapter. Focal partial- or full-thickness cartilage erosions on the major weight-bearing parts of the trochlea of the talus can exist but may not be apparent on radiographic examination. Surgical arthrodesis and facilitated ankyloses of the DT joints can change the dynamics of the lower joint function, which can lead to the development of OA within the PIT joint, which can manifest as TC effusion. Intra-articular tearing of the TC joint capsule has recently been recognized as a cause of effusion that can only be diagnosed arthroscpically.[5]

Figure 5.73. Horses with a straight limb conformation particularly with a straight tarsal region and a dropped fetlock appear to have a predisposition for DT joint disease presumably due to continuous trauma to the articular cartilage.

It is important to differentiate between TC effusion and periarticular edema. The two may exist concurrently, but they may indicate different problems. Periarticular edema often occurs with CL injury. Any indication that the injury is associated with the intra-articular portion of the short collateral (reported to be more common laterally) is a contraindication for intra-articular injections of corticosteroids (normally used for bog spavin). Scintigraphic examination may be considered with more acute and moderate to severe lameness when there is associated TC joint effusion. Diagnostic arthroscopy is indicated to evaluate the intra-articular environment and initiate treatment when intra-articular injection of anti-inflammatories fails to resolve the effusion or the effusion returns after a short period of time.[5,51]

Many clients want their horses to have a more normal appearance of the tarsus (cosmetically acceptable). Attempts to treat the swelling with HA and corticosteroids may have short-lived success, but the effusion usually recurs. A support bandage can be applied to assist in preventing of the return of the effusion. Repeated injections should be avoided. Some have reported that the use of atropine in nonresponsive cases may have an effect when the corticosteroids do not. There is no known pharmaceutical mechanism of action, but 4–6 mg is being used with noticeable success.



Diagnostic arthroscopy is a very important imaging tool in the evaluation of the effusion of the TC joint. It is considered the gold standard to assess the articular cartilage is many joints, and a study by Barker et al.[5] in 30 horses with soft tissue injuries found that TC arthroscopy provided diagnostic information that was not apparent with radiographic and ultrasonographic examination. TC joint arthroscopy also allows the direct inspection of the intra-articular portion of the CLs and permits completion of necessary surgical procedures (i.e. OC debridement). Arthroscopy is a particularly important imaging tool for many horses with idiopathic TC joint effusion.

OA of the TC Joint

Although uncommon, OA of the TC joint is usually readily apparent. There is usually marked swelling of the entire tarsus, and flexion of the tarsus is extremely painful. Radiographic examination of horses with OA of the TC joint can demonstrate chronic changes with significant periosteal new bone formation and enthesophytosis of the joint capsular attachments (Figure 5.74). A complete ultrasonographic exam is indicated in these cases to evaluate the periarticular tendons and ligaments, the joint capsule, and the joint fluid as well as providing valuable information about the cartilage and subchondral bone surface. In the TC joint, OA tends to cause cartilage degeneration and thinning on the trochlear ridges of the

VetBooks.ir

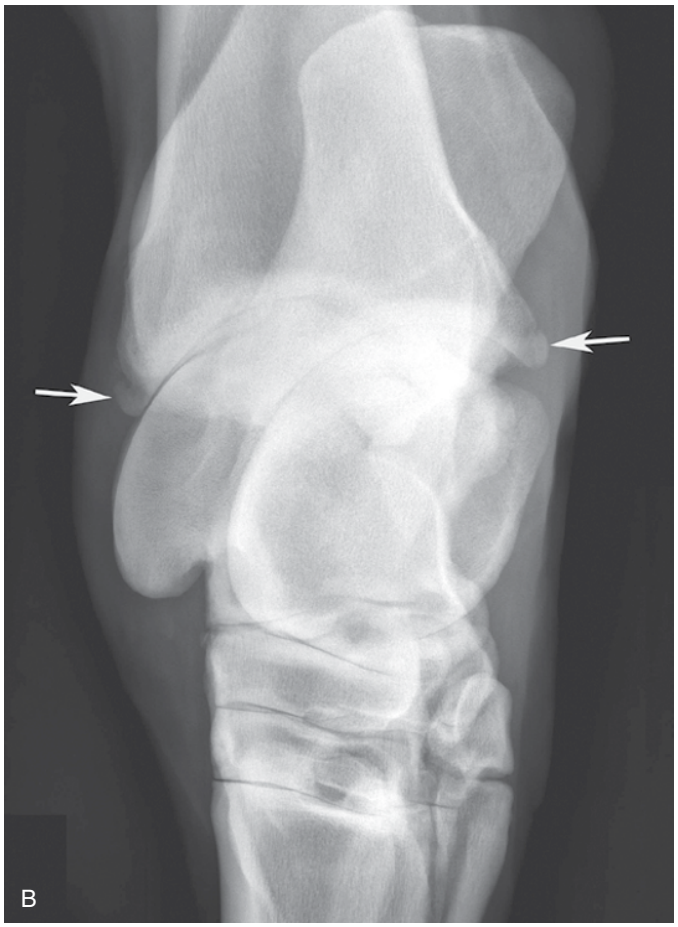


Figure 5.74. Horses with OA of the TC joint can develop chronic thickening of the joint capsule (A; small arrows) and significant enthesophytes of the joint capsular attachments (A and B; large arrows). The longitudinal US image of the lateral trochlear ridge (C) demonstrated significant loss of articular cartilage (arrowheads) and periarticular osteophyte formation (arrow). Proximal is to the left of the image.

talus (Figure 5.74C). Joint capsule thickening, with or without metaplasia, is also a common feature of OA.

Diagnostic analgesia is usually not necessary but may be indicated in some horses that have had persistent swelling but have only recently started to manifest lameness. Intra-articular analgesia of the TC joint may not effectively eliminate the lameness due to the presence of an intact articular cartilage and the presence of substantial subchondral bone pain associated with OA of the TC joint. Perineural analgesia of the tibial and peroneal nerves may be required to improve the lameness.

Most TC disorders have joint distension (bog spavin) as a component of the clinical presentation. As discussed before, not all horses with bog spavin are lame. In addition, the majority of horses with benign effusion of the TC joint will not have a marked response to proximal limb flexion (spavin test). However, the presence of a bog spavin in a horse manifesting lameness needs more careful evaluation of the TC joint. However OA of the TC joint can occur as a primary disease but usually develops due to an underlying problem such as an OC lesion (long-standing DIRT lesion left *in situ* is most common), or it can be a sequela to some traumatic injury of the joint. Long-term administration of corticosteroids into a chronically effusive TC joint can lead to OA particularly when treatment is instituted without an accurate diagnosis. As mentioned earlier, OA of the TC can be seen in conjunction and may be due to extension of OA of the DT joints (it is possible that there is a causal relationship). Some horses that are diagnosed with TC pain may have concurrent talocalcaneal OA as these two joints freely communicate.

Acute onset of a marked to severe weight-bearing lameness associated with swelling of the TC joint frequently indicates a traumatic event. This is often associated with joint distension and/or periarticular swelling of the tarsus. Intra-articular fractures or synovial infections are typically easy to localize and demand immediate attention. Penetrating wounds that breach the synovial membrane of any of the four pouches can lead to significant heat, swelling, and pain of the TC joint. Management of these types of injuries is discussed later in this section.

The presence of a partially mobile OCD fragment such as a DIRT lesion may predispose to OA of the TC joint. Asymptomatic OCD of the intermediate ridge of the tibia is often left alone with the horses placed in show regularly. It is not uncommon to have chronic long-standing DIRT lesion in a horse that suddenly

VetBooks.ir

develops synovitis, effusion, and moderate lameness later in their career. These horses should have these fragments removed arthroscopically. It is not uncommon to find cartilage damage consistent with OA at time of surgery. These horses can be difficult to keep sound because of persistent low-grade lameness.

OA of the Talocalcaneal Joint

The talocalcaneal joint is a curved articulation between the plantar aspect of the talus and the dorsal aspect of the calcaneus. Its soft tissue support arises from 4 ligaments—the medial, lateral, proximal, and interosseous talocalcaneal ligaments.[60] The mechanics of this joint have not been described, but it is considered a low-motion joint.

OA of the talocalcaneal joint is not common, and descriptions of this condition are based on case reports.[134,139] However, when it occurs, it is usually a moderate to severe unilateral hindlimb lameness. There are usually no localizing clinical signs. Lameness is typically exacerbated by proximal limb flexion of the hindlimb. The clinical signs resemble those of horses with DT OA but tend to be more severe. The cause of this condition is unclear, but because of the usually sudden onset of lameness, it is assumed to be an acute soft tissue injury probably related to disruption of the talocalcaneal ligaments.

Diagnosis requires elimination of the lameness by diagnostic analgesia and confirmation with diagnostic imaging. Talocalcaneal joint analgesia has not been found to effectively eliminate the lameness and at best gives only partial improvement. Perineural tibial and peroneal analgesia has been the most reliable method of reducing the lameness. Clinical examination, history, results of regional analgesia of the tibial and peroneal nerves, the presence of radiographic changes of this joint, and nuclear scintigraphy can help to confirm talocalcaneal OA as the cause of lameness (Figure 5.75). The lateromedial radiographic view is the best projection to evaluate this joint for changes consistent with OA including subchondral bone lysis, sclerosis, and irregular joint space width. Nuclear scintigraphy can demonstrate marked IRU in the plantaromedial aspect of the tarsus.

In the largest reported case series of 18 horses with talocalcaneal OA, 14 horses were treated conservatively with stall or pasture rest, with or without intra-articular corticosteroids, HA, or PSGAG, and all remained lame. Intra-articular corticosteroids appeared to have little effect on any horse.[133] Follow-up exams often demonstrated a rapid progression of radiographic changes. Because of the poor response to conservative management, more aggressive therapies are now being attempted. Subchondral forage and local neurectomy have been utilized but have been unsuccessful. Six horses have had a surgical arthrodesis using 2 or 3 5.5-mm screws placed in a neutral fashion. All of these horses improved significantly, but none became sound. Interestingly, one of these horses developed contralateral talocalcaneal OA 2 years later. While surgical arthrodesis is now the treatment of choice, the prognosis remains poor for a return to performance soundness.

Developmental Orthopedic Disease of the Tarsus

Developmental orthopedic disease (DOD) is a term used to describe many orthopedic problems seen in the young horse. It is discussed in further detail in Chapter 10. The term describes a series of growth disturbances of young horses including OC (OCD), SCLs, angular deformities, flexural deformities, physitis, cuboidal bone abnormalities, and juvenile OA. All the forms of DOD can occur in the tarsus.

OC of the TC joint occurs at very consistent sites.[64,66] TC OC tends to occur at the edges/limits of the talus

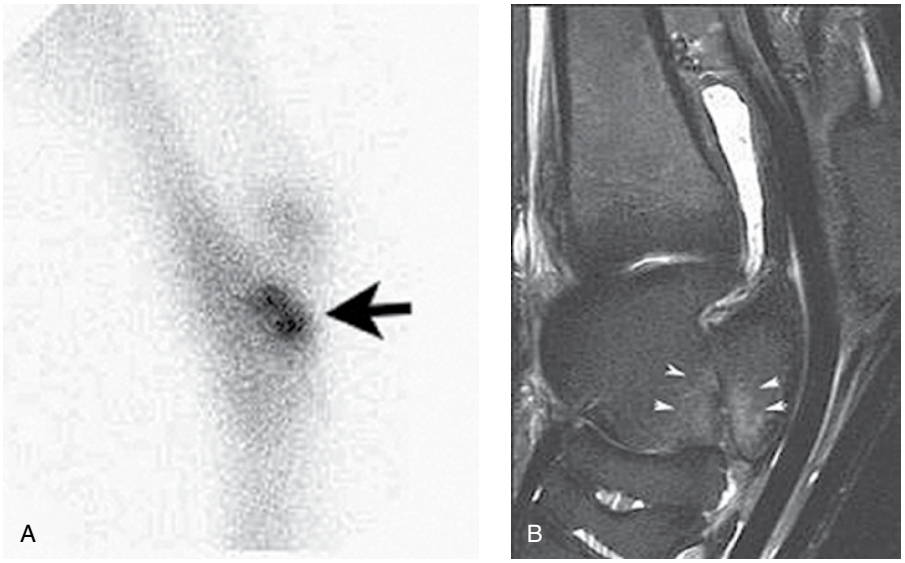

Figure 5.75. Horses with talocalcaneal osteoarthritis (OA) usually present with unilateral moderate to severe hindlimb lameness without localizing clinical signs. Nuclear scintigraphy (A) and MRI (B; arrows) can be very helpful to identify the site of bone remodeling/pathology within the joint.

VetBooks.ir

and tibial articular surfaces where the makeup of the cartilage between articulating and non-articulating surfaces is different. Weight-bearing produces sheer stresses within the immature cartilage at these sites, which damages the vascular supply to the articular cartilage. Increases in weight and activity of the foal increase the biomechanical stresses placed on the articular cartilage that can increase the incidence of lesion development. Silent or quiescent lesions may become apparent only when the horse is started into training and the joints become challenged by athletic activity. The age at which this occurs can vary with the discipline of the horse. For example, Warmblood horses commonly present with clinical signs of TC OCD (TC joint effusion) around 3 years of age or older, whereas racing TB and STB manifest signs much earlier (2 years of age) because they begin race training earlier in life. OC lesions can also undergo spontaneous resolution. This occurs by intramembranous ossification of granulation tissue that forms deep in the lesions progressively filling of the OC defects with bone. While OC of the DIRT and LTR of the TC joint can be radiographically evident within a few months of life, they may not be clinically detectable until later. Lesions found before the age of 5 months may not persist, but those lesions detected after 5 months typically will persist thereafter.[36]

OC can occur in all joints, but most often they occur in the hock, stifle, and fetlock joints. Multiple joints can be affected, but usually only one joint is involved. Bilateral involvement (i.e. both stifle joints or both hock joints) occurs often enough so that the opposite joint should always be radiographed. Bilateral occurrence can also occur with only one joint becoming clinically apparent (manifesting effusion). This can occur in the TC and femoropatellar (FP) joints in more than 50% of clinical cases. However, it is uncommon for both the hocks and stifles or the hocks and fetlocks to be involved in the same animal at the same time. Lameness is seen more often in FP OC than in TC OC and is most likely to occur with an acute onset of effusion. Lameness also often occurs when there is a loose or semi-loose osteochondral fragment observed radiographically. It is also uncommon to treat OCD in one joint(s) and have it develop at a later time in other joints.

Osteochondritis Dissecans of the Tarsocrural Joint

OC occurs in the TC joint commonly.[10,12,22,66,84,89,92,93,110,122,136] Horses of all ages can be affected. Many horses are sound at a walk and trotting in hand, but may display lameness at faster speeds or when put into work. Lameness when it does occur varies with location and severity of the OCD. These fragments are usually found when radiographs of the joint are taken for another reason, most often during prepurchase examination. TB sales horses are routinely radiographed as a screening for the yearling sales. The most common clinical sign of OC in the tarsus is **effusion** in the TC joint. Lesions can be identified as fragments *in situ* (intermediate ridge) or surface irregularities of the trochlear ridge(s) or malleoli (Figure 5.76). OC lesions of the TC joint often develop into OCD lesions because they often form separated fragments. This is probably due to the site vulnerability at the edges of the articulation mentioned earlier. The most common locations for OCD in order of occurrence are the DIRT (81%), the distal aspect of the LTR (16%), the cranial distal aspect of the MM (3%), the MTR, and the LM.[5] The distal end of the tibia is the most common site of OC formation and may be related to impact to or impingement of the DIRT onto the talus/central tarsal bone when the tarsus is in full flexion. Acute severe synovial effusion can occur when the fragment(s) is disturbed presumably by hyperflexion and impact onto the central tarsal bone. The synovial distension can present clinically as severe lameness. If clinical signs appear after training has begun, lameness is more likely. However, once the horse has adjusted to the capsular stretching, the lameness quickly subsides. Once loose, micromotion of the fragment(s) can create persistent inflammation within the parent bone with

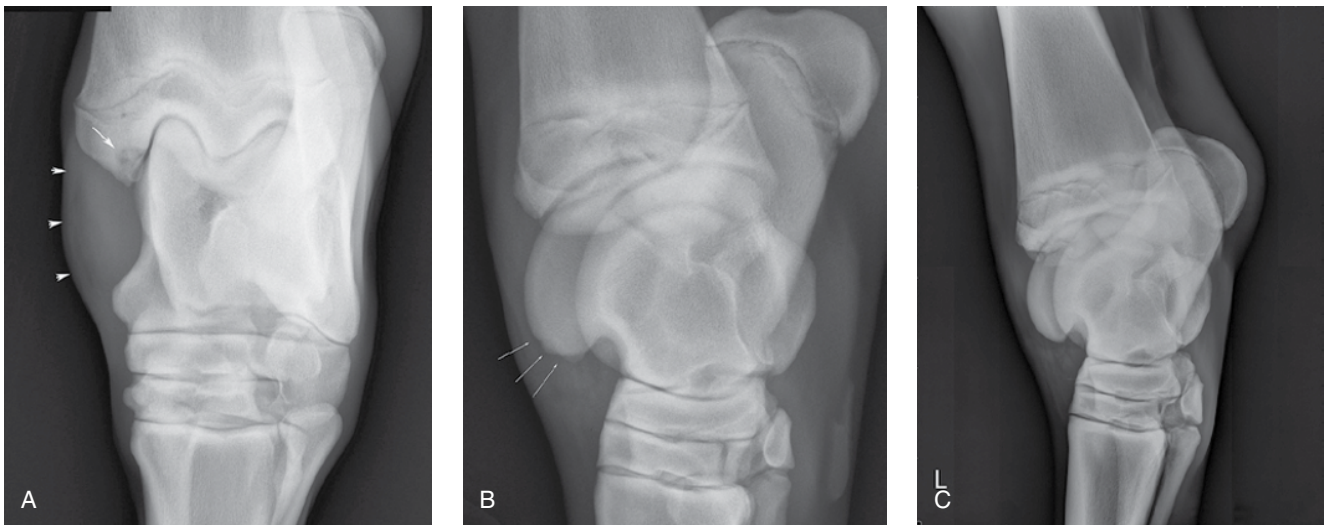

Figure 5.76. The most common clinical sign of OC in the tarsus is effusion (A; small arrowheads) in the TC joint. Osteochondrosis lesions can be identified as in situ fragments of the distal intermediate ridge of the tibia (C), surface irregularities of the lateral trochlear ridge (B; arrows) but occasionally the medial trochlear ridge, and lucency of the medial malleolus (A; large arrow).

VetBooks.ir

release of biochemical/inflammatory and physical debris into the joint. Continual shedding of biochemical and physical substances into the joint can lead to chronic synovial effusion or thickening of the fibrous joint capsule of the joint. In sites other than the DIRT, the OCD lesions often remain loosely attached in their bone of origin, but the debris that is released into the joint from beneath the flap results in synovitis or joint inflammation. Occasionally an OCD fragment is made entirely of cartilage and cannot be identified on radiographs. The radiolucent defect left in the parent bone may be all that is apparent in many cases. If the OC and cartilage flap is more chronic, then the cartilage flap may begin to ossify and be radiographically apparent. In contrast, some older horses are diagnosed with OCD incidentally without apparent clinical signs.

The radiographic abnormalities associated with OC/OCD include fragmentation; irregular, flattened contour of the subchondral bone surface, with or without subchondral radiolucencies and/or sclerosis; and occasionally secondary OA. DIRT lesions are best visualized on the DM-PlLO projection. Lesions of the trochlear ridges may be evaluated on the DM-PlLO (lateral ridge), DL-PlMO (medial ridge), or LM projections. OC of the MTR is rare and must be differentiated from the normal variably sized protuberance of this ridge, where normal spurs and fragments can occasionally be seen.[23,27] Free fragments seen in the dorsal aspect of the joint can originate from the trochlear ridges (usually at the distal aspect of the LTR) but can also originate from the DIRT area.[137] OC/OCD of the MM is best demonstrated with a DPl or DL-PlMO projection and must be differentiated from avulsion fractures of the CLs. Flexed projections may be useful to demonstrate loose fragments in the plantar recesses of the TC joint or OC lesions in the proximal trochlear ridge.[17,104]

Radiography often underestimates the extent of the cartilage and bone damage that is later identified at surgery, particularly for LTR lesions. The TC joint can manifest radiographically silent lesions (lesions identified at surgery where no abnormality was seen on radiographs) more commonly than in other joints. Occasionally, purely cartilaginous loose bodies that are not seen radiographically can be well identified using arthroscopy.[17]

The use of diagnostic US should be considered in the evaluation of tarsal OC to complement radiography. Diagnostic US can be a very useful tool to help evaluate the thickness of the articular cartilage and the surface of the subchondral bone plate (Figure 5.77). It can also help provide valuable information about the joint environment (synovial membrane, synovial fluid, articular cartilage, and subchondral surface) in any horse with joint effusion. Diagnostic US can be particularly useful in cases where OC is suspected, but the radiographs are inconclusive. This examination of the joint can be quite useful to help determine the primary site of OC and to assess the size and the extent of the lesion before surgery.

Resolution of the effusion generally requires surgery and the removal of the abnormal tissue. In the tarsus, surgery can be considered early after the recognition of the OC assuming the foal is older than 7 months of age. Unlike stifle lesions, OC lesions in the tarsus are not at risk of maturing or increasing in size. The earlier the OC is removed, the more likely the effusion and joint capsule swelling will resolve, although not all horses with OC of the tarsus require surgery. Horses with small lesions, with minimal effusion, and without lameness may not require surgery particularly if they are pleasure horses or light use horses. However, loose flaps and large areas of abnormal cartilage and subchondral bone can lead to persistent inflammation in the joint and over time may lead to the development of OA. If significant degenerative changes of the articular cartilage are identified at surgery, the prognosis for the return to soundness is less favorable.

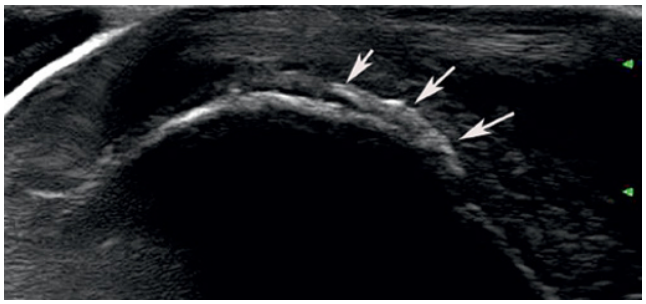

Figure 5.77. Osteochondrosis lesions can also be accurately identified on ultrasound examination as an irregularity to the subchondral surface, as thickening of the articular cartilage, and occasionally as a calcifying flap separating from the subchondral surface (arrows) as demonstrated in this transverse ultrasound image of the lateral trochlear ridge.

Treatment of choice for OCDs of the TC joint is arthroscopic removal of the fragment and debridement of the damaged cartilage and subchondral bone. The removal of the OCD lesion surface (unstable articular surface) stops the inflammatory process within the parent bone and eliminates the shedding of debris into the joint. If surgical removal of the fragment(s) and debridement of the parent bone occurs before permanent damage to the articular cartilage occurs, the prognosis is excellent for resolution of the synovial effusion and restoration of normality to the joint.[92,94] Fortunately OCD of the TC joint often occurs at sites that are easily accessible/amenable to surgical removal and debridement. Osteochondral fragmentation of the distal aspect of the MTR is not often a surgical problem as it is usually within the synovial attachment of the TC joint capsule. Because the OC lesion is embedded within the synovium, it does not shed debris within the joint and rarely becomes a clinical problem.

The clinical significance of DIRT lesions and the effect they have on performance have often been questioned. There appears to be little apparent influence on performance of the young Thoroughbred racehorse.[10] Comparisons between the racing performance of horses with TC OC treated conservatively and those without TC OC were unable to demonstrate any significant differences in the lifetime racing performance.[22] More subjective influence on performance may exist in more mature performance horses. Historically, DIRT lesions that were found in sport horses on prepurchase or on routine radiographic examination of the tarsus were left *in situ* provided they were not creating effusion or lameness. However, it is not uncommon to have these horses

VetBooks.ir

develop synovitis and lameness later in their career. To appropriately manage these horses, the fragments should be removed arthroscopically. Cartilage damage consistent with OA is often found at time of surgery, and some of these horses can be difficult to keep sound because of persistent low-grade lameness. It has previously been suggested that older show jumpers may dislodge intermediate ridge fragments resulting in acute lameness. Based on these experiences, it may be advisable to remove potentially mobile fragments in the TC joint because of the potential for horses to develop OA as mature performance horses.

In young horses the prognosis for athletic activity after surgical removal is good. TC effusion resolved after surgery in 89% of racehorses and 74% of nonracehorses. Effusion appears to be less likely to resolve if the lesions were on the LTR or MM. However, there appears to be no correlation between resolution of effusion and athletic performance. Lesion location and unilateral vs. bilateral lesions had no effect on ability to start. Although the trend was present in all groups, only 2-year-old Standardbreds were significantly less likely to start a race when multiple sites within the TC joint were affected.[12]

Proximal Intertarsal Joint Synovitis and OA

Loose fragments, usually shed from the intermediate ridge of the distal tibia, can become lodged in the dorsal pouch or dorsal joint capsule of the PIT joint. Although rarely of clinical significance, these fragments can be removed arthroscopically through the TC joint if considered necessary.[136] Because of their limited clinical significance and the relative difficulty of finding and removing the fragments, it has been recommended that they be removed only if this can be easily accomplished during surgery for the primary lesion of the TC joint (Figure 5.78). Synovitis/osteoarthritis of the PIT joint is usually due to progression of DT OA but can also occur from external trauma. Radiographic signs of PIT OA are very similar to those of the distal joints and are usually more prevalent on the medial aspect of the tarsus (Figure 5.79).

Figure 5.78. Loose fragments (arrows) usually shed from an OCD lesion on the distal intermediate ridge of the tibia can become lodged in the dorsal pouch or dorsal joint capsule of the PIT joint. Although rarely of clinical significance, these fragments can be removed arthroscopically through the TC joint.

Subchondral Cystic Lesions (SCLs)

SCLs are typically seen in young horses but can occur in any aged animal.[55,69,71,98] Not all horses with SCL are lame and many can be clinically quiescent. Cystic structures associated with the tarsus have occurred in the MTR or LTR of the talus, the intertrochlear groove, the MM or LM, DIRT, distal aspect of the tibia, calcaneus, CT, T3, and proximal MT3 (rare). SCLs are characterized by radiolucent areas of bone (from several millimeters up to and even larger than 3 cm) and are often accompanied by a thin, but well-demarcated, sclerotic rim (Figure 5.80). The cysts can be uni- or multi-loculated and may or may not communicate with the joint. Lesions that are close to or involve the articular surface are more likely to cause lameness. Lameness associated with SCL is believed to be the result of synovitis and increased intracystic or intraosseous pressures leading to subchondral bone pain. However, it is unclear why some SCLs are asymptomatic.

There are three predominant hypotheses about the possible etiology for SCLs in the tarsus: (1) related to a developmental failure of endochondral ossification, (2) acquired and caused by some form of cartilage injury and subchondral bone trauma and (3) due to an infectious cause. SCLs occur in younger animals and are thought to be related to OC lesions that occur at sites of major weight-bearing.[98] Compressive loads on an OC lesion can lead to a further weakening of the subchondral bone and formation of SCLs. Mature animals can develop SCLs potentially from some form of mechanical trauma. A supraphysiological load on a normal articular surface may initiate sufficient bone injury that can lead to the creation of an SCL. The *hydraulic theory* assumes the formation of SCLs is caused by joint fluid being forced into a cartilage defect. Infection is known to cause SCLs in many locations in young animals.

The standard radiographic examination of the tarsus may not adequately demonstrate SCLs because of their small size and position within a complex joint. Nonstandard radiographic views may be necessary to document these lesions. When visible, an SCL appears as a discreet radiolucency varying in size and shape but often surrounded by a sclerotic border. Advanced diagnostic imaging modalities such as CT and/or MRI that represent the limb in cross section are ideal to document their location but not always practical as they require general anesthesia. Scintigraphic examination can be helpful

VetBooks.ir

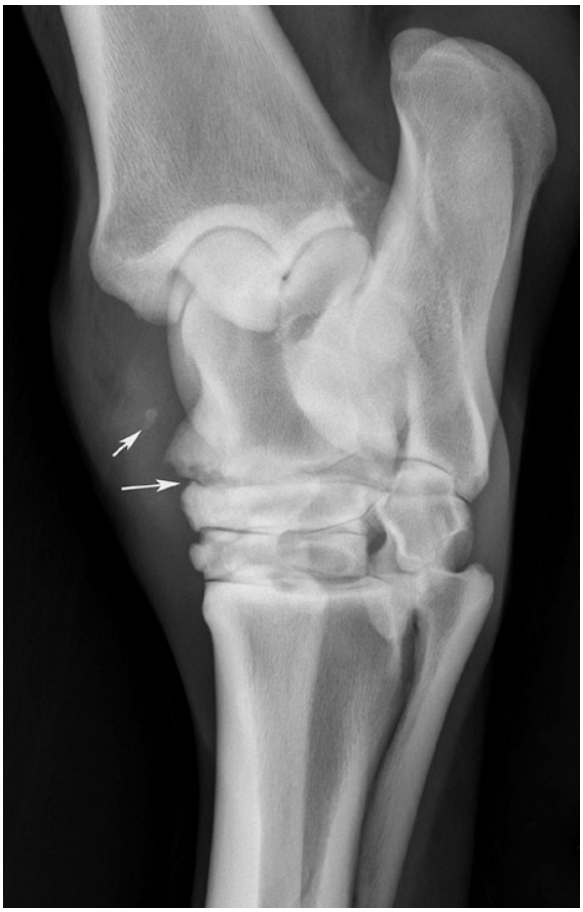

Figure 5.79. Osteoarthritis (OA) of the proximal intertarsal joint (PIT) tends to occur in conjunction with and in progression with OA of the distal tarsal joints. Radiographic changes typically are more evident medially as seen on this radiograph (arrows).

to identify SCLs as discrete foci of IRU in the tarsus consistent with an active bone remodeling response.[58] However, scintigraphy lacks the specificity to characterize the size and to accurately locate the cystic structure and determine communication with the joint. In fact some cystic lesions are portrayed as a photopenic area, making them difficult to see these small cystic structures. Visualization of SCLs in the talus and distal aspect of the tibia by diagnostic arthroscopy has been described.[69]

Depending on the location and extent of the lesion, surgery may be required to prevent cyst enlargement and promote filling of the lesion with osseous material. Depending on the cyst location, this can be performed arthroscopically or via an extra-articular approach. Additional techniques to improve the healing response in bone and cartilage may be indicated to preserve articular function.

Malformation of the Distal Tarsal Bones

Malformation of the DT bones can occur in dysmature/immature foals but is most often recognized in premature foals.[2,3] The small cuboidal bones of the carpus (knee) and tarsus (hock) begin as a cartilage model with a central area of ossification *in utero*. As the wave of ossification progresses, the carpal/tarsal bones change from a circular central area of ossification into a bony cube. In normal foals, tarsal bone ossification continues after birth and is recognized radiographically by a wider appearance of the joint space due to the presence of more cartilage compared with an adult horse.[23] If a foal is born prematurely or is dysmature at birth, standing and normal activity on an incompletely ossified bone can crush the soft cartilage model.[3] (Figure 5.81A) Wedging of the dorsal/dorsolateral aspect of the central/third tarsal bones can occur (Figure 5.81B). These foals will often appear to have an angular limb deformity (lateral or medial crushing) in the carpus or a sickle-hocked conformation (dorsal crushing) in the tarsus.

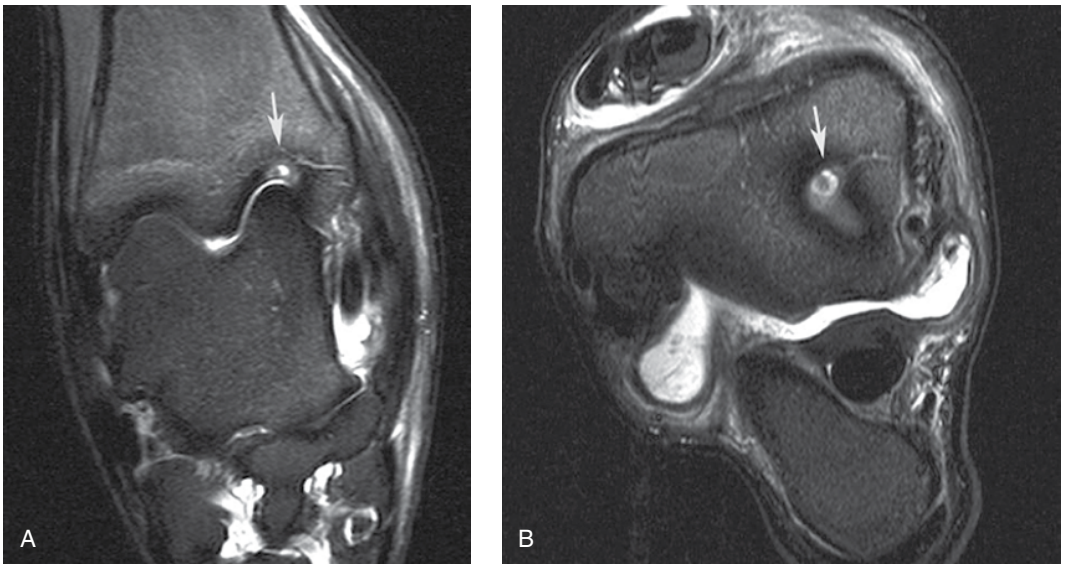

Figure 5.80. An SCL in the distal tibia identified on these two MR images (A and B; arrows) communicated with the TC joint in this horse and caused significant effusion.

VetBooks.ir

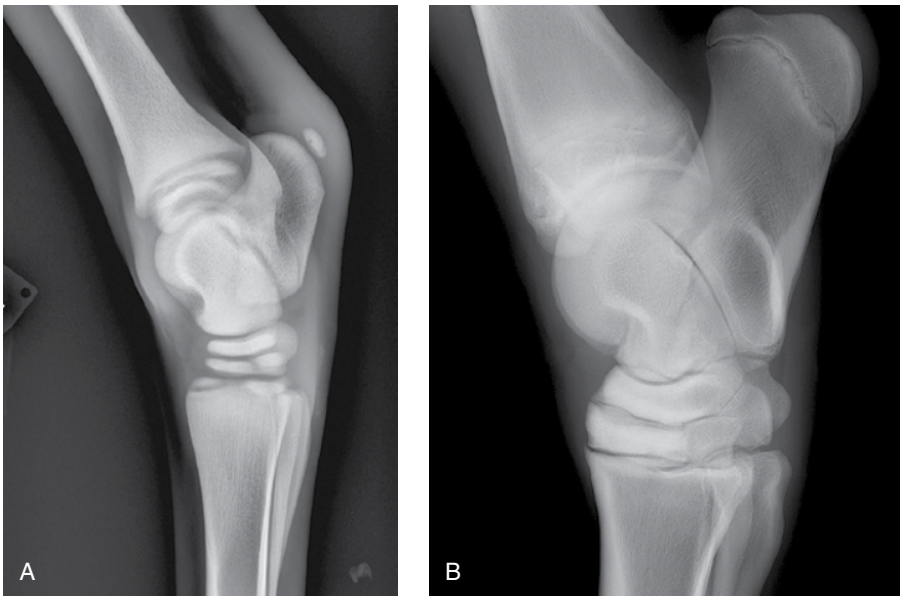

Figure 5.81. Malformation of the distal tarsal bones can occur in dysmature/immature foals but more often occurs in premature foals (A). Developmental abnormalities such as wedging of the third tarsal bone may be a predisposing factor to formation of degenerative changes within the distal tarsal joints (B).

The disorder is often bilateral.[2,23] Once the cartilage model/immature bones are crushed, the malformation becomes permanent. The cuboidal bones continue to ossify around the malformed cartilage model. Continued loading on these immature bones may result in valgus deformities and/or pathological fracture or collapse of the tarsal bones. The reader is referred to Chapter 10 for more information about this condition.

Angular Deformities of the Tarsus

Angular limb deformity refers to an axial deviation of a limb in the frontal plane. The nomenclature to describe an angular deformity is derived by combining the name of the involved joint (i.e. with cuboidal bone abnormalities) or the joint immediately distal to the affected growth plate and the type of deviation. A lateral deviation of the distal limb is termed valgus, while a medial deviation is termed varus. Tarsal angular deformities often originate from within the physis of the distal tibia but can also occur from the cuboidal bones of the tarsus (see above). Tarsal valgus deformities are more common than tarsal varus deformities. Perinatal factors are usually involved when a foal is born with an angular limb deformity. In neonatal foals angular deformity can be a consequence of laxity of the supporting soft tissues of the tarsus or related to hypoplasia and/or incomplete ossification of the tarsal bones. A large number of foals are noticed to have some type of angular deformity at birth. The cause of angular limb deformities is complex and probably multifactorial and is discussed in more detail in Chapter 10.

FRACTURES AND LUXATIONS OF THE TARSUS

Fractures and luxations of the tarsus are rare probably due to the dense supporting structures that cover the bones in this area.[29,52,75,97,104,105] Fractures when they do occur are usually associated with a significant external force or impact, such as a kick from another horse. Twisting and torqueing of the tarsus while the lower limb is fixed is felt to contribute to disruption of collateral and periarticular ligaments and subsequently lead to fractures. These animals are almost always non-weight-bearing lame, and the tarsus is diffusely swollen. Fractures of the talus can range from simple fragmentation of the trochlear ridges to comminuted fractures of the entire body of the talus. The degree of comminution usually determines the severity of the lameness and the extent of associated swelling. The degree of lameness associated with fractures of the tarsus can be mild to moderate in the case of chronic central tarsal bone fractures to severe and non-weight-bearing such as in comminuted fractures of the talus or calcaneus. External trauma can fracture specific areas of exposed bone such as the tibial malleoli, trochlear ridges, tuber calcaneus, and fourth tarsal bone. Injuries that involve the TC joint are frequently more apparent due to swelling of the dorsomedial and dorsolateral synovial pouches. Fractures of bones within the TMT and DIT joints are less noticeable due to the dense ligamentous coverage and tight joint capsules that limit swelling and effusion. Luxations of the tarsus are uncommon and often involve significant trauma that disrupts many of the support structures around the tarsus.

Traumatic Luxations of the Tarsus

Traumatic luxations that involve the tarsus are usually created from kicks from other horses, trauma from moving objects, or by having the limb entrapped in fixed objects such as a fence or cattle guards. The soft tissue injuries and fractures that accompany TC luxation are often so significant and incapacitating that salvage of the horse is frequently not possible. Lameness is usually

VetBooks.ir

severe with significant soft tissue swelling and palpable instability and crepitus. The diagnosis is normally not difficult and is substantiated through radiographs. Luxation of the TC joint is often accompanied by a severe angular limb deformity centered at the affected articulation of the tarsus. Traumatic luxations of the other joints of the tarsus usually occur at either the TMT joint or the PIT joint presumably because of the stabilizing effect of the fourth tarsal bone (Figure 5.82). Clinical diagnosis is not difficult, but it is best to verify the injury through diagnostic imaging (radiographic and ultrasonographic examination). Stress radiographs of the tarsus can be helpful to demonstrate abnormal hock motion (in a sagittal plane) not easily seen with conventional radiography. Specific stress maneuvers can include traction, axial rotation (clockwise and counterclockwise), hyperextension, hyperflexion, and fulcrum-assisted medial and lateral flexion. Each maneuver is designed to demonstrate instability in a particular part of the tarsus and, in the process, to identify damage to one or more specific ligaments. Some luxations and subluxations of the tarsus may reduce spontaneously, but they can still be demonstrated with stressed dorsoplantar radiographs. The presence of fracture(s) associated with a luxation generally decreases the chances for successful treatment. General anesthesia is usually required as it can be very painful to the horse. Luxations need to be carefully evaluated for vascular injury to the arterial supply to the distal limb before moving forward with management.

Treatment usually requires first aid to safely transport the horse to a surgical facility for reduction and stabilization in some fashion.[19] TC joint luxation with intact CLs can be difficult to reduce, and manipulation of the tarsus with the limb in a flexed position may help to facilitate reduction (Figure 5.83). A decision about repairing the injury should be made quickly and attempted during the same anesthetic period. While luxation through the TMT or PIT joints can be repaired, these injuries usually significantly compromise athletic soundness. Treatment is aimed at reestablishing comfortable weight-bearing. Reduction of the luxation with either cast stabilization or surgical repair should be performed, and an assisted recovery performed if available. Tarsal luxations in the absence of significant fractures can be treated with a full-limb cast for 2–3 months. Full-limb cast application should extend from the foot to the level of the tibial tuberosity. Cast immobilization of a hindlimb is not without problems and can often be associated with significant complications. The most common cast complications included pressure sores, cast breakage, and secondary fractures. To minimize the risk

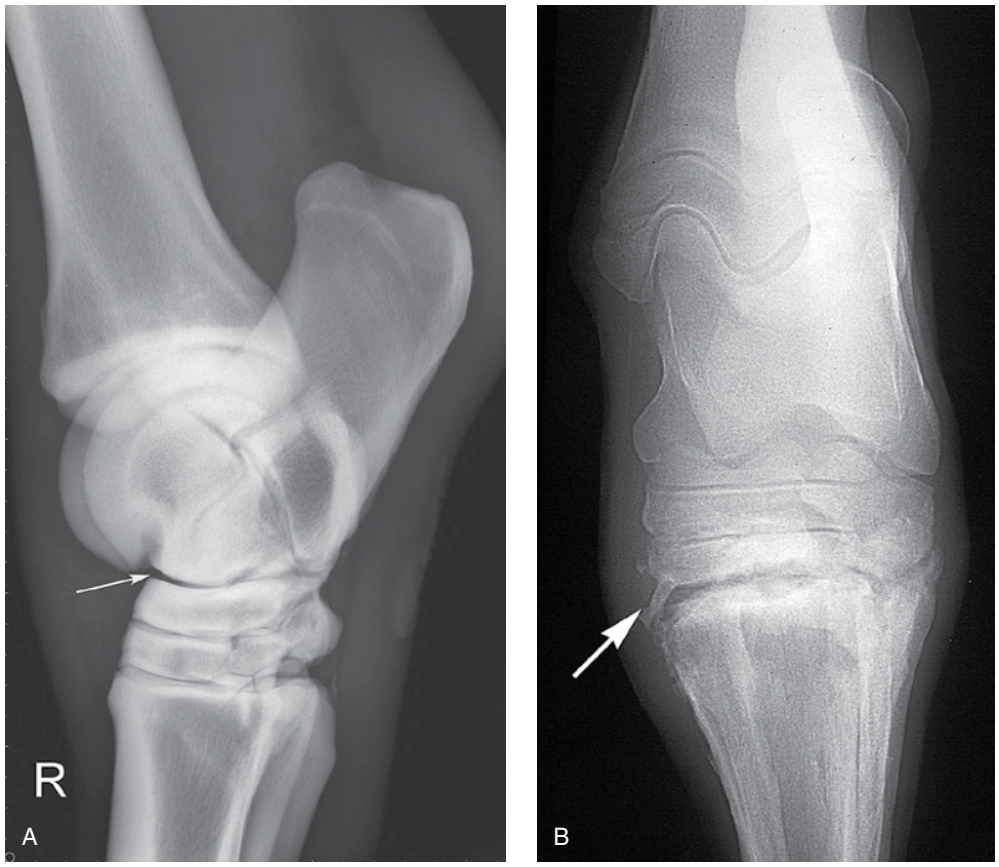

Figure 5.82. A stressed lateromedial radiograph (A) used to help demonstrate opening of the joint surface in this horse with a PIT joint luxation. This horse was maintained in a full-limb cast. Dorsoplantar radiograph (B) of a foal with luxation of the medial aspect of the TMT joint (arrow). A medial plate was used to stabilize the luxation and arthrodese the distal tarsal joints concurrently. *Source*: Courtesy of Dr. Gary Baxter.

VetBooks.ir

of complications of a full-limb cast application, the limb can be maintained in a cast for 4–6 weeks if the CLs are intact and 6–8 weeks if the CLs are ruptured. After the cast is removed, the hindlimb is placed in a heavy cotton bandage with rigid splints for an additional 4–6 weeks before turnout in a small area is allowed.

Surgical arthrodesis of tarsal luxations can be performed to help achieve pasture soundness for breeding purposes.[1,105] However, the prognosis is still guarded. Surgical techniques described for management of tarsal luxations in horses include articular cartilage removal combined with internal fixation using transarticular screws or bone plating. Cast immobilization is usually combined with surgical management. Open reduction and internal fixation with a plate is usually recommended for tarsal luxations when there are associated fractures. Surgical arthrodesis of the TMT, DIT, and PIT joints can be achieved by placing a plate on the plantar surface of the joint. The plate is placed on the plantarolateral aspect of the tarsus and extends from the top of the calcaneus to mid-MTIII.

Figure 5.83. TC luxation can cause significant soft tissue injury(s) and secondary fractures that are often so significant and incapacitating that salvage of the horse is frequently not possible.

Slab Fractures of the Small Tarsal Bones

The DT bones are subjected to axial compression, torsional, and tensile forces during exercise. Their main function is to absorb concussion and neutralize these forces. The DT joints resist these forces and are stabilized by a thick layer of ligamentous tissue that surrounds and unites the small tarsal bones. The dorsal tarsal ligament (DTL) is a major component of these ligamentous structures. The DTL originates from the distal tuberosity of the talus on the medial aspect of the tarsus and spreads out as a sheet over the face of the DT bones restricting/limiting movement. The dorsal aspect of the tarsal region also has the extensor bundle comprised of the tendons of insertion of cranialis tibialis and PT and, laterally, the long digital extensor.

Slab fractures of the CT or T3 bones occur most often in racing disciplines or other high-speed events.[101,141] Slab fractures are felt to be exercise-induced injuries in racehorses and result from accumulated bone damage on the dorsal aspect of the DT bones.[141] They occur at similar locations and configurations in the absence of specific trauma (Figure 5.84). Third tarsal bone slab fractures occur most commonly in young racehorses with one study reporting the median age of 2 years. Fractures of the T3 bone are more common in TB and STB racehorses and are normally found on the dorsal and dorsolateral aspects of the bones (dorsomedial to plantarolateral orientation). Tarsal slab fractures do occur in other breeds and disciplines but are less likely to be due to adaptive remodeling from exercise but more likely due to some

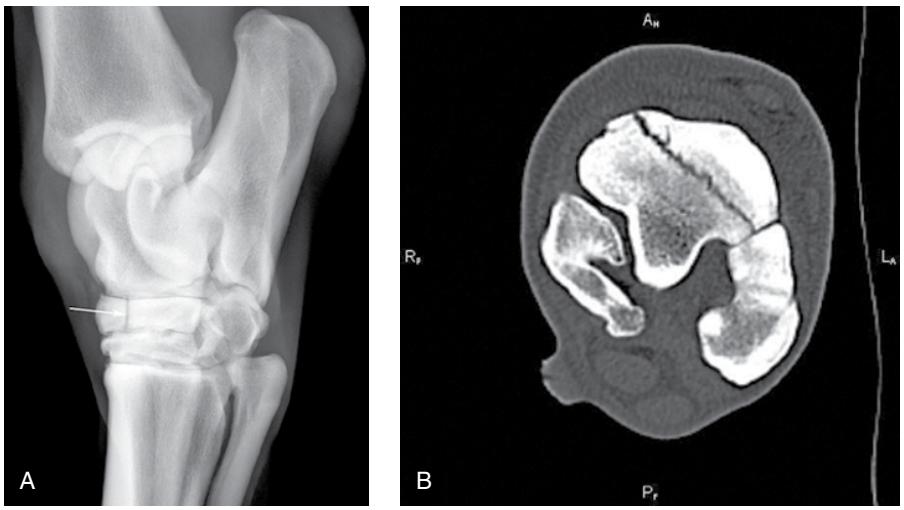

Figure 5.84. Tarsal radiograph (A; arrow) and CT (B) demonstrating a slab fracture of the central tarsal bone. These slab fractures occur most often in horses used for racing disciplines and other high-speed events.

VetBooks.ir

form of specific trauma. These fractures are more likely to involve both the CT and T3 bones and are more likely to be comminuted (Figure 5.85).

Horse with slab fractures can initially present with severe lameness that diminishes over several weeks. There can be little indication of a slab fracture. Simple slab fractures of the T3 bone often have minimal swelling or synovial effusion to indicate the location of the injury. Synovial effusion may occur with CT fractures that enter the PIT joint. Racehorses that have a moderately positive response to proximal limb flexion test when compared with the opposite limb should be evaluated for tarsal slab fractures. When the CT bone is fractured, intra-articular anesthesia of the TC joint may partially alleviate lameness, but it can take 30–45 minutes for maximal effect. Diagnosis of CT and T3 bone fractures is confirmed with standard radiographic views but can require multiple oblique projections. Radiographic confirmation of these fractures may prove difficult because the radiographic beam angle must be tangential to the fracture plane to identify them. This requires that radiographic exam includes a series of different oblique angles to more accurately demonstrate the fracture. The radiographic diagnosis can be further complicated because the curved nature of the fracture plane makes it difficult to image. In addition, because the fracture line may be difficult to appreciate soon after injury, serial radiographic examinations may be necessary to identify the presence of a slab fracture. When conventional imaging techniques (radiography and ultrasound) cannot detect a problem, nuclear scintigraphy can be utilized to demonstrate active bone remodeling associated with the fracture. CT and MRI can provide cross-sectional imaging that is ideally suited for an accurate diagnosis but also a prerequisite for surgical repair. Multiple fracture lines that were undetectable with standard radiographic exam can often be identified making the surgical treatment (screw placement) more accurate even though the prognosis becomes less favorable.

Developmental abnormalities such as wedging of the T3 may be a predisposing factor to formation of slab fractures of the DT bones. These tend to occur in dysmature foals with hypoplastic tarsal bones that have collapsed on the dorsal or dorsolateral portion of the third tarsal bone creating a wedge shape. Third tarsal bone slab fractures occurred more commonly in the left hindlimb of racehorses, while TC bone fractures were more often complex and comminuted.

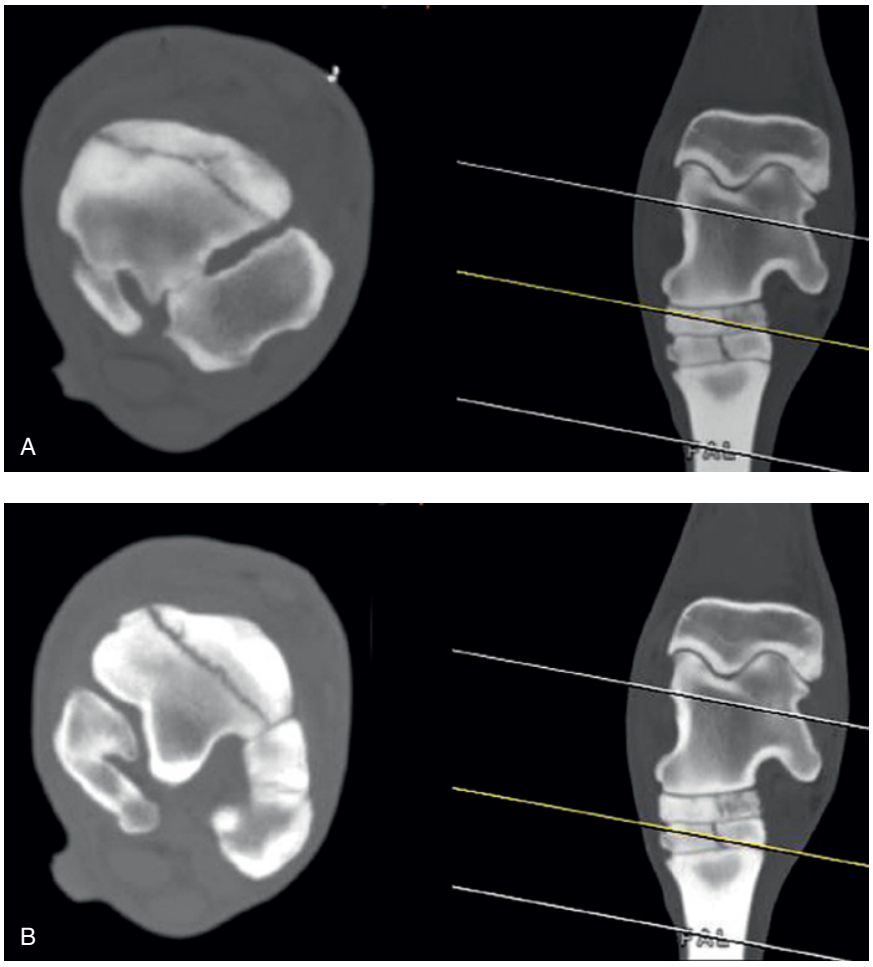

Figure 5.85. Slab fractures that occur in nonperformance breeds are often due to some form of external trauma and are more likely to involve multiple tarsal bones and be comminuted. A comminuted CT bone fracture can be seen in the top CT image (A), and a T3 bone fracture is visible in the bottom CT image (B).

VetBooks.ir

Treatment of choice is lag screw fixation of the slab fracture(s) of CT and T3 bones. Conservative treatment (prolonged stall rest) has also been utilized successfully with some horses returning to athletic use.[101] However, treatment by screw fixation offers the best prognosis, because conservative management usually results in increasing dorsal displacement of the fracture fragment creating articular incongruity leading to OA. The goal for articular fracture fixation is to promote primary bone healing and maintain and/or restore bone congruity and diminish the chances for the development of OA. The screw placement should be placed as close to perpendicular (90°) to the fracture line as possible and as close to the middle of the fragment (usually in a dorsolateral to plantaromedial orientation). Some comminuted CT fractures are impossible to repair and are best treated conservatively. Horses are rested for 4–6 months after surgery.

Prognosis is dependent on the detection of all of the fracture lines, particularly with CT fractures. If prolonged lameness persists in spite of apparently successful repair, removal of the screw may be necessary. Horses that undergo very strenuous activity will likely do better if treated by lag screw stabilization. Residual lameness can persist after either surgical or conservative management and eventually may require intra-articular medication, chemical or surgical arthrodesis, or screw removal after fracture healing.

Sagittal Fractures of the Talus

Stress fractures associated with high-speed exercise tend to occur at similar locations and configurations and usually without a known specific traumatic event. Racing or competitive speed events can occasionally create exercise-induced sagittal fractures of the talus.[31,69,95] These fractures are rare and most commonly diagnosed in the STB and TB racehorse but occasionally can be encountered in other breeds. The diagnosis is suspected when there is moderate to severe lameness in association with distension of the TC joint. These fractures are often incomplete and nondisplaced and may prove challenging to diagnosis with standard/conventional radiographic techniques. Extra views including a dorsal 10°–20° lateral to plantaromedial oblique and a flexed dorsoplantar (skyline) view can be helpful. Nuclear scintigraphy can be very helpful in confirming the presence of a stress reaction or fracture, usually by revealing an intense focal IRU in the proximal aspect of the talus. Eleven racehorses with a history of chronic, mild hindlimb lameness that became acutely lame during a race were diagnosed with a sagittal fracture of the talus.[31,69] Sagittal fractures of the talus found in other types of horses are thought to be associated with trauma and may be more complicated than what is found in the racehorse. Stall rest until the horse becomes sound, and then 2 months of paddock exercise will normally result in resolution of the problem and a favorable outcome.

Horses with complete sagittal fractures can be treated with lag screw compression of the talus using two 4.5-mm cortical bone screws.[31,69,95] Prognosis may be favorable in horses with simple acute fractures, but the prognosis for horses with comminuted fractures is poor. The use of CT is advantageous and can improve the prognosis by providing accurate fracture assessment and is the best imaging tool to accurately direct screw placement. The medial fragment is usually smaller, and fractures can be repaired with two or three 4.5- or 5.5-mm cortex screws placed in lag fashion from medial to lateral. Prognosis is thought to be favorable if accurate anatomic reduction can be achieved.[69] Comminuted fractures of the talus are often associated with severe soft tissue trauma that can lead to destabilization of the TC joint. These cases are inoperable in most cases.

Fractures of the Trochlear Ridges of the Talus

Significant effusion of the TC joint exists with most fractures of the talus. As with most fractures of the tarsal area, flexion tests are often moderate to severely positive. The clinical signs vary considerably and depend on the size and location of the fragment, the amount of displacement, and the presence of any comminution. The position that the limb was in when the horse was kicked (i.e. flexed or extended) dictates the location of the fracture (point of contact). For example, the caudal aspect of the proximal MTR can be traumatized when the limb is flexed (Figure 5.62B), and the distal aspect of the LTR is exposed when the limb is extended. Fractures to both trochlear ridges are more serious because of the loss of TC joint stability created by the anatomic interdigitation of the trochlear ridges with the cochlea of the distal tibia. Fractures that involve both trochlear ridges can develop during severe twisting movements of the affected limb with the hock partially flexed, which transfers the tibial contact region to the distal areas of the trochlear ridges of the talus. Fractures of the trochlear ridges are not typically difficult to differentiate from OCD fragments particularly of the LTR. Standard radiographic examination of the tarsus should help to confirm the diagnosis but often needs to be supplemented with a flexed lateromedial and flexed lateromedial obliques to highlight the different trochlear ridges.

Conservative therapy in most cases is unrewarding. Surgical treatment is often indicated to alleviate the lameness and persistent effusion. Intra-articular fragmentation of the trochlear ridge(s) warrants arthroscopic removal. Large fragments consisting of the distal one-third to one-half of the LTR may be candidates for anatomic reduction and lag screw compression of the fragment to the talus. This may require recessing the heads of 3.5-mm cortical bone screws or small cannulated screws. Diverging polydioxanone (PDS) resorbable pins may also be useful in these fractures. The plantar aspects of the TC joint should be examined to evaluate the proximal portion of the trochlear ridges for damage and to clean up floating debris. Fragmentation of the plantar trochlear ridges can also occur and usually require removal. The arthroscopic portal is placed on the same side of the joint as the fragment(s) and arthroscopic removal of the fragment(s) via the plantar pouch is performed on the ipsilateral side.

Fractures of the Tibial Malleoli

Traumatic injuries of the tarsus can lead to fragmentation of the CL attachment onto the malleolus (most often the LM of the short lateral collateral ligament

VetBooks.ir

[sLCL]). These fractures may exist intra- or extrasynovially. Fragmentation that occurs intrasynovially may cause a persistent synovitis, and this may be a primary indication for surgical removal. However, US examination of the affected CL is critical to assess its degree of damage to prevent further injury that may occur on recovery from general anesthesia.

The origin of both medial and lateral CLs are located both on the LM and MM of the tibia, respectively. Fragmentation of the attachment of the sCL is most common although avulsion fractures of the long lateral collateral ligament (lLCL) do occur. Fractures and/or bony change associated with the CLs is best demonstrated on the dorsoplantar radiographic projection. Multiple radiographic projections may be necessary to assess the extent of bony change(s) associated with the injury. Fragment removal should not compromise the stability of the TC joint provided that the long CLs (MCL, LCL) are not affected. The LM appears to be more frequently affected than its medial counterpart; 42 of 44 cases that have been reported in the literature have involved the LM.[75,108,148] This is probably due to the fact that the LM is considered to be the distal end of the fibula and develops as a separate center of ossification that fuses to the distal tibial epiphysis by 1 year of age.

Lateral malleolar fractures are usually associated with a fall or kick (Figure 5.86). A traumatic force from lateral to medial on the limb fractures the LM. Common localizing signs such as TC effusion and periarticular/periligamentous swelling occur soon after injury. Tensile forces applied by CL to the attachments on the malleoli fragments probably contribute to displacement. Fragments can rotate and displace distally. Ultrasonography is a very useful tool to determine the exact location of the fragment(s) and to assess the extent of injury to other structures. For example, a fragment from the LCL is often located within the dorsolateral pouch of the TC joint but may displace into the plantar pouch necessitating a different surgical approach.

Surgical removal of the fragment is frequently recommended. Healing is compromised due to the displacement of the fragment inhibiting primary bone healing. In addition, the intrasynovial position of this fracture fragment perpetuates the shedding of debris into the joint, increasing the chance for widespread cartilage injury and the development of OA. Lateral malleolar fractures are typically smaller, displaced, and comminuted but carry a reasonably good prognosis compared with MM fractures. Two recent reports document that LM fragments can be successfully removed with arthroscopic techniques. In those reports, horses with fractures of the LM had a favorable prognosis for return to full athletic performance following arthroscopy and that arthroscopic fragment removal is the preferred treatment method. Medial malleolar fractures are often larger, are more difficult to remove, and may have lMCL involvement. Surgical removal of LM fragments carries a reasonably good prognosis for attaining soundness.

Large fractures of the tibial malleoli are almost always articular (Figure 5.87). Large fragments with significant CL compromise may result in significant instability if removed. Fractures of the malleoli typically have significant displacement, making primary bone healing unlikely. Large fragments should be repaired rather than removed. Successful repair requires accurate anatomic reconstruction with internal fixation. Lag screw fixation is considered sufficient to stabilize the fracture and counteract the distracting forces applied by the CLs. Fragments of the LM larger than 3 cm are best reattached to the parent bone using 3.5-mm cortical screws placed in lag fashion. Large avulsion fractures of the MM can be repaired with one or two 4.5- or 5.5-mm cortex or cancellous screws placed in lag fashion. A full-limb cast is applied to provide mediolateral stability during recovery from anesthesia and maintained during the initial postoperative period. Nondisplaced fragments

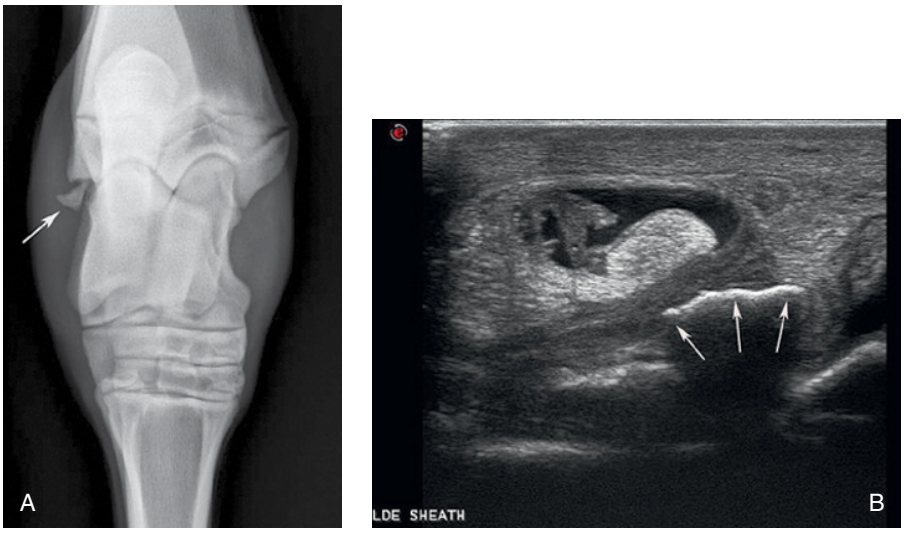

Figure 5.86. Lateral malleolar fractures are usually associated with a fall or kick that creates a traumatic force from lateral to medial on the limb. The DP radiographic projection on the left (A) demonstrates displacement of the fragment due to the pull of the collateral ligament. The ultrasound image (B) demonstrates the fragment (arrows) and effusion within the lateral digital extensor tendon sheath because of their close anatomical position.

VetBooks.ir

of the malleoli are at risk of displacing over time and, therefore, may also be ideally managed with lag screw fixation.

Fractures of the Calcaneus and Sustentaculum Tali

Calcaneal fractures are almost always the result of some external traumatic event leading to injury to the TC. Kicks that impact a fixed object such as walls, doors, fences, or machinery can injure the calcaneus and often lead to open fractures. Skin lacerations may result from the fracture fragments penetrating the skin from the interior or from the fixed object externally. The clinical signs reflect the severity of the bony derangement and possible secondary complications. Swelling and crepitus can be severe with major fractures. Significant lameness and a lack of Achilles tendon function are the primary indications for surgical repair (Figure 5.88). Diagnosis is made by radiographic examination, which should include a flexed lateral and a flexed skyline projection for complete examination of the calcaneus. Stressed radiographs may help to demonstrate minimally displaced fractures of the calcaneus. Accurate determination of the fracture configuration of the calcaneus is necessary to help provide a prognosis and determine if surgical repair is possible.

Figure 5.87. Oblique radiograph of a horse that had been kicked on the medial aspect of the tarsus. This articular fracture of the medial malleolus was repaired with lag screws. *Source*: Courtesy of Dr. Gary Baxter.

The prominent ST is positioned on the medial aspect of the tarsus. The tarsal canal is formed by the ST of the calcaneus dorsally, the TC laterally, and the flexor retinaculum plantar and medially. The ST is prone to injury from direct trauma. In the event of a fracture of the ST, involvement of the TS and lateral digital flexor tendon (LDFT) should be evaluated.[30,47,70,123,124] Bone damage may be confined to the medial edge of the ST and not affect the TS and LDFT. Larger fractures however can disrupt the fibrocartilaginous gliding surface and can lead to damage of the LDFT and are much more serious. Wounds associated with the traumatic incident may introduce debris and bacteria into several synovial structures such as the TS, the TC joint, or possibly the calcaneal bursa. Any wound in this area should be investigated for possible synovial involvement as synovial sepsis and osteomyelitis of the medial border of the ST may occur. Osteomyelitis, sequestration of fracture fragments, and chronic drainage are potential complications of fractures in this area (Figure 5.89). Fractures on the medial surface of the calcaneus and the ST can be difficult to manage surgically. In cases in which the TS is involved but not infected, the bony fragments may be removed, but the trauma incurred often results in a guarded prognosis.

Tenoscopy allows the exploration of the TS to assess the presence of tendon injury and to explore the recesses of the sheath. Some bony lesions might be outside of the tendon sheath and are best approached by direct cut down and dissection of the fragment. Careful curettage of the fracture bed and flushing of the tendon sheath with copious amounts of fluids is indicated after fragment removal. Conservative management is contraindicated,

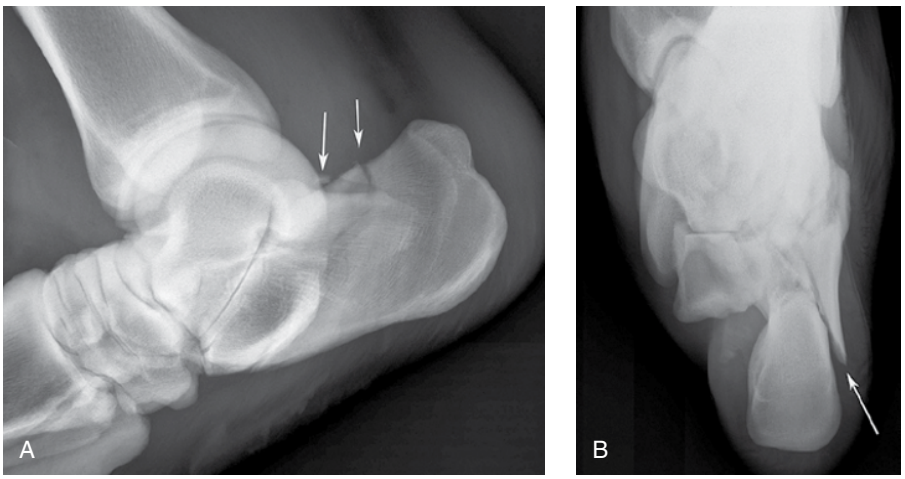

Figure 5.88. These flexed lateromedial (A) and flexed skyline (B) radiographic views demonstrate a comminuted calcaneal fracture in a horse that was hit by a car. Both views were helpful in determining the severity of the injury.

VetBooks.ir

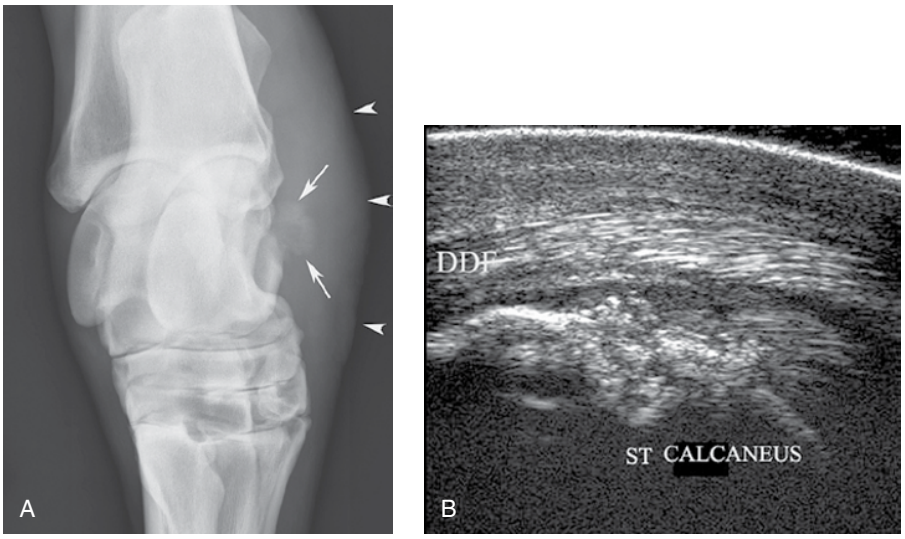

Figure 5.89. Chronic infection of the ST may lead to substantial proliferative bone response and an established infection of the tarsal sheath. (A) Oblique radiograph demonstrating extensive new bone production arrows) and soft tissue swelling (arrowheads). (B) Ultrasound image of tarsal sheath demonstrating moderate bone lysis of the ST associated with osteomyelitis.

especially in open injuries. Involvement of the gliding surface of the ST is a key parameter in the decision for surgery. If the fracture involves a significant amount of the flexor surface, reconstruction and reattachment with cortical screws may be considered, especially if the tendon sheath was not penetrated at the time of injury. If treatment is delayed, proliferative changes can develop, leading to chronic lameness with a poor prognosis for future usefulness of the horse. With immediate, effective treatment, a guarded prognosis for return to athletic is typical. Neglected cases have a grave prognosis.

Fragmentation of the Proximal Tubercle of the Talus (PTT)

The proximal tubercle of the talus (PTT) is situated in the plantar aspect of the tarsus on the proximal and medial region of the talus. The anatomy of this region of the tarsus is complex with a variety of ligaments and synovial attachments associated with the PTT. Fragmentation of the PTT in horses is rare, and its clinical significance is questionable. The etiology of fragmentation of PTT is unknown, but OC has been suggested to have a role. The dorsal 45° medial to plantarolateral oblique view or lateromedial view is reported to demonstrate the fragment best. A flexed lateromedial, flexed dorsoplantar, and plantaroproximalplantarodistal oblique (calcaneal skyline) views may also help identify the fragment.

In one report 9 horses with fragmentation of PTT were identified, seven of which were Warmbloods.[50] Diagnosis was made based on radiographic findings, but ultrasonography and CT were also utilized in some of the horses. Less than half (3/9) had TC joint effusion, and only one horse was lame and that horse had a history of prior trauma and resultant lateral tibial malleolus fracture. Flexion tests did not produce lameness. One horse underwent arthroscopy, but the fragments were not visible and it was presumed that the fragments were extra-articular.

Conclusions of that study were that fragmentation of PTT appeared to occur more frequently in warmbloods but more importantly that it was not usually associated with lameness. Affected horses remained clinically and radiographically stable over time. The information from this report is important for practitioners who perform radiographic screenings during prepurchase examinations. Finding fragmentation of PTT does not appear to be a risk factor for the development of lameness associated with the tarsus (Figure 5.90).

SOFT TISSUE INJURIES OF THE TARSUS

Tarsal Collateral Ligament Injury

The distal tibia is quadrangular in form and larger medially than laterally. These grooves and the corresponding trochlear ridges of the talus are directed obliquely forward and laterally and are bound on either side by the tibial malleoli. The tibial malleoli have extensive CL attachments from both the long and short components, and their anatomy has been previously described in detail.[143] The lLCL has distal attachments to the talus, calcaneus, T4, T3, and MT4 bones. There are two sLCLs that lie axial to the lLCL. The long medial collateral ligament (lMCL) has distal attachments to the fused first and second tarsal bones, talus, CT and T3 bones, and MT2 and MT3 bones. There are three short medial collateral ligaments (sMCL) that, like their lateral counterparts, lie axial to the MCL and are named according to their respective insertions.

The stability of a TC joint is a product of the congruency of the joint surfaces, the integrity of the joint capsule, and the strength of the CLs. In general, CLs typically have a uniform fascicular orientation and, therefore, a homogeneous sonographic appearance. The lLCL spirals during flexion and straightens during extension as it takes the load from the sLCLs. A mixed arrangement of fascicles is necessary to allow the CLs to function in both extension and flexion.[34,35] In the TC

VetBooks.ir

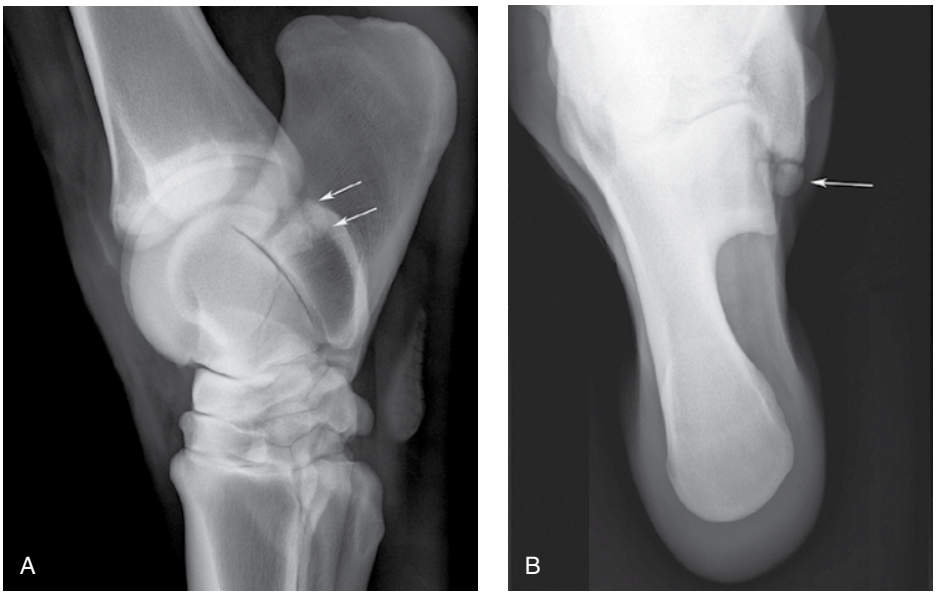

Figure 5.90. Lateral (A) and skyline (B) views demonstrating a fragmentation of PTT lesion (arrows). This fragmentation does not appear to be a risk factor for the development of lameness but must be differentiated from OC that develops on the plantar trochlear ridges.

joint, the superficial CLs are under tension while the limb is extended and relaxed while the limb is flexed, whereas the short CLs are tensed only when the tarsus is flexed. Therefore, the short CLs should be examined while the leg is flexed.

CL injury of the TC joint most often occurs due to some form of traumatic injury.[15,131] Lameness varies from mild to severe, depending on the degree of damage. Hindlimb proximal limb flexion significantly worsens the lameness. Physical exam findings usually include tarsal swelling with edema and/or fibrosis localized over the medial CL (MCL) or lateral CL (LCL) region. The presence of TC effusion often occurs but the amount can be quite variable. Desmitis associated with the enthesis of the CLs is often performance limiting. The diagnosis is usually made with a combination of radiographic and ultrasonographic examinations. Stress radiographic examination may occasionally be necessary to more effectively demonstrate instability associated with the MCL and/or LCL. The initial radiographic exam of acute injuries often only reveals soft tissue swelling, but by 6–8 weeks after the injury enthesophytes may become evident along the origin and attachment sites of the CLs. Fragmentation of the malleolar attachment of the CL attachment (most often the LM of the sLCL) can occasionally occur.

Enthesopathy of the lLCL and less commonly the sLCL has been reported in STB racehorse.[15] Pacers were found to be more at risk of this condition than trotters. Distension of the TC joint capsule and subtle, localized soft tissue swelling were present, and lameness improved with analgesia of the TC joint. Scintigraphy was also utilized to show focal, intense IRU on the lateral aspect of the calcaneus, and enthesopathy of the CL was detected radiographically. The authors of that study theorized that cyclic stress associated with the speed of racing was responsible for the injury. Local injections with MPA and sarapin resulted in improvement in the lameness.

Ultrasonographic evaluation can be quite helpful to identify CL injury and define the type and severity of the injury. The ultrasonographic appearance of the CLs should always be compared with the opposite CL, and this should always be used as a reference for normal. Injury can change the size, shape, linearity, and architecture (appearance) of these structures. Serial US examinations are critical to monitor the repair process and to evaluate healing. The malleolar insertion of the CLs should be carefully evaluated in longitudinal view as changes can often at this location. Chronic injury may be recognized as calcification (enthesis new bone) within the insertion of the CL. Insertional change can also occur in the short CL attachment onto the talus. Treatment for the disease is restriction of exercise for 2–3 months. A gradual reintroduction to exercise is predicated on the improving sonographic appearance. The prognosis is favorable for resolution after a period of rest.

Desmitis of the CLs, particularly the long CL, has been described.[34,35,131] Injury to the CLs are thought to occur with twisting and torqueing of the tarsus while the lower limb is fixed to the ground. Increasing tensile stress (and probably the rate at which it is loaded) within the CLs may lead to fractures of the malleoli. High loads are felt to develop within the sMCL/sLCL when the horse falls on the lower limb while it is flexed. Initial treatment involves stall rest, cold water therapy, topical treatment (diclofenac or dimethyl sulfoxide with or without corticosteroids), and systemic NSAIDs. Rehabilitation will require increasing periods of controlled exercise determined by an improving ultrasonographic appearance of the injured structure. Prognosis depends on the severity of injury and effective treatment and rehabilitation. Horses with moderate injuries (and develop extensive periosteal new bone) have been able to return to full athletic function, although some residual enlargement of the hock has persisted.

Injuries to the CLs that exist within the intrasynovial space of the TC joint may be difficult to accurately

VetBooks.ir

assess with standard imaging techniques. These types of injuries usually present with moderate effusion of the TC joint, and confirmation of the structure(s) involved may require arthroscopic exploration. Arthroscopy permits direct visualization and debridement of torn fibers of the sCL. In a recent report of 20 horses with intrasynovial CL, all injuries involved the sCL with four also involving the lCL.[5] Medial sCLs were torn in 14 cases and lateral sCLs in 11 (including five cases with medial and lateral tears). No arthroscopic evidence of joint instability was found when the tarsus was manipulated in any case. All horses recovered uneventfully from general anesthesia, and there were no significant postoperative complications.

Nonseptic Tenosynovitis of the Tarsal Sheath

In the normal horse the TS is not often apparent on clinical or ultrasonographic examination of the plantar aspect of the tarsus.[34,35,116,146] Thoroughpin is a morphologic description of swellings of the TS that occur from a variety of problems and with varying degrees of inflammation (Figure 5.91). Often the causes of effusion within the TS are unknown and called idiopathic as nothing is found on radiographic and ultrasonographic examination. Many of these cases can be reclassified if endoscopy of the sheath is performed because LDFT tendinitis or injuries to the ST are often found as the cause. True idiopathic tenosynovitis of the TS can occur and is often bilateral and most likely related to limb conformation.

Clinically, moderate effusion of the TS typically presents as two swellings cranial to the calcaneal tendon on both the medial and lateral aspects of the distal crus. In more pronounced effusions of the TS, a swelling may be seen distal to the tarsus on the medial aspect of the DT joints just proximal to the chestnut. Distension of the TS must be distinguished from TC joint distension. If the TC joint is distended, fluid can be moved from the plantar synovial pouches to the dorsal pouches by manual compression. Unilateral benign distension associated with idiopathic tenosynovitis often decreases with exercise and worsens with shipping or stall confinement. Effusion will often resolve spontaneously. Treatment is unnecessary if no lameness is present. Horses with effusion combined with lameness and/or a positive response to tarsal flexion most likely have an underlying cause. An accurate diagnosis and directed treatment provide the best chance for a return to soundness.

Intrathecal analgesia of the TS can be performed to confirm the TS as a source of lameness particularly if nothing is found with diagnostic imaging. However, intrasynovial diagnostic analgesia of the TS is not often performed and does have limitations. It is not uncommon for analgesia of the TS to manifest significant improvement but not alleviate lameness. However, more improvement is often seen following a tibial and peroneal nerve block. Intrathecal analgesia of the TS can be difficult when there is minimal effusion. A good landmark for injection is a site dorsal to the LDFT, 2 mm plantar to the middle of the palpable plantar edge of the flexor groove of the ST. However, without recovery of synovial fluid, it can be difficult to determine if the needle is actually in the TS. Therefore, synoviocentesis of the TS should be performed either directly with US guidance or after seeing fluid pockets with US examination in one of the several recesses of the sheath.

A 10- to 14-MHz sector-scanner transducer with a standoff pad at a display depth of 5–6 cm should be used to evaluate the character of the synovial fluid and detect fibrin deposition, adhesion development, and lesions within the LDFT. This technique can be used to assess the integrity of the fibrocartilaginous groove, flexor retinaculum, and edge of the ST. The course of the LDFT

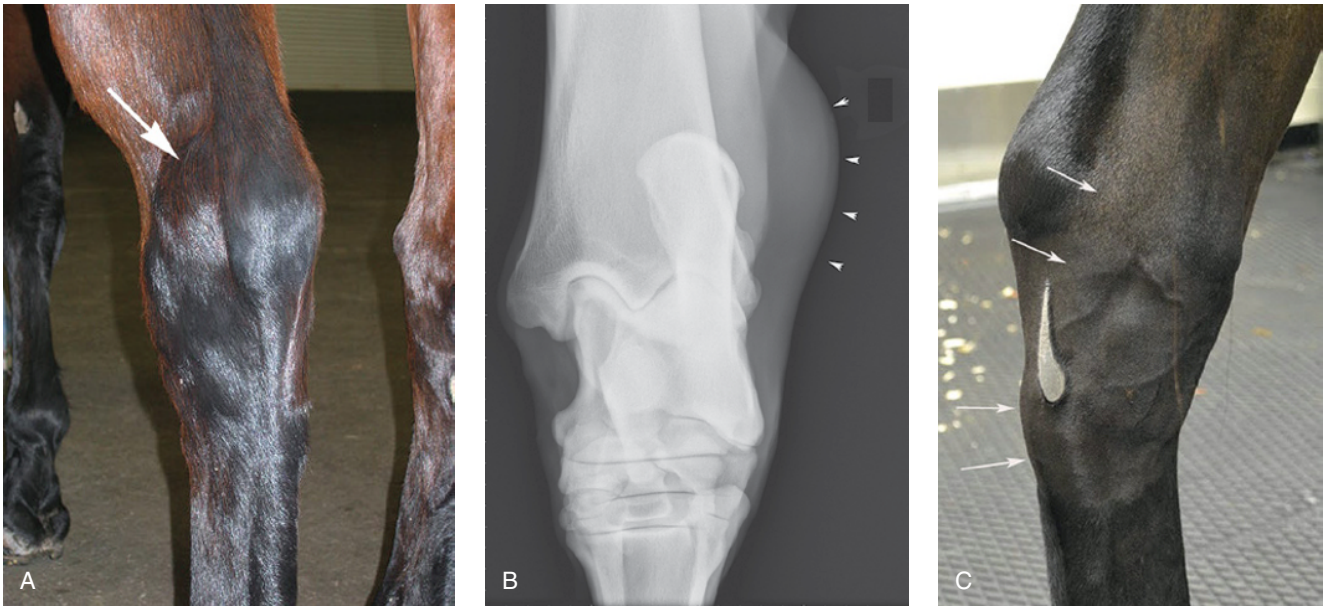

Figure 5.91. Clinical (A; arrows) and DP radiographic observations (B; arrows) of a horse with thoroughpin presenting with swelling primarily on the lateral aspect of the tarsus. Thoroughpin may also be observed on the medial aspect of the tarsus (C; arrows).

VetBooks.ir

around the ST requires constant manipulation of the scan head for proper evaluation of the architecture throughout its course on the medial aspect of the limb. The chestnut can interfere with scan head footprint limiting interpretation of the LDFT at this site. Longitudinal tears in the LDFT and superficial fraying of the tendon are the most common types of lesions detected via ultrasonography and should not be confused with proliferative synovial hyperplasia of the TS. The LDFT may be examined from the plantaromedial aspect of the tarsus and is a large oval-shaped structure with well-defined margins. The dorsolateral aspect of the tendon may appear slightly less echogenic than the remainder of the tendon, and care should be taken not to misinterpret this as a lesion. Sonographic examination infrequently visualizes associated tendon injury. Primary lesions of the LDFT in the tarsal region are rare but do occur in mature horses.[32]

In addition to the standard radiographic views of the tarsus, the skyline and flexed lateromedial projections should be included to emphasize the ST and plantar regions of the tarsus. Acute injuries such as fracture(s) of the ST may be identified. More chronic diseases create destructive and/or proliferative changes to the ST and may appear as mineralization of the LDFT, the long plantar ligament (LPL), and parts of the TS. Contrast radiography/tenography can be useful to evaluate the position and shape of the TS and allow some delineation of the LDFT, but this technique is rarely utilized. Contrast radiography/tenography or contrast fistulography may help to identify foreign bodies.

TS effusion can occur due to a variety of soft tissue and bony injuries. Acute TS effusion usually occurs unilaterally, with sudden onset of moderate to severe lameness. Acute tenosynovitis of the TS is most often due to a traumatic insult to the medial aspect of the tarsus. The medial edge of the ST is a prominent structure on the medial aspect of the tarsus and is prone to fracture from direct trauma. Overstretching of the sheath may cause aseptic tenosynovitis of the TS. Intrathecal hemorrhage from synovial trauma induces marked inflammatory response, and it can lead to formation of restrictive intrasynovial adhesions. Lameness that develops in these animals may be due to the formation of intrathecal adhesions. In the event of a fracture of the ST, the LDFT may be unaffected if bone damage is confined to the medial edge of the ST, but larger fractures can disrupt the fibrocartilaginous gliding surface.

Horses with lameness thought to be associated with chronic unilateral TS effusion should have thoroughly investigated with US and radiography. Common findings visible on US include synovial proliferation, intrathecal hemorrhage, adhesions, fibrous masses, and mineralization/calcification within the TS wall. US examination may demonstrate fibrillation of the LDFT, or more severe architectural changes include enlargement and/or hypoechoic areas consistent with tendon injury. Mineralization in the LDFT and the surface of the ST does occasionally occur. Radiographically, new bone proliferation can be seen in the region originating from the original trauma or possibly in response to chronic tendon sheath distension. Mineralization may also occur within the LDFT and is felt to be a poor prognostic indicator.

Treatment of acute tenosynovitis should include rest, NSAID therapy, and cold therapy. Intrathecal injection of hyaluronan and short-acting corticosteroid should help resolve acute synovitis, but corticosteroids should be used with caution if tendon damage is found or suspected. If inflammation and lameness continue (especially in the event that no structural damage can be found) but particularly if bone or tendon damage is documented, tenoscopy of the TS is indicated.

Accurate treatment of these chronic problems involves tenoscopic exploration to assess the specific pathology that exists.[26,47,123,124,145,147] Lesions of the TS and LDFT and fragmentation of the ST are visible with tenoscopy and can be addressed directly with this technique. Debridement of the damaged tendon is most effective when the tendon injury is peripheral and associated with tendon fiber fraying. Distension of the sheath is often resolved when the tendon is appropriately debrided. Synovial masses and fibrous adhesions can be identified and resected. Fragmentation of the ST is best managed with fragment removal and fracture site debridement via tenoscopic technique. If the fragments are outside the retinaculum on the medial aspect of the ST, they can be removed by making a separate extrasynovial incision directly over the fragment.

The prognosis of horses with TS tenosynovitis is variable and quite dependent on the cause. Horses with idiopathic synovitis have a very good prognosis except for the cosmetic blemish. Horses with small fractures of the ST can do well, provided damage to the LDFT is minimal. However, chronic changes associated with fracture of the ST have been associated with a poor prognosis for return to athletic soundness.[47]

Septic Tenosynovitis of the Tarsal Sheath

Lacerations and puncture wounds on the medial aspect of the tarsus can be highly problematic. Soft tissue swelling often accompanies these injuries, making an early accurate diagnosis difficult. Lameness is often quite severe particularly when the puncture wounds heal over quickly. The size, depth, and direction of the wound can affect many vital structures. The potential for the involvement of any of several synovial structures dictates that a careful evaluation be performed. Contaminates such as hair and/or debris may be driven deep into the wound providing a nidus for infection. Wounds that have bony involvement (fragmentation) of the tarsal groove of the ST can cause severe lameness due to the motion of the LDFT against the roughened bone even without infection (Figure 5.92). In addition the tarsal retinaculum can act as a constricting band when the LDFT or TS is inflamed and swollen. Other bony abnormalities such as osteomyelitis or sequestra of the ST or calcaneus can also be associated with wounds to the tarsus and can further complicate treatment.

Clinical pathological analysis of synovial fluid and diagnostic imaging are necessary to determine what structures are affected and the necessary treatment(s). Early diagnosis and aggressive treatment are critical for a successful outcome. Septic synovitis is best treated with a combination of systemic antimicrobial therapy, joint lavage, and/or regional intravenous perfusion with

VetBooks.ir

antimicrobials.[9] Chronic cases of TS sepsis are candidates for tenoscopic evaluation. Surgical intervention in such cases may involve incision into the sheath to allow drainage of fluid, placement of indwelling drains, TS tenoscopy, and transection of the tarsal flexor retinaculum. Bony abnormalities involving the ST or tuber calcanei should be treated as the primary source of infection and addressed surgically. The prognosis for return to athletic function is frequently guarded and often requires a protracted course of treatment. Further information on treating synovial sepsis can be found in Chapter 12.

LDFT Tendinitis

Primary injury to the LDFT is a rarely reported cause of hindlimb lameness in performance horses but has recently been reported in 4 horses that had MRI examination of the tarsal region (Figure 5.93).[32] Lameness was mild/moderate in severity and insidious in onset in all horses. Responses to flexion tests were variable. TS effusion was slight in three horses and mild/moderate in one horse. Two horses were positive to DBLPN block, but all horses showed improvement (70%–90%) in lameness after TS analgesia (US-guided injection). Radiographic, scintigraphic, and ultrasonographic findings were

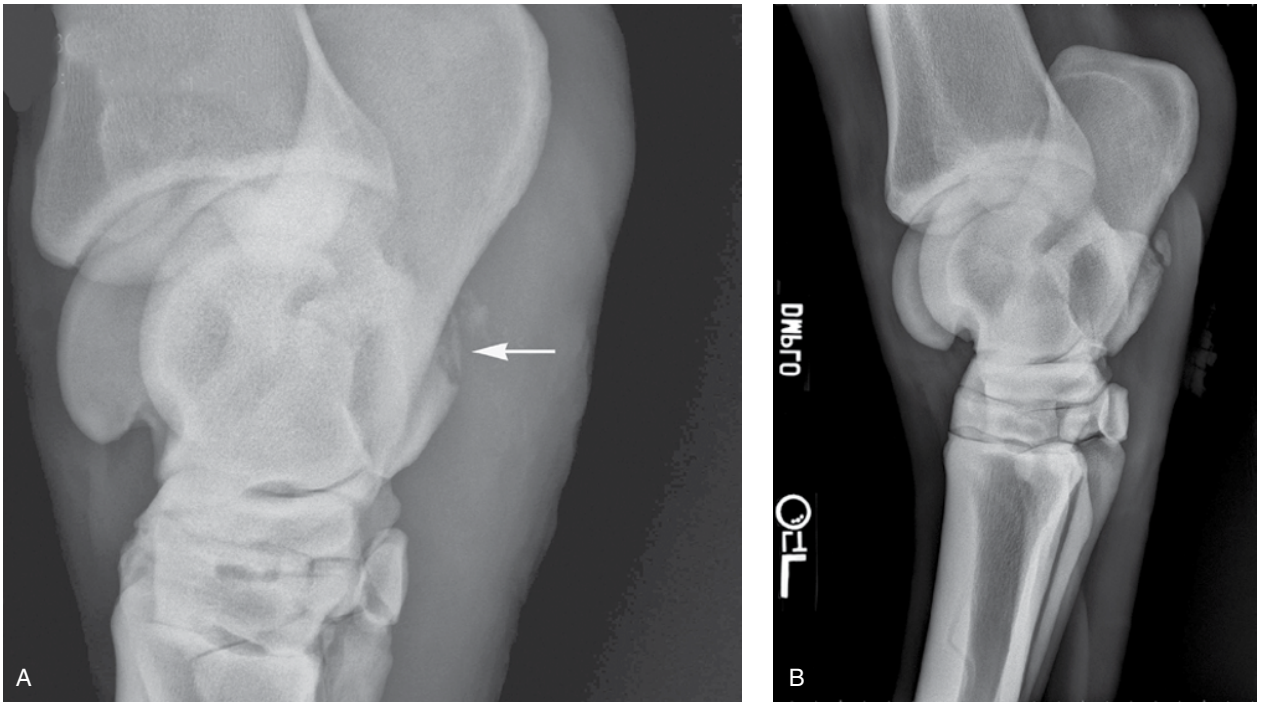

Figure 5.92. (A) Oblique radiographs of two different horses demonstrating an acute, open (A) and chronic, closed (B) fracture of the sustentaculum tali (arrows).

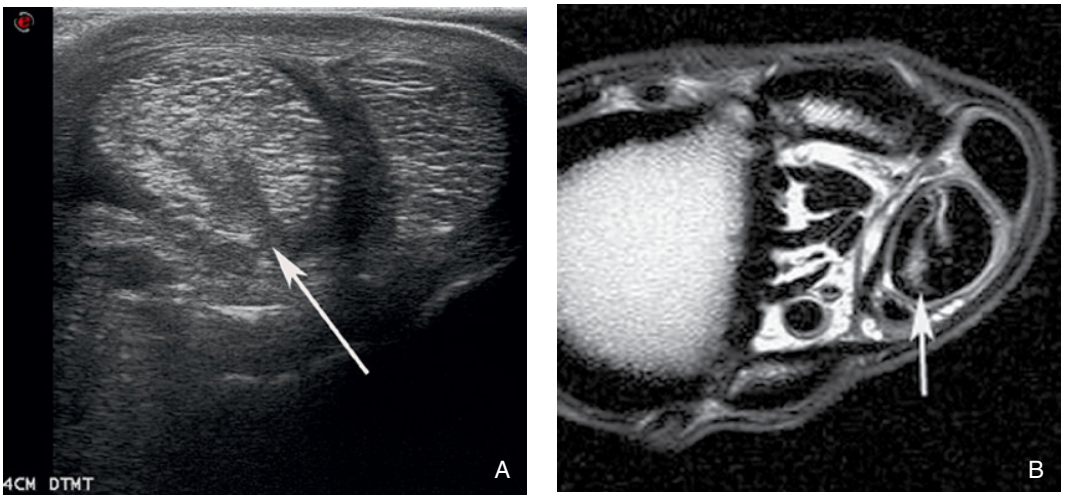

Figure 5.93. Ultrasound (A) and MR image (B) of an LDFT injury (arrows) that occurred within the tarsal sheath at the level of the distal tarsal region. These lesions can be difficult to detect with ultrasound alone.

VetBooks.ir

inconclusive. MRI characteristics included increased T2, PD, and STIR signal intensity within the LDFT in the area of the TS. Ultrasonography was able to distinguish LDFT injury when examined with the knowledge of the MR findings. This study supports the use of MRI for diagnosing LDFT within the TS in horses. Affected horses appear to have a good prognosis for return to athletic performance following appropriate medical treatment.

Calcaneal Bursitis/Capped Hock

The anatomy and nomenclature of the calcaneal bursae (CB) is complicated and can be confusing. The CB includes the subcutaneous calcaneal bursae (SCB), the intertendinous calcaneal bursae (ICB), and the gastrocnemius calcaneal bursae (GCB).[113] The SCB is a potential bursa between the subcutaneous tissue and the superficial digital flexor tendon (SDFT) at the point of the TC. The SCB and ICB have also been called the calcaneal bursa of the SDFT. The intertendinous calcaneal bursa (ICB) is further divided into the gastrocnemius calcaneal bursa (GCB) and the intertendinous calcaneal bursa (ITB). However, these two bursae communicate in most horses and should be considered as a single synovial structure. The CB extends approximately 9–10 cm proximally and 6–7 cm distally to the TC. The ICB is a true synovial cavity analogous to the bicipital bursa and navicular bursa, and problems within this anatomic structure are much more problematic than those within the subcutaneous bursa. However, the ICB and the GCB appeared to communicate with the SCB in 39% of limbs.

Swelling at the point of the hock (tuber calcaneus or TC) is usually caused by damage to the SCB, giving the appearance of a capped hock (Figure 5.94). This is usually caused by self-inflicted trauma, typically from the horse's kicking a fixed object (wall or trailer). These injuries may or may not be associated with a wound. The SCB at the TC is analogous to the acquired bursa at the point of the olecranon. Because there is a communication between the SCB and the ITB in about 40% of horses', wounds that involve point of the hock down to and including the SDFT should be considered at risk of developing an infection of the ICB. Sonographic examination typically reveals the subcutaneous position of the bursa and, in the early stages, a primarily fluid-filled pocket. The fluid may have fibrin or the appearance of a large clot within the cavity. Careful evaluation of the ITB is critical to rule out more extensive involvement and appropriate treatment of all affected structures. Radiographic examination should be performed to evaluate bony lesions.

A capped hock appearance has been reported in cases of gastrocnemius tendinitis and in some bony abnormalities of the TC[41,109] (Figure 5.95). Lameness and swelling in the region of the distal common calcaneal tendon are most commonly due to a tendonitis of the gastrocnemius tendon (GT). A mild to moderate enlargement of the ICB and a "capped" appearance can be present possibly attributable to distension of the bursa dorsal to the insertion of the GT that may communicate with the ICB. LPL desmitis or curb should also be differentiated from swelling of the ICB and GT (see gastrocnemius tendinitis later in this section for further information).

Horses with signs of chronic swelling of the calcaneal bursa should be evaluated for osteolytic lesions on the tuber calcanei associated with the insertion of the GT ("gastrocnemius enthesitis"). A flexed, proximoplantar to distoplantar tangential (skyline) radiographic view of the calcaneus is advantageous for identifying this lesion and is recommended for all horses with calcaneal bursitis. The prognosis for athletic soundness in horses with chronic calcaneal bursitis and associated osteolytic lesions of the tuber calcanei should be considered guarded. Well-circumscribed osteolytic or osseous cyst-like lesion(s) on the TC at the insertion of the GT may be evidence of an enthesopathy or enthesitis and calcaneal osteitis (Figure 5.96). A US exam may reveal mild thickening of the wall of the calcaneal bursa, often distended with anechoic fluid. The GT, SDFT, LDFT, and TS should all be evaluated with US.

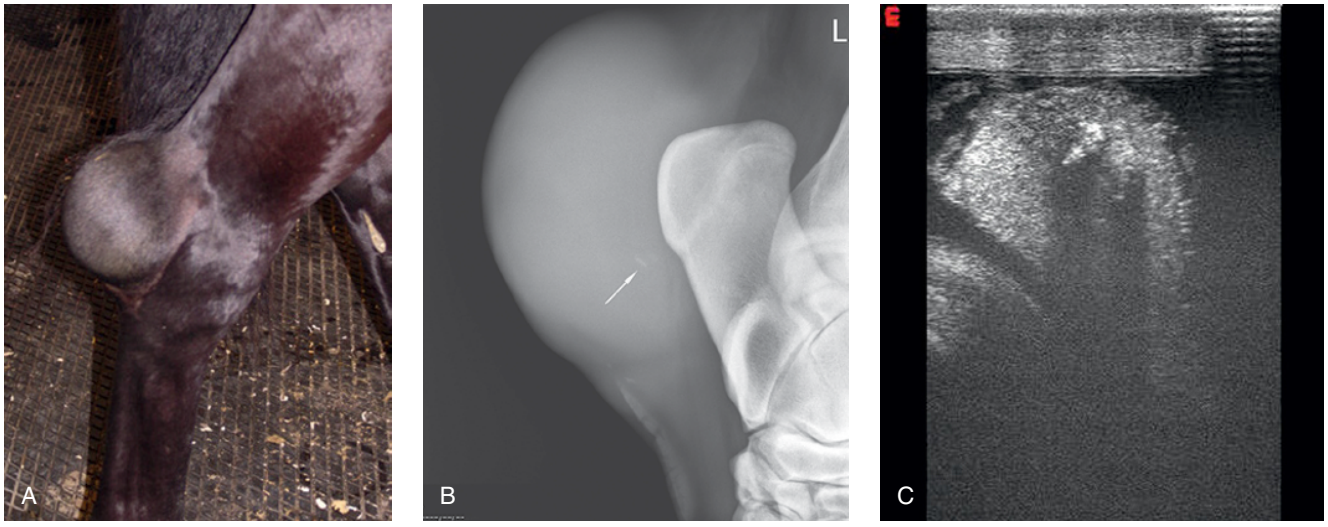

Figure 5.94. Clinical (A) and radiographic (B) appearance of a horse with swelling at the point of the hock (capped hock). Ultrasound (C) revealed a radiodense object within the swelling that can also be seen on the lateral radiograph (arrow).

VetBooks.ir

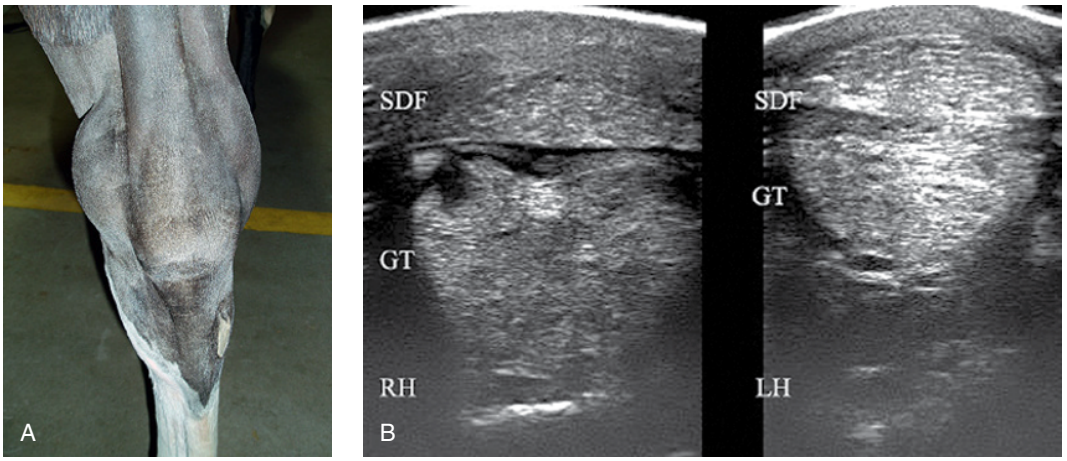

Figure 5.95. Severe swelling in the region of the calcaneal tendon has been reported in cases of gastrocnemius tendinitis and in some bony abnormalities of the TC (A). Ultrasound can be used to confirm the diagnosis (B). Comparison to the opposite side can help confirm changes associated with injury to the calcaneal tendon.

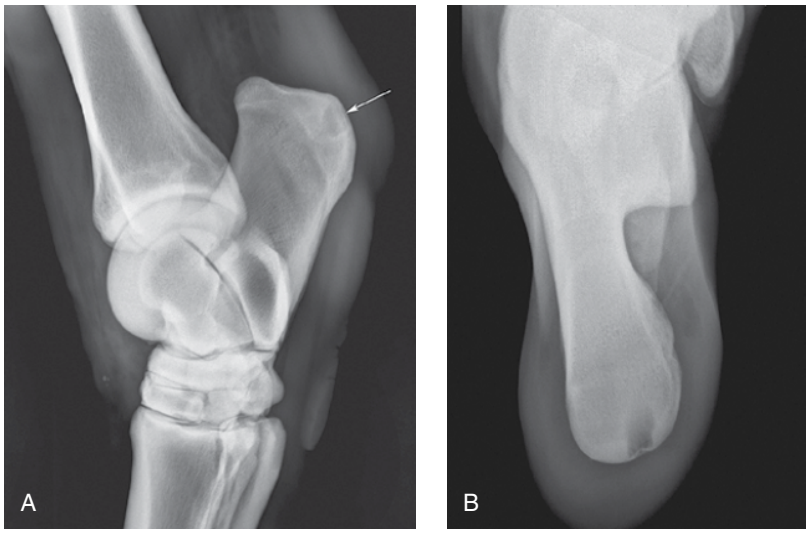

Figure 5.96. Well-circumscribed osteolytic or osseous cyst-like lesion (arrow) on the TC at the insertion of the GT may be indicative of an enthesopathy and calcaneal osteitis (A). A flexed, proximoplantar to distoplantar tangential (skyline) radiographic projection can often help identify bony lesion(s) of the TC (B).

Wounds that involve the plantar surface of the TC need to be carefully evaluated as communication with the SCB can increase the risk of extension of the septic process into the ICB. Wounds superficial to the subcutaneous bursa can often resolve with routine wound care and have a good prognosis. Wounds that directly involve the ICB can be more problematic and should be treated aggressively to prevent an established synovial infection. Radiographs are recommended to document sequestrum formation or osteomyelitis, which may be the primary problem, with the bursa secondarily infected. Contamination of the CB must always be considered to be possible with wounds in the plantar tarsal region.

Endoscopic exploration (bursoscopy) of the ICB can be a very useful diagnostic tool to help identify and treat the cause(s) of ICB bursitis.[74,112,113] For example, peripheral tendon lesions of the GT or SDFT can occasionally only be identified and treated effectively with endoscopy. Endoscopy can also be used in cases of infectious bursitis.

Osteitis of the Calcaneus

The TC has minimal soft tissue protection and is at risk of traumatic injury and subsequent infection.[8,70,87] Management of these injuries can be complicated if the TC joint, ICB, and TS are involved. Traumatic injuries generally occur from kicking a fixed object or being kicked by another horse. Calcaneal involvement can lead to a focal osteitis, which often causes moderate to severe lameness, cellulitis, and synovitis. The injury often compromises the vascular supply to the periosteum resulting in cortical bone damage that often leads to sequestrum formation. Bone infection of the tuber calcaneus rarely extends into the medullary cavity so that an accurate description of the condition is an osteitis rather than osteomyelitis.

Lateromedial, flexed lateromedial, and plantaroproximalplantarodistal (skyline) radiographic views are the most helpful (Figures 5.62A and 5.96B). Radiographic

VetBooks.ir

signs of calcaneal osteitis or sequestrum formation may take several days or weeks to appear, and thus sequential radiographic evaluation is recommended. The radiographic appearance of calcaneal osteitis depends on the duration of infection before treatment and if other structures are involved. Ultrasonography can be useful to assess synovial structure involvement and provide direct visualization of needle placement into a pocket of fluid for the aspiration of synovial fluid for analysis.

Acute injuries to the TC with minimal contamination may resolve with local wound management without the development of bony lesions. Osteitis of the TC is best addressed by curettage of the affected bone. Sequestrectomy is indicated if a sequestrum develops. Secondary sepsis of the ICB or TS should be treated aggressively similar to any synovial infection. More complex surgical intervention may be required in more traumatic injuries with heavy contamination and devitalized and infected soft tissue and/or bone. The prognosis for horses with calcaneal osteitis depends on the structures involved and the duration of infection before treatment. In one study, 9 of 18 horses with infection of the TC were used as broodmares, and 9 horses returned to athletic function.[87]

Dislocation of the Superficial Digital Flexor Tendon (SDFT)

The SDFT contains very little muscular tissue and consists almost entirely of a strong tendon forming part of the stay apparatus in the hindlimb. Its action is to flex the digit and extend the hock, but this is considered largely to be a mechanical effect resulting from the action of other muscles of the stifle joint. A wide, flat, fibrous bundle arising from the SDFT attaches the tendon to the calcaneus laterally and medially. This structure, called the retinaculum, stabilizes the tendon at that level of the TC. The dislocation occurs when one of the fascial attachments (usually the medial retinaculum) of the SDFT to the calcaneus ruptures with displacement laterally (Figure 5.97).[118,127,128,135,149]

Figure 5.97. Caudal view of the tarsi in a horse with severe swelling within the right calcaneal bursa and evidence of lateral luxation of the right SDFT from the tuber calcanei (arrows). *Source*: Courtesy of Gary Baxter.

Because of the severe swelling over the point of the hock, an inaccurate diagnosis of capped hock or calcaneal bursitis may be made. The tendon may remain completely luxated (stable luxation) or can reduce and then displace while walking (unstable luxation). Most common is a tearing of the medial retinaculum with a lateral displacement, but medial displacement does rarely occur. One case report described a situation where the tendon fibers of the SDFT split near its center over the point of the hock (one-half of the SDFT displacing medially and the remaining half laterally).[127]

Luxation of the SDFT tends to be an injury that occurs in horses that compete at speed or due to trauma. Initially, affected horses appear quite uncomfortable after the injury. In the acute to subacute injury, diffuse swelling around the point of the hock can make it difficult to accurately define what is injured. However, an unstable luxation of the SDFT tendon allows the tendon to move back into its original position only to luxate again when the horse walks off. Typically, the tendon tends to luxate when the tarsus is flexed. The position of the tendon can become more easily appreciated as the swelling subsides. On palpation, the luxation of the SDFT can often be appreciated. Horses with actively luxating tendons may become quite distressed. If the tendon remains permanently luxated, the horse's distress diminishes quickly. Horses with a permanently luxated tendon (usually laterally) can, with conservative management, return to useful work. By contrast, those with unstable subluxations, in which the tendon spontaneously reduces and then displaces, often remain permanently compromised frequently with continued anxiety. There have been rare cases of horses that have had the SDFT luxate bilaterally.

A definitive diagnosis is usually made by visualizing the displacement of the tendon. However, radiographs and US examination should be performed to more accurately define the extent of injury. Radiographs are taken to rule out the possibility of a fracture or other associated bony disorders of this area. US can assist in the diagnosis by defining the structures that are involved and the degree of damage. Most often the medial retinaculum is torn completely. However, partial tears of the retinaculum exist with subluxation of the SDFT occurring rather than complete luxation. Because the retinaculum exists within the ICB, fraying and tears of this structure can create moderate effusion of the calcaneal bursa. Partial tears could easily be misdiagnosed as a simple capped hock.

The literature would suggest that the treatment of choice for luxated tendons (unstable displacements) is surgical correction with postoperative immobilization in a cast for 4–6 weeks. There have been a number of surgical procedures recommended, all of which include open reduction with some form of suture of the torn retinaculum, some of which had a retinacular reinforcement with or without imbrication and some using a synthetic (polypropylene) mesh. There are only a few reports of reduction representing a total of nine documented cases, but the results have often been disappointing. Recovery in a full-limb cast and the possibility of cast complications are always a concern.

Endoscopy of the CB may provide another alternative approach to luxation of the SDFT.[148] Exploratory

VetBooks.ir

endoscopy of the bursa allows surgical debridement of the torn tissue and exploration of the calcaneal bursa for any other damage. Horses with unstable displacement of the tendon also have disruption of the tendon fibrocartilage cap. Removal of this tissue (torn retinaculum and the damaged fibrocartilage cap) results in stable subluxation and can return horses to athletic activity. Both lesions can be detected with preoperative ultrasonography.[149]

With conservative management the prognosis for breeding soundness or light pleasure riding is usually good for stable luxations. Realistically, too few cases have been treated surgically with long-term follow-up to make an objective comment about the prognosis for athletic ability, because every case is different.

Gastrocnemius Tendinitis

The SDFT begins medial to the GT and rotates/courses from medial to caudal to attach to the calcaneus before continuing distally. The LDFT is deep to both the SDFT and GT and courses distally over the plantaromedial aspect of the calcaneus and the ST. The combined SDFT and GT form the common calcaneal tendon, which is the major extensor of the tarsus. Severe injuries to the common calcaneal tendon can cause partial or complete loss of support to the tarsus. Lameness and swelling in the region of the distal common calcaneal tendon are most commonly due to tendonitis of the GT, which is considered a rare cause of hindlimb lameness in the horse.[41,114] Lameness may be sudden or gradual in onset, and the severity of lameness varies depending on the injury. Lameness is usually exacerbated by a proximal limb flexion test. Lameness is usually improved by perineural analgesia of the tibial nerve.

In association with enlargement of the GT, there can be a mild to moderate enlargement of the calcaneal bursa (ICB and CB) (Figure 5.98). This can give the limb a "capped" appearance possibly attributable to distension of the bursa dorsal to the insertion of the GT that may communicate with the ICB. Ultrasonography may be used to best detect enlargement of the tendon, poorly defined margins, focal or diffuse anechoic to hypoechoic lesions, and loss of normal fiber alignment (diffuse > focal). The lesions seem to occur predominantly in the body of the tendon and less frequently at the insertion on the TC. In the majority of horses, however, GT occurs without concurrent tendinous or ligamentous injury. Severe injuries may allow the point of the hock to "drop" because the reciprocal apparatus is no longer functional.[76,85,142] Radiographs should be obtained for the detection of a fracture of the calcaneus that can manifest a similar appearance. Diagnostic US can help confirm the location of the injury but is not necessary for an accurate diagnosis. Conservative treatment with stall rest and controlled exercise for 6–12 month is usually indicated.[85,142] Rehabilitation protocols can include water treadmill exercise. Horses with mild to moderate lesions have a reasonable prognosis for return to athletic work, but the prognosis for horses with more severe lesions is guarded.

Horses with chronic calcaneal bursitis often have insertional changes of the GT. Chronic calcaneal tendinitis may have osteolytic lesions at the insertion of the GT on the TC ("gastrocnemius enthesitis"). Well-circumscribed osteolytic or osseous cyst-like lesion(s) on the TC at the insertion of the GT may be associated with enthesopathy or a calcaneal osteitis as a component of focal nonseptic osteitis. A radiographic examination of the tarsus should include a flexed, proximoplantar to distoplantar tangential (skyline) view, and a flexed lateral radiographic view of the calcaneus is advantageous for identifying this lesion and is recommended for all horses with calcaneal bursitis. Radiographic signs include increased soft tissue swelling, osseous lysis, fragments/sequestra, and new bone production more commonly associated with chronic conditions.

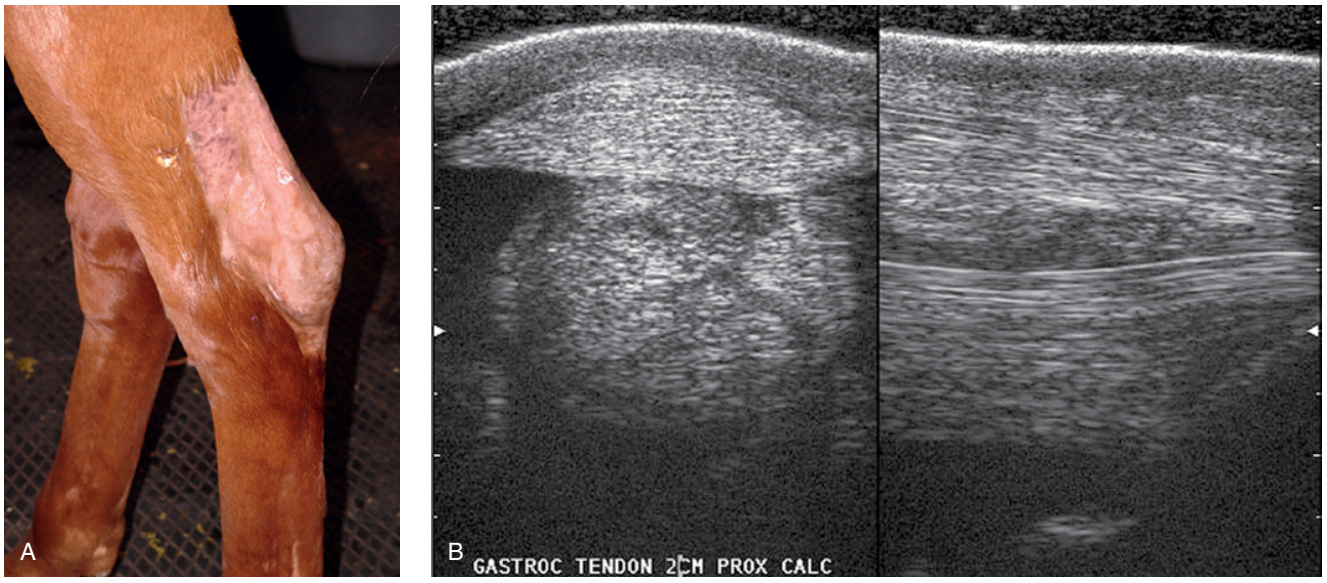

Figure 5.98. Thickening and swelling was identified in the calcaneal tendon of this horse (A). Ultrasound demonstrated enlargement of the gastrocnemius tendon with focal and diffuse hypoechoic areas with loss of normal fiber alignment on both the transverse and longitudinal planes (B).

VetBooks.ir

US frequently shows enlargement of the GT with focal or diffuse hypoechoic areas with loss of normal fiber alignment when viewed in the longitudinal plane. Mild thickening of the wall of the calcaneal bursa due to chronic distension with primarily anechoic fluid may be identified. Infection and trauma tend to involve the attachments of the GT, SDFT, and calcaneal bursa. The GT and SDFT and the LDFT and TS should all be evaluated with US. The prognosis for athletic soundness in horses with chronic calcaneal bursitis and associated osteolytic lesions of the TC is guarded.

Curb

The term curb describes a swelling along the plantar aspect of the calcaneus distal to the point of the hock/tarsus but does not typically addresses etiology. While desmitis of the long plantar ligament (LPL) can manifest as a swelling in this region, it is not the only cause of curb.[120] It is felt that curb may result from excessive violent tension or direct trauma. Trauma may occur from kicking walls or tailgates in trailers and violent attempts to extend the hock. In addition, there is some speculation that conformation may predispose to the development of curb. Lameness, if it occurs, is typically minimal and of short duration. Horses with persistent lameness, particularly those with swelling more distal to the LPL, should be evaluated more carefully. Superficial digital flexor (SDF) tendinitis of the proximal metatarsus may have a similar appearance, with swelling distal to the calcaneus. Occasionally, a similar swelling exists without lameness. This swelling has a fluid consistency and appears sonographically as a fluid pocket surrounding the SDFT. Drainage of the fluid may alleviate the problem, but persistence of the fluid may warrant corticosteroid injection.

While curb is primarily an injury of racehorses, and most commonly the STB racehorse, it does occur in nonracehorse sport horses (Figure 5.99). US examination of this area reveals thin subcutaneous fibrous tissue layer, the SDFT as a crescent shape, narrow in a medial to lateral direction, and somewhat thickened from that seen proximally. In the longitudinal scan, the normal SDFT has a dense parallel fiber pattern. Deep to the SDFT, the LPL is at full thickness (plantar to dorsal direction), is rectangular in shape, and is firmly attached to the calcaneus. At this level, the DDFT is out of view medially and must be evaluated by placing the transducer plantaromedially. In fact, only 30% of horses in one study had injury of the LPL.

Curb was reported to be caused by excessive stress or strain from race training (80 horses), direct trauma (11 horses), previous injection (3 horses), associated injuries (3 horses), and an apparent "bad step" or unknown cause (13 horses). The most common reported form of direct trauma was stall or wall kicking. Horses with LPL desmitis, SDF tendonitis, or DDF tendonitis or those with combined soft tissue injuries exhibited most pronounced lameness. Horses with curb are more likely to have swelling and injury of peritendinous and periligamentous tissue and/or SDF tendonitis than injury of the LPL. Horses with severe SDF tendonitis, LPL desmitis, LDF tendonitis, or combined soft tissue injury received long-term rest (3 months) and controlled return to exercise, but they were the most likely group to do poorly or to remain lame. Diagnostic US examination may reveal that the swelling is due to peritendinous or periligamentous fibrosis, SDF tendinitis, DDF tendinitis, or LPL desmitis. Curb is primarily an injury of racehorses but does occur in nonracehorse sport horses. Within racehorses, the STB is predisposed. Gait differences between the STB and TB may account for this predisposition, but conformation may play a role. Sickle-hocked conformation is more prevalent in the STB breed and seems to predispose these horses to the development of curb. It is felt that overload or excessive strain of plantar soft tissue structures would be exacerbated in horses with sickle-hocked conformation. Etiology of curb in the sport horse may be different than that in racehorses because direct trauma was a common etiology in nonracehorse sport horses. Horses with more severe lameness may have acute LPL inflammation and tearing due to violent exertion, trauma from kicking, and violent attempts to extend the hock.

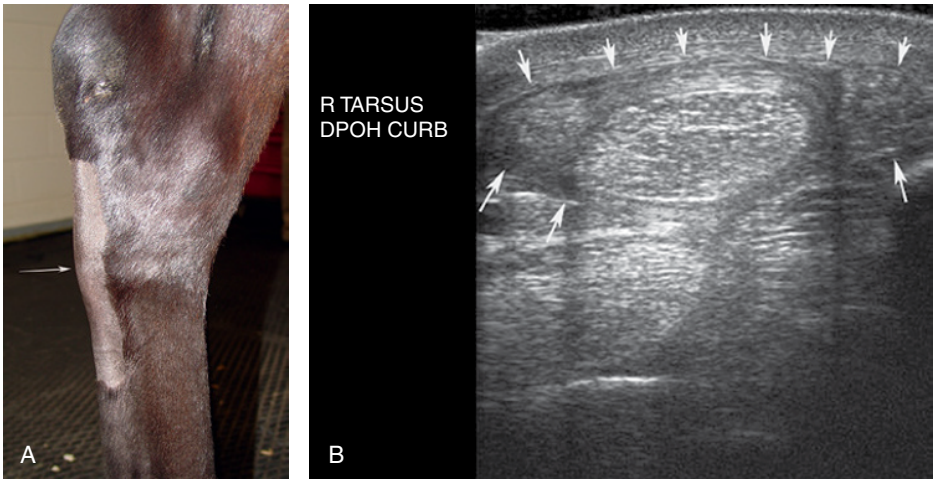

Figure 5.99. Horse with swelling along the plantar aspect of the calcaneus distal to the point of the hock (A; arrow). Often the swelling has a fluid consistency and appears sonographically as a fluid pocket surrounding the SDFT (B; arrows demonstrate a swelling consistent with an organizing hematoma surrounding the SDFT).

VetBooks.ir

Acute Tenosynovitis of Extensor Tendons

The long digital extensor tendon (LoDET) lies on the cranial aspect of the crus and courses over the dorsum of the tarsus just lateral to the MTR of the talus. A proximal, middle, and distal extensor retinaculum cover the LoDET at the level of the tarsus. The tendon courses over the tarsus within a synovial sheath from approximately the level of the LM and continues coverage through the distal retinaculum almost to the junction with the lateral digital extensor tendon (LDET). At this level, the conjoined tendons of the LoDET and LDET muscles continue distally similarly to the common digital tendon of the front limb. The LDET of the hindlimb courses distally across the lateral surface of the tarsus.

Direct trauma is the most likely cause of tenosynovitis of the extensor tendons of the tarsus. Blunt trauma to the dorsal and lateral surface of the tarsus can create acute tenosynovitis of extensor sheaths, particularly the LDET. The LDET sometimes develops idiopathic or acute tenosynovitis. The swelling within the synovial sheath may protrude proximally and distally to the retinaculum of the lateral digital extensor. Lameness when it occurs is sudden in onset and moderate in severity. Mild distension of the sheath may occur initially. These effusions often persist in spite of appropriate treatment. The LoDET is rarely affected. The distal aspect of the PT tendon can be injured as well. Diagnostic US should be utilized to assess the tendon for damage. Treatment is determined based on the specific structure(s) involved. If the tendon appears to be normal, then the treatment may be directed at the synovial sheath.

Rupture/Tendonitis of the Peroneus Tertius (Fibularis Tertius)

The PT muscle is tendinous over its entire length. It arises from the extensor fossa of the lateral femoral condyle and inserts with two distinct tendons to the tarsus. Rupture of the PT is uncommon with trauma being the most common cause.[78,86,117,132] The muscle or tendon can rupture anywhere along its course and can result in an avulsion fracture at its origin in the extensor fossa. When this muscle is ruptured, the stifle flexes, but the hock does not. Rupture of the PT is usually due to overextension of the hock joint (Figure 5.100). Entrapment of a limb with violent struggles can cause this condition. Rupture also may occur during the exertion of a fast start causing overextension of the tarsus such as in jumping. It can also occur after a full-limb cast is applied to the hindlimb. PT injury in adult horses may cause swelling of the distal cranial aspect of the crus near the TC joint (usually between the trochlear ridges), but lesions in the mid-crus seem to be more common and often are not associated with significant swelling. If the PT is ruptured, the tarsal joint can be extended while the stifle is flexed, indicating loss of the reciprocal apparatus function. There is often a dimpling that occurs within the common calcaneal tendon. If the origin of the PT fractures from the femur, femoropatellar effusion is a prominent feature, and the gait deficit is similar. On US, the acute ruptured PT is enlarged and shows multiple small focal anechoic to hypoechoic lesions. On a longitudinal scan, the normal fiber orientation disappears.

Figure 5.100. Rupture of the peroneus tertius disrupts the reciprocal apparatus allowing extension of the tarsus and fetlock with the stifle flexed. *Source*: Courtesy of Dr. Gary Baxter.

Careful monitoring of the healing process with US is necessary to prevent reinjury.

Complete rest is the best treatment. The horse should be placed in a stall and kept quiet for at least 4–6 weeks, and then limited exercise should be given for the next 2 months. Most cases heal and show normal limb action, and if properly conditioned, most horses can return to normal work. After rupture of the PT tendon, 71% of horses returned to their previous level of exercise with a mean rehabilitation period of 41.5 weeks. If a horse was a performance horse at the time of injury, it was 11 times less likely to return to its intended use. Furthermore, if an additional structure was injured at the time of rupture of the PT, the horse was 14.6 times less likely to return to its intended use.[78] Prognostic indicators previously reported for this type of injury include location and degree of rupture. Prognosis has been reported to be favorable when rupture occurs in the tibial region and poor if the rupture occurs at the point of origin from the extensor fossa of the lateral femoral condyle with any associated fracture. Performance horses have a decreased prognosis to return to their intended use after rupture of the PT.

PERIARTICULAR TARSAL CELLULITIS

Spontaneous cellulitis can develop around the tarsus that can present as an unusual cause of an acute-onset, severe non-weight-bearing lameness. One report described this condition in a series of TB racehorses.[111] Skin abrasions were identified in some horses somewhere in the more distal part of the limb, and the onset of swelling usually began on the dorsal aspect of the hock. The cellulitis was quite painful to palpation. These clinical signs were associated with a fever, neutrophilia, and hyperfibrinogenemia. Prompt, aggressive treatment

VetBooks.ir

with oxytetracycline (5 mg/kg IV SID) or other antimicrobial agents and phenylbutazone (4.4 mg/kg) for at least 5 days combined with forced walking exercise for as much as possible daily resulted in rapid resolution of lameness. The prognosis was usually favorable; 1 of 10 horses developed osteomyelitis of the third tarsal and fourth tarsal bones, although this horse ultimately made a complete recovery.

TIBIA AND CRUS

W. Rich Redding

INTRODUCTION

The tibia is one of the major weight-bearing bones of the hindlimb. The tibia extends obliquely downward and backward from the stifle to the hock. It is a tubular bone with a triangular-shaped cross section proximally changing to an oval shape as it courses distally. The tibia has three chief centers of ossification and two supplementary ones for the tibial tuberosity and the lateral malleolus.[14] The proximal articular surface of the tibia is roughly triangular in shape with the intercondylar eminence protruding from the center of the triangle providing attachment for the patellar ligaments. The proximal articular surface of the tibia has a flat table surface with a centrally located intercondylar eminence. The tibial tuberosity contains a deep extensor groove/muscular sulcus, which is filled by the cranial tibial (CT) and the long digital extensor tendon (LoDET) muscles. The tibia is covered by muscle and tendon on the cranial, lateral, and caudal aspects. The medial surface is without muscle covering and easily palpated under the skin. Proximally the medial surface is broad where it furnishes insertion to the medial collateral ligament of the stifle and the sartorius and gracilis muscles. The caudal surface is flattened and provides attachment for the popliteus muscle proximally and for the deep flexor muscle of the digit via a series of roughened lines that fade distally. The nutrient foramen is situated among these lines and can be quite prominent. The distal articular surface contains two deep sulci oriented in caudomedial to craniolateral direction, which articulate with the trochlear ridges of the talus.

The primary axis of tension strain in the tibia occurs on the cranial surface, while the caudal surface experiences compressive strains.[26] These strains are particularly large in the proximal metaphyseal and mid-diaphyseal region. Distally the tibia experiences large torsional forces. Casting the hindlimb does not alter the strains experienced by the tibia. Casts may be effective to immobilize the tarsus and distal limb of the horse, but they do not protect the tibia from weight-bearing loads. For more information on the muscular anatomy and innervation of the tibia, refer to Chapter 1.

DIAGNOSTIC ANALGESIA OF THE CRUS

There is no practical method to use diagnostic analgesia to differentiate conditions of the tibia and crus. The distal portion of the crus can be desensitized with a peroneal and tibial nerve block. Pain from injuries involving the distal tibia and caudal soft tissues of the crus may also be abolished with this block, but the results are unreliable. Lameness of the crus becomes more likely in horses in which perineural and intra-articular techniques for the rest of the limb have been exhausted.

IMAGING THE TIBIA/CRUS

In a foal or young horse, the tibia can be radiographed easily. However, in an adult, it is better to focus on a particular region of the tibia and center the X-ray beam appropriately. Large plates should be utilized to obtain radiographs of the entire length of the tibia. Orthogonal views should be acquired, and specific oblique projections can be focused at specific areas of interest depending on the tentative diagnosis. The proximal fibula is notorious for simulating fractures. The tibial tuberosity forms from a separate ossification center and varies greatly with age. The appearance of the tibial tuberosity varies substantially with different projection angles. The parallel ridges located on the caudal and caudolateral surfaces of the tibia (termed *muscular lines*) mark the attachment of the deep digital flexor muscle and must not be mistaken for a so-called bone reaction. The opposite tibial region can be used as a normal comparison.

Ultrasonographic examination can be very helpful in evaluating the soft tissues of the crus, particularly the caudal and cranial muscle masses (gastrocnemius and peroneus tertius/CT). The patellar ligaments can be evaluated quite effectively with diagnostic ultrasound. Puncture wounds and lacerations of the crus can be carefully investigated to document the extent of soft tissue involvement with ultrasound. Clinical conditions that ultrasound may be helpful to define include gastrocnemius injury, peroneus tertius/CT tendon damage, thoroughpin (or "false" thoroughpin), calcaneal bursitis, and tarsal sheath tenosynovitis.

Nuclear scintigraphy should be considered when the lameness cannot be blocked out or cannot be confirmed/defined to a specific region with radiographic and/or ultrasound examination. Any young racehorse with an acute hindlimb lameness potentially due to a stress fracture of the tibia is a candidate for scintigraphy. Lameness conditions suspected to originate more proximally on the limb or to involve multiple sites within the limb are also candidates for scintigraphy. In older horses scintigraphy may permit detection of subtle bony changes undetected by other diagnostic methods.

CLINICAL CONDITIONS

Conditions that affect the tibia/crus can affect the large muscle mass surrounding the tibia, the shaft of the tibia, and/or the articulations of the tibia (stifle joint proximally and TC joint distally). Traumatic events are the most common cause of injuries to the tibial region. Injuries in this area can manifest a wide variety of clinical signs apparently dependent on the structures involved. In the young racehorse soft tissue injuries are not as common as injuries to the bone. In the mature sport horse, husbandry practices can increase the incidence of soft tissue injuries, particularly lacerations and

VetBooks.ir

puncture wounds. More extensive injuries may involve the tibia. Fractures can occur in about the same frequency as other long bones. Fracture types include incomplete, proximal physeal fractures (in young horses), diaphyseal fractures, and tibial crest fractures.[2–13,15–18,26,27,29,34–36] Training-related bone injuries also occur in the shaft of the tibia.[1,19–22,24,25,28,31] In racehorses stress-related bone injury occurs in the tibial cortex and often present as a subtle, high-speed lameness. In addition, enostosis-like lesions (ELLs), similar to what is seen in humans, have been described in horses and occur as focal or multifocal sclerotic lesions within the medullary cavity of long bones.[1]

Traumatic fractures of the tibia are typically catastrophic injuries (Figure 5.101). Kicks or traumatic injuries can impart enough energy to this unyielding bone to cause it to shatter.[3,6–9,13,15,16,26,29] As bone deforms, it stores the applied energy as strain energy, and this energy ultimately is released when the bone fractures. Bone loaded rapidly fails at a higher load and releases more energy than if it is loaded slowly. Unfortunately these fractures are usually associated with an explosion of bone, which can cause significant damage to the skin and increases the risk of contamination of the fracture since they become open. Younger animals are subjected to the same types of traumatic injuries as adults, but because they are actively growing, fracture configurations will often involve the growth plate(s). As in all long bone fractures in horses, maintaining the integrity of the skin and appropriately stabilizing the limb before shipping are critical to a successful outcome if surgery is being considered.[5]

Figure 5.101. Injuries that impart significant energy to the tibia often cause the bone to shatter and usually cause significant damage to the skin and surrounding soft tissues that increase the risk of contamination of the fracture.

ENOSTOSIS-LIKE LESIONS

ELLs were first described in horses as focal or multifocal sclerotic lesions within the medullary cavity of the long bones. Their role in causing lameness has been questioned. ELLs are typically recognized on scintigrams as variable intensity focal intramedullary IRUs.[1,4,23] Lesions are most often detected in the tibia and radius more commonly than the humerus and third metacarpal/metatarsal bones. Lameness severity is often correlated to radiopharmaceutical uptake intensity (Figure 5.102). The ELLs located in the humerus are felt to cause more severe lameness than ELLs in other anatomic locations. Radiographic findings tend to lag behind scintigraphic findings and when seen are not always associated with lameness. However, radiography is not a sensitive method for detection of acute bone injury. A period of bone remodeling is required before lesions become radiographically evident. ELLs have a characteristic radiographic appearance with a focal area of increased opacity usually close to the nutrient foramen and within the medullary cavity. Orthogonal views are critical to confirm the intramedullary location of the bone response as ELLs. In many horses these lesions appear to be incidental findings and often are considered unrelated to lameness.

Diagnosis of ELLs as a cause of lameness is by the exclusion of other causes in the face of positive diagnostic imaging findings (scintigraphy or radiography). The intramedullary location of the lesions makes them difficult to confirm as the source of lameness without the use of diagnostic analgesia. This can be accomplished with the use of a tibial and peroneal nerve block in the hindlimbs and a median and ulnar nerve block in the forelimbs.

There appears to be little evidence of predisposing causes for the development ELLs. Conformation seems to have little effect on the development of ELLs. However, there does appear to be a risk factor for Thoroughbreds to develop ELLs. High concussive loads associated with race training may be related to the development of ELLs. Interestingly ELLs can cause pronounced, recurrent lameness within the same animal but in different locations. Some animals have been diagnosed with ELLs annually for several years. Differentiating ELLs from stress reactions and fractures in racehorses is especially important. Identifying the location of the IRU within the tibia (cortical vs. cancellous) is critical to successfully diagnose and manage the horse's lameness. Continued training on cortical stress reaction(s) or stress fracture(s) may lead to fracture propagation and a catastrophic injury. However, horses (racehorses in particularly) with an intramedullary location are more likely to be ELLs. The presence of ELLs does not seem to have long-term adverse effects on athletic performance.

VetBooks.ir

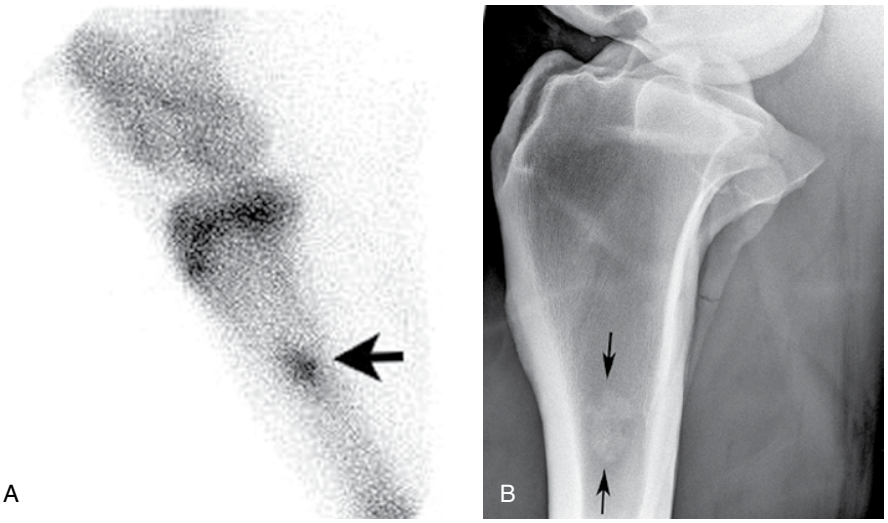

Figure 5.102. ELLs are typically recognized initially with scintigraphy (A) and appear as focal intramedullary areas of variable intensity IRUs (based on comparison of the lateral and caudal bone scan images). Lateral radiograph of the tibia of the horse in image A demonstrating typical ELL (B; arrows).

Tibial Stress Reaction

A stress fracture refers to a fracture that occurs in normal bone caused by repetitive stresses with resultant failure of the normal integrity of cortical bone. Stress fractures are a well-recognized cause of lameness in racehorses. Tibial stress fractures typically occur in young unraced but heavily trained Thoroughbreds but also occur in racing Quarter horses and Standardbreds.[19–22,24,25,28,31] The diagnosis usually involves a combination of radiology and scintigraphy. Eleven of 13 fractures were located in the tibial midshaft in Standardbreds[24] as compared with the proximal diaphysis in Thoroughbreds.[21,22,28,31] Stress fractures of the tibia occur predominantly in 2-year-old horses, while humeral stress fractures occur predominantly in 3-year-old horses and seem to occur more commonly in heavily trained animals. Horses with stress fractures of the tibia often have a history of sudden, severe hindlimb lameness that quickly resolves with stall rest. Recurrence is common often during the next strenuous exercise (speed work). This condition typically presents as a unilateral lameness with a shortened cranial phase of the stride and a stabbing hindlimb gait. Physical exam findings are often negative, but on rare occasions mild swelling and pain can be elicited by deep compression. Hindlimb flexion tests usually accentuate the lameness. Unfortunately, diagnostic analgesia is not practical except to eliminate the lower limb as a source of lameness.

Tibial stress fractures frequently involve the caudolateral cortex in the distal metaphysis or the caudal diaphysis (Figure 5.103). Proximal caudolateral fractures can occasionally be seen. Although a discrete fracture may be apparent as an oblique linear radiolucency on radiographs, more often radiographic confirmation is lacking. Oblique views may help demonstrate the presence of an endosteal and/or periosteal callus. Scintigraphic examination is a very sensitive tool to evaluate bone remodeling and is the diagnostic tool of choice. Scintigraphic findings consistent with stress remodeling are marked focal caudolateral diaphyseal or metaphyseal uptake.

Horses with tibial stress fractures should be removed from training and allowed to rest until the fracture is fully healed. In general this requires 4–6 months of rest with the horse returning to training based on follow-up examinations including either radiographic or scintigraphic examination. There is a definite risk of the tibial fracture propagating if training and racing activity is continued. Spiral fractures can develop commencing proximally in the lateral cortex and extending distally to the craniomedial cortex. Location of the IRU either within the cortex (stress fracture) or the medullary cavity (EELs) of the tibia can provide important information about the correct management of these horses. More information and images illustrating tibial stress fractures can be found in the racehorse sections in Chapter 9.

FRACTURES OF THE TIBIA

Horses with complete tibial fractures usually present with acute, non-weight-bearing lameness with moderate swelling and significant angular deformity. These fractures are typically trauma related associated with management and during pasture turnout and are not performance-related injuries. They occur in all types of horses of all different ages. Diaphyseal and proximal physeal fractures usually manifest valgus deformity or angulation of the limb laterally distal to the fracture site. Radiography is necessary to confirm the diagnosis and allows the characterization of the bone injury. Despite recent advances in fracture treatment, comminuted fractures of the equine tibia are among the most difficult to repair successfully. The integrity of the skin and soft tissues can also negatively influence the outcome of the surgical repair of these fractures. Contraction of the craniolateral muscle mass overlying the tibia abducts the distal limb and forces the fracture fragments medially. The sharp ends of the fractured bone can be easily forced through the thin soft tissues of the medial aspect of the crus and penetrate the skin. Limb stabilization is critical as continued use of the unstable limb damages

VetBooks.ir

the fracture ends and fracture reduction and the ultimate stability of the construct/repair can become significantly compromised.

Optimal surgical candidates need intact skin to reduce the risk of infection of the fracture repair. In most fractures stabilization prior to shipping is critical to minimize further damage to the soft tissues and the bone at the fracture site.[3,5,7,9,32] Regrettably, tibial fractures are difficult to adequately stabilize because immobilization of the stifle (the joint proximal to the fracture) is impossible. Casts and splints simply add weight to the distal limb, causing further motion at the fracture site. A Robert-Jones bandage with a lateral splint attached to the bandage with nonelastic tape should be applied to the limb. The horse should be shipped facing forward in the trailer so that as the vehicle brakes, the increase in weight-bearing can be borne through the front limbs.

INCOMPLETE FRACTURES

Incomplete fractures of the tibia often present as an acute severe lameness.[15,16] The relative stability of the tibia and therefore the limb does however allow partial weight-bearing. Radiographs are necessary to confirm the presence of and configuration of the fracture (Figure 5.103B). A complete series including oblique projections are necessary to assess the severity of the fracture. Incomplete and nondisplaced complete fractures can be managed by conservative therapy, which involves cross-tying the horse in the stall. Providing significant pain relief should be adjusted to avoid overuse of the fractured limb. In general, horses with shorter visible fissure lines (3–7 cm) are more likely to survive than those with longer spiral fissure fractures (12–15 cm). Additionally, nondisplaced fractures on the caudal compression side of the tibia tend to become unstable (Figure 5.104).[10]

Figure 5.104. Lateral radiograph of a horse with a long spiral oblique tibial fracture that exits the caudal cortex and is likely to displace further if left untreated. *Source*: Courtesy of Dr. Gary Baxter.

VetBooks.ir

Incomplete fissure fractures of the distal metaphysis of the tibia may benefit from a cast. These can be applied in the sedated standing horse in a normal weight-bearing position. Stall rest is recommended until there is evidence of fracture healing. This usually requires a minimum of 3–4 months. Maintaining a cast on the hindlimb can be problematic and may require several cast applications/resets to keep the horse comfortable on the limb. During the last 30 days of confinement, once the cast has been removed, a program that incorporates a gradual increase in hand walking is recommended. In the best of circumstances, these fractures can heal without significant complications. However, propagation of the fracture is not uncommon. Careful daily monitoring to assess the comfort level of the horse may provide an indication about the integrity and stability of the fracture. Any trend toward increasing discomfort may indicate a compromise in the stability of the fracture and a need for surgical repair.

PROXIMAL PHYSEAL FRACTURES

The bones of young horses are more elastic than mature animals and are less likely to develop into severely comminuted fractures. Young horses have an increased risk to develop fractures through the epiphyseal growth plate (physis). Physeal fractures are called Salter–Harris (SH) fractures and are further classified based on the relative involvement of the physis, metaphysis, and epiphysis.[3,12,13,33] The young horse that develops a tibial fracture will most commonly develop an SH type II through the proximal epiphyseal growth plate. A type II SH fracture involves the growth plate and a component of the metaphysis (Figure 5.105). Fracture separation begins at the medial aspect of the physis and propagates laterally through the zone of proliferating chondrocytes within the physis and breaks out into the lateral metaphysis. This is a consistent configuration of proximal tibial physeal fractures and implicates lateral to medial bending as the primary force responsible for the injury.

Blunt trauma to the lateral aspect of the stifle while the foal is weight bearing on the limb can create this type of physeal fracture. This injury can also occur when a recumbent foal attempts to stand while the uppermost limb is positioned under a stationary object or when the mare steps on the recumbent foal's uppermost hindlimb. There is usually marked soft tissue swelling on the medial aspect of the physis. These fractures can be relatively straightforward to repair with a good prognosis for healing but not necessarily for soundness. Fracture repair is best achieved by reestablishing support on the medial aspect of the proximal tibia. Screw fixation, pinning, and plate fixation have all been described for treating these fractures either alone or in combination.[3,12,13,34,35] Medial plate application is currently the most common fixation technique utilized for repair and can be significantly improved by the placement of a tension band along the tibial crest. This neutralizes the distracting forces of the quadriceps muscle that is transmitted across the stifle joint to the tibial crest via the patella and the patellar ligaments' attachment to the tibial crest.

These fractures usually heal quickly and the prognosis is good. Rapid reestablishment of the vascular system to the physis occurs with the stabilization of the fracture and allows fracture healing to occur quickly, normally in 3–4 weeks. The amount of damage to the soft tissues, growth cartilage, and the stability of the repair are major factors that can significantly affect the outcome. The amount of damage to the growth cartilage depends on the time from injury to surgery and the adequacy of preoperative immobilization. The trauma that created the

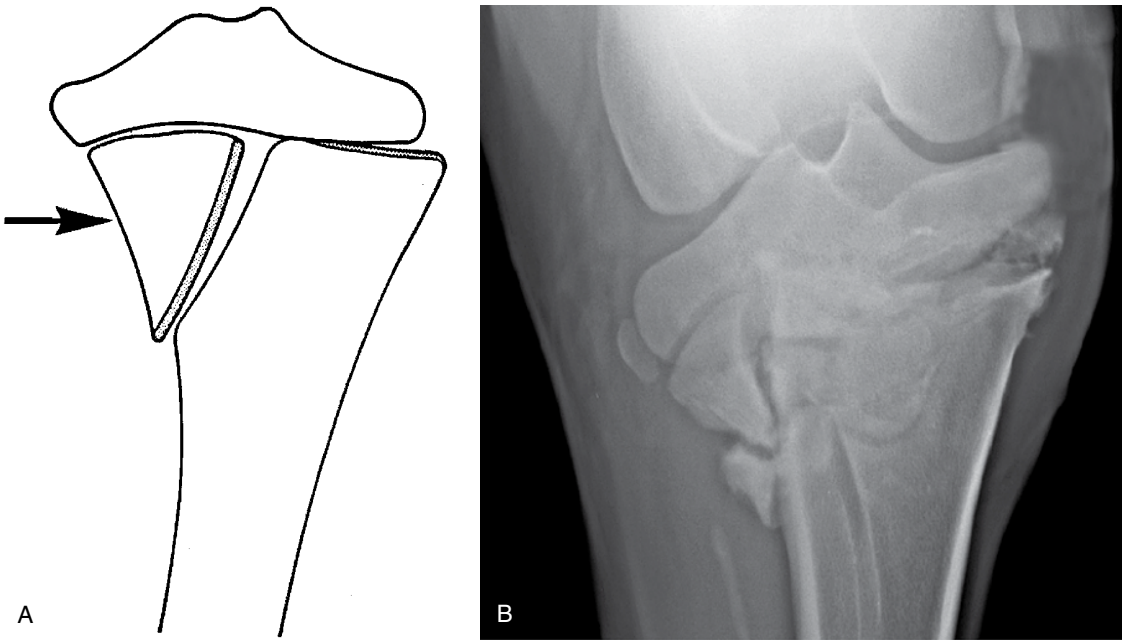

Figure 5.105. Line illustration (A) and caudocranial radiograph (B) of the stifle demonstrating a Salter–Harris type II fracture of the proximal tibial physis. The metaphyseal component is always lateral (arrow) and usually involves approximately one-third of the distance across the physis. *Source*: Courtesy of Dr. Gary Baxter.

VetBooks.ir

fracture often damages the physis leading to growth disturbances. The entire growth plate can close, which can lead to shortening of the tibia. Compensatory bone growth in the rest of the limb may counteract the shortening of the tibia. Implant removal may be considered to prevent or reduce the likelihood of premature physeal closure and limb shortening. This can be done in most instances at 8 weeks postoperatively. In general, the smaller the foal, the better the prognosis.

DIAPHYSEAL FRACTURES

Fractures of the diaphysis of the tibia are the second most common type of tibial fracture and occur in all ages of horses. Fracture type can range from simple oblique to highly comminuted.[3,6–9,13,15,16,26,29] Diaphyseal fractures are thought to occur when the tibia is loaded under considerable torque in combination with an excessive external force. Most diaphyseal fractures have a spiral configuration and many are severely comminuted. These fractures are characterized by sudden onset of non-weight-bearing lameness. Diaphyseal fractures are easily diagnosed but require radiographs to assess the fracture configuration. These fractures are often catastrophic injuries characterized by extensive comminution especially in mature horses. However, simple long oblique fractures of the mid-diaphysis do occur and are often repairable provided that they are not open. Because the tibia has very little muscle coverage on the medial aspect, fracture fragments often disrupt the skin and soft tissues (Figure 5.101). Attempts at repair of open tibial fractures are seldom practical because of the very poor prognosis. However, diaphyseal fractures in foals tend to be simple oblique or spiral in configuration and closed, making foals much better candidates for surgical repair (Figure 5.106).

The Thomas splint has been utilized but has rarely been successful as a treatment for tibial fractures in some foals. It consists of an aluminum frame with a ring that fits over the thigh and into the groin of the horse with cranial and caudal extensions reaching the foot to apply traction to the limb. Traction is applied with 1-in. white tape attached to the distal limb and pulled to the lower bar of the splint to stabilize the entire limb. Long-term management of fractures of the tibia in this manner can become quite expensive, and these splints are often difficult and tedious to apply.

Surgical repair is compromised when the location of the fracture is in the distal diaphyseal or metaphyseal location, which frequently precludes adequate implant purchase in the distal fragment. Because of the reciprocal apparatus, traction on the distal limb does not help reduce a diaphyseal tibial fracture—in fact, it causes overriding—hanging the limb in tension is not helpful. Placing the injured tibia down with the horse in lateral recumbency impedes surgical manipulation of the diaphyseal fracture and necessitates a medial surgical approach, which is not ideal because of the lack of soft tissue coverage. A cranial approach with the horse positioned in dorsal recumbency with minimal traction on the limb is the recommended approach for surgical repair. One or two bone plates are usually required depending on the fracture configuration and the size of the horse.

Figure 5.106. Lateromedial radiograph of a tibial fracture in a foal at the time of repair using a single plate placed on the cranial aspect of the tibia. The single screw was used to compress the fracture line. Note the solid caudal buttress on the caudal aspect of the tibia. *Source*: Courtesy of Dr. NA White.

TIBIAL TUBEROSITY FRACTURES

The large cranial eminence of the proximal aspect of the cranial tibia is called the tibial tuberosity. This tuberosity has a prominent groove that serves as the site for attachment of the middle patellar ligament and is flanked by rough areas for attachment of the medial and lateral patellar ligaments.[14] The cranial border of the proximal tibia distal to the groove for the middle patellar ligament is referred to as the tibial crest. The tibial tuberosity is a supplementary center of ossification that is completely ossified between 36 and 42 months of age.[14] The three patellar ligaments also serve as the site of insertion for the quadriceps femoris muscle group onto the tibial tuberosity.

Fractures of the tibial tuberosity occur infrequently.[2,4,11,17,18,27,36] They often present with severe non-weight-bearing lameness. It is not unusual to have a wound or abrasion on the cranial aspect of the stifle/tibia from the traumatic event. When they occur, it is often in mature sport horses that have sustained a direct impact of the stifle on a fence or jump.[11] Tibial tuberosity fractures may also occur due to a direct kick to the stifle area. Swelling of the cranial aspect of the stifle region can be

VetBooks.ir

diffuse and crepitus is often palpable over the tibial crest (Figure 5.107). These fractures can be articular or nonarticular with the fragment frequently being displaced proximally. Synovial effusion often accompanies fractures with articular components, but the effusion may be difficult to delineate from the overall swelling. A complete radiographic study of the stifle is necessary to accurately define the fracture. The oblique orientation of the tibial crest requires an oblique Cd35″L-CrMO radiographic view as the most useful in visualizing the fracture line and determining the fracture configuration.

The most common fracture of the tibial tuberosity is a nondisplaced nonarticular fracture. These fractures can heal satisfactorily with conservative management in the form of stall confinement and cross-tying. Careful radiographic monitoring is critical to assess fracture fragment displacement and to monitor healing. Most nondisplaced fractures with adequate stability are successfully managed and do not require internal fixation.[2] Stall confinement for a period of 60 days with serial radiographs to confirm appropriate healing is used to determine when exercise can begin. Smaller fracture fragments that are associated with wounds may require surgical removal (Figure 5.108).

Fractures that displace frequently displace proximocranially. Displaced fractures of the tibial tuberosity may be candidates for surgical repair. Stabilization should employ some form of a tension band applied cranially (Figure 5.109). The implants should stabilize the fracture while accurately reconstructing the joint surface. Most often this is in the form of a plate with the plate oriented obliquely along the tibial crest. The screws should be directed mediad and laterad in an alternating pattern to avoid aligning them in a straight line, which may predispose the underlying bone to fracture. Fractures of the tibial tuberosity have a reasonably good chance for successful repair.

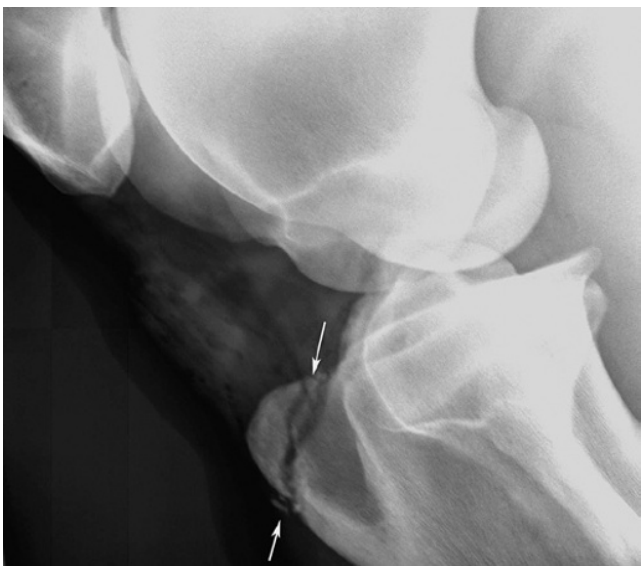

Figure 5.107. Fractures of the tibial tuberosity most often occur in mature sport horses usually due to a direct impact of the stifle on a fence or jump. Some nondisplaced fragments (arrows) may heal with stall confinement.

GASTROCNEMIUS DISRUPTION IN FOALS AND ADULTS

Disruption of the gastrocnemius muscle can cause dysfunction of the reciprocal apparatus. Gastrocnemius muscle injury is rare but can be a source of lameness in the

Figure 5.108. This small chronic fracture of the lateral tibial tuberosity (arrow) was removed because it was contributing to chronic drainage and lameness. *Source*: Courtesy of Dr. Gary Baxter.

VetBooks.ir

adult or the neonate. In the foal injury is usually severe and can cause recumbency and an inability to stand (Figure 10.60). Disruption occurs when the tarsus is maintained in flexion and the stifle is subsequently extended. Foals are often reported to have been through difficult births, many of which had a "hip lock" dystocia.[30]

Clinically, gastrocnemius disruption is demonstrated by hyperflexion of the tarsus when standing. The muscular injury usually occurs at the musculotendinous junction. The femoral vein, artery, and associated branches traverse the caudal aspect of the crus in close association to the gastrocnemius muscle. Disruption of these vascular structures can occur along with the muscular damage and can significantly affect the prognosis. Ultrasound can be a very useful tool to confirm the muscular damage and associated hematoma formation. Foals with moderate to severe gastrocnemius disruption are thought to have a guarded prognosis for future athletic function.[30] External coaptation can be required in some cases in the form of sleeve casts or splints. Gastrocnemius disruption in foals usually has a favorable prognosis for athletic function. This injury in foals is also discussed in Chapter 10.

Injury of the gastrocnemius muscle, often to the origin of the muscle, is an unusual case of lameness in adult horses. Forceful extension of the hindlimb may cause injury to the gastrocnemius muscle. Affected horses may have a gait abnormality characterized by lateral rotation of the point of the calcaneus and medial rotation of the toe. Nuclear scintigraphy is critical in the diagnosis and may demonstrate a focal area of intense radioisotope uptake in the caudodistal aspect of the femur in horses with injury to the origin of the gastrocnemius muscle. Roughening of the caudodistal cortex of the femur may be apparent radiographically in chronic injuries. However, radiographic imaging of this area can be difficult due to the thickness of the overlying soft tissues. A lateral radiographic of the femur (not the stifle) is necessary to reveal proliferative changes in this location. This condition can occur in mature animals but carries a poor prognosis for return to soundness. Horses with partial disruption of the gastrocnemius have a chance to return to athletic function. An extended period of rest followed by a gradual return to exercise can be successful in returning the horse to soundness. The amount of time required should be sufficient to allow the muscle to repair adequately. Some form of stabilization of the affected limb may be required. The decision to use external coaptation is based on the degree of caudal reciprocal apparatus dysfunction and the systemic status of the horse.

THE STIFLE: FEMOROPATELLAR REGION

Gary M. Baxter and Ken E. Sullins

INTRODUCTION

The stifle is the largest and most complex joint in the horse, and not surprisingly injury to the stifle is an important cause of hindlimb lameness. The stifle consists of three synovial compartments (the femoropatellar [FP] joint, the medial femorotibial [MFT] joint, the lateral femorotibial [LFT] joint), three individual patellar ligaments, medial and lateral collateral ligaments, and a complex array of intrasynovial ligaments and menisci that are necessary to support the function of the joints. The reader is referred to Chapter 1 for more detailed anatomy of the stifle region.

Historically, stifle problems in horses have been reported to represent between 2% and 8% of horses presenting for lameness.[4,99] In one series of 553 horses with hindlimb lameness, 326 of 795 stifles that were radiographed had visible abnormalities.[87] Femoropatellar and femorotibial lesions occurred at similar rates of 27% and 32%, respectively, and there was an overall incidence of 32% with evidence of osteoarthritis (OA). In general, clinical problems involve the FP and MFT joints more commonly than the LFT joint in athletic horses. Regardless of the type of horse, stifle problems appear to be quite common in routine referral practice and may increase as more advanced imaging capabilities continue to improve our abilities to make specific diagnoses.[7,60,67]

Clinical Findings and Diagnostics

The evaluation of stifle lameness is made by visual observation, palpation of the joints, gait evaluation, and elimination of other types of lameness. The examiner should become acquainted with normal palpation and normal variations; asymmetry within the stifle usually indicates a problem. Swelling may be impressive with acute injuries, especially with extracapsular swelling, which complicates the ability to make precise anatomic characterization. Acutely painful horses usually do not bear full weight by fixing the limb in extension when walking or standing. Bruising from external trauma is common from being kicked and in horses that jump over fixed fences. Local and systemic anti-inflammatory therapy may be required to reduce the swelling before a complete diagnosis can be made, although improvements in diagnostic imaging, namely, diagnostic ultrasound, can make characterization possible.[7,27,28]

Distension of the FP joint is better observed when viewing the horse from the side and may be obvious (Figure 5.110). On palpation, distension and thickening of the FP joint capsule may be detected between the patellar ligaments. The patellar ligaments provide useful landmarks for locating the three synovial joints of the stifle. Comparison with the opposite stifle should be made; both stifles can be palpated while standing behind most horses. Some normal horses, especially athletic horses, often retain mild femoropatellar effusion without a clinical problem being present. Femoropatellar effusion can be secondary to a problem in the MFT joint, but is often less severe than with primary FP joint involvement. Femoropatellar effusion may be simple fluid distension or there may be thickening of the periarticular soft tissues. Such thickening may be edema or consist of fibrosis from chronic inflammation. With chronic lameness, atrophy of the gluteal and quadriceps muscles on the affected side may be apparent. This may be obvious, or careful comparison from the rear and side may be necessary. Hindlimb flexion, either upper limb or full limb flexion, induces a painful response in most cases.

Stifle pain causes typical hindlimb lameness. Viewed from the side, the cranial phase of the stride is shortened, and the foot is carried closer to the ground. The toe may drag when the horse advances the limb at a trot, and toe wear may be obvious. When viewed from the rear at a trot, asymmetry in pelvic movement is often observed. The duration of gluteal rise is shorter, resulting in an early unweighting of the lame limb. This often results in a pelvic rise on the lame limb, which can often be seen best when viewed from the side (the reader is referred to Chapter 2 for more details on the lameness exam). The degree of lameness varies according to the severity of the injury. Stifle lameness usually cannot be definitively distinguished from hock pain or other sites of pain in the hindlimb. In some cases the horse may

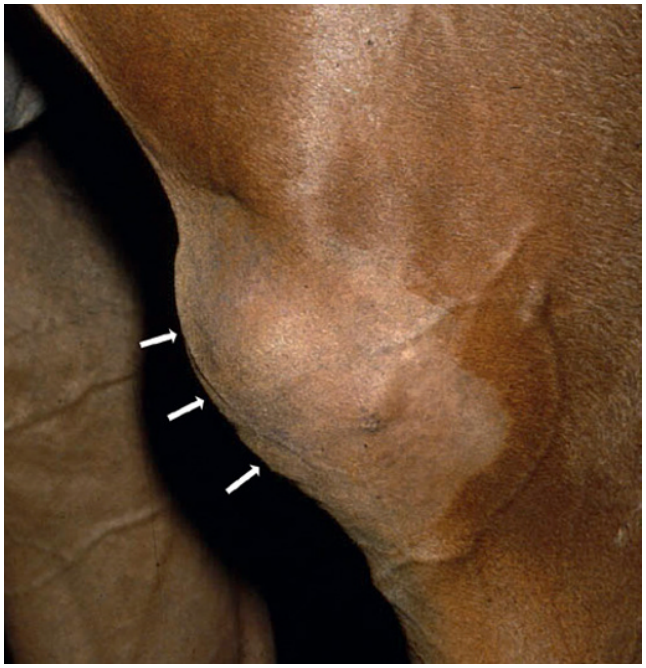

Figure 5.110. Lateral view of the stifle in a horse with severe femoropatellar effusion (arrows).

VetBooks.ir

demonstrate a subtle lameness under saddle or during specific movements.

Flexion of the hindlimb affects the digit, hock, stifle, and hip. Digital flexion is minimized if the limb is held loosely around the fetlock. However, the source of any increased pain following flexion must still be localized. The upper limb flexion (commonly referred to as the stifle flexion test) can provide the examiner with some assuredness that the region is involved if the horse reacts in a painful manner to flexion and the test exacerbates the lameness. See Chapter 2 for more information on flexion tests. However, the stifle flexion test is not specific for the stifle.

Lameness can be localized to the stifle with intrasynovial anesthesia if necessary. In some cases in which physical examination shows strong indications of stifle disease, diagnostic imaging may be performed prior to intrasynovial anesthesia in order to prevent fluid or air artifact from interfering with image quality. The number and sequence of blocking is dependent on the signalment of the horse, clinical findings, and clinician preference. For instance, a western performance horse with effusion of the MFT joint would warrant blocking the MFT joint alone. A horse with lameness that you are trying to rule out the stifle as the location of lameness may warrant blocking all three joints simultaneously. Without effusion, the MFT joint is the logical starting point if each joint is to be blocked separately, because the FP joint will usually have effusion if there is a problem, and the LFT joint is not the site of a problem as often. In spite of the frequent FP–MFT joint communication, communication between the FP joint and LFT joint is rare.[81] However, the FP joint in horses with OA occasionally communicates with both femorotibial joints.[81] None of the femorotibial joints usually communicate with their counterpart. However, pathologic changes within the LFT joint can be blocked with an MFT block, and both joints should be investigated with diagnostic imaging or surgery when needed.

A complete series of good-quality radiographs is the initial imaging tool to evaluate the stifle joints in most cases.[7] Digital radiography has made it possible to obtain very good films in the field.[10] Routine survey views include caudocranial (CaCr) and lateromedial (LM) views. The 30° lateral craniomedial oblique separates the lateral from the medial trochlear ridge, if that is needed.[35] The articular surface and sagittal integrity of the patella are demonstrated best by a flexed craniproximal to craniodistal tangential (skyline) view.[23,30,83] Some horses may have radiographically inapparent lesions or more extensive bony involvement than radiographs demonstrate.[19,67]

Ultrasonography is extremely helpful for evaluating the femoropatellar and femorotibial regions. The character of the articular surfaces, menisci and subchondral bone,[11,22,78] joint capsule,[67] synovial fluid,[60,79] patellar and intra-articular ligaments,[78] and periarticular tissues can be viewed with ultrasound.[22,67,79,80] However, the articular surface of the patella is not readily accessible.[7,67]

The benefit of scintigraphy for diagnosis of stifle lameness is variable. Some have reported it beneficial for lesions in the stifle region,[67,71] whereas others have questioned its ability to diagnose osteochondrosis (OC) or subchondral cystic lesions due to the lack of increased vascularity or increased bone remodeling required to sequester the radiopharmaceutical.[92] Normal horses have patterns of uptake highlighting the patella and caudoproximal tibia that should not be mistaken for pathologic change, especially in young athletic horses.[31]

Studies of both CT and magnetic resonance imaging (MRI) to image the stifle of horses have been reported although infrequently, since specially designed units are required to image the stifle (Figure 5.111). MRI provides the most anatomic detail available for imaging the equine stifle,[20,46,73,88] and CT can accurately image the trochlear ridges, condyles, and proximal tibia.[96] Of most value of using CT was the detail that it provided in the caudal portions of the femorotibial joints and within the intercondylar fossa.[72,96] When combined with contrast,

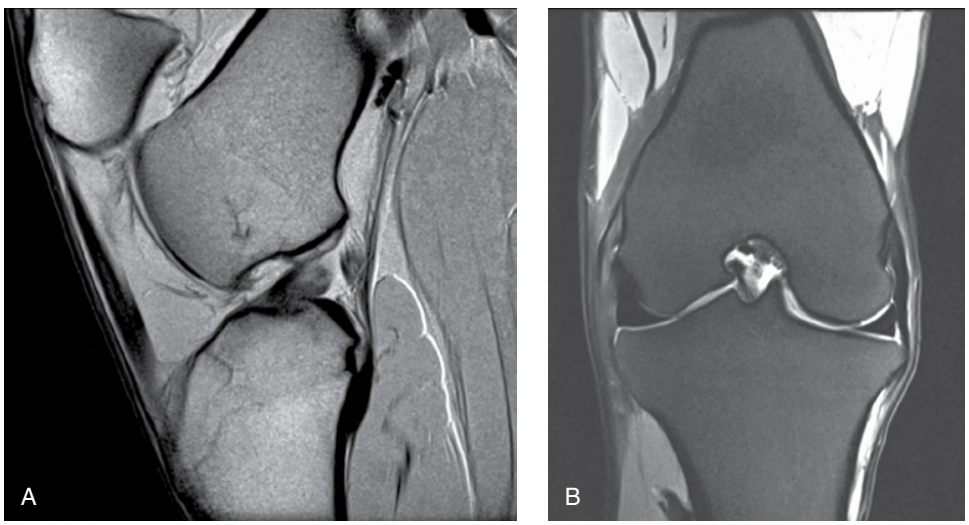

Figure 5.111. Sagittal T1 (A) and cranial to caudal PD fat saturation (B) MR images of a normal stifle joint illustrating the anatomic detail that can be obtained. Specially designed wide-bore units are required to perform MRI of the stifle in horses. *Source*: Courtesy of Dr. Kurt Selberg.

VetBooks.ir

CT offers more potential to image intra-articular soft tissues within the stifle than other techniques currently available.[9,72] The reader is referred to Chapter 3 for more information on the capabilities of CT and MRI.

Arthroscopy remains both a diagnostic and treatment tool for all of the stifle joints. Multiple different techniques and approaches have been developed, and arthroscopy remains the standard for exploration and surgical treatment of all three stifle joints without significant risk of incisional complications.[65,76] Arthroscopy is the definitive diagnostic tool for problems isolated to the FP, MFT, or LFT joints that are inapparent with other types of imaging.[35,64,65,93] Needle arthroscopy in the standing horse has been advocated to improve characterization of lesions although treatment of lesions may be limited with this technique.[36]

FEMOROPATELLAR JOINT

Osteochondritis Dissecans (OCD)

Femoropatellar osteochondritis dissecans (OCD) is a very common cause of stifle lameness rivaled in occurrence only by that in the tarsocrural joint.[51,63] In one study, Thoroughbreds were the most commonly affected of a series of 161 horses having surgery.[34] Seventy-eight percent were 2 years old and younger (most were yearlings), twice as many males as females were affected, and they were typically the better individuals in the herd.[104] Femoropatellar OCD primarily affects the lateral trochlear ridge.[34,63,64] However, lesions may be located on the medial trochlear ridge, the trochlear groove, the articular surface of the patella, or in any combination.[34,65]

Clinical Signs

Femoropatellar OCD usually causes visible joint effusion (Figure 5.110) and variable hindlimb lameness. In some cases the lesions might be incidentally visualized prior to lameness in horses that are imaged for sale. The lesion is a cartilage or osteochondral defect with separation, producing synovitis. Subtle effusion can be compared to the contralateral stifle, but at least half of affected horses have bilateral lesions.[34,63] Synovial fluid analysis is usually unremarkable. Uncommonly, horses with stifle lesions may also be affected in other joints; a complete physical exam noting effusion in other joints is indicated.[34,65] Clinically silent OC lesions may be present in other joints, and survey radiographs may be of benefit to best set expectations for clients.

The lameness may be so mild that joint effusion is the only presenting complaint; however, hindlimb flexion is usually positive in horses with clinically significant OCD. Others may be extremely lame, and some youngsters may have difficulty rising from recumbency. Chronic hindlimb lameness in foals may cause secondary forelimb flexural deformities, which could be the actual presenting complaint in some horses. The severity of synovitis depends upon the lesion itself and the amount of inflammation caused by physical activity; the degree of synovitis was not always comparable to the size of lesions in one report.[11] Uncommonly, the lateral trochlear ridge defect can be so severe that the patella may luxate laterally. Conversely, previously immobile OCD fragments may separate, causing sudden clinical signs in athletes.[27]

The usual age at presentation varies from weanling to 2- to 3-year-olds in training; more than half of a series of 161 horses were 1 year of age or younger.[34] Training may be required to cause clinical signs; presumably the osteochondral defect becomes disrupted, causing synovitis. Horses presenting after training has begun generally have less severe lesions than weanlings or yearlings that present earlier, which is probably why the older group has an overall better outcome after surgery.[34,65] Some horses have radiographic evidence of OCD without clinical signs. The clinical significance of the lesion should be confirmed by intrasynovial analgesia, particularly among horses in active training or older horses with minimal femoropatellar effusion or radiographic change. Weanlings with femoropatellar OCD may present with joint effusion, lameness, and no radiographic changes.[19] Horses with OCD lesions that appear on radiographs but are not causing clinical signs at the time should be monitored, especially during early training, with the goal of considering treatment if they become clinically significant.

Diagnosis

LM radiographs usually demonstrate a flattened defect in the proximal portion of the lateral trochlear ridge of the femur where it articulates with the distal patella (Figure 5.112 and 10.48). Ossification within the defect is variable, and loose bodies may be present.[19,34,64] Less commonly, deeper ossification defects or subchondral cystic lesions may occur, or the defect may be so large that the patella is unstable (Figure 5.113).[19,64,65] Caudolateral to craniomedial oblique films may provide more information about the severity of lateral trochlear ridge defects, which may extend over the lateral side of the trochlear ridge. Patellar changes may be due to primary OCD or secondary to irritation from a severe lateral trochlear ridge lesion, but may not be discovered until surgery is performed. However, severe patellar lesions can be observed in the LM view and typically contribute to a worse prognosis (Figure 5.114).

In one study, radiographically normal areas contained lesions detectable only by arthroscopy in 40% of 72 FP joints,[93] and more than half had lesions worse than anticipated from the radiographs.[19,93] Young foals normally have irregular contours of the proximal trochlear ridges that should not be confused with OC (Figure 5.115).[1,44]

Ultrasound should be considered as an adjunct to radiographs as the trochlear surfaces of the distal femur are readily visualized using ultrasound.[7,11] In addition, the LM extent of defects and the trochlear groove can be imaged, whereas they may be obscured on radiographs. The sensitivity and specificity of detection of lateral trochlear ridge OCD is quite good.[11] The cartilage on the lateral trochlear ridge is reported to be thicker than that of the medial ridge.[79] Underscoring the value of exploratory arthroscopy, accuracy on the proximal medial trochlear ridge is not high for ultrasound or radiography.[11,67,93] Although numbers were low, lesions in the midportion of the medial trochlear ridge were better detected by ultrasound than radiography in one study.[11]

VetBooks.ir

In summary, a minority of horses with mild lateral trochlear ridge defects have no cartilage defect during surgery (Figure 5.116). Conversely, horses with more severe radiographic changes probably have cartilage defects at that location and possibly elsewhere in the same joint. When radiographic lesions are absent, lameness and synovial effusion often dictate the clinical significance of the OCD lesion.

Treatment

Surgical management is the mainstay of treatment for OC in young athletic horses.[76] Surgical debridement is also thought to produce better results than conservative therapy when clinical signs are present in adults.[63] However, in one study, some lesions detected up to 8 months of age were found to resolve over time,[24] and no worsening of the lesion occurred after 11 months of age. Stall confinement is recommended in very young horses with OCD lesions to protect the articular surface from disruption and to facilitate healing,[66] but surgery is indicated if the clinical signs persist after 1 year of age.[63,76]

Intra-articular and systemic anti-inflammatory therapy to minimize the chance of degenerative change and improve cartilage healing is advisable in young horses. Biologic therapies such as autogenous conditioned serum are recommended for intrarticular (IA) treatment, and polysulfated glycosaminoglycan is most often used for systemic treatment. Intra-articular corticosteroids are inadvisable where cartilage healing is needed,[15] and negative effects of steroids have been observed in immature equine joints.[39] The excess fluid can be drained at the time of treatment so that resolution of the synovitis can be monitored. In one study, half of 23 affected foals that were diagnosed early with OCD and treated with stall rest eventually raced.[66] Generally, the successfully treated horses tended to have less severe lesions.

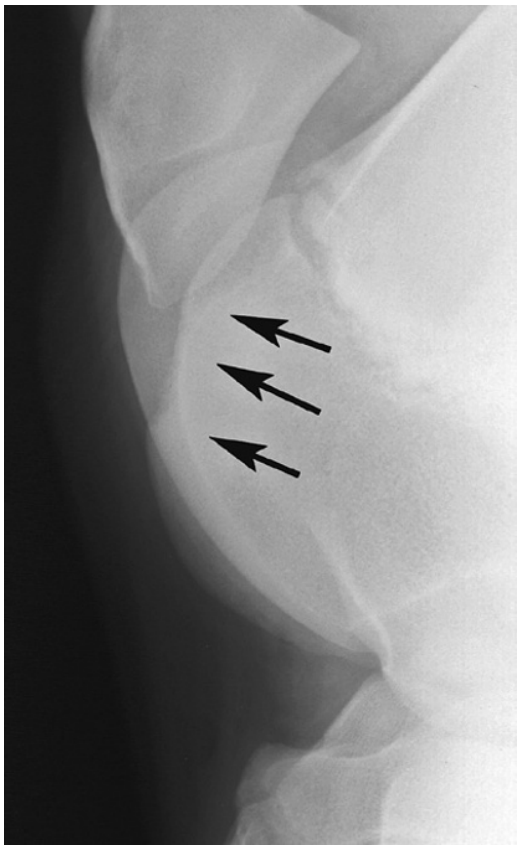

Figure 5.116. Lateromedial radiograph of a yearling with radiographic signs of lateral trochlear ridge OCD. Femoropatellar effusion was mild and arthroscopically the cartilage was slightly elevated but was intact. No debridement was performed, and as a 3-year-old, the horse was sound.

Sequential radiographs and clinical response to therapy are used to determine whether surgery is advisable. Surgery has been recommended for young horses with radiographic lesions greater than 2 cm in length or deeper than 5 mm or lesions with ossification in the defect and femoropatellar effusion.[63,65] However, the need to progress with the horse's conditioning schedule may dictate earlier surgical intervention, or preemptive removal is often requested by some owners and trainers in order to minimize the chances of the lesion affecting training and early competition.

Weanlings and short yearlings can present with effusion and lameness but no radiographic lesions.[9,66] Conservative therapy is indicated unless clinical signs persist. Subsequent radiographs may demonstrate healing or larger trochlear ridge ossification defects because the lesion has persisted while the surrounding trochlear ridge has ossified normally as the epiphysis has expanded.[19] Some believe that surgical lesions in foals and weanlings may progress, suggesting that surgery should be delayed until the lesion has fully developed.[19] This consideration will have passed after a period of conservative therapy. Medical therapy in cases without radiographic abnormalities can be diagnostic as well because a permanent response indicates that there is likely no articular surface lesion.

Arthroscopic surgery is indicated when it is obvious that the lesion will not heal with conservative therapy and in horses beyond a year of age with persistent clinical signs. The technique for arthroscopic debridement of femoropatellar OCD lesions has been well described,[63,65,68,76,101] and there are multiple different techniques and approaches.[65,68] The objective of surgery is to remove all loose osteochondral tissue and debride the lesion to leave healthy subchondral bone to fill with fibrocartilage and resolve the synovitis (Figure 10.49 in Chapter 10). A thorough evaluation of the joint is indicated as silent OCD lesions may be visible with the arthroscope that were not apparent on radiographs. It is also important to remove all the debris generated during the debridement process because it can contribute to continued synovitis.[48,68] Arthroscopic reattachment of OCD cartilage flaps has been reported in select horses but is not performed routinely.[90]

Prognosis

The prognosis for athletic activity following arthroscopic surgery for femoropatellar OCD is generally good. Of a series of 134 horses, only 16% were unsuccessful for reasons related to the OCD.[34] Slightly fewer were successful when OCD in other joints underwent surgery concurrently. Increased lesion size had a significantly negative effect upon outcome (Figure 5.117). A recent arthroscopic study also indicated that horses with larger OCD lesions had an increased risk of developing

VetBooks.ir

Figure 5.117. Horse with a very large OCD lesion of the lateral trochlear ridge seen at necropsy. Lesion size is thought to correlate with prognosis.

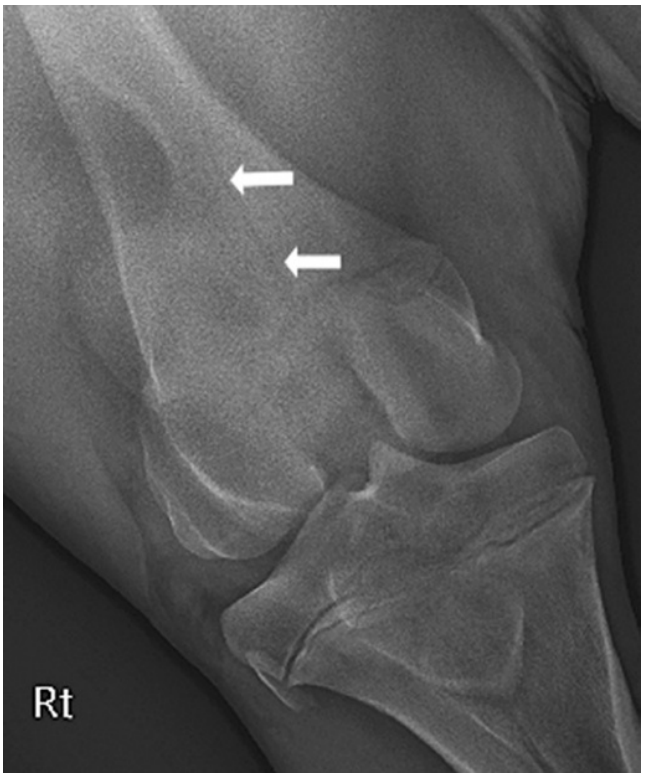

Figure 5.118. Craniocaudal radiograph demonstrating a suspected Salter–Harris type IV fracture of the medial aspect of the distal femur (arrows). This foal was lame at the walk and had significant FP and MFT joint effusion. The foal was managed conservatively.

surgical site infections, which corresponded to an increased risk of septic arthritis in the FP joint compared to other joints.[13] The overall success rate of 64% reported by Foland et al. was comparable to the starting rate of normal Thoroughbred horses in the same time period. Outcome is usually not correlated to sex, function of the horse, lesion location, uni- vs. bilateral involvement, or the presence of loose bodies.[34] However, a recent study of Warmblood stallions found that OCD lesions of the FP joint limited future performance of affected horses compared with OCD lesions at other locations.[100] Also, horses with concurrent patellar and large lateral trochlear ridge lesions tend to have a worse prognosis, and many surgeons recommend extended periods of inactivity after surgery in these horses to help minimize the development of OA (Figures 5.114 and 5.117).

Intra-articular Fractures: Femoral Trochlea

Etiology and Diagnosis

The cranial aspect of the FP joint is subject to direct blunt trauma, contributing to fractures of the trochlear ridges. Kick injuries to the stifle from other horses usually damage the patella instead of the trochlear ridges. Chip fractures have been reported in both trochlear ridges of the distal femur.[69] One horse sustained the injury by striking a jump (stone wall), and the other two occurred from punctures. Sepsis should be considered in these cases. Dyson has reported medial or lateral trochlear fragmentation in eventers after hitting jumps.[27] Separation of previously quiescent OCD fragments can also occur after direct trauma and should be considered in the differential diagnosis.[27]

SH type IV fractures of the distal femur in young horses that communicate with the FP joint can also occur from direct trauma.[103] Lameness is usually severe and femoropatellar effusion is obvious when the fracture enters the joint (Figure 5.118). The fracture may involve one or both trochlear ridges. The tangential view in addition to the CaCr and LM radiographic projections may be helpful to determine the fracture configuration.

Treatment and Prognosis

Fractures of the trochlear ridges are best removed using routine arthroscopic approaches regardless of the cause or if concurrent infection is present. Acute SH type IV fractures can generally be reduced, and fixation performed using internal fixation such as lag screws.[103] Nondisplaced fractures can also be managed conservatively. Although it may be possible to accomplish the fixation arthroscopically in some cases, the spatial orientation can be challenging. Depending upon the case, it

VetBooks.ir

may be more efficient to use the direct approach. The prognosis for these horses is usually reasonable for normal activity.

Intra-articular Fractures: Patella

Patellar fractures occur infrequently in horses, but several configurations including sagittal,[3,23,27,59] transverse,[47] comminuted,[77] basilar (proximal),[18,27,108] and distal fragmentation of the patella[62,84] have been described. Combinations of types of patellar fracture and associated fracture of the femur may also occur.[27]

Etiology

Direct trauma to the patella while the stifle joint is in a semiflexed position is commonly the cause. The patella is immobilized when the stifle is semiflexed, making it more susceptible to direct trauma.[21] Horses that jump can strike jumps and sustain bilateral patellar fractures,[59] or the fractures can occur as a result of a kick. Sudden lateral slips may cause a separation of the medial fibrocartilage.[23] The prominence of the medial trochlear ridge may be a point of contact, causing a relative higher incidence of fractures toward the medial side of the patella.

Some horses suffer fragmentation of the distal patella (FDP) when they return to work too soon after undergoing a medial patellar ligament desmotomy (MPD) and may be caused by direct trauma secondary to temporary patellar instability.[62,84] This condition is discussed in the next section.

Clinical Signs

Horses usually present with an acute onset of lameness and a significant painful swelling associated with the cranial aspect of the stifle. Femoropatellar effusion is usually profound, but significant soft tissue swelling may obscure palpation. Pain and sometimes crepitation may be found, and occasionally fragments may be palpable. Flexion of the stifle joint exacerbates the lameness and the painful response. Weight-bearing may be difficult with compromise of the quadriceps or from pain, so the horse may stand with the limb partially flexed without locking the stifle (Figure 5.119). Comminuted patellar fractures that compromise the middle patellar ligament and disrupt the reciprocal apparatus may cause an inability of the horse to support any weight on the limb. Clinical signs may diminish over a period of days to weeks of rest if smaller fragments do not affect the mechanics of the stifle.

Diagnosis

Radiographs are required to document the type and extent of the fracture. Routine LM and CaCr projections usually demonstrate transverse or comminuted fracture. The caudolateral to craniomedial oblique projection accentuates the apex (distal border) of the patella. Although swelling and pain may cause some resistance, flexed views are helpful or required to demonstrate some lesions. The flexed LM projection may accentuate some transverse fractures, and sagittal fractures, particularly the relatively common small medial fragments, require a cranioproximal to craniodistal (skyline) projection (Figure 5.120). Placing the plate proximal to the stifle with the beam traveling distoproximad separates the patella more completely from the trochlea, making it more visible.[23,77] Ultrasound is useful for identifying small fracture fragments, patellar ligament disruption, or lesions that may not be radiographically visible, such as medial fibrocartilage separation.[80]

Figure 5.119. Typical stance of a horse with a patella fracture. This horse had been kicked, and there was a wound over the cranial aspect of the stifle.

Treatment

Patellar fractures are often accompanied by severe soft tissue trauma involving the ligaments and joint capsule of the stifle joint.[28] Therefore, time and anti-inflammatory therapy may be required before treating the fracture. Nonarticular or small medial or basilar fragments may heal with rest and anti-inflammatory therapy.[27] Horses with relatively large incomplete apical fractures have become sound with extended confinement.[3,23] Some horses have returned to work with fibrous unions of the fracture.[23,77]

Horses with intra-articular fractures seldom remain sound when returned to work,[23,30,59] and stable fragments may displace when horses return to sustained work.[30] With adequate quadriceps stability, fragments approximating one-third of the patellar substance

VetBooks.ir

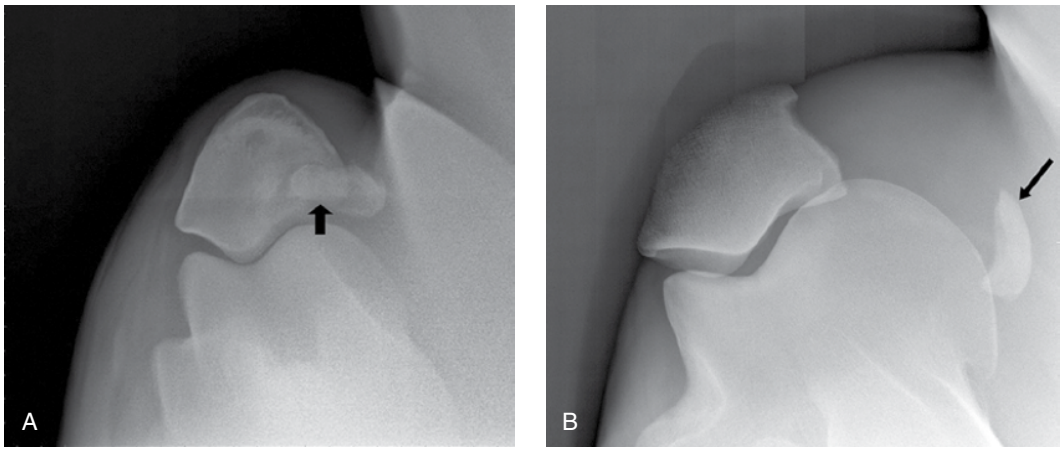

Figure 5.120. Cranioproximal to craniodistal (skyline) projections showing a typical medial patellar fracture fragment (A; arrow) and a large displaced sagittal fracture (B; arrow). Arthroscopic removal is indicated in (A). Arthroscopy was attempted in B, but an arthrotomy was necessary for removal.

can be successfully removed, and arthroscopy is recommended.[18,30,59]

Arthroscopy provides the best visualization of the fractures, facilitating complete removal of fracture fragments and exploration of the remainder of the joint without the risk of incisional complications of an open approach (Figure 5.121).[59] The fragment can be dissected from the patellar tendon with a large elevator or a motorized soft tissue resector. If the fragment is large, it can be divided with an osteotome or reduced with motorized equipment.[59]

Internal fixation should be considered for distracted or displaced fractures with sizable fragments. The patellar ligaments are the insertions of the quadriceps femoris and biceps femoris muscles. The goals of repair of larger articular fractures are integrity of the quadriceps mechanism and prevention of OA. Successful internal fixation of transverse distracted and longitudinally displaced fractures of the patella has been reported.[2,21,41,47,77] Transverse fractures require firm fixation because of the tendency of the proximal segment to become distracted by the pull of the quadriceps muscles,[21,47,77] although perfect anatomic reduction may not be required in every case. Tension band support is a good option for transverse patellar fractures.[47] Large extra-articular fractures can be removed, but it may not be necessary in all cases.[106]

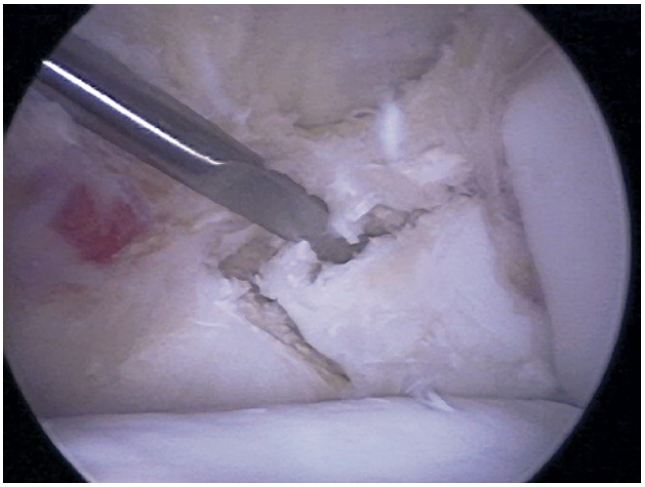

Figure 5.121. Arthroscopic view of a medial patellar fragment. The elevator is separating the patellar fragment from the soft tissue attachments.

Prognosis

The ultimate outcome depends upon retaining quadriceps function and adequate congruent articular surface; instability or persistent synovitis will result in OA. Following conservative or surgical therapy, lameness may persist for an undetermined period, while the synovitis resolves and any patellar ligament desmitis or enthesopathy heals.[23,59,79,80]

In a combined series of 19 horses from which articular medial fragments were removed, 16 returned to full work.[30,59] Failures occurred primarily because of preexisting OA, luxated patella during recovery from anesthesia, and one unexplained ensuing OA. These failures may point to the value of thorough preoperative ultrasonographic evaluation or more prolonged postoperative stall rest.

Internal fixation provides the most ideal set of circumstances for a favorable outcome for displaced and distracted fractures. Recovery from anesthesia may be the most critical point in the postoperative period. Horses with severely comminuted fractures are likely to remain lame. Some of these may attain breeding soundness with prolonged stall rest. However, if the quadriceps function is compromised or if severe OA develops, euthanasia should be considered.

Fragmentation of the Distal Patella

Etiology

FDP is an uncommon condition associated with previous medial patellar desmotomy (MPD),[40,62,84,91,102,108] and not all horses with this condition have undergone surgery.[62] Malalignment of the patella has been reported shortly after MPD,[8,90] and radiographically evident

VetBooks.ir

fragmentation was experimentally reproduced in 11 of 12 horses following MPD.[38] However, it is important to remember that fragmentation of the patella can occur from trauma or use-related injuries of the FP joint.

Clinical Signs

The clinical signs consist of variable uni- or bilateral hindlimb lameness and stiffness. FP joint effusion is common and palpable thickening of the joint capsule is often present, particularly in horses that have undergone an MPD.[62] Radiographic changes include bony fragmentation, spurring, subchondral roughening, and subchondral lysis of the distal aspect of the patella (Figure 5.122).[62,84,108] Cartilage fibrillation without radiographic abnormalities also has been reported.[38]

Treatment

Horses are usually best treated with arthroscopic surgery. The lesions observed at arthroscopy vary from flaking, fissuring, undermining, or fragmentation of the articular cartilage to fragmentation or lysis of the bone at the distal aspect of the patella. The subchondral bone is involved in most cases that had previous MPD. Fragments may be buried in the synovial membrane and tend to emanate from the more lateral portion of the distal patella.[62,102]

Prognosis

In one study, 8 of 12 horses that had a previous MPD became sound for their intended use after arthroscopic treatment of the FP joint.[62] In another study of horses undergoing MPD, 3 of 49 horses remained lame.[8] One of these horses had patellar fragmentation and did not become sound following arthroscopic debridement of the lesion. One additional horse with documented patellar fragmentation in that study was able to work with intra-articular medication. In most cases, the patellar misalignment was reported to correct within 5 months after MPD[84] and was not reported in horses 3 months after experimental MPD.[38]

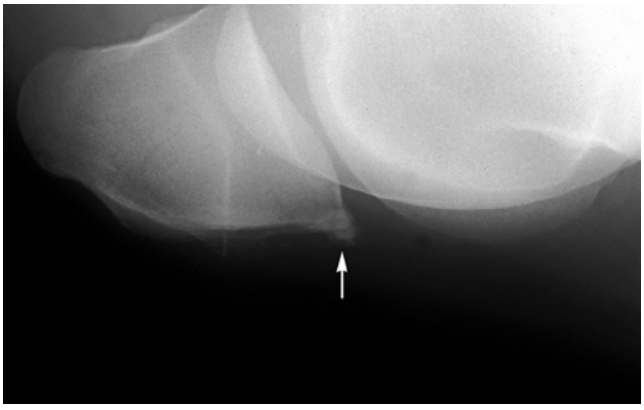

Figure 5.122. Flexed lateromedial radiograph of the stifle demonstrating fragmentation of the apex of the patella (arrow).

UPWARD FIXATION OF THE PATELLA (UFP)

Upward fixation of the patella (UFP) occurs when the medial patellar ligament (MPL) becomes caught over the medial trochlear ridge. In severe cases it becomes fixed in that position, the hindlimb cannot be flexed, and the horse assumes a posture with the affected limb extended in a caudally abducted position with the fetlock flexed due to the reciprocal apparatus (Figures 5.123 and 2.92). More commonly, intermittent UFP occurs, and a delayed release of the limb from extension is seen at a walk.

Etiology

UFP generally has been considered to occur in horses that have exceptionally straight hindlimbs; however, it can occur in horses with any conformation. Rooney considers most horses to have femorotibial angles approximating 135° and has stated that the problem occurs when the angle reaches 143°–145°.[86] Although the exact angle of occurrence likely varies among horses, it is reasonable to say that a straight-legged horse has a greater chance of reaching its individual point of injury. Furthermore, hyperextension of the limb exacerbated by walking a horse downhill causes the UFP to occur more frequently. Body type is strongly inherited; thus it is

Figure 5.123. The horse has upward fixation of the patella. The limb is locked in extension and extended caudally and slightly laterally. The digit is also fixed in the flexed position.

VetBooks.ir

likely that the tendency for UFP could be congenital. Shetland ponies are particularly affected, and UFP predisposes them to develop coxofemoral luxation.[17]

The condition also appears when the MPL becomes long enough to reach over the medial trochlear ridge in spite of normal conformation. Examples of this include loss of quadriceps muscle tone and traumatic hyperextension of the hindlimb. The ligaments may become stretched once upward fixation occurs, so recurrence is common. The MPL is thought to be weaker than the other two patellar ligaments, predisposing it to elongation.[89] Furthermore, younger horses, when they begin training, often lack the muscle tone they will acquire as they work. Upward fixation also has been observed in horses abruptly taken out of training and confined to a stall.

A recent report of 76 horses affected with UFP cites hoof balance and angle as predisposing factors, along with reduced muscle tone from seasonally reduced work.[26] Higher medial hoof wall and elongated toes were reported to cause hyperextension of the stifle and outward rotation of the limb, contributing to UFP. Corrective trimming and shoeing alleviated UFP in half of the horses and reduced the severity in an additional 20% of the horses (see "Treatment").

Clinical Signs and Diagnosis

In acute UFP, the hindlimb is locked in extension, as described above. The condition may relieve itself, or it may remain locked for several hours or even days. In other cases, there is only a "catching" of the patella as the horse walks. Hyperextending the stifle by walking down an incline may cause a jerking gait from intermittent catching of the MPL, and the horse may assume a crouched position, presumably to prevent stifle extension. Backing or moving in a tight circle also exacerbates the signs. When the MPL releases, the hindlimb usually jerks up quickly, mimicking stringhalt. Both hindlimbs usually are predisposed to the condition; however, truly unilateral cases often have a history of an inciting cause in the affected limb.

Palpation when the limb is locked in extension reveals tense patellar ligaments and that the patella is locked above the medial trochlear ridge of the femur. The horse drags the front of the hoof on the ground when it is forced to move forward with the limb locked. When the limb is in a normal position, the predisposition can be evaluated by forcing the patella upward and outward with the hand. If the limb can be manually locked in extension for one or more steps, it is predisposed to UFP; manual induction of UFP should not be possible in a normal horse.

Lameness usually is not severe or constant, but femoropatellar synovitis and distension may occur with repeated episodes. In some horses, UFP can be extremely difficult to manually reduce or correct by backing the horse. Coxofemoral strain may be associated with persistent UFP, and ponies are prone to secondary coxofemoral luxation.[17]

Radiographs of the stifle should be taken to eliminate conditions that predispose to UFP. Although uncommon, hypoplasia of the medial trochlear ridge, such as occurs with OCD, facilitates the displacement. Most affected horses do not develop radiographic abnormalities from intermittent UFP.[26]

Treatment

For a persistently fixed patella, a sideline may be applied to the affected limb so that as the limb is drawn forward, the patella is pushed medially to unhook the MPL, or downward, it often disengages the fixed patella. Backing the horse may also dislodge the patellar ligament. Personnel should take care to be out of the range of the "jerk" when the MPL releases. If the UFP cannot be reduced by manipulation, then a medial patellar ligament desmotomy is indicated.

Many horses respond to controlled conditioning to increase quadriceps strength and tone, which serves to tighten the MPL.[74] However, if the horse's fitness level drops below optimal, the UFP can recur. Obviously, rest or confinement is contraindicated. Conditioning, including going up hills without coming back down the incline, which exacerbates the hyperextension of the stifle, strengthens and tones the quadriceps.

Dumoulin et al. reported higher medial hoof walls and elongated toes along with reduced muscle tone from seasonally reduced work as predisposing factors in horses with UFP.[26] Shortening the toe and lowering the medial hoof wall sufficient to move break-over medial to the toe alleviated UFP in half of the horses and reduced the incidence in an additional 20%. Anecdotally, other farriers share this opinion.

Estrogen therapy has been used to treat intermittent UFP in horses.[29] The rationale is that estrogens can cause tendon and ligament relaxation, but it is unclear whether horses with upward fixation have overly tense patellar ligaments and if estrogen has any effect on patellar ligaments and tendons. It has been hypothesized that estrogen affects muscle cell metabolism and muscle tone leading to the anecdotal benefit sometimes reported. However, no studies currently exist examining whether this therapy is beneficial as a medical treatment. Recommended therapy is 1 mg of estradiol cypionate IM for every 45 kg of body weight (i.e. 11 mg/500 kg) once weekly for 3–5 weeks.[36] Concurrent anti-inflammatories along with exercise to strengthen the quadriceps muscles are usually recommended.

If conditioning and shoeing or medical therapy fail to halt the incidence of UFP, the MPL can be tightened with scar tissue by creating a series of longitudinal incisions in the MPL. This procedure can be performed using a scalpel blade or 14-gauge needle with the horse either standing or under anesthesia. The incisions are usually confined to the proximal third of the MPL.[49,82,97] This substantially thickens the MPL and presumably causes a functional shortening and tightening of the MPL.[82] In one study, UFP was eliminated in all seven reported cases.[97] A large advantage of this procedure compared with MPD is that the patella remains stable.

An older treatment that has been commonly used for horses with intermittent upward fixation and no palpable swelling of the FP joint capsule is the injection of counterirritants into the middle (MidPL) and MPL.[74] The injections are usually performed on the standing horse using mild sedation and nose twitch. Commonly used irritants contain 2% iodine; 1–2 mL is injected in

VetBooks.ir

six equally distributed sites along the MPL. The description includes a similar amount in the MidPL. Most horses exhibit a slight stiffness and swelling for a few days after the injections. Daily mild exercise is recommended, so there is minimal loss of muscle tone. While most horses respond well to this treatment, a few require re-treatment.

The commonly held opinion about the effectiveness of counterirritant injections into the MPL is that the ligament tightens, thereby mimicking increased tone from conditioning. In one histologic study the majority of the (severe) inflammatory reaction and all of the drug were found in the endotenon and peritenon.[12] The solutions appeared to follow the planes of least resistance. Within the dense collagen bundles, collagen fibers were disrupted without the same severe reaction, although there was fibrous tissue production and overall thickening. The mechanism of action, although still unproven, could be a reduction in the expansile ability of the fibrous MPL.

Ethanolamine oleate, a sclerosing agent, was compared with 2% iodine in almond oil for injection of MPL and MidPL in experimental horses.[98] Although both induced inflammation, 2% iodine in almond oil caused more thickening and a more significant inflammatory reaction, which would be expected to lead to more functional shortening of the ligaments. None of the horses were lame after the injections. A report of 70 horses treated with weekly homeopathic anti-inflammatory injections two to four times revealed an 82% success, with the remainder requiring surgery.[25] Possibly the number and frequency of injections may have contributed to local fibrosis.

When nothing else helps or the UFP cannot be reduced, an MPD can be performed using local anesthesia in the standing horse. Complications from that procedure should deem it the treatment of last resort.[38,50,62,84,91,102] The procedure is usually performed in the standing horse, although an alternative procedure performed with the horse under general anesthesia in dorsal recumbency has been described.[107] The ligament is usually isolated with hemostats and transected with a suitable blunt bistoury. The horse should be confined to a stall, with hand walking gradually increasing over a period of 90 days. A conservative conditioning program can then begin until regular work resumes.[102] Failure of MPD to correct the problem has been reported supposedly due to persistent tissue continuing to displace over the medial trochlear ridge.[26,45] Accidental transection of the middle patellar ligament produces a catastrophic result.[107]

As early as 1979, FDP following MPD was reported.[40] Gibson et al. observed articular cartilage fibrillation or fragmentation in all horses 3 months after MPD.[38] The patellar lesions were located distolaterally or centrally. There are also several other reports of distal patellar fibrillation, fragmentation, or subchondral lysis associated with varying degrees of lameness, femoropatellar synovitis, periarticular fibrosis, or enthesopathy at the origin or insertion of the MPL in horses having undergone MPD.[62,84,91,108]

A lateral shift in the patellar position[6] and increase in the patellofemoral angle[6,84] along with traction from the MidPL may explain the distal and lateral lesions that typically appear on the patella following MPD. Ultrasonographic evidence of MidPL desmitis was observed in experimental horses subjected to MPD and stall rested for 120 days, but no patellar fragmentation was detected.[61] Long-term MidPL desmitis and enthesopathy were discovered in a horse presented for purchase with obvious previous MPD and patellar fragmentation,[56] and 2 of 9 horses with patellar ligament desmopathy had MidPL desmitis associated with previous MPD.[30]

Although not in its original form, the MPL heals after MPD.[56] Most suggest that the risk of lameness and complications subsides after a suitable convalescence; therefore a minimum 90-day rest period has been recommended.[102] One experimental study that kept the horses stall confined for 120 days revealed positional change in the patella and MidPL enthesopathies, but neither lameness nor patellar fragmentation or femoropatellar synovitis was reported.[6]

Prognosis

The prognosis is good for horses that respond to a conditioning program and maintain that fitness level. After conditioning and ensuring correct shoeing, the logical progression is counterirritant injection, MPL splitting, and then medial patellar ligament desmotomy. The diagnosis should be confirmed before surgery is performed because more complications have appeared when MPD is performed on unaffected horses. A 90-day convalescence period following surgery is also recommended.

In one retrospective study, 46 of 49 diversely occupied horses undergoing uni- or bilateral MPD over a 10-year period by multiple surgeons became sound.[8] The authors theorized that the good results were because the surgery was only performed on horses that were actually suffering from UFP and that these horses had different stifle angles than normal horses that may prevent the development of complications. In another study of 15 horses and 6 ponies, no recurrence of UFP was observed in 19 of 21 horses following MPD.[70] However, postoperative radiographs revealed no abnormalities in the ponies but FDP was present in 4 horses and ossification at the tibial insertion of the MPL was seen in 8 horses.[70]

DESMITIS OF THE PATELLAR LIGAMENTS

Desmitis of patellar ligaments is an infrequently reported condition most often diagnosed in the MidPL (Figure 5.124).[30,79,80] Affected horses are usually athletes, mostly eventers, jumpers, or steeplechasers for which direct trauma from striking a jump is a risk factor.[27,30,79] Among event horses, the frequency of patellar ligament injuries followed only cruciate ligament and meniscal injuries in one report.[27] Many cases are diagnosed after a prolonged lameness with no recognized inciting incident.[28] Injuries to the MidPL combined with lateral patellar ligament (LPL) injury is thought to be most common followed by LPL desmitis alone and MidPL injury alone.[28] Desmitis of the LPL may accompany fracture of the tibial tuberosity.[79]

Clinical Signs and Diagnosis

Lameness is variable and usually exacerbated by stifle flexion.[28] The desmitis may not be evident upon physical

VetBooks.ir

The black arrows on the longitudinal view on the right outline the same areas at the same horizontal level as the image on the left. *Source*: Courtesy of Dr. Anne Desrochers.

examination, and palpable swelling or eliciting pain from a specific point may require partial flexion of the stifle.[28] More extensive lesions or ruptured patellar ligaments are usually easy to locate based on the horse's stance. Intra-articular or regional local analgesia produces equivocal diagnostic results.[28]

LPL injury was observed simultaneously with MidPL injury and less commonly alone.[28] In addition to direct trauma, MPL injury may accompany palpable patellar instability.[28] Middle patellar ligament lesions have been described as a linear lucency with fiber tearing or central hypoechoic regions similar to other desmopathies.[28,107] Some suspect that ultrasonographic abnormalities in patellar ligaments detected after injury bear more pathophysiologic significance than those reported following MPD. Proximal and distal enthesopathies may reflect bony disruption in addition to the soft tissue lesion,[79] but their role in lameness if the inciting inflammation subsides is unclear.[80,107]

The MPL is affected less commonly by primary desmitis. Similar trauma seems to cause avulsion fracture of the medial aspect of the patella instead of ligament injuries.[9] However primary MPL rupture can occur but usually heals quickly with stall confinement (Figure 5.125).

Figure 5.125. This horse developed a ruptured medial patellar ligament with an obvious palpable defect after hitting a jump. It healed completely and the horse became sound, although there were subtle radiographic changes on the distal patella.

Treatment

When the injury is confined to the soft tissue, therapy consists of rest and local and systemic anti-inflammatory therapy. Smaller enthesopathies or fragmentation also may be treated conservatively with stall rest and/or extracorporeal shockwave therapy. Injections of biologics, such as autogenous conditioned serum and platelet-rich plasma, into the affected ligament(s) may also be considered. Ultrasonographic monitoring of the healing process is advisable. Rest should be extended if MPL laxity has occurred to prevent distal patellar changes. Progressive rehabilitation exercises should also be considered to gradually strengthen hindlimb musculature and provide mobility.

Prognosis

In a series of nine patellar ligament injuries, no horses became completely sound for athletic performance, although working soundness was achieved in one.[28] These injuries may heal better with prolonged periods of restricted activity or with desmoplasty with or without regenerative medicine intervention. Pain control should be used cautiously with continued training due to the potential for patella instability leading to secondary OA.

PATELLAR LUXATION/SUBLUXATION

Although patellar subluxation and luxation have been well documented in the literature, they are still considered to be uncommon.[33,43,52,55,57,58] The condition is usually recognized shortly after birth, but may be delayed in acquired cases. Acquired patellar luxation also occurs in older horses but even less commonly than congenitally.[58] Lateral[14,33,37,55,58] medial,[5,42,75] distal, unilateral, and bilateral patella luxations have all been described. Lateral luxation is most common. Severity can range from a mild intermittent subluxation to a complete luxation that is difficult to manually replace.

Etiology

Hypoplasia of the trochlear ridges (primary bone deformity) and hypoplasia of the ligamentous support structures have been suggested as causes.[85,95] The MPL is not as large or substantial as the MidPL or LPL.

In ponies and miniature horses, lateral patellar luxation is considered heritable.[43] The lack of adequate trochlear groove and/or lateral trochlear ridge is major factor. Congenital trochlear inadequacy is not always bilateral, at least in the pony.[42] Lateral patellar luxation can also occur in association with defective development of the lateral trochlear ridge caused by OCD.[94] When the condition occurs in the mature horse, trauma is thought to be the cause. Partial tearing of the insertion of the quadriceps femoris muscles on the proximal patella has been cited as the cause for distal patellar luxation between the femoral trochlear.[95]

Clinical Signs and Diagnosis

Foals with bilateral lateral luxation may not be able to stand or may stand in a crouched position because the displaced patella causes the quadriceps muscle group to become a flexor rather than function as an extensor (Figure 5.126). Signs vary according to the frequency, position, and degree of displacement of the patella.

Figure 5.126. This foal has bilateral patellar luxation. The quadriceps muscles cannot extend the stifle without the pulley of the patella on the trochlea. *Source*: Courtesy of Dr. Cliff Honnas.

Periods of normal ambulation occur if the displacement is intermittent. On palpation, there are varying degrees of patellar displacement and joint capsule distension. The intermittent patellar subluxations are usually readily replaced, whereas complete patellar luxation can be difficult to replace.

Persistent lateral subluxation of the patella presents much like a horse with UFP.[52] The limb is held in extension, causing the patella to be placed caudolaterad. When the limb is advanced, an awkward swinging toe-dragging gait occurs. Because some of these animals have a fairly normal gait, the condition may be missed until serious degenerative changes within the joint occur.[58]

Radiographs should be taken to confirm the diagnosis and identify the amount of degenerative changes within the joint. The flexed cranioproximal to craniodistal tangential (skyline) view is particularly beneficial to assess the degree of displacement and the depth of the trochlea. In the neonate, the normal irregular borders of subchondral ossification in the proximal trochlea should not be confused with degenerative changes (Figure 5.115).

Treatment

In one reported case of bilateral congenital lateral patellar luxation in a miniature horse, the foal overcame the crouched stance and began to walk normally by 6 months of age, although the patellae remained luxated. Most are treated surgically to minimize permanent deformity of the soft tissues and the development of OA.

When a sufficient femoral trochlea is present, stabilization of the patella in the correct position by imbrication can be performed. Release of the opposite soft tissue, including the contralateral patellar ligament, is often required to reduce tension on the repair.[33,52,58,75]

Horses with hypoplasia of the lateral trochlear ridge resulting in an insufficient trochlear groove to stabilize the patella require reconstruction by sulcoplasty and/or tibial tuberosity transposition.[5,32,37,55] Significant misalignment of the patellar tendons also requires transposition of the tibial tuberosity.[5] When OCD is the cause of the hypoplastic trochlear ridge, the cartilage surface and underlying bone are usually insufficient to sustain correction.[94,95]

Prognosis

The outlook for soundness without surgical correction is poor,[58] although pasture soundness may be possible, at least in miniature horses. The outcome is better for horses undergoing stable correction before the soft tissues contract and OA develops. Although successful cases have been reported in horses, they are rare, and miniature horses and ponies have fewer athletic expectations. In general, it appears that horses have more difficulty recovering from the repair than ponies or miniature horses in most situations.

In one study, a miniature horse requiring medial release, sulcoplasty, and tibial transposition became sound for its intended use.[5] In another report, 4 miniature foals undergoing imbrication alone to stabilize bilateral lateral patellar luxations survived to be functional, although one experienced a recurrence of unilateral lateral luxation.[33] Three of five horses that were surgically treated by release

VetBooks.ir

of the LPL and imbrication of the medial joint capsule succumbed to wound dehiscence, infection, or failure of the repair.[58] Only one horse was sound in light work 1 year postoperatively. However, the same procedure was successful for stabilizing a congenital bilateral lateral patellar luxation in a 6-week-old Shetland pony.[37]

Two of 3 horses that underwent sulcoplasty and medial imbrication of the joint capsules to stabilize lateral patellar luxations became sound 2 years after surgery.[55] In another report, a newborn Shetland pony with medial patellar luxation underwent sulcoplasty and lateral imbrication and was sound 6 months postoperatively.[42] Early recognition and correction of the problem likely contributed to the success in this pony.

SYNOVIAL OSTEOCHONDROMA IN THE HINDLIMB

Osteochondroma is a uni- or bilateral benign mass associated with cartilage growth centers. It is discussed as a distinct entity in Chapter 7. Young horses generally present with the problem, but they can remain clinically silent for long periods of time; therefore, it may be seen in older horses.[54] In the hindlimb, osteochondroma has been reported in the femorotibial bursa on the proximal lateral tibia,[54] in the plantar distal tibia within the tarsocrural joint,[53] within the tarsal canal on the fibular tarsal bone,[105] and on the calcaneus.[16] However, they can also be associated with the FP joint (Figure 7.50).

Clinical Signs and Diagnosis

Synovial effusion with or without lameness is the usual presenting complaint. The location depends upon which synovial structure is affected. Often the mass can be palpated percutaneously and may be bilateral. Radiographs usually demonstrate a focal semi-ossified variably sized mass associated with a growth plate or ossification center. The presenting signs and radiographic findings are often sufficient to make a presumptive diagnosis. Biopsy is usually better performed as excision. The radiographic appearance usually indicates that trauma is unlikely.

Treatment and Prognosis

In spite of the likelihood of it being a benign lesion, complete excision should be accomplished if possible. If the horse is actively competing, palliation of the synovitis may be accomplished by local and/or IA anti-inflammatory therapy. Routine postoperative bandaging and exercise restriction are tailored to the affected site. Although intrasynovial therapy is worthy of consideration, the prognosis for horses following surgical excision is generally good. Each case is different, and the lesions are likely to occur in more unusual locations than have been reported in the past.

THE STIFLE: FEMOROTIBIAL JOINT REGION

Chris Kawcak

The medial femorotibial (MFT) and lateral femorotibial (LFT) joints are separate structures that usually lack physical communication except in cases of severe osteoarthritis (OA) and cruciate ligament damage and occasionally after arthroscopy in which the septum separating the two structures was perforated. The MFT joint usually communicates with the femoropatellar joint through a fenestration in the proximal aspect of the joint. This is important from the standpoint that disease in the MFT joint can manifest as femoropatellar joint effusion, sometimes leading to confusion about the true site of damage, since diagnostic anesthesia of one joint can influence the other. Consequently, heavy emphasis is placed on diagnostic imaging and sometimes arthroscopy to resolve the confusion.

Both MFT and LFT joints are each composed of a femoral condyle and tibial plateau and a meniscus between the two. A soft tissue septum separates the two compartments, which continues caudally to surround the cranial and caudal cruciate ligaments, making these structures extrasynovial in this location. The same is true for the medial and lateral collateral ligaments.

Horses with lameness originating from the femorotibial joints can vary in severity. Some cases are subtle enough to create a training issue without the presence of noticeable lameness, whereas others are severe enough to lead to non-weight-bearing lameness. In more severe and chronic cases, horses typically stand with the limb abducted, and there is usually noticeable atrophy of the hip and quadriceps musculature.

Whereas effusion in the LFT joint is difficult to palpate, effusion of the MFT joint is readily palpable, especially in the recess just cranial to the medial collateral ligament and proximal to the meniscus and tibial plateau (Figure 2.91) However, in more severe and chronic cases, significant soft tissue thickening can also occur in this area, often obscuring the ability to palpate effusion. This is referred to as a tibial buttress and is usually associated with advanced OA within the joint. The degree of effusion and swelling is usually graded as normal, mild, moderate, or severe, and any pain and thickening of the collateral ligament is noted.

There are no distinguishing characteristics to limb use in horses with stifle pain compared with those with pain at other sites in the hindlimb. All horses should be walked and trotted in a straight line. Subtle lameness is sometimes more noticeable in soft footing, especially when horses are jogged in a circle. Although most horses are more lame when the limb is on the inside of the circle, occasionally the lameness is worse when the limb is on the outside of the circle. Observing the horse under tack or in work can also improve characterization of the lameness.

Horses with stifle pain are typically responsive to full limb flexion. However, some information can be gained by attempting to isolate flexion to the stifle area. This is done by keeping the tarsal area as straight as possible and bringing the limb caudally from the tibia distally (Figure 2.108). A positive response to this flexion is not absolutely indicative of stifle pain, but it can give important information about the site of pain.

More severe cases of lameness attributable to the stifle are often obvious on clinical examination due to severe effusion, soft tissue swelling, pain on palpation, and severe response to flexion. However, diagnostic anesthesia is needed to confirm the site of pain in many horses. The approach to diagnostic anesthesia of the stifle can be complex. Intra-articular pain in one joint can be improved with anesthesia of the other joints, but the response is much better in the joint of pain.[57] Some clinicians block all three joints of the stifle at once to expedite the process, rather than starting with one joint and then blocking the other joints. Single-needle technique is preferred by the author.[22] Consequently, if all three joints are blocked at once, the clinician may need to further isolate the joints later to determine which ones contribute to the lameness.

Regardless of how stifle pain is confirmed in affected horses, accurate imaging of the joints is difficult. Improvements in radiography, ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) have helped to characterize the disease processes, but the lack of visualization during arthroscopic surgery and a minimal number of postmortem studies have prevented investigators from truly correlating imaging results to gross damage. Unlike other species, the femorotibial joints in the horse are closely packed, preventing arthroscopic visualization of most of the joints. Consequently, the ability to truly characterize and repair damage in many parts of the femorotibial joints is limited.

Diagnostic imaging has been well described in this text and others. Radiography has been most relied upon for characterization of bony changes in the joint, and the importance of proper positioning cannot be emphasized enough. There is recent evidence to show that joint space width can be accurately measured and followed with a properly performed caudoproximal to craniodistal oblique projection made at 10° from horizontal.[58] Diagnostic ultrasound is routinely used to assess lameness localized to the stifle and is helpful for characterizing meniscus and periarticular damage. However, it is limited compared to arthroscopic surgery for characterizing articular cartilage and cranial meniscal ligament damage.[1] Nuclear scintigraphy is moderately specific but insensitive for characterizing stifle lesions.[18] Computed tomography has demonstrated good correlation to radiography and ultrasound for detection of osteophytes in cadavers.[13] However, in a prospective clinical study, Nelson et al. demonstrated better characterization of cruciate disease, entheseal changes, and proximal tibial changes using CT and CT arthrography compared with

VetBooks.ir

other modalities.[38] MRI is the gold standard imaging modality for joint disease characterization in humans and is gaining some use in horses. High-field MRI has shown good correlation to soft tissue characteristics of the stifle.[11] In addition, low-field MRI has shown good correlation with gross and histologic findings[50] and has demonstrated usefulness for clinical cases.[35]

SUBCHONDRAL CYSTIC LESIONS (SCLS) OF THE STIFLE

This section focuses on the clinical signs, diagnosis, and treatment of subchondral cystic lesion (SCL) in the stifle. Although this occurs most commonly in the medial femoral condyle, it also can occur in the lateral femoral condyle and proximal tibia. See Chapter 10 for further discussion of SCLs as they relate to osteochondrosis and developmental orthopedic disease.

Etiology

Although SCLs are usually attributed to developmental orthopedic disease,[28,31] some clinicians strongly believe, and experimental evidence has shown, that it can also occur after trauma to the subchondral bone.[44,59] Ray et al.[44] have shown that creation of a lesion 3 mm deep and 5 mm in diameter into the subchondral bone created SCL in 5 of 6 horses. Furthermore, von Rechenberg et al.[45] showed that the lining of the cysts contains significant inflammatory mediators that may be responsible for enlargement and persistence of the cyst. The tissues from postmortem cystic material had significant osteoclastic function on bone. Therefore, regardless of the cause of cyst formation, persistent enlargement of some lesions may be due to a vicious cycle of inflammation.

Clinical Signs

Horses with SCL of the stifle can present in several different ways. Historically, many of these lesions are found on survey films of yearlings in which no lameness is present. They can also be found in any age horse in which no lameness is apparent. However, most horses with stifle SCLs present at or near the time that training begins when a mild to moderate degree of lameness is usually found. Effusion may or may not be present within the MFT and femoropatellar joints. When lameness is present, the horse is usually positive to upper limb flexion that is isolated to the stifle joint.

Horses with SCL in the stifle commonly improve 50% or more with intra-articular analgesia of the joints. It is important to evaluate these horses within 15 minutes of performing the intra-articular analgesia and after 30 minutes to get a full appreciation for the improvement in lameness. In older horses that have been in training and competition, it is particularly important to perform intra-articular analgesia to prove the significance of an SCL because if a horse has been working well with the presence of an SCL, other factors may be involved in the lameness. In some of these cases, in which the horse has an SCL but it is not the source of pain, the horse may have an intact subchondral bone plate.

Imaging and Diagnosis

Radiography

Radiography is standard for accurate diagnosis (Figure 5.127). In a grading scheme for SCLs developed by Howard et al., type 1 lesions are less than 10 mm in depth and typically dome shaped; type 2 lesions are greater than 10 mm in depth and either dome, conical, or spherical shaped; and type 3 lesions are flat or irregular bone surface.[25] Wallis et al. modified the grading scheme to include type 2A, which are more than 10 mm deep and have a lollipop or mushroom shape with a narrow cloaca and a round cystic lucency; type 2B lesions are more than 10 mm deep with a large dome shape extending down to a large articular surface defect; type 3 lesions are condylar flattening or small defects in the subchondral bone, usually noted in the contralateral limb to that of the clinically significant SCL; and type 4 lesions are those that have a lucency in the condyle with or without an articular defect but no radiographic evidence of a cloaca in the subchondral bone plate (Figure 5.127).[60]

A grading scheme for characterizing presale films in yearlings and 2-year-old Quarter horses has been developed that describes lesions in general.[5] In yearlings that do not show clinical signs, it is important to follow the progression of the lesions with radiographs over time to monitor the SCL, because some may resolve. Likewise, they should be monitored clinically because some may worsen and begin to induce lameness. It is not uncommon in older horses to see radiographic signs of OA such as periarticular osteophytes and joint space narrowing in addition to the cyst. It is also important to compare radiographs in both limbs because SCLs may be bilateral, especially if they are developmental in origin.

SCLs are not uncommon in the proximal tibia (Figure 5.128).[56] In horses younger than 2 years of age, tibial SCLs have been shown to occur in the cranial aspect of the lateral condyle of the tibia, and in horses older than 2 years, they commonly occur in the medial condyle of the tibia, either cranial or caudal. The author's colleagues have seen SCLs of both the medial femoral condyle and the tibia in a single horse. It is also typical in older horses to see OA changes concurrent with these lesions (Figure 5.128).

Nuclear Scintigraphy

The usefulness of nuclear scintigraphy in diagnosing SCL is questionable. It may be helpful for identifying the significance of SCL in the tibia,[56] but it has not been shown to demonstrate high specificity other than for identifying joint disease. Therefore, especially in older horses, it is difficult to rely on nuclear scintigraphy to determine the significance of an SCL because it cannot be used to discern an SCL from generalized joint disease, such as OA.

Ultrasonography

Ultrasonography helps to evaluate articular cartilage surface, joint effusion, debris, and changes that may occur in the meniscus and cruciate ligaments. SCLs

VetBooks.ir

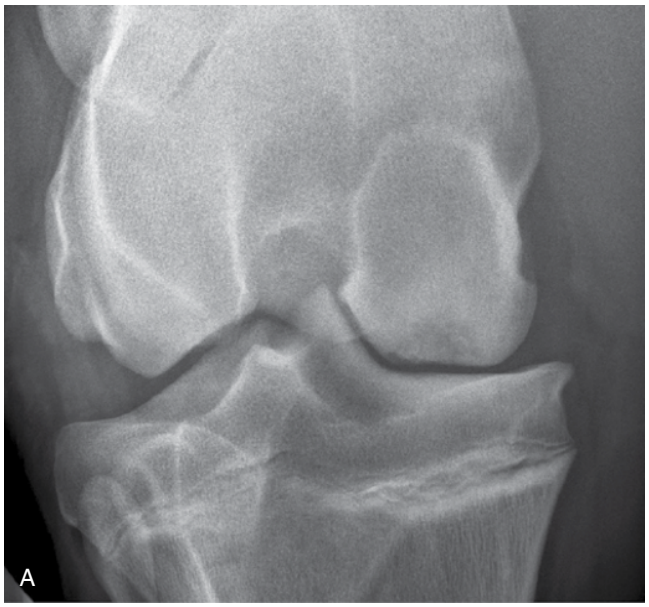

Figure 5.128. A caudal to cranial radiographic image of a proximal tibial subchondral cystic lesion with concurrent signs of osteoarthritis within the MFT joint.

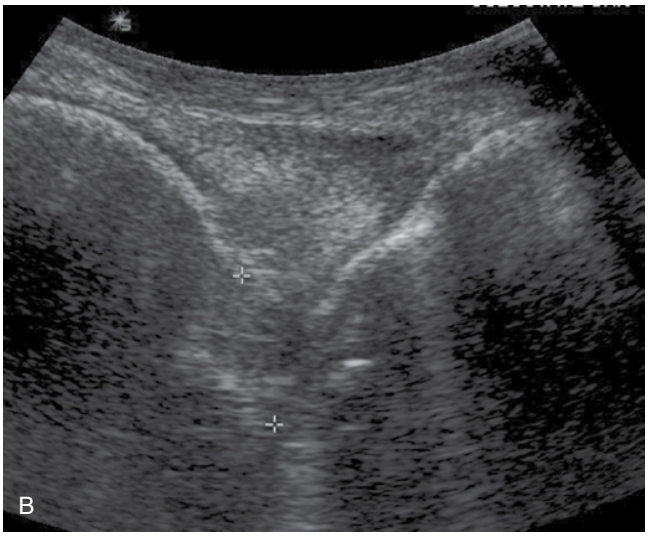

typically show an irregularity on the condylar surface and thickening of the articular cartilage (Figure 5.129). Because most cases of SCL are examined arthroscopically for treatment, the author does not routinely perform ultrasound of these cases unless there is concern about the integrity of the medial meniscus. However, if surgery is not an option at the owner's request, then ultrasound examination is recommended to obtain further information about the integrity of the surrounding articular cartilage and to later guide cyst injection. The femoral condyle becomes quite superficial beneath the skin when the limb is flexed, and the smooth, anechoic nature of the articular cartilage on the curved condyle can be easily appreciated superficial to the hyperechoic subchondral bone (Figure 5.129B). In cases of SCL, a defect is appreciated in the subchondral bone, the depths of which sometimes cannot be appreciated.[27] See Chapter 3 for further details on the use of ultrasonography to evaluate the MFT joint.

Treatment

Conservative therapy can be used in horses younger than 1 year old in which lameness may or may not be present. These horses may be treated with intra-articular medication if lameness is present. Corticosteroids in particular may have an effect on the cystic lining to prevent cyst enlargement, when physically injected into the cyst lining. Whether intra-articular administration of corticosteroids would have the same affect is unknown. Young horses with SCLs should be confined to a small

VetBooks.ir

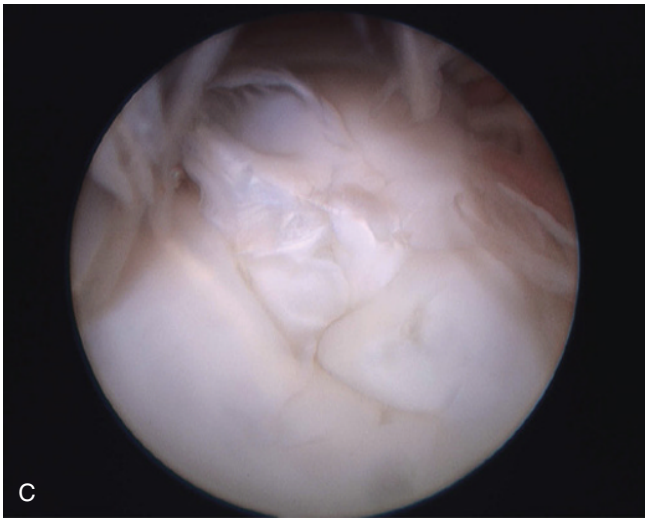

Figure 5.129. Radiograph (A), ultrasound (B), and intraoperative (C) images demonstrating an SCL that involved a large percentage of the articular surface. Note the joint space narrowing on the radiographic image (A) and the presence of the SCL as demonstrated by a defect in the subchondral bone on the ultrasonographic images (B). Thickening of the articular cartilage can be seen arthroscopically (C).

pen, and radiographs reevaluated every 4–6 weeks. If no change is present or if the cyst is enlarging, then surgical options should be considered. However, there are some horses of various ages that respond well to intra-articular and systemic medications and in some instances may be maintained for competition. Cases that respond to medical management have SCLs that are either small, have a small articular component, or may show limited communication between the cyst and the joint surface. The latter may demonstrate an intact subchondral bone plate. It is unknown whether the SCL is relatively stable in these cases, leading to adequate support of the articular surface. Rest has also been reported to be successful in treating some cases of SCL in the tibia[56].

Surgery is a common therapy for SCLs because horses that suffer lameness from this problem can rarely perform with the existence of the cyst.[31] Several methods of surgical treatment have been used with varying degrees of success, including debridement of the cyst contents, injection of the cystic lining with corticosteroids, grafting of the debrided cyst with various products, and transcystic screw placement.

Debridement of cystic contents has been shown to be effective in 56%–77% of cases that undergo surgery. In these cases, the joint is arthroscopically explored, and the contents of the cyst are removed. It is important to remove the lining of the SCL because it contains inflammatory mediators.[45] Some have advocated drilling of the subchondral bone to facilitate access of blood supply to the cyst; however, Howard et al. showed that in some of these cases, the drill holes lead to enlargement of the lesions.[25] Nevertheless, some advocate using microfracture on the cyst wall, especially when sclerosis is present. These horses are typically rested 6–12 months after surgery.

The prognosis generally is good for these lesions. Lewis has shown that 72% of horses had returned to intended use, although 14 of the 67 horses studied had occasional lameness that was managed medically.[29] Howard et al. showed that although 74% were successful,

VetBooks.ir

that the prognosis was relatively lower for Quarter horses compared with other breeds.[25] Sandler et al. showed that 77% of 150 Thoroughbreds intended for racing raced after debridement of the SCL. However, horses in which more than 15 mm of the surface of the joint was involved had a reduced prognosis compared with those with less than 15 mm.[49] Therefore, it appears that the depth of the cyst is of little importance in the prognosis but the percent of joint surface involved is important (Figure 5.129).

An osteochondritis dissecans (OCD) lesion may be present at the cyst opening and require debridement at the time of surgery.[25] Smith et al. showed that horses older than 3 years had a dramatically lower chance of soundness and return to work than horses 3 years and younger.[54] This study also confirmed that the presence of articular cartilage lesions within the MFT joint remote to the site of the SCL negatively impacted the prognosis. In addition to age and other articular lesions, SCL enlargement[25] and damage to the menisci and/or meniscal ligament can further reduce prognosis.

Some have advocated bone grafting to facilitate repair and filling in the bony defect. However, the prognosis is really no different than debridement.[26] Others have advocated the use of some form of bone graft (cancellous bone graft, tricalcium phosphate, or hydroxyapatite) with an overlay of fibrin, growth factors, and chondrocytes or stem cells to improve the prognosis.[19,33]

SCLs of the tibia that occur laterally can be approached with an arthroscope and are typically beneath the cranial ligament of the lateral meniscus. They too can be debrided. However, in some lesions, especially those involving the medial tibial condyle of older horses, an extra-articular approach may be required for debridement.[56]

Some surgeons advocate intralesional steroid therapy for treating SCLs. Based on the work of von Rechenberg et al., in which they showed the presence of inflammatory mediators within the cyst lining, this treatment makes sense.[45] However, it is important to inject corticosteroids into the cystic lining and not just into the depths of the cyst. Cyst injection is best facilitated by an arthroscopic approach[60] so that concurrent articular cartilage lesions can be debrided if necessary, and successful injection is often demonstrated by the extrusion of fibrinous material from the cyst. However, injection of the lesion can be done with ultrasound guidance of a needle into the cystic material. In the author's opinion, this technique is more difficult in assuring that the lining itself is actually being injected. Triamcinolone acetonide (10–30 mg/cyst) or methylprednisolone acetate (40–80 mg/cyst) or both are typically injected into the SCL. These horses are rested postoperatively and re-radiographed after 2 months, at which time clinical signs often improve and the horses can be put into light work.

Wallis et al. showed that this technique was successful in 67% of horses and 77% of cysts.[60] There was no significant influence of age, 90% of horses that had unilateral cysts were successful vs. 67% that were affected bilaterally, and the presence of osteophytes within the MFT joint reduced the success to 63% vs. 87% for those without.

The latest technique being advocated for treatment of SCL is placement of a screw across the cyst. In a retrospective study, Santschi et al. demonstrated that approximately 75% of horses responded successfully to the procedure.[51] Of note in this study is a reduced prognosis in horses older than 3 years, similar to other studies.

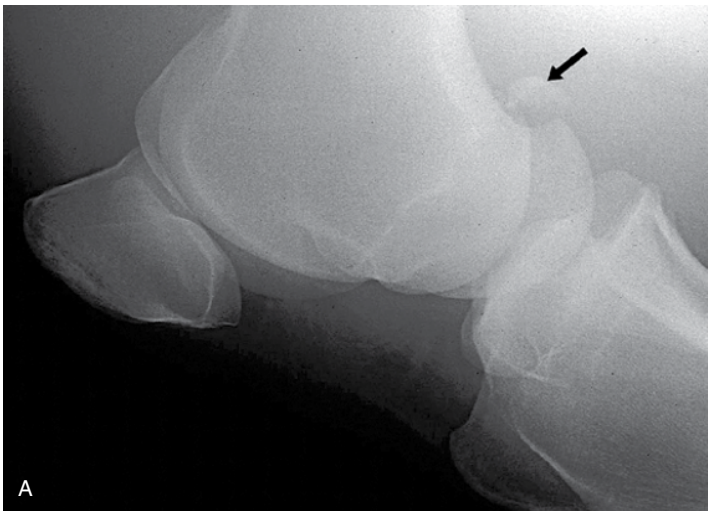
Prognosis

Overall, 56%–77% of horses returned to their intended use with surgery for SCL of the medial femoral condyle. A couple of studies have now demonstrated the reduced rate of return to work for horses over 3 years of age, regardless of treatment, and this should be taken into consideration when treatment options are given. The limited work in tibial cysts has shown that in horses younger than 2 years, 3 out of 4 returned to work. Older horses with tibial SCLs had reduced work. The prognosis was poor for those with lesions in the caudal aspect of the joint in which access was limited.

FRACTURES

Etiology

Intra-articular fractures of the stifle usually are due to acute trauma from internal forces as it is uncommon to see these problems in horses with outward signs of external trauma. They likely occur with rotation and may involve an avulsion fracture, usually of the intercondylar eminence of the tibia. However, the cruciate ligament insertion is typically lateral to the common site of fracture, and many fragments do not involve the ligament.[48,61] Intra-articular fractures of the femorotibial joints are rare, and horses with medial intercondylar eminence (MICET) fractures commonly have a history of acute lameness and traumatic event. It is hypothesized that fractures of the MICET are due to lateral movement of medial femoral condyle against the MICET.[61]



Clinical Signs

Horses typically present with significant acute lameness, often with significant synovial effusion and joint capsule swelling. They may or may not be painful on palpation, and they often show an outward rotation of the distal limb when standing. Horses are typically very painful to flexion, both passively and with movement. Horses with tibial tuberosity fractures can be painful on palpation of the area and are mentioned here because concurrent damage to the soft tissues of the femorotibial joints has been reported with this fracture.[2]

Diagnosis and Imaging

Radiographs typically demonstrate the presence of fractures. They can occur on the caudal aspect of the medial femoral condyle (Figure 5.130A),[10,21] caudal aspect of the medial tibial condyle, intercondylar eminence (Figure 5.130B and C),[37,61] Salter–Harris type III fracture of the lateral condyle,[20] Salter–Harris type IV fracture of the distal femoral physis,[20] or the origin of the long digital extensor muscle (Figure 5.131) or peroneus tertius muscle[6,24] and as loose fragments within the lateral femorotibial joint.[55]

VetBooks.ir

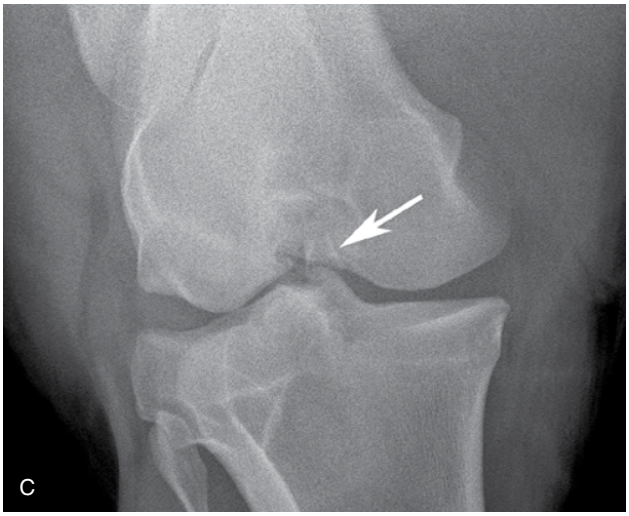


Figure 5.130. (A) Flexed lateral radiograph identifying a fracture of the caudal aspect of the medial femoral condyle (arrow). (B) A flexed lateromedial radiographic image that demonstrates fragmentation of the intercondylar eminence of the tibia (arrow). The fragment was attached to the cranial cruciate ligament, but was loose during arthroscopic examination. (C) A caudal to cranial radiograph demonstrating fragmentation of the intercondylar eminence of the tibia (arrow).

Peroneus tertius origin avulsion fractures usually induce flexion of the stifle with corresponding extension of the hock, and fragments are usually contained within the femoropatellar joint. Fragmentation of the origin of the long digital extensor muscle can induce lameness (Figure 5.131), although the author has seen these as incidental lesions on routine radiographs of yearlings. Fragments can be removed arthroscopically, and the prognosis is good. Radiographs can confirm the diagnosis, and ultrasound is sometimes useful in identifying the exact location of the fragment. Fragments originating from the MICET are thought to be avulsion fractures from the insertion of the cranial cruciate ligament; however, some fragments in this location do not involve the ligament insertion.[48] Walmsley demonstrated that the cranial cruciate ligament insertion was not involved in 7 of 12 horses with MICET fractures. Cranial ligament of MM can also be damaged. Ultrasound[48] examination is valuable in assessing prognosis, which can be worsened by significant secondary damage to soft tissues of the joints.[2]

Treatment

Small intra-articular fragments can be excised and removed arthroscopically in most cases. It is important to explore the entire joint, both front and back, because fragments and debris can migrate to the caudal aspect of the joint, and to determine if secondary damage to the soft tissues (such as the meniscus and the articular cartilage) is present. Proliferative lesions can be found in the intercondylar area of the tibia and femur, which can be debrided if they are clinically significant. Specifically, fibrous proliferation of the soft tissues can be present in chronic cases, as can bony proliferation that may impinge on soft tissue structures with movement. Large fragments in the MICET that have a stable fibrous adhesion often can be left intact. If the fragment is large and involves a large portion of the intercondylar eminence, then lag screw fixation can be used to stabilize the area.[61]

Fragment removal should be performed if there is no compromise to the weight-bearing aspect of the joint; however, internal fixation is recommended if the joint

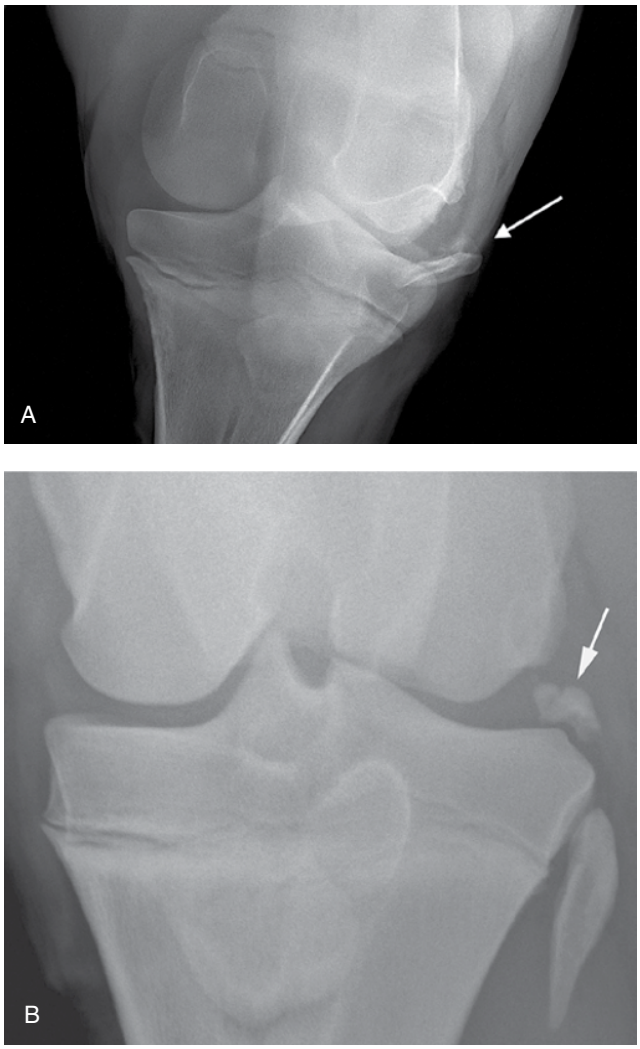

Figure 5.131. Caudal to cranial radiographic images of acute (A) and more chronic (B) fragmentation of the origin of the long digital extensor tendon (arrows).

surface needs to be reconstructed and/or vital attachments need to be retained.[61] For the condylar surface, a cannulated screw can be used to stabilize a fracture of the medial femoral condyle. Conservative therapy is sometimes best in horses with Salter–Harris fractures.[20]

Prognosis

Prognosis is often good for horses with fragmentation in which minimal soft tissue debridement occurs and minimal secondary damage is present.[48] For MICET fractures, 76% were sound after removal.[48] The prognosis is reduced for horses with larger fracture fragments involving more of the articular surfaces and for those with significant soft tissue and articular cartilage damage.[48]

FEMORAL CONDYLE LESIONS

Etiology

Femoral condyle lesions fall into two broad categories based on the age of the horse: septic or developmental

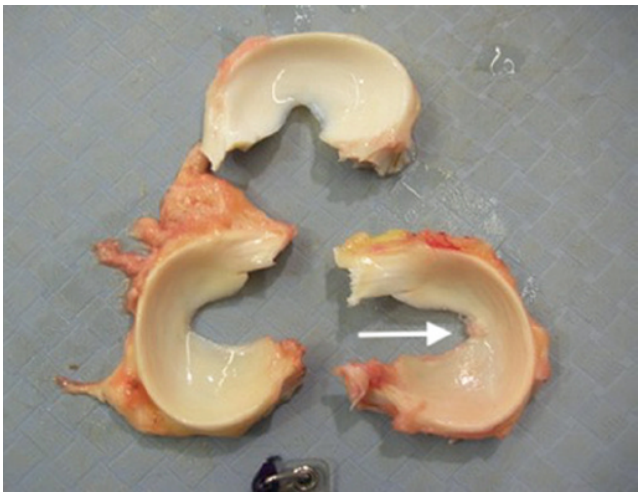

Figure 5.132. Menisci from a 5-year-old cutting horse that had chronic left medial femorotibial pain (Bottom) and a 9-year-old Warmblood with no history of femorotibial pain for comparison (Top). Both bottom menisci appear to lack substantial axial integrity, with the right meniscus showing axial damage and striation (arrow) compared with the normal top meniscus.

lesions in foals and osteochondral disease in adults. In foals, Hance et al. showed that three separate categories of femoral condyle lesions can occur.[21] Type I lesions are septic, and subchondral bone lysis is present in the face of septic arthritis and osteomyelitis. Type II lesions show osseous irregularity in less than 50% of the femoral condyle surface. Type III lesions show widespread irregularity and some have a thin osseous fragment. The authors of the study concluded that type II and III lesions may be some form of developmental orthopedic disease or vascular insult.

Osteochondral lesions of the femoral condyles in adult horses nearly always involve the medial femoral condyle. These lesions are usually considered to be traumatic in origin; however, there is growing concern that some of the lesions may be developmental in origin because abnormalities in condylar shape, such as dimpling or flattening, may predispose horses to this problem. However, a postmortem study showed no correlation of MFC flattening to OA,[13] and Barret et al. showed no correlation of flattening to performance in cutting horses at 3–4 years of age.[5] However, the effect of meniscal integrity on development of articular cartilage lesions is unknown, and considering how meniscal damage can affect prognosis for various lesions within the MFT joint and the findings in young horses on postmortem examinations (Figure 5.132), further work is needed.[14]

Clinical Signs and Diagnosis

Foals with type I and III lesions are typically severely lame, and those with type II lesions are usually moderately lame. However, all cause clinical signs that obviously point to a stifle problem. Radiographs typically reveal subchondral bone lucency indicative of the damage (Figure 5.133).

For nonseptic cases, medial femoral condyle osteochondral lesions are common in young western performance athletes; however, they can occur in any type of

VetBooks.ir

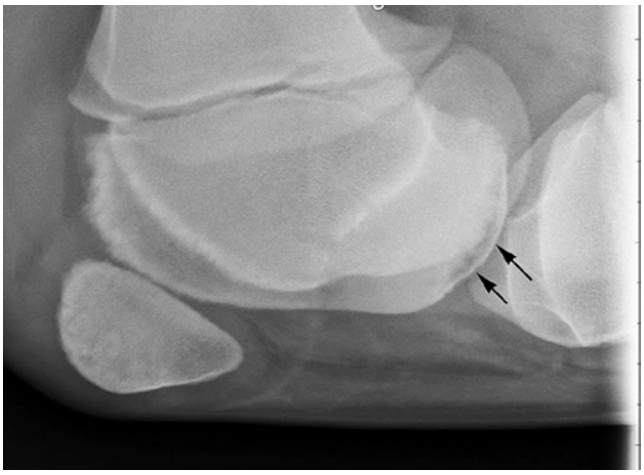

Figure 5.133. Subchondral lysis of the medial femoral condyle (arrows) was present on the lateromedial radiographic image of this foal's stifle. Arthroscopic examination revealed severe articular cartilage and subchondral bone degeneration.

horse. Adult horses with medial femoral condyle lesions may or may not have effusion, are usually positive to hindlimb flexion, and respond to intra-articular analgesia. Although these horses may not respond 100%, anything over 50% improvement is often considered significant.[29,52]

Radiographs are commonly unremarkable or only show mild OA changes in these horses. Flattening and sclerosis of the medial femoral condyle are subtle radiographic abnormalities that may suggest osteochondral lesions.[52] However, although flattening is a common finding, its clinical significance on performance is limited.[5] Ultrasound is essential to best characterize lesions, especially to the soft tissue structures such as menisci, meniscal ligaments, articular cartilage, and periarticular tissues. CT with and without contrast can be helpful to characterize lesions, and MRI is growing in use, allowing for visualization of most all tissues. Correlation of imaging findings to disease site, severity, and prognosis is contentious.

For horses with equivocal imaging results that block to the femorotibial joints, who may or may not have responded to medication, arthroscopic visualization can be beneficial to further characterize the lesions. A standing needle scope procedure has been reported and found useful for characterizing site and severity of lesions.[17] Therapeutic procedures are often limited with this approach, although it can be helpful in determining the need for further conservative versus surgical therapy.

Treatment

Arthroscopic surgery in foals should be preceded by obtaining a synovial fluid sample for culture and sensitivity. Debrided bone also may be submitted. Care should be taken during debridement because the normal subchondral bone of foals is soft and easily removed. Therefore, it is difficult to assess the extent of damage.

Arthroscopic findings in adults usually include focal or generalized articular cartilage lesions (Figure 5.134). Focal lesions are usually dimples, wrinkles, or folded pieces of articular cartilage that may or may not be detached from the subchondral bone.[52] Articular cartilage fibrillation, erosion, or subchondral bone lysis also can be involved.[9,29]

Walmsley has classified the types of articular cartilage lesions using human classification systems and in particular uses the Outerbridge classification for reporting. The Outerbridge system grades the lesions on a scale of 1–4: grade 1 includes softening and swelling of the articular cartilage, grade 2 includes partial-thickness defects with fissures on the surface that do not extend to the subchondral bone and/or do not exceed 1.5 cm in diameter, grade 3 includes fissuring to the subchondral bone and/or a lesion that exceeds 1.5 cm in diameter, and grade 4 includes those with exposed subchondral bone.

Schneider et al. reported that 6 of 7 horses with focal disease returned to intended use, whereas only 1 of 4 with generalized condylar damage recovered.[52] Lewis stated that only 6 of 20 horses returned to intended use.[29] Walmsley et al. found that in horses with Outerbridge grades 1 and 2, 78% returned to their intended use, compared with 63% of those with Outerbridge grades 3 and 4. In the study by Cohen et al., 60% of horses improved, of which 46% became sound and 37% returned to intended use. In general, however, the severity of articular cartilage lesions was an inconsistent indicator of prognosis (Figure 5.134).[9,30]

There is no consensus on how best to treat these cases. In horses with fibrillation, the fibrillated tags of tissue should be debrided. For those with partial-thickness cracks and erosions, only superficial debridement should be performed. Some surgeons have proposed using radiofrequency probes to shrink the involved areas of cartilage to cause them to recede and theoretically alleviate loading on the area. This procedure is untested, and in human medicine is contentious, because the radiofrequency procedure has been shown to cause chondrocyte death. Lesions with subchondral bone lysis can be lightly debrided. Some cases of full-thickness erosion have visible evidence of subchondral bone necrosis that require debridement. Some surgeons advocate the use of microfracture to augment healing; however, in the medial femoral condyle, this procedure could lead to the development of SCL. For the micropick procedure, care must be taken to remove all calcified cartilage as failure to do so can result in poor healing.[32] The use of mesenchymal stem cells along with the microfracture procedure has been found to be useful.[16,32]

It is currently unknown why medial femoral condyle lesions occur. Although some think that they may be developmental in nature, acute trauma and/or chronic repetitive trauma cannot be ruled out. There is also concern that flattening or dimpling of the subchondral bone may predispose these horses to this injury. Contino showed that these lesions are common in young Quarter horses,[5] but there has been no correlation in clinical studies.[5] Scott et al. found that horses with flattening or mild lysis are likely to have articular cartilage lesions that require debridement.[53] Of those horses, 7 of 9 with focal lesions were sound postsurgery compared with 2 of 6 with generalized lesions. Care must be taken, however, because overly aggressive debridement and microfracture may lead to secondary SCL formation.

VetBooks.ir

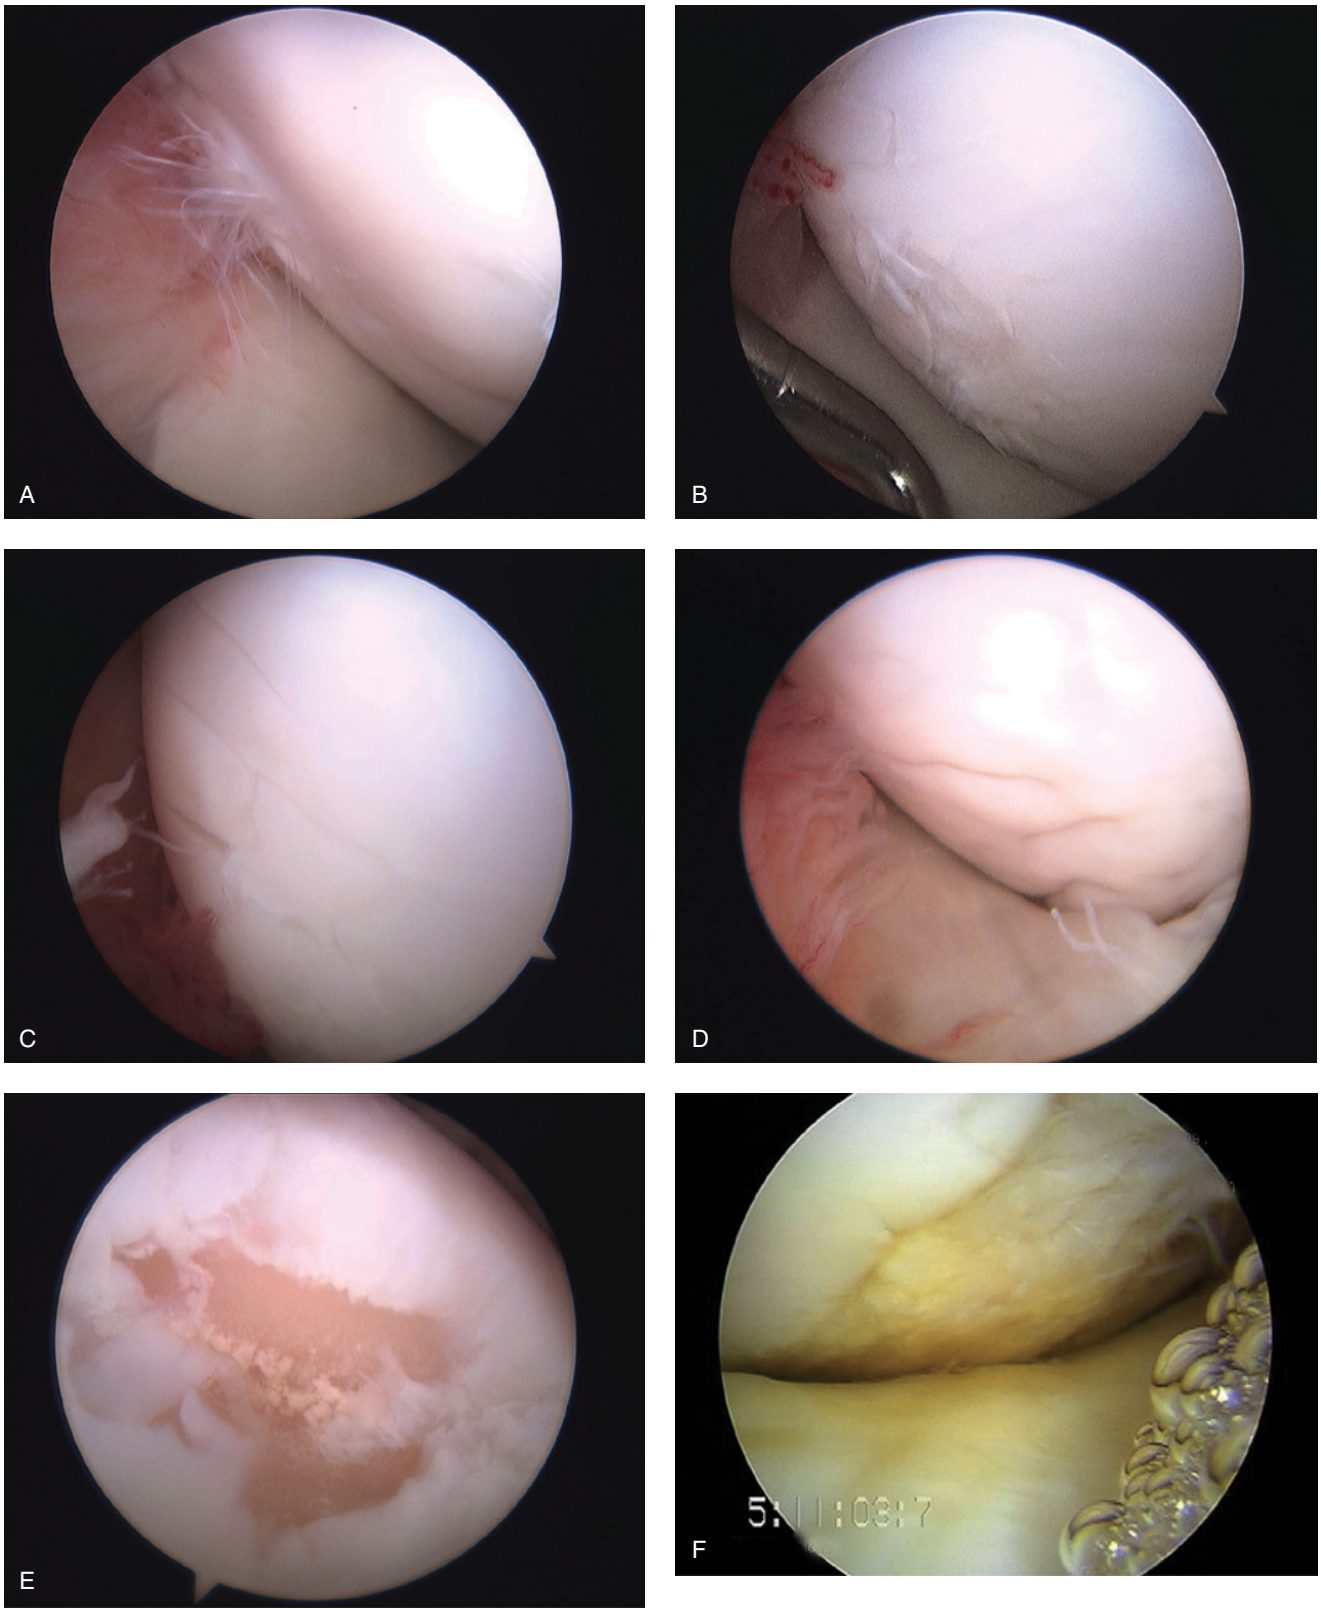

Figure 5.134. Various articular cartilage lesions that can be seen arthroscopically in adult horses. Small focal area of cartilage fibrillation (A) or partial-thickness cracking can be seen (B). More extensive cracking, some of them full thickness, can also be present (C). More extensive cracks can also contain soft, thickened articular cartilage in between the cracks (D), and in some cases, dead, necrotic subchondral bone can be present (E). In advanced cases of OA, extensive articular cartilage erosion can be seen as well as fibrocartilage healing (F).

VetBooks.ir

Prognosis

The prognosis for foals with type III lesions is guarded, even with surgical debridement; 11 of 20 horses in one study were euthanized due to poor prognosis.[21]

As noted under the treatment section, the prognosis for medial femoral condyle lesions in adults depends on the severity of articular cartilage and associated soft tissue damage and must be estimated on a case-by-case basis.

COLLATERAL LIGAMENT INJURY

Etiology

Collateral ligament injury primarily occurs to the medial collateral ligament in the femorotibial joint, usually in adults. It is not uncommon to see that other structures are involved, including the meniscus and the cranial cruciate ligament.[7] These injuries are usually acute in nature, although chronic low-grade damage to the ligament may be seen in cases of chronic intra-articular disease.

Clinical Signs

Clinical signs are usually acute and severe, but minor injuries cause more subtle signs. Often there is swelling in the medial collateral ligament area and pain on palpation. The horses are usually very positive to flexion and worsen after manipulating the limb into a valgus position. This involves placing pressure over the lateral aspect of the femorotibial joints with one hand and pulling the limb laterally to stress the medial collateral ligament. Horses with complete rupture may show significant lateral movement of the distal limb and a palpable widening of the MFT joint space on the medial aspect of the stifle.

Diagnosis

Radiographic findings often are normal; however, the MFT joint may distract on a stressed caudocranial view (Figure 5.135). Signs of OA, such as an enthesophyte, in the area of attachment in the medial collateral ligament are not uncommon in more chronic cases. Ultrasound is usually the primary method of diagnosis, which often shows fiber disorganization either in the body or the insertions of the ligament.

Treatment and Prognosis

Treatment is usually conservative in nature and may include rest, intra-articular medication, topical anti-inflammatory medication such as diclofenac acid, ESWT at both the body and the insertions of the ligament, or stem cell therapy into any hypoechoic region of the ligament. Surgical therapy has been advocated in some cases. The prognosis is often poor overall, except in horses with mild injuries to the ligament.

CRUCIATE LIGAMENT DISEASE

Etiology

Damage to the cranial cruciate ligament is usually acute in nature due to a traumatic event in which the limb is stressed in an abnormal direction, although the cause is rarely recognized. Other structures are usually involved, including the medial meniscus and the medial collateral ligament. Partial degeneration of the cranial cruciate ligament can occur in jumpers and racehorses. Horses with these lesions are less lame and tend to have a better prognosis with treatment.

Figure 5.135. Caudal to cranial radiographic image of a stifle with a ruptured medial collateral ligament. Notice the widened joint space medially on this stressed view.

The types of stresses that induce this problem are truly unknown. In an *ex vivo* study by Rich et al., in which mechanically induced tearing of the cranial cruciate ligament was assessed, 9 of 15 limbs failed in the ligament, 5 failed at the tibial insertion, and 2 failed at the femoral origin. This study suggested that there is no consistent change due to the type of injury that occurs.[46]

Clinical Signs

The degree of lameness is often associated with the degree of damage, and most horses present for an acute lameness, with significant effusion and response to flexion. However, in an attempt to mechanically assess the joint using the cranial drawer test, Prades et al. found that only 1 of 10 horses was deemed to be unstable in the standing position and 6 of the 10 were deemed to be unstable under anesthesia.[43] A tibial thrust test in the caudal direction may worsen the lameness in some horses, but this is not considered specific for cranial cruciate ligament damage.

VetBooks.ir

Diagnosis

Radiographs are usually unremarkable unless the origin of the ligament avulses from the intercondylar fossa,[15] a midbody tear shows dystrophic mineralization, or a medial tibial eminence fragment is present. However, the latter finding is not pathognomonic for cranial cruciate ligament damage because a fracture at the apex of the eminence often does not involve the ligament. Ultrasound gives variable results because the cranial cruciate ligament area is difficult to image; however, a small section of the cranial cruciate ligament insertion on the tibia can be visualized with the limb flexed. Contrast-enhanced CT has some merit if the ligament tear communicates with the joint.[38] MRI is available in limited locations and probably demonstrates the best chances of acquiring an accurate diagnosis. High-field, short-bore magnets can accommodate some horses for accurate imaging. Low-field scanners are gaining favor and have shown promise for accurate diagnosis.[35] Arthroscopic surgery can be used to explore the joint and assess the extent of damage and is currently the best method to accurately diagnosis cranial cruciate damage.[39,42]

Treatment

Osteochondral fragments from the tibial eminence can be removed and damaged tissues debrided arthroscopically. Microfracture may help stimulate endogenous repair of avulsed ligament from bone in the intercondylar space. Damaged tissue can be debrided, and although no repair technique has been successfully developed for the horse, partial tears can be augmented with platelet-rich plasma (PRP) or mesenchymal stem cells injected into the tissues or joint.[39] Other therapies to consider include intra-articular stem cell or IRAP therapy to use the growth factor properties that these two treatments are meant to induce. Overall, the prognosis depends on the extent of damage, but is often considered poor. However, some horses have returned to work.[29,39,43] Caudal cruciate ligament injuries have been reported, and most of them involve longitudinal fraying and not true ligament rupture.[3,8,36,41,47]

MENISCAL INJURIES

Etiology

Meniscal lesions can be acute or chronic. Acute damage can occur with a bad step or an accident that leads to shifting or shear forces between the femur and tibia. Lesions are often seen in other structures such as cruciate ligaments and articular cartilage. Horses of any breed and use are susceptible to these lesions. Degenerative lesions of meniscus are seen to associate positively with articular cartilage degeneration and osteophyte scores.[14] Pathogenesis is unknown. Both lateral and medial meniscal lesions occur, but damage to the medial meniscus is most common.[14]

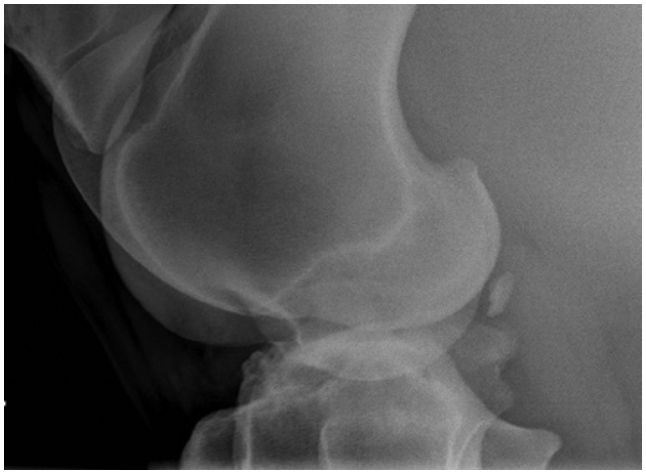
Clinical Signs

Meniscal injuries are acute or insidious in onset and usually affect the medial meniscus. Signs of medial meniscal injury can vary. In a study by Walmsley, 40% of cases presented acutely, and 53% were insidious in onset.[65] The median lameness grade was 3 out of 10, 66% were positive to upper limb flexion, 47% had MFT joint and/or femoropatellar effusion, and 93% responded to intra-articular analgesia.[65] However, meniscal injury can be secondary to chronic OA or SCLs, and signs can include capsule thickening of the MFT joint and disuse atrophy of the surrounding musculature.

Diagnosis and Imaging

Radiographs can be normal in acute cases of primary meniscal damage. However, damage to the meniscus may lead to joint space narrowing, so it is important that these images be reassessed because poor positioning can lead to false interpretation of the radiographs.[58] In addition, radiographic abnormalities often accompany meniscal tearing in more chronic cases, as has been shown in several studies[4,12,62] Mineralization of the meniscus (Figure 5.136) and osteophytes on the medial tibial plateau (Figure 5.137) and intercondylar eminence of the tibia are common in horses with more chronic lameness. In updated results from Walmsley,[64] 23% of horses with meniscal damage had new bone formation at the medial intercondylar eminence of the tibia, and this was associated with cranial cruciate injury in only 7% of cases.[34]

Ultrasonographic findings can include characterization of an abnormal size, thickness, variability in echogenicity, location of the meniscus, prolapse of the meniscus medially, and overt meniscal tearing.[4,8,12,23] It is important when assessing for a tear that the area is imaged in both weight-bearing and non-weight-bearing stances (Figures 5.138 and 5.139). Non-weight-bearing imaging often causes opening of the meniscal tear for better demonstration of the defect. For acute severe injuries, the cranial cruciate ligament and medial collateral ligament may also be involved, but it is not uncommon to see isolated meniscal injuries. Despite its widespread use to diagnose meniscal lesions, it is difficult to validate



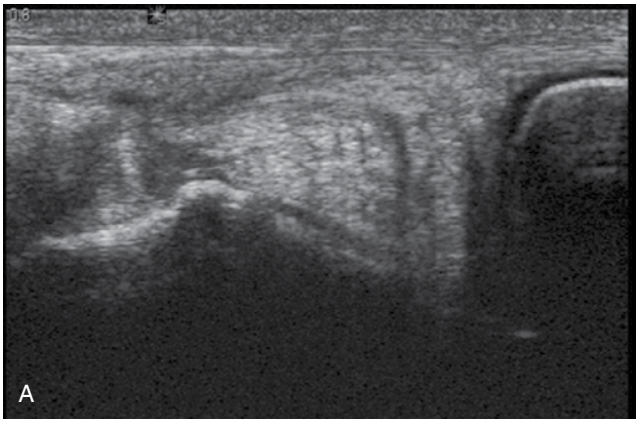


Figure 5.136. A lateromedial radiographic image demonstrating mineralization of the caudal aspect of the meniscus. Arthroscopic removal of this mineralization is rarely indicated because the OA is often advanced.

VetBooks.ir

Figure 5.137. A caudal to cranial radiographic image showing osteophytes on the medial aspect of the tibia and the intercondylar eminence, which are common in many types of diseases involving the femorotibial joints.

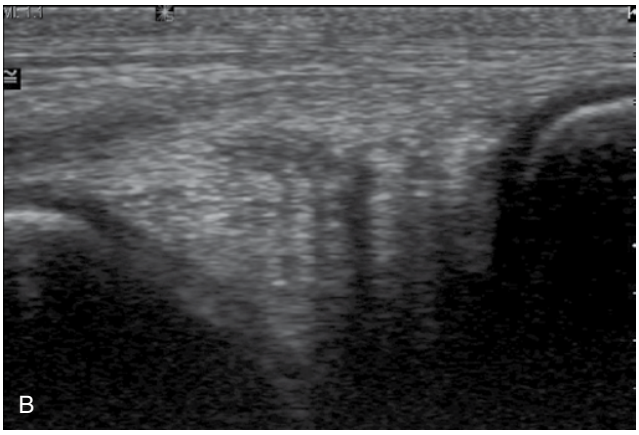

Figure 5.138. Ultrasonographic images of the medial meniscus in both weight-bearing (A) and non-weight-bearing positions (B). Notice how the meniscal tear becomes more apparent in the non-weight-bearing position.

ultrasonographic findings since most of the meniscus is inaccessible at surgery, leading to potential false-positive and/or false-negative findings.

Other diagnostic techniques include nuclear scintigraphy, which has poor sensitivity and modest specificity for stifle disease in general;[4,18] MRI, which is useful but limited in availability; contrast CT, which requires communication of the tear with the synovial cavity; and arthroscopy, which is an important diagnostic tool that is readily available but unable to visualize much of the weight-bearing surface of the meniscus. Therefore, the lack of findings of a meniscal lesion with arthroscopy does not necessarily rule out the absence of a lesion.

Treatment

Treatment usually involves arthroscopic surgery and debridement of the disrupted meniscal fibers that can be

VetBooks.ir

seen. In addition, it is common to test the looseness of the meniscus with a probe during surgery. The significance of this finding is unknown, but subjectively seems to be associated in some cases with damage and protrusion of the meniscus identified on ultrasound. In addition, manipulation of the meniscus permits better visualization of the tibia for evidence of secondary damage.

Walmsley developed a grading scale for meniscal injuries: grade I is characterized by axial tearing through the cranial ligament of the medial meniscus and into the meniscus, grade II is the same as grade I but with torn tissue and visible extent of the damage, and grade III is a severe tear that extends beneath the femoral condyle.[65]

In an updated review of horses with meniscal injuries, Walmsley found that of 126 cases, 111 were medial and 25 were lateral and 53% were grade I, 28% grade II, and 17% grade III.[63] In that study, 76% had articular cartilage damage, and 14% had damage to the cranial cruciate ligament. Of those with medial meniscal tearing, 45% were sound compared with 75% of those with lateral meniscal involvement. Sixty percent of horses with grade I tearing were sound compared with 65% of those with grade II and 10% of those with grade III. Overall, 51% of the horses were sound with surgery.[63] Similarly, Cohen et al. found decreasing prognosis with increasing meniscal damage, with no horses with grade III tearing returning to previous use.[9] Because most of the meniscus cannot be visualized arthroscopically, a tear or lesion in the body of the meniscus may be treated by extracapsular injection of stem cells or PRP into the lesion(s) or into the joint. Horses with meniscal lesions treated with bone marrow derived stem cells returned to work more often than those historical controls.[16] If the tear is visible arthroscopically, then various suturing and staple techniques are also available.[40] In general, suturing is preferred over stapling. The efficacies of these latter techniques to treat meniscal lesions are currently unknown.

Prognosis

As noted above, the prognosis for lesions of the medial meniscus is relatively guarded, but for the lateral meniscus can be quite good. In addition, horses with small lesions that can be debrided can do relatively well, although horses with significant tearing carry a poor prognosis. Great efforts are currently being made to provide augmentative therapies, such as stem cells, which have shown some promise.[16]

SYNOVITIS/CAPSULITIS/OA

Etiology

Horses that undergo chronic repetitive stress to the hindlimbs, such as young western performance horses, are susceptible to synovitis in the femorotibial joints, especially the medial compartment. This is similar to racehorses that develop synovitis in their metacarpophalangeal and carpal joints. A primary source of synovitis is usually not apparent in these horses. However, all of the diseases described in this section can lead to synovitis and in some cases, ultimately, OA.

Clinical Signs and Diagnosis

Horses with synovitis of the femorotibial joints may not be lame, but have mild to moderate effusion in the MFT joint. These horses may show some response to flexion and a gait that can be described as stiff. Some horses can compete well with this finding, but they should be monitored closely. As mentioned previously, all diagnostic techniques can be negative in these cases, including arthroscopic surgery.

Horses with synovitis secondary to other primary lesions within the MFT joint usually have a history of a short response period to intra-articular medication. However, trainers and owners usually note that the horse either never fully regained its level of performance or constant medication was needed. In these cases, additional diagnostics, including diagnostic arthroscopy, are often required to fully characterize the problem.

Horses with significant OA of the femorotibial joints are usually lame at the walk with loss of muscle mass and soft tissue swelling and effusion of the MFT joint. Concurrent abnormalities such as OA, SCL of the medial femoral condyle, and medial meniscal damage are common (Figure 5.140). Although a history of predisposing injury and disease of the stifle is usually noted, some horses may develop this problem insidiously without a notable injury.

Treatment

Horses with synovitis usually respond well to intra-articular medication, topical anti-inflammatories, systemic medication, and extracorporeal shockwave therapy. These medications are described in depth in Chapter 8. Horses typically respond well to rest or a reduction in training, which are often recommended. However, failure to respond to medication and recurrence of lameness are often the key findings that lead to more intensive imaging and possibly diagnostic arthroscopy.

Figure 5.140. Caudal to cranial radiograph of the stifle of a 6-year-old Quarter horse mare with multiple radiographic abnormalities within the MFT joint (arrows). Concurrent medial meniscal injuries should also be suspected in these types of horses. *Source*: Courtesy of Dr. Gary Baxter.

VetBooks.ir

Treatment of OA of the femorotibial joints is the same as for other joints. However, arthrodesis is not an option, and clinicians are often forced to try several different treatment options. Exercise in the form of small paddock turnout appears to help, although owners must ensure that another horse does not induce overstressing of the patient. Arthroscopic surgery can help to reduce the progression of OA by removing debris and fibrillated articular cartilage, but it must be stressed to the owners that this is not a cure and the disease process will most likely progress.[16]

Prognosis

Horses with synovitis are easily managed medically as long as a primary disease process is not present. However, there is concern that chronic persistent synovitis can lead to secondary damage to the articular cartilage, which may predispose to the onset of OA in the future. The prognosis for OA of the femorotibial joints depends on severity and appears no different than for other joints in the horse. However, severe OA can lead to significant lameness, making it difficult for the horse to stand, and secondary complications such as decubital ulcers.

FEMUR AND COXOFEMORAL REGION

Nicolas S. Ernst and Troy N. Trumble

VetBooks.ir

THE FEMUR

Conditions of the femoral region that contribute to lameness are uncommon and can vary greatly in severity. For example, femoral fractures usually cause significant swelling in the region and severe non-weight-bearing lameness. In contrast, horses with fibrotic myopathy may not be lame but have a gait alteration due to fibrosis of the muscle. Careful palpation and physical examination of the femoral region are often very important in making a diagnosis because imaging of the femoral region can be difficult, especially in adult horses.

DIAPHYSEAL AND METAPHYSEAL FEMORAL FRACTURES

Fractures of the femur are relatively common in horses.[7,14,21,26,36,57] Intra-articular (IA) fractures involving the stifle and coxofemoral joints are described in those respective sections.

Etiology

Foals frequently sustain femoral fractures during initial handling or during halter breaking. Occasionally a mare will step on a foal, or the foal may become trapped under a fence. In a study of 38 horses under 1 year of age, causes included a fall or severe adduction, external trauma, or being caught in a fence.[36] In young animals, fractures often involve the proximal or distal growth plate, and diaphyseal fractures are usually oblique and spiraling.[35] Adults often sustain irreparable comminuted fractures of the femoral shaft from trauma. A common history in an adult is slipping on ice, causing the leg to splay out (adduct), transferring a large force of the body as it falls to the femur. It has also been described that femoral condylar avulsion fractures can occur in horses that had been cast with a sideline for castration without sedation.[88]

Clinical Signs

The obvious sign is non-weight-bearing lameness. When viewed from the side, the affected limb may appear slightly shortened with the hock held higher than the opposite hindlimb; a dimpling of the musculature overlying the fracture may be observed. Obvious swelling may be present, especially in horses with diaphyseal fractures (Figures 5.141 and 2.96). Uncommonly, clinically significant or fatal hemorrhage results, usually due to laceration of the femoral artery.[36,73] These horses will have pale and tacky mucous membranes, and if hemorrhage into the musculature becomes excessive, they can develop a compartment-type syndrome, making them extremely uncomfortable to any movement and palpation of the swollen region.

Diagnosis

Excessive movement of the distal limb is usually present on palpation. Fractures of the distal growth plate are usually evident because of displacement, instability, or swelling in the stifle region. For mid-diaphyseal fractures, moderate to severe swelling is often associated with the fracture site (Figure 5.141), and crepitation may be apparent. A stethoscope may be helpful for detecting crepitation, although sounds may be muffled due to the massive musculature and swelling (e.g. hematoma) or just minimal with severe comminution. Because of overriding, the patella may feel loose and may be manipulated easily in a horizontal direction. If the horse is extremely sensitive to palpation or movement of the limb, compartment-like syndrome should be considered with suspicion of femoral artery laceration.

The clinical appearance of horses with proximal femoral fractures (slipped capital epiphyses or femoral neck fractures) can be similar to those with coxofemoral luxation. If the fracture overrides proximally, the hock on

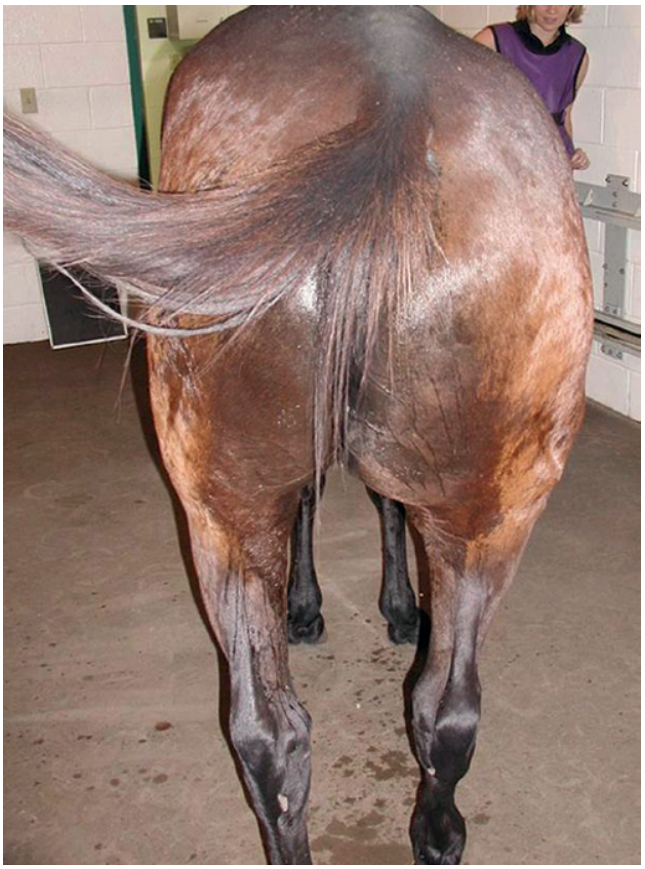

Figure 5.141. Caudal view of an adult with severe swelling of the femoral region associated with a diaphyseal femoral fracture. Notice that the horse is sweating and non-weight-bearing on the right hindlimb.

VetBooks.ir

Figure 5.142. Image of the hind end of a pony demonstrating a shorter left hindlimb than the right hind. Notice that the point of the hock is higher, the heel does not completely contact the ground, and the limb is externally rotated. Horses with slipped capital epiphyses, femoral neck fractures, or coxofemoral luxations can all have this clinical appearance.

the affected limb may be higher than the hock on the normal limb, with some degree of external rotation of the limb (Figure 5.142). Often the horse will not have any swelling present and may appear to bear weight on the limb, but often will not completely load the heel. If the fracture is several days old, swelling may be palpated on the medial aspect of the thigh. Palpation (± auscultation) over the greater trochanter while the limb is being manipulated may reveal crepitus. If the horse is large enough, a rectal exam may reveal subtle crepitation when the limb is manipulated.

Although physical exam findings may suffice to diagnose a femoral fracture, radiographs are important to make a definitive diagnosis and demonstrate the exact location and configuration of the fracture such that treatment and prognosis can be determined. For the distal one-third of the femur, standing views will usually identify the fracture, but for the proximal two-thirds of the femur, particularly in adults, a recumbent position is required to obtain quality radiographs (Figure 5.143). The most useful radiograph of the proximal two-thirds of the femur is taken medial to lateral with the horse in dorsal recumbency but tipped onto the injured limb (Figure 5.143B). Adequate penetration is difficult for the cranial to caudal projection, but the image may still be useful. A standing view of the proximal femur/coxofemoral region may suffice in certain cases.[56] Digital radiography has significantly facilitated acquisition of quality images of this region, and standing oblique projections of the femoral shaft may demonstrate a lesion almost as well as in an anesthetized horse. The quality of the images often depends on the size of the horse and swelling present; as both increase, the quality will decrease. The suspected gravity of the injury and the anticipated ability for the horse to recover from general anesthesia without further injury must be considered.

Ultrasound may demonstrate cortical disruption to prove that a femur fracture is present when radiographs are not possible or advisable.[29,71] Scintigraphy, particularly for less severe or more chronic injuries, also may localize femoral lesions not amenable to radiographic imaging (Figure 5.144).[83]

(B) and (C) Radiographs taken with the horses in a recumbent position under anesthesia. Image B demonstrates a closed, oblique, mid-diaphyseal fracture of the femur in a miniature foal, and image C demonstrates a neck fracture of the proximal femur (Salter–Harris type II).

VetBooks.ir

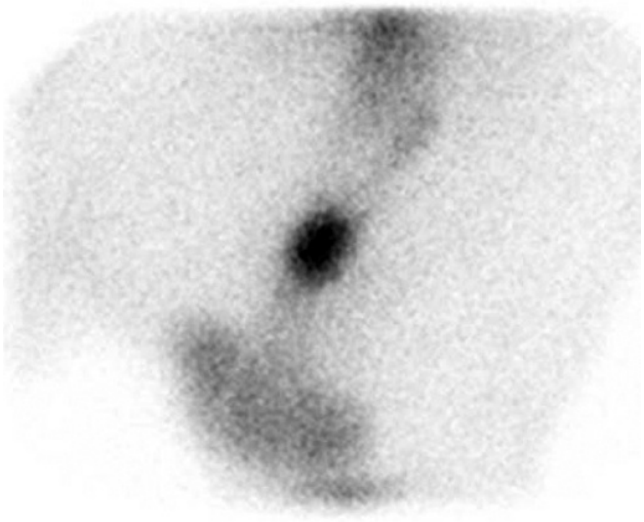

Figure 5.144. Lateral scintigraphic image of the femur in an adult mare who was chronically lame (stifle is at the bottom and coxofemoral joint at the top). Note the increased radiopharmaceutical uptake at the junction of the middle and distal one-third of the femur.

In a series of 38 foals with femoral fractures, 26 had fractures of the femoral diaphysis (Figure 5.143B), and 18 involved two-thirds of the length of the diaphysis.[36] Twelve foals had distal physeal fractures with the most common configuration being Salter–Harris type II (Figure 5.143A). A separate series of 25 foals sustained fractures of the capital femoral physis (Figure 5.145), neck (Figure 5.143C), or greater trochanter.[41]

Treatment

Treatment of femoral shaft fractures depends on the age of the animal and the type and location of the fracture. Generally, euthanasia is indicated for adults that have sustained femoral shaft fractures unless exceptional circumstances exist. If compartment-type syndrome is present, a fasciotomy should be considered to relieve pain while making diagnostic and treatment decisions.

Diaphyseal fractures have been treated with stall rest in foals weighing up to approximately 200 kg[57]; however, misalignment and nonunions are risks in young horses (Figure 5.146). Compression plating is the treatment of choice for foals that have sustained diaphyseal fractures when athletic soundness is desired. Fourteen of 15 foals in which diaphyseal fractures were plated were repaired using 2 plates, 1 lateral and 1 cranial.[36] However, single-plate application has been used occasionally.[7,36] A very stable repair can result when the fracture is midshaft and transverse.[97] More distal fractures can be repaired using angled blade plates or dynamic condylar screw plates.[11,36] The plates are not removed when there are no complications. Fractures without caudal cortical buttress remaining are at risk of an unstable repair and should be given a poor prognosis.[36]

Intramedullary pinning using the stacked pin technique or a single half-inch pin has been used successfully in young foals with femoral diaphyseal fractures.[85] However, problems with pin migration should be expected. One report in experimental fractures in donkeys (65–140 kg) reported some success.[90] However, the work was performed in adult donkeys. Creating controlled, relatively atraumatic fractures in what is really adult bone does not simulate clinical fractures in foals.

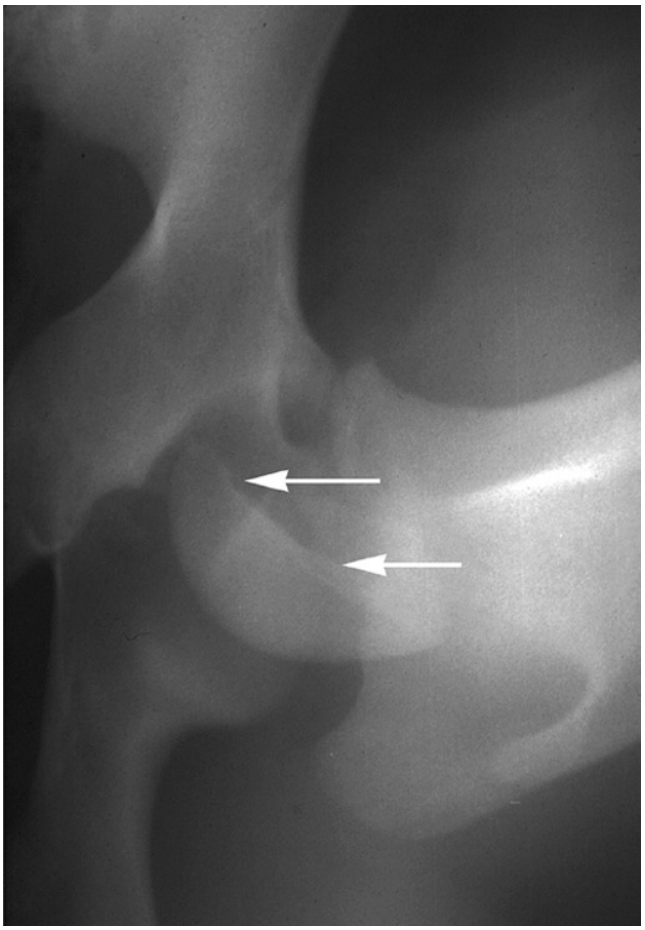

Figure 5.145. Recumbent radiograph of the pelvis of a foal with a capital physeal fracture (arrows) of the left proximal femur.

Interlocking nails (ILN) have been investigated for repair of diaphyseal femoral fractures (Figure 5.147).[58,70] In general, the less the horse weighs, the better the chance for success. Three successfully managed transverse midshaft femoral fractures in neonates have been reported using the ILN alone, along with 4 of 6 successfully managed with an ILN–dynamic compression plate combination.[99] Double-plate fixation has been reported to provide greater stiffness compared with ILN alone.[70]

Proximal growth plate fractures (slipped capital physeal fractures) are covered in the section on the coxofemoral joint. Most distal physeal fractures are Salter–Harris type II fractures (Figures 5.143A and 5.148). Minimally displaced distal physeal fractures may heal quite well with conservative therapy (Figure 5.149)[35] or with a modified Thomas splint/cast in small horses.[48] Unstable distal physeal fractures have little space for an adequate number of screws to be placed distal to the fracture, and many are not treated.[36] Options for stabilizing distal physeal fractures include an angled blade plate,[36] condylar

buttress plate,[67] locking compression plates,[50] a cobra head and dynamic compression plate,[46] and cross-pins or rush pins (Figure 5.148). Successful repair of a Salter–Harris type II fracture in a yearling Pony of America was reported using a condylar buttress plate.[67] A displaced Salter–Harris type IV fracture in a yearling was successfully treated using a lag screw repair countersunk into the articular surface.[20]

Prognosis

The prognosis for fracture of the femur depends on the age of the horse, the location and configuration/type of fracture, and its intended use. Generally, femoral fractures in horses older than yearlings carry a very poor prognosis for a successful outcome. A much better prognosis can be expected in young animals with nondisplaced fractures or oblique midshaft fractures that are stabilized by internal fixation.[36] Nine of the 17 surgically repaired diaphyseal fractures healed.[7,36] Six of those were considered to have no sign of previous fracture.[36] The mean age for successfully treated foals was 2 vs. 4 months for unsuccessfully treated foals.[36] Aside from size of the foals being an influence, development of a postoperative seroma was negatively associated with success.[36] Three of 4 foals with oblique midshaft femoral fractures treated by stall rest alone became sound for breeding, but fracture disease associated with prolonged non-weight-bearing presented problems during the healing period.[57] Despite the improvement and advances in instrumentation, surgical techniques, and implants, femoral fractures are still among the ones that become infected, and those cases are less likely to be discharged from the hospital.[3,50]

In one report, only 1 of the 2 surgically repaired distal physeal fractures healed.[36] Even if successful, repair of distal physeal fractures can also lead to early physeal closure and a shortened limb.[50] A minimally displaced Salter–Harris type IV fracture treated conservatively in a yearling healed to racing status.[36] Aside from size of the foals being an influence, development of a postoperative seroma was negatively associated with success.[36]

FRACTURES OF THE THIRD TROCHANTER

The third trochanter is a prominent tuberosity that is located on the lateral aspect of the proximal third of the femur. It provides insertion to the tendon of the gluteus superficialis muscle, which is mainly a flexor of the coxofemoral joint and abductor of the limb.[30] Due to the superficial location, this tuberosity is prone to trauma causing fractures or injuries such as avulsion of the tendon of the gluteus superficialis muscle.[6] It is an uncommon cause of lameness with most horses showing severe lameness in acute cases. Clinical diagnosis can be challenging without advanced diagnostic techniques. Generally, it can be diagnosed with radiographs (50° cranial, 30° lateral caudomedial oblique, or craniolateral to caudomedial 25° oblique); however in horses with chronic displaced fractures, scintigraphy and ultrasound can help further evaluate the area.[18,76] This type of fracture is often displaced and heals with a fibrous union. Treatment consists of conservative management with rehabilitation including stall rest (1–2 months), controlled hand walking, and turnout (2–12 months).[6,76] The prognosis for return to athletic activity is good after an appropriate period of rest and restricted exercise.[6] However, another report showed 8 of 12 horses returning to athletic activity with 2 of these horses returning at a lower level.[76]

FIBROTIC AND OSSIFYING MYOPATHY

Fibrotic and ossifying myopathy is a fibrosis with or without ossification of the muscle tissue in the crus that often results in adhesions between the semitendinosus, semimembranosus, gracilis, or biceps femoris muscles (Figure 5.150).[1] It is significant because the fibrosis and adhesions limit the action of the semitendinosus muscle, causing an abnormal gait. Rarely, the condition occurs in the forelimb.[1] The largest case series reported in the United States related a predisposition for occurrence in Quarter horse mares.[52] A congenital form of fibrotic myopathy-type syndrome has been reported.[8] Foals are born with an altered gait characteristic of fibrotic myopathy in the hindlimb. On palpation, a tightening of the semitendinosus muscle was appreciated, but no firm thickening of the muscle typical of fibrotic myopathy was palpated. Because no fibrous thickening of the muscle is present, congenital restrictive myopathy may be a more appropriate description of this entity.

Etiology

Trauma causes fibrosis and adhesions of the semitendinosus, semimembranosus, gracilis, or biceps femoris muscles. It is typical for the semitendinosus to be involved, but any of the gaskin muscles can be affected. The involved muscles may be injured during sliding stops in rodeo work or from slipping and catching the hindlimb on the underside of a horse trailer, resisting a sideline, catching a foot in a halter, receiving intramuscular injections, being kicked, or cast for castration without sedation.[8,88] The lesions are usually unilateral, but a case of bilateral fibrotic myopathy resulting from a trailer accident has been reported.[8] In some cases the exact cause of the injury is not known; cumulative injury

VetBooks.ir

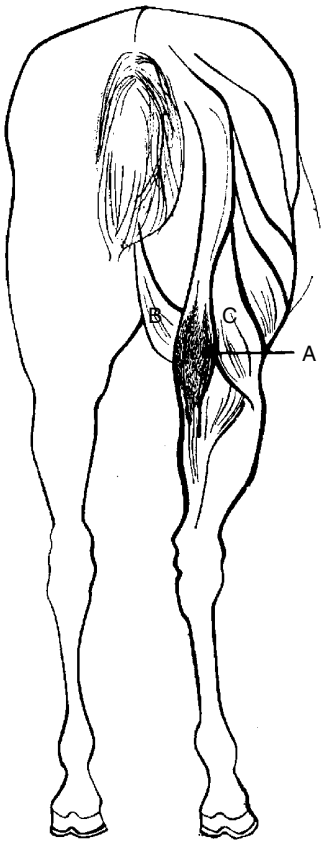

Figure 5.150. Drawing depicting the muscles in the fibrotic area in the gaskin of a horse affected with fibrotic myopathy. (A) Semitendinosus. (B) Semimembranosus. (C) Biceps femoris.

must be considered in cases such as western performance horses or those that involve any other repetitive situation. As the injury heals, fibrosis of the injured muscle as well as adhesions to surrounding musculature partially inhibits the normal action of the muscles, causing a shortened cranial phase of the stride (inability to extend the limb forward due to lack of muscular compliance). In some cases, the fibrosis will become ossified and is believed to be a more severe progression.

The etiology of the congenital form is unknown, although parturient muscle trauma has been described to cause rupture of the gastrocnemius muscle.[79] It is conceivable that similar trauma could also affect the semitendinosus under different stresses at birth or shortly after.

Three cases of fibrotic myopathy accompanied by neurogenic atrophy of the affected muscles have been reported.[98] All three underwent necropsy, where peripheral nerve and muscle degeneration were discovered. One horse had a fracture of the greater trochanter and accompanying sciatic nerve impingement. No gross lesions were found in the other 2 horses.

Clinical Signs

In the acute stages, generalized swelling and sensitivity to palpation of the gaskin area are present. As the injury starts to heal, an area of firmness with a variable pain response can be palpated over the affected muscles on the caudal surface of the limb at the level of the stifle joint and immediately above it (Figure 5.150). Most often, the main area of fibrosis can be felt over the semitendinosus. Occasionally, the lesion is deep and difficult to palpate, or it may be in the medial gaskin affecting the gracilis muscle. In the chronic stages, no pain is present on palpation.

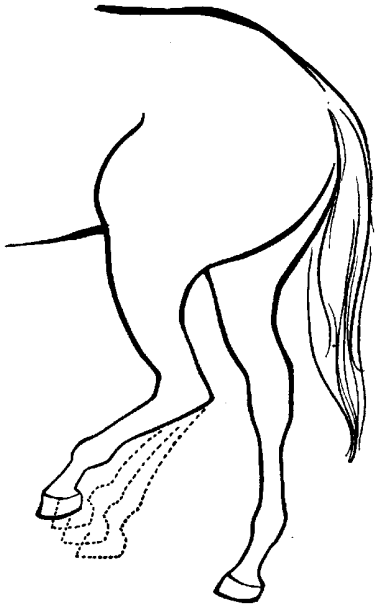

Figure 5.151. Characteristic action of the hindlimb of a horse affected with fibrotic myopathy. The limb jerks backward and downward (dotted outline of the affected foot) during the last 3–5 in. of the stride, resulting in slapping of the foot on the ground. If the gracilis muscle is affected, the swing of the hindlimb is lateral to medial instead.

Fibrotic myopathy demonstrates a gait abnormality characterized by a slapping down of the foot at the end of the cranial phase of the stride (Figure 5.151). Usually the lameness is most noticeable when the horse walks and is diminished when the horse trots. The character of the gait of a semitendinosus-affected horse has been described in detail.[13] In the cranial phase of the stride, the foot of the affected hindlimb is suddenly pulled caudally 3–5 in. just before contacting the ground (Figure 5.151). The affected hindlimb approaches the ground more vertically than normal and strikes it toe first, making more of a slap than the normal heel–toe manner of landing. Ultimately, the cranial phase of the stride is shortened with the caudal phase lengthened. If the semitendinosus is more affected, the slap is cranial to caudal. If the gracilis is more affected, the slap is from lateral to medial. Some have reported a semiflexed stance at rest with the toe touching the ground.[13,31]

Diagnosis

In chronic cases, the diagnosis is straightforward as it is based upon the altered gait and palpation of a hardened area on the caudal or caudomedial surface of the limb proximal to the level of the stifle. In making the diagnosis, stringhalt should also be considered. In stringhalt, the limb is pulled sharply toward the abdomen during the cranial phase of the stride, while in fibrotic myopathy the foot is pulled toward the ground in a caudal direction just before the foot contacts the ground.

VetBooks.ir

However, in the acute case, it can be more difficult to diagnose due to the amount of swelling and pain that can occur in the gaskin region. Nuclear scintigraphy (Figure 5.152), ultrasound, thermography, and local infiltration of the area may all be necessary in horses with acute injuries.[17]

Treatment

Treatment is often based on chronicity of the lesion. In general, the more acute the lesion, the more the clinician can attempt to minimize the formation of a fibrotic scar (Figure 5.153). Once the mature scar tissue is present, then surgery should be considered.

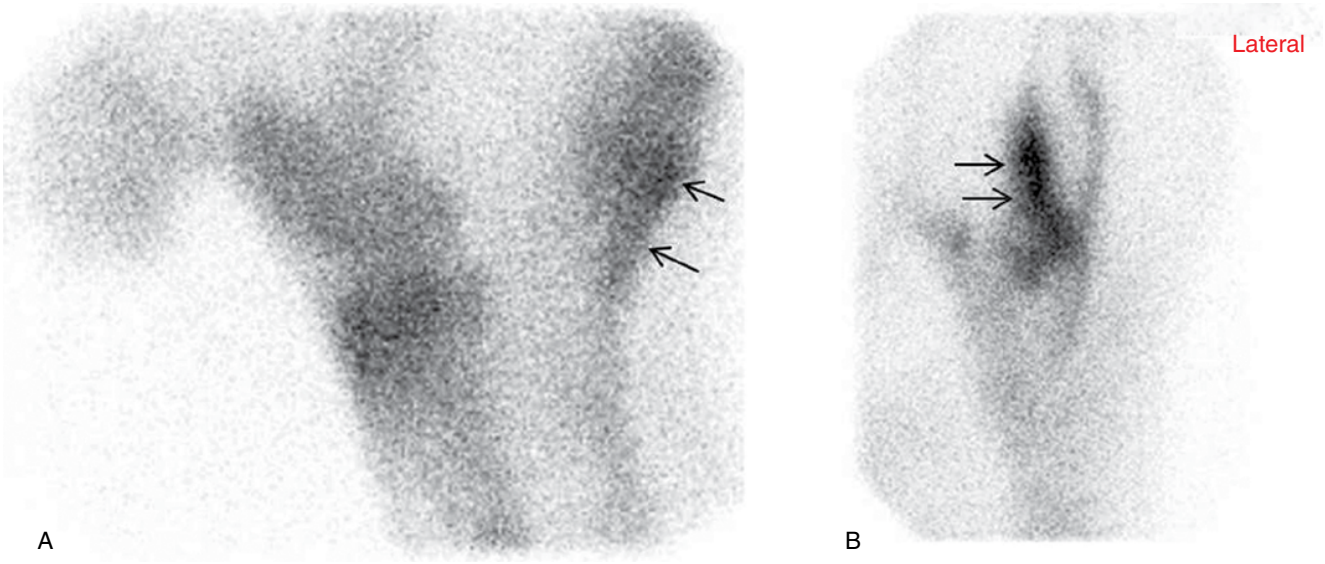

Figure 5.152. Nuclear scintigraphy performed on an adult horse that presented for an acute injury to the gaskin region secondary to trauma. (A) Lateral image showing increased radiopharmaceutical uptake in the musculature of the caudal aspect of the limb (arrows) just proximal to the level of the stifle. (B) Caudal cranial image with the lateral side of the limb labeled. There is increased radiopharmaceutical uptake just proximal to the level of the stifle (arrows) in the location of the semitendinosus muscle.

Figure 5.153. Images of the adult horse that sustained an acute muscle injury identified with scintigraphy in Figure 5.152. (A) Six months after injury. (B) One and a half years after injury. Note that the thickened area of fibrous tissue in image A (arrows) is more distal than the final fibrous tissue after 1.5 years. This horse had multiple treatments to minimize the development of scar tissue.

VetBooks.ir

In the acute stages, nonsteroidal anti-inflammatory drugs (NSAIDs) or other pain medication are usually required to help minimize the swelling and pain in the gaskin region. It is ideal to try to move and stretch the muscles as soon as the horse can tolerate it. The hope is to create as elongated and functional scar of the muscle(s) as possible. Initially, the hindlimb can be stretched cranially and caudally (Figure 5.154) working in deep massage of the affected muscle once the horse can handle it. Hand walking should start on a hard surface over the first few weeks, but range of motion exercises should be added in as soon as possible. This could include walking them part time in arena footing, followed by walking them over logs, progressing to cavaletti or an underwater treadmill, if available. The ideal water level to use in an underwater treadmill is fetlock depth.[59] In addition, as the fibrous scar develops, one can use shockwave. This can help break up the scar and make them more comfortable for moving and stretching exercises. In addition, once the scar is chronic, shockwave can periodically help if the size enlarges or new painful areas develop. Additional therapies such as therapeutic ultrasound and acupuncture could also be used during the initial phases of treatment.

Three approaches for surgical correction of fibrotic myopathy have been described; each must be adjusted if more than the semitendinosus muscle is involved. Adams originally described complete removal of the affected fibrotic/calcified muscle tissue.[1] In a retrospective study of 18 horses undergoing this procedure, all of the 11 horses available for follow-up had mild to complete persistence of the gait deficit.[96] Anecdotally, quadriceps rupture has been observed following resection of an extensive calcified mass. The failures were most likely due to recurrence of fibrosis in the defects created, but it is possible that there was more extensive involvement in some cases. A modification of this technique was reported by Janicek et al. using a Nd:YAG laser to transect fibrotic mass (fibrotomy). Advantages reported were a more controlled and complete hemostasis, which improved the visualization of the fibrotic mass and facilitated the differentiation from normal tissue.[44]

Bramlage described a semitendinosus tenotomy at the level of its insertion on the proximal medial tibia caudal to the saphenous vein.[8] The procedure is much less invasive and is expected to be effective if the problem is unaffected by other muscles. The tenotomy is performed at the insertion of semitendinosus tendon on the proximal to medial tibia with the horse positioned in lateral recumbency with the affected limb down.[8] Three of four (1 mature and 2 congenital) horses recovered completely; the fourth (a congenital) case underwent more distal transection of the calcaneal insertion of the semitendinosus tendon 2 months later, which provided sufficient improvement for race training.[8] Of 2 additional cases in mature horses, 1 experienced complete recovery and 1 improved slowly but incompletely.[31] In a more recent report in which the semitendinosus muscle was affected in 6 horses, 2 improved with no gait deficit remaining, with 3 more improving some after standing surgery.[87] Interestingly, when the surgery was performed under anesthesia in another 8 horses, none improved all the way, with only 3 improving some.[87]

Magee and Vatistas reported a series of 39 horses that underwent a standing focal semitendinosus myotomy.[52] Average wound healing time was 4.7 weeks overall. Eighty-three percent of horses were able to perform at their pre-injury level. Nineteen were considered normal and 10 had some persistent restrictive gait. The incision is made directly over the affected semitendinosus muscle, which is transected using a blunt bistoury. The incisions are left open, partially closed, or completely closed, depending upon the surgeon's preference (Figure 5.155).

Figure 5.154. Cranial (A) and caudal (B) stretching exercises being performed on an adult Quarter horse that sustained an injury to its semitendinosus muscle. These exercises are most important within the first 2 weeks after injury.

VetBooks.ir

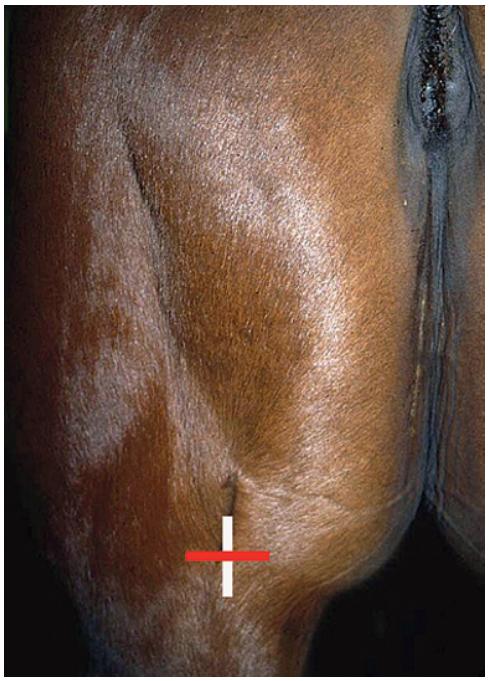

Figure 5.155. Caudal thigh region where the myotomy procedure is performed to correct fibrotic myopathy. The skin incision is made vertically (white line) and the fibrotic muscle is transected with a bistoury horizontally (red line).

No cases of involvement of muscles other than the semitendinosus were reported.

Prognosis

If it is possible to see the horse acutely, it is possible to minimize the scar tissue development and adhesions between different muscles. It is important to note, however, that although the characteristic gait will be harder to see, it will still be present. With partial myectomy, some relief is evident in all cases. After healing, some cases develop characteristic, but less pronounced, signs, although limb function is nearly normal and signs are not noticeable except in the walk. Occasionally, 3–7 days are needed for the maximum benefits of surgical correction to become evident. The semitendinosus tenotomy prognosis is fair, with horses improving more when only the semitendinosus muscle was affected compared with when the semimembranosus muscle is also affected.[87] With the standing myotomy technique, 83% of horses were able to perform at their pre-injury level, although the restrictive gait pattern did not resolve in all horses.[52] In the modified fibrotomy technique with the Nd:YAG, of the 6 horses with long-term follow-up, 4 returned to full use with no abnormalities and 1 with partial improvement.[44] A specific diagnosis of the muscles affected can help prepare owner expectations, recognizing that in those cases where more muscles are affected, a lower prognosis should be given. The prognosis for successful surgery in horses affected by neurogenic atrophy of the muscles is poor. If the muscle mass appears abnormal, nerve conduction studies or electromyography is advisable.

FEMORAL NERVE PARALYSIS (CRURAL PARALYSIS)

Paralysis of the femoral nerve affects the quadriceps femoris group of muscles. This muscle group is composed of the rectus femoris muscle, vastus lateralis muscle, vastus medialis muscle, and vastus intermedius muscle. This large muscular mass covers the front and sides of the femur and inserts onto the patella to extend and fix the stifle.

Etiology

Femoral nerve paralysis may arise from trauma or unknown causes and may be associated with rhabdomyolysis. Injury to the nerve may occur from overstretching the limb during exertion, kicking, slipping, or while the horse is tied in a recumbent position. It has also been reported as a complication of general anesthesia.[24]

Hemorrhagic neuritis has been described in 1 horse that was euthanatized due to femoral paralysis.[24] Unaffected horses had no such lesion at necropsy. The affected horse also had lesions of rhabdomyolysis, and the urinary system was affected by myoglobinuria. Postmortem studies with cadavers revealed that the femoral nerves were placed in tension by extending the hindlimbs behind the horse, whereas lifting the horse by the hindlimbs did not place tension on the femoral nerves.[24] The potential roles or interaction of femoral paralysis and rhabdomyolysis warrant further investigation.

Clinical Signs and Diagnosis

The horse assumes a crouched position with the fetlocks flexed and the toes on the ground and is unable to bear full weight on the affected limb. There is difficulty advancing the limb, but the affected horse can do so because the hock can be sufficiently flexed to pull the limb forward. After the condition has been present for some time, atrophy of the quadriceps muscles occurs, causing them to lose their normal softness and become more like tendinous structures. If rhabdomyolysis is present, the horse is more painful and less willing to attempt to stand.

The signs listed above are characteristic and are used for diagnosis. The condition should be differentiated from lateral (true) luxation of the patella, rupture of the quadriceps femoris muscles, avulsion of the tibial crest, and distal luxation of the patella. Any of these conditions could cause a similar syndrome; however, all are rare. Lateral luxation of the patella can be diagnosed by palpation of the displaced patella; rupture of the quadriceps femoris muscle also can be palpated. A radiographic examination can determine avulsion of the tibial crest where the patellar ligaments insert. Electromyography of the quadriceps femoris muscles 5 days after the first signs of femoral nerve paralysis provides a definitive diagnosis.

Treatment

No treatment is known. If the condition is due to injury of the femoral nerve, the animal should be stalled until improvement occurs. If rhabdomyolysis is present,

VetBooks.ir

intensive care and support is indicated, and repeated attempts to use the muscles should be discouraged.

Prognosis

The prognosis is guarded to unfavorable. In a report of two cases of post-anesthetic femoral paralysis, one had concurrent rhabdomyolysis and was euthanatized. The other responded to supportive therapy and was standing well 7 days after the onset.[24,51] The prognosis should be withheld until sufficient time has elapsed to determine whether any function will return.

CALCINOSIS CIRCUMSCRIPTA

Calcinosis circumscripta in the horse is a calcified mass commonly located on the lateral aspect of the gaskin adjacent to the stifle (Figure 5.156).[22,33,43,86] The condition has also been observed in other locations such as the carpus, tarsus, shoulder, and pectoral region.[22,34,86] The locations can be unilateral, bilateral, or multiple locations on the body.[22,43,86] Males appear to be affected the most, as only a few of the total cases presented in the literature are females.[22,33,43,86] The age at presentation has ranged from 1 to 13 years, with mention that the condition has not been reported in foals younger than 6 months of age.[22,33,34,43,86]

Etiology

The etiology is unknown. The description of the lesion best fits that of dystrophic calcinosis characterized by calcinosis circumscripta. Tumor calcinosis implies a metabolic derangement in calcium/phosphorus metabolism leading to hyperphosphatemia and resulting accumulation of deposits of calcium phosphate.[86] Although few have investigated the serum chemistries of affected horses, hyperphosphatemia has not been a reported feature of the condition in horses.[43,86]

Clinical Signs and Diagnosis

Because clinical signs of lameness seldom occur, horses may carry the lesion for years before presentation to a hospital. The masses are generally 3–12 cm in diameter. The skin is freely movable over the density because it lies beneath the superficial and deep fascia. They are often attached to the joint capsule of the lateral femorotibial joint. Diagnosis is confirmed on radiographs (Figure 5.156).

Once dissected free, the lesions are encapsulated in a tough, white, fibrous capsule.[22,43] The interior is composed of loculations of finely granular, gritty, white, paste-like material.[22] Histologically, the granules are surrounded by a granulomatous inflammatory reaction.[22] Although it is difficult to make a broad comparison, the lesion in humans is believed to be secondary to collagen necrosis.[91]

Treatment

The only treatment is surgical excision.[22,43] However, the lesions seldom cause a clinical problem. The location is one that tends to dehisce following surgery and must be taken seriously in that respect.[43] Also, due to the proximity to the femorotibial joint, there is a potential to create a septic arthritis.[22] If surgery is performed, a tension-relieving closure using mattress sutures and a sutured stent bandage is advised. A circumferential adherent surgical drape is helpful in preventing swelling.

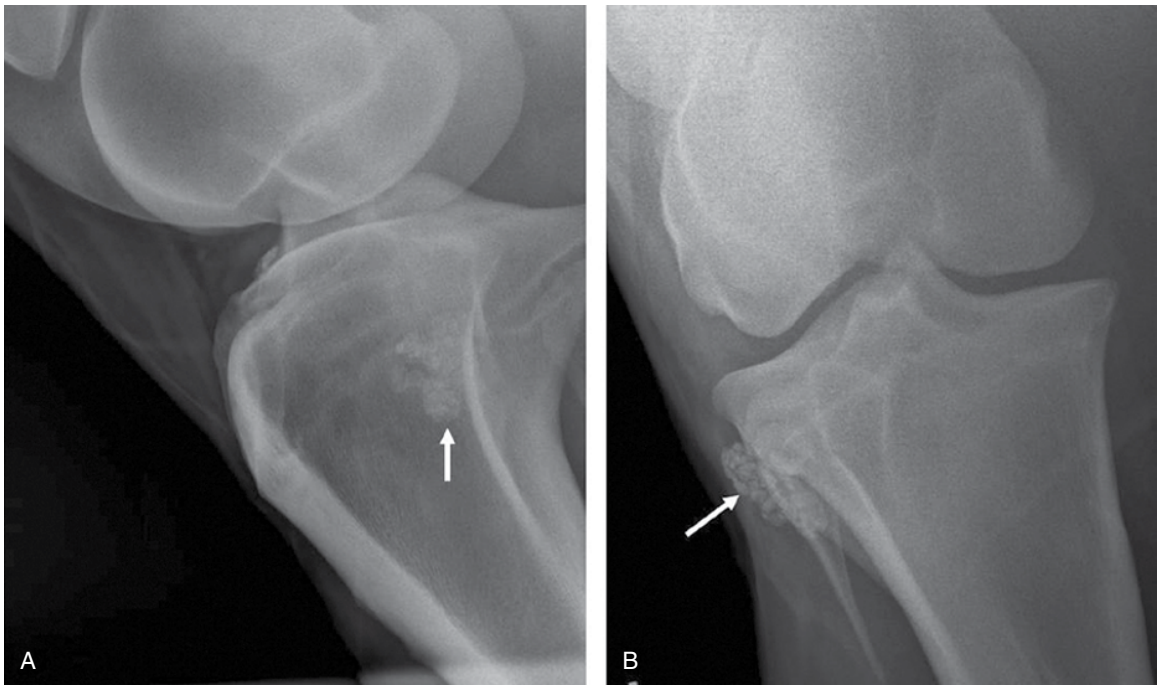

Figure 5.156. (A) Lateral and (B) caudal to cranial radiographic images of the stifle in a 5-year-old horse showing a calcified mass on the lateral aspect of the stifle (arrows).

VetBooks.ir

Prognosis

The prognosis is good for soundness and future use. Clinical problems or lameness is uncommon. The prognosis after surgery is guarded, depending upon the size of the lesion due to potential for incisional complications.[5,22,43]

TROCHANTERIC BURSITIS (TROCHANTERIC LAMENESS, WHIRLBONE LAMENESS)[81]

Trochanteric bursitis is inflammation of the bursa beneath the tendon of the accessory gluteal muscle (deep portion of the gluteus medius muscle) as it passes over the greater trochanter of the femur. The tendon of the gluteus medius muscle also may be involved, as well as the cartilage over the trochanter. The deep portion of the gluteus medius muscle has a strong flat tendon that passes over the convexity of the trochanter before it inserts into the crest, and it functions to extend the coxofemoral joint and to abduct the limb. The trochanter is covered with cartilage and the trochanteric bursa is interposed between it and the tendon.[30]

Etiology

In many cases, there is a concurrent source of chronic lameness in the same limb, particularly distal tarsitis. Chronic forelimb lameness may also contribute to trochanteric bursitis by causing the horse to place more strain on the hindlimbs.[12,37] Lameness may also be caused by bruising as a result of the horse falling on the affected side or by strain during racing or training.

Trochanteric bursitis occurs in horses racing on small tracks, where the turns are close together, and in horses working on their hindlimbs that are frequently exercised in soft, deep arenas. Short heels and long toes in the hindfeet seem to predispose to this lameness. When the etiology is severe trauma, such as a direct kick, the cartilage or the bone of the trochanter may be fractured, causing persistent lameness. It also has been found following an attack of strangles.

Clinical Signs and Diagnosis

Pain may be evident when pressure is applied over the greater trochanter. Careful interpretation is required, because some horses naturally tend to shy away when pressure is applied over the hip joint. When pushing on the greater trochanter, a normal horse should lean back into the clinician, but in cases of trochanteric bursitis, horses will move away from the examiner. At rest, the limb may remain flexed; as the horse moves, weight may be placed on the inside of the foot so that the inside wall of the foot wears more than the outside wall. This can be best seen when observing the horse from behind—the foot is carried inward and the horse sets the foot down on a line between the forelimbs. The horse tends to travel "dog fashion" since the hindquarters move toward the sound side because the stride of the affected limb is shorter than that of the sound side. After the condition has been present for some time, atrophy of the gluteal muscles occurs.

The foregoing symptoms should be used in diagnosis. The condition is difficult to differentiate from inflammation of the coxofemoral joint. The lameness, which is not common, may be confused with spavin lameness. A lameness of unknown cause is sometimes ascribed to trochanteric bursitis. Injection of a local anesthetic into the bursa is helpful in differentiating the condition from coxofemoral joint osteoarthritis (OA). Nuclear scintigraphy should identify the area as inflamed. Toth et al. compared four different techniques for trochanteric bursa centesis and concluded that centesis performed using a spinal needle with the ipsilateral foot non-weight-bearing and placed in a Hickman block positioned caudal to the contralateral foot.[93] Using the ultrasound can further increase the likelihood of successful centesis.[93]

Treatment

It is important to address any associated source of lameness. Rest and anti-inflammatory treatment may be helpful in some cases. Injection of the bursa with corticoids appears to be the most effective method of treatment. The authors have had success in treating the bursa with shockwave (1–3 treatments). Other reported treatments consist of injections of Lugol's solution of iodine into or around the bursa as a counterirritant. Hot packs applied to the affected area in the acute stages relieve some pain. Phenylbutazone therapy for 3–4 weeks may be useful. Treatment is difficult when the cartilage or bone has been damaged with fracture or periostitis. Although surgery may be indicated in these cases, no reports could be found regarding the use of surgery.

Prognosis

The prognosis is usually associated with the prognosis of a second source of lameness. If the other source is treated, as well as the bursa, the horse will usually return to soundness within 4–6 weeks. However, if there is no other source of lameness, or the injury is more severe, the prognosis is guarded to unfavorable, and the lameness may remain indefinitely or may recur when the horse is put back into training.

RUPTURED QUADRICEPS MUSCLE

Ruptured quadriceps muscle is a rare condition that causes the horse to present with a dropped stifle.[61] A single case of unknown etiology was observed in a nursing foal. The patella was prominent due to the cranial position of the stifle without the quadriceps attachment.[82] Anecdotally, quadriceps rupture has been observed following extensive resection of a calcified and fibrotic mass causing a fibrotic myopathy.

THE COXOFEMORAL JOINT

The femoral head and the acetabulum form a ball-and-socket articulation that makes up the coxofemoral joint. The heavy musculature and extensive ligament network surrounding and within the joint make the hip joint inherently stable.[23] The transverse acetabular ligament, ligament of the head of the femur (round), and

VetBooks.ir

femoral accessory ligament help to stabilize the coxofemoral joint.[23,45] In addition, the acetabulum is surrounded by a fibrocartilaginous rim that increases the bony margin of the acetabulum.

The accessory ligament is the largest and strongest ligament and is unique to equids.[45] It arises from the fovea capitis of the femoral head, passes through the acetabular notch to the pubic groove, and becomes part of the prepubic tendon. The smaller ligament of the head of the femur (round) arises in the head of the femur adjacent to the accessory ligament and attaches to the pubic groove.[45] This ligament of the head of the femur can be seen and debrided arthroscopically, but the accessory ligament is difficult to visualize.[62–64] The transverse ligament courses from the outer fibrocartilaginous rim medially across the acetabular notch.[45] The reader is referred to Chapter 1 for more detailed anatomy of the coxofemoral region.

In general, problems related to the coxofemoral joint appear to occur most commonly in foals, miniature horses, and ponies.[23,28,41,53,64] However, horses of any age may sustain damage to the coxofemoral joint from trauma. Most conditions are either developmental (osteochondrosis, osteochondritis dissecans, hip dysplasia), infectious (sepsis involving the coxofemoral joint or proximal femoral physis), or traumatic (tearing of the femoral accessory ligament, rupture of the round ligament, capital physeal fractures, hip luxation, IA acetabular fractures, and OA) in origin.

Many of these conditions cause a moderate to severe lameness and the limb is often outwardly rotated when viewed from the rear (toe-out, hock-in conformation) (Figures 5.157 and 2.97). In addition, the limb may appear straighter than the contralateral limb, and the horse may lean away from the affected limb (Figure 5.142). External swelling of the coxofemoral joint is often difficult to detect, but visual enlargement over the greater trochanter may be evident (Figure 5.158). Pain can often be elicited with direct inward pressure of this area. Rectal palpation may reveal swelling along the axial aspect of the joint but can only be performed in larger horses and gives many false-negative results. Crepitus with limb manipulation is not a common finding except with acetabular or more extensive pelvic fractures, hip luxations, or some cases of complete ligament rupture. Muscle atrophy (gluteal and quadriceps) can be found in some horses with chronic injuries to this area (Figure 2.98).

A definitive diagnosis of a hip problem can be challenging without additional diagnostics. Many horses can lack specific clinical signs such as pelvic asymmetry and/or crepitus. Arthrocentesis of the joint with or without IA anesthesia can be performed but is often difficult in large horses.[38,64] Transcutaneous ultrasound-guided arthrocentesis may be helpful in these cases.[19] In addition, it is often much easier to perform arthrocentesis of the hip in foals and ponies in lateral recumbency under anesthesia. In many cases of chronic hindlimb lameness, IA anesthesia is necessary to confirm that the hip is the site of the lameness. Rectal and transcutaneous ultrasound may be helpful to document capital physeal and acetabular fractures and hip luxations.[9,32] In foals, ultrasound provides good-quality images, but is unable to assess an accurate fracture configuration.[74] Nuclear scintigraphy has improved the potential to localize lameness to the hip region but does not provide a definitive diagnosis (high sensitivity/low specificity).[18] In many cases, radiography of the coxofemoral region using a standing technique or under anesthesia is necessary to either rule in or rule out a problem in the coxofemoral joint.[55,56,89] Geburek et al. reported an agreement of 73% between ultrasonographic and radiographic diagnosis of pelvic–femoral disorders.[29] In another report, a CT of two Warmblood fillies (270 and 210 kg) was performed under general anesthesia with good results, providing valuable information for both cases. However the authors acknowledged the cost and risk of this procedure under anesthesia.[95]

In general, the prognosis for horses with hip disease is guarded to poor for athletic use. However, this depends on the type of lesion, the extent of secondary OA, and whether the lesion is accessible for arthroscopic debridement.[62–64] Young horses with OCD lesions that can be debrided arthroscopically and foals with joint ill without secondary osteomyelitis appear to have the best

Figure 5.157. Young horse with asymmetry of the pelvis, muscle atrophy over the left hip, and a toe-out stance. The horse was lame at the walk and an acetabular fracture was present on radiographs.

VetBooks.ir

Figure 5.158. An older Quarter horse mare with grade 3 of 5 hindlimb lameness. Swelling over the left greater trochanter could be seen when compared with the opposite side, and pain was elicited with firm palpation. Radiographs revealed severe OA of the coxofemoral joint (Figure 5.163).

prognosis. Horses with complete rupture of the ligament of the head of the femur or accessory ligament, complete joint luxation, and OA tend to do poorly, regardless of treatment.

OSTEOCHONDROSIS OR OSTEOCHONDRITIS DISSECANS (OCD)/HIP DYSPLASIA OF THE COXOFEMORAL JOINT

Developmental lesions of the coxofemoral joint are rare in comparison with other joints in the horse. Malformation of the joint, hip dysplasia, osteochondritis dissecans, and subchondral cystic lesions (SCLs) have been described in the coxofemoral joint.[38,64,65,78,89]

Etiology

The cause of these developmental lesions is assumed to be the same as for other OCD-type lesions. It is unknown why there is a low prevalence of OCD-type lesions in the hip compared with other locations. Much of the coxofemoral joint is weight bearing; therefore, the development of SCLs could be trauma induced, similar to other weight-bearing joint surfaces.

Clinical Signs

Clinical signs of young horses with OCD of the hip may be similar to those of any hindlimb lameness. They may include a stilted hindlimb gait, low foot flight arc, shortened cranial phase of the stride, and dragging of the hindfeet.[65] In cases of bilateral disease, the hindlimbs may be carried very straight, and the weight shifted toward the forelimbs.[38,78,89] Physical abnormalities of the limb(s) or palpable pain may be difficult to document.

Diagnosis

Lameness in young horses may be localized to the hip by eliminating the remainder of the limb as the source of pain along with the characteristic stance of the limb. Physical examination findings may reveal pain on palpation and manipulation of the hip. IA anesthetic of the coxofemoral joint can be performed to aid diagnosis, but young horses do not tolerate the procedure very well. A definitive diagnosis is usually achieved via radiography. Better quality radiographs can generally be obtained under general anesthesia, although ventrodorsal and oblique radiographs of the pelvis can be performed in the standing horse.[55,56,64] Radiographic abnormalities consistent with OCD of the hip are similar to those of other locations and include SCLs, osteochondral fragments, abnormal contour of the femoral head or acetabulum, and shallow and irregular acetabulum (Figure 5.159A).

Treatment

Depending on the severity of the OCD lesion, conservative or medical treatment is usually unsuccessful. However, palliative treatments aimed at cartilage and joint healing may be used in young horses with the hope of joint remodeling over time. Surgical debridement of the lesion is usually the treatment of choice, especially if osteochondritis dissecans lesions are present.[64] Arthroscopy of the coxofemoral joint is more easily performed in foals and weanlings, but can be accomplished in older horses with proper equipment.[39,62–64] Surgical debridement is also the treatment of choice for affected cartilage and subchondral bone. However, access to all areas of the coxofemoral joint is not possible. In severe cases of unilateral hip malformation or dysplasia (Figure 5.159A), a femoral head ostectomy may provide a salvage procedure for breeding soundness.[80] These procedures are performed infrequently in the horse.

Prognosis

The coxofemoral joint is a major weight-bearing joint, and articular abnormalities such as OCD often lead to OA. Young animals with small OCD lesions that can be debrided arthroscopically and have minimal evidence of OA may do well.[64] However, the prognosis for most horses with hip OCD should be considered guarded to poor for future athletic use.

INFECTIOUS ARTHRITIS/PHYSITIS OF THE COXOFEMORAL JOINT

Infection of the coxofemoral joint and the capital physis of the femur are part of the joint ill complex in foals.[56,69] Infections around the hip occur less frequently than at other sites in foals and can be very difficult to diagnose.

Etiology

Joint and physeal infections in foals are hematogenous in origin, and bacteria usually gain access to the circulation through the umbilicus, gastrointestinal tract, or

VetBooks.ir

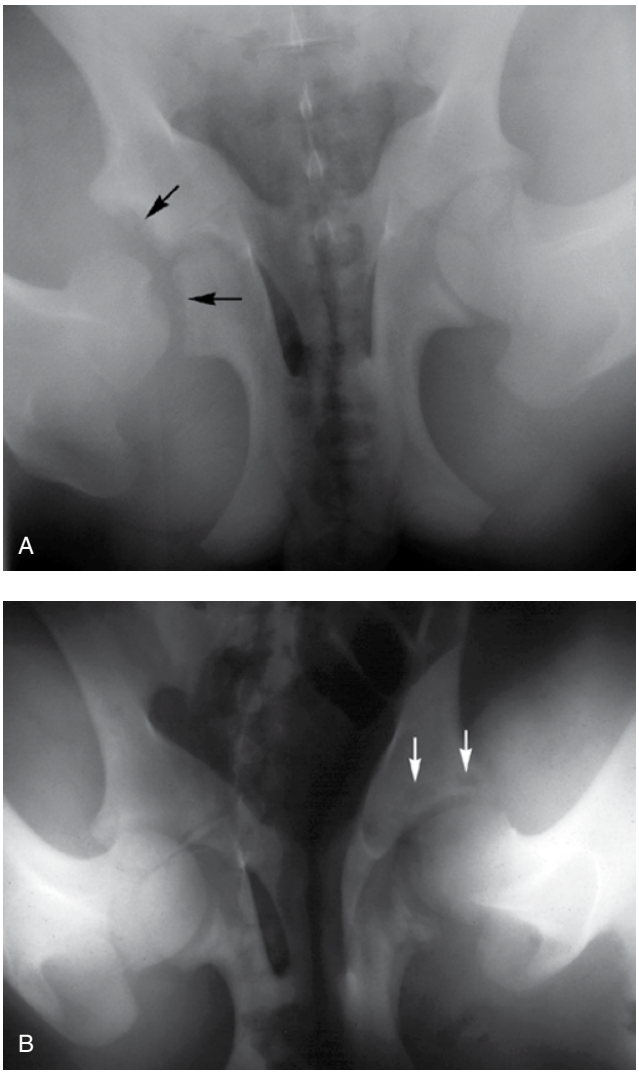

Figure 5.159. Ventrodorsal radiographs of the pelvis of two 3-month-old fillies with a history of increasing lameness. (A) Remodeling of the femoral head and acetabulum (arrows) consistent with a developmental abnormality. (B) Lysis of the left acetabulum (arrows) consistent with infectious arthritis and osteomyelitis.

respiratory tract.[54,68,84] Affected foals usually have a history of failure of passive transfer. Bacteria localize in and around the physes and joints because of the specific low-flow circulation that is present in these areas. The syndrome may be classified according to the location of the lesion: S-type involves the synovium/joint, E-type involves the epiphysis, and P-type involves the physis.[54] Most infections are from Gram-negative bacteria. Infection of the proximal femoral physis may spread to the coxofemoral joint and surrounding tissues of the hip region.

Clinical Signs

Infection of the coxofemoral joint can be a diagnostic challenge because joint effusion, heat, and pain are often not found on physical examination. Typically, these foals are less than 4 months of age and often present with a unilateral hindlimb lameness of unknown cause.[60] They may have a characteristic toe-out, stifle-out, hock-in appearance. Pain is often elicited with deep palpation over the greater trochanter and hip region. It can often be confused with trauma to the limb but the infection and therefore the lameness is often progressive, whereas a traumatic injury often improves with time. Any young foal with severe hindlimb lameness but no definable lesions in the lower limb should be suspected of having infection of the hip joint. In addition, infections of the capital physis can spread to the hip musculature, and the foal may present with an abscess in the gluteal region.

Diagnosis

A complete blood count is often very helpful to help differentiate trauma from a potential hip infection. High white blood cell counts and fibrinogen concentrations help confirm the presence of an infection.[60] However, a definitive diagnosis of infectious arthritis is made by analyzing the synovial fluid of the hip joint following arthrocentesis, with or without adjunctive IS anesthesia.[4] Synovial white blood cell counts of 30,000 cells/μL or more and total protein concentrations of 4.0 g/dL or more are consistent with infection. Physeal infections can be documented with radiographs of the hip region, where lysis around the capital physis, epiphysis, and occasionally the acetabulum is seen (Figure 5.159B).

Treatment

Treatment is similar as for any other joint/physis with a hematogenous infection. Broad-spectrum systemic antimicrobials, IA antimicrobials, and joint lavage/drainage are all important. Arthroscopy can be performed in small horses and foals to help lavage and debride these lesions, but cannula lavage alone can be very helpful.[4,39,62–64] Unfortunately, many of these infections are not diagnosed in the early stages, and significant osteomyelitis is often present, worsening the prognosis (Figure 5.159B).

Prognosis

The prognosis is usually poor because the diagnosis is seldom made before significant joint abnormalities and osteomyelitis have occurred. However, foals with coxofemoral infectious arthritis without radiographic abnormalities should respond well to aggressive treatment, and their prognosis for athletic use is similar to that of foals with joint ill at other locations.[4]

PARTIAL TEAR/RUPTURE OF THE LIGAMENT OF THE HEAD OF THE FEMUR (ROUND LIGAMENT)

A partial tear or rupture of the ligament of the head of the femur (round ligament) of the coxofemoral joint is a relatively rare condition that can affect any age or breed of horse. Nevertheless, it appears to be more common in small-breed horses (miniatures and ponies) and young horses.[64] The hip joint is usually very stable, but occasionally a partial tear or complete rupture of ligament of the head of the femur can occur without a complete joint luxation. In these cases, the head of the

VetBooks.ir

femur may have greater range of motion within the joint, contributing to synovitis, joint effusion, and lameness.[38] Subsequent degenerative changes within the joint often lead to OA. Definitive diagnosis of a ruptured ligament of the head of the femur can be difficult.

Etiology

Trauma is the most common cause of either a partial tear or complete rupture of the ligament of the head of the femur. The same type of forces/stresses that cause luxation of the coxofemoral joint may also damage this ligament without resulting in a joint luxation.

Clinical Signs

Affected horses with complete rupture of the ligament of the head of the femur often have an acute onset of lameness and a history of trauma. Visible swelling over the hip is often difficult to detect, but gluteal atrophy may be present if the condition is chronic. Horses often stand with a toe-out, stifle-out, and hock-in appearance of the affected hindlimb that is typical of problems in the coxofemoral region.[38] Unlike horses with a complete hip luxation, the limbs are the same length, and the points of the hocks are at the same height.[38] Firm intermittent pressure applied over the greater trochanter usually elicits a painful response. Limb manipulation, flexion of the hip joint, and upper limb flexion tests may also be painful. Crepitation over the joint may be present because of the excessive motion of the femur but can be difficult to document.[2]

The clinical signs associated with partial tearing of the ligament of the head of the femur are not as clear as those seen with complete rupture of the ligament. The hock-in and stifle and toe-out appearance is generally not observed, and these horses may present with a chronic hindlimb lameness. Varying degrees of gluteal muscle atrophy may occur in chronic cases, but this is not a consistent finding. Limb manipulation, particularly hip abduction and flexion of the joint, may be present but less so than with complete ligament rupture. Intermittent firm pressure applied externally to the greater trochanter usually elicits a painful response.[2]

Diagnosis

A presumptive diagnosis of a complete rupture of the ligament of the head of the femur is based on a history of trauma combined with an acute lameness with clinical signs characteristic of a hip problem. However, several other hip-related injuries (capital physeal fractures, other ligamentous injuries, acetabular fractures) may present with similar histories and clinical signs. Hip luxations usually can be ruled out based on the limb length.[38] Although the clinical signs often localize the problem to the hip region, intrasynovial anesthesia may be required to prove that the joint is affected. Aspiration of hemorrhagic synovial fluid during arthrocentesis is consistent with joint trauma. See Chapter 2 for additional information regarding the technique for intrasynovial anesthesia of the hip joint.

Radiography or ultrasound of the hip region is necessary to rule out other possible problems. Ventrodorsal and oblique radiographs of the hip can be performed with the horse under general anesthesia or standing. Radiographs of the hip may be normal with rupture of the ligament of the head of the femur and avulsion of the insertion of the round ligament,[66] or an abnormal position of the femoral head within the acetabulum may be identified.[2] Subluxation of the coxofemoral joint may also be diagnosed with dynamic ultrasound (weight-bearing and non-weight-bearing views) of the hip region in standing horses.[9] An abnormal position of the femoral head seen on radiographs or with dynamic ultrasound together with hemarthrosis of the hip identified with arthrocentesis is highly suggestive of an acute ruptured round ligament. If the condition is chronic, radiographic signs consistent with OA are often present. These include osteophytes on the cranial and caudal rim of the acetabulum and at the capsular attachment on the femoral neck.[64]

Diagnostic approaches used to identify a partial tear of the accessory ligament may include scintigraphy, radiography, and arthroscopy. Although not diagnostic for a partial tear, scintigraphy may show a mild to moderate radionucleotide accumulation in the affected hip, particularly if secondary degenerative joint changes are present.[38,49,63,64] This is often recognized as being able to clearly recognize the entire ball of the proximal femur on the scan. Radiography may identify changes associated with OA of the hip joint but is not specific for damage to the ligament of the head of the femur. Subluxation of the coxofemoral joint due to partial tearing of the ligament of the head of the femur was diagnosed in 2 horses with dynamic ultrasound and should be considered in these cases.[9] Arthroscopy of the coxofemoral joint also may be used to diagnose and potentially treat (debridement) partial and complete ruptures of the ligament of the head of the femur.[62–64]

Treatment

There is no effective treatment for complete rupture of the ligament of the head of the femur of the hip joint. Affected horses often develop OA and remain lame.[64] However, arthroscopy of the hip joint has been used successfully to debride partial tears of the round ligament and to perform a synovectomy.[62–64] Ligament tearing in small breeds of horses, particularly miniature horses, can be adequately debrided, and a return to soundness is possible.[64]

Prognosis

The prognosis is poor for horses with complete rupture of round ligament, regardless of treatment. Secondary OA of the hip joint appears to be a likely sequela. However, the response to debridement of partial tears in small-breed horses has been favorable in a limited number of cases.[64]

COXOFEMORAL SUBLUXATION AND LUXATION (DISLOCATION OF THE HIP JOINT)

Subluxation or luxation of the coxofemoral joint is an uncommon condition in horses compared with cattle because of the numerous ligaments and heavy musculature surrounding the joint. The femoral accessory ligament

VetBooks.ir

and the round ligament both attach to the femoral head and provide the primary stability to the hip.[23] The fibrocartilaginous rim around the acetabulum further stabilizes the head of the femur within the joint. In horses, the ilium tends to fracture before the hip luxates.[38] Foals, miniature horses, and ponies are most frequently affected.[23,38,53,69,72] Coxofemoral subluxation and luxation are generally unilateral, and the head of the femur nearly always becomes craniodorsal to the acetabulum.[10,23]

Etiology

Both the accessory and the ligament of the head of the femur (round) must rupture for a luxation to occur.[38] Trauma is nearly always the cause. Violent overextension and falling on the point of the stifle with the femur in a vertical position occasionally produce fracture and/or subluxation or luxation of the coxofemoral joint.[10,38] A tethered horse that catches its foot in a rope or a halter may dislocate the hip in the struggle to free itself.

Because the acetabulum is deep and the head of the femur is large, excessive trauma is usually necessary to dislocate this joint. Fractures of the dorsal rim often accompany the luxation because of the deep acetabulum in the horse.[38] Additionally, absence or partial tearing of the ligament of the head of the femur may predispose to subluxation and luxation with or without associated trauma.[2,9,38]

Coxofemoral luxations may be complicated by upward fixation of the patella.[16,28,38] The upward patellar fixation may potentially contribute to the luxation or occur because of it. If it precedes the luxation, the secondary hip luxation is believed to occur as a result of the violent contraction of the quadriceps muscles trying to flex the limb while the stifle is locked in extension. The net result is that the head of the femur luxates out of the acetabulum rather than the stifle flexing.[38] The patella usually becomes unfixed at the time of the luxation. Alternatively, the patella becomes locked following the luxation because the craniodorsal position of the femur causes the limb to become much straighter, predisposing to upward fixation of the patella (Figure 5.160). Luxation of the hip also may occur secondary to wearing a full-limb hindlimb cast, especially in foals.[94]

Figure 5.160. Horse with luxation of the hip and concurrent upward fixation of the patella. The craniodorsal positioning of the femoral head straightens the limb, contributing to upward fixation.

Clinical Signs

A history of trauma resulting in a severe non-weight-bearing lameness is common; other horses present with a chronic history of lameness of varying degrees at the walk. Gluteal and quadriceps atrophy can be a common feature in many horses. Some horses may toe touch when walked because the affected limb is shorter than the opposite limb due to the craniodorsal position of the femur.[23] In the case of luxation, the limb may "dangle" somewhat because of shortening and the point of the hock on the affected side is higher than that of the opposite limb (Figure 5.142). The toe and stifle turn outward and the point of the hock turns inward (Figure 2.97). In cases of subluxation, such findings are usually not observed. Affected horses generally have a limited cranial stride because of limb shortening and a more prominent greater trochanter of the femur. Soft tissue swelling may make this prominence difficult to see in the early stages. Crepitus with limb manipulation may be present as a result of the femur rubbing on the shaft of the ilium.[38] This may also occur with acetabular and pelvic fractures. Pushing the greater trochanter in a caudal to cranial direction may displace the femur further cranially than normal when a hip luxation is present.

Diagnosis

A presumptive diagnosis can often be made based on the history and clinical signs. Radiography confirms the diagnosis and also rules out other possible causes of the lameness such as pelvic fractures, acetabular fractures, and capital physeal fractures (Figures 5.161 and 5.162).[55,56] In cases of the subluxation, radiographs should be performed with the limb weight-bearing in order to identify the problem (Figure 5.161).[100] Ultrasound is being used in the ambulatory and hospital setting to examine the pelvic region and may be able to confirm subluxation or luxation of the femoral head.[10,32] A low-frequency (2.5–5.0 MHz) curvilinear transducer should be used, and the area should be evaluated with the horse in a weight- and non-weight-bearing position.[10] The evaluation of the coxofemoral

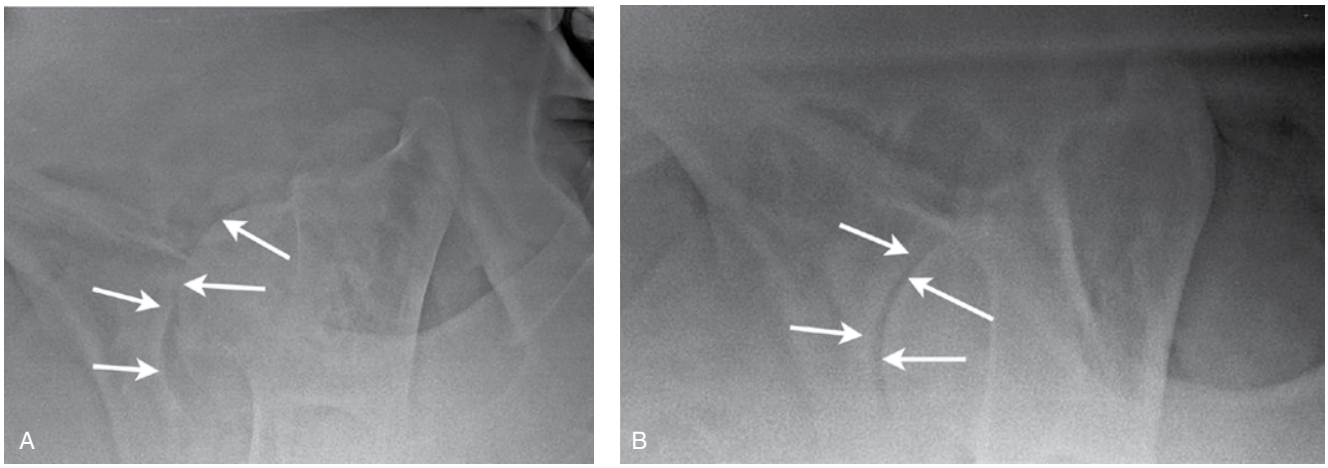

Figure 5.161. Standing, weight-bearing, lateral oblique radiographs of the pelvis in an adult horse confirming a subluxation of the femoral head (A; arrows) compared with the normal opposite limb (B).

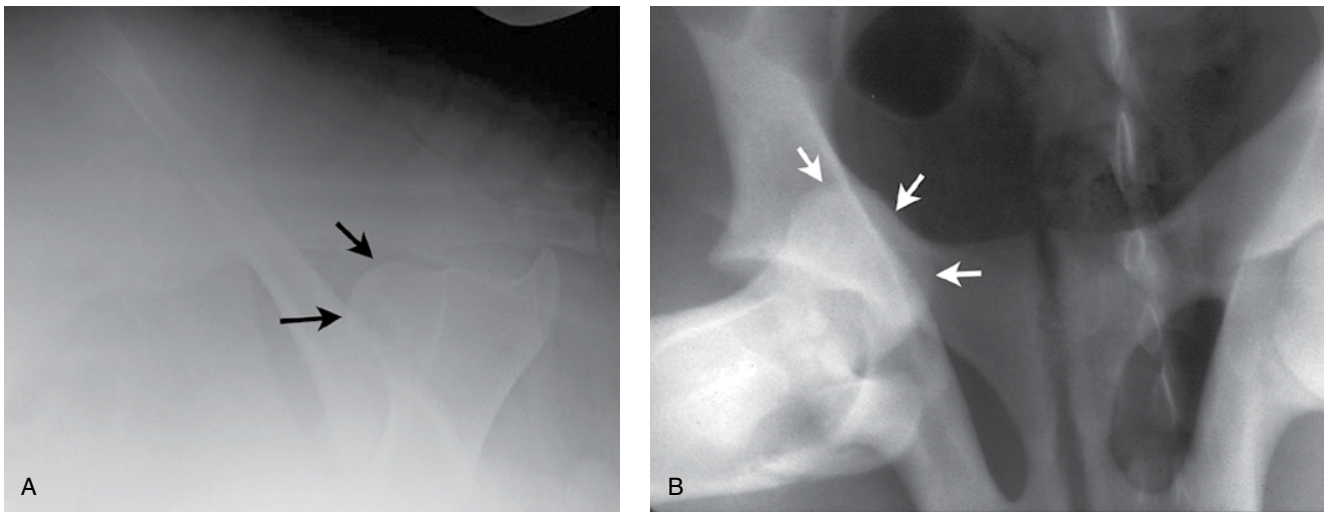

Figure 5.162. Lateral standing radiograph of the pelvis in a miniature horse (A) and ventrodorsal radiograph under general anesthesia in an adult horse (B) confirming craniodorsal luxation of the femoral head (arrows).

joint during weight-bearing is very important in the ultrasonographic diagnosis because the subluxation might only be seen in this phase. The differentiation with luxations can be based on the ability of the head of the femur to return to its normal position when horses rest the affected limb.[10] In both subluxation and luxation of the coxofemoral joint, there is usually craniodorsal displacement of the femoral head from the acetabulum (Figures 5.161 and 5.162). On ultrasound severe OA, acetabular rim fractures and severe effusion and synovitis (cranioventral recess) may also be seen.[100]

Treatment

In general, treatment of hip luxation is problematic, especially in adult horses. Many horses with this condition are euthanized because of the often unsuccessful treatment options and the poor prognosis. Closed reduction of the luxation is usually the best treatment option, but it can be very difficult to perform in adult horses and re-luxation is common. The likelihood of re-luxation after closed reduction increases if the dorsal rim of the acetabulum is fractured. If the luxation is chronic, the acetabulum may be filled with fibrin and granulation tissue, preventing a successful closed reduction. In a recent report of 17 cases of coxofemoral luxation, 35% had other orthopedic injuries, and no form of closed or open reduction was successful.[53]

Horses with an acute luxation with no secondary fracture of the dorsal rim of the acetabulum are the best candidates for closed reduction. General anesthesia with or without muscle relaxation is required. The luxation may be reduced by manual traction and

VetBooks.ir

manipulation if good muscle relaxation is obtained.[38,53] Traction also can be applied by using a hoist with the horse placed in dorsal recumbency or with a calf jack if lateral recumbency is selected. Traction combined with external rotation and adduction of the limb followed by internal rotation as the traction is reduced completes the reduction. Reduction can be appreciated when the hip clicks or pops into place. Closed reduction is often difficult, and even when it is successful, re-luxation may occur within a few days.[28,53] An Ehmer sling was used to prevent re-luxation after the second closed reduction in a pony and successfully improved the outcome.[16] However, this is only possible in foals or small-breed horses.

Several surgical approaches have been described for cases that re-luxate or those that cannot be corrected with closed reduction. However, these are most applicable for foals or small-breed horses. They include open reduction alone, transposition of the greater trochanter, femoral head and neck resection, toggle pinning, or augmentation of the lateral joint capsule with synthetic sutures attached to screws.[2,23,28,47,69,72,92] A combination of toggle pinning, synthetic capsular repair, and trochanteric transposition was used to successfully repair a hip luxation in an adult miniature horse.[28] In a case report, a hip arthroplasty was performed in an 8-week-old dwarf Friesian filly with a history of traumatic subluxation of the coxofemoral joint. Initial short-term success was reported; however the horse died 5 days after the surgery.[40] Open surgical approaches should be performed soon after the luxation occurs; otherwise, contraction of the musculature will make reduction difficult. In addition, excision of the femoral head and neck and dorsal rim of the fractured acetabulum should be considered in smaller horses to aid in the development of a pseudoarthrosis.[27,38,80]

Prognosis

In cases where there is a combination of acetabular fractures and subluxation, the prognosis is poor. In cases where the subluxation is the only problem, the prognosis can be better.[10] In horses with complete luxation, the prognosis is typically guarded to poor because successful closed reduction is not always possible. Conservative treatment is not an option and euthanasia is recommended. A minority of horses may return to complete soundness after the head of the femur is replaced, but this is the exception.[38] There is usually a better chance of maintaining permanent reduction if the femur stays in place for approximately 3 months.[38] Most horses can become sound enough for breeding purposes if the reduction can be maintained.[38] Surgical correction may be warranted if the horse is valuable and small, but is performed infrequently.

OSTEOARTHRITIS (OA) OF THE COXOFEMORAL JOINT

OA of the coxofemoral joint is a sequela to all of the conditions described in this section. It can also occur from any type of soft tissue trauma to the hip region that does not necessarily result in a ligament injury or IA fracture. Trauma to the joint capsule and surrounding musculature can contribute to the development of OA. It is seen most frequently in older animals and must be considered in any horse with chronic hindlimb lameness.

Etiology

Any hip-related traumatic injury can lead to OA. Reported causes of coxofemoral joint OA include idiopathic infection,[15] abnormal development of the coxofemoral joint,[78,94] joint ill, and trauma.

Clinical Signs

No clinical signs are specific for coxofemoral joint OA. However, hip OA should be suspected in older horses with chronic hindlimb lameness problems that have a history of trauma (Figure 5.158). Many of these horses have significant lameness (grade 3–4 on a scale of 5) and have a low arc of foot flight and a reduced cranial phase of stride. Horses with hip pain tend to move with the limb rotated externally and carry the limb abducted during advancement. Firm swelling over the greater trochanter and hip area may be present in chronic cases, and the characteristic toe-out, hock-in stance may or may not be observed. In horses with bilateral disease, the hindlimbs are often carried very straight with a shift of weight onto the forelimbs.[38]

Diagnosis

A presumptive diagnosis of severe hip OA often can be made based on the history and clinical exam. Milder cases of OA can be a diagnostic challenge. IA anesthetic of the coxofemoral joint is the best method to localize the lameness to the hip. Nuclear scintigraphy may be helpful to localize the problem to the hip but is not very sensitive nor specific for coxofemoral joint OA.[18] Radiographs are often necessary for a definitive diagnosis and usually reveal evidence of bone remodeling and osteophyte production in chronic cases (Figure 5.163). Good-quality radiographs of both hips (to permit comparison between the two) are necessary to diagnose mild to moderate hip OA. Ultrasound can also be used; however it is challenging to determine whether the ultrasonographic changes noted are result of the progression of OA or whether they are there from the initial injury.[100]

Treatment

Treatment of hip OA is usually palliative because there is no cure. Horses with unilateral mild or moderate OA may benefit from coxofemoral joint arthroscopy to debride cartilage lesions and determine the inciting cause. Focal femoral head cartilage lesions have been debrided with good results in a limited number of cases.[64] Horses with hip OA usually respond well to oral NSAIDs and/ or IA treatment with hyaluronan and

VetBooks.ir

Figure 5.163. Ventrodorsal radiograph of the pelvis of the horse in Figure 5.158 demonstrating severe OA of the coxofemoral joint. The OA was reportedly secondary to trauma to the area from a previous fall.

corticosteroids. However, IA injections are often needed every 4–6 months. Horses with mild or moderate hip OA may benefit from medications directed at joint healing such as IV hyaluronan, IM polysulfated glycosaminoglycans, and oral nutraceuticals.

Prognosis

There are no long-term reports on the prognosis of horses with coxofemoral joint OA. In general, any treatment is a temporary fix, and the prognosis for athletic use in horses with severe OA is thought to be poor. However, many of these horses can be used for breeding or maintained as pets because they tend to do well at the walk. Horses with mild or moderate OA may respond well to treatment and may be used at a reduced performance level.

CAPITAL PHYSEAL FRACTURES OF THE FEMORAL HEAD

Fractures of the capital physis of the femoral neck occur commonly in foals under 1 year of age.[25,41] They are usually a type I Salter–Harris physeal fracture (Figure 5.145), but types II (Figure 5.143C) and III are also observed.[25,41] Another term that has been used to describe them is a "slipped capital physis" (Figure 5.145).

Etiology

Traumas such as violent falls, struggles, and kicks are the cause of these fractures. In particular, falling on the greater trochanter is thought to cause shearing forces across the physis, resulting in displacement between the epiphysis and metaphysis.

Clinical Signs

There is usually a history of trauma with an immediate severe lameness. However, some foals are still able to bear some weight but often stand with a toe-out, hock-in appearance. Swelling and pain over the hip, pelvic asymmetry, gluteal muscle atrophy, and crepitus with hip manipulation may be present. However, these signs were found inconsistently in a report of 25 foals with capital physeal fractures.[41]

Diagnosis

Because of the inconsistency of clinical signs, radiography of the hip is necessary for an accurate diagnosis. Separation of the epiphysis and metaphysis of the femoral neck confirms the diagnosis (Figures 5.143 and 5.145). However, other radiographic abnormalities are often found, such as comminution of the epiphysis, greater trochanter or acetabular fracture, or coxofemoral joint luxation/subluxation.[15] Concurrent radiographic findings often make potential surgical repair unlikely. Ultrasound has also been used to diagnose a gap between the femoral head and neck with varying degrees of displacement. Careful interpretation in the appearance of the cartilage and physes is important when ultrasounding foals. The contralateral limb should be evaluated for comparison.[74]

Treatment

Nonsurgical management of these fractures is not recommended because malunion, avascular necrosis, and secondary hip OA can lead to debilitating lameness.[41,97] However, surgical treatment is difficult and is not recommended in foals with concurrent radiographic abnormalities. Surgical treatments that have been used to repair capital physeal fractures include the use of cancellous or cortical bone screws, IM or Knowles pins, and an interfragmentary compression system.[41,42,50,77,97] Small foals with a Salter–Harris type I or II physeal fractures are the best candidates for surgery.

Prognosis

Unfortunately, the majority of foals with this condition are euthanized because of the poor prognosis with nonsurgical treatment and the questionable results with surgery. If the epiphysis can be reduced and maintained until healing, athletic soundness can be achieved.

INTRA-ARTICULAR ACETABULAR FRACTURES

Acetabular fractures can occur independently or together with other fractures of the pelvis. They may be nondisplaced but more frequently are comminuted and displaced. They appear to be more common in young horses and frequently result when the horse slips or splits (spread eagle).[38]

VetBooks.ir

Etiology

Trauma is the cause in nearly all cases. Stress or fatigue fractures occur elsewhere in the pelvis such as the ilium, but are usually not confined to the acetabulum.[23]

Clinical Signs

Horses with acetabular fractures present with similar clinical signs as horses with pelvic fractures or hip disease. They usually have a significant unilateral lameness and may have gluteal muscle atrophy if the condition is chronic. Swelling, pain, and crepitus may be palpable over the greater trochanter, and there is often pelvic asymmetry if other pelvic fractures are present (Figure 5.157). A rectal examination may also reveal swelling axial to the coxofemoral joint, but it may be difficult to detect with acetabulum fractures alone.

Diagnosis

Nuclear scintigraphy can be valuable in identifying that the cause of lameness is in the hip,[18] but ultimately radiography or ultrasound is necessary to document an acetabular fracture and rule out other possible problems in the hip and pelvis (Figure 5.164).[23,32,55] Nondisplaced acetabular fractures may be difficult to visualize with ultrasound. However acetabular rim fractures are easier to diagnose with ultrasound. Both transcutaneous and transrectal ultrasound should be performed to evaluate the area. Concurrent fractures of the pelvis and hip are not uncommon.

Figure 5.164. Ventrodorsal radiograph of the coxofemoral joint demonstrating a minimally displaced acetabular fracture. Intra-articular fragmentation was not identified, and the horse was treated with stall confinement.

Treatment

Conservative treatment with stall confinement is often the treatment of choice with acetabular fractures. Euthanasia may be indicated with severely displaced fractures because there is no known surgical treatment. Small IA fractures from the cranial and caudal perimeter of the acetabulum may be removed from the joint with the arthroscope to potentially improve the prognosis.[64] However, removal of large fragments appears to rarely be successful. Minimally displaced acetabular fractures heal very well with confinement, and horses often can achieve their full athletic potential (Figure 5.164).

Prognosis

In general, horses with fractures of the acetabulum have a worse prognosis for soundness than those with fractures elsewhere in the pelvis.[23,72,75] However, most acetabular fractures respond better to conservative treatment than many other hip problems such as capital physeal fractures, luxation, and round ligament rupture. Approximately 20% of horses with articular fractures are capable of athletic performance.[76] However, this greatly depends on the fracture configuration and degree of displacement.

ACKNOWLEDGMENT

The authors thanks Dr. Kenneth E. Sullins and Gary Baxter for their contributions to this chapter in the previous edition.

CHAPTER

Lameness Associated with the Axial Skeleton

THE AXIAL SKELETON

Rob Van Wessum

Back pain is increasingly recognized as contributing to or even causing equine lameness.[1,4,8,16,19] Previously back pain was generally considered to be a secondary problem, with the primary lameness of a limb causing changes in movement and affecting the spine. In recent years, more and more primary spine injuries have been acknowledged.[2,8,10,11,19] To understand the function of the vertebral column, its attached tissues, and their relationship to the physics of equine locomotion, some basic anatomical and biomechanical knowledge is necessary.

ANATOMY AND BIOMECHANICS OF THE VERTEBRAL COLUMN

There are approximately 260 joints between the vertebrae; the vertebrae and ribs, the sacrum and pelvis, and the head and the first cervical vertebra all contribute to mobility in the entire spine. In most of these joints, the total range of motion is limited in both direction and degree, but the overall effect of all of the joints within the spine creates a significant amount of motion in the entire spine.[3,9] Because of its connection to the limb, a major function of the spine and the attached muscles is the positioning of the limbs. Some of the muscles controlling limb position have their origin at the spine and their insertion on an extremity; other muscles with both origins and insertions on the spine regulate mobility in the spine itself.

Joints of the spine allow mobility dorsally, ventrally, and laterally, and some allow rotation. In particular areas of the spine, the vertebrae have specific ranges of motion within the three basic axes: lateroflexion, dorsi- and ventroflexion, and rotation. Any specific change in the posture of the horse causes a change in the direction in one or more of these three planes. The cervical intervertebral joints allow a relatively large range of flexion dorsiventrally as well as laterally, while the intervertebral joint between the first and second cervical vertebra permits rotation. In the thoracic vertebrae the mobility is mainly lateral flexion, with some minor dorsiventral motion. In addition, the mobility of the costovertebral joints is necessary for breathing. In the lumbar spine the main mobility is in dorsiventral flexion with some rotation. In the sacral region there is a small amount of dorsiventral flexion, while in the tail there is considerable dorsiventral and lateral flexion but no rotation.[3,4]

The pattern of motion of the spine also is gait specific. The support and the positioning of the spine are a specific function of each gait, enhancing the range of motion of the extremities by facilitating optimal positioning of the limb relative to the spine and the other limbs. The axial muscles can function as a stabilizer of the spine and hold certain portions of the spine during locomotion. The epaxial muscles are symmetrically arranged between the transverse and dorsal spinous processes. The spinalis muscle, semispinalis muscle, and multifidus muscle form the most axial and deepest epaxial muscle group. The multifidus muscle consists of a large number of separate muscle units, each covering only two to six vertebral segments along the entire vertebral column. The middle epaxial muscular layer, called the lateral system, extends from C1 to the pelvis and sacrum. The iliocostal muscle forms the most abaxial part of this system, and longissimus muscle forms the

medial part, which is very well developed in the lumbar region. The splenius muscle in the cervical and cranial thoracic region forms the most superficial layer of epaxial muscles.

Walk

In the walk, the main motion of the spine can be described as a "snakelike" motion. A sinusoidal pattern of motion is present in the spine with lateral flexion in the thoracic region, some rotation in the lumbar spine, and dorsiventral flexion in the cervical region, all contributing to support the walk.[5] Electromyographic evaluation has shown the action of the splenius muscles is to elevate the head and neck and facilitate forelimb protraction by the elongated brachiocephalicus muscle. The sternocephalicus muscle contributes to the stance phase of the front limb. The longissimus dorsi muscle acts during the stance phase of the hindlimb, whereas the rectus abdominus muscle is not active at all but limits vertical acceleration of the abdominal visceral mass. The multifidus lumborum muscle is active in the intermediate part of the stance phase of the ipsilateral limb, and the obliquus externus abdominal muscle shows intermittent activity.[4]

Trot

At the trot there is only modest dorsiventral flexion in the thorax and the neck. The maximal thoracolumbar extension occurs in the mid stance phase due to the visceral inertia. The splenius muscle acts before and during the first part of the stance phase of each forelimb to limit lowering of the neck, and the sternocephalicus muscle controls neck elevation. The brachiocephalicus muscle acts to achieve protraction of the forelimb. The rectus abdominus muscle limits the passive thoracolumbar extension caused by the visceral mass inertia during the stance phase. The longissimus dorsi muscles act at the end of the stance phase and during the suspension phase to induce lumbosacral extension to facilitate hindlimb protrusion. In the trot, most muscles act to stabilize the spine, not to move it.[5,6]

Canter

There is more lumbar and sacral motion in the canter than in any other gait, with lumbar rotation and dorsiventral flexion in the lumbar, thoracic, and sacral spine.[7] In the neck, the splenius muscle is active during the trailing diagonal stance phase. It limits the neck to lower and causes neck extension during the leading stance phase, and the sternocephalicus muscle shows reciprocal activity. The brachiocephalicus muscle is mainly active during the stance phase. The longissimus dorsi muscles are active during the suspension phase and during the trailing hindlimb stance phase. The rectus abdominus muscles act reciprocally during the support phase of the non-leading diagonal to support the visceral mass and initiate thoracolumbar flexion. The sublumbar muscles, psoas major and minor, are active during the suspension phase and are part of the propulsion forces in the canter.[4]

Table 6.1. Mobility of the spine.

		Part of the spine			
Gait	Axis	Cervical	Thoracic	Lumbar	Sacral
Walk	DV	++	+	+	+
	Lat	+	++	–	+
	Rot	+–	–	+	–
Trot	DV	+	+	–	–
	Lat	–	–	–	–
	Rot	–	–	–	–
Canter	DV	++	+	+++	++
	Lat	+–	+	–	–
	Rot	–	–	++	+

DV = dorso- and ventroflexion, Lat = lateroflexion, Rot = rotation, – = not present, + = minor mobility, ++ = major mobility, +++ = maximum mobility.

Table 6.1 is an overview of the degrees of mobility and their relationship to the three gaits. It is easy to understand that this relationship can make a lameness examination more of a challenge. Some common symptoms are associated with specific parts of the spine, as shown in Table 6.2.

History

As in every examination, investigating the horse with back pain starts with the history.[12] Taking time for a good interview with the client is the first step to better comprehend the problem. Listening to the information provided by the client is a good start. Asking guiding questions such as whether there are time-related changes in the quality of the gaits or difficulties in keeping the correct lead can provide information about the gait in which the complaints are more evident. Common complaints from owners of horses with back problems include resistance to bending to one direction more than to another; not accepting the bridle; kicking and bucking (especially in one gait, most commonly the canter); poor-quality canter, cross canter, or switching leads; or generalized stiffness.[1] The poor-quality canter may be a no-sound, 4-beat canter, more "bunny-hop-like" with less separation between the subsequent footfalls of the hindlimbs.

Some complaints are specific to the discipline. Complaints indicative of back pain in dressage horses include difficulties in the walk and canter pirouettes, a poor quality or a lateral walk, and unsatisfactory collection and "coming under" (carriage of the hindquarters). In jumpers, common complaints are unsatisfactory bascule (balance above the fence), lack of

propulsion and power, unwillingness to jump and/or turn, and landing in the wrong lead canter. The quality of the lope is a complaint in Western pleasure horses. In racing horses, back pain is often located in the lumbar region, which can limit dorsiventral flexion, thus decreasing propulsion and reducing the efficiency of the canter and gallop and ultimately leading to poor performance.

Other usual lameness issues also may be mentioned. Forelimb lameness can be a result of thoracic problems because the attachment of the scapula to the thoracic spine causes painful mobility in the thoracic vertebrae.[4,13,15] A reduced stride length of a hindlimb or lack of propulsion can be caused by pain in the lumbosacral region,[10,11,14,15] and a lowered hip can be a sign of back pain as well as an indication of hindlimb lameness.

VetBooks.ir

Clinical Examination

Clinical examination of the horse is performed as with any lameness case, with more emphasis on observation of lateral bending in walking serpentines and circles at the walk, trot, and canter. The quality of the walk (4-beat) and canter (3-beat) can give essential information about location of a lesion within the spine due to the specific loads that are generated by these gaits to specific parts of the spine (Table 6.1).

In the walk and trot in hand on a straight line, observation of the gait and the position of the hindlimbs in relation to the front limbs and the position of the tail can assist in assessing for the presence and location of back pain. For example, do the hindlimbs track the forelimbs, and are the haunches more to one side? Because there is more mobility of the lumbosacral spine in the canter, lumbosacral pain is more obvious at this gait. By contrast, thoracic pain appears more as stiffness in the trot and resistance to going downhill, or in making downward transitions from canter to trot or trot to walk. More detailed signs and the locations they may identify are presented in Table 6.2.

Information gleaned from palpation of the back can be confusing. Most horses with any kind of back pain exhibit some muscle tension in the epaxial muscles. It is nearly impossible to differentiate between muscle tension caused by guarding spinal structures and primary muscle tension due to muscle problems. See the section on muscle diseases in Chapter 7.

Sensitivity to touch or pressure is another symptom that can be difficult to interpret. Some horses initially show a defensive reaction to every contact with their back, even when there is no pathological condition present. To make an initial differentiation, touch or apply pressure very gently and when the horse resists, maintain it and wait for the initial reaction to fade. In behavioral issues, when the pressure persists without correction or change, quite often the initial resistance will diminish. With pain, the same reaction will be shown over and over again.

Manual compression of the muscles in the withers area can give information about sensitivity of this region, which can indicate saddle fit issues (see the section on saddle fit in Chapter 10), as can spots of white hairs in this region. Bald spots or spots with damaged hairs are another indication of poor saddle fit as a cause for back pain and related muscle tension.

Specific Tests

Passive mobility tests should be performed to assess the mobility of the spine and the range of motion within every part of the spine.[18] Symmetry of range of motion is very important because muscle tension, which is a manifestation of pain, impedes symmetrical movement.[17] Gentle bending of the neck to the left and right, with one hand of the examiner on the head of the horse and the other fixing a specific cervical vertebra, provides information about the intervertebral mobility as well as the range of motion to the left and the right (Figure 6.1). A carrot or other palatable treat used to tempt the horse to move its head can indicate the willingness of the horse to bend its neck laterally and dorsoventrally. Lifting the head allows assessment of the amount of dorsiflexion as well as the symmetry of the muscles and location of anatomical landmarks on the ventral aspect of the neck (Figure 6.2).

In the thorax, a similar manipulation (pulling on the tail with one hand and placing the other arm as a fulcrum at an individual horizontal process of a specific vertebra) provides information about the range of motion and intervertebral mobility in the lateral plane (Figure 6.3). Palpation of the withers, dorsal processes of the thoracic vertebrae, and associated muscles indicate pain in this region that is very susceptible to discomfort caused by poor saddle fit. Triggering the dorsiflexion reflex by pressure with a pen in a paramedian motion

Figure 6.1. Flexion of the neck to the right. The left hand of the examiner is at C6, while the right hand gently asks for lateral motion.

Figure 6.2. Extension of the neck. The examiner lifts the head of the horse, evaluating the extent of stretching of the neck and symmetry of the cervical vertebrae in a ventral aspect.

VetBooks.ir

Figure 6.3. Lateroflexion of the caudal thoracic spine. The examiner pulls on the tail with the left hand to gain lateral excursion of the spine, while the right hand functions as a fulcrum on the transverse process of T17 so the mobility between T17 and the more caudal spine can be evaluated.

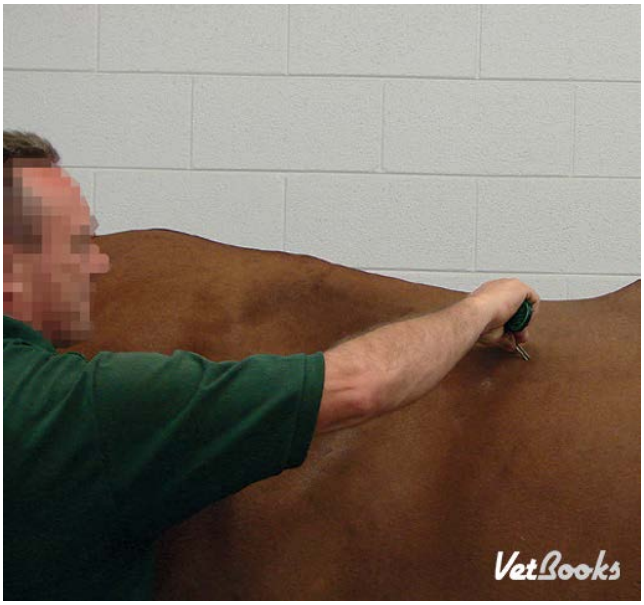

Figure 6.4. Moving a key on the back from cranial to caudal in a paramedian line checks for the reflectory movement of the horse with dorsiflexion and some lateroflexion.

from cranial to caudal (Figure 6.4) gives information about dorsal mobility in the thoracolumbar spine as well as symmetry in these reflexes. The same technique applied to the ventral aspect of the thorax and abdomen provides information about ventral mobility. An evasive reflex to these procedures is normal and absence of such reflexes can be neurological in origin (lack of skin sensation) or a consequence of pain that occurs when the spine is in motion.

Figure 6.5. Lateroflexion of the lumbar spine, as in Figure 6.3, now with the hand as a fulcrum on the transverse process of L3.

Specific manipulation techniques in the lumbosacral region can yield information about the mobility of the spine. Lateroflexion of the lumbosacral spine and rotation of the lumbar spine can be tested by pulling intermittently on the tail base with one hand while fixing the spine at the tuber coxae with the other "fulcrum" hand (Figure 6.5). Information is obtained about the mobility of individual intervertebral regions by moving the fulcrum hand more cranially to the lateral process of each lumbar vertebra. Introducing a wavelike motion in the spine by gentle but powerful manipulation between tail base (pulling) and the tuber coxae facilitates evaluation of tension in all epaxial muscles. This wave can be observed to move over the spine to the head in a horse with relaxed muscles. Abruptly halted motion of this induced wave is a good indicator of higher muscle tension in that part of the spine.

Specific tests to localize pain include manual pressure on the individual dorsal processes of the thoracic and lumbar vertebrae (Figure 6.6) and on the tuber sacrale (Figure 6.7), as well as testing for sacroiliac pain by lateral manipulation of the pelvis. The latter provocation test introduces rotation and friction in the sacroiliac joints, so a positive response to the test is indicative for sacroiliac pain. The tests are executed with one hand on the tuber coxae and the other hand on the tuber ischium to manipulate the pelvis in cranial, ventral, dorsal, and caudal directions to cause friction and rotation in the sacroiliac and lumbosacral regions (Figures 6.8 and 6.9). Finally, standing on a step stool can facilitate inspection of the entire spine. The higher position permits more thorough evaluation of the spine for potential deviations that have not been noticed previously.

PRIMARY VS. SECONDARY BACK PAIN

A common topic in equine back pain discussions is whether the back pain is primary, caused by a primary lesion in the spine, or secondary, due to altered use of the

VetBooks.ir

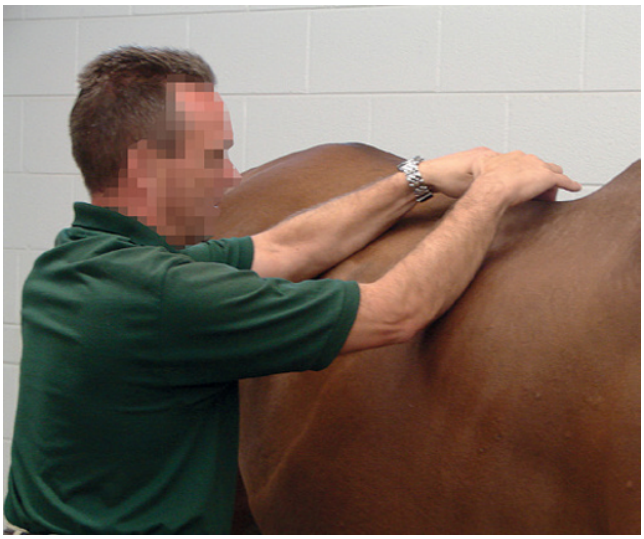

Figure 6.6. Digital pressure on the dorsal process of T16. Both index fingers are located on the dorsal process with strong downward pressure to place load on the intervertebral ligament, facet joints, and the intervertebral disc.

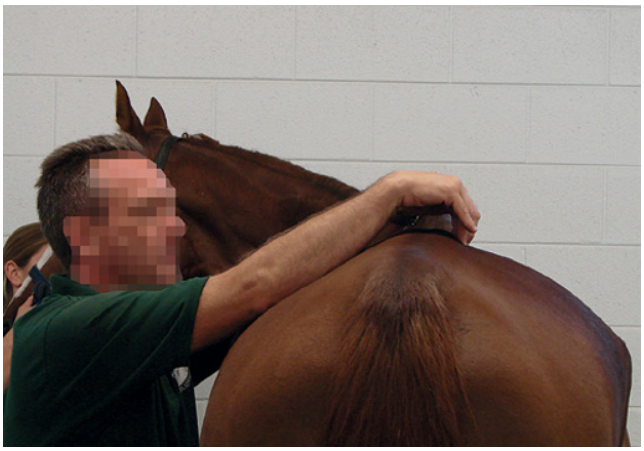

Figure 6.7. Digital pressure on the right tuber sacrale. Pressure is placed downward and slightly to the median so pressure is placed on the bone, dorsal sacral ligaments, and sacroiliac joint.

Figure 6.8. Provocation test for sacroiliac joint pain. The left hand of the examiner is on the right tuber ischium, and the right hand is on the tuber coxae, making rocking motion in the cranial direction.

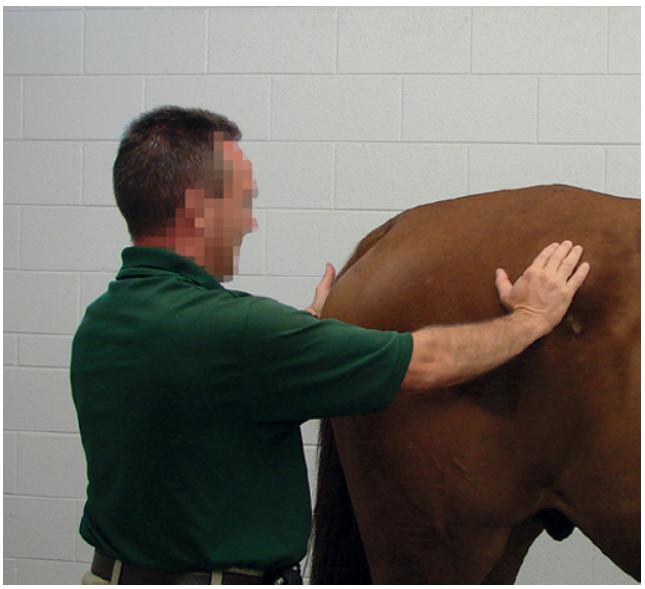

Figure 6.9. Pain provocation test for sacroiliac joint pain, making a rocking motion in the caudal direction.

spine that stems from limb lameness. In humans, contrary to the belief that secondary back pain is very common, there is little literature on this topic other than some papers on the influence of leg amputation or secondary back pain due to tumor metastasis in the spine. One can assume that specific changes in gait in humans can eventually lead to (over)compensation in the spine, resulting in secondary pathology in the spine. However this requires a considerable duration of time to occur because this phenomenon typically presents in people in their 50s. One could question whether secondary pathology of the spine has time to develop in horses, since most performance horses are much younger, between 4 and 16 years of age.

In the author's experience, in cases with clear pathology of the spine such as facet joint osteoarthritis, pathology of the intervertebral disc, desmopathy of spinal ligament structures, and sacroiliac disease, as well as cases with fractures of spinal structures, very often in the history, there is an incident that indicates significant trauma to the spine, resulting in later symptoms of back pain. In the author's opinion, these are clear cases of primary back pain. When the pathology is located more in the soft tissues of the spine, with strain of spinal ligamentous structures or muscles, it is more difficult to assess whether this is primary or secondary back pain.

Complete physical examination is necessary to evaluate the complete condition of the horse and assess potential sources of coexisting limb lameness (primary or secondary). In the author's experience, when no clear pathology is found in the spinal structures and coexisting limb lameness is present, back pain is secondary. When the coexisting limb lameness is treated, the accompanying back pain diminishes or dissolves.

THE PELVIS

Rob Van Wessum

VetBooks.ir

FRACTURES OF THE PELVIS

Fractures of the pelvis are rather uncommon, ranging from 0.9% to 4.4% of all equine lameness cases.[15] Most reports in the literature are from before 2000, and in the last few years no real new information about treatment of pelvic fractures has emerged. Therefore, the emphasis in this chapter is given to diagnosis and imaging modalities.

Diagnosis of pelvic fractures can be a challenge in practice. In most cases, therapy focuses on stall confinement and adjuvant therapy rather than invasive surgery.[16,26] However, for prognosis it is important for the veterinarian to have a confirmed diagnosis. Some pelvic fractures have a favorable prognosis for return to an athletic career; others only guarantee a breeding career. Some fractures are accompanied by severe pain and invalidation of the animal; therefore, euthanasia is a favorable option.

Etiology

Most pelvic fractures are traumatic fractures; common causes include falling, slipping, fighting, and accidents with cars or in trailers. The history of a sudden onset of the lameness is usually a clear indication of a traumatic event. Often the event is observed, but simply finding the horse very lame in the field is a common finding in the history.

However, ilial wing fractures are an example of common stress fractures caused by repetitive overloading of certain portions of the pelvis. These occur in young, immature Thoroughbred racehorses. The lameness is usually less severe with a more gradual onset than that of horses with a traumatic injury.[2,6,7,9,18,22,23,30]

Clinical Examination and Signs

Clinical examination of the horse with a suspected pelvic fracture starts with a complete inspection of the horse, emphasizing symmetry of the hindquarters. Important observations include muscle atrophy, position of the tuber sacrales, limb length, and pelvic height (height of the tuber coxae). The tuber coxae height is easier to determine when standing behind the horse and palpating both tuber coxae, left and right, to exactly determine their position. For accurate inspection, the horse should be taken out of its stall and made to stand completely square on a firm, level surface. This may be difficult when the horse is severely lame.

Particular attention should be paid to limb position; an abnormally straight limb may reflect luxation of the coxofemoral joint and secondary upward fixation of the patella. Toe-out, hock-in position is more often found with pelvic fractures. The muscles of the lumbar and pelvic regions should be assessed carefully to identify abnormal muscle tension and pain as well as swelling or hematoma. Firm manual or digital pressure on bony prominences such as the tuber sacrale, tuber coxae, and tuber ischium should be applied to identify pain or defensive reactions. Keeping contact with the hand on these bony prominences when the horse is asked to walk can assist in detecting crepitation or abnormal (and asymmetrical) motion of the pelvic region. Auscultation during motion also can reveal crepitation.

Careful examination of the pelvic canal per rectum is indicated to assess the aorta and iliac arteries; psoas muscles; and the caudal aspect of the ilial shaft, pubis, and ischium. Some authors advocate rectal examination, while the horse is rocked or even walked, but this can be dangerous for the horse (risk for rectal tear) and examiner (when horse acts up or falls). This author does not recommend such examination.

Most horses with pelvic fractures have a significant lameness, depending on the duration of the fracture. Most are lame at the walk, and gluteal muscle atrophy tends to occur more quickly in horses with pelvic fractures than with other severe lameness conditions of the hindlimb. Horses often stand with the affected limb outwardly rotated (toe-out, hock-in stance) and often lean away from the affected limb. Pelvic asymmetry, muscle atrophy, and pain and crepitus on manipulation of the pelvis are common clinical findings. The exceptions are horses with stress-type fractures or other types of nondisplaced fractures.

Diagnosis

Diagnostic imaging involves radiography, ultrasonography, and scintigraphy. Particularly when the horse is reluctant to move and transportation to the clinic is difficult or dangerous, on-site imaging is needed to make decisions about first aid and follow-up examination. Standing radiography with mobile equipment is possible[8,20,22] but does not always give a final diagnosis. More complete radiography in dorsal recumbency under general anesthesia may be needed, with all of its associated risks during recovery.

Ultrasonography can be performed on site and is capable of imaging ilial wing fractures, ilial shaft fractures, and acetabular fractures with percutaneous probe placement. Transrectal ultrasonography can be used to diagnose acetabular and pubis fractures.[1,13,14,22,31] Due to the risks associated with radiography under general anesthesia and the potential for ultrasonography to confirm a tentative diagnosis of pelvic fracture, radiography has fallen out of favor as the first choice of imaging of horses suspected of having a pelvic fracture, in the author's opinion.[6,12] Ultrasonography has the advantage of not adding to the risks associated with transport when the horse must be taken to a facility for radiography. Most portable ultrasound equipment, in the hands of skilled clinicians, can confirm the diagnosis of pelvic fracture (PA Pease and MB Whitcomb, personal communications). When radiography is available at the location where the horse is presented for evaluation, it is still

VetBooks.ir

very useful, especially when the procedure can be performed in the standing horse.

On-Site Management

Because of their traumatic origin, many of the pelvic fractures occur during a workout, in competition, in a race, or in the pasture. With the more serious injuries, such as ilial shaft and acetabular fractures, the horse may be down or impossible to move. In these cases it is good practice to establish a preliminary diagnosis with a thorough clinical exam, which should at least include a rectal and/or vaginal exam. Crepitation and major swelling in the pelvic region at least can provide a severe suspicion for pelvic fractures, but not confirmation. Transportation to a clinical facility to perform more diagnostics can be contraindicated or at least undesirable. In the field, ultrasonography can be a perfect technique to confirm the diagnosis of a pelvic fracture and make transportation unnecessary.[1,13,22,31]

Treatment and Prognosis of Pelvis Fractures

Treatment for pelvic fractures is conservative, including with anti-inflammatory medication (NSAIDs).[6,15,21,24,26,29] Strict stall rest for at least 30 days is most important. Some clinicians advocate tying the horse in its stall for periods of up to 30–60 days to minimize the chance of a complete fracture when getting up. In general, any horse will lie down after some time, tied or untied. Therefore, tying the horse may increase the risk of other injuries associated with trying to lie down or getting up when tied. Furthermore, stress levels of horses that are tied up, or the public opinion about the possible stress this procedure can evoke in the horse, decrease the acceptability of this procedure.

Normal bone healing of pelvic fractures takes 2–3 months, so motion must at least be restricted during this period. Brief periods of hand walking (with the horse under control) can assist in keeping muscle tension and development more progressive than when complete stall rest is recommended. The use of hot walkers or treadmills must be avoided, because there is no permanent control with these types of rehabilitation equipment. Use of this equipment risks the chance of a brief moment of joy or fear, in which the horse can damage itself severely. Ultrasonographic examination can be a good technique to monitor healing and determine when to increase the workload.[1,31]

It is important to realize that complete healing of pelvic fractures (e.g., tuber coxae or tuber ischium fractures) and the adaptation of the adjacent structures to a changed anatomical conformation can take several months to a year. Sometimes it is possible after this period to give a final prognosis for the return to an athletic career. It is a good practice to communicate this at an early stage with the owner and/or trainer so they are aware that the final outcome after such a long period of treatment and rehabilitation may be unfulfilling. A recent paper however showed a better prognosis for Thoroughbreds with pelvic fractures than previously reported, so it is wise to incorporate these findings in your communication with clients.[21]

SPECIFIC TYPES OF PELVIC FRACTURES

Ilial Wing Fractures

Ilial wing fractures are most commonly found in the young Thoroughbred racehorse, age 1–2.5 years, with an immature skeleton. Lameness is sudden in onset and can vary in severity from 2 to 5 on a scale of 5, according to the AAEP grading scale. The horse has the tendency to plait with the hindlimbs or cross over the hindlimbs in a trot. The severity of the lameness diminishes or decreases in 24–48 hours. Profound muscle atrophy can occur within the first 2 weeks after injury, which can give the horse a very asymmetric appearance when the injury is unilateral. When a complete fracture is present, the ipsilateral tuber sacrale can be displaced. Manual pressure on the tuber sacrale (see the section on clinical examination above) can be painful, as when sacroiliac injuries are present (see the section on the sacroiliac region below).

The major risk in these cases is when an initial incomplete fracture extends to a complete fracture. When this is the case bilaterally, the horse can become recumbent with the chance for adjacent severe neurological damage or a catastrophic injury during workout or race. Therefore, correct diagnosis is important.[26,28,30]

Ultrasonography is the first choice for a diagnosis in a practical field situation.[1,13,22,31] With a 3.5–5 MHz transducer, nearly all commonly available ultrasound equipment will facilitate imaging of the ilial wing. Moisturizing the skin and coating it with alcohol is all that is necessary to prepare the site for imaging. A better image can be obtained by clipping the coat before imaging. Following the contour of the ilial wing with the probe in a craniocaudal position and moving the probe from tuber sacrale out to the tuber coxae provides an outline figure of the ilial wing, and steplike changes can be observed at the fracture site (Figure 6.10).

Scintigraphy is very useful for evaluating incomplete stress fractures (Figure 6.11) as well as evaluating the adjacent structures of the tuber sacrales and sacroiliac joints for involvement. In most cases, scintigraphy is the most sensitive technique 5–10 days after initial injury.[10,12,20] Prognosis in most cases is good for a full recovery to an athletic career when no involvement of the sacroiliac joint(s) is present. When sacroiliac joint involvement is present and not diagnosed correctly, osteoarthritis of the sacroiliac joint(s) can be career limiting at a later stage. See the sacroiliac region section.

Tuber Coxae Fractures

Tuber coxae fractures are nearly always associated with trauma, such as running into a door post or fence, fighting, and kicking, and trailer accidents.[15] In cases of high-energy impact to the tuber coxae (e.g., high-speed collisions), adjacent structures in the sacroiliac region may be involved and require attention later. See the sacroiliac region section. Tuber coxae fractures are associated with moderate to severe lameness that decreases to mild lameness in 24–48 hours.

These fractures are fairly easy to recognize because the contour of the tuber coxae is changed (Figures 6.12 and 6.13). The fractured portion moves cranioventrally due to traction of the internal abdominal oblique muscle.

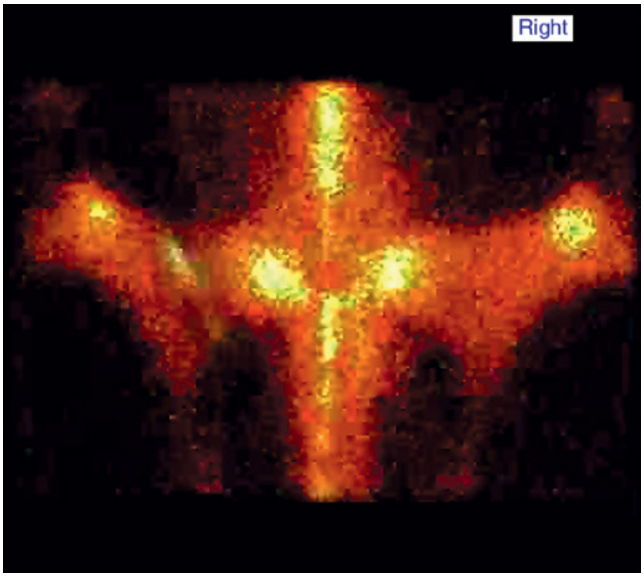

Figure 6.11. Scintigraphy image of a stress fracture of the left ilial wing. Increased radiopharmaceutical uptake (IRU) in the left ilial wing, as well as IRU at both tuber sacrales and the right tuber coxae, is indicative for trauma to these structures.

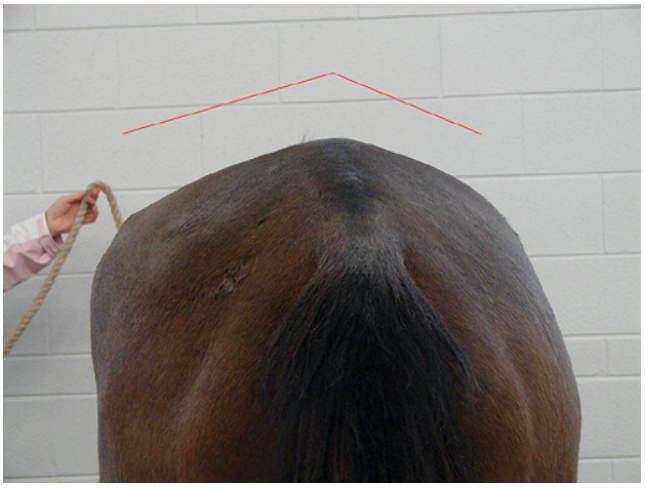

Figure 6.12. Fracture of a large part of the right tuber coxae. Note the shorter distance between the right tuber sacrale and tuber coxae compared with this distance on the left.

The edges of the remainder of the tuber coxae are palpable through the skin. In rare cases the sharp edges of the ilium can penetrate the skin and cause a fresh laceration. In a later stage, sequestration can cause draining tracts or nonhealing wounds, and the sequestrum must be removed.

Ultrasonographic examination is again the first choice for imaging, because it can show the irregular bone edge of the ilium and the displaced part of the tuber coxae (Figure 6.14).[1] Ultrasonography can identify a draining tract when present and provide a guide to the sequestrum. Radiography in this region can be disappointing; however, sometimes a mediolateral oblique projection can show the fragmentation of the tuber coxae.[8,18,20,26] A recent study described a dorsomedial–centrolateral 50° oblique radiographic view in the standing horse as being very helpful.[8]

Scintigraphy is a very sensitive technique to show involvement of the tuber coxae[12,20] but is unnecessary in most cases, at least in the initial diagnostic procedure. Later, when sacroiliac problems are suspected due to the initial trauma, scintigraphy is the first choice for imaging. The prognosis is favorable in most cases. A fibrotic and functional union between the dislocated

VetBooks.ir

fragment and the adjacent structures facilitates recovery to full athletic performance. In a recent study, up to 93% of the horses returned to athletic performance.[8] For higher level dressage, however, prognosis is less favorable due to the asymmetric position of the pelvic region. The horse appears to be asymmetrical and gives the judge the impression that it cannot do certain exercises. Some minor gait asymmetry (altered motion pattern of the hindlimb(s) and slight change in stride length and path) can affect scores at the higher levels of dressage competitions, when judging is more strict and sensitive to small gait irregularities.

Fractures of the Pubis and Ischium

Isolated fractures to the pubis and ischium are rare. In cases of severe trauma to the pelvic region with high-energy impact (e.g., fall, car accident), fractures to these structures can be complementary to fractures of other pelvic structures. When they are isolated fractures, they often cause unilateral hindlimb lameness combined with clear swelling of the thigh area. After a few days, the swelling can progress downward due to gravity and cause remarkable swelling around the stifle, femur, or hock.

This descending swelling can lead the examiner away from the initial injury and place suspicion at the stifle or hock as being the initial injury site.[5] With palpation it is often quite difficult to feel crepitation because of the muscle spasm that accompanies the injury. The injury is very painful, and muscle spasm is very common, sometimes leading to an asymmetric position of the tail or even the entire pelvic region. Sweating can be noticed, sometimes in localized patches, especially when nerve involvement is apparent.

Scintigraphy can be used to diagnose these types of fractures (Figure 6.15). Again, this technique is very sensitive but should be done 1–2 weeks after the initial trauma. Ultrasonography can be used to identify displaced fragments of the tuber ischium (Figure 6.16), often after scintigraphy has identified the region of interest. Prognosis for isolated fractures of the tuber ischium is favorable for a return to an athletic career. The exceptions are horses competing in upper level dressage, as mentioned above in the tuber coxae fractures section, for the same reasons.

Ilial Shaft Fractures

Ilial shaft fractures are associated with non-weight-bearing lameness.[24] The horse is extremely painful, with sweating, and has severe muscle spasms. When the fracture ends of the

VetBooks.ir

ilial shaft damage the internal iliac artery, shock and exsanguination can occur. When the fracture is complete, the tuber coxae will be asymmetric, and the affected limb will appear to be shorter. Rectal or vaginal examination reveals a possible hematoma and crepitation. Many of these fractures are multiple fractures that involve the pubis, ischium, and ilium. Prognosis is unfavorable, and often euthanasia is performed.

Acetabular Fractures

Acetabular fractures are traumatic in origin (e.g., falling, slipping, trailering accidents) and very painful. In most cases the horse is non-weight-bearing lame and reluctant to move at all. Some horses are found non-weight bearing standing in the pasture or paddock without any clear signs of the origin of the trauma. Crepitation can be found with a rectal or vaginal examination, especially when the horse is rocked a bit during the examination. Profound swelling can also be felt with the rectal or vaginal examination. Sometimes swelling is noticeable around the stifle and thigh area. Ultrasonography[1,31] (transcutaneously or transrectally) can assist in the diagnosis when there is a complete fracture (Figure 6.17). Radiography under anesthesia can confirm acetabular fractures but adds the challenge of safe recovery afterward. Scintigraphy is the most sensitive technique but should be performed at least 7–10 days after the initial cause; otherwise, the

Figure 6.18. Radiograph of a horse with bone proliferation between the coccygeal vertebrae 1 and 2 at the dorsal aspect as the result of an avulsion fracture of the intervertebral ligament.

chance of false-negative findings is great. Prognosis is unfavorable because of the chance of development of osteoarthritis of the coxofemoral joint, leading to permanent and progressing lameness.[22]

Fractures of the Sacrum and Coccygeal Vertebrae

Fractures of the sacral bone (primarily dorsal processes) or coccygeal vertebrae are rare but can cause lameness. When the proximal coccygeal vertebrae are involved, the normal locomotion pattern at the walk (the snakelike motion) and the canter can be influenced by pain in this region. Backing up (lowering the tail region) may be painful, and the horse may be reluctant or completely refuse to back up. Often the owner regards this as a dominance problem more than a physical issue. Some owners and trainers may think the horse's unwillingness to back up is showing the horse is not respectful to the handler and they do not understand there is a physical cause for this behavior (many disciplines use backing as an obedience test). Clinical examination can show enlargement of the soft tissues in the sacral or coccygeal region, and passive mobility can be painful. Radiography can be used to image the fracture site when coccygeal vertebrae are involved (Figure 6.18), as can a lateral image for sacral dorsal process fractures. Ultrasonography is also a good tool for imaging this region, but scintigraphy is the most sensitive.

Treatment can focus on anti-inflammatory therapy and reducing the workload. When nerves are involved, caudal epidural steroid administration has been used to treat this condition successfully.[17] Methylprednisolone acetate (200 mg) mixed with 10–20 mL of saline can be used to perform an epidural injection. Surgery may be indicated when fracture fragments are displaced or sequestration occurs. The prognosis is generally good for a return to athletic performance. Sometimes coccygeal fractures are a coincidental finding during a prepurchase examination, because they do not cause clinical symptoms.

THROMBOSIS OF THE CAUDAL AORTA OR THE ILIAC ARTERIES

Etiology

Thrombus formation in arteries of the limbs can cause blood supply interruption. Specific locations for these thrombi are the caudal aorta, iliac arteries, femoral artery in the hindlimb, and very rarely the brachial artery in the front limb. Circulatory problems in the muscles (and later in all tissues) can cause pain, resulting in lameness. The etiology has been described as being caused by the migrating larva of *Strongylus vulgaris*, but it is not clear why only these locations are affected. It is more likely that any damage to the intima of the blood vessels can cause a thrombus to form.

Clinical Signs and Diagnosis

This lameness is specific in that it occurs after or during work, is sudden in onset, and can be very severe (grade 3–5 of 5) but can diminish or disappear within minutes to hours after ceasing work. Because of the severe pain, horses may sweat, show anxiety, and be very restless, which can make the condition look like azoturia or even colic. Blood chemistry and a clinical workup for colic are negative.[11,16]

Clinical examination shows lower perfusion in the affected limb, lower temperature (thermography can be useful in these cases), and absence or lower pressure of arterial pulse. On the nonaffected limb, the veins can show clearly, while they are indistinct on the affected limb. Ultrasonography can show lower blood flow in the blood vessels of the affected limb (using Doppler).[25] With transrectal ultrasonography it is sometimes possible to find the thrombus and measure its size,[32] but with a rectal examination one can determine the decrease or absence of arterial pulse or fremitus in the iliac arteries.

Treatment and Prognosis

Treatment is focused on medication: anticoagulants (heparin 100 IU/kg sc SID, aspirin 5–10 mg/kg po SID, phenprocoumon 0.08–0.16 mg/kg IV initial bolus, gradually reduced), nonsteroidal anti-inflammatory drugs, and antimicrobial drugs (metronidazole 25 mg/kg PO BID and thiabendazole 4 g/45 kg PO once weekly for 3 weeks or ivermectin or moxidectin) to act against *S. vulgaris* larvae when they are expected to be the cause.[16]

Successful surgical removal of the thrombus has been performed with a thrombectomy catheter,[4] but this requires that the exact location of the thrombus be determined by ultrasonography or scintigraphy.[3,19,27] Prognosis for thrombosis of the aorta and the iliac arteries is guarded, especially when the underlying cause is not known.

SACROILIAC REGION

Rob Van Wessum

Diseases of the sacroiliac region are recognized more and more as a cause for low-grade lameness or lack of performance.[2,3,20] Recent studies show that the sacroiliac joint may not always be involved, but the soft tissue structures adjacent to the joints in this region can be the cause of sacroiliac disease.[19,23,24]

The skeletal structures involved in sacroiliac diseases include the pelvic bones and spine, especially the sacroiliac joints where the ventral aspect of the ilium and ilial wing come into close contact with the sacral bone. At this junction there are two synovial joints, one at the ilial facet with a thin layer of fibrocartilage and one at the sacral facet with hyaline cartilage (Figure 6.19).[9,12,15]

At the ventral aspect of the sacroiliac joint, support is provided by several ligamentous structures, the capsule of the joint itself, and a package of small fibrous ligaments known as the ventral sacral ligaments.[12] On the top of the pelvic bones, ligamentous structures called the dorsal sacral ligaments, originated from the tuber sacrale. These include a long ligamentous branch, called the long part, that adheres to the fibrous structures of the pelvis (the sacrosciatic ligament), and a shorter portion, called the short part, that adheres to the sacral bone and the coccygeal vertebrae and ligaments (Figures 6.20–6.22). From the ventral aspect of the ilial wing, the interosseus sacroiliac ligament supports the sacroiliac joint (Figure 6.23).[9,12]

ETIOLOGY

The muscles of the caudal spine and pelvis are major contributors to the stability of the sacroiliac region. On the dorsal aspect, the middle gluteal and superficial gluteal muscles and their fasciae support the sacroiliac region. On the caudal aspect are the semimembranosus and semitendinosus muscles, and at the ventral part of the pelvis are the psoas muscles, all of which are important contributors to stability. Under normal conditions, the muscles in this region maintain the mobility of the sacroiliac joints within their physical limits. However, when the muscles are not powerful enough to compete with the external forces that result from massive trauma due to falling, slipping, tipping over, etc., primary ligament damage and primary or secondary joint trauma can be sustained. Weakness in these muscles can be associated with sacroiliac injury. This weakness can have many causes, including fatigue from improper training techniques, overuse, and repetitive stress injuries that can occur in young horses not yet capable of the desired level of performance.[18]

The pelvic region is not a rigid structure, as was previously thought. Haussler et al.[16] discovered that there is a small amount of deformation of the pelvic bone structures during the loading cycle in motion, and all of the involved structures (the bone, ligamentous structures, and muscles) form a semiflexible complex to assist propulsion and transport this propulsion from the hindlimbs onto the spinal column.[10] These findings make it easier to understand the major impact of the dysfunction of the pelvis structures regarding locomotion and performance.

Three different types of injury occur in the sacroiliac region. In the author's experience, the most common seem to be those that cause damage to the dorsal sacral ligaments (the structure with the greatest span between tuber sacrale, sacral bone, and the sacrosciatic ligament and the most potential motion between these structures). When trauma to the ligamentous structures of the sacroiliac region is more profound, the interosseus sacral ligaments and ventral sacral ligaments also can become damaged, with (sub)luxation of the sacroiliac joint(s) as a result. The last injury to the sacroiliac region occurs when damage to the sacroiliac joint is sustained with resultant osteoarthritis of the sacroiliac joint. In the author's experience, this only occurs in 5–10% of sacroiliac disease cases.[24]

CLINICAL SIGNS

Horses with sacroiliac pathology may come with a great diversity of owner/rider complaints, including reduced stride length in one or both hindlimbs, asymmetry of the hind end with one hip lowered, and occasionally obvious atrophy of the croup muscles. Owners report changes in both the rhythm and quality of the walk, with a more lateral walk seen especially during serpentines and circles, and a reduced stride length in one or both hindlimbs. There are no clear signs at the trot, perhaps just a little stiffness with slightly reduced propulsion and engagement. Downward transitions from canter to trot or from trot to walk can be of lower quality with a disturbance of the rhythm of the new gait in the first strides after the transition. Going downhill, even when the incline is small, can be difficult, and a refusal to jump in hunting, cross-country, or eventing can be a major complaint of the rider.[2,3]

The most remarkable signs of sacroiliac problems are usually shown when cantering. The pattern of the canter causes a very unilateral loading of the hindlimb and the

VetBooks.ir

sacroiliac region during the phase when the leading hindlimb (left hindlimb in left lead canter) carries the entire body load after the suspension phase. When sacroiliac lesions are present, the horse often alters its gait to relieve this unilateral loading by cantering more as a bunny hop in which there is less separation of footfalls of the hindlimbs. Horses with sacroiliac pathology also change leads or cross canter frequently. Due to this augmentation of signs in the canter, disciplines that are judged on the quality of the canter, for example, dressage and Western pleasure, or those that require a good-quality canter for optimum performance, as in hunting, jumping, and racing, comprise a greater proportion of clients who bring their horses with sacroiliac pathology to the author's practice.

Racing horses with poor performance often have mild signs of sacroiliac disease, especially the young, immature Thoroughbred in which mild to moderate strain to the dorsal sacral ligaments is diagnosed frequently.[24] Sacroiliac disease is very common in Standardbred racehorses, again with desmopathy of the dorsal sacral ligaments as the most prominent diagnosis; however, in the author's experience, osteoarthritis of the sacroiliac joint(s) is diagnosed in this breed more often than in any other breed. Incomplete or complete rupture of the dorsal sacral ligaments and incongruence of the position of the tuber sacrales (as a sign for clinical subluxation of the sacroiliac joint) are seen, mostly in racehorses.

Behavioral issues such as kicking, rearing, striking, and bucking, as well as resisting going forward, are quite often associated with sacroiliac pathology. Riders frequently report that these behaviors occur when the horse is asked to canter, and it can be difficult to determine whether these are training/behavior issues or a reaction to pain.[2,3]

Some horses do not show evidence of sacroiliac disease until ridden under saddle. However, severe sacroiliac injury such as acute subluxation or even dislocation of one of the sacroiliac joints or rupture of the sacral ligaments can cause severe hindlimb lameness, even non-weight-bearing lameness.

DIAGNOSIS

Clinical examination of horses with suspected sacroiliac disease is the same as any other lameness examination. Emphasis is placed on observation of the gaits, in the walk, especially with serpentines, and at the canter in softer footing as well as eventually under saddle. Lateral walk (movement of the ipsilateral pair of legs at the same moment, like a camelid) in serpentines is a reliable sign of reduced mobility of the spine. When sacroiliac pain is present, especially when the dorsal sacral ligaments are involved, mobility of the tail can be reduced. Very often the tail is fixed in one position and does not move when the horse walks in a serpentine. Loss of the quality of the canter in one lead is a very strong sign for sacroiliac pain. This can be presented as less propulsion, less engagement, cross canter, no-sound 3-beat canter, or even a bunny hop canter. Asymmetry of the tuber sacrales can be observed; however, this is also found in clinically normal horses.[2,3,9,12,15]

With acute sacroiliac disease there is clear pain in the hindquarters or back. The horse can exhibit severe muscle spasm, clear asymmetry of the tuber sacrales, and favoring one hindlimb. Even non-weight-bearing lameness is sometimes found in cases of acute sacroiliac disease, as with subluxation.

The lameness is less pronounced in more chronic cases. Muscle atrophy of the affected side may be noticed with unilateral sacroiliac disease. Shorter stride length, mostly in the cranial phase, of the affected limb is a very common finding, as is lack of propulsion, less hindlimb engagement, and lack of collection (coming under).[24] The horse may appear stiff and rigid with lack of lateroflexion in the lumbosacral region. Asymmetric positioning of the tail is often observed, with a deviation of the tail in the direction of the affected ligament; this releases tension to the short part of the dorsal sacral ligament when the ligament is involved (Figure 6.20).[24]

In stance as well as in motion, the affected side often has a slight hip drop. This is different than with hindlimb lameness, in which the hip drop often is just evident in motion and less so in stance. Flexion tests of the hindlimbs may be positive; note that secondary overload of hindlimb structures may become more obvious in sacroiliac disease. In most cases with primary sacroiliac disease, the flexion tests are questionable or negative. However, standing on the affected limb when the contralateral limb is lifted and flexed can pronounce lameness of the affected side after the flexion test, resulting in more pronounced lameness on the contralateral side. During the flexion tests the horse may show reluctance to stand on the affected limb or lean over to the affected side, so the stance limb is in midposition, which reduces rotational forces to the pelvic structures.

Examination of the mobility of the spine can give specific information about reduced range of motion in the sacroiliac and lumbosacral region. Reflexes that induce dorsal and ventral flexion can be suppressed due to pain in the sacroiliac region. Passive lateral flexion is quite often reduced to the side of the location of the sacroiliac pain.

Provocation tests are useful to determine the location of the pain within the sacroiliac region. Manipulation of the tuber ischium forward with one hand and moving the tuber coxae of the same side upward and downward introduces ventroflexion and rotation in the sacroiliac joints. Pressure on the tuber sacrale identifies pain at the insertion of the dorsal sacral ligament.

Recently, a retrospective study has provided some clinical guidance to help determine if sacroiliac dysfunction is likely to be present based on the observation of six clinical parameters during the standard lameness examination.[22] These parameters are tracking narrow behind, lateral walk on a serpentine, haunches in or out in a straight line and on circles, an asymmetric tail position, a bunny hop canter, and a reduced mobility of the lumbosacral region. Ultrasound examination provides more detailed information about the condition of the dorsal sacral ligaments.[4,17,19] Dorsal percutaneous ultrasonography using a linear probe with a higher frequency (10–15 MHz) is very useful for evaluating the dorsal sacral ligaments and their attachment to the tuber sacrale. Transverse views are used to identify the ligaments, check their size, and compare the left and right

VetBooks.ir

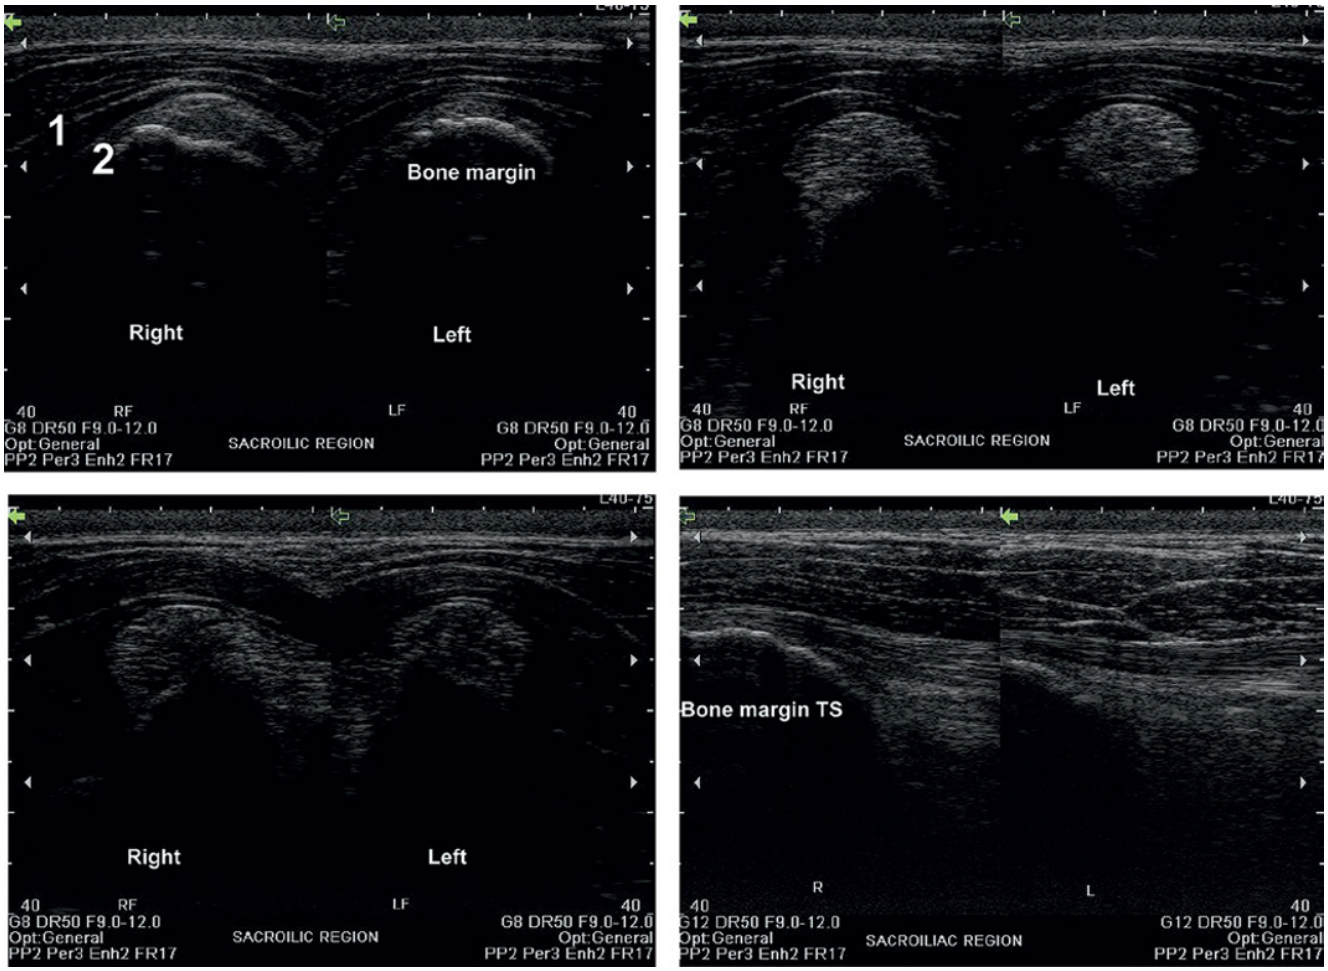

Figure 6.24. Ultrasonographic images. Right top view: transverse view. 1 = short portion of the dorsal sacral ligament (DSL), 2 = long portion. Note the enlargement of the right DSL and the loss of echogenicity in the medial aspect when compared with the left. The bone margin on the right, however, is more smooth and normal than at the left, where the tuber sacrale is more irregular.
Left top view: Transverse view, more caudal than in right top view; the bone margin is no longer visible. Only ligament is visible, where it crosses the space between the tuber sacrale and the dorsal processes of the sacral bone. The right DSL is larger when compared with the left.
Right bottom view: Transverse view, more caudal than in left top view; the DSL starts to attach to the dorsal process of the sacral bone in the midline. Note again the increase in size of the right ligament. However, there is some loss of echogenicity in the body of both ligaments.
Left bottom view: Longitudinal view. In the right DSL there is loss of echogenicity and fiber pattern alignment, indicating desmitis of the DSL.

sides of these structures (Figure 6.24). Evaluation of the structures and the adjacent muscle tissue with Doppler ultrasonography can give valuable information about vascular activity in this area. Longitudinal views are better for evaluation of the alignment of the tissue and the contour of the tuber sacrale bone.

Ultrasonographic transrectal examination of the sacroiliac joints has been described to evaluate the bony edges of the joints[6] for bone proliferation (Figure 6.25). However, in the author's opinion, there is little clinical relevancy for this technique, because necropsy findings show bone proliferation in this region in many horses without clinical symptoms. Radiographic techniques have been described for evaluation of the sacroiliac joint,[11] but they require general anesthesia and may not show a high correlation between radiological findings and clinical symptoms. Nuclear scintigraphy is the gold standard for showing clinically relevant involvement of the sacroiliac joint.[3,21,24]

Desmitis and enthesopathy (inflammation where ligaments attach to the bone) are the most commonly diagnosed entities at the author's practice. Desmitis is seen as an enlargement of the dorsal sacral ligaments, usually combined with reduced echogenicity of the ligament in comparison with the contralateral one. The acute phase, often caused by a partial rupture of the ligament, is observed as an area with very low echogenicity. The vascular activity around the ligaments is clearly increased when compared with the healthy contralateral ligament. Quite often small avulsion fragments can be observed within the ligament.

More chronic desmitis and enthesopathy can be recognized as a higher echogenicity of the ligament, nearly comparable with the contralateral one, but enlarged and

VetBooks.ir

with an irregular and less clearly defined bone margin. This is more a repetitive stress injury than an acute trauma.

In cases with massive damage to the ligamentous structures, a more complete displacement of the sacral bone is visible with the ilial wings displaced dorsally and the sacral bone displaced ventrally. In this case, one or both of the tuber sacrales are more pronounced (Figure 6.26). The latter condition is often called "hunter's bump."

In the case of significant displacement of the sacral bone, the incongruence in the articular surfaces of the sacroiliac joints leads to osteoarthritis. Osteoarthritis also can be a consequence of sacroiliac instability due to chronic desmitis of the dorsal sacral ligaments.

Scintigraphy facilitates evaluation of the sacroiliac joints as well as identification of enthesopathy of the tuber sacrale and the dorsal processes of the sacral bone.[3,21] Lateral (Figure 6.27), dorsoventral, and oblique views of the sacroiliac region pinpoint increased bone

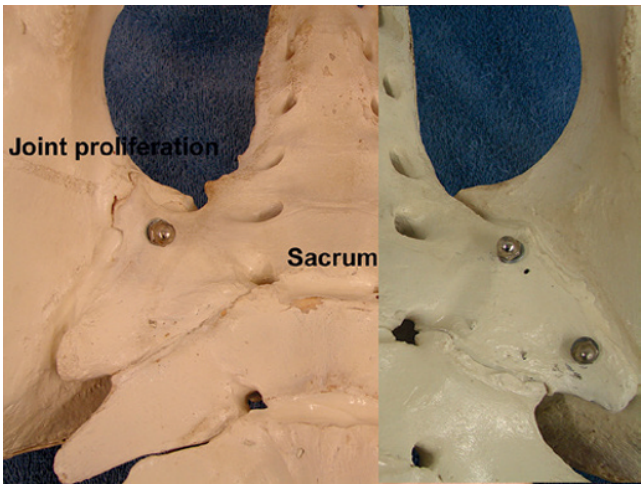

Figure 6.25. Anatomic specimen of the sacroiliac joint region. Note the visible bone proliferation at the ventral edge of the joints at the left view when compared with the right smooth joint margins.

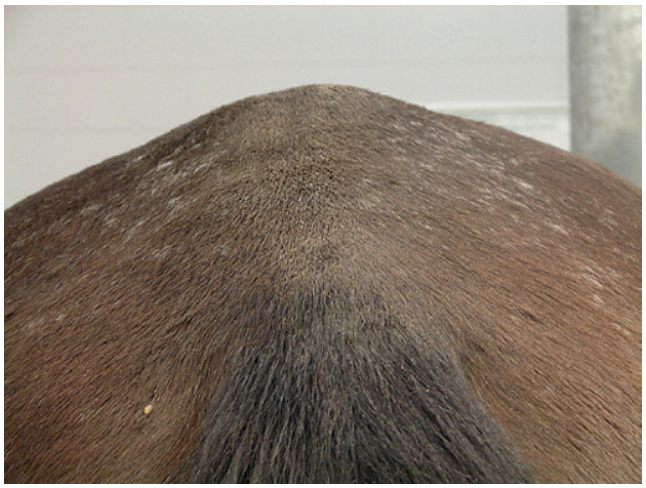

Figure 6.26. Caudal view of a horse with asymmetric tuber sacrales. Due to ligament damage, the right tuber sacrale is much higher than the left.

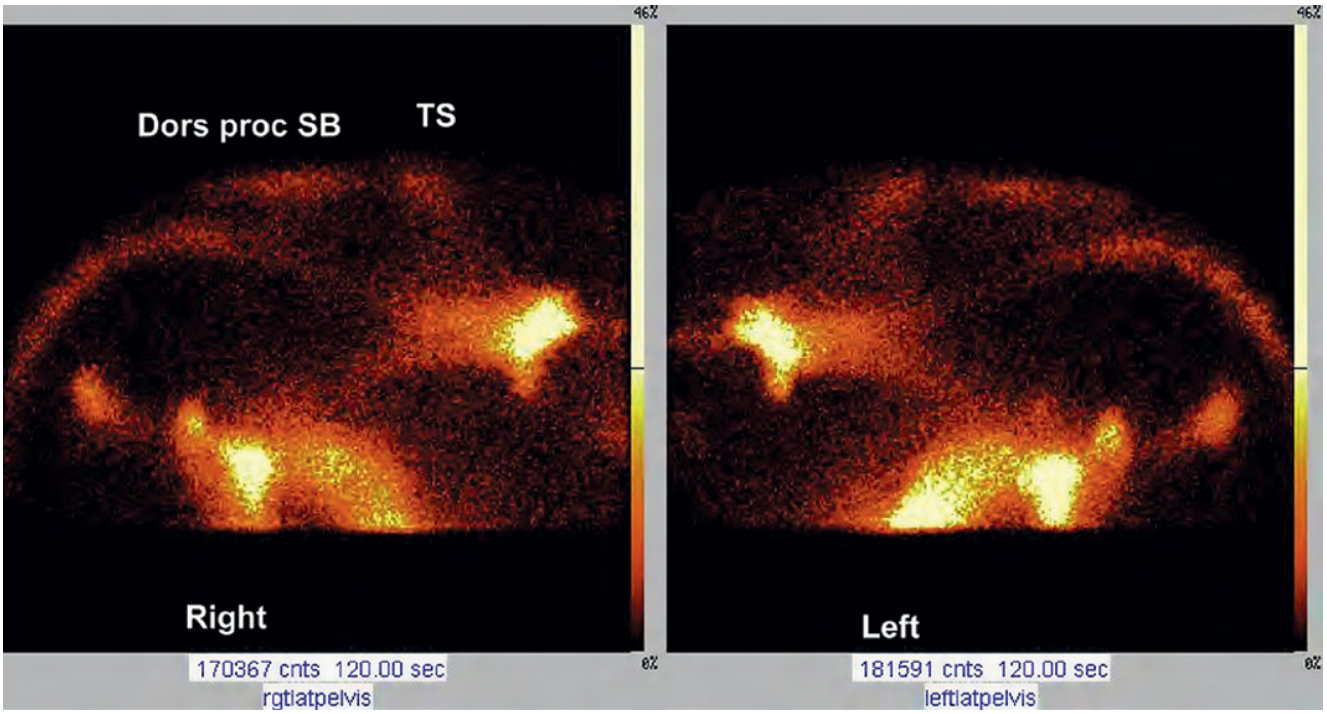

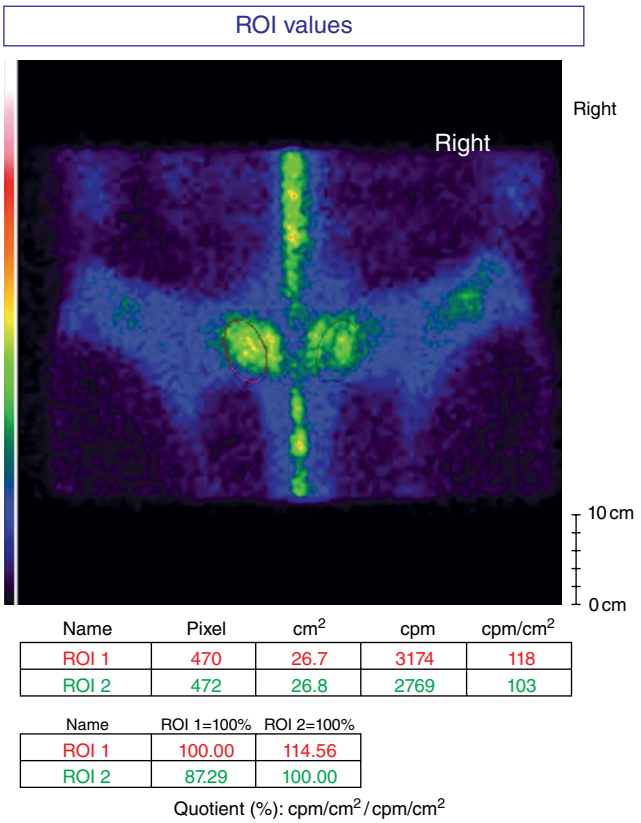

Figure 6.27. Scintigraphic images of the pelvic region in lateral view from left and right. Note the slightly higher uptake in the left tuber sacrale when compared with the right. There is also slightly increased uptake visible in the dorsal processes of the sacral bone. This can be a sign of enthesopathy of this structure or an indication of lower musculature size in this region.

metabolism of the tuber sacrale in the case of enthesopathy and a more condensed higher bone metabolism in the ilial wing in the case of sacroiliac joint pathology (Figure 6.28). Lateral views taken in the first stage of uptake of radiopharmaceutical (soft tissue phase) can show increased uptake in the dorsal sacral ligaments as well as in the epaxial muscles.

TREATMENT

In all cases of sacroiliac disease, a complete and intensive rehabilitation program is of paramount importance for the complete recovery of the horse.[2,3,13,23,24] When enthesopathy and desmitis are the most obvious diagnoses, an initial 2-month period of rest to immobilize the region is the first step of treatment. Uncontrolled motion in the pelvic region must be prevented, and complete stall rest with no turnout for the first 2 months of treatment is the only effective way to achieve immobilization of the pelvic region. During this period of stall rest, the horse is hand-walked on a straight, flat surface 2–3 times a day for 10–15 minutes. During this time oral medication with NSAIDs is needed to assist in the complete reduction of inflammation in the ligaments and bones. In the author's practice, phenylbutazone (1 g q 12 hours for a 500- to 600-kg horse) is the drug of choice.

After the initial 2 months of stall rest, 1 month of walking under saddle can begin. During this time, the horse is walked in serpentines and circles to increase lateroflexion and rotation in the lumbosacral and sacroiliac region. The rider should make the horse bend on the circles and gradually reduce the circle to a smaller diameter, thus increasing lateroflexion.

In the fourth month of rehabilitation, the same exercises are done at the walk and also at the trot to increase speed and thus loading of the lumbosacral and sacroiliac region.

In the last 2 months of rehabilitation, the horse is ridden for longer periods, until achieving 1–1.5 hours of work daily. The canter is introduced with emphasis on brief episodes with many downward transitions to trot, creating more dorsal and ventral flexion in the lumbosacral and sacroiliac region. Short intervals of canter are extremely important to prevent fatigue of the muscles that support flexion and extension of the joints and their supporting ligaments to avoid mobility beyond their physical limits, which may be diminished by the primary injury.

This rehabilitation program gradually introduces more mobility and develops better muscle support of the sacroiliac region. The exercises develop more muscle power in the epaxial muscles as well as in the muscles of the croup, which are of eminent importance in limiting the range of motion of the sacroiliac joints and their supportive ligamentous tissue.

When the sacroiliac joints are involved (in the author's practice this is only 10–15% of all cases and is almost always unilateral), injection of the joint with a corticosteroid may be needed. The author prefers triamcinolone to prednisolone, and it causes less tissue irritation (AP Pease, personal communication).

A single injection of the affected joint with triamcinolone (20–30 mg) coupled with concurrent phenylbutazone and the rehabilitation program described above gives results that are quite similar to those described for treatment of enthesopathy and desmitis. In the author's experience, when scintigraphy findings lead to the diagnosis of sacroiliac joint disease, results of oral medication and a prolonged rehabilitation program without an injection are disappointing.

Injection directly into the sacroiliac joint is very difficult because the ilial wing makes access into the joint nearly impossible. However, depositing a corticosteroid very close to the joint can be effective in reducing inflammation within the joint. There are several different techniques for depositing a corticosteroid close the joint.[1,4,5,7,8] At Michigan State University, a novel technique for injection of the sacroiliac joint (region) has been tested and is preferable to the author.[25] This approach is with a straight needle (15-gauge, 20–25 cm) with an insertion site 3–4 cm cranial and 1–2 cm paramedian to the contralateral tuber sacrale, through the interspinous ligament of L5 and L6, and aimed toward the ipsilateral tuber ischium (Figure 6.29). The medication is deposited when the tip of the needle makes contact with the ventral aspect of the ilial wing as ventral as possible. Landmarks for the location of the insertion site of the needle are the dorsal process of L5 and the tuber coxae. The insertion site of the needle is located on the contralateral side of the joint to be injected. The length between the cranial palpable tips of the dorsal processes of L5 and L6 is measured. Half of this length is the distance that the insertion site is lateral of the cranial tip of L5 on the contralateral side. This technique facilitates insertion of the needle at the correct location in horses of different sizes.[25]

VetBooks.ir

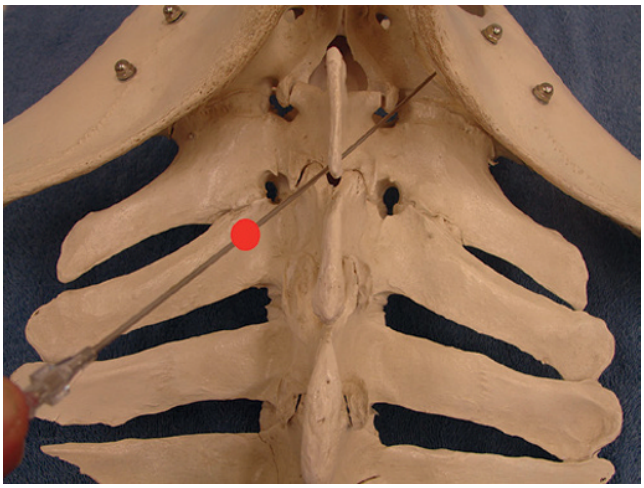

Figure 6.29. Injection of the sacroiliac joint: needle insertion at the left side 2 cm out of the median, through the intervertebral ligament between the dorsal processes of L5 and L6 into the right sacroiliac joint. The red dot indicates the location of needle insertion on the skin.

In cases with severe damage to the dorsal sacral ligaments (disruption of the fiber pattern) as with partial or complete rupture of these ligaments, injection of platelet-rich plasma (PRP) into the damaged tissue has shown impressive results at the author's hospital. In comparison with cases that were treated conservatively, the architectural structure of the ligament improved much faster and was more completely restored after treatment with PRP. However, no change of overall rehabilitation time (4–6 months) has been observed.[26]

PROGNOSIS

In nearly all of the past reports, prognosis for sacroiliac diseases has been rather guarded.[3,14,20] In the author's experience with more than 200 cases in the last 4 years involving desmopathy of the dorsal sacral ligaments and unilateral OA of the sacroiliac joint, more than 90% of the horses returned to work at their original level or higher. All of these cases were on a 6-month rehabilitation program with rechecks at 2-month intervals. The horses were evaluated clinically and ultrasonographically at every recheck, and adjustments to the rehabilitation program were made based on the outcome of this evaluation.

For cases with partial or complete rupture and subluxation of the sacroiliac joint, prognosis seems to be favorable; however, at Michigan State University the author has seen fewer than 10 cases with this type of injury over the last 4 years. With enough time for initial healing of the ligamentous structures (2-plus months of stall rest with some hand walking) and 4–6 months for rehabilitation exercises, these horses were able to return to their original level of performance.

THORACOLUMBAR SPINE/BACK

Rob Van Wessum

VetBooks.ir

OVERRIDING/IMPINGEMENT OF DORSAL SPINOUS PROCESSES

Etiology

The impingement of the summits of the dorsal vertebral processes, also known as "kissing spines," is a relatively common diagnosis in horses with back pain.[7,8,12] The most common location for these lesions is in the thoracic spine (between T5 and T18), but impingement of the lumbar dorsal processes has also been reported.[8,17] Pathology may be caused by the repetitive, traumatic contact between the dorsal processes. Sclerosis of the cortical margins of the dorsal processes, narrowing or loss of the interspinous space, and osteolysis of the spinous processes are affirmative signs of bony pathology. When the supraspinous ligament or the interspinous ligaments are involved, enthesiophytes and avulsion fragments may be present at the summit (supraspinous ligament) or at the caudal or ventral aspect of the dorsal spinous process (interspinous ligament).[11]

When adjacent structures are damaged, they can lead to impingement of the spinous processes. A primary injury to the ventral and ventrolateral supportive structures of the annulus fibrosis of the intervertebral disc can cause asymmetrical narrowing or collapse of the intervertebral joint, which may tilt the dorsal vertebral processes toward each other.[30] In that case, the impingement may be a secondary finding at the initial radiological examination, underestimating the extent of the trauma. Spondylosis at the ventral aspect of the spine and narrowing or the loss of definition of the intervertebral disc space can be an additional radiological finding, pointing to the involvement of more spinal structures than just the spinous processes.

Clinical Signs

Impingement most often reduces the ventrodorsal mobility of the spine, but when pain is present, the lateral mobility may be limited due to reflectory muscle spasm, thus affecting performance.[12] Horses with impingement of spinous processes have a variety of symptoms, often related to the discipline in which they perform. Although show jumpers and hunters seem to be more affected, many horses that perform without clinical signs of back pain show radiological evidence of impingement. When impingement is present in the cranial part of the thoracic spine (T5 to T12 or T13), the horse may have a painful or violent response when putting the saddle on or when the rider mounts. Differentiating an injury from saddle fit issues can be a challenge.

Diagnosis

Palpation along the back may reveal irregularities in the size of the summits of the spinous processes of the thoracic or lumbar vertebrae. Deep digital palpation is necessary in most cases to reveal these changes. Examination should begin at the withers and work toward the sacrum. It is important to differentiate the resentment shown by some horses to this examination from distress resulting from other back conditions.[12] Clinical examination can show pain with localized digital pressure of the specific dorsal process or the supraspinous ligament.[7] Limitation of dorsoventral mobility as well as possible lateral reduction of motion is limited to the specific part of the spine.

Radiological examination can clearly identify bony changes as sclerosis and osteolysis.[26,37] Ultrasonographic examination is very useful to evaluate the contact and remodeling between two adjacent spinous processes, transverse thickening of the processes, and abnormal alignment. Concomitant lesions in the supraspinous ligament and enthesopathy on the summits of the spinous processes also can be imaged with ultrasonography.

Scintigraphy may help to identify evidence of active bone metabolism and remodeling of the spinous processes (Figure 6.30), as well as adjacent structures of the spine that can be involved (intervertebral disc, facet joint, vertebral body).[33] Localized increased activity may be observed or absent in completely sound and clinically asymptomatic horses, as well as in horses with clear symptoms of back pain caused by impingement of spinous processes.[15]

Infiltration with a local anesthetic of a site that is suspect for pain caused by impingement can give more information about the likelihood of the observed impingement causing the symptoms.[10,13] The most comprehensive and complete examination of the thoracolumbar spinous processes should incorporate radiography, scintigraphy, and diagnostic analgesia.[39]

Treatment

Conservative therapies include rest, nonsteroidal anti-inflammatories, local injections of anti-inflammatory agents, acupuncture, and physiotherapy. Horses that are rested often improve during the rest period but become sore again shortly after reinstating exercise. Systemic therapy with NSAIDs helps horses with very minor lesions, but does not cure more severe lesions. Injections of corticosteroids between affected spinous processes, combined with nonsteroidal systemic therapy, can be quite helpful in reducing or removing pain.

Several surgical techniques have been described to remove an affected part of a dorsal process.[27] Newer techniques are less invasive, and endoscopic resection of the spinous process and the interspinous ligament has been performed.[14]

Prognosis

The prognosis for impingement of spinous processes is guarded when the signs are primarily attributable to this disease. In a study by Erichsen,[15] scintigraphic and

VetBooks.ir

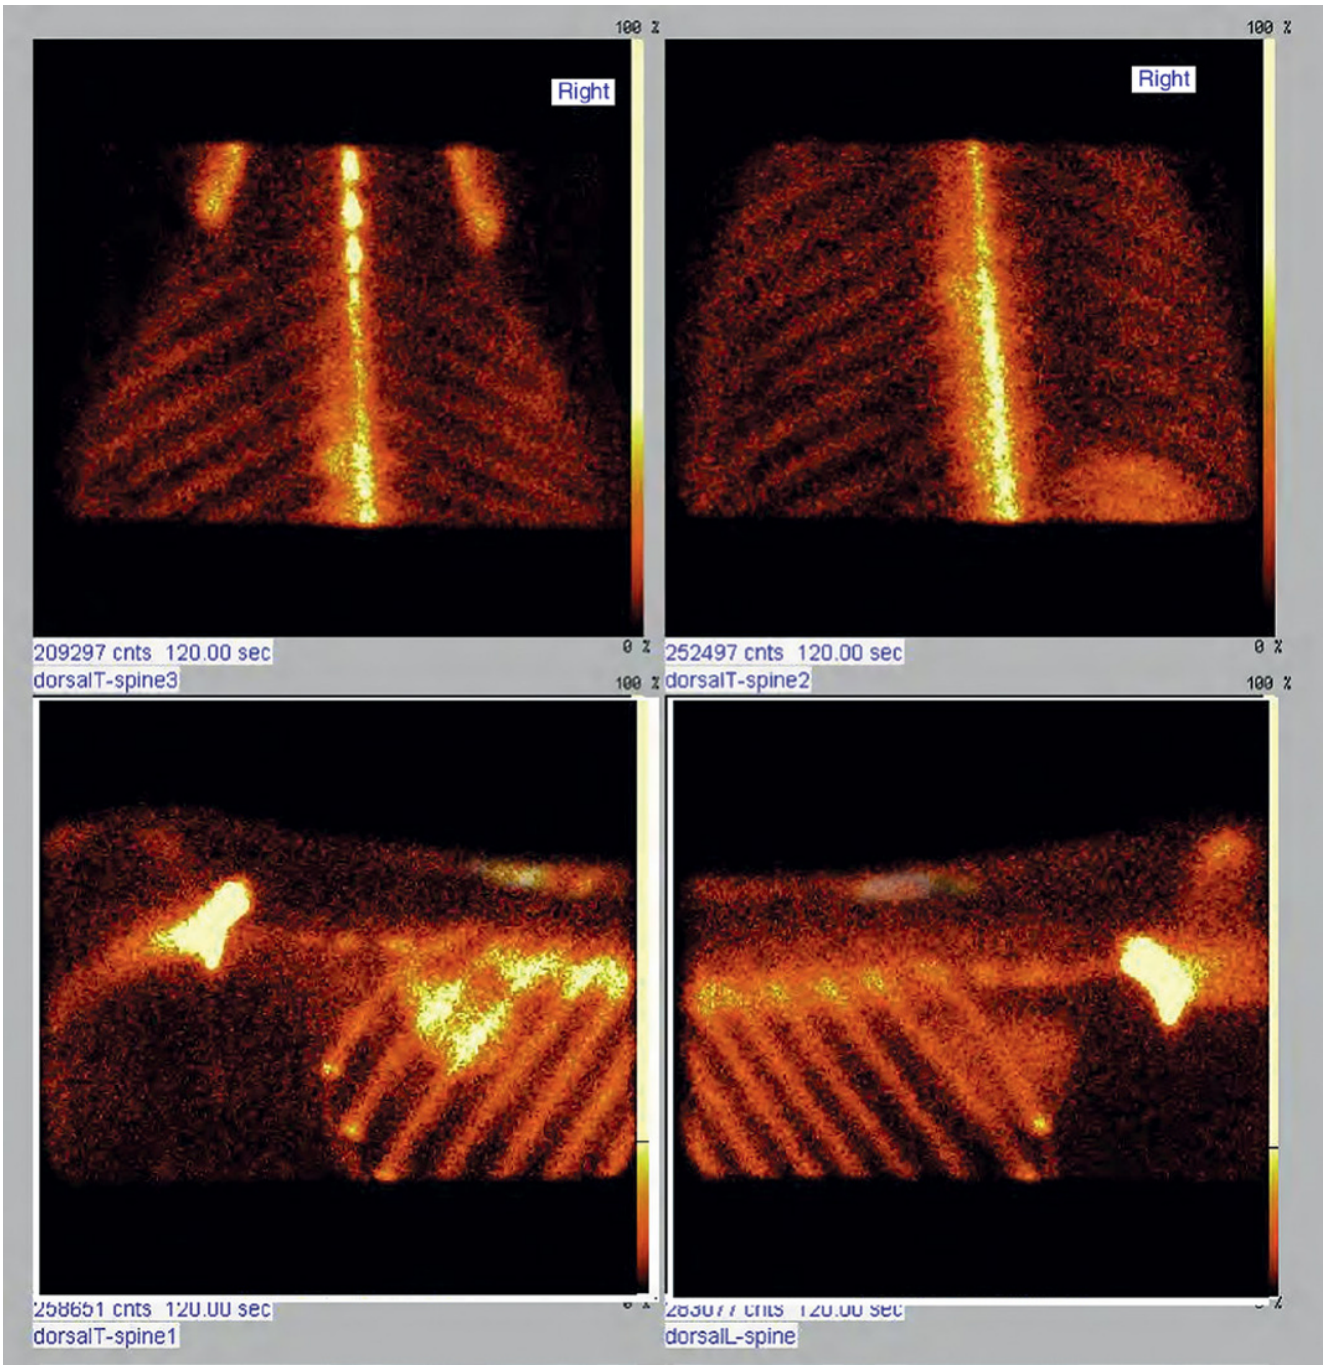

Figure 6.30. Scintigraphic image showing IRU in the dorsal processes of the caudal thoracic spine, visible on lateral views and a dorsal view. This horse was a 13-year-old show jumper with an international Grand Prix career that had no major clinical problems.

radiological signs of impingement were found in completely sound horses. The most important factor in determining the prognosis for impingement of the spinous processes is the complete diagnosis. When ligamentous structures are involved (e.g., supraspinous ligament, intraspinous ligament, ventral longitudinal ligament), the prognosis for a quick recovery to the original workload is less favorable than when just osseous changes are seen on radiographs. When there are adjacent pathologic conditions in the intervertebral disc or the facet joints, prognosis is also less favorable. For more severe cases, prognosis for a return to the original work level after months of rehabilitation seems to be better when resection is performed than when surgery is not performed.[14,27]

SUPRASPINOUS LIGAMENT INJURIES

Injuries of the supraspinous ligament are most common between T15 and L3.[7] They can be associated with localized thickening and pain.

VetBooks.ir

Clinical Signs

Signs of desmopathy of the supraspinous ligament are similar to those of impingement of dorsal spinous processes. When only ligament pathology is present, signs can be mild and very difficult to detect. Occasionally owners may recognize the increased size of the ligament (focal thickening), and this can be the primary complaint. In cases with more swelling in and around the ligament, the appearance of the shape of the spine can resemble kyphosis. In that case, radiography shows a normal configuration of the spine, but ultrasonography can show the soft tissue involvement and edema.

Diagnosis

Ultrasonography is the tool of choice to image these injuries.[22] Diagnosis of the pathology of the supraspinous ligament can be made with ultrasonographic examination. Radiography and scintigraphy can give additional information about the involvement of the spinous processes. Radiographic examination of desmopathy of the supraspinous ligament may show irregular bone margins of the summit of the dorsal spinal processes, avulsion fragments, and sclerosis. Scintigraphy may show increased uptake in the summits of the spinous processes (Figure 6.31). These findings are similar to those of impingement of the dorsal spinous processes, and quite often both pathologic conditions are found in the same horse.

A study of Henson et al. found ultrasonographic changes in the supraspinous ligament in clinically normal horses as well as in horses with signs of back pain.[22]They concluded that when ultrasonography alone does not confirm the diagnosis of desmitis of the supraspinous ligament, then local (infiltration) anesthesia should be performed as well.

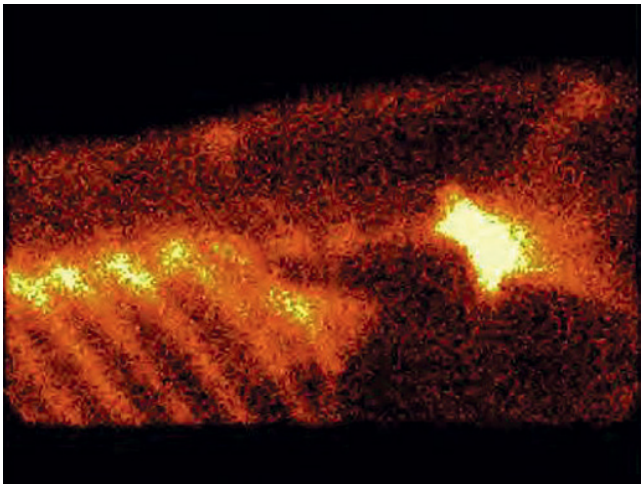

Figure 6.31. Scintigraphic image showing mild focal IRU at the summit of T18, indicative of desmitis of the supraspinous ligament. Radiography did not show any change, and ultrasonography showed mild desmitis with roughened bone margin of the summit of the spinous process of T18.

Treatment

As with any ligamentous structure, treatment is focused on rest, medication, and rehabilitation. Controlled stretching of the ligament with a lower position of the head (i.e., in pasture, with hay on the ground, when ridden with a lower head and a longer neck) and a gradual increase in the workload is recommended.

Prognosis

When the ligament is the only affected structure and adequate time for a complete recovery before resuming the original work is allowed (4–6 months), the prognosis is usually favorable. When more structures are involved, as with impingement of dorsal spinous processes, facet joints, or intervertebral discs, the prognosis tends to be less favorable.

FRACTURES OF THE SPINOUS PROCESSES

Etiology

Fractures of the dorsal spinous processes occur mostly in the cranial thoracic spine (the withers region) when horses flip over, fall backwards, or run into objects with their withers (such as when the door is lower than the horse).[3,24] Sporadic fractures of the dorsal spinous processes in the lumbar spine can be caused by excessive trauma such as falling and turning at high speed, for instance, in cross-country riding, jumping, barrel racing, hunting, or traffic accidents. This places rotational force on the spine, which can cause fractures of the lumbar lateral spinous processes.[19]

Clinical Signs

Fractures of the withers have very clear symptoms, with swelling in this region and deformation of the normal contour of the withers. A significant dent can be observed in the normal curvature of the withers region, and the distal fragment will dislocate in most cases and end up lateral to the remaining spinous process, giving the withers a wider appearance. Fractures of the spinous processes of the more caudal thoracic spine and the lumbar spine are less pronounced in appearance. When the tips of the spinous processes are viewed from above, a clear change in the alignment may be visible, with the tip of the fractured spinous process out of line to the lateral side, possibly with some dislocation to the ventral side. A fracture of the lateral spinous process in the lumbar spine may be difficult to see when observing the horse due to the fact that they may not be dislocated.

In the acute stage, pain is present with generalized back stiffness, localized swelling, and muscle spasms in the epaxial muscles. In older cases, the change in the alignment of the withers or the caudal spine is the clear remains of the fracture, with few other clinical signs. When the mobility of the spine is evaluated, there may be slight alterations at the location of an older fracture, due to remodeling of the fragments and attached muscles.[20,28]

VetBooks.ir

Diagnosis

Radiographic examination is the first diagnostic technique to image the spinous processes because the fragments, which are often dislocated, show clearly on the radiographs.[37] The summits of the thoracic spinous processes, especially in the withers region (T3 to T12), can vary in shape, show a variety in the pattern of accessory centers of ossification, and easily be misinterpreted as a fracture. Dislocation of the fragment is a very common finding in fractures of the spinous processes in the withers region, which helps to distinguish them from irregularities and delayed ossification. In the more caudal thoracic spine and lumbar spine, radiographic examination may be less useful because the muscle mass in these regions can make radiographic imaging incapable of identifying a nondisplaced fracture.

Ultrasonographic examination can give good additional information, especially to identify fractures of the lateral spinous processes in the lumbar spine.[9]

Scintigraphy can show increased radiopharmaceutical uptake after a fracture, but is not specific enough to identify the fractures. For lateral spinous process fractures, scintigraphy can be useful to identify the location of a possible fracture (Figure 6.32), but adjacent ultrasonography is needed to verify this.

Treatment

Treatment for fractured spinous processes is often not required, other than medication to deal with the associated pain of an acute fracture. Surgery is usually not required. Rest and controlled exercise for 1 to several months to keep the horse in good muscular condition usually are sufficient. The saddle should not be used when the withers region is involved.

Prognosis

Prognosis for most spinous process fractures is favorable. Sometimes after a fracture in the withers region, it is difficult to make the saddle fit properly due to the changed shape of the withers. When the horse is judged on shape and conformation in its discipline (i.e., hand showing, breeding championships), the abnormal shape of the withers can influence the judging. Providing the client with a clear veterinary statement that the abnormality is caused by a traumatic event and not genetic and that the horse is capable of competing facilitates a successful show career.

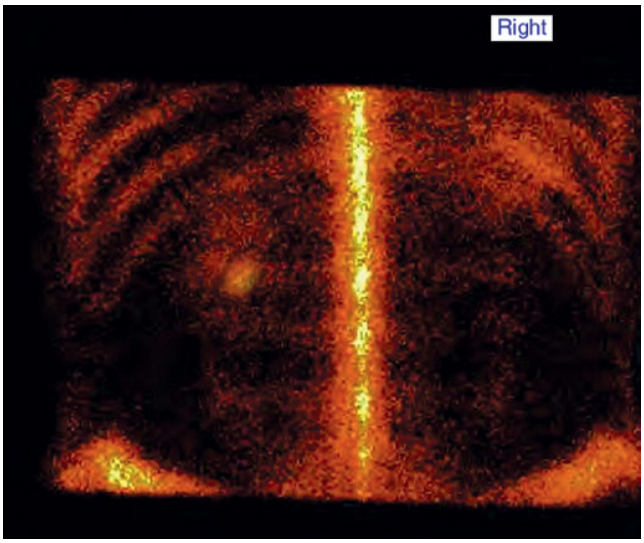

Figure 6.32. Scintigraphic image of the lumbar spine, dorsal view. Note the IRU in the left transverse spinous process of L2. This is indicative of a fracture of the transverse process.

VERTEBRAL FRACTURES

Etiology

Most vertebral fractures are traumatic in origin; however, pathological fractures can occur with processes affecting the vertebrae such as neoplasia, metastasis, and osteomyelitis.[34]

Stress fractures of the vertebra most likely occur more frequently than previously believed. In one study, 18 of 36 specimens had incomplete fractures and focal periosteal proliferation of the lamina stemming from vertebral stress fractures.[19] The fractures occurred most often near the junction of the cranial articular process and the spinous process.

Clinical Signs

Acute vertebral fractures are accompanied by severe pain. The horse is reluctant to move the affected part of the spine and shows increased muscle tension in the region of the fracture. Neurological symptoms are present when soft tissue swelling, hemorrhage, or fragments compress the spinal cord or root nerves. Unilateral root nerve compression can cause the horse to bend to the affected side when root nerve compression leads to irritability of the nerve and to the opposite side when the compression causes complete loss of neurotransmission.

Most stress fractures result in a lack of performance without clear-cut symptoms. Stiffness, lack of propulsion from behind, and mild back pain are common signs associated with laminar stress fractures in the young Thoroughbred racehorse. These are most often seen at the thoracolumbar junction and the lumbar vertebrae.[19,20]

Diagnosis

Radiography can image larger fragments; however, with the initial radiographic examination, these fractures can be easily overlooked when there is little dislocation present. In addition, fractures with a longitudinal fracture line are nearly invisible on lateral views. Scintigraphy is a sensitive technique for vertebral fractures and is nearly the only way to determine active stress fractures.[33]

Treatment

Treatment is conservative in most cases of vertebral fracture without neurological symptoms. Stall rest with very controlled exercise and medication with NSAIDs and often muscle relaxants to reduce the pain and muscle spasms are sufficient. When neurological symptoms are present, treatment focuses more on reducing swelling

VetBooks.ir

around the spinal structures; medication with systemic corticosteroids and DMSO may be indicated.

Prognosis

The prognosis for nondisplaced vertebral fractures without neurological symptoms is favorable, as is the prognosis for most stress fractures. When neurological symptoms are present, the amount of time needed to reduce these symptoms with medication is a good indicator for future expectations. The longer it takes for the recovery of neurological functions, in general, the poorer the prognosis.

FACET JOINT ARTHRITIS AND VERTEBRAL FACET JOINT SYNDROME

Etiology

When facet joint osteoarthritis is present in the thoracolumbar spine, similar to this process in humans,[31,32] a complex of processes in and around the vertebral facet joints can lead to a painful condition known as facet joint syndrome. In the cervical spine, however, osteoarthritis of the facet joints seems to be less frequently related to facet joint syndrome than in the thoracolumbar spine, and the accompanying muscle spasms in the segmental muscles are absent. This gives the impression of an isolated joint disease with a reduced range of motion and pain in just the affected joint. However, compression of nerve roots due to proliferation of the bone around the facet joints is a more common observation in the cervical spine than in the thoracolumbar spine.

The initiating incident in facet joint syndrome is damage to the facet joint, primarily to the joint capsule and the adjacent connective tissue, or else to the cartilage and/or subchondral bone. In the horse, this primary incident quite often is trauma, caused when the horse slips, falls, flips over, gets cast, or injures itself in any other way. Due to the rich innervation of the facet joint tissues, the inflammation reaction caused by the primary trauma starts a cascade of reactions that is more obvious than in the joints of the limbs.

One of the first reactions of the horse is stabilization of the spine by muscular contraction and spasm of the epaxial and subaxial muscles. This can occur in just the segment that is related to the injured vertebral facet joint, but a larger portion of the vertebral column may be involved. This muscle contraction can be short, last hours to days, or last weeks or even months. It is very likely that the prolonged contraction or spasm is very painful and partially immobilizes the spine, as is the situation in humans.[31,32]

As a consequence of this immobilization, the facet joint is more or less fixed in one position, which makes regaining later mobility a painful experience.[18] Due to the muscle spasm, no normal sequence of contraction–relaxation occurs in the muscle, and the normal supportive function is less effective.[21] Consequently, when excessive force is applied to the spine again, repetitive injury to that facet joint can be the result.

Clinical Signs

Due to the contribution of the spine to the normal gait pattern in the horse, as described earlier in this chapter, horses that suffer from vertebral facet joint syndrome are often presented for lameness. In acute cases, the pain in and around the facet joints can be so severe that the horse does resist all movement and stand with the hindfeet parked out and the back lowered. This position closes the facet joints in the thoracic and lumbar spine, causing less tension in the joint capsules. The muscles of the back and hind end are contracted. This attitude can be difficult to differentiate from tying-up syndrome; however, with vertebral facet joint syndrome, the serum levels of creatine kinase (CK) and aspartate aminotransferase (AST) are within normal limits or only slightly elevated.

With severe pain in the thoracic or lumbar spine, signs can be similar to those of colic, with restlessness, pawing, looking back, or standing with the hindlegs parked far out, giving the impression of wanting to urinate. In those cases, the heart rate can be as high as 60–80 beats per minute, but an examination for colic reveals that the horse is within normal limits.

In more chronic cases, the locomotion of the horse can be altered and a stiff back noticed. At the trot, the propulsion of the hindlimbs can be reduced unilaterally or even bilaterally.[21,25] Due to the attachment of the front limbs with ligaments, tendons, and muscles to the thoracic vertebrae, motion of the front limbs also affects the position of the thoracic facet joints. At the trot, due to the diagonal gait, the thorax moves between the scapulae, with a maximum extent of motion in the dorsal processes of the withers of 1–3 cm to left and right. Pain in the facet joints of the thorax thus can lead to less mobility in the thoracic spine, and an altered gait pattern in the trot is best described as stiff or shortened.[21]

During the canter the thorax moves less, except in downward transitions (changing from canter to trot or trot to walk) when there is more loading of the facet joints, as well as in landing after a jump or going downhill. Therefore, when thoracic facet joints are involved, signs mentioned by the owner or rider can include stiffness, reluctance to go downhill or jump, and refusal or difficulty in extended trotting. Especially in jumping, a trainer or rider may note a preference of the horse to go left or right after a jump, and this is quite often thought to be related to an injury to the distal limb but in fact is caused by facet joint problems.

Because lateral bending is a prominent mobility feature of the thoracic vertebrae, lateral bending of the horse may be reduced when thoracic vertebrae are involved with facet joint syndrome. This can be observed during circles and serpentines and in lateral exercises such as shoulder in, travers, and half pass of dressage, as well as in turns in barrel racing, polo, and eventing, or in between fences when jumping. Tightening the girth or putting the saddle on also can reveal an adverse reaction of the horse, because these actions can load the thoracic facet joints.

When lumbar facet joints are involved in facet joint syndrome, the most affected gait is the canter, because it is then that the dorsoventral flexion of the lumbar spine is most prominent. The lateral exercises—shoulder in,

VetBooks.ir

travers, and half pass—can show alterations when lumbar facet joints are involved because the rotation in the lumbosacral region makes an important contribution to these movements. In racing, dorsoventral flexion of the lumbar spine is a prominent contribution to the propulsion phase of the hindlimbs, so loss of performance may be caused by lumbar facet joint syndrome.

Diagnosis

The thoracic vertebrae can be viewed with radiography with the lungs facilitating radiographic imaging in the cranial part of the thorax. In most horses, the vertebral bodies of T1 through T15–T16 can be imaged adequately to evaluate the intervertebral disc spaces and vertebral body as well as the ventral aspect of the vertebrae.[32] In the more cranial part of the thorax, it is difficult to get a clear image of the intervertebral disc space and the facet joints because of the superimposing structures of the scapulae. Depending on the conformation of the horse, the width of its thorax, musculature, and body condition, oblique lateral views can isolate the unilateral facet joints from T5–T7 to T18 (Figure 6.33). When pathology of the facet joints is present, there are signs of sclerosis of the bone just around the facet joint, narrowing of the joint space, irregular shape of the joint space, and spur formation at the edges of the joint space or complete ankylosis visible on the radiographs. Lumbar vertebrae are the most difficult to visualize with radiography. Especially well-muscled horses of the bigger breeds often give disappointing images, and it is difficult to differentiate their facet joints from the massive vertebral bodies of the lumbar spine. Oblique lateral views can sometimes facilitate imaging of the unilateral facet joints of the lumbar spine. Even under general anesthesia, the facet joints of the sacrum and the adjacent pelvic bones cannot be viewed accurately with radiography. However, the coccygeal vertebrae are easy to see with radiography.

Ultrasonography is a very useful tool for examining the facet joints of the vertebral column.[9] It can give information about ligamentous structures and muscle conditions (Figure 6.34), high muscle tension can be shown as increased muscle echogenicity, and fasciculations can be visualized in real-time ultrasonography. The supraspinous ligament, interspinous ligaments, and dorsal sacral ligaments can be examined with this as well. Paramedian longitudinal views of the facet joints can be used to determine the edges of these joints, which should normally be smooth and bilaterally symmetrical. Possible effusion of these joints, bony proliferations at the joint margins, and fractures and avulsion fragments and ankylosis of the facet joints (Figures 6.34–6.36) can be seen with ultrasound.

Doppler ultrasonography can provide valuable information about vascular activity around the facet joints (Figure 6.37). In cases of synovitis or osteoarthritis of a facet joint, increased vascular activity can be visualized around the facet joint, especially when the adjacent facet joints and the contralateral facet joint are compared.

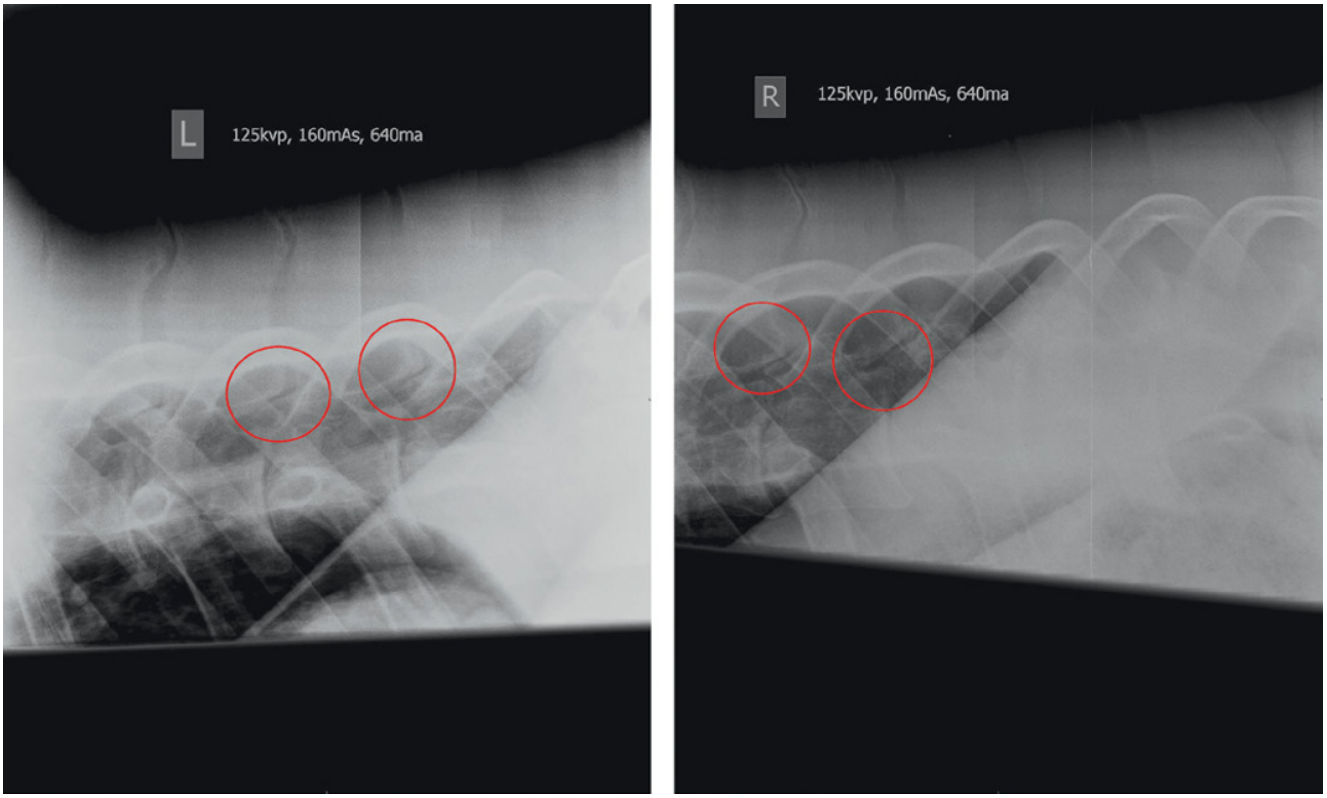

Figure 6.33. Radiographic image of the thoracic spine, (oblique lateral view) to expose the left facet joints (circles) at the left, and the right facet joints at the right. Note the more irregular joint space and some sclerosis in the right facet joints. This is indicative of osteoarthritis of the right thoracic facet joints.

VetBooks.ir

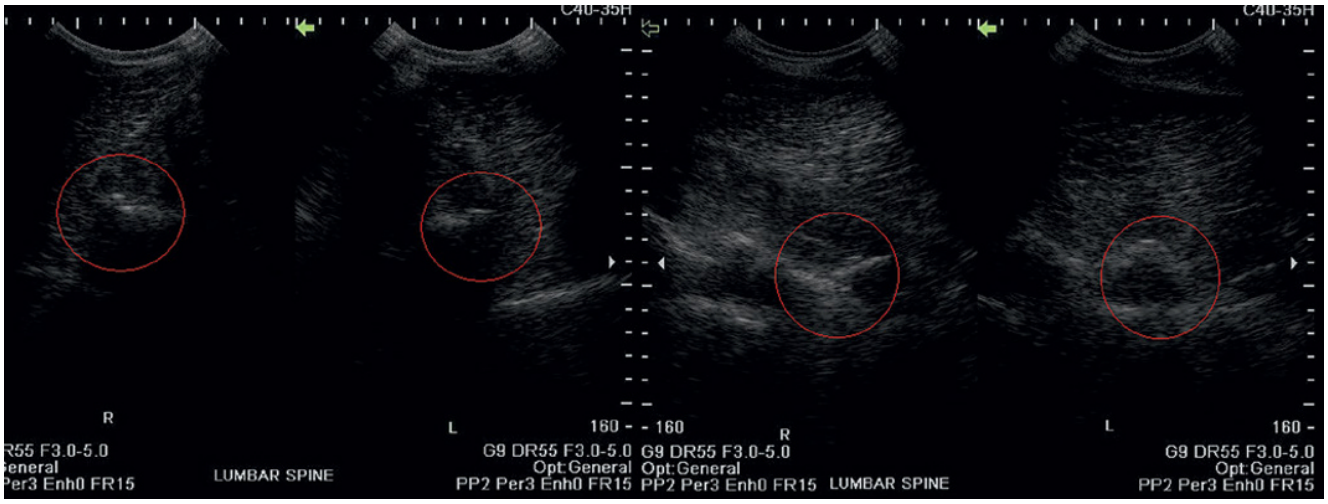

Figure 6.34. Ultrasonographic images of the lumbar spine. Transverse views (left images) of the left side and right side; the facet joint surfaces and the joint spaces are seen in the circles. Right side, two longitudinal paramedian views. The respective facet joints are seen in the circles; the joint space and both facets are in the left circle, and in the right circle the joint space is not visible.

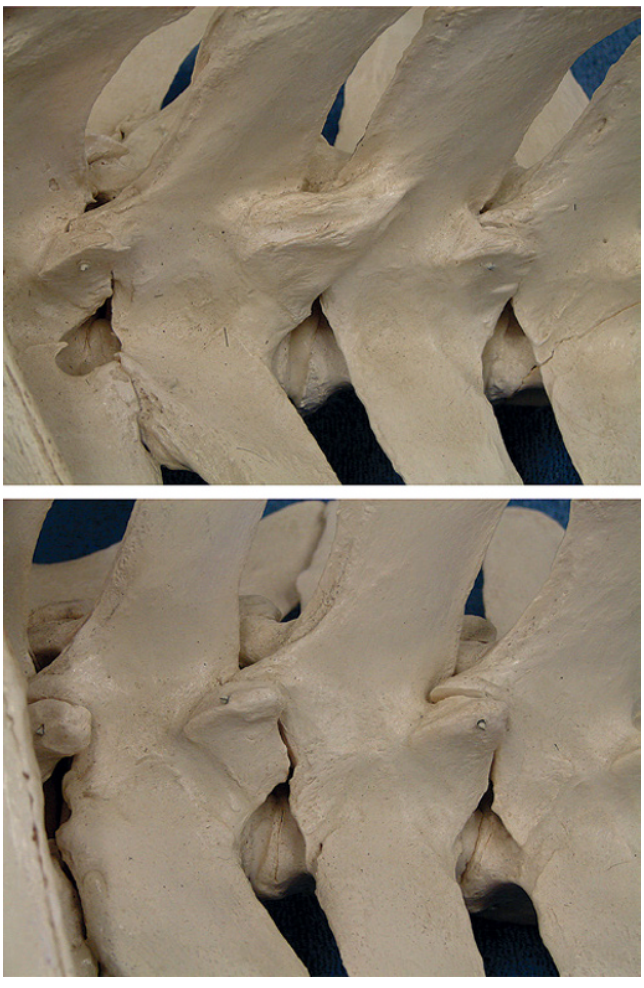

Figure 6.35. Anatomical specimen of the lumbar spine with the facet joints visible. In the lower image, the facet joints have smooth edges and appear to be normal. In the upper image the facet joints have more irregular edges when compared with the facet joints in the lower image. Complete ankylosis is present in one of the facet joints.

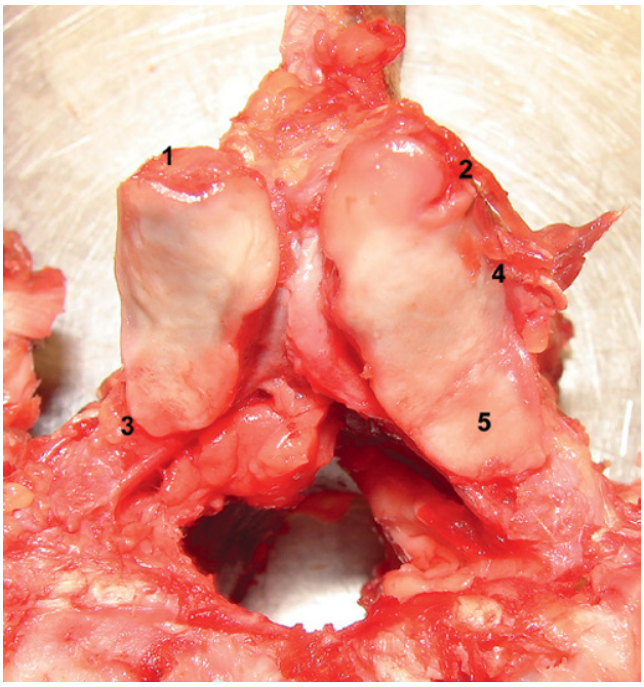

Figure 6.36. Necropsy specimen of the thoracic facet joints of T7. Note the asymmetry and difference in size from the left and right facet joint. 1 = erosion of cartilage and hemorrhage from the subchondral bone, 2 = fraying of the cartilage, 3 = compression damage of the cartilage, 4 and 5 = some ulceration of cartilage.

When muscles are evaluated with Doppler ultrasonography, vascular patterns within the muscles can provide information about myositis and muscle tension, in which cases increased and decreased vascular activity can be present, respectively.

Scintigraphy is a perfect modality for imaging the vertebral column. When the resolution of the gamma camera is adequate, it is possible to differentiate increased uptake of radiopharmaceutical in the vertebral body from that

VetBooks.ir

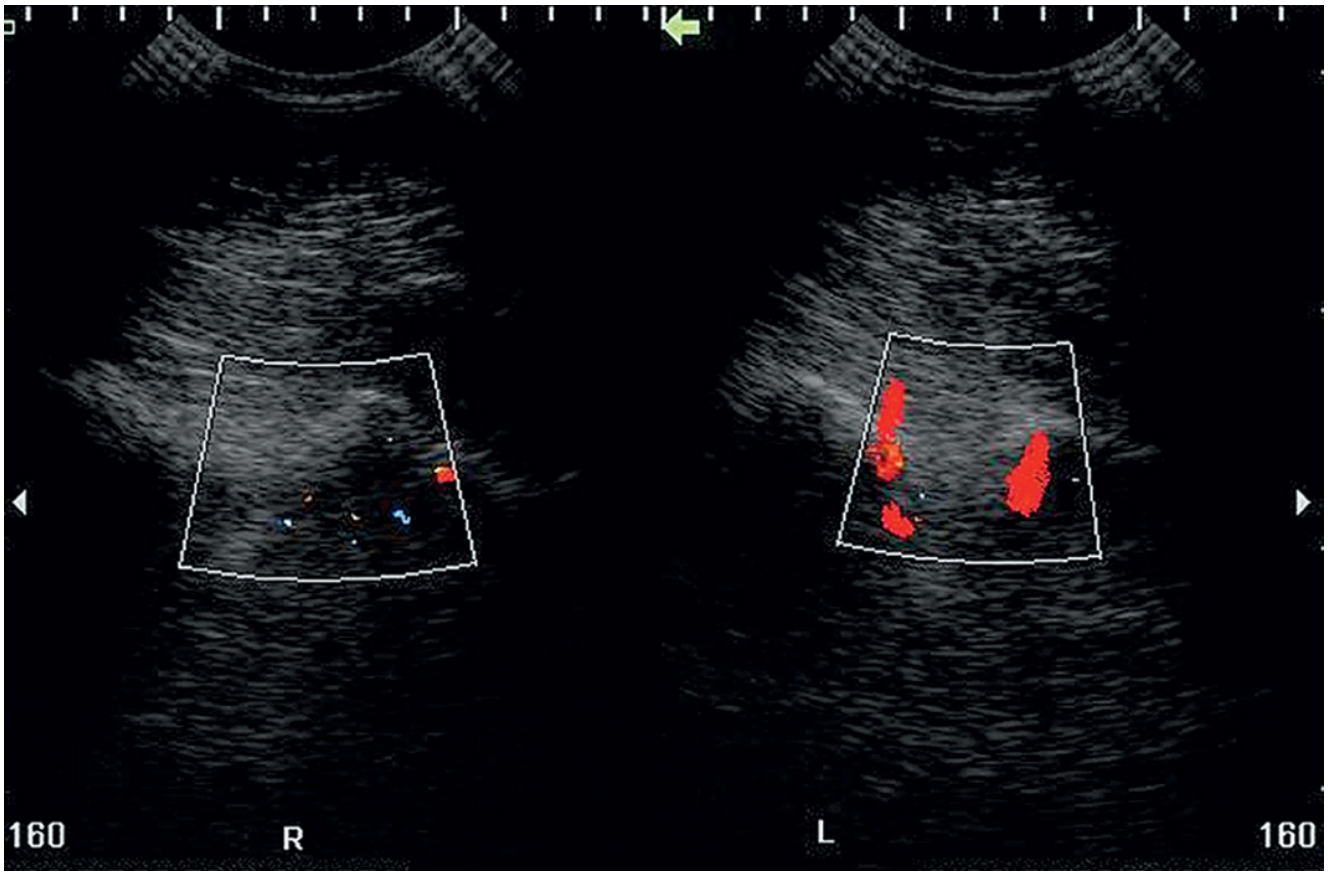

Figure 6.37. Ultrasonographic image of the lumbar facet joints. Doppler is used to identify higher blood flow around the facet joint at the left facet joint (right in the image).

just dorsal in the facet joint. A recent study showed 61.5% of horses with back pain complaints had an increased uptake of radiopharmaceutical in one or more facet joints.[16] Comparison of images obtained from the left, right, and dorsal aspects can assist in determining the exact location of higher bone metabolism in a facet joint.

The final diagnosis of equine vertebral facet joint syndrome is often a summation of the results of two or three imaging techniques. When the results of Doppler ultrasonography and scintigraphy are combined, it may be possible to differentiate between synovitis with its increased vascular activity around the facet joint and osteoarthritis, which can have both increased uptake of radiopharmaceutical in the region of the facet joint and increased vascular activity.

The study by Gillen concluded a high predictive value for negative scintigraphy findings to exclude osteoarthritis of facet joints as the cause of back pain in horses.[16] The authors found a high predictive value for scintigraphy in the detection of radiographic lesions and back pain. Thus, scintigraphy is a valuable tool in the evaluation of thoracolumbar pain.[16]

Local anesthesia is not a reliable tool for confirming facet joint pain. Anesthetic solution is deposited in muscle tissue rather than in the facet joint or its capsule and diffuses rapidly within the muscle, affecting nerve sensation in the rami of the spinal nerves. Furthermore, the reflectory spasm that is caused by the facet joint arthritis takes several hours to relax, making it very difficult to adequately interpret the results of the block. In humans, anesthesia of a suspect facet joint is performed on a more regular basis, but people can communicate and tell the examiner when the main joint pain they were experiencing is diminished, even when a muscle spasm is still present.[31]

Treatment

Rehabilitation is a significant factor influencing the final outcome of facet joint arthritis and vertebral facet joint syndrome.[29] The primary goal is to break the vicious cycle of inflammation that triggers the nerves, which leads to muscle spasm, immobility of the spine, and repeated injury. Treatment can be aimed at multiple spots in this cycle, but the best outcome can be expected with complex treatment plans that deal with as many aspects as possible.

Anti-inflammatory therapy is essential. NSAIDs, especially phenylbutazone (1 g/500 kg BID), flunixin meglumine (0.5 mg/kg SID), naproxen (10 mg/kg SID), and meclofenamic acid (2 mg/kg SID), must be administered for a prolonged time, often up to 1–2 months. In that case, additional medication to prevent gastrointestinal side effects may be needed. The newer NSAID firocoxib may be a good choice for horses with gastrointestinal side effects that are on other NSAIDs, but it must be limited to a 3-week period of medication, according to the manufacturer. Some positive experience

VetBooks.ir

has been obtained in back pain cases with bisphosphonates, especially when osteolysis is present.[6]

More localized anti-inflammatory therapy is obtained by direct injections of a corticosteroid into or close to the facet joint. The author's drug of choice is triamcinolone (10–30 mg intra-articularly). The triggering facet joint must be established by scintigraphy that shows increased uptake of radiopharmaceutical in the area of the joint, possible radiographic changes, and/or ultrasonography that reveals increased vascular activity around the facet joint. With ultrasound guidance, a 20-gauge spinal needle is inserted into the dorsal aspect of the facet joint, and 10–30 mg of the corticosteroid is injected into or close to the joint capsule. Because the medication is deposited in the joint capsule or in the adjacent multifidus muscle with an important proprioceptive function in intervertebral motion (the multifidus muscle stabilizes the spine and facilitates limb motion without deformation of the axial skeleton), the use of sarapin to reduce pain sensation is contraindicated.

Anti-inflammatory treatment should diminish muscle spasms, and quite often, muscle relaxation is observed within 2–3 days of facet joint injection. When only systemic medication is used, beneficial effects occur more slowly, and muscle relaxation can take up to 2–3 weeks. Use of a muscle relaxant such as methocarbamol (15–25 mg/kg slow IV infusion) can be effective in reducing the muscle spasm, but the supportive function of the spinal muscles may be diminished, so care must be taken to reduce the possibilities for injury to the spinal structures. No turnout and a reduced workload are important in a horse that is on muscle relaxants; however, this may compromise an effective rehabilitation program.[29]

After reduction of inflammation and the adjacent muscle spasm, the next step in treatment is the design of a rehabilitation program aimed at gaining more mobility in the affected part of the spine as well as the development of better muscle support for that region. In the author's practice, rest is prescribed for 4–6 weeks. Pasture is ideal, but if the horse is turned out with others, it must only be with pasture mates that will not force the patient to run. The more the horse walks, trots, and canters at its own pace, the better the mobility achieved. Grazing with the head down opens the facet joints in the thorax and lumbar region, thus counterbalancing the spasms in the dorsal epaxial muscles. In humans, one of the modern rehabilitation techniques with tendon and ligament injury is eccentric exercise. The stretching effect of the grazing position on the dorsal epaxial muscles as well as the tendons and ligaments around the spine may be a very important side effect of being out in pasture. When a patient cannot go out in pasture, mimicking this position by feeding small portions of feed and hay on the ground at multiple times during the day is a good alternative.

After the initial period of rest, a period of gradually increased work must be incorporated in the rehabilitation program. At first, just circling exercises at the walk and later at the trot facilitate more lateroflexion, thus providing stretch to the outside part of the spine and some compression and rotation to the inside part of the spine. By modulating the size of the circle and the direction of the circle in a 1- to 2-minute pattern, gradual mobilization of the entire spine can be achieved. In a later stage, some cantering can be introduced in circles as well as at the track or over terrain, together with more strenuous exercises to stimulate more powerful muscle contraction. In the author's clinic, a complete rehabilitation program can easily take 4–6 months, after which a large number of cases are fully serviceable at the original level of performance or even higher.

Prognosis

The prognosis for horses with thoracic or lumbar facet joint arthritis depends on a number of factors. The discipline in which the horse performs is very important. In the racing horse, thoracic facet joint arthritis has a better prognosis than facet joint arthritis of the lumbar facet joints, whereas the prognosis for thoracic facet joint arthritis for a barrel racer may be more performance limiting than lumbar facet joint arthritis. Three-day event horses and jumpers often have a more guarded prognosis than dressage horses. In the dressage discipline, rehabilitation of the core muscles of the trunk can assist in stabilizing the spine and prevent recurrent injury. Racing trotters seem to have the worst prognosis for full return to a racing career when diagnosed with facet joint arthritis or thoracolumbar pathology in general.

DISCOSPONDYLITIS

Etiology

Discospondylitis is an inflammatory condition involving the vertebral bodies adjacent to the symphysis between two vertebrae, and includes the intervertebral disc.[30] The most common cause is a septic process, in which the infection is caused by hematogenous spread. The primary site of infection should be identified. Blood flow through vertebral endplate venous channels is relatively slow and tortuous, which may promote localization of the infection in the vertebra and spread to adjacent discs.[36] Bacteria isolated from cases of equine adult discospondylitis include *Brucella abortus*, alpha-hemolytic *Streptococcus*,[1] coagulase negative *Staphylococcus*,[5] and *Staphylococcus aureus*.[35] *Rhodococcus equi* has been implicated in a foal.[4]

Traumatic discospondylitis has been documented in clinical cases and at postmortem examination.[30] Intervertebral disc lesions, including fissuration, calcification, and herniation, have been described ultrasonographically and at postmortem examination at the lumbosacral junction and the cervical spine.[11]

Clinical Signs

Signs of weight loss, back or neck pain, fever, stiffness, and ataxia may all be notable in discospondylitis. Atrophy of the epaxial muscle in the thoracolumbar region may be evident in some horses suffering from chronic discospondylitis in this region.[2] Some horses are so affected that they are reluctant to eat off the ground. Lateral neck flexion can be markedly obtunded as well, and the abdomen may be held rigid as though intra-abdominal pain were present. When compression of the spinal cord or root nerves is present, neurological

VetBooks.ir

symptoms can be observed.[10] Blood analysis may reveal a leukocytosis and elevated fibrinogen.

Diagnosis

Diagnosis of discospondylitis is based upon appropriate clinical signs and radiographical findings.[1] Radiographic features of discospondylitis include lysis and/or proliferation of the vertebral bodies adjacent to the affected disc. As the disease progresses, the intervertebral disc space may narrow and collapse, and a smooth bony bridge may unite the affected vertebrae.[36] Scintigraphy,[23] computed tomography,[34] and ultrasonography[35] have been used to facilitate the diagnosis of equine discospondylitis and vertebral osteomyelitis. Scintigraphy may be useful to determine whether multiple sites of bone involvement are present.[37]

Treatment and Prognosis

Successful treatment of discospondylitis usually involves long-term antimicrobial administration.[2,23,36] In specific cases surgical curettage of the lesion is an option when access to the lesion is possible.[35] If the causative organism is not isolated, as is usually the case, broad-spectrum antimicrobials should be administered. Intravenous antimicrobials often reach higher tissue concentrations than oral medication and are recommended at the onset of therapy. Antimicrobials allowing distribution and penetration into the bone should be administered; therapeutic options may include fluoroquinolones, macrolides, cephalosporins, and potentiated sulphonamides.[2] The total duration of antimicrobial treatment can be 4–6 months, which can make the treatment very costly.

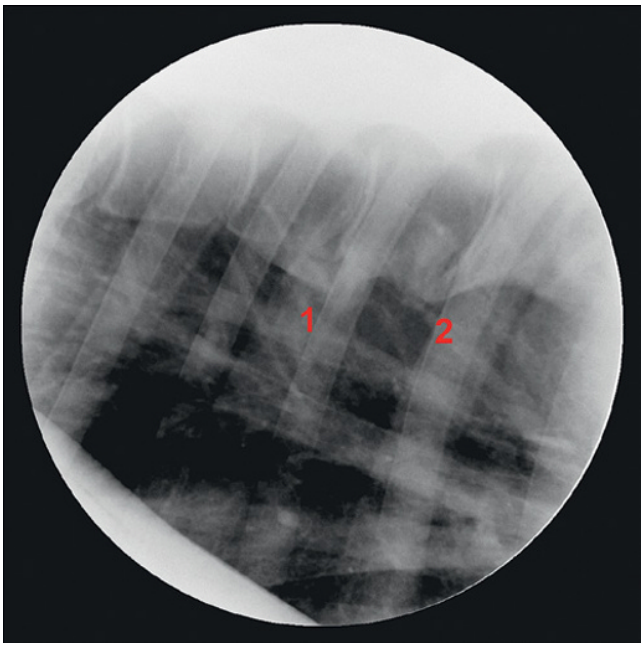

Figure 6.38. Radiographic image of the thoracic spine of a horse with severe spondylosis. There is proliferation of bone at the ventral aspect of the vertebral bodies. 1 = no complete contact between the proliferations, 2 = seemingly complete bridging of the intervertebral disc space.

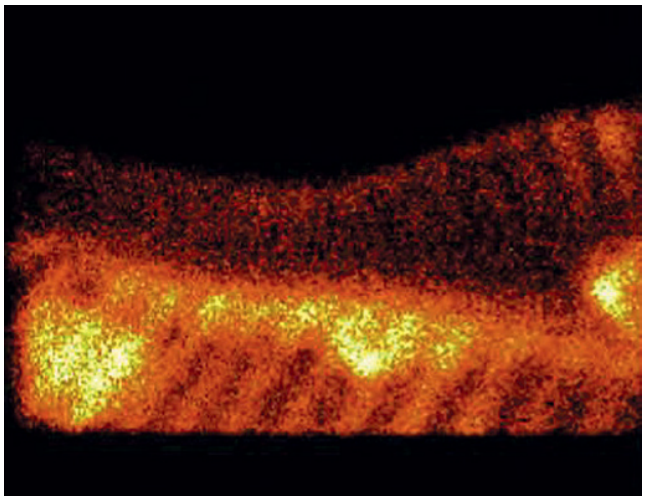

Figure 6.39. Scintigraphic image of a horse with IRU in the midthoracic spine, suggestive of spondylosis.

Although the prognosis for horses with discospondylitis has generally been considered guarded, favorable outcomes have been associated with early detection, nonseptic lesions, the absence of spinal cord compression, administration of long-term antimicrobial therapy, and surgical curettage.[1,23,35]

SPONDYLOSIS

Etiology

Spondylosis (deformans) is more common than discospondylitis. It involves the vertebral body only, without including the intervertebral disc.[30] It is a degenerative condition affecting the vertebral body on the ventral aspect in the thoracic spine and merely the lateral aspect in the lumbar spine. Spondylosis results in osteophytes, often seen in several adjacent vertebrae. The most common location for these osteophytes is the vertebral segment between T10 and T14.[10,13] Probably because of regional biomechanical influences, the osteophytes are located at the ventrolateral aspect of the vertebral bodies in the thoracic region. Pathogenesis of osteophyte formation involve mechanical stress at the attachment of the most peripheral fibers of the intervertebral disc and the ventral longitudinal ligament (enthesiophytes).

Postmortem results of acute cases showed hemorrhage and fraying of collagen fibers of the intervertebral disc, no deeper than the annulus fibrosis. The facet joints in these cases had been jammed together, and there was evidence of fraying and erosion of cartilage and hemarthrosis.[30] The osteophytes resulted in reduced mobility of the spine at the site of the osteophytes (with the end stage of complete ankylosis), putting more of the motion load on the adjacent vertebrae that induces more active bone remodeling, often visible on scintigraphic examination.

Clinical Signs

In the more acute stage, when active bone remodeling is in progress, the horse can show severe back

VetBooks.ir

Figure 6.40. Seven-year-old Thoroughbred with marked kyphosis in the thoracolumbar spine. No clinical symptoms of back pain were present.

pain with generalized stiffness and reluctance to work. These cases seem to relate to the lay term of cold back, in which saddling, mounting, or starting to ride initiates a violent reaction of the horse, including bucking, running away, and laying down. In older cases the condition is less painful but more limiting in the motion of the spine, giving the horse a more stiff appearance. In chronic cases, there is often loss of cartilage in the facet joints, and the dorsal spinous processes can come close or make contact, giving the horse the appearance of a hollow back or acquired lordosis. This condition seems to be more common in event horses, show jumpers, and hunters than in Thoroughbred and Standardbred racehorses. Working draft horses endure enormous forces on their spine when pulling heavy loads and seem to be more predisposed for spondylosis.[30]

Diagnosis

Radiography and scintigraphy (Figures 6.38 and 6.39) are the main diagnostic tools to confirm spondylosis. Scintigraphy can show the amount of bone activity as an indicator for acuteness and activity.

Treatment

Medication with NSAIDs is the only option. No surgical techniques have been described in the horse to stabilize the spine.

Prognosis

Prognosis for spondylosis to return to athletic career is guarded.

SCOLIOSIS, KYPHOSIS, AND LORDOSIS

These conditions can be congenital defects. The basic pathological defect of both scoliosis and lordosis is hypoplasia or aplasia of the articular facets of the intervertebral articulations, primarily in the thoracic spine.[38] Acquired lordosis can be seen in the older horse with osteoarthritis and ankylosis of the facet joints.[30]

Kyphosis in the lumbar spine seems to occur in Thoroughbreds (Figure 6.40). No data is available on the performance of horses with this condition.[6] With congenital deformities, it is likely that these conditions are not painful, but that they can limit athletic careers due to limitations in motion and propulsion. In the acquired cases, the initiating condition (osteoarthritis) can cause pain and clinical symptoms, as can localized pathology of the supraspinous ligament caused by focal kyphosis.

THE NECK AND POLL

Rob Van Wessum

VetBooks.ir

This section emphasizes the cervical disorders that directly cause or contribute to lameness. The developmental cervical disorders, most often causing neurological symptoms, are covered in Chapter 12.

As described in the first part of this chapter, the cervical spine has an important function in locomotion.[6] Any dysfunction of the cervical spine can cause an altered gait pattern, often described as lameness. Sometimes the symptoms of the dysfunction of the cervical column are observed as altered behavior (head shaking, not connecting with the rider's hand, pulling, bucking, rearing, etc.) but are presented to the veterinarian as lameness. Other cases are presented as lower limb lameness or shoulder lameness.[15] The following sections cover the common causes of cervical dysfunction and their symptoms, diagnosis, and treatment.

NUCHAL LIGAMENT

The nuchal ligament connects the caudal aspect of the skull, dorsal processes of the cervical vertebrae, and withers region (the dorsal processes of the first thoracic vertebrae) and has an important function in supporting the entire neck. Elastic fibers in this structure store kinetic energy during locomotion and release the energy at specific phases of the locomotion when certain muscle groups move or activate parts of the cervical spine and the attached front limbs, thus contributing to an efficient gait. The head and neck function as a sling during propulsion and have a coordinating function in the specific pattern of the gait. For instance, the periodic sinusoid motion instigates activation patterns in the muscles of the neck and shoulder.[10]

Desmopathy at the origin of the nuchal ligament located at the base of the skull and the insertion to the dorsal processes of the cervical and cranial thoracic vertebrae is associated with pain and can alter this sinusoid pattern, thus altering the gait.[4,12,13] Tension in the nuchal ligament and its attachments is greater, and symptoms of desmopathy can be more pronounced in specific positions, such as when the neck is more flexed, the head is more parallel to the vertical or even behind the vertical, or the head is in a higher or lower position.

Etiology

Etiology of desmopathy of the nuchal ligament is very often associated with trauma. Falling down or pulling backward when tied, being caught in fences, and trailering accidents can put extreme force on the ligament and its attachments, causing trauma to the nuchal ligament and other structures in the neck and poll. Training methods such as tying the horse's head to the side or between the front limbs, as is sometimes practiced in preparation for Western pleasure, or hyperflexion or "Rollkur," as is practiced by some dressage trainers, can predispose horses in these disciplines for nuchal ligament pathology.

Clinical Signs

Symptoms of nuchal ligament pathology are diverse and very often more visible when the horse is worked. The horse may appear stiff, the neck does not move up and down as much as usual at the walk, and when worked on circles the head is out with no flexion of the neck according to the diameter of the circle.

When ridden or driven, the contact with the bit through the reins or lines can feel different to the rider/driver, with one side feeling more rigid or as if the horse is pulling on one side. Dental issues can have the same symptoms, so excluding dental problems helps to confirm or at least suspect neck problems. Particular head positions can cause pain, making the horse behave defensively or reluctant to perform certain exercises.

The neck is an important balancing tool for the horse during work, so in disciplines in which balance is of major importance for performance, such as jumping, dressage, and eventing, general lack of performance can be one of the more indistinctive signs.

Diagnosis

Desmopathy can be found at the attachment of the ligament to the bone, which may cause enthesophytes that can be seen with radiographs. It also may be located in the ligament itself, in which case the altered fiber pattern is visible on ultrasonographic examination. Nuclear scintigraphy can show the increased bone turnover at the attachment sites (Figure 6.41). MRI and CT can give detailed information about the condition of the

Figure 6.41. Radiographic image of the cervical spine with C5, C6, and C7 in view. There is mild enlargement of the facet joints between C5 and C6 and C6 and C7, with irregular joint spaces. This is indicative of mild to moderate osteoarthritis of the caudal cervical facet joints and is a common finding in horses without clinical signs.

VetBooks.ir

more cranial cervical vertebrae and the ligament. Newer MRI equipment (with smaller bore and larger aperture) facilitates imaging of the more caudal vertebrae, but in most cases imaging is limited to the level of the fourth or fifth cervical vertebra.

Treatment

Therapy for desmopathy of the nuchal ligament is similar to that of any desmopathy: rest and anti-inflammatory medication, as well as possible extracorporeal shock wave treatment. Biological treatments with stem cells, A-cell, and PRP are in the stage of experimental use, and studies to be published in the near future on these therapy modalities will show their effectiveness in treatment of desmopathies in general and in the nuchal ligament in particular.

A specific structure in the poll, the nuchal bursa, which is present at the dorsal aspect at C1 in nearly all horses and less frequent at C2, can be involved in pathology of the nuchal ligament. Bursitis is considered to be a rare condition. However, many veterinarians in the field of sports medicine diagnose bursitis of the nuchal ligament quite frequently. It is difficult to completely confirm this diagnosis on ultrasonographic examination alone. CT or MRI imaging, performed under general anesthesia, can give a more detailed image of the bursa(e) and its adjacent structures along with a more confirmed diagnosis. A common treatment modality for bursitis of the nuchal bursa is the ultrasound-guided injection of corticosteroids into the bursa. Calcifications in the bursa region are observed quite frequently in the author's clinic on routine radiographs of this region; however, in these cases the owner of the horse may not always remember any treatment or problem in this region.

Prognosis

When given enough time for complete recovery and rehabilitation, prognosis for nuchal ligament desmopathy is favorable.[4] The only exception may be the high-level dressage horses when the initial injury to the ligament has not been recognized and has developed into a more chronic phase or is considered to be a repetitive stress injury. In these cases, when the horse's head is in a very high and upright position, as needed for the highest grades of collection, strain to the ligament is the highest, and the horse can show pain or defensive behavior such as rearing or shaking the head.

When calcifications are present due to mineralization of a hematoma or corticosteroid deposition, signs of altered behavior or performance are common, and prognosis is guarded for complete recovery to the initial level of performance.

CERVICAL FACET JOINTS

Osteoarthritis of the cervical facet joints is very common in many horses, even without clinical signs.[4,11] Enlargement of the more caudal facet joints with irregularly shaped or narrowed joint spaces is common on cervical radiographs in horses of any breed at a slightly older age (older than 4–5 years) (Figure 6.41).

Etiology

Osteoarthritis of the cervical facet joints can be the result of osteochondrosis of the articular surfaces, as in any other joint affected by osteochondrosis. Trauma to the neck is often a cause for facet joint arthritis. The trauma may be the result of trailering accidents, falling or hanging in cross ties, running into objects with the neck, falling during exercise (racing, eventing, jumping), flipping backwards, etc. Instability of the neck due to malformation of vertebrae or joint surfaces predisposes the horse to facet joint arthritis, and it is often found in conjunction with several congenital or developmental cervical malformation syndromes.

Clinical Signs

Osteoarthritis of the cervical facet joints can cause a great diversity of symptoms. At first, pain can cause behavior similar to that described for nuchal ligament pathology.

When severe bone proliferation is present at or around the facet joints, mobility can be limited, thus limiting athletic performance. In dressage, the horse may be reluctant to bend the neck in a lateral direction, bring the head vertical in the collection position, or stretch down. A jumper can be difficult when asked for short turns or lack balance during the jump due to neck stiffness, while the barrel racer can be difficult to turn around the barrels.

Due in which several muscles originate at locations in the neck and have their insertion to the scapula (trapezius muscle, rhomboideus muscle) or humerus (brachiocephalicus muscle), contraction of these muscles can cause pain in the arthritic facet joints and thus alter the gait (e.g., shorter anterior stride, reduced protraction of the scapula) and mimic shoulder or even lower limb lameness.[15]

Neurological symptoms can occur when bone proliferation of the arthritic joint structures protrudes into the spinal canal, with lower hindquarter activity as the most common sign. When the bony proliferation invades the intravertebral foramen, root nerves can be compressed.[11] The cervical nerves between C5 and C6, C6 and C7, and C7 and T1 (the sixth, seventh, and eighth cervical nerves) form the brachial plexus, so compression of these root nerves can be sensed as pain in the limb, and limb lameness may be observed.[11,14] When root nerve compression is present, a patchy spot of sweating may be noticed on one or both sides of the neck and/or thorax.

Diagnosis

At the clinical examination, cervical facet joint arthritis can be suspected when the range of motion in the neck is limited. With complete flexion to the side, the horse should be able to flex the neck laterally, touching the thoracic wall with its nose without rotation in C2 in both directions. A 20–30% limitation in the total range of motion in the lateral plane is found in many older horses without clinical symptoms and can be considered normal. Cervical facet joint arthritis is highly suspected with an asymmetric limitation of the range of motion.

VetBooks.ir

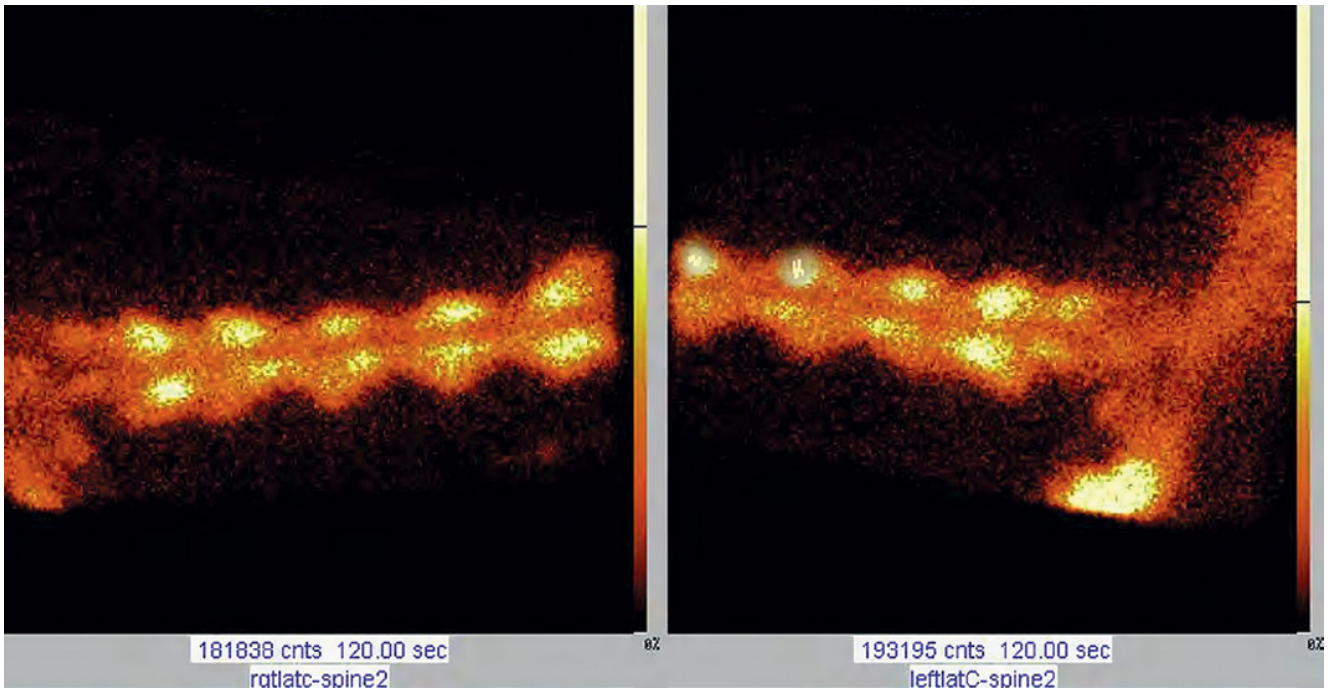

Figure 6.42. Scintigraphic images of the cervical spine. In the left image, IRU in C7 is visible at the right side of the neck in the arch and the body of C7; this is normal. In the right image, there is IRU visible in the arches of C4 and C5 on the left side of the neck, indicative for active facet joint osteoarthritis.

Range of motion in the dorsoventral plane can be tested by manually stretching the neck upward, while a carrot stretch between the front limbs can show the range of motion in the ventral direction. The dorsoventral range of motion tests are not as easy to interpret as the lateral plane, because they cannot be checked for symmetry, so there is no clear maximum range of motion to be defined. Palpation of the facet joints, left and right, can provide information about their size and shape, as well as pain when palpated.

When a particular joint is identified as highly suspected for causing the symptoms, ultrasound-guided intra-articular block of the facet joint can be used to verify the cause. This can best be seen when the horse is performing the work in which the symptoms are most obvious, for instance, so under saddle, at work, etc.

Radiography is the first imaging technique of choice.[1,7–9] Lateral views with a small degree of angle from the horizontal plane can be used to project the left or right facet joint without superimposing on top of the ipsilateral joint.

Ultrasonography can be used to image the facet joints as well, providing visual information about joint space size and shape and bone proliferation at the edges of the facet joint. Ultrasonography is also very helpful in treating cervical facet joint arthritis, because ultrasound-guided injection of the facet joint is not difficult.[2]

Nuclear scintigraphy (Figure 6.42) can be used to identify facet joints with an increased uptake of radiopharmaceutical as a sign of active inflammation to distinguish the older, consolidated proliferations, which are visible on radiographs, from signs of active arthritis/synovitis. This is useful in making decisions about the injection of corticosteroids.

MRI and CT imaging give much more detailed information about the size and shape of the facet joints and their potential compression effects on root nerves and the spinal cord but are limited to the more cranial facet joints. These techniques also involve general anesthesia and carry higher costs.

Myelography is considered the gold standard for identifying possible involvement of root nerves and/or spinal cord compression; however, this technique is only 50% accurate at identifying the specific location of compression of the spinal cord when compared with necropsy findings (Pease AJ, personal communications). Electromyography can be used to identify changes in muscle signals in the segmental muscles in the neck and thorax to show decreased innervation of these muscles as a sign of root nerve compression.[16]

Treatment and Prognosis

As with any osteoarthritis, treatment for cervical facet joint osteoarthritis can include medication with NSAIDs. Intra-articular medication with corticosteroids, deposited in or close to the joint under ultrasound guidance, has been described as a useful treatment. Triamcinolone is the corticosteroid of choice because it does not cause as much irritation in the adjacent structures such as the ligamentous tissue and muscle as methylprednisolone acetate when not deposited in the joint itself.

VetBooks.ir

RADICULOPATHY

When one or more segmental root nerves in the cervical spine are compressed, damaged, or irritated due to trauma or enlarged facet joints, lameness symptoms may occur.[5] In these cases, blocking of the distal limb nerves will give a negative outcome. Physical exam might show a reduced mobility in the neck, but sometimes the musculoskeletal exam is uneventful. The neurological exam however will show clear signs of nerve impingement with loss of skin sensitivity in the affected area, while often the adjacent segments show an augmented response to skin sensitivity testing. Ultrasonography can be a useful tool in identifying enlargement of the soft tissues of the cervical facet joints with enlargement of the synovial membrane and joint effusion when radiographs are not showing clear indication of affected cervical facet joints. Imaging using Doppler can identify the most affected region.

Osteoarthritis of facet joints, especially in the more caudal aspect of the cervical spine or cranial thoracic spine, may result in an associated enlargement of the joint capsule and subsequent pressure to the spinal cord or root nerves. Oral dexamethasone may be used to reduce this swelling and the signs of nerve compression, or infiltration of the epidural space with corticosteroid can be performed.[11]

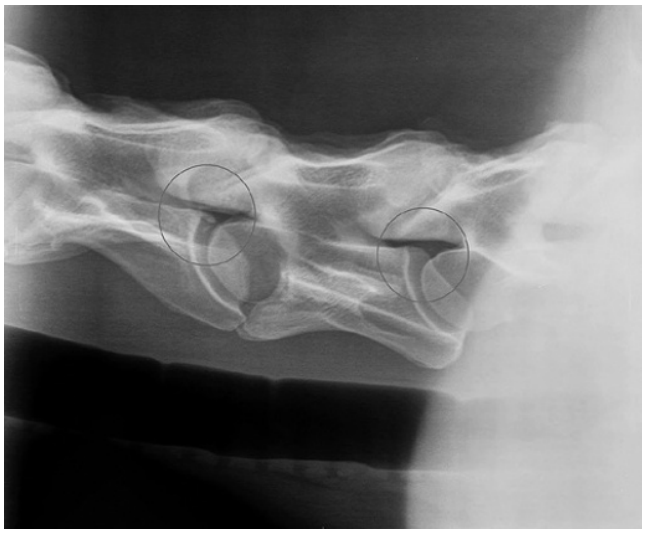

Figure 6.43. Radiographic image of the cervical spine. Note the change at the caudal aspect of the end plate of C5 and the small fragment (left circle) when compared with the clean appearance at C6 (right circle). This not only is most likely caused by trauma to the intervertebral ligament at the ventral base of the spinal canal but also can be caused by local mineralization within the intervertebral disc. In the acute stage, swelling can cause neurologic symptoms related to compression of root nerves or the spinal cord.

DISCOSPONDYLITIS

As described in the section on the thoracolumbar spine, discospondylitis can occur in the cervical spine, most likely in the caudal cervical vertebrae. Signs of neck pain and front limb stiffness or lameness may be present. Diagnosis can be made with radiography and scintigraphy, and the prognosis is guarded.[3,4,14]

CERVICAL FRACTURES

As described earlier in this chapter, fractures of cervical vertebrae can occur, and in nearly all cases this is due to severe trauma. Fractures of facet joint surfaces are rather common, but laminar fractures and fractures of the body or the arch of the cervical vertebrae also have been described. Depending on the location and the extent of the fracture, hemorrhage and swelling can extend to the spinal cord and cause ataxia. Horses with an acute fracture show pain and are unable to move the cervical spine in the affected region. Radiography is the diagnostic tool of choice, and in most cases lateral views are sufficient to show the fracture. Ventrodorsal views can assist in determining the extent and location. In specific cases scintigraphy can give adjacent information from 7 to 10 days after the injury, when displacement of the fracture and recognition of the fracture line are difficult on the initial radiological examination. Ultrasonographic examination of the cervical spine is an option but primarily shows fractured facet joints. It is difficult to make an interpretation of larger fractures through the body or arch of the vertebra.

When there is no damage to the spinal cord or the adjacent root nerves, and there is no displacement of the fragments, the prognosis can be moderate. Treatment includes stall rest or confinement in a small pen or paddock to reduce motion. However, callus formation can cause compression of the root nerves or the spinal cord in a later stage, and fractures of facet joint surfaces often result in facet joint arthritis. Trauma to ligamentous structures and the intervertebral disc may be not visible on initial radiographs (Figure 6.43) and can easily be overlooked or not recognized, but may result in discospondylitis, spondylitis, or osteoarthritis in a later stage.

CHAPTER

Principles of Musculoskeletal Disease

JOINT INJURIES AND DISEASE AND OSTEOARTHRITIS

C. Wayne McIlwraith

Arthritis may be defined simply as inflammation of a joint. It is a nonspecific term and does little to describe the nature of the various specific entities that affect equine joints. The role of inflammation also varies considerably among the different conditions. Such general terms are no longer appropriate in the management of equine joint conditions. Specific diagnoses must be made to effectively treat the horse and make accurate prognoses.

Updated knowledge of etiology, pathogenesis, diagnosis, and treatment of each of the different equine joint conditions has been recently published in a separate textbook on equine joint disease.[68] To understand joint disease in the horse, a basic knowledge of the anatomy and physiology of joints, as well as their pathobiologic responses, is necessary.

ANATOMY AND PHYSIOLOGY OF JOINTS

Classification

Joints are most often classified according to their normal range of motion. Three groups are recognized: synarthroses (immovable joints), amphiarthroses (slightly movable joints), and diarthroses (movable joints), also known as synovial joints. Synovial joints have two major functions: (1) to enable movement and (2) to transfer load.[107] The entire structure is invested by a fibrous capsule. Diarthroses include most of the joints of the extremities. Because these are the joints that we are essentially concerned with in equine lameness, their anatomy and physiology are described in detail.

General Anatomy

The synovial or diarthrodial joint consists of the articulating surfaces of bone that are covered by articular cartilage and secured by a joint capsule and ligaments and a cavity within these structures containing synovial fluid (Figure 7.1). The joint capsule is composed of two parts: the fibrous layer, which is located externally and is continuous with the periosteum or perichondrium (and, ultimately, bone), and the synovial membrane, which lines the synovial cavity where articular cartilage is not present.

The fibrous portion of the joint capsule is composed of dense fibrous connective tissue that provides some mechanical stability to the joint. The collateral ligaments are associated with the joint capsule. Intra-articular ligaments normally have a synovial membrane cover. Type I collagen predominates in the fibrous connective tissues of the joint.[108] It is vascular and has afferent pain fibers. Using immunohistochemistry with substance P as a more sensitive way of identifying the distribution of nociceptor fibers, it has been shown that sensory nerve fibers are present in the synovial membrane and subintimal layers as well as collateral ligaments, suspensory ligament, and distal sesamoid ligament attachments.[10]

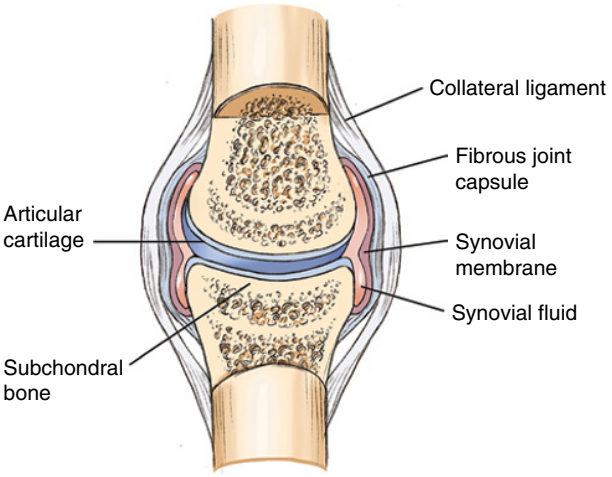

Figure 7.1. Diagram of a typical synovial joint.

The insertions of the fibrous capsule and articular ligaments into the adjacent bones demonstrate a zonal organization with a gradual transition of joint capsule and ligaments to mineralized fibrocartilage and then to bone. This enhances the ability of the insertions to distribute forces evenly and decrease the likelihood of pull-out failure.[55]

Stability of the joint is provided by the bony configuration of the joint, the ligamentous and capsular support systems, and the musculotendinous units controlling the joint. In addition, there is a negative hydrostatic pressure within the synovial cavity of normal joints, and this is considered to impart a "suction" and stabilizing effect.[85]

It has also been demonstrated that only the periarticular soft tissues (capsule, ligaments, and synovial tissue) and bone have significant force-attenuating properties (these studies were done with longitudinally applied, external impulsive force on adult bovine interphalangeal joints).[83] Articular cartilage and synovial fluid have little effect on force attenuation. This emphasizes the importance of both soft tissues of the joint and bone in providing shock absorption.

Synovial Membrane Structure and Function

Equine synovial membrane (also called synovium) is smooth and glistening in some regions of the joint and is formed into numerous villi in other regions. These villi have specific locations and a diverse morphology. Although villi proliferate in association with trauma and other insults, they are present in the fetus and, therefore, at birth.

Histologically, the synovial membrane is a modified mesenchymal tissue and consists of two layers: the intima, an incomplete cellular lining layer that lies next to the joint cavity and overlies a deeper layer of connective tissue (fibrous, areolar, or adipose) termed the subsynovial layer, or the subintima. Generally, the synovial membrane is fibrous and flat in regions where it is subjected to increased pressure; it is areolar and may be folded where it must move freely and independently of the joint capsule. The areolar subintima consists of loose

Figure 7.2. Diagram of a portion of synovial membrane demonstrating synoviocytes (types A and B, a and b) within the intercellular stroma of the intima, capillary (c), and collagenous matrix of intima (d). Tissue deep to this is considered subintimal.

fibrous connective tissue that continues into the central core of the villi. Numerous blood vessels are present.

The synovial cells of the intima (synoviocytes) form an incomplete layer that is 1–4 cells thick, and no basement membrane can be detected (Figure 7.2).[63] The synoviocytes have been classified at the ultrastructural level into two principal types designated as types A and B. The type A cells resemble macrophages and type B cells resemble fibroblasts. Intermediate cells are also observed. A concept has evolved in which type A and type B cells are not distinct, but rather merely cells whose differences in morphology reflect the functions they currently perform.[63]

Numerous blood vessels are present in the subintima and extend to within 5–10 μm from the intimal surface.[63] It appears that each joint has a dual nerve supply consisting of specific articular nerves that reach the joint capsule as independent articular branches of adjacent peripheral nerves and by articular branches that are nonspecific and arise from related muscle nerves.[63]

The three principal functions of the synovial membrane are phagocytosis, regulation of protein and hyaluronan (HA) content of the synovial fluid, and regeneration.[63] Excessive phagocytic activity or disruption of lysosomal or cellular membranes releases enzymes into the environment (a typical feature of

VetBooks.ir

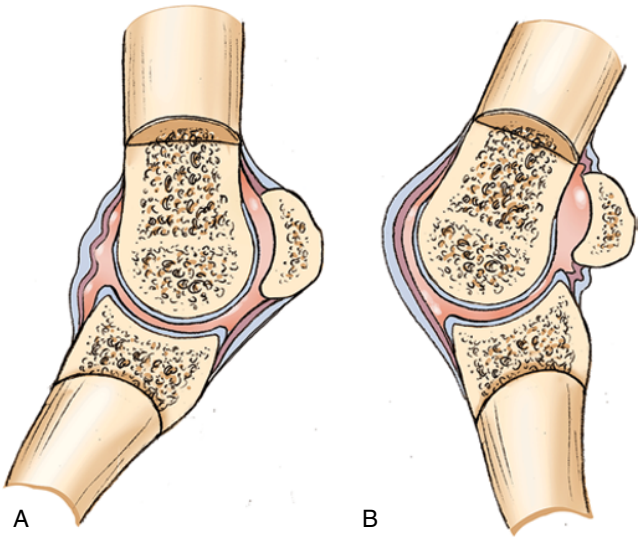

Figure 7.3. Diagram of a metacarpophalangeal joint demonstrating how redundant synovial membrane gathers at the dorsal aspect on extension (A) and at the palmar aspect on flexion (B).

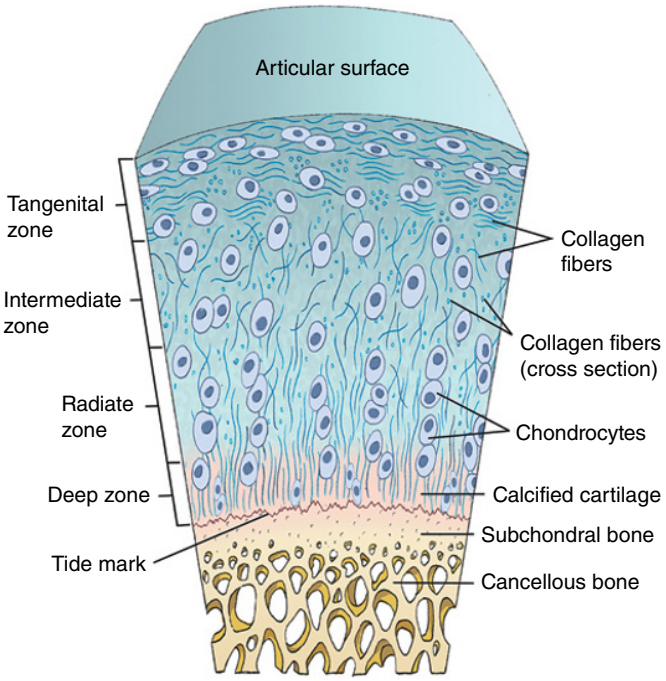

Figure 7.4. Diagram of adult articular cartilage showing the four layers and the arrangement of the chondrocytes and collagenous fibers.

synovitis). The synovial membrane acts as an important permeability barrier that, in turn, controls synovial fluid composition. Most small molecules cross the synovial membrane by a process of free diffusion that is limited by the intercellular spaces in the synovial membrane rather than by blood vessel fenestrations.[101] In traumatic effusions, changes in protein content and composition have been associated with both increased vascular permeability and increased protein synthesis by the synoviocytes.

The ability of the synovial membrane to reform following synovectomy has been described in the horse[40,107] and reveals that 120 days after subtotal synovectomy, there is evidence of restoration and an intimal layer was present.[107] However, the synovium was devoid of villi and there was subintimal fibrosis.

Another important property of the joint capsule is its ability to allow complete range of motion. The example of a metacarpophalangeal (fetlock) joint, illustrated in Figure 7.3, shows that synovial membrane gathers at the dorsal aspect of the joint in extension and at the palmar aspect in flexion. This property of gathering is called "redundancy."[101] Inflammation and fibrosis impede this property and result in joint stiffness. Elasticity of the joint capsule is also important because of its role in shock absorption.[85]

Articular Cartilage Structure and Function

Grossly, normal articular cartilage appears milky and opaque in the thicker regions and translucent with a slight bluish tinge in the thinner regions. The surface is not smooth. Studies using the scanning electron microscope have demonstrated undulations and irregular depressions.[28] The articular cartilage of equine joints is generally of the hyaline type, but fibrocartilage is also present at the junction of articular cartilage, synovial membrane, and periosteum (called the transition zone) and in menisci.[63]

Histologically, adult articular cartilage has been divided into four layers, and the chondrocytes have different appearances within these layers (Figure 7.4):

1. The tangential or superficial layer, containing flattened or ovoid chondrocytes and tangentially oriented collagenous fibrils
2. The intermediate or middle layer, containing larger chondrocytes that may be single or paired and randomly oriented collagenous fibrils
3. The radiate or deeper layer, containing chondrocytes arranged in vertical columns separated by collagenous fibrils that have an overall radial arrangement
4. The calcified cartilage layer, composed of mineralized cartilage and chondrocytes in various stages of degeneration

A basophilic-staining, undulating line of division between the radiate layer and the layer of calcified cartilage is termed the "tide mark" or "tide line." It delineates the elastic, nonmineralized layers of the articular cartilage from the layers of calcified cartilage that has little resilience. The extracellular matrix of the articular cartilage is a complex of collagen fibrils, proteoglycans, glycoproteins, and water (Figures 7.5 and 7.6).[63]

Collagens

Type II collagen comprises 90%–95% of the collagen in articular cartilage and forms fibrils and fibers intertwined throughout the matrix. Equine type II collagen has been characterized biochemically by cyanogen bromide-cleaved peptide profiles[111] and is secreted as a procollagen.

VetBooks.ir

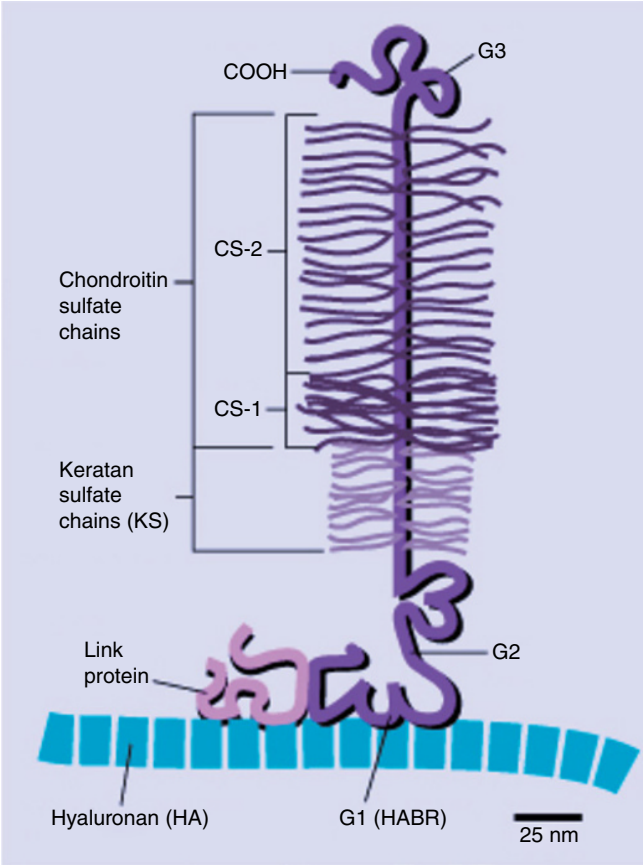

Figure 7.5. Diagram of a proteoglycan monomer formed by a protein core and glycosaminoglycan (chondroitin sulfate and keratin sulfate) side chains. Each proteoglycan core of the proteoglycan molecule is attached through a G-1 domain to an HA backbone through link protein to form aggregating proteoglycan (aggrecan). There are two other globular domains (G2 and G3).

The complete sequence of equine type II procollagen messenger RNA has been reported[88] and these authors also showed that chondrocytes harvested from juvenile horses exhibited more synthetic activity in culture with high steady-state levels of messenger RNA for type II procollagen. These authors also showed that IL-1β and tumor necrosis factor-α (TNFα) produced a dose-dependent decrease in the steady-state mRNA levels for type II collagen. Type II procollagen is expressed at very low levels in adult horses compared with younger ones. This may be relevant to naturally occurring changes of cartilage in the joints of older horses.

There are small amounts of type VI, IX, XI, XII, and XIV collagen, which help form and give stability to the type II fibril network.[76] The collagenous fibrils provide tensile strength to the articular cartilage in adult articular cartilage; this property chiefly resides in the superficial layers where the collagenous fibers are oriented parallel to the surface of the cartilage. In the middle layer of the cartilage, the collagenous fibrils are randomly arranged, and they become radially arranged in the deep layer. Tensile strength is not as critical in these deeper layers in normal cartilage, but if superficial erosion occurs, the collagen of these deeper layers is vulnerable to disruption. It has been shown that in immature cartilage the deeper layers also possess considerable tensile strength, but this is lost with maturation.[95] The tensile properties automatically change with enzymatic degradation of hydroxy-pyridinoline cross-links, which emphasizes the importance of these cross-links in providing cartilage stiffness, strength, and tension.[95]

Collagen fibers are also arranged concentrically around chondrocytes to form a capsule, called a chondron. Each chondron contains one or more chondrocytes, is invested by collagenous pericellular capsule, and is surrounded by a proteoglycan-rich territorial matrix.[82] Collagen type VI, fibronectin, and thrombospondin are present in this chondron capsule and help anchor the chondrocyte within the chondron and attach the chondron within the extracellular matrix.[77]

Proteoglycans

The proteoglycans (previously called mucopolysaccharides) are the other major solid component of the articular cartilage matrix. They occupy the spaces between the collagen fibrils. The basic proteoglycan molecule is a monomer formed by a protein core and glycosaminoglycan (GAG) side chains (Figure 7.5). Most of the proteoglycans (85%) form large aggregates by noncovalent attachment of the core protein of the proteoglycan to HA under the stabilization of a link protein (Figure 7.6). This aggregate is called aggregating proteoglycan or aggrecan.

The major GAG in adult articular cartilage are chondroitin-6-sulfate and keratan sulfate. Chondroitin-4-sulfate is an important constituent of immature articular cartilage, but its level decreases to a low percentage with cartilage maturity. The GAG consist of repeating units of disaccharides, which are important because of their polyanionic nature (carboxyl and sulfate radicals in chondroitin sulfate and sulfate radicals in keratan sulfate). The charges of the polyanionic GAG side chains both repel each other and attract a hydration shell. These properties, in turn, provide the articular cartilage with a physicochemical stiffness and affect cartilage permeability.[56] The aggrecan molecules are contained by the collagen network, and hence the proteoglycans impart compressive stiffness.[46] It should be noted that enmeshment of the proteoglycans by the collagenous framework and specific interactions between the two components are necessary for the proteoglycans to function.[7]

The average proteoglycan unit in articular cartilage has a molecular weight of 3 million Daltons and contains 100 chondroitin sulfate side chains and 100 keratan sulfate side chains.[76] More than 100 of these proteoglycan monomers attach to a HA backbone to form the proteoglycan aggregate aggrecan, which has a molecular weight of more than 200 million Daltons (Figure 7.6). The proteoglycan monomer has been the subject of many studies. There are two globular domains (G1 and G2) at the HA-associated end followed by an extended glycosaminoglycan-containing region (E_2), with a third globular domain (G3) at the other end. The N-terminal region of the aggrecan is attached to HA, and the region that contains the majority of the GAG is an extended region lying between G2 and G3.

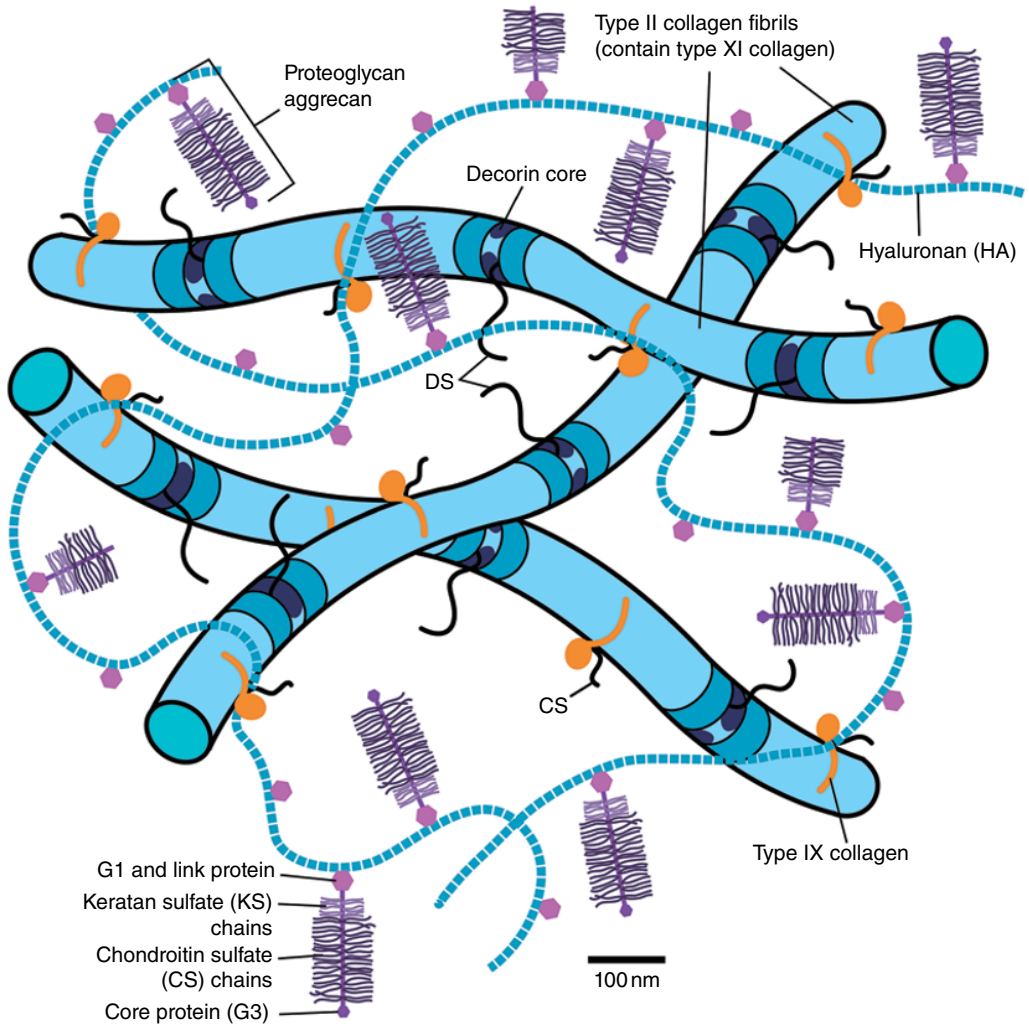

Figure 7.6. Diagram representing a portion of extracellular matrix showing organization of type II collagen fibers and multiple proteoglycan molecules that bind HA to form aggrecan entrapped within the collagen fibers. *Source*: Adapted from Poole.[81] Reproduced with permission of JAMA.

Other nonaggregating proteoglycans in articular cartilage include biglycan, decorin, and fibromodulin. Equine decorin has been characterized biochemically in the horse,[80] as have the gene sequences of biglycan and decorin.[81]

Glycoproteins

Noncollagenous, nonproteoglycan glycoproteins constitute a small but significant portion of articular cartilage.[108] There are three fractions of equine link protein: LP1, LP2, and LP3.[23,79] Other glycoproteins of cartilage include chondronectin (thought to adhere chondrocytes to type II collagen surfaces), fibronectin (adheres cells to molecules and surfaces), cartilage oligomeric matrix protein (COMP), thrombospondin, and anchorin C-II, as well as cartilage-derived growth factor.

Cartilage Nutrition and Innervation

The articular cartilage is avascular, lacking both blood and lymph vessels. The deep layers of immature cartilage are penetrated extensively by vascular buds from the ossified portion of the epiphysis, which appear to play an important role in nutrition of the cartilage from the subchondral region.[63] Immature articular cartilage is an articular–epiphyseal complex with the deeper layers constituting a growth zone. In adults, the articular cartilage is separated from the subchondral vascular spaces by an end plate of bone (the subchondral plate), and nutrition of the articular cartilage occurs by diffusion from the synovial fluid. Chondrocytes function by anaerobic glycolysis. Under physiologic loads, cartilage can be compressed to 40% of its original height. The depth to which the diffusing nutritional gradient can extend is limited and was calculated to be a maximal cartilage thickness of 6 mm.[56] Because of this limit, necrosis secondarily occurs when retained thickened cartilage, as develops in some cases of OCD, exceeds diffusion limits.

There are no nerves in articular cartilage, and the bearing surface of the joint depends on nerve endings in the joint capsule, ligaments, muscle, and subchondral bone for appreciation of pain and proprioception.

Biomechanics

As indicated previously, articular cartilage is a tissue consisting of aggrecan that is stiff in compression, collagen that is stiff and strong in tension, and somewhat freely moving fluid carrying mobile ions (interstitial fluid). These components interact to provide the following mechanical and physical characteristics when young and healthy: (1) a permeable matrix that is stiff in compression, (2) a fibrous network capable of withstanding high tensile stresses, (3) a fluid that flows under load or deformation and aids in dissipating high stresses in the tissue, and (4) a high swelling pressure that results in a matrix swollen with water.[73] It has also been noted that an important function of aggrecan in cartilage is to retard the rate of stretch and alignment when a tensile load is suddenly applied and that this mechanism may be useful in protecting the cartilage collagen network during physiologic situations.[97]

In an unloaded joint, the opposing articular surfaces are not completely congruent.[28] However, under physiologic loading, because the cartilage is soft, deformation causes an increase of contact area (reducing tissue stress levels) and increases joint conformity (which provides additional stability). The adaptation of the shape of loaded cartilage may also help to form and retain boundary lubrication (see below). As articular cartilage directly under load is compressed, the surrounding areas are subjected to transverse tensile strains. These forces tend to redistribute fluid away from the compressed area and into the stretched regions. As mentioned previously, the major contribution to the osmotic pressure provided by the proteoglycans is derived from negatively charged sulfate and carboxyl groups of the GAG and the associated cations (ionic or Gibbs–Donnan effect).[108] Water is attracted by the high charge density, and this osmotic pressure may contribute up to 50% of the compressive stiffness of the articular cartilage. The swelling pressure is balanced by the tensile stress of the collagen framework.

Mow and colleagues have described the extracellular matrix as a cohesive porous composite.[73] Their biphasic model for articular cartilage considers the tissue as an interacting mixture of two continuums: a porous permeable elastic solid and interstitial fluid. Because of swelling pressure, the collagen network of the articular cartilage is under a tensile prestress even when unloaded. During compression, the concentration of the organic material and the charge density increase because the interstitial fluid is forced to flow from the matrix. A new equilibrium is reached when the charge density, collagen tension, and applied load are in balance (Figure 7.7). The deformation of this cartilage in association with fluid exudation is called creep. The compression time curve consists of the creep phase, controlled by fluid exudation, and the second phase, which is related to the collagen proteoglycan matrix component. During prolonged periods of stationary loading, fluid is slowly exuded and redistributed within the cartilage until an equilibrium position is reached. At this stage, the increased concentration of the fixed charge density is counterbalanced by the increased osmotic swelling pressure of the proteoglycan. When fluid motion ceases, the entire external load is borne by the solid extracellular matrix.

Intermittent pressures created by the interaction of the opposing articular surfaces pump fluid through the cartilage for nutrition and the removal of metabolic byproducts.[63] Expressed fluid from the articular cartilage resembles synovial fluid except for its low protein content and viscosity.[49] It has been shown that the concentration of fixed charges from GAG is the prime determinant of cartilage permeability.[56] Simple diffusion seems sufficient for nutrition of all but the deepest layers of articular cartilage, but joint movement probably facilitates the process.

Studies have shown that proteoglycans restrict solute movement within the tissue matrix. The proteoglycans restrict the diffusion of large, uncharged solutes but do not affect the diffusion of small, uncharged solutes. The molecular size and conformation of the solute is also an important factor. Removal of proteoglycans increases the influx of large molecules into the matrix, and this suggests that proteoglycan removal may also increase the efflux of large molecules out of the tissue matrix.[108] It has been suggested that the marked loss of aggrecan and newly synthesized proteoglycan monomer from the matrix in osteoarthritis (OA) is probably a direct result of the increased mobility of these macromolecules as the tissue matrix components continue to degrade.

It is also well accepted that mechanical forces modulate the metabolic activity of chondrocytes; clarification of the specific mechanisms of mechanical signal transduction in articular cartilage is emerging.[71] One proposed pathway is that chondrocytes may perceive changes in their mechanical environment through cellular deformation.[33] More recently it is demonstrated that the chondrocytes possess a primary cilium that is involved in mechanotransduction events related to cartilage extracellular matrix synthesis.[114] This study confirmed that primary cilia were essential organelles for cartilage mechanotransduction, as well as identified a novel role for primary cilia not previously reported in any other cell type, namely, cilia-mediated control of ATP reception. It is well established that the GAG content of habitually loaded areas of cartilage is greater than that of habitually unloaded areas. Work in sheep stifle joints has shown that different areas of articular cartilage subjected to differing mechanical stresses contain a phenotypically distinct chondrocyte population.[50] Chondrocyte phenotypes were identified by the relative biosynthesis of aggrecan, biglycan, and decorin.

Articular Cartilage Metabolism and Matrix Turnover

The chondrocytes synthesize all of the components of the cartilage matrix. At each stage of growth, development, and maturation, the relative rates of matrix synthesis and degradation are adjusted to achieve net growth, remodeling, or equilibrium. A unique interaction exists between chondrocytes and the surrounding matrix. This may be facilitated by a cilium from each chondrocyte that extends into the matrix and acts as a probe, sensing changes in the matrix composition such as a loss of proteoglycan or collagen or an increase or decrease in HA concentration. This information is relayed to the cell. Interaction between the pericellular and territorial matrix and the chondrocyte cell membrane also may include transmission of mechanical

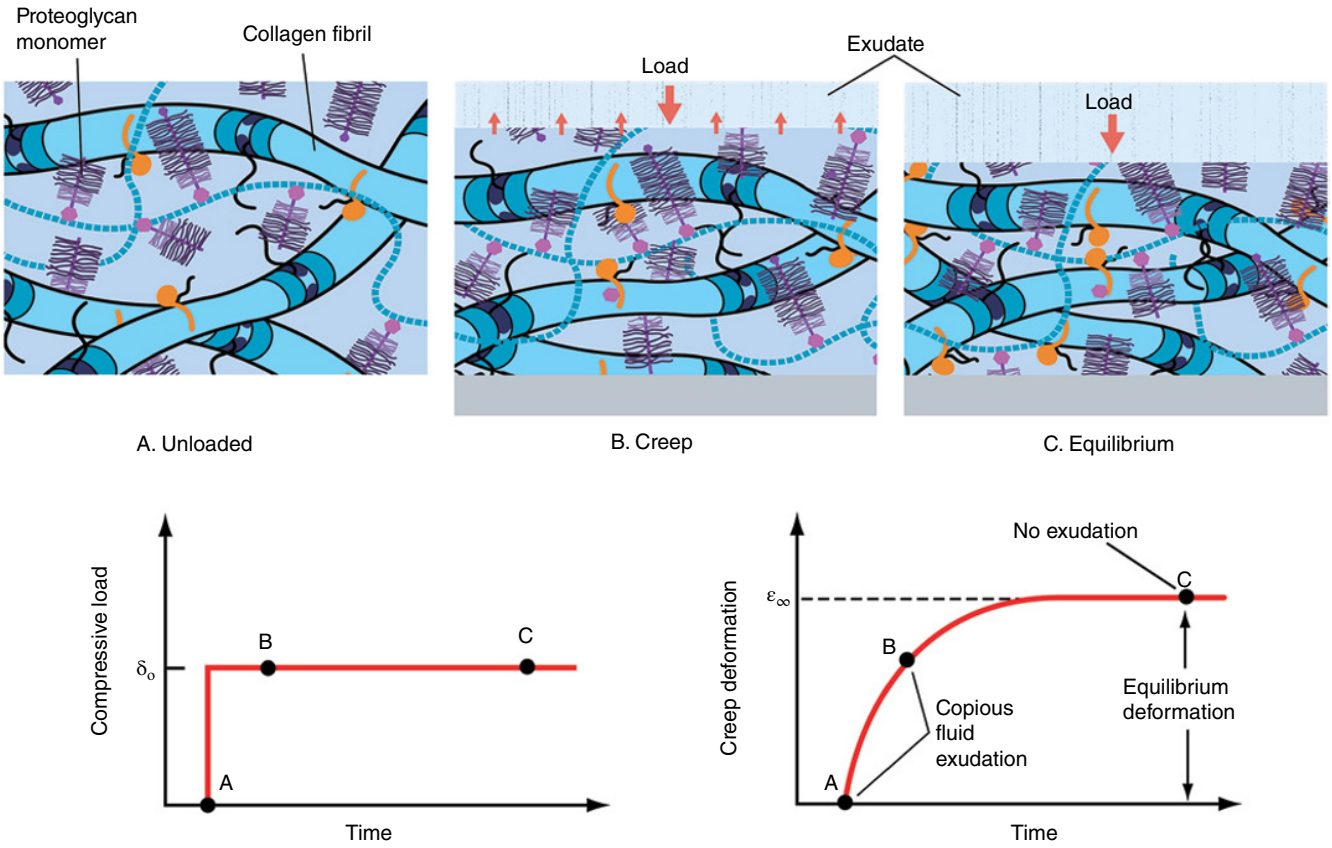

Figure 7.7. Deformation changes occurring over time during confined compression testing of articular cartilage. When a load is applied instantaneously to a confined piece of cartilage and held constant, compressive deformation increases with time (i.e. creep occurs) until an equilibrium position is obtained. The drawings at the top of the figure illustrate consolidation of the matrix under a constant load. The first phase component corresponds to the elastic spring of the biphasic model of cartilage behavior. The fluid is the second phase of the model and is exuded under load. The behavior of a nonviscoelastic material is shown by the graph on the lower left. The behavior of a viscoelastic material (articular cartilage) is shown by the graph on the lower right. The transient portion of the curve results from compression from a viscoelastic material as controlled by fluid exudation and equilibrium position by the elastic spring. *Source*: Adapted from Myers and Mow.[74] Reproduced with permission of Elsevier.

signals by changes in matrix tension or compression. Other investigators have provided support for the idea that forces perceived by chondrocytes dictate their shape and then stimulate alterations in cellular biochemistry and matrix metabolism.[36]

Collagen turnover times within normal articular cartilage have been estimated to be 120 years in the dog and 350 years in adult human articular cartilage.[108]

However, collagen breakdown is an early event in OA and can be detected with biomarkers before it is apparent morphologically (see below).[65] On the other hand, the protein core of aggrecan is commonly cleaved, particularly the portion between the G1 and G2 domains. Cleavage here leaves a large C-terminal proteoglycan fragment, which diffuses out of the tissue. The overall proteoglycan turnover time in adult rabbit and dog articular cartilage is about 300 days.

Dynamic load and the action of cytokines are thought to be involved in matrix turnover. The cytokines of principal interest at the moment are the interleukins and TNFα. These factors act on chondrocyte receptors and influence the production and activation of metalloproteinases (MMPs), PGE_2, and aggrecanase. The activity of MMPs, in turn, is inhibited by tissue inhibitors of MMPs (TIMPs 1 and 2), and it has been shown that there is a slight excess of TIMP over metalloproteinase concentration in normal articular cartilage.[18] See the section on pathobiology for further information on the action of cytokines.

Not all cytokines cause degradation. There are a number of growth factors such as insulin-like growth factor 1 (IGF-1) and various members of the transforming growth factor (TGF) superfamily, which includes bone morphogenic proteins (BMPs), that are positively involved in articular cartilage synthesis.

Lubrication of Joints

The synovial joint contains two systems that require lubrication: a soft tissue system, involving the sliding of synovial membrane on itself or other tissues, and a cartilage-on-cartilage system. Lubrication of the synovial membrane is by boundary lubrication, and HA is the important component in the synovial fluid that performs this function.[63] The HA molecules stick to the surface of the synovial membrane and allow sliding of synovial

VetBooks.ir

membrane over the opposing surface. This function is important because a major part of the frictional resistance in joint movement is in the synovial membrane and fibrous joint capsule.[55]

Considerable investigations have clarified the lubrication of articular structures in synovial joints, and the modes have been classified as fluid filled or boundary. The operative lubrication modes depend on the normal and tangential forces on the articulating tissues, the relative rate of tangential motion between these surfaces, and the time and history of both loading and motion.[73] One type of fluid-mediated lubrication is hydrostatic. At the onset of loading and typically for a prolonged duration, the interstitial fluid within cartilage becomes pressurized and rises to the surface by a weeping mechanism. In boundary lubrication, the load is supported by surface-to-surface contact, and the associated frictional properties are determined by lubricant surface molecules. This mode is thought to be important because the opposing cartilage surfaces make contact over approximately 10% of the total area, and this may be where most of the friction occurs.[70]

With increasing loading time and dissipation of hydrostatic pressure, lubricant-coated surfaces bear an increasingly high proportion of the load relative to pressurized film, and consequently the friction coefficient is dominated by this mode of lubrication. Boundary lubrication is therefore important in reducing articulation-induced shear and wear. Boundary lubrication is mediated by synovial fluid.[99] Components of the synovial fluid involved in boundary lubrication include HA,[78] proteoglycan 4 (PRG4),[101] and surface active phospholipids (SAPL).[99] Maintenance of normal lubricating functions is considered critical to the health of articular cartilage.[95]

Subchondral Bone

The subchondral plate and epiphyseal bone beneath it form an integral part of the joint structure, providing structural support to the overlying articular cartilage. The subchondral plate consists of cortical bone that varies in thickness depending on the joint. With exercise, remodeling occurs, and the amount of dense cortical bone can increase, at least in the carpus and fetlock, but there is marked variation between horses.[44]

The relationship between the mechanical properties and morphometry of the bones of horses has been explored.[119] In the third carpal bone, maximal subchondral bone stiffness occurs 10 mm palmar to the dorsal margin. There is also a significant negative correlation between subchondral stiffness and the porosity of the radial facet of the third carpal bone. Acquisition of such basic data is important in studying traumatic joint disease in the horse. Kawcak et al. have shown microdamage in the subchondral bone (including microcracks and osteocyte death) as relatively early events in exercising horses.[44]

Cytokines and growth factors similar to those in articular cartilage are also present in bone. These include IGF-1, the TGFα family (including the BMPs 2–7), platelet-derived growth factor, and fibroblast growth factors. These peptides are produced by bone cells and are present in bone matrix. IL-1 and TNFα are also present in bone. Presumably, disease in subchondral bone would expose the articular cartilage to these cytokines. More details on the relationship between articular cartilage and subchondral bone are presented in the section on pathobiology.

The innervation of the subchondral bone plate has been a subject of controversy. However, recent immunohistochemical techniques identifying substance P (a neuropeptide specifically located in sensory nerves and CNS elements) have helped study the innervation of the subchondral plate further.[76] Substance P immunoreactive neurofilaments have been identified in the subchondral bone of normal equine metacarpophalangeal joints. The nerves existed in the small cancellous spaces and diversion canals. Previous immunohistochemical studies of the subchondral plate of diseased human patellae revealed substance P fibers in the periosteum and subchondral plate of patellae affected with degenerative disease.[115] Another interesting finding in the human study was the observation of substance P fibers in erosion channels running through the subchondral plate to the deep surface of the articular cartilage, where nerve terminals were seen. Because the erosion channels were not seen in normal patellae, the presence of the substance P fibers in the erosion channels may represent a morphologic change explaining why degenerative patellae become painful.

PATHOBIOLOGY OF JOINTS AND THEIR REACTION TO INSULT AND INJURY

Traumatic Arthritis: Multiple Manifestations

In its broader sense, "traumatic arthritis" includes a diverse collection of pathologic and clinical states that develop after single or repetitive episodes of trauma and may include one or all of the following:

1. Synovitis (inflammation of the synovial membrane)
2. Capsulitis (inflammation of the fibrous joint capsule)
3. Sprain (injury of specific ligaments associated with the joint)
4. Intra-articular fractures
5. Meniscal tears (femorotibial joints)
6. OA (when degradative changes have occurred in the articular cartilage)

Any of 1 through 5 above can potentially progress to OA. To facilitate the discussion of pathobiology, it is convenient to divide articular trauma into three entities:

Type I: Traumatic synovitis and capsulitis without obvious disturbance of the cartilage or destruction of major supporting structures. This includes acute synovitis and most sprains.

Type II: Disruptive trauma with damage to the articular cartilage or complete rupture of a major supporting structure. This includes severe sprains, meniscal tears, and intra-articular fractures.

Type III: Posttraumatic OA. Equine OA may be considered as a group of disorders characterized by a common end stage in which progressive deterioration of the articular cartilage is accompanied by changes in

VetBooks.ir

the bone and soft tissues of the joint. It is inevitably the result of severe trauma to the joint or ineffective treatment of any of the predisposing conditions.

The joint is an organ and all of its tissues can be injured. Cyclic trauma to the synovial membrane and fibrous joint capsule results in synovitis and capsulitis and is a common entity in the equine athlete. Direct trauma can occur to the articular cartilage and subchondral bone, whereas inflammatory mediators resulting from synovitis can cause biochemical damage. Intra-articular and extra-articular ligaments of the joint can be injured, as can the menisci in the stifle.

The reaction in the various joint-associated tissues should not be considered in isolation, as evidenced by the example of the carpus of a racehorse. Considerable damage may be inflicted directly to the articular cartilage and bone, resulting in cartilage ulceration and intra-articular fractures of the carpus that cause varying degrees of articular cartilage loss. However, cyclic fatigue damage to the collagen network could be an important step in the pathogenesis of a more insidious osteoarthritic entity, exposing chondrocytes to deleterious physical forces and inducing injury and metabolic changes.

Primary damage to the subchondral bone other than fracture also may occur (subchondral bone disease) and lead to secondary damage to the articular cartilage, either from loss of support or secondarily from release of cytokines. Subchondral sclerosis may also lead to further physical damage to the articular cartilage because of decreased shock absorption. Acute synovitis and capsulitis is a common problem in these same joints and may also contribute to the degenerative process by the release of deleterious mediators.[63]

Physiologic Trauma Leading to Osteoarthritis

OA is a disease that results from an interaction of a number of complex mechanical and biological processes and predominantly, but not solely, affects the diarthrodial joint. As noted above, the end result is progressive deterioration of the articular cartilage. While a definitive characteristic of OA is articular cartilage destruction, we have come to recognize the accompanying changes of synovitis and shown that it can be a primary disease process leading to OA. We also know that many of the mediators involved in early deterioration of the articular cartilage are present in increased amounts (or there are decreased amounts of their inhibitors), which represents an exaggerated normal metabolic process.

Athletic Activity Potentially Leading to a Pathologic Process

It is well accepted that equine athletes carry an increased risk for development of OA. It should be noted that intact articular cartilage possesses optimal load-bearing characteristics that adjust to the level of activity. Increasing weight-bearing activity in athletes and adolescents has been shown to improve the volume and thickness of articular cartilage[41] and increase cartilage GAG content in the human knee.[94] In the healthy human athlete, a positive linear dose–response relationship apparently exists for repetitive loading activities and articular cartilage function.[60] However, studies also indicate that the dose–response curve reaches a threshold and activity beyond this threshold can result in maladjustment and injury of articular cartilage.[47]

High-impact joint loading above this threshold has been shown to decrease cartilage proteoglycan content, increase levels of degradative enzymes, and cause chondrocyte apoptosis.[1,52] If the integrity of the functional weight-bearing unit is lost, either through acute injury or chronic trauma in the high-impact athlete, a chondropenic response is initiated that can include loss of articular cartilage volume and stiffness, elevation of contact pressures, and development or progression of articular cartilage defects.[61,62] It has been proposed that concomitant histologic factors such as ligamentous instability, malalignment, meniscal injury, or deficiency can further support progression of the chondropenic cascade and without intervention, chondropenia leads to progressive deterioration of articular cartilage function and may ultimately progress to OA.

Evidence has accumulated with regard to various inflammatory mediators having an impact on matrix homeostasis of articular chondrocytes by altering their metabolism.[57] The authors of a recent paper on inflammatory factors involved in human OA cited evidence that points to the proinflammatory cytokine interleukin-1β (IL-1β) as the most important factor responsible for the catabolism in OA.[57] However, the authors pointed out that new members of the IL-1 superfamily have recently been identified (ILF-5, ILF-10), some of which have been suggested to be of interest for arthritic disease, and that other proinflammatory cytokines such as tumor necrosis factor (TNF)-α-6 and other interleukins can be contributing factors. They also noted that the exact role and importance of each within the OA process are not yet clearly identified. In addition to cytokines, other inflammatory mediators that may play a major role in the OA process include nitric oxide (NO), eicosanoids (prostaglandins and leukotrienes), and a newly identified cell membrane receptor family, the protease-activated receptors (PARs).

Discussion of mediators for equine traumatic joint disease and OA in this chapter focus on mediators that have been shown to be increased in equine joint disease and/or their inhibition can ameliorate progression of OA.

When considering a traumatically injured joint, two basic pathobiologic processes should be considered: inflammation of the synovial membrane and fibrous joint capsule (synovitis and capsulitis) and physical or biochemical damage to the articular cartilage and bone. Acute synovitis and capsulitis can cause significant clinical compromise and may also contribute to the degenerative process by releasing enzymes, inflammatory mediators, and cytokines.[64] These processes are outlined in Figures 7.8 and 7.9.

Synovitis and Capsulitis

Treatment of synovitis and capsulitis, particularly the acute form, is indicated to (1) alleviate the immediate compromising effects of inflammation, including pain and reduced function; (2) prevent the development of

VetBooks.ir

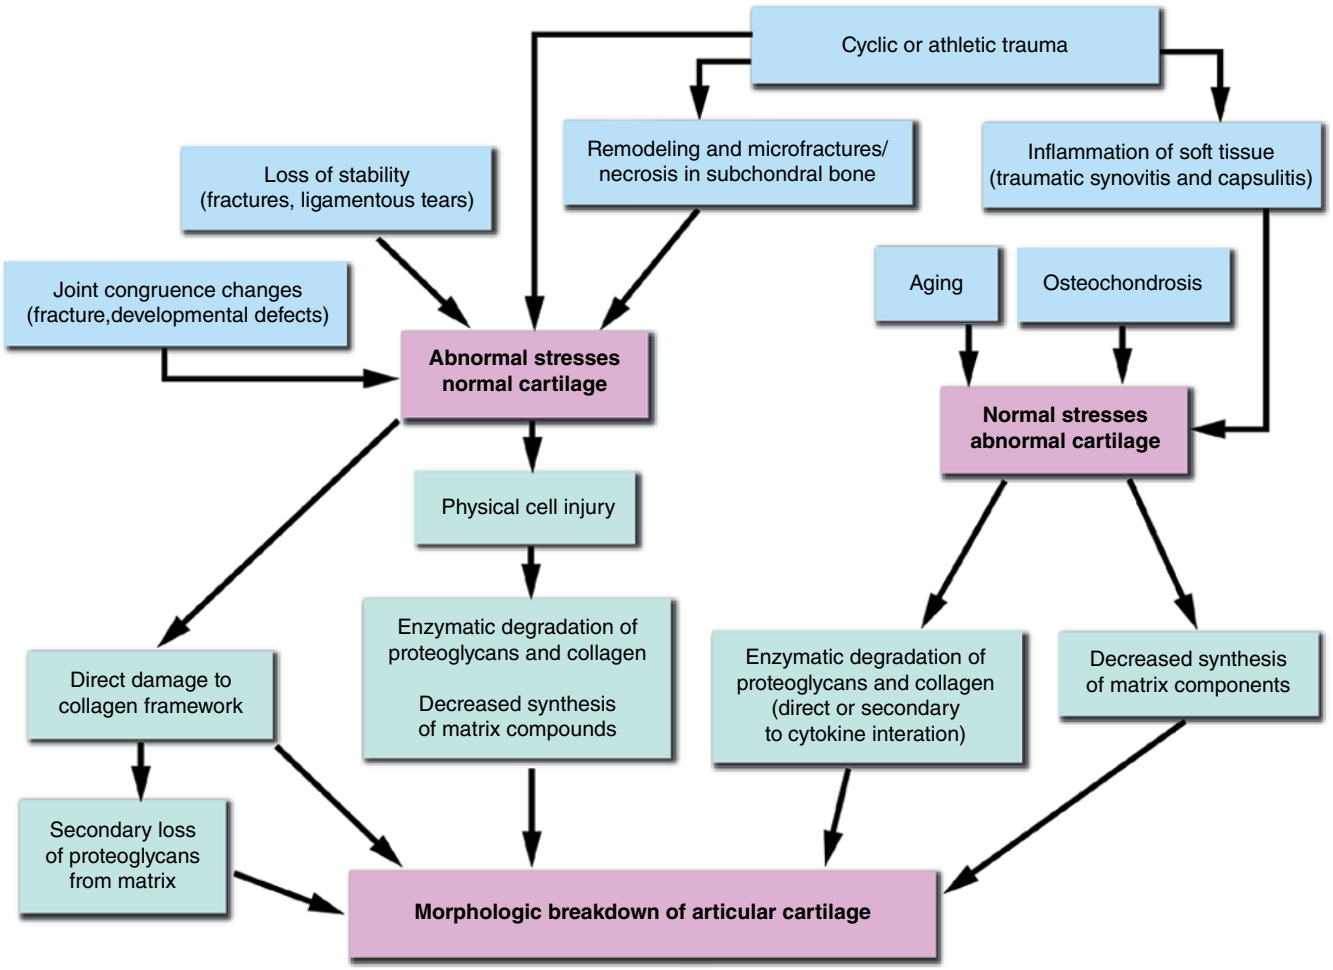

Figure 7.8. Possible pathways for degradation of articular cartilage secondary to joint trauma. *Source*: Redrawn from figure 4, McIlwraith.[64] Reproduced with permission of American Association of Equine Practitioners.

permanent fibrosis in the joint capsule, which in turn causes decreased motion and compromised shock absorption capabilities in that joint; and (3) prevent or minimize the development of OA.

Synovitis and capsulitis as primary entities in athletic horses are presumed to be associated with repeated trauma.[61] Severe injury to the fibrous joint capsule also can cause instability. The synovial membrane itself is mechanically weak and has no known biomechanical role, but it is recognized that synovial injury may have pathophysiologic consequences in the joint.[24] Some injuries may affect diffusion across the synovial membrane, and others have a primary effect on the metabolism of the chondrocyte.[24] Mechanically damaged synoviocytes may release degradative enzymes and cytokines, which alter the intra-articular environment and possibly affect articular cartilage. It has also been suggested that high intra-articular pressures in injured joints associated with effusion could be sufficient to impair the flow of blood through the synovial capillaries and potentially lead to reperfusion injury.[48] Flexion of a joint with sufficient synovial effusion could raise the intra-articular pressure to levels of impaired blood flow through the synovial capillaries.

In addition to direct injury that may occur to the synovial membrane, the reaction of the synovial membrane to articular cartilage damage or other mechanical destruction of intra-articular tissues is well recognized. The presence of cartilaginous wear particles increases the cellular production of prostaglandin E_2, cytokines, and the neutral metalloproteinases (collagenase, stromelysin, and gelatinase).[24] It has also been shown that the proteoglycans released into synovial fluid cause synovitis.[6]

The ability of synovial membrane inflammation alone in the absence of trauma and/or instability to damage articular cartilage has previously been demonstrated in the horse.[66]

The Importance of Synovitis

Synovitis (and capsulitis) is important to the horse because it produces pain, the increased synovial effusion is uncomfortable and it eliminates the normal small negative pressure within the joint (therefore promoting micro-instability), and it produces products that are deleterious to joint health as a whole and articular cartilage in particular. The mediators currently considered to be

VetBooks.ir

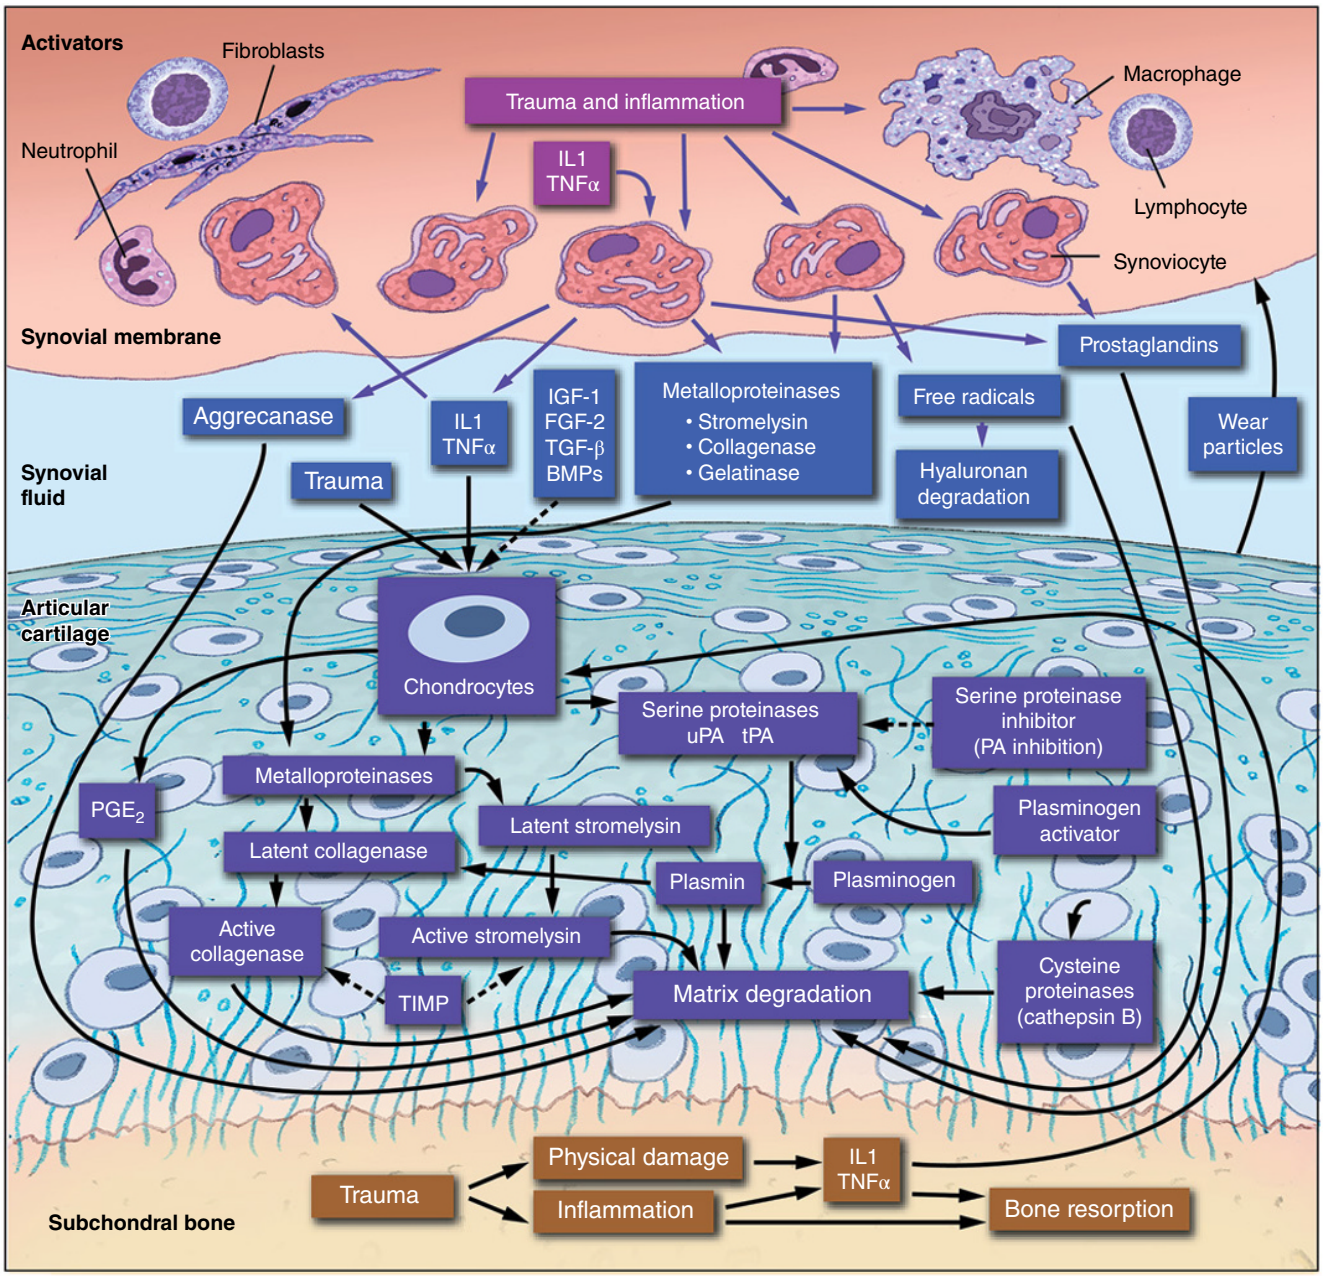

Figure 7.9. Factors involved in degradation of the articular matrix: interleukin-1, tumor necrosis factor-α (TNFα), fibroblast growth factor-2 (FGF-2), PLA2, urokinase plasminogen activator (uPA), tissue plasminogen activator (tPA), plasminogen activator (PA), insulin-like growth factor-1 (IGF-1), transforming growth factor-β (TGF-β), and bone morphogenic protein (BMP). *Source*: Redrawn from figure 5, McIlwraith.[64] Reproduced with permission of American Association of Equine Practitioners.

of significance in equine joint disease include metalloproteinases and aggrecanases, prostaglandins, free radicals, cytokines, interleukin-1 (IL-1), and possibly TNFα (Figure 7.9).

Matrix Metalloproteinases and Aggrecanases

Matrix metalloproteinases (MMPs) may be subdivided into collagenases, gelatinases, and stromelysins. Three collagenases have been identified, and they are interstitial or tissue collagenase (also called MMP-1), PMN collagenase (or MMP-8), and collagenase 3 (also known as MMP-13). Based on evidence in both human and equine studies, it appears that the primary collagenase involved in the degradation of type II collagen of articular cartilage is collagenase 3.[10,70] Caron et al. found that MMP-13 is produced by equine chondrocytes and that MMP-13 expression was significantly stimulated by rhIL-1.[10]

Consideration of the breakdown of aggrecan initially focused on stromelysin (also called proteoglycanase or MMP-3), but now recognizes an initially undefined enzyme called "aggrecanase" (now known as aggrecanase-1 and aggrecanase-2 or ADAMTS-4 and ADAMTS-11). Stromelysin has a wide variety of substrates, including

VetBooks.ir

proteoglycans (aggrecan, decorin, fibromodulin, link protein) and type IV, V, VII, IX, and XI collagen.[25] It also cleaves type II collagen in nonhelical sites.[118] *In vitro* study of IL-1-induced cartilage degeneration has revealed evidence of collagen degradation that could be attributed to stromelysin in addition to that attributed to collagenase.[21] Molecular cloning and cartilage gene expression of equine stromelysin 1 (MMP-3) has been described by Balkman and Nixon.[2] Stromelysin cleaves the protein backbone of cartilage proteoglycans at the asparagine 341–phenylalanine 342 bond.[57] Cleavage due to aggrecanase, on the other hand, occurs at the GLU373-ALA373 site.[68] Based on preliminary work in the horse using markers that differentiate these two cleavage sites, it appears that aggrecanase is the principal enzyme degrading proteoglycan in equine joint disease.[51]

Equine MMPs 2 and 9 are two gelatinases that have been characterized in the horse.[11,12] It is known that the one-fourth and three-fourth fragments generated by cleavage by fibrin or collagens by collagenases can unwind and are then susceptible to further cleavage by MMP-2 and MMP-9. MMPs 2 and 9 are produced by a variety of equine cell types, and these enzymes have been demonstrated in elevated levels in synovial fluids from horses with joint disease.[11,12]

The metalloproteinases are inhibited by two tissue inhibitors of metalloproteinase and these are known commonly as TIMP (TIMP-1 and TIMP-2).[75,102] TIMP is found in many connective tissues and may be the most important inhibitor found in articular cartilage. This current belief is that the balance between MMPs and TIMP is important to prevent progression of articular cartilage degradation.

In summary, MMPs are considered to play a major role in articular cartilage degradation. They are secreted as latent proenzymes and activated extracellularly by serine proteinases. Plasmin may activate stromelysin, which in turn is an important activator of collagenase. Upregulation of these enzymes in synovial membrane and articular cartilage samples from traumatic equine joint disease has been demonstrated.[110] It is also known that the production of MMPs is upregulated by IL-1.

Prostaglandins

Prostaglandins (primarily E group) are produced in inflamed joints and can cause a decrease in the proteoglycan content of the cartilage matrix.[104] The presence of prostaglandin E_2 in synovial fluid from inflamed joints has been demonstrated in the horse.[105] In the author's laboratory, PGE_2 measurements are used as an objective index of the level of synovitis.[26,43] Actions of PGE_2 in joints include vasodilation, enhancement of pain perception, proteoglycan depletion from cartilage (by both degradation and inhibition of synthesis), bone demineralization, and promotion of plasminogen activator secretion. PGE_2 is released from chondrocytes on stimulation of these cells by IL-1 and TNFα.

Oxygen-Derived Free Radicals

Oxygen-derived free radicals, including superoxide anion, hydroxyl radicals, and hydrogen peroxide, may be released from injured joint tissues. Studies have demonstrated cleavage of HA by free radicals.[32,116] There is also evidence that superoxide can degrade the alpha chains of collagen based on the finding that superoxide treatment inhibits gelatin.[31] Proteoglycans may be cleaved by free radicals.[31] Increased free radicals in the synovial fluid of cases of equine joint disease have been demonstrated more recently.[20]

Nitric oxide has been recognized as an important physiologic mediator. It combines avidly with superoxide anion, and although this was originally thought to provide a protective function, it has been suggested that this reaction can generate further destructive species, including peroxynitrite anion and hydroxyl radicals.[81] A recent review has noted that the specific effect of a radical on a given cell function very much depends on experimental context. Specifically, the simultaneous presence of superoxide, which leads to the formation of peroxynitrite (due to interaction of NO and supraoxide), a stronger and highly reactive radical, is likely to lead to cell and tissue damage.[53] However, NO has certain protective effects in cartilage and other tissues, and inhibition of NO *in vitro* or *in vivo* can potentially lead to undesired exacerbation of inflammation and tissue destruction under certain conditions. Selective scavengers of peroxynitrite must be more promising candidates for the treatment of OA than specific inhibition of NO. The role of nitric oxide in joint disease needs, and is receiving, further attention.

Cytokines and Articular Cartilage Degradation

Cytokines are soluble peptides produced by one cell affecting the activity of other cell types. Studies of cytokines in joint tissues suggest that IL-1 and TNFα modulate the synthesis of metalloproteinases by both chondrocytes and synovial cells[16,17,117] and are therefore important mediators in joint disease. Because IL-1 and TNFα may be produced by synovial cells,[17] they may therefore be of importance in the deleterious effects of synovitis on articular cartilage. It is thought that the normal turnover of the extracellular matrix of the articular cartilage is regulated by the chondrocytes under the control and influence of cytokines and mechanical stimuli. Articular cartilage degradation in association with disease represents an exacerbation of these normal processes. It is widely accepted that the cytokine IL-1 induces proteoglycan depletion in articular cartilage by either increasing the rate of degradation or decreasing synthesis in association with the release of proteinases and prostaglandins from chondrocytes (Figure 7.10). IL-1 produces its effects by binding with an IL-1 receptor on the cell. The presence of IL-1 in equine osteoarthritic joints was first reported by Morris et al.[72] An equine IL-1 containing extract was produced by May in 1990.[59]

The significant role of equine IL-1 has been further consolidated, starting with the cDNA sequences for IL-1α and IL-1β being constructed.[34,35] After generation of these DNA sequences, the IL-1α and IL-1β recombinant proteins were purified. Prior to that, only human recombinant IL-1 protein was available. Using equine articular cartilage explants, significant proteoglycan release was induced by both rEq-IL-1α and rEq-IL-1β at concentrations greater than or equal to 0.01 ng/mL with 38%–76% and 88%–90% of total GAG released by 4 and 6 days, respectively.[42,104] Significant inhibition of

VetBooks.ir

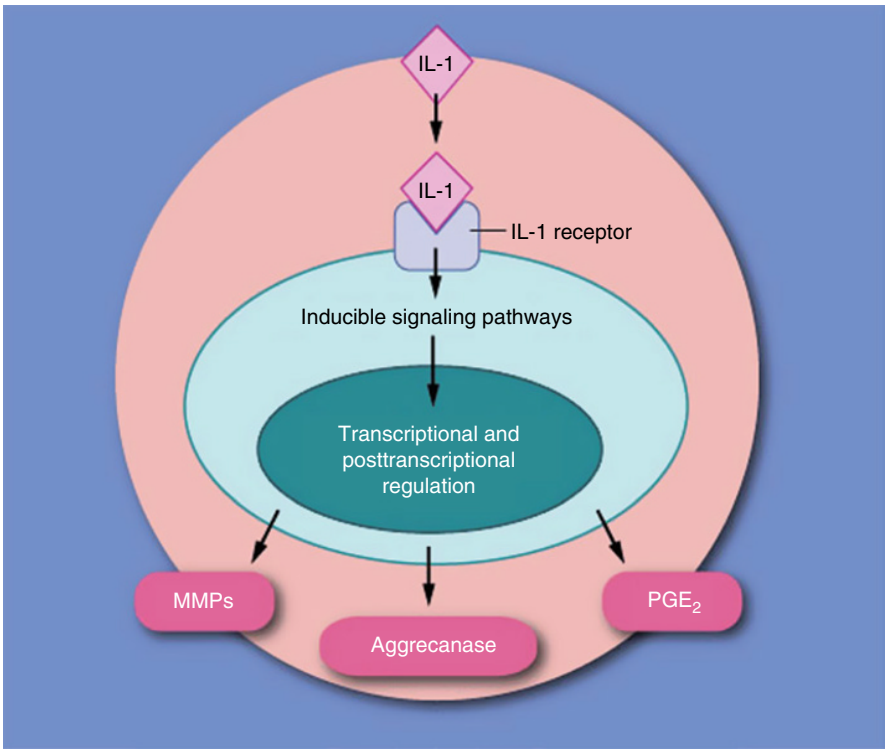

Figure 7.10. Diagram of IL-1 activation of MMPs, aggrecanase, and PGE_2 release acting through IL-1 receptors on the cell membrane. *Source*: Redrawn from figure 6, McIlwraith.[64] Reproduced with permission of American Association of Equine Practitioners.

proteoglycan synthesis (42%–64%) was observed at IL-1 concentrations greater than or equal to 0.01 ng/mL at 2 and 4 days. Increased PGE_2 concentrations were observed at IL-1 concentrations greater than or equal to 1.0 ng/mL at 2 and 4 days. This work showed that the much lower concentrations of equine IL-1 could cause these effects compared with previously reported studies using human recombinant IL-1.[104]

The IL-1 system consists of the two agonist members IL-1α and IL-1β, and these evoke signal production in response to binding IL-1R transmembrane receptors to induce downstream effects (Figure 7.10). The significant role of IL-1 in the pathogenesis of cartilage degradation in the horse was best demonstrated by the work of Frisbie et al.[27] with interleukin-1 receptor antagonist (IL-1ra) using gene therapy. This study demonstrated that if IL-1 can be inhibited, articular cartilage degradation in experimental OA can essentially be stopped.

The role of TNFα in equine OA is less certain. Billinghurst et al. first demonstrated induction of intra-articular TNF during acute inflammatory responses in equine arthritis.[5] It appears that IL-1 is the principal cytokine responsible for articular cartilage degradation and TNFα contributes more to clinical morbidity and pain. IL-1 and TNFα have been demonstrated using RT-PCR in the synovial membrane of inflamed equine joints,[110] and increased serum concentrations of soluble TNF receptors (S TNF-r) have been detected in human patients with RA and OA in comparison with healthy controls.[14] A mini review of the role of cytokines as inflammatory mediators in OA concluded that it is generally accepted that IL-1 is the pivotal cytokine in early and late stages of OA, while TNFα is involved primarily in the onset of arthritis.[29] Both receptors of TNF have been identified in synovial tissue, with greater numbers seen in joints affected by RA in comparison to OA.[19]

The Pathways to Morphologic Breakdown of Articular Cartilage: The Critical Manifestation of OA

Trauma can cause an immediate physical defect or initiate a degradative process by direct damage to chondrocytes, causing release of enzymes as well as cytokine-initiated release of metalloproteinases and PGE_2 from chondrocytes in response to IL-1. As outlined in Figure 7.8, any instability in a joint can lead to damage of normal cartilage. On the other hand, cartilage compromised by loss of GAG or collagen is vulnerable to normal forces.

As has been previously discussed, as cartilage is compressed, the collapse of the collagen network is countered by the resistance offered by the proteoglycan gel. The precise nature of the forces exerted through the network is complex and related to both mechanical entrapment and chemical bonding effects between the fibers and the proteoglycans.[7] The same author has addressed the general problem of abnormal softening in articular cartilage with simultaneous micromechanical testing, interference-like microscopy, and transmission electron microscopy. A model has been developed in which this abnormal softening in articular cartilage is related to the presence of collagen fibers strongly aligned in a

(A) Diagram of a normal joint, as well as macroscopic and microscopic views of articular cartilage. (B) Stage 1 acute synovitis without morphologic change in the articular cartilage. (C) Stage 2 with synovitis persisting and early development of superficial fibrillation in the articular cartilage. (D) Stage 3 synovitis and capsulitis becoming chronic and articular cartilage fibrillation down into the deep zone of articular cartilage. (E) Stage 4 development of full-thickness erosions in the articular cartilage that are visible macroscopically and microscopically. Joint capsule change is chronic with fibrosis, but some degree of active synovitis is still present.

radial direction and this structure, having lost its three-dimensional character, would have limited ability to contain the swelling proteoglycan aggregates remaining in the tissue and would therefore reflect a state of softening in articular cartilage.[7]

The most common reason for degradation of articular cartilage and the development of OA is generally synovitis and capsulitis. There is a progression, beginning with acute synovitis, when biochemical change can take place in the articular cartilage, but there is no morphologic change. With critical loss of matrical components, however, morphologic damage ensues, going through a cycle of chondromalacia with softening of the cartilage and swelling due to absorption of water, superficial fibrillation, and fibrillation down to the middle zone of cartilage, followed by fibrillation progressing through the deeper layer of cartilage, which then allows for loss of articular cartilage components and full-thickness erosion. Figure 7.11 illustrates four stages of OA in which the synovitis and capsulitis become more chronic. Close examination of articular cartilage shows change, and the histologic equivalent of these macroscopic lesions is reflected as well.

Articular Cartilage Repair

Healing refers to restoration of the structural integrity and function of the tissue after injury or disease, but repair usually has a more restricted meaning.[8] Repair refers to the replacement of damaged or lost cells and matrix with new cells and matrix, a process that does not necessarily restore the original structure or function

VetBooks.ir

of a tissue. Regeneration may be considered a special form of repair in which the cells replace lost or damaged tissue with a tissue identical to the original. It has been suggested that with the exception of bone fractures, most injuries and diseases of the musculoskeletal tissues do not stimulate regeneration of the original tissue.[8]

The limited potential of articular cartilage for regeneration and healing has been appreciated for more than two centuries. In 1743, Hunter stated, "From Hippocrates to the present age, it is universally allowed that ulcerated cartilage is a troublesome thing and that when once destroyed it is not repaired."[37] There are a limited response of cartilage to tissue damage and an inability of natural repair responses from adjacent tissues to produce tissue with the morphologic, biochemical, and biomechanical properties of articular cartilage.

The major limiting factor in the successful rehabilitation of any joint after injury or disease is the failure of osteochondral defects to heal.[65] Three mechanisms have been recognized as possible contributors to articular cartilage repair. Intrinsic repair (from within the cartilage) relies on the limited mitotic capability of the chondrocyte and a somewhat ineffective increase in collagen and proteoglycan production. Extrinsic repair comes from mesenchymal elements from the subchondral bone participating in the formation of new connective tissue that may undergo some metaplastic change to form cartilage elements. The third phenomenon, known as matrix flow, may contribute to equine articular cartilage repair by forming lips of cartilage from the perimeter of the lesion that migrate toward the center of the defect.[38,39]

The depth of the injury (full or partial thickness), size of defect, location and relation to weight-bearing or non-weight-bearing areas, and age of the animal influence the repair and remodeling of an injured joint surface.[9,13,62]

With a partial-thickness defect, some repair occurs with increased GAG synthesis and increased collagen synthesis.[62] However, the repair process is never completely effective. In humans, complete repair of chondromalacia of the patella has been reported to occur if matrical depletion and surface breakdown are minimal.[4] However, more recent work with arthroscopic debridement of partial-thickness defects in humans questions any actual regeneration.[98] In addition, superficial defects are not necessarily progressive and do not necessarily compromise joint function.

With full-thickness defects, the response from the adjacent articular cartilage varies little from that after superficial lesions and provides only the limited repair necessary to replace dead cells and damaged matrix at the margins of the wound. These defects heal by ingrowth of subchondral fibrous tissue that may or may not undergo metaplasia to fibrocartilage.[13,30,39,54,113]

Subchondral bone defects either heal with bone that grows up into the defect or fill in with fibrocartilaginous ingrowth.[113] Duplication of the tide mark in the calcified cartilage layer is rare, and adherence of the repair tissue to surrounding noninjured cartilage is often incomplete.[30,54]

A number of equine studies demonstrate that the size and location of articular defects significantly affect the degree of healing achieved. Convery et al. first reported that large defects were less likely to heal.[13] A more recent study distinguished between large (15 mm^2) and small (5 mm^2) full-thickness lesions in weight-bearing and non-weight-bearing areas of the antebrachiocarpal (radiocarpal), middle carpal (intercarpal), and femoropatellar joints.[39] At 1 month, small defects were filled with poorly organized fibrovascular repair tissue; by 4 months, repair was limited to an increase in the amount of organization of this fibrous tissue, and by 5 months, small radiocarpal and femoropatellar lesions were hardly detectable because of combinations of matrix flow and extrinsic repair mechanisms. Large lesions showed good initial repair, but at 5 months, perilesional and intralesional subchondral clefts developed.

The repair tissue that forms after full-thickness injury to hyaline cartilage or as a natural repair process in joints with OA is primarily composed of type I rather than type II collagen, at least at 4 months.[9,13] Identification of type II collagen is the critical biochemical factor distinguishing hyaline cartilage from repaired fibrous tissue and fibrocartilage. It is thought that the presence of an abnormal subchondral bone plate and the absence of a tide mark reforming may create a stiffness gradient and that shear stresses of the junction of the repair tissue and underlying bone develop. The propagation of such shear stresses would lead to the degradation of repair fibrocartilage and exposure of the bone. This mechanical failure has been observed experimentally and clinically in the horse.[39,67]

In a study looking at the long-term effectiveness of sternal cartilage grafting, the repair tissue in the non-grafted defects at 12 months consisted of fibrocartilaginous tissue with fibrous tissue in the surface layers, as was seen in control defects at 4 months. However, on biochemical analysis, the repair tissue of the non-grafted defects had a mean type II collagen percentage of 79%, compared with being non-detectable at 4 months.[112,113] On the other hand, the GAG content expressed as milligrams of total hexosamine per gram of dried tissue was 20.6 ± 1.85 mg/g, compared with 26.4 ± 3.1 mg/g at 4 months and 41.8 ± 4.3 mg/g DW in normal equine articular cartilage.[112,113]

The fibrocartilaginous repair seen in normal full-thickness defects is therefore biomechanically unsuitable as a replacement-bearing surface and has been shown to undergo mechanical failure with use. The lack of durability may be related to faulty biochemical composition of the old matrix and incomplete remodeling of the interface between old and repaired cartilage or to increased stress in the regenerated cartilage because of abnormal remodeling of the subchondral bone plate and calcified cartilage layer. Although recent work implies that it may be possible to reconstitute the normal collagen type in equine articular cartilage,[111] clearly there is continued deterioration of GAG content, and these are important components in the overall composition of the cartilage matrix.

The presence of a cartilage defect may not represent clinical compromise. In the equine carpus, loss of up to 30% of articular surface of an individual bone may not compromise the successful return of a horse to racing.[67] However, loss of 50% of the articular surface or severe loss of subchondral bone leads to a significantly worse prognosis.

VetBooks.ir

The inadequate healing response may not necessarily apply to immature animals or to non-weight-bearing defects. An example is the young horse after surgery for osteochondritis dissecans (OCD) that shows impressive or at least functional healing responses. This may be related to increased chondrocytic capacity for mitosis and matrix synthesis and the presence of intracartilaginous vascularity. Complete restoration of the ultrastructure and surface configuration in a hinge-like gliding joint surface such as the femoropatellar joint may be unnecessary for clinical soundness, compared with the more severe loading on an osteochondral defect located on the weight-bearing portion of the medial condyle of the femur or the midcarpal joint.

It has been suggested that increasing age may affect the response of cartilage to injury in humans because the ability of the chondrocytes to synthesize and assemble matrix micromolecules could decline with age.[8] Buckwalter cites a study of transplanted chondrocytes, suggesting that older chondrocytes produce a more poorly organized matrix than do younger chondrocytes,[8] and other studies demonstrate that the proteoglycan synthesized by the chondrocytes changes with age.[3,84] Much research is continuing to be done to develop better methods of cartilage repair, and these have been reviewed elsewhere.[64]

PRIMARY DISEASE OF SUBCHONDRAL BONE

In addition to synovial-mediated degradation of articular cartilage and direct mechanical damage, the subchondral bone can play a primary role in disease development (Figure 7.12).[78]

When considering possible pathways for mechanical destruction of articular cartilage in human OA, it has been suggested that early subchondral bone sclerosis causes a reduction in the joint's shock-absorbing ability and therefore places cartilage at risk of shear-induced tensile failure of cartilage cross-links, particularly under repetitive impulsive loading conditions.[85] Work in the author's laboratory[44] has demonstrated that when horses are subjected to athletic exercise on the treadmill, microdamage in the subchondral bone can develop early. On postmortem examination of racehorse joints (euthanized for catastrophic injuries in another limb), the range of microdamage includes not only microfractures but also primary osteocyte death. It is thought that not only is the mechanical support of the articular cartilage lost when subchondral bone microdamage progresses to macrodamage but that cytokine release from the bone also can potentially influence that state of the articular cartilage.[44,45,78] Figure 7.12 illustrates a specimen from a horse euthanized because of catastrophic injury in the other limb. An incidental finding at postmortem was the presence of subchondral bone necrosis, with a peripheral area of sclerosis and intact cartilage in the distal palmar area of the metacarpus. Figure 7.13 shows microdamage that can occur quite early in association with exercise.

Gross examination of MCP/MTP joints from racehorses revealed defects on the condylar surface that ranged from cartilage fibrillation and erosion to focal

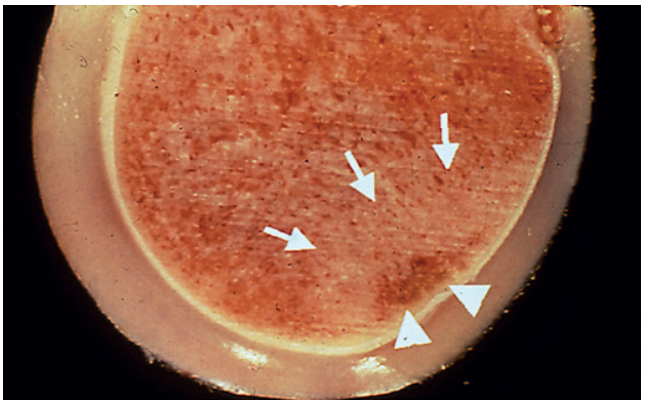

Figure 7.12. Postmortem sample of a distal metacarpus from the leg opposite to that suffering a catastrophic injury in a racehorse. Although there is intact articular cartilage, subchondral bone necrosis (arrowheads) and sclerosis (arrows) can be seen. *Source*: Norrdin et al.[78], figure 10. cartilage indentation and cavitation in subchondral bone. These lesions represented a spectrum of mechanically induced arthrosis in which microdamage is thought to play a role.[78] Lesions in the subchondral bone ranged from thickening of subchondral bone and underlying trabeculae, advancing sclerosis with increasing amounts of osteocyte necrosis, vascular channels with plugs of matrix debris, and osteoclastic remodeling. Apparent fragmentation lines in the subchondral bone suggested increased matrix fragility. Trabecular microfractures developed at a depth of a few millimeters, with increased vascularity with hemorrhage, fibrin, and fibroplasia seen in the marrow spaces at the more advanced stage. The articular cartilage in most of these instances was variously indented but remained largely viable, with degeneration and erosion limited to the superficial layers. Focally, breaks in the calcified layer appeared to lead to collagen and cartilage infolding. In metacarpal

VetBooks.ir

condyles from experimental horses run on a treadmill,[45] change in the metacarpal condyles was milder. The significance of osteochondral injury in joint disease has also been well reviewed by Riggs.[93]

In addition to its role in contributing to OA, the presence of subchondral bone injury contributing to complete failure of the subchondral bone and fractures is important.[58] "Impact fracture" is a term that has been used recently to describe a pathologic fracture that shows up as an area of lucency in the bone.[15] Pathologic change in the distal condyles of the third metacarpal and third metatarsal bones of the horse as a predisposing factor for condylar fractures was first investigated in detail by Riggs et al.[89,91,92] Recognition of this change potentially leading to fractures has led to investigations of imaging techniques to diagnose this at an early stage.[22]

BONE INJURIES AND DISEASE

Chris Kawcak and Gary M. Baxter

VetBooks.ir

THE IMMATURE SKELETON

Bone growth occurs by both longitudinal (endochondral) and circumferential (membranous) growth. Membranous bone formation is responsible for increases in long bone width and formation of flat bones and is independent of a cartilaginous template. Longitudinal bone growth results from a series of events occurring at highly specialized regions at one or both ends of the bone. These regions are referred to as the physes, growth plates, or, more correctly, the metaphyseal growth plates.[31] The process that occurs at the growth plate, termed endochondral ossification, is characterized by rapidly differentiating and maturing cartilage cells and the replacement of cartilage by bone. There are two types of growth plates: discoid and spherical. The discoid growth plates are seen at the ends of long bones. Some bones have a physis at each end of the bone, whereas others, such as the third metacarpal/metatarsal bone and the proximal and middle phalanges, have only one distinguishable physis. A discoid physis is located between the metaphysis (the flared end of the bone that contains spongy bone) and the epiphysis. An apophysis (which is a type of discoid physis) is an epiphysis that is subject to tensile rather than compressive forces, such as at the olecranon process, calcaneal tuber, and tibial tuberosity. The growth plate of an apophysis contains greater amounts of fibrocartilage than a true discoid physis, which is an adaptation to withstand tensile forces.[85] Spherical physes are also located in the small cuboidal bones of the foal's carpus and tarsus. These growth plates develop into bones by centrifugal expansion around a central cartilage core. They begin to ossify in the center and gradually assume the contours of the bone of an adult as bone development reaches the margins of the cartilage model. (The reader is referred to Chapter 10 for further information on the morphology and physiology of the physis.)

Effect of Trauma on the Physis

When an excessive force is applied to a joint and its nearby physis, an epiphyseal or physeal injury is likely to occur. Similar to other injuries in adults, chronic repetitive trauma, such as occurs in young human athletes, can also result in damage to the physis. This is because the cartilaginous growth plate is weaker than the surrounding bone, ligamentous structures, and joint capsule. Physeal and epiphyseal injuries account for approximately 15%–18% of all fractures in children and also occur commonly in foals. Injuries that would normally produce a ruptured ligament or joint dislocation in an adult may produce traumatic separation of the physis in a young animal. For example, trauma to the fetlock region usually causes fetlock luxations in adult horses and distal metacarpal/metatarsal physeal fractures in foals. Joint luxations are rare in young horses. (The reader is referred to Chapter 10 for further information on physeal fractures in horses.) Non-fracture injuries are not uncommon in foals. Chronic angular limb deformity (ALD) and the resultant overstress of both local and distant physes in the limb can result in growth abnormalities and permanent deformity. More subtle, chronic stresses to the physes, as is common in juvenile human athletes, are not recognized in horses. However, the size and rapid growth of horses seem to make them predisposed to such problems.

Developmental Orthopedic Diseases

Developmental orthopedic disease (DOD) complex is a group of abnormalities that occurs in foals and young growing horses.[131] Other terms that are often used interchangeably with DOD include osteodystrophy or osteochondrosis although this is considered erroneous. Most of the diseases included in the DOD complex can be attributed to alterations in bone growth or development (endochondral ossification) either at the metaphyseal or epiphyseal growth plates. These include physitis, ALDs, OCD, subchondral cystic lesions (SCLs), cuboidal bone collapse or incomplete ossification, juvenile arthritis, cervical vertebral malformations (CVM), and flexural deformities.[48,131] The more specific term "juvenile osteochondral conditions" has been proposed to describe those DOD lesions specific to the immature joint and growth plate.[21] These include osteochondrosis/OCD, cuboidal bone disease, bone cysts, osteochondral collapse, insertion site avulsions, and physitis. Clinical signs of these conditions are variable but are usually seen in young horses since this is an abnormality of developing bone. Signs include variable degrees of lameness, alteration in posture or positioning of the limb, crooked legs, joint effusion, limb enlargement, ataxia (CVM only), and possible fractures. Additionally, multiple DOD conditions may be present in the same animal.

Although the exact cause for DOD is not known, the basic pathologic mechanism of disturbed endochondral ossification has been agreed upon, and there are multiple risk factors that appear to predispose young horses to the development of these diseases. Despite the lack of identification of single factors that cause DOD, a primary pathologic mechanism of vascular insult has been widely accepted.[126] Damage to the vasculature as it courses through the cartilage canals has been seen in foals, but in many cases a reparative cascade of events is often present, leading to a mix of clinical outcomes from clinical disease to healing.[87]

Despite the apparent common pathogenetic mechanism of vascular insult, the etiologic factors that incite disease are diverse. Many of the risk factors are man-made such as management and breeding practices, and others have been extrapolated from research work in other species.[27,39,86] For instance, the incidence of developmental problems in wild horses is low compared with

VetBooks.ir

domesticated breeding practices.[122] In addition, breeding for rapidly growing offspring that hopefully will do better in the show ring and feeding rations high in energy and protein appear to predispose these animals to DOD abnormalities presumably by contributing to rapid bone growth. Other risk factors include mineral imbalances such as copper deficiency or excess zinc, trauma, and genetic predilection.[99,125] Trace mineral deficiencies, copper in particular, have been incriminated in physitis and angular deformities in cattle,[105] and copper has been shown to cause clinical signs and joint pathology consistent with osteochondrosis in foals.[43,44] Copper is required for the enzyme lysyl oxidase, which itself is necessary for collagen cross-linking. Therefore, defective collagen cross-linking may impair the strength of bone collagen, producing essentially a "soft bone syndrome" particularly in the metaphyseal regions.[44] Excess zinc or alterations in the calcium/phosphorus ratios in the diet may also lead to clinical problems of DOD, but these are less well defined in horses than copper deficiency.[99]

Trauma to the metaphyseal or epiphyseal growth plates can contribute to altered growth, subchondral bone damage, and avulsion of defective bone (Figure 7.14), all of which may also predispose to DOD conditions. Abnormalities in vascular integrity of the developing osteochondral complex appear to be a factor in the pathogenesis of DOD.[88] Septic arthritis/osteomyelitis has been shown to cause cartilage canal abnormalities, leading to chondronecrosis in the articular–epiphyseal cartilage complex, causing OCD-type lesions.[132] Lecocq et al. demonstrated the histologic changes that occur in fetal and newborn foals at common sites of DOD and concluded that abnormalities in proteoglycan and collagen metabolism, cartilage canals, and vascularization of the epiphyseal growth cartilage play a role in DOD.[55] However, in most cases, the underlying cause of the DOD condition is multifactorial, usually obscure, and often never determined.[131] (The reader is referred to Chapter 10 for further information on specific DOD conditions such as physitis and ALDs.)

Incomplete Cuboidal Bone Ossification/Juvenile Spavin

Incomplete ossification of the cuboidal bones of the carpus or tarsus occurs most commonly in premature, twins, or underdeveloped newborn foals. At birth, the cuboidal bones have not ossified sufficiently to withstand the forces of normal weight-bearing, predisposing to variable degrees of carpal or tarsal bone wedging or collapse (Figure 7.15). Incomplete ossification without collapse is not readily apparent clinically and is best diagnosed with radiography to document abnormal cuboidal bone appearance. Moderate to severe incomplete ossification of tarsal bones has been seen in Thoroughbred foals born after a short gestational length, and those horses had less successful racing

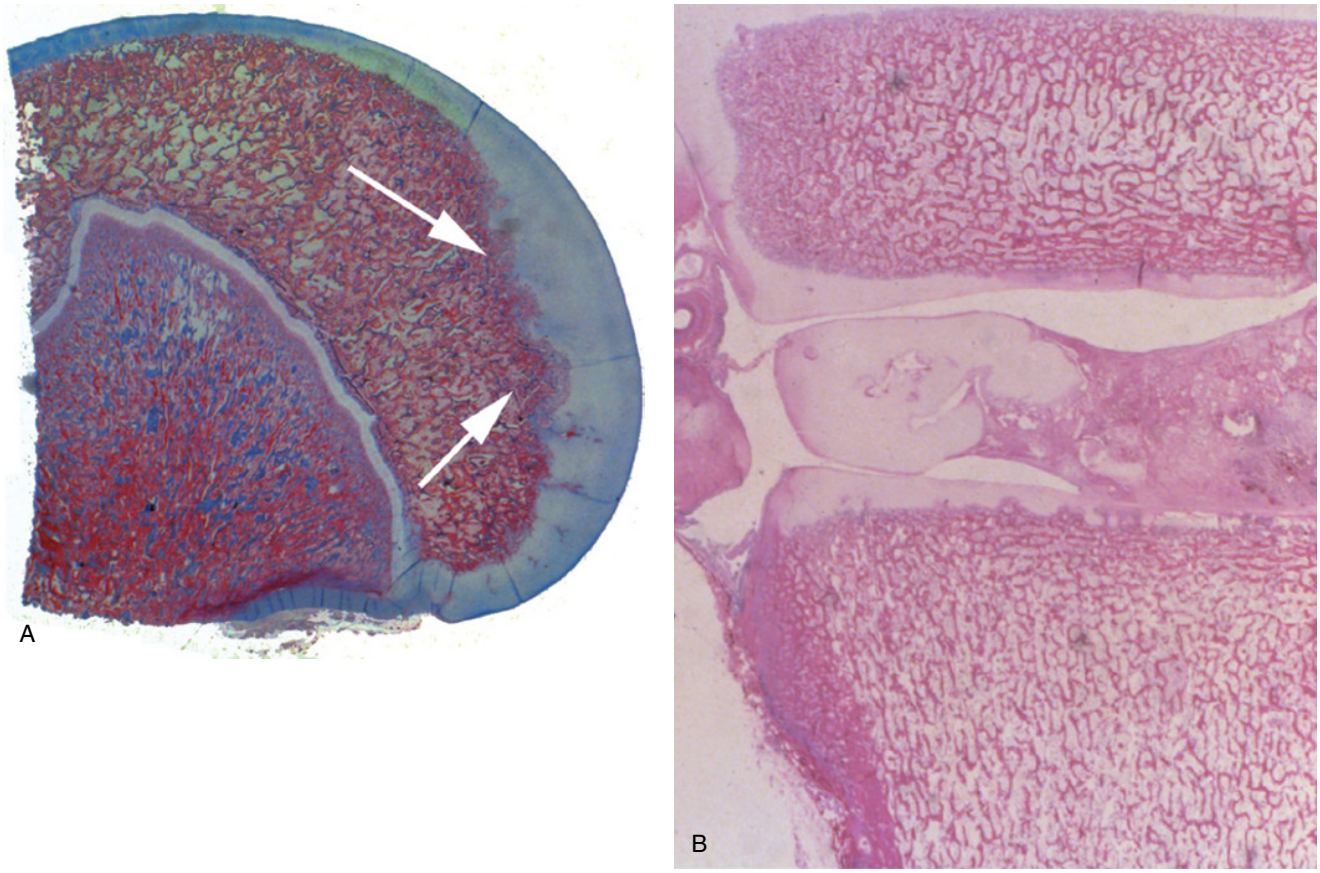

Figure 7.14. Histologic examples of abnormal bone formation typical of developmental orthopedic diseases. careers than a group of normal foals.[38] Clinical signs associated with cuboidal bone collapse may be evident in the newborn foal as an ALD of the carpus or tarsus. Collapse of the tarsal bones is much more common than that of the carpal bones. Tarsal collapse is often associated with a sickle or cow-hocked conformation of the tarsus or the tarsus looks like it has a "curb." The degree of lameness is variable and may not become clinically apparent until later in life. Preventing cuboidal bone collapse in newborn foals with incomplete ossification involves minimizing compressive forces on the bones until they ossify. Confinement, sleeve casts, bandages, or bandages and splints may be used depending on the severity. In a previous study, foals with only minor tarsal bone collapse were able to perform as intended, whereas foals with more severe tarsal bone collapse and fragmentation could not be used for their intended purposes.[23] Additionally, incomplete ossification and mild collapse or wedging of the tarsal bones are thought to predispose to juvenile spavin in young horses. Horses with juvenile spavin have relatively severe signs of bone spavin at a young age with a history of minimal work (Figures 5.81, 10.27, and 10.58). Inherent abnormalities of the central and third tarsal bones are thought to contribute to the development of osteoarthritis (OA) in the distal tarsal joints at such an early age. In those young horses with obvious signs of juvenile spavin, surgical arthrodesis is often effective in salvaging the animal for athletic use.

Figure 7.16. Lateromedial radiographic view demonstrating a typical lateral ridge OCD lesion of the distal femur (arrow) and the fragments that have migrated within the joint (arrowhead).

Osteochondritis Dissecans (OCD)

OCD refers to cartilage or cartilage and bone (osteochondral) fragments or flaps that develop along the articular surfaces of joints in horses. These abnormalities are probably the most common manifestation of the DOD complex in horses. They usually occur along the non-weight-bearing surfaces of the joint and are especially common in the stifle, tarsus, and fetlock joints (Figure 7.16).[125] Horses with OCD lesions typically are only mildly lame but usually have joint effusion of the affected joint(s). These lesions are often bilateral and may or may not require arthroscopic surgery to remove the osteochondral fragment(s). The prognosis

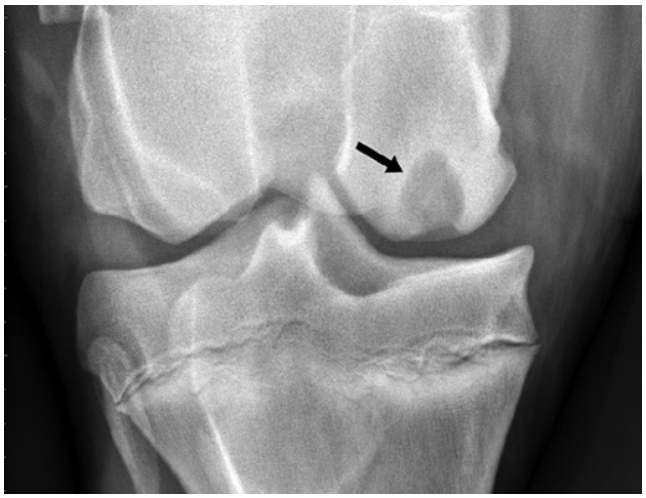
VetBooks.ir

for performance of horses with OCD lesions is usually very good. More detailed discussion of OCD lesions can be found in Chapter 10.

Subchondral Cystic Lesions (SCLs)

SCLs (bone cysts or osseous cyst-like lesions) are commonly recognized pathologic entities of bones and joints in horses that may or may not cause lameness. SCLs may be nonarticular or articular. However, most lesions that contribute to lameness involve the weight-bearing area of an articular surface. Nonarticular lesions (which may or may not be classified as SCLs) usually involve the metaphysis and can go undiagnosed because they may not cause clinical signs and normal bone remodeling may resolve the defect. The most common age for diagnosis of SCLs, or at least the time when clinical signs develop, is usually 3 years or less.[6,42] However, horses demonstrate clinical signs related to SCLs over a wide age range, and the relationship between when the lesion develops and when the horse begins to show clinical signs is not known.[47] This relationship probably varies depending on the specific site of the SCL (most common location is the medial femoral condyle), the age when the lesion develops, and the occupation of the horse. Although most cases of SCL have a developmental cause, older horses with OA can develop SCL likely due to trauma. What causes or initiates the appearance of clinical signs in horses with articular SCLs remains unknown; however, the consistent morphologic characteristics of the lesions suggest a common pathologic mechanism of development.[123]

SCLs have been reported to occur at multiple locations in horses.[6,12] However, the most common sites that contribute to clinical problems involve the stifle, fetlock, pastern, coffin, and elbow joints (Figure 7.17). Controversy exists as to whether these lesions are caused by a defect in endochondral ossification, intra-articular subchondral bone trauma, or a combination of both.[6,12,47] Joint trauma can lead to the development of SCLs, and this has been shown experimentally and has been seen clinically (Figure 7.18).[6] However, many of these lesions are seen in young horses and are bilateral, suggesting a developmental defect. SCLs



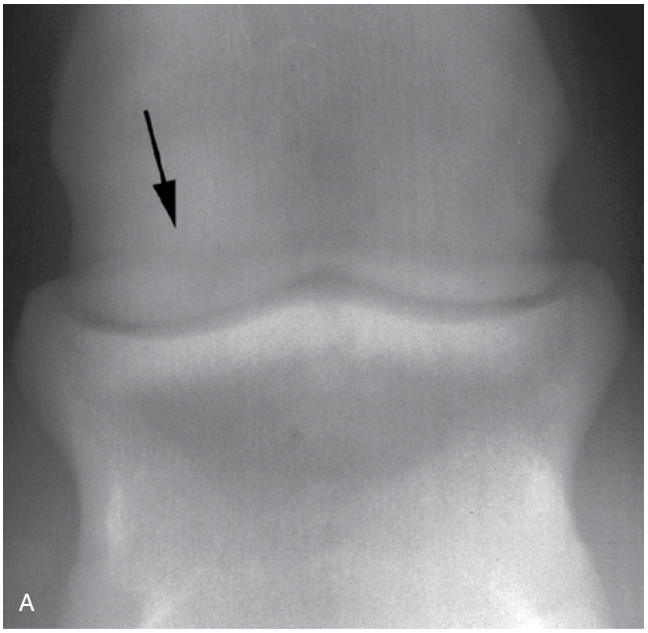


Figure 7.17. Caudocranial radiograph of the stifle reveals a subchondral cystic lesion within the medial femoral condyle (arrow) of this yearling Quarter horse filly.

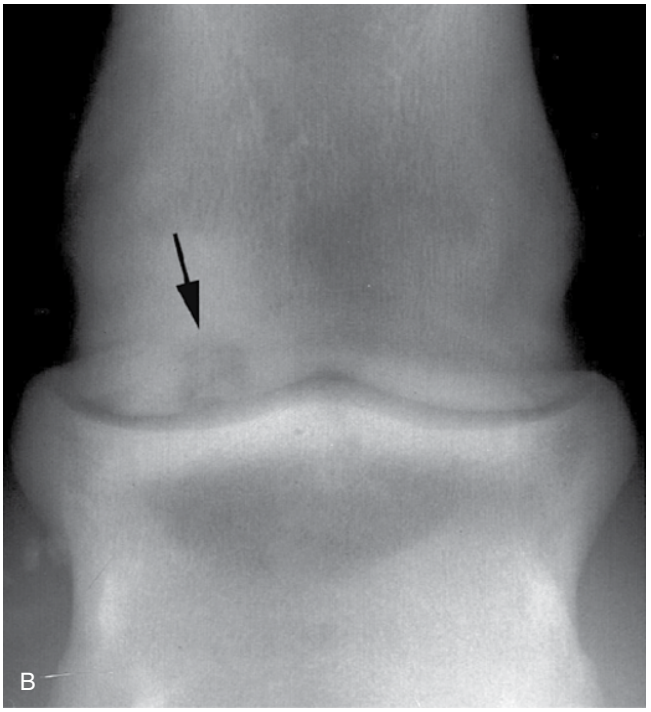

Figure 7.18. Dorsopalmar radiographs of the pastern in a 12-year-old Thoroughbred with a grade 4 out of 5 hindlimb lameness. Minimal radiographic abnormalities were visible on the initial radiograph (A, arrow). However, a subchondral cystic lesion with surrounding sclerosis was evident within the proximal phalanx on radiographs taken 6 months later (B, arrow).

VetBooks.ir

have been described as resulting from an infolding of abnormal cartilage into the underlying bony spongiosa.[6] The infolded cartilage becomes necrotic and its matrix remains nonmineralized so that osteoclasts and blood vessels do not migrate into the defect to enable repair of the defective cartilage and bone. The cystic lining is made up of fibrous tissue with active fibroplasia and capillary proliferation present in the tissue adjacent to the bone. The cyst lining has been shown experimentally to contain significant inflammatory mediators that likely contribute to the formation and progression of the cyst.[90]

Treatment of SCLs involves the use of either intra-articular medications (combined with systemic joint therapies), surgical debridement of the lesion, surgical debridement with bone graft, surgical debridement with augmentative therapies such as chondrocytes or stem cells, intralesional injection with corticosteroids, or transcystic screw placement (with or without intralesional therapy).[41,98,124] Because of the variable prognosis in horses with debridement of the lesion alone, additional treatment(s) of the bone defect is(are) being attempted by some surgeons. These include packing the entire defect with cancellous bone or packing the depth of the lesion with cancellous bone and filling the remaining bone defect with fibrin-laden chondrocytes containing growth factors. The goals of the latter treatment are to promote healing of both the bone and articular cartilage defects. Although nonsurgical treatment was usually recommended initially in most horses because of the variable success with surgical debridement of the lesions with or without the adjunctive treatments, the use of intralesional corticosteroid injections appears to give a more dependable prognosis. Use of a transcondylar screw reportedly eliminated lameness in 75% of treated horses but was reported to be less successful in horses >3 years of age.[98]

Effects of Exercise on the Immature Skeleton

Exercise can have a profound effect on the musculoskeletal system beginning at birth, and there has been considerable interest in the effects of early exercise on foals in an attempt to strengthen the system to reduce the incidence of injuries later in life. In initial studies by van de Lest et al., foals that were box stall rested were more likely to have reduced development than foals that were turned out full time and those that were turned out intermittently along with box stall rest.[58] Lepeule et al. have also shown an association between irregular exercise soon after birth and poor osteoarticular status.[57] The first author (CEK) has performed density studies in foals before and after exercise and found that prior to exercise, the subchondral bone pattern is blank, but at 6 months of age, the density pattern reflects the articulation between the joint surfaces (Figure 7.19).

In an attempt to strengthen musculoskeletal tissues later in life, a large study was performed in which foals that had additional exercise early in life were compared with those that were turned out. The goal was to provide galloping exercise in addition to normal pasture turnout to a group of foals and compare tissue responses as yearlings and as 3-year-olds. The investigators found minimal effects on tendons and ligaments, but fairly significant effects on articular cartilage. Namely, exercised foals had significantly higher viable chondrocyte content in their joints than pasture-reared foals, and they had less gross lesions in the carpi at 18 months of age.[24,54] However, there was no effect on articular cartilage changes that occurred in the palmar aspect of the parasagittal groove in the fetlock joints, a site of fracture and OA.[78] In the carpus though, Kim et al. showed that the incidence of gross lesions was significantly lower in the exercised group compared with the control group.[54] Subchondral bone formation was increased, but the overall bone content and density were no different between the groups. Overall, enforced galloping exercise did not produce negative effects and actually provided benefit to the joints.

Clinically, lack of exercise seems to have a profound effect on bone. For instance, it is not uncommon for young foals to fracture their proximal sesamoid bones during normal pasture exercise after being confined, usually in a hospital setting (Figure 7.20). The stall

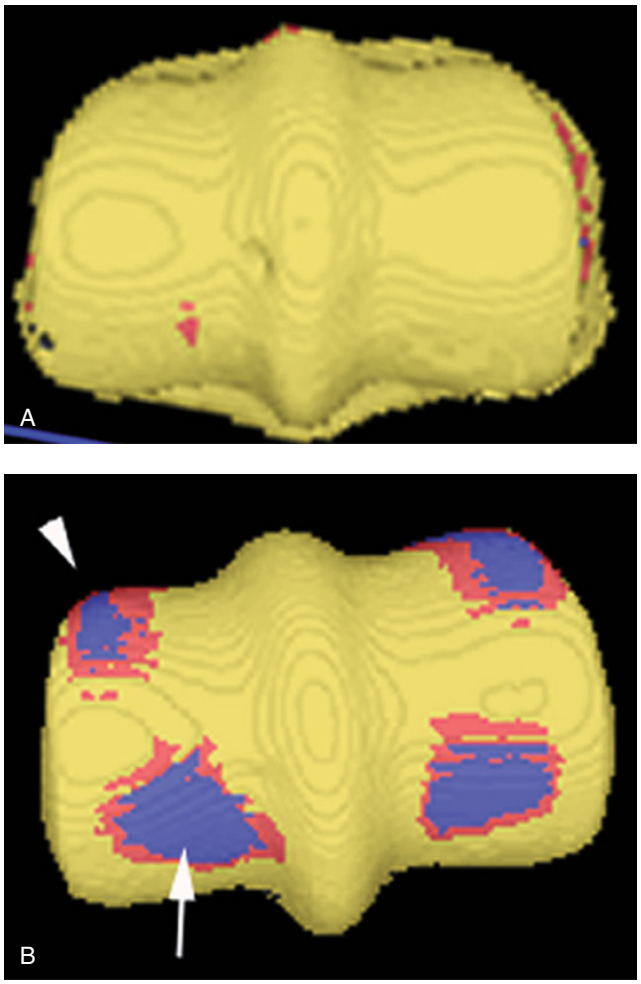

Figure 7.19. Three-dimensional computed tomographic images of the third metacarpal condyles, demonstrating the adaptation of bone to exercise in foals. In this example, subchondral bone density shortly after birth is homogeneous across the joint surface (A); however, after 6 months (B), the subchondral bone density increases in the areas that articulate with the proximal sesamoid bones (arrow) and the dorsal aspect of the first phalanx (arrowhead).

VetBooks.ir

Figure 7.20. A fracture of a proximal sesamoid bone in a foal that was initially stall confined at birth.

confinement appears to prevent normal adaptation to occur to the bones, especially the proximal sesamoid bones, and therefore create a situation in which the bones cannot withstand normal exercise. Therefore, care must be taken in introducing foals to turnout, especially if the mares sense competition with others in the pasture. The proximal sesamoid bones seem to be the most sensitive to lack of exercise. For instance, cast application to a limb will lead to radiographically apparent loss of bone density in the proximal sesamoid bones (Figure 7.21). The density of these bones will be 30%–40% lower with 6 weeks of casting.[35] This indicates that bones require a normal threshold of loading to maintain strength.

LOCAL DISEASES OF BONE

Exercise-Induced Bone Remodeling

Bone is very metabolically active under normal physiologic circumstances and in response to many types of injury. Its intricate micro- and macrostructural

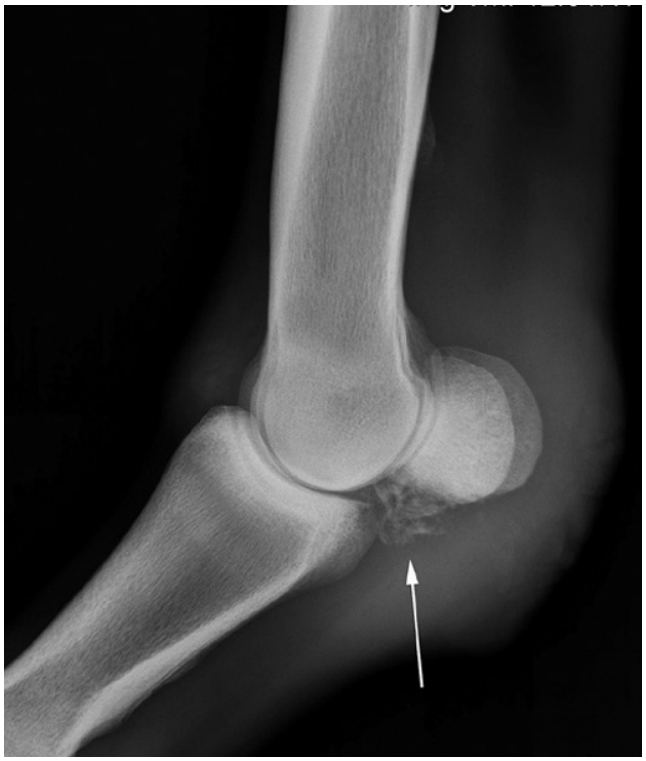

Figure 7.21. Lateromedial radiograph from a horse that was casted for 6 weeks. Notice the loss of bone density in the proximal sesamoid bones, as well as the formation of enthesophytes distally (arrow).

organization, combined with its high rate of metabolic activity, allows it to respond rapidly to many physical and biomechanical demands, especially in young animals.[62] Normal daily activity and exercise impose complex forces on the skeletal system that cause varying quantities of deformations of bone. Deformations within a bone are referred to as strains, and the local force intensities at these sites are the stresses, defined as a given force per unit area. The direction and magnitude of these stresses and strains are dependent on the geometry of the bone, the direction and magnitude of the load imposed on the bone, and the material properties of the bone. That is why joint surface geometry, limb conformation, and shoeing are so important to the pathogenesis and management of lameness. Bone in any species can undergo "remodeling" or "modeling." Equine bone remodels in response to the stresses placed on it according to Wolff's law, which in brief states that bone is laid down where it is needed and is resorbed where it is not needed. Examples of adaptive remodeling in equine bone include the cancellous portion of the proximal sesamoid bones that becomes less porous (stiffer and stronger) when trained on dirt tracks compared with untrained horses,[133] and the shape changes the metacarpus undergoes during training and racing to withstand the added forces applied to the bone.[79,83,84] Bone modeling occurs when the resorptive phase does not occur, and instead bone is laid down on top of normal trabecular structures. Examples of this are the palmar aspect of the third metacarpal condyle as it becomes dense and the radial facet of the third carpal bone

VetBooks.ir

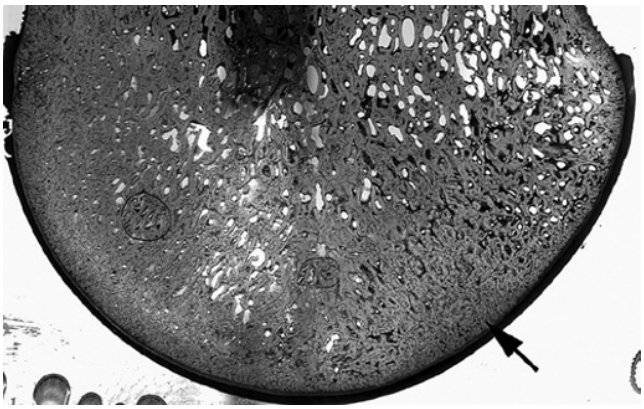

Figure 7.22. A histologic section through the palmar aspect of the third metacarpal condyle of a racehorse.

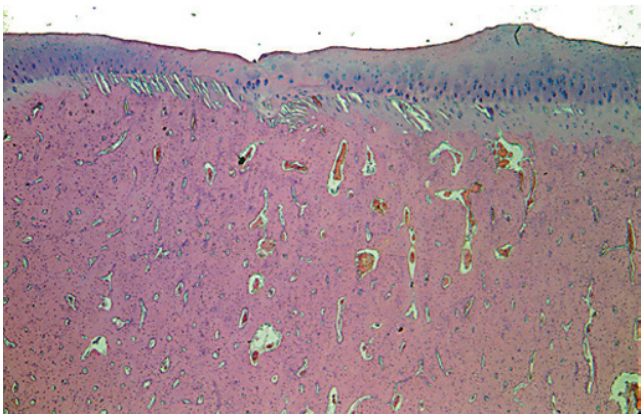

Figure 7.23. A histologic section through the palmar aspect of the third metacarpal condyles showing not only severe bone modeling but also overlying articular cartilage damage. This example appears to represent a modeling response beyond the threshold of normal adaptation to exercise.

with training[19,52] (Figure 7.22). These are only a couple of examples of bone's response to exercise, which undoubtedly occurs in every bone during training and performance. Unfortunately, there is a fine line between what is considered to be normal adaptive training (repetitive stress response) and overtraining that may be pathologic to the bone (repetitive stress injury)[106] (Figure 7.23). In addition, there is no objective means of characterizing that threshold between normal and pathologic loading.

The osteogenic response of bone to remodeling stimuli such as training or exercise appears to be most dependent on the strain magnitude and strain rate. In other words, the greater the load, the faster the load is applied, and the more times bone is loaded (repetitions), the greater will be the remodeling response. Increased magnitude of loading could be achieved by going at higher speeds or on harder surfaces (or a combination of each). Excessive repetitions of normal loads or too high of loads are thought to contribute to the development of dorsal metacarpal disease or stress or fatigue fractures in racehorses.[83,84,114] Fatigue fractures indicate that the bone has not remodeled or gained enough strength to withstand the forces (loads) applied to it.[84] In most cases, the exercise regimen should be altered to permit the bone to gain adequate strength to tolerate the higher loads. However, the clinical signs of fatigue fractures are vague, and often the horse will show no clinical signs until the fatigue fractures coalesce and cause a complete fracture. If excessive load is applied to a bone as a single event, the ultimate stresses and strains that the tissue can tolerate are exceeded, and a complete fracture occurs. Single-event trauma is a cause of complete fractures in many horses and foals. However, fatigue or stress fractures predispose to complete fractures especially in performance horses, presumably by decreasing the ultimate load that the bone can withstand before fracturing. This has been shown repeatedly at sites of injury in racehorses.[19,52] Examples include fatigue fractures of the cortical bone of the third metacarpus, the tibia, pelvic structures and humerus, and the subchondral bone of the carpal bones, proximal sesamoid bones, and third metacarpal condyles[5,65,115,118,130] (Figure 7.24). In addition to fracture, stress-induced modeling can lead to pathologic sclerosis of subchondral bone, especially in the third carpal bone and third metacarpal condyles (palmar osteochondral disease) that can lead to OA.

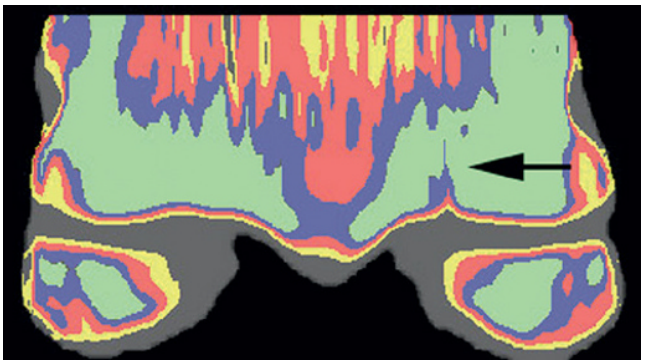

Figure 7.24. A computed tomographic image of the third metacarpal condyle of a Thoroughbred racehorse. Note the vertical demineralization in the area where condylar fractures typically occur (arrow).

Fractures

When a fracture occurs, there is usually a loss of structural continuity of the bone, and its function is impaired to varying degrees. The degree of altered function and the particular bone that is fractured often determine the type and severity of lameness. For example, a displaced fracture of the olecranon process or a fracture of one of the major load-bearing bones such as the radius or tibia usually produces a severe lameness. Conversely, a so-called osteochondral or "chip" fracture of a carpal bone produces a mild lameness that usually responds well to surgical removal, but if severe enough may predispose the horse to OA and cause a secondary lameness. However, most acute fractures will cause significant lameness regardless of their size and location. A fracture should always be considered as a possible cause of any non-weight-bearing lameness.

Fractures in horses are often due to a single high-energy traumatic event that completely disrupts the

VetBooks.ir

bone (breaks the bone into at least two pieces). In contrast to most complete fractures, fatigue fractures are due to chronic trauma that weakens the bone, rather than a single traumatic event that fractures the bone.[114] Specifically, chronic repetitive stress normally induces a bone strengthening cascade as a form of adaptation to withstand these forces (repetitive stress response). This is a normal process in all athletes, especially the horse, and creates normal patterns of bone enlargement or thickening, such as sclerosis through the processes of bone modeling and remodeling. Specifically, repetitive stress can induce the response one of two ways. Microdamage can stimulate remodeling events and lead to replacement of the damaged bone. Since osteoclastic function is more rapid than the osteoblastic response, this does create a window of vulnerability in which further high stresses can induce more damage within the relatively porous bone. The second form of bone strengthening in response to stress is through bone modeling, in which osteoid and mineral are added to existing bone to create either a dense sclerotic region (such as in subchondral bone) or geometric changes to bone architecture in order to maximize stress resistance (such as in cortical bone). This modeled bone is often more brittle than normal and in some instances can create pain and necrosis in these areas.

Fatigue fractures (repetitive stress injury) of the humerus, tibia, pelvis, and metacarpus/metatarsus (Figure 7.25) are commonly diagnosed in performance horses (primarily racehorses).[114,115] Initially these lesions cause variable degrees of lameness but may contribute to complete fracture of the involved bone with continued use.[114] Diagnosis of incomplete fractures in racehorses is critical to prevent catastrophic bone failure, but this can be difficult and the timing is critical. These horses may not be overtly lame at the time of examination, but may have a history of not working correctly, or be lame intermittently or immediately after work. If lameness is present, then diagnostic analgesia can be performed, but the proximal location of many of these fractures often precludes its use. In addition, many subchondral bone lesions may not extend into the joint early in the disease process, making intra-articular analgesia of little use.[21] Nuclear scintigraphy can be very helpful in locating suspected fatigue fractures that are not apparent on radiographs. Care must be taken in overinterpretation though, as young exercising horses will typically show sites of intense remodeling, especially in the fetlock joints.

Treatment of incomplete fractures is much less complicated than treating complete fractures and usually involves a period of inactivity combined with a change in training schedule.[119] In contrast, complete fractures of long bones of horses are one of the most difficult injuries to treat successfully, and many horses are still euthanized because of the severity of the fracture (Figure 7.26). The prognosis of repairing complete fractures in horses depends on the specific bone affected, the temperament of the horse, the age and size of the horse, the specific characteristics of the fracture, and the expertise of the surgeon, to name just a few. However, proper stabilization of the fracture for transport to a surgical facility for repair is crucial to achieving a favorable outcome, and newer repair techniques and implants have improved prognosis.

Figure 7.25. A radiograph of the third metacarpal bone from a 2-year-old racing Quarter Horse showing a fatigue fracture of the dorsal aspect of the bone (arrows).

Fracture Stabilization for Transport/Fracture Immobilization

Fractures are a frequently diagnosed problem in horses that often require emergency first aid treatment (Table 12.1). Horses are not readily ambulatory on three limbs and often become very anxious when they are unable to place weight on a fractured limb, which potentially can result in further injury. First aid measures should be directed toward minimizing further damage to the fractured limb and maintaining it in a position and condition that will facilitate repair. The goals of first aid fracture management are to prevent damage to neural and vascular elements of the limb, to prevent skin penetration of the fracture fragments or minimize further contamination of an existing wound, to relieve anxiety of the animal by stabilizing the fractured limb, to prevent deterioration of the patient's physiologic status, and to minimize further damage to the fractured bone ends and surrounding soft tissue.[11,13] Most of these objectives can be accomplished by proper stabilization or splinting of the fracture. However, fractures of the upper forelimb and hindlimb in horses are nearly

VetBooks.ir

Figure 7.26. A severely comminuted, open, displaced fracture of the distal third metacarpus. Even though the condylar portion of this fracture is common and amenable to repair (arrow), the comminuted nature of the cortical portion of this fracture makes any repair futile, especially since the area was avascular from the degree of comminution (arrowhead).

impossible to stabilize with external splints. Luckily, the bones in these locations are surrounded with large muscle groups, which inherently stabilize the fracture ends, making external coaptation less important.

Fracture immobilization serves several purposes. In horses, immobilization is more important to preserve limb vascularity than to prevent hemorrhage at the fracture site. Severe hemorrhage infrequently accompanies fractures in horses, but vascular thrombosis from continued stretching and direct trauma often lead to diminished vascularity of the distal limb. This can result in compromise to the hoof capsule and subsequent loss of the hoof. Limb immobilization also reduces the animal's anxiety enabling the horse to regain control of the limb even though the limb cannot bear weight. Once stabilized, most horses will rest the limb instead of continually trying to place it in a normal stance, which will cause further soft tissue and bone damage. Probably the most important purpose of immobilization is to prevent the development of an open fracture. Loss of intact skin coverage over a fracture predisposes the site to contamination and subsequent infection, especially if internal fixation is performed. Equine skin is thin and readily penetrated by sharp bone fragments, and there is little soft tissue support, such as muscle, below the carpus and tarsus. In general, fractures of the distal (phalanges) and upper (humerus, ulna, and femur) aspects of the horse's limbs rarely become open, suggesting that proper immobilization of fractures involving the metacarpus/metatarsus, radius, and tibia is the most critical to prevent the development of an open fracture during transport. Fractures at these sites often require emergency surgical repair to prevent open fracture configuration. The reader is referred to the section on musculoskeletal emergencies in Chapter 12 for specific details on fracture immobilization.

Fracture Healing in Horses

Fracture healing can be considered a series of processes that occur in sequence but are often overlapping. The healing process can be divided into three distinct phases: inflammatory, reparative, and remodeling.[63] During this process the bone will unite by one of two patterns: primary or direct healing and secondary or indirect healing. With primary bone healing, the bone ends heal directly by Haversian remodeling in contact and noncontact areas without the formation of a bone callus. Rigid fracture stabilization and correct anatomical reduction of the fracture are required for primary or direct bone healing to occur. With indirect or secondary bone healing, fibrous tissue or fibrocartilage is formed initially between the fracture fragments with subsequent replacement with new bone. Periosteal and endosteal callus is formed to unite the bone ends.[63] In horses, because of their large size and weight, primary healing is rare, and even with rigid internal fixation, a combination of primary and secondary bone healing is likely to occur.

Inflammatory Phase

The inflammatory phase occurs over the first 2–3 weeks after injury, and it is considered critical for the reparative phase of fracture healing that follows. During this phase the cellular mechanisms necessary for repair and the processes protecting the healing tissue from infection are activated. If the inflammatory response is impaired, tissue healing is compromised. Chemical messengers mediate the inflammatory reaction by causing vasodilation, migration of leukocytes, and chemotaxis of substances necessary for the repair process. In particular, bone morphogenetic proteins play an important role in the initiation of fracture repair.[91] The "osteoimmunological" response is being given greater investigation lately as it is key to cell signaling and recruitment for fracture healing. Polymorphonuclear cells remove debris, macrophages and monocytes stimulate osteoclastic and progenitor cell migration, and based on the integrity of the vascularity, chondrocytes and osteoblasts are stimulated to the site. The role of nonsteroidal antiinflammatory medication in fracture cases is being critically reviewed in human medicine, and its use is being limited.

Reparative Phase

During the reparative phase, the pattern of fracture healing is highly susceptible to mechanical factors such as interfragmentary motion. With spontaneous fracture healing, the initial hematoma and fibrous tissues provide

VetBooks.ir

some internal stress and support, and periosteal and endosteal callus formation provides interfragmentary stabilization, and bone union occurs by intramembranous and endochondral ossification.[63] This process can take from 2 to 12 months to be completed depending on the method of fracture fixation that was utilized, the stability of the fracture, and the size of the fracture gap (fracture displacement).

Remodeling Phase

The remodeling phase occurs during and following the reparative phase. Avascular and necrotic regions of bone are replaced by Haversian remodeling.[63] Malalignment of fracture fragments may be corrected during this phase of healing by remodeling of the fracture site and functional adaptation, particularly in young animals. With weight-bearing and loading of the fracture, bone is removed from the convex surfaces and laid down on the concave surfaces. This process tends to realign the bone after malunion (Figure 7.27). However, fracture remodeling cannot correct torsional deformities associated with fracture healing. Theoretically, bone can heal completely and regain pre-fracture strength and function.

Figure 7.27. Radiograph of the third metacarpal bone of a horse that presented several months after the fracture had been treated with external splinting. The fracture had healed but was severely malaligned.

Fracture Fixation

In horses, more than any other domestic animal one has to carefully define "successful" fracture healing. For centuries, bone has been observed to heal by production of callus, but the end result was often angulation, rotation, or limb shortening. With intra-articular fractures, a certain amount of OA was often the end result. Fixation techniques used to achieve primary bone healing with intra-articular fractures have greatly decreased the morbidity associated with OA in these cases. In addition, improved techniques in internal fixation of long bone fractures have emphasized improving the implants to withstand massive functional forces, thus preventing failure due to mechanical overload. Such implants must also be strong enough to maintain their integrity until the bone has united, without breaking under fatigue. However, despite improvements in fracture fixation equipment, anesthetic protocols, and recovery methods, successful repair of some long bone fractures in horses remains very difficult.

Stress protection is a phenomenon seen when a bone that has been rigidly immobilized by a plate(s) undergoes certain histologic events, including loss of bone mass without a corresponding reduction in size (quantitative osteopenia).[119] Stress protection results in Haversian remodeling and has generated considerable interest in man and small animals because of the potential for refracture of the bone following removal of the plate. Stress protection is almost an unknown occurrence in the horse, even in foals, because of the greater loads imparted on the implants compared to man and other smaller animals.[119] In fact, the size and weight of horses often stress the limits of stress tolerance in implants. While the emphasis of research activity in man and small animals has focused on the development of more flexible implants, in horses the emphasis has been in the reverse direction to provide stronger implants in an attempt to overcome the massive loading of the implants.

An important consideration in the horse is stress concentration. This is where biomechanical loads are concentrated in a small area of normal or weakened bone, potentially leading to complete bone failure.[119] This primarily occurs in the diaphysis of long bones but may also develop elsewhere along the bone. Examples of stress concentration include drill holes that are not filled with implants during internal fixation and vacant screw holes after implant removal (such as after metacarpal stress fracture repair).[119]Additionally, stress concentration occurs at the ends of bone plates especially if they stop in the mid-diaphyseal region of a bone and at intramedullary (IM) pin hole sites following removal of external fixators. These locations are all areas where small areas of cortical bone are absent or have been weakened and can fail if excessive loading of the bone occurs.

Compression Fixation

The use of various methods of compression in the treatment of fractures in man and animals is widely accepted. Under stable conditions it is recognized that both cancellous and cortical bones heal by primary bone

VetBooks.ir

union, without callus formation. Under these circumstances Schenk and Willenegger[102] showed that healing resulted by proliferation of new osteons growing parallel to the long axis of the bone, first through the necrotic bone ends and then across the fracture. This is termed "primary bone healing" and is the ultimate goal for repairing any fractures in horses or any species. With compression across the fracture, the mechanical stability with little or no motion between the fragments creates more favorable conditions for primary bone healing. Therefore, with internal fixation, the function of the implant (plate and/or screws) is to hold the bone fragments under compression with little to no movement until fracture union has occurred.[119]

Compression fixation of fractures is often the goal for fracture repair in horses. Intra-articular fractures when rigidly compressed usually heal rapidly without the development of secondary OA. Long bone fractures repaired with bone plates can heal without exuberant callus that would interfere with nearby soft tissue structures. However, compression fixation cannot be achieved in many cases due to the nature of the fracture and the temperament and size of the patient. In general, compression fixation and primary bone healing can be accomplished with most intra-articular fractures in horses, but is usually not completely achieved in long bone fractures. Most long bone fractures will develop varying degrees of callus formation during the healing process, which in most cases is not a major problem. Specific methods for repair of certain fractures, in particular those amenable to lag screw fixation, are discussed in Chapter 5 when a particular bone or joint is discussed. Below are general principles regarding fracture fixation in horses.

Figure 7.28. A fracture of the lateral condyle of the distal third metacarpus that requires lag screw fixation to achieve precise alignment of the joint surface.

Lag Screw Principle

One method to compress a fracture is to use a lag screw, a basic technique used routinely by carpenters and engineers. It is particularly suited for intra-articular fractures in horses where accurate anatomic alignment of the joint surface is essential to avoid secondary OA (Figure 7.28). Lag screws alone are used rarely to repair major long bone fractures in horses or even small foals, because they are simply not strong enough. Lag screws are ideally suited to repair slab fractures of the third carpal bone (Figure 7.29), condylar fractures of the distal third metacarpus and metatarsus (Figure 7.28), sagittal fractures of the proximal phalanx, and some tarsal bone fractures. Additionally, lag screws can be used in conjunction with plates to repair comminuted fractures where fracture reconstruction is performed with screws, and a plate is applied, or the lag screws are inserted through the plate holes. Varying sizes of cortical bone screws (3.5, 4.5, or 5.5 mm in diameter) can be used as lag screws. The 5.5-mm screw is being utilized more commonly in horses because of its increased strength and holding power compared with the 4.5-mm screw.

To achieve the lag screw principle, threads must gain purchase only in the far bone fragment. For cortical screws this is achieved by overdrilling the fragment next to the screw head to such a size that the screw threads will not engage this portion of the bone. This hole is termed the glide hole (Figure 7.30). If this hole is not overdrilled, when the screw is tightened the gap between the fracture fragments would be maintained and no compression would be achieved. Therefore the screw should only achieve purchase in the "far" or transcortex, i.e. cortex away from the head.

In certain bone regions, particularly in the metaphysis of bones in foals, the bone may be too soft for cortical screws to gain purchase. Cancellous screws can be used to achieve compression between fragments in these locations but should be used with caution in dense cortical bone. Therefore, whenever possible, cortical bone screws should be used in horses with the exception of young foals with very soft bone. To exert the maximum amount of interfragmentary compression, a lag screw should be inserted at right angles to the fracture plane. However, if the bone is under some axial load, the screw ideally should be inserted at right angles to the long axis of the bone. Therefore, the ideal direction to achieve maximum interfragmentary compression and resistance to axial loading is a direction between these two extremes.[119] In general two or more lag screws are used if possible to prevent rotation of the fragment. This is not always possible especially for fractures involving the small carpal or tarsal bones.

Pre-tapped cortical screws are used primarily for lag screw fixation in horses. Self-tapping screws were

VetBooks.ir

originally thought to provide poor bone holding qualities compared to the pre-tapped screws.[119] Both 5.5- and 6.5-mm screws inserted into cadaver foal metacarpal/metatarsal bones pre-tapped had significantly greater holding power than the same size screws inserted self-tapped.[134] However, Schatzker et al. and Andreas et al. in similar studies demonstrated that self-tapping screws had the same holding power and pullout strength as pre-tapped screws.[2,4,100,101] Use of self-tapping screws may be difficult in very dense cortical bone, and the screws may actually break. Self-tapping screws (4.5 mm) inserted into equine third metatarsal bones did not break, but could not be inserted continuously.[3] In addition, pre-tapped screws can be placed in the bone with greater precision, thereby producing better holding power.[100,101] In general, most cortical screws inserted into equine bone are pre-tapped. Self-tapping screws are used in locking plates for better security at the screw-plate location.

Figure 7.29. Lateral radiograph of the carpus in a racehorse following lag screw fixation of a third carpal bone slab fracture with a 3.5-mm cortical screw. Larger third carpal bone fractures in horses are often stabilized with 4.5-mm cortical screws.

Cannulated and bioabsorbable screws are also available for use in horses. Cannulated screws are hollow enabling screw placement over a guide pin that helps maintain fracture reduction and precise screw positioning during the lag screw procedure. They are available in a variety of sizes, but the concerns of using cannulated screws in horses are their questionable strength (since they are hollow) and the expense.[3,4,16] Bioabsorbable screws are made of polylactic acid derivatives and once placed would theoretically not need to be removed. They are used sparingly in horses because of the expense and their questionable strength especially in shear.[28] However, one *in vitro* experimental study using equine third carpal slab fractures as a model suggested that they have comparable biomechanical properties to 4.5-mm cortical screws.[76] A headless tapered variable pitch screw has also been advocated for use in horses.[14] The variable pitch nature of the screw allows for interfragmentary compression to occur without the presence of a screw head, which some surgeons feel can be a source of inflammation and irritation.

Other Methods of Internal Fixation

Many fractures in horses, especially those involving long bones, cannot be repaired with lag screws alone. Other methods of repairing long bone fractures include bone plating, tension band wiring (Figure 7.31), IM

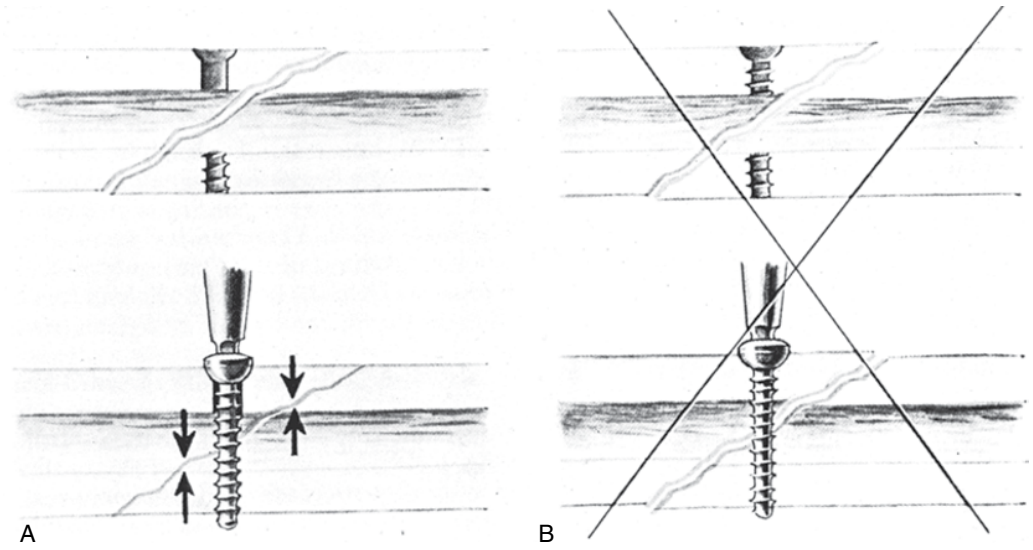

Figure 7.30. (A) Correct execution of the lag screw principle. (B) Incorrect execution of the lag screw principle. The cortex under the screw head was not overdrilled, and the gap between the bone fragments cannot close.

pinning, IM interlocking nails, and the use of external fixators.[3,4] Bone plating provides the most rigid fixation of fractures but cannot be used in all cases because of the specific characteristics of the fracture and the expense. For those fractures amenable to bone plating, one and many times two plates are used to provide adequate fixation (Figure 7.32). The plates (usually 4.5 mm in thickness) are best placed on the tension side of the bone and at right angles to each other when two plates are used. Either 4.5- or 5.5-mm cortical screws can be used to secure the plates to the bone, and these should be placed as lag screws across the fracture if possible. Special-purpose bone plates used occasionally in horses include the dynamic condylar screw (DCS), dynamic hip screw (DHS), angled blade plate (ABP), and the cobra head plate.[3,4,42] Plate luting refers to placing polymethylmethacrylate (PMMA) either under the plate or around the screw heads to further increase the strength and stability of the fixation.[81,111] Improved bone plate contact is achieved, and therefore luting is most beneficial in large horses to increase the overall strength of the implant.[81,111] However, locking plates have made the use of plate luting unnecessary. The locking plates are designed so that the screw heads fix into the plate with a screw mechanism and do not rely on friction between the plate and the bone for stability (Figures 7.32 and 7.33). Shearing of the screw heads is a common mode of failure, and this mechanism reduces the stress between the screw head and the plate, allowing for a more stable fixation. This has been used routinely in equine fracture repair and arthrodesis and lends itself well for use in minimally invasive percutaneous plate osteosynthesis.[46,59,92]

IM interlocking nails are relatively new in equine orthopedics and have primarily been used to repair humeral, femoral, and some metatarsal/metacarpal fractures.[3,70] The IM nail is placed within the medullary cavity of the bone and is transfixed to the bone above and below the fracture using bone screws.[70,71] This method of repair is thought to create a more biomechanically sound fixation by placing the implant within the bone, rather than applying bone plates to the external surface of the bone. The potential benefit of interlocking nails in equine orthopedics awaits further clinical use.

External Fixation of Fractures

External fixators or transfixation pin casts have become more widely used for fracture repair in horses over the last several years.[68,69,77] They are most useful to stabilize or prevent collapse of comminuted fractures of the distal limb where other forms of internal fixation cannot be used and to treat open fractures where placement of implants would likely result in osteomyelitis.[69,77,80,82,92,94,97] The fixator pins (usually 0.25 inch or 6.35 mm in diameter for average adult horse) can be placed above and below the fracture, but in most cases pins are placed only above the fracture (Figure 7.34). Polymethylmethacrylate or stainless steel sidebars can be used as the construct of the fixator to connect the pins if used above and below the fracture or

VetBooks.ir

Figure 7.33. A partial carpal arthrodesis performed using two locking compression plates.

a fiberglass cast is applied to the limb to support the pins.[69,77,80,82,92] In most cases of phalangeal fractures, 2–3 pins are placed in the distal to middle aspect of the metatarsus/metacarpus and a lower limb fiberglass cast is applied to the limb to serve as the sidebars of the external fixator.[68,69] The transfixation cast permits the horse to ambulate on the limb without further displacement of the fracture during the healing process. Alternatively, a specially designed external fixator for horses (Nunamaker external fixator) that does not utilize a fiberglass cast may be used.[80,82] Catastrophic failure of the bone through one of the external fixator pinholes is the most severe complication of this form of fixation. Other potential problems include infection around the pins, premature pin loosening, chronic pain associated with the pins, and prolonged fracture healing.

Fractures as a Cause of Lameness

Consequences of fracture healing may lead to subsequent lameness. This has been termed "fracture disease" in humans and is seen under certain circumstances in horses. A major cause of disability in humans following fracture healing is stiffness of joints from disuse. This is rarely seen in horses and should not be confused with stiffening due to ankylosis of joints associated with the development of OA.[119] In fact, joint laxity, especially in young animals with fractures treated with casts, seems to occur more commonly than joint stiffness in horses. However, most fractures are accompanied by varying degrees of soft tissue (muscle, tendon, and ligament) damage that may be replaced with scar tissue. Subsequently there is obliteration of normal tissue planes that may impair tendon function, produce stiffening of neighboring joints, and cause flexural deformities in growing animals. A nonunion can occur due to infection, lack of vascularity, or relative instability (Figure 7.35). This instability leads to accumulation of fibrous tissue and fibrocartilage, which due to constant micromotion cannot mineralize. A malunion of the fracture may also lead to athletic disability in some horses (Figure 7.27). In addition, implant-associated pain from bone plates or screws may cause chronic lameness or poor performance in athletic horses. In some cases, implants used for

VetBooks.ir

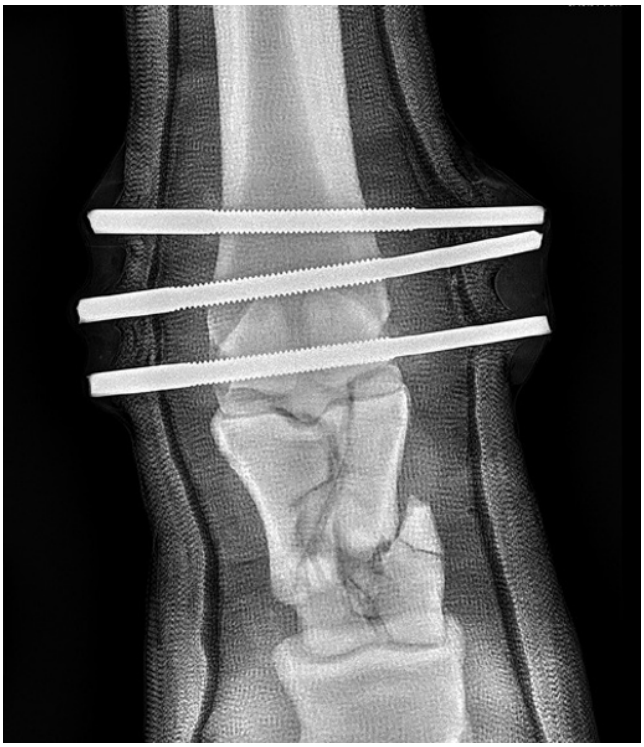

Figure 7.34. Three 0.25-in. (6.35-mm) diameter threaded intramedullary (IM) pins were placed through the distal metatarsus and incorporated into a fiberglass cast (transfixation pin cast) to prevent collapse of this severely comminuted first phalanx fracture. Two transfixation pins are usually recommended with the most distal pin placed in the center of, or slightly proximal to, the condylar fossa. *Source*: Rossignol et al.[97] Reproduced with permission of Veterinary Surgery.

internal fixation of fractures may need to be removed in performance horses to prevent these problems.

Another problem that can arise secondary to fracture fixation is the secondary problems related to casting. It is not uncommon to see significant loss of bone density, especially within the proximal sesamoid bones[35] (Figure 7.21). Clinically significant lameness unrelated to the primary disease can also result, as has been seen in several experimental studies in which lower limb casts have been applied to horses. Lameness, pain on flexion, and significant physical changes to bone density and soft tissue integrity have been observed.

Tendon and muscle flaccidity and atrophy of surrounding muscles are also seen in horses with fractures treated with external immobilization such as casts. This usually is a temporary problem that is self-correcting with time, but may lead to permanent lameness. Other aspects of so-called fracture disease in the non-fractured limb include ALDs due to excessive axial loading on active growth plates in young horses, stretching of flexor tendons and associated muscles, and support limb laminitis due to excessive weight-bearing. Support limb laminitis with rotation of the distal phalanx is unique to the horse and is a potentially devastating complication of equine fracture repair.

Infection is a serious complication of fractures that can eventually lead to permanent lameness or a nonunion of the fracture. Infection is most likely to occur with

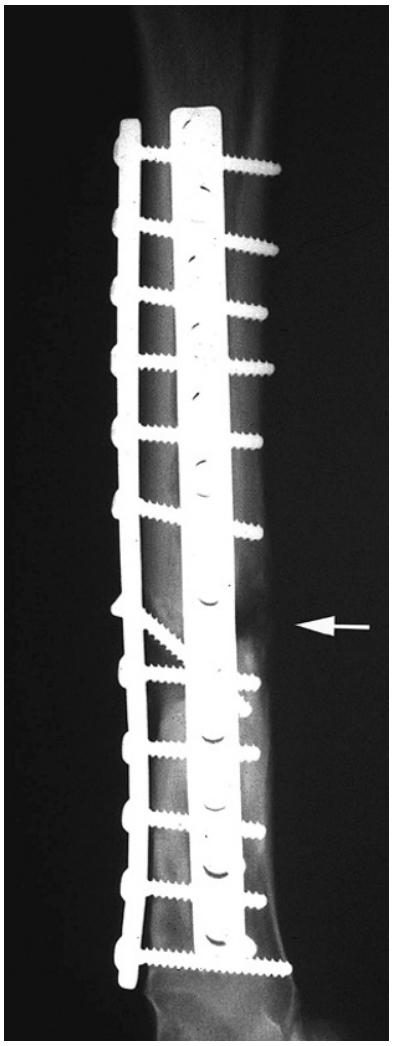

Figure 7.35. A radiograph of the third metacarpal fracture repaired with internal fixation. Note the lysis at the fracture line that is indicative of a nonunion (arrow).

open fractures or those repaired with internal fixation.[7] Severe infections may necessitate euthanasia of the animal, whereas milder more chronic infections may necessitate removal of the implants or necrotic bone to resolve the infection. Open infected fractures that eventually heal are often accompanied by considerably more fibrosis with a greater chance of loss of function of surrounding structures than closed noninfected fractures. The limb may be permanently thickened due to scar tissue and callus formation, which may lead to impaired limb function.[119]

Bone Infections

Osteitis and osteomyelitis are terms used to describe inflammation of bone involving the periosteum and connective tissues of the Haversian and Volkmann canals as well as the medullary cavity.[119] If the process begins or involves the periosteum and outer bone cortex, the term osteitis or osteoperiostitis is used. If the infection involves the medullary cavity, the term osteomyelitis is used. The prognosis and treatments for osteitis and osteomyelitis

VetBooks.ir

are quite different, and it is important to make a distinction between the two categories of bone infection.[7]

Infectious Osteitis

Osteitis commonly occurs in the extremities of the horse (mostly metacarpal/metatarsal regions) because of the sparse soft tissue coverage in this location. It is usually the result of infection from a nearby septic process or from a break in the skin.[7,10] Osteitis is seen frequently when a horse is kicked without breaking the overlying skin and may be similar to a bone bruise when no sequestrum develops. If the skin is broken, exposing the periosteum, the outer layers of cortical bone may eventually die, whereas the deeper cortical layers of bone survive due to the blood supply from endosteal vessels. For example, lacerations with bone exposure of the dorsal aspect of the metacarpus/metatarsus frequently develop osteitis and sequestration.[7,10] Bacteria that gain entrance to the bone lodge in the superficial layers of the bone, resulting in a thin layer of dead bone (bone sequestrum) within the wound (Figure 7.36). Although granulation tissue may advance over the bone sequestrum, the rate of advancement is usually slow. Occasionally granulation tissue advances under the sequestrum and extrudes it from the wound. The rate of healing of a wound can usually be accelerated by early removal of the sequestrum.

By definition the two requirements for the formation of a sequestrum are avascularity and infection. Therefore, most surgeons feel that blunt trauma to the bone cortex does not cause sequestration in the absence of infection.[7,10]

Figure 7.36. A sequestrum on the lateral aspect of the fourth metatarsal bone (arrow) secondary to trauma.

Sequestration without skin penetration does occur in horses although it is rare. In cases in which there is no break in the skin, the hematoma may become infected hematogenously leading to sequestrum formation, fistulation, drainage, and a nonhealing wound. This appears to occur most commonly with injuries to the splint bones, but most have skin wounds that lead to secondary bacterial infection. Chronic persistent drainage from any wound in the horse suggests the presence of a bone sequestrum or foreign body. Drainage will rarely subside or at least wound healing will be substantially prolonged without surgical removal of the sequestrum. This is because the pathogenic organisms reside within the necrotic bone, which is avascular, thereby resisting the animal's immune defenses.

The severity of lameness accompanying osteitis in horses is variable and inconsistent. In addition, the radiographic signs of osteitis will depend on the duration that has elapsed between the injury and time of examination. Initially there may be soft tissue swelling with evidence of bone resorption seen radiographically. At 7–14 days following the injury, periosteal proliferation may be evident. Sequestrum formation may also be visible at that time as osteoclastic resorption occurs at the periphery of the damaged bone. Radiographic evidence of a sequestrum is usually not visible for a minimum 2–3 weeks after the injury.[10] At this time, the sequestrum and the sclerotic margin around the sequestrum called the involucrum are usually visible.[7]

Occasionally an osteitis may resolve spontaneously, especially if there is no infectious component or if the sequestrum is small and extruded from the wound (which rarely occurs on its own). If bacteria and necrotic bone are present, the wound will be exudative indefinitely until the sequestrum is removed.[119] Wound debridement of unhealthy scar tissue and necrotic bone is usually required for healing to occur. Removal of bone sequestra is best performed with the animal under general anesthesia. However, thin cortical sequestra associated with avulsion injuries of the dorsal aspect of the cannon bone can often be removed in the standing sedated horse. After the surrounding granulation and scar tissue have been excised, the area should be curetted until the bone appears to be healthy. Most wounds are either closed primarily or left to heal by second intention following debridement.

Parenteral antibiotics are of limited value when used alone to treat bone sequestra because of poor penetration of the antibiotics into the necrotic bone. Antibiotics are indicated if there are signs of cellulitis (phlegmon) associated with the lesion and following surgical debridement of the wound. Occasionally a mild sequestrum can be effectively treated with antibiotics administered through regional limb perfusion, which is a technique commonly used regardless if surgery is performed. Usually a wide variety of organisms (secondary pathogens) can be cultured from the wound, and occasionally these bacteria are resistant to antibiotics that are of practical use in the horse. Culturing the sequestrum itself usually gives the most accurate diagnosis as to the causative bacteria. The prognosis for horses with osteitis and sequestrum removal is usually excellent.

VetBooks.ir

Osteomyelitis

Osteomyelitis is a more extensive inflammation of the bone than osteitis that begins within or extends into the medullary cavity. Osteomyelitis in horses can be divided into three categories based on the origin of the infection: hematogenous, traumatic, or iatrogenic.[7] Osteomyelitis from hematogenous origin occurs primarily in neonates and only rarely in adults. Traumatic osteomyelitis can occur in any age horse and is usually due to penetrating wounds or open fractures. Iatrogenic causes of osteomyelitis include surgery such as internal fixation of fractures or intra-articular injections of medications.

Hematogenous Infection

The localization of hematogenous osteomyelitis in the metaphyseal region of neonates can be explained by sluggish metaphyseal blood flow where the blood vessels form terminal sinusoids. This permits the bacteria to localize in these areas and to establish an infection (Figure 7.37). The infection in the bone spreads by way of Haversian and Volkmann's cavities, and prostaglandins are considered responsible for bone destruction.[119] Thrombosis of blood vessels also occurs as the infection spreads, producing death of the osteocytes in their lacunae.[7,119] The inflammatory process may increase pressure within the bone, further impairing blood supply. The end result is bone necrosis with possible sequestrum formation. Firth has classified hematogenous infections in foals into three categories depending on the location of the infection. S-type infections involve the synovial membrane of joints, P-types involve the physis and usually the metaphysis, and E-type infections involve the epiphysis.[29] However, these infections are not completely isolated, and foals may have multiple types of hematogenous infection at multiple sites (Figures 7.38 and 7.39). Bone infection due to *Salmonella* spp., for example, typically has multiple bones involved.[119]

Hematogenous osteomyelitis is frequently secondary to infections elsewhere in the animal's body, such as the umbilicus, gastrointestinal tract, or lungs.[7,29] Foals with a compromised immune system due to failure of passive transfer or septicemia appear to be predisposed to hematogenous osteomyelitis. Many of these foals may have multiple body systems involved with signs referable to the

infection in these regions, and, therefore, a complete physical examination is essential. However, some foals will recover completely from the initial infection only to develop bone or joint infections several days later when they appear to be very healthy. The most common bacteria that cause hematogenous infections in foals are Gram-negative enterics such as *Escherichia coli*.[7,29] Other causative organisms include *Staphylococcus* spp., *Streptococcus* spp., *Rhodococcus* spp., and *Salmonella* spp.

Traumatic Osteomyelitis

An open fracture or a penetrating wound may lead to osteomyelitis in any age horse (Figures 7.40 and 7.41). There is usually some degree of trauma to the skin and surrounding soft tissues with these injuries, and the pathogenic organisms may directly enter the medullary cavity through the open wound. Bacteria associated with these types of infections include Gram-negative enterics, *Staphylococcus* spp., *Streptococcus* spp., and anaerobes.[7,117] Infection spreads through the bone in a similar manner as for hematogenous osteomyelitis. Occasionally there is no overt break in the skin, but the necrotic tissue provides a medium for bacterial proliferation and infection develops from a hematogenous route. Avascularity is a major factor in the pathogenesis of osteomyelitis, and therefore, fractures with bone fragments isolated from a blood supply will be at risk to develop infection.[7] Treatment of an open fracture without providing absolute stability is usually futile unless the dead avascular fragments can be removed or reincorporated into the healing fracture where they can be revascularized.[119] Alternatively, some type of external fixator may be used to stabilize the fracture without disrupting the soft tissues around the fracture site.[69,80,82] In this manner, the potential for osteomyelitis is decreased because no implants are placed near the fracture, and the vascularity to the fracture is not further impaired.

Iatrogenic Osteomyelitis

The cause of osteomyelitis following internal fixation of fractures is usually due to contamination from an open wound (open fracture). Regardless of the type of internal fixation utilized, infection following repair of open fractures is much more common than following repair of closed fractures. However, contamination of the fracture during the surgical procedure can and does occur, particularly if it is prolonged (greater than 3 hours).[7] Usually the fracture hematoma and avascularity at the fracture site and the implantation of foreign material (pins, plates, screws, etc.) contribute to the development of osteomyelitis, because they provide favorable conditions for bacterial growth. Once bacteria become

VetBooks.ir

established where nutrients are available, proliferation occurs within a polysaccharide slime, forming a biofilm-enclosed colony. This biofilm or bioslime is formed by bacterial extracapsular exopolysaccharide that binds to surfaces of the implants and help maintain infection by protecting the bacteria from the host defenses. Because of this, osteomyelitis may develop despite prophylactic antibiotic coverage at the time of fracture repair especially in open fractures. Highly resistant bacteria such as methicillin-resistant *Staphylococcus aureus* or Gram-negative enterics often cause these types of infections.[7]

Clinical Signs of Osteomyelitis

Hematogenous osteomyelitis may be missed in its early stages and often presents after the lameness has become unresponsive to medical therapy. Frequently the owner feels that the lameness was due to an injury such as a sprain or being stepped on by the mare. There is usually a very severe lameness with cellulitis similar to that seen with fractures. Pain is usually elicited with direct pressure and manipulation of the joint(s) adjacent to the infection, and a fever is commonly seen in foals. Clinical signs of traumatic or iatrogenic osteomyelitis are similar and include lameness, soft tissue swelling, and retarded wound healing over the implants, drainage, and fistulation. Signs can be present as early as 7–10 days of injury or surgery or may be delayed for 3–4 weeks. Bloodwork usually demonstrates most consistently an increase in fibrinogen and occasionally increased white blood cell count. Serum amyloid A is often increased dramatically in these cases.

Radiographic Signs of Osteomyelitis

Loss of bone density due to a reduction in the calcium salt content of the bone occurs gradually with osteomyelitis. Lytic changes in the bone are not visible until 30%–50% of the bone mineral has been removed.[89] This is usually evident 10–14 days after the onset of infection (Figure 7.42). In more chronic cases there are often sclerotic margins around the lytic regions due to new bone formation. Sequestrum formation with a surrounding envelope (called the involucrum) and endosteal and periosteal thickening may also be evident. Occasionally osteomyelitis may penetrate into an adjacent joint, producing signs of a septic arthritis. With osteomyelitis following fracture repair, blurring of the cancellous trabeculation and a "moth-eaten" appearance at the fracture site will be seen on radiographs.[119] Lysis along the screw threads or under the plate may become evident with time. Usually a piece of bone that is decalcified and surrounded by a lucent zone is a sign of sequestrum formation. A zone of bone destruction adjacent to the implants typically occurs under the plate and directly along the screw threads. In more chronic cases of osteomyelitis, zones of both bone production and destruction are visible radiographically.[7]

Diagnostic Ultrasound

Diagnostic ultrasound is often helpful in characterizing fluid overlying an implant as a sign of infection. Aspiration of the fluid can be facilitated with ultrasound for culture and sensitivity. Changes in the ultrasonographic appearance can be monitored to dictate the appropriate course of therapy.

Figure 7.42. Osteomyelitis after internal fixation of a fractured third metatarsal bone. Lysis of the bone is occurring under the plate at the fracture site (arrow).

Treatment

The lameness in many foals with hematogenous osteomyelitis is frequently attributed to trauma but is, in fact, the early stages of infection. Therefore, at the time of initial examination, the infection is often well advanced with or without obvious radiographic signs, making it difficult to treat medically.[7,96] However, if acute hematogenous osteomyelitis is suspected in foals despite no radiographic signs, broad-spectrum bactericidal antimicrobials should be administered. The duration of antimicrobial use is largely empiric (usually minimum of 3 weeks) and should be based on the clinical response of the animal. However, antimicrobials alone may be unsuccessful due to the ischemic nature of the disease and poor penetration of the antimicrobial into infected avascular bone. Antimicrobials are best used early in the course of the infection and at high doses. Antimicrobials used most commonly to treat horses and foals with osteomyelitis include penicillin, gentamicin, amikacin, ceftiofur, cefazolin, enrofloxacin, and vancomycin. Nonsteroidal anti-inflammatory drugs (NSAIDs) have been beneficial

VetBooks.ir

to treat acute osteomyelitis in humans and animals in conjunction with antimicrobials.[119] Many times the pain is due to acute synovitis from infection spreading to an associated joint, and lavage of the joint can provide significant pain relief and treatment.

If there is no response to medical therapy and/or the osteomyelitis is localized, then surgery in conjunction with medical therapy is recommended. If the lesion can be accessed through a joint, which is often seen with hematogenous infections, then arthroscopy should be used to remove the damaged bone. A sample of the bone should be obtained at surgery and submitted for culture and sensitivity testing. Debridement of infected fractures or open wounds should be performed to remove avascular bone and infected soft tissue and to decrease bacterial numbers. Cancellous bone grafting is often utilized with infections of fractures to speed fracture healing. However, a major priority for treatment of osteomyelitis associated with fractures is to achieve stability of the fracture. Stability needs to be maintained not only for fracture healing but also to limit the spread of infection.[119] Loose implants should be removed, and fracture stability achieved by other means such as re-plating, external fixators, interlocking nails, external immobilization, or a combination of these techniques. If it is impossible to stabilize the fracture either with internal fixation, external fixation, or both, euthanasia may be the only alternative since it is unlikely that the infection will resolve.

Other methods used to treat osteomyelitis include regional perfusion of antimicrobials directly into the medullary cavity of the bone or within the vascular system of the limb.[127,129,130] The goal is to obtain very high tissue concentrations of antibiotics to achieve better bacterial kill. A tourniquet should be placed above and below the site of infusion and maintained for a minimum of 20–30 minutes to achieve optimal results.[7,127–129] In addition, antimicrobial-impregnated PMMA may be placed locally into the wound to achieve high antibiotic concentrations in and around the fracture.[40,116] The antimicrobials are incorporated into the PMMA during mixing and will elute from the PMMA into the wound for several days to weeks after they are placed. The PMMA is usually molded into bead or cigar shapes and placed adjacent to the implants, fracture, or site of infection.[40] The use of antibiotic-impregnated PMMA is thought to greatly improve our ability to successfully treat iatrogenic osteomyelitis in horses such as those associated with internal fixation.[40]

Prognosis

The prognosis for foals with hematogenous osteomyelitis is variable but is usually poor if multiple sites are involved. However, if the site of osteomyelitis can be thoroughly debrided, then the infection can usually be resolved. The prognosis with traumatic osteomyelitis is also variable depending on the bone involved and the duration and severity of the infection. Traumatic osteomyelitis is usually less difficult to resolve than iatrogenic infections. Osteomyelitis following internal fixation of a fracture is one of the most difficult diseases to successfully resolve in horses.[7,40] Therefore the prognosis for these animals is extremely guarded particularly for adult horses.

Infectious Physitis

Hematogenous infections of the physes are not uncommon in foals and have similar predisposing factors as other bone and joint infections in foals. The physis is often the initial location of hematogenous bacteria and infection, which can subsequently spread to the neighboring epiphysis and joint (Figure 7.37). Multiple physes can be infected simultaneously, but this is uncommon. Clinical signs, radiographic findings, and treatment are similar to other bone infections. However, foals with primary infectious physitis without accompanying septic arthritis might demonstrate a stiff gait at most in multiple limbs. Pinpoint palpation over the physis can oftentimes elicit a significant pain response, making radiographic evaluation critical to early diagnosis.

Bone Cysts

True bone cysts (here defined as those other than SCLs) that occur in other species (primarily aneurysmal and unicameral) have been reported to occur rarely in horses.[8,45,112] The most common site appears to be the mandible. Unicameral bone cysts are defined as solitary intraosseous cysts lined by thin connective tissue membranes.[45] Aneurysmal bone cysts are defined as expansile lesions consisting of anastomosing cavernous spaces filled with unclotted blood and lined with fibrous walls of varying thickness.[61]

These cysts usually contain osteoid tissue or osseous components, without elastic laminae or muscle layers.[61] Aneurysmal and unicameral bone cysts are more characteristic of true cystic lesions since they do not involve an articular surface and are usually solitary, expansile, intraosseous lesions. The majority of these true bone cysts reported in dogs and people occur in the distal or proximal metaphyses of long bones.

The cause of aneurysmal and unicameral bone cysts in any species is uncertain. Unicameral cysts are thought to result from the encapsulation and alteration of a focus of intramedullary hemorrhage supposedly from trauma. Alternatively, trauma results in a disturbance in endochondral ossification, resulting in a cystic defect within the metaphysis.[15] Aneurysmal bone cysts are generally believed to develop secondary to a preexisting lesion such as fibrous dysplasia, hematoma from trauma or bleeding disorders, or neoplasia.[113] An aneurysmal bone cyst of the distal metaphysis of the metatarsus in a horse was thought to be caused by trauma.[112] Whether the pathogenesis of aneurysmal and unicameral bone cysts and SCLs are interrelated is controversial. Most of the evidence (including pathogenesis and clinical characteristics) suggest that SCLs, at least in horses, are a distinctly separate clinical entity from aneurysmal or unicameral bone cysts.[6] Additionally, aneurysmal and unicameral bone cysts can be difficult to differentiate from some bone tumors in horses (Figure 7.43). Treatment of true bone cysts in horses usually involves surgical curettage of the lesion with or without autogenous cancellous bone grafting. Spontaneous resolution of the cyst may also occur, and some bone cysts in people respond to intralesional steroid injections.[61] The prognosis for resolution of bone cysts in horses is usually good depending on the location of the cyst.

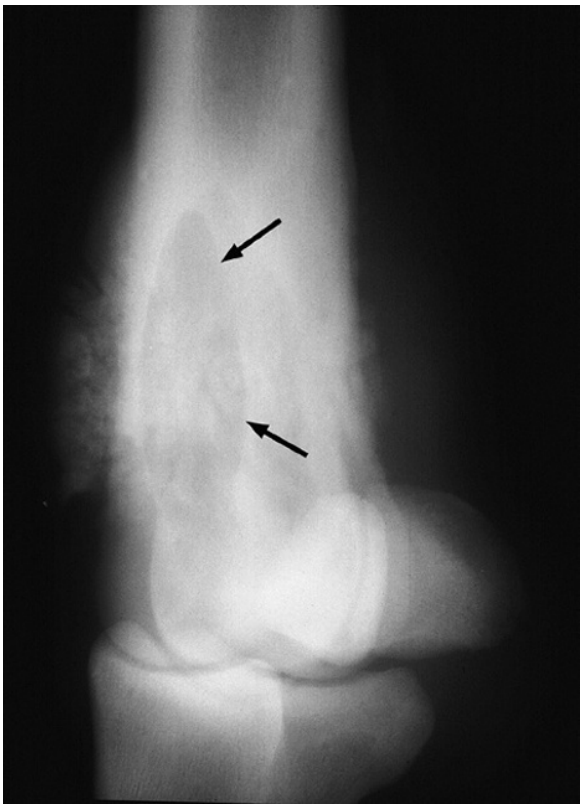

Figure 7.43. Oblique radiograph of the metatarsus in an adult horse with firm swelling of the metatarsus and mild lameness. Radiographs reveal a large lytic lesion within the bone with extensive periosteal new bone growth suggestive of neoplasia (arrows). The lesion was debrided and a biopsy suggested a possible osteosarcoma. However, this horse continued to do well with minimal progression of the lesion. Therefore, the lesion may be a true bone cyst and not a bone tumor.

Figure 7.44. Large, firm swelling of the rostral aspect of the mandible in a young Quarter horse filly that was consistent with an ossifying fibroma (arrow). A rostral mandibulectomy was performed to completely remove the tumor.

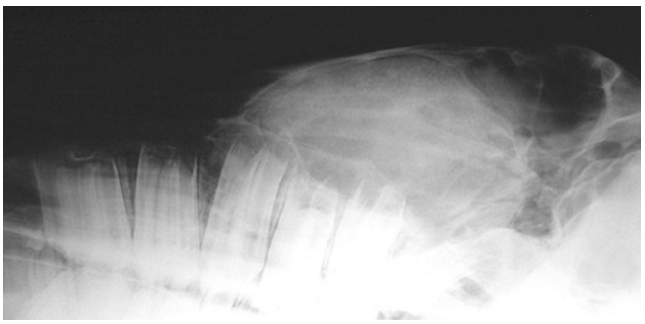

Figure 7.45. A lateral radiograph of the paranasal sinus region of a 3-year-old Quarter horse gelding revealed the presence of a large osseous mass within the maxillary sinus. A biopsy of the mass suggested a diagnosis of multilobular osteochondroma.

Bone Tumors

Primary bone neoplasia is rare in horses. The most common bone tumors that occur in horses include osteoma, ossifying fibroma, multilobular osteoma or osteochondrosarcoma, and osteosarcoma.[36] Although these tumors may develop at any location, the face and head (mandible, skull, and paranasal sinuses) appear to be the most common sites of occurrence. Osteomas are benign tumors that consist of well-differentiated bone that typically occur within the paranasal sinuses or on the skull. Ossifying fibromas are benign fibro-osseous lesions that usually involve the rostral aspect of the mandible, premaxilla, or paranasal sinuses (Figure 7.44).[36] Multilobular osteomas or osteochondrosarcomas are very rare in horses but usually involve the skull or paranasal sinus (Figure 7.45). These tumors are generally benign but locally aggressive and can be removed surgically. Osteosarcomas are malignant tumors, arising from mesenchyme, in which neoplastic cells produce osteoid or bone. In horses, the skull, axial skeleton, ribs, and occasionally the limbs are commonly affected sites. The clinical signs caused by these tumors will depend on the location and specific type of neoplasia. The diagnosis of neoplasia is usually made based on its radiographic appearance and is confirmed by histopathology of biopsy or autopsy specimens. Treatment will depend on the location of the tumor, involvement of the parent bone, and the specific type of osseous tumor present. In general, all tumors except osteosarcomas can potentially be removed successfully with minimal recurrence if complete tumor excision is achieved.[36] Unfortunately complete tumor excision is not always possible.

Bone Contusion/Bruising/Periostitis

Bone contusions from direct or indirect trauma are known to occur in people and contribute to orthopedic pain and lameness. The majority of joint pain in people is thought to originate from bone and is typically seen as bone marrow lesions of the subchondral bone with MRI.[53] With the amount of trauma that horses seem to encounter, bone bruising probably occurs much more often than we currently recognize or are able to diagnose. In fact, many of the retrospective MRI studies of athletic horses are demonstrating bone marrow lesions to be common and in many instances might be the initial pathologic lesion leading to joint or enthesis disease.[53] Diagnosing bone contusions and bruising in

VetBooks.ir

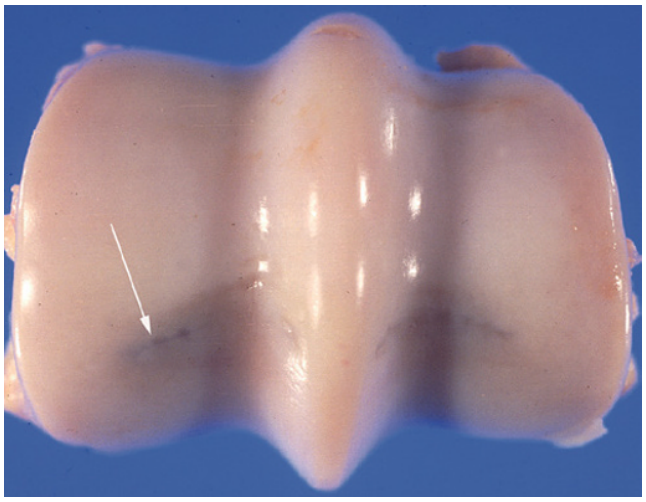

Figure 7.47. The distal aspect of the third metacarpal condyles typically shows subchondral bone bruising in racing Thoroughbred horses (arrow).

horses is very difficult and mostly subjective. This is especially true for bone pain originating in joints. Most bone contusions or bruises are diagnosed based on the history, clinical findings, and lack of radiographic abnormalities. However, MRI is now used routinely to diagnose bruising and edema within bone (Figure 7.46). With some bone contusions of cortical bone, evidence of pain can be elicited with direct pressure over the affected site. In addition, bone pain can sometimes cause more severe lameness than most soft tissue injuries, and pain is often elicited with manipulation of the affected bone or joint. Radiographs are useful only to document the absence of fractures or other abnormalities within the affected bone or joint. Nuclear scintigraphy would be useful to document abnormal bone metabolism of the affected site, but cannot be used to definitively diagnose a bone bruise or contusion. MRI and computed tomography (CT) are used in people to help diagnose bone damage/contusion and are available for use in horses at referral hospitals.[66,73,108] Positron emission tomography (PET) has also been used to identify potential lesions, but more work is needed on this modality.[109,110] Treatment of bone contusions would be similar to any type of acute musculoskeletal trauma and would include reduced activity, cold therapy, hydrotherapy, bandaging, and NSAIDs. Suspected bone contusions/bruising within joints could also be treated with intra-articular medications; however, they are somewhat limited in their effectiveness. Systemic bisphosphonate therapy has been advocated for treating bone bruising and edema; however efficacy has not been proven in horses.[50] The prognosis of horses with bone contusions is usually very good unless damage to the subchondral bone of a joint contributes to joint pathology and secondary OA (Figure 7.47).

SYSTEMIC DISEASES OF BONE

Osteoporosis

In osteoporosis, the bone mineral density (BMD) of the bone matrix is reduced. The bone becomes porous, light, and fragile and is prone to fracture. Osteoporosis in horses is an uncommon or at least an uncommonly recognized clinical problem. The term osteopenia is used if BMD is reduced, but spontaneous fractures do not occur. Clinically, osteopenia is much more commonly recognized in horses than osteoporosis.

Generalized Osteoporosis

The generalized osteoporosis seen in postmenopausal women has no counterpart in the aged horse. However, older mares may be more prone to long bone fractures during recovery from general anesthesia. Whether this may be due to declining estrogen levels associated with reproductive senescence is unknown. Osteoporosis is seen occasionally with undernutrition rather than actual deficiencies of calcium, phosphorus, or vitamin D. However, in most affected horses, osteoporosis is usually associated with a diet low in calcium, high in phosphorus, or low in vitamin D. Osteoporosis is associated with copper deficiency and chronic lead poisoning in lambs, but this has not been seen in foals.[9] A condition first recognized in Thoroughbred foals may be a manifestation of generalized osteoporosis.[26] The condition is characterized by fractures of the proximal sesamoid bones and typically occurs when foals gallop to exhaustion trying to keep up with their dams. Foals seem more prone to the condition if they are confined after birth. During this time of relative inactivity, the bones are not subjected to the stresses required to strengthen them and are a potential weak link in the skeletal system (Figure 7.21). Some underlying metabolic problem or deficiency producing osteoporosis may exist, but at this time it is undefined. Other lameness problems and unexplained fractures in horses may be attributed to generalized osteoporosis, but their pathogenesis and cause are often unexplainable. The combination of age and pregnancy have also been shown to negatively influence bone strength,[37] with increased age and parity leading to significantly decreased bone strength.

VetBooks.ir

Localized Osteopenia (Disuse Osteopenia)

This condition is fairly common, especially in horses following rigid external immobilization of their limbs (casting). Disuse osteopenia may also occur in horses with severe or chronic lameness (Figure 7.48) or neuropathies such as radial nerve paralysis where weight-bearing is reduced. With decreased weight-bearing, there is increased resorption of bone and decreased bone formation. Immobilization of the thoracic limb of a pony in a cast for 6 weeks caused a significant decrease in weight and specific gravity of the third metacarpal bone.[25] Histologically, osteopenia was caused by atrophy of osteoblasts with failure of bone apposition.[25,119] However, external immobilization of the distal limb in horses has also been shown to have only a minor effect on articular cartilage with very little clinical significance.[93] If horses are brought back into work too quickly, distal sesamoidean ligaments can tear from the distal aspect of the proximal sesamoid bones, leading to significant lameness (Figure 7.21). Osteopenia is usually more severe in young animals due to the inherent rapid bone turnover compared with the adult horse. Bone cortices become thinner and more lytic. Although this is thought to rarely contribute to a clinical problem and is easily reversed when the external immobilization device is removed and the animal commences normal weight-bearing, recent evidence suggests that the pathologic changes can be significant.

Localized osteopenia is essentially a radiographic diagnosis characterized by lack of cortical density and a more lucent appearance to the bones compared with normal (Figure 7.49).[119] The sesamoid bones are often the first bone to manifest the problem radiographically. Loss of bone that can be seen radiographically indicates an approximately 30% BMD reduction.

Further experiments have shown that treatment of osteopenia with 25-hydroxycholecalciferol has been beneficial.[25] Fortunately, localized osteopenia following immobilization rarely causes any problems. If the external

Figure 7.48. A lateromedial radiograph showing a comminuted fracture of the femur in a 23-year-old mare. This mare had severe lameness in the stifle of that limb since she was a yearling and fractured it while getting up in her stall. It is likely that the bone was osteoporotic due to chronic, reduced weight-bearing from the lameness.

VetBooks.ir

support is suddenly removed, however, a pathologic fracture may result. To prevent this, the rigidity of the external support should be diminished gradually over time. For example, following cast removal, a cotton bandage with a PVC splint incorporated into the bandage should be used to provide less stability than a cast but more support than a bandage alone.[119] Following removal of the splint, a lighter, less rigid bandage should be used until eventually no external support is applied to the limb. It may take several months before the bone regains normal density and strength following external immobilization. Occasionally, the original BMD is never reached.

Stress protection is another example of localized osteopenia seen in fractured bones that have been repaired with rigid internal fixation devices such as stainless steel bone plates.[119] Initially, rigid internal fixation enhances healing and permits mobility of neighboring joints. Over a period of months, however, the bone under these plates becomes lytic. This produces a weakened bone with the possibility of a fatigue fracture when the plate is removed. Theoretically, plates should be removed as soon as healing has occurred. Plates with a lower modulus of elasticity have been designed to minimize stress protection, especially in people and small animals. In horses, however, osteopenia generally does not occur to the same degree because a much larger animal places a greater force on the healing bone. Therefore, stress protection due to internal fixation is of minimal clinical significance in horses. In general, bone plates and other forms of internal fixation are not removed in horses unless they contribute to infection or cause lameness in performance horses, and when they are removed, they are usually done so in a staged fashion.

Bone Fragility Disorder

Bone fragility disorder has been recently characterized by Anderson et al.[1] These horses typically present with variable degrees of lameness that is difficult to regionalize on physical examination. The key diagnostic finding is that the horses have multiple sites of radioisotope uptake, mostly in the axial and proximal appendicular skeleton, and occasionally radiographic and ultrasonographic signs of bone remodeling at various sites. Rest appeared to help some horses, but most were euthanized for humane reasons in the report.[1] Bisphosphonate therapy, namely, zoledronate, has shown some efficacy in treating signs of disease.[51]

Osteopetrosis

Osteopetrosis is a rare skeletal disease of horses characterized by an imbalance of bone apposition and resorption. It is an inherited disease of people, rabbits, mice, and cattle and may be an inherited disease in horses.[104] The underlying problem is a failure of bone resorption by osteoclasts. There is complete closure of the medullary canal at the mid-diaphysis of the bone because the canal has not been remodeled by osteoclasia during development from its embryologic state. The disease is also characterized by fractures due to a lack of a normal bone structure. Since there is no evidence of bone marrow in such bones, an anemia commonly accompanies this condition. Osteopetrosis has been reported in a Peruvian Paso foal,[104] and it may be an inherited condition in this breed. In the case described by Singer and Whitenack,[104] metaphyseal diameters of long bones were wider than normal, and the cortices were abnormally thick with complete obliteration of the medullary canal. Trabecular bone was soft and could be easily crushed, and the bones were not as strong as normal bones in an animal of this age. Large calluses were formed at fracture sites, suggesting that such fractures had occurred *in utero*. Because of the inherited nature of the disease in other species, owners should be advised against future matings.[104]

Hereditary Multiple Exostosis (Multiple Cartilaginous Exostosis, Osteochondroma)

Hereditary multiple exostosis is an inherited skeletal disorder characterized by numerous abnormal projections from growing bones that result in an abnormal bone contour.[75,102,103] The condition affects most of the long bones as well as the ribs, scapula, and pelvis in horses and is used as a model for the condition in man.[103] The characteristic swellings of hereditary multiple exostosis are usually present at birth, and the lesions are probably initiated during fetal osteogenesis. They are usually bilaterally symmetrical and consist of multiple firm bony enlargements of various shapes and sizes that are firmly attached to bone.[103] Swellings on the limbs do not appear to enlarge as the animal matures, but others such as those located on the ribs and scapulae usually enlarge until maturity is reached (about 4 years of age). Lameness, if present, is usually due to impingement of various tendons and muscle groups by the bony masses. Some horses may be presented for various joint and tendon sheath swellings.[75] Grossly the tumors adopt a variety of shapes, ranging from conical, rounded, pedunculated, multilobulated, or spur-like. Histologically such tumors appear as osteochondromas and do not appear to undergo malignant transformation.[103] They usually have a small cartilage cap covering underlying spongy cancellous bone. There is no known treatment for this condition.

Solitary osteochondromas occur more commonly in horses and usually develop on the caudomedial aspect of the distal radial metaphysis.[56,107] Solitary osteochondromas are not considered to be an inherited condition like hereditary multiple exostosis. Horses with osteochondromas on the caudal aspect of the radius usually present for lameness and swelling of the carpal canal. The masses resemble hereditary multiple exostosis, but the lesions are usually not symmetrical.[60,107] Radiographic examination usually reveals an osteocartilaginous exostosis protruding from the caudal aspect of the radius. Large exostoses may cause lameness by interfering with muscle movement such as the humeral head of the deep digital flexor muscle or pain from carpal canal effusion.[60,107] Carpal sheath effusion is usually due to the exostosis and usually will not resolve unless the bone is removed. Surgical removal of the lesion via tenoscopy of the carpal canal is now commonly performed.[107] Solitary osteochondromas may also develop in joints associated with previous trauma or surgery. Small dislodged pieces of cartilage may become trapped in the synovium,

VetBooks.ir

develop a blood supply, and grow to form osseous masses. These may or may not cause a clinical problem, but will often lead to persistent synovial effusion. The dorsal aspect of the fetlock and the femoropatellar joint appear to be particularly susceptible to osteochondroma formation (Figure 7.50).

Tumoral Calcinosis (Calcinosis Circumscripta)

Tumoral calcinosis is the formation of calcified, granular, amorphous deposits in the subcutaneous tissues that induce a fibrosing granulomatous reaction.[113] The deposits usually occur in the subcutis near joints and tendon sheaths.[22,34] It occurs infrequently in the horse although it may be more common than is actually recognized.[34] The etiology of the condition is unknown. Affected horses are usually presented for unsightly swellings that are becoming progressively larger, and lameness is uncommon. The swellings are firm and painless, and the skin is usually intact and movable over the swellings. The most common location for tumoral calcinosis lesions is the lateral aspect of the stifle, lateral to the fibula, and beneath the aponeurosis of the biceps femoris and lateral crural fascia. Of 18 cases reported in the literature, lesions occurred over the lateral surface of the tibia close to the femorotibial joint in 16 horses.[34] Radiographically, the lesions are characterized by radiopaque calcified deposits. On cut surface of the lesions, there is a honeycomb-like appearance with a calcareous, gritty deposit enclosed in a dense fibrous capsule.

The treatment for calcinosis circumscripta is surgical excision. This should be performed only in cases in which lameness can be directly attributed to the lesion. The lesion may be so firmly attached to the stifle joint capsule that it is impossible to dissect it free without opening the joint. Therefore, surgical excision of these lesions should be performed cautiously.

Osteodystrophia Fibrosa (Nutritional Secondary Hyperparathyroidism)

Osteodystrophia fibrosa or nutritional secondary hyperparathyroidism is a generalized bone disease caused primarily by a dietary calcium deficiency in the face of phosphorus excess.[18] Due to awareness and sensitivity about the condition, it is rarely seen today. It occurs in all equids, although the horse is more susceptible than its relatives.[49] It is most common in horses being fed cereal and cereal by-products such as bran (diets high in phosphorus and low in calcium), hence the name "bran disease." Addition of legume hay, which is high in calcium, to the diet can usually prevent the disease.[18,72] It is also seen in horses grazing plants high in oxalates, which chelate the calcium and interfere with the absorption of calcium. Horses in Queensland, Australia, developed osteodystrophia fibrosa when grazed on tropical grasses.[119] A subclinical form of the disease may also occur but is difficult to diagnose because the clinical manifestations are subtle.

The underlying pathogenesis in osteodystrophia fibrosa is defective mineralization of bone. The diet high in phosphorus leads to increased absorption of phosphorus and elevation of serum phosphate levels. This tends to lower serum calcium and stimulate the parathyroid glands to increase secretion of parathyroid hormone. Parathyroid hormone increases activation of remodeling, leading to resorption of bone. With bone resorption there is a compensatory replacement with fibrous tissue.[30] This causes poorly mineralized bone that is eventually replaced with cellular connective tissue. Horses of both sexes and all ages are susceptible. Lactating mares and foals appear to be at increased risk to develop osteodystrophia fibrosa.

The classic form of osteodystrophia fibrosa is called "bighead" because of the predilection of the jaws and flat bones of the skull to respond to parathyroid hormone.[31] The classic clinical signs of the disease include a

VetBooks.ir

symmetrical enlargement of the mandible and facial bones. There is loss of lamina dura around the teeth due to osteoclastic resorption of alveolar margins, and the teeth may eventually loosen. This can be identified radiographically and is one of the first signs of the disease. Swelling initially begins just above the facial crest and in the mandible producing a reduction in intermandibular space. There may also be enough swelling of the palate, maxillae, and incisor bones to produce dyspnea.

The subclinical form of nutritional secondary hyperparathyroidism may cause a nebulous shifting limb lameness in horses that is difficult to localize with standard perineural anesthesia.[119] The condition may also contribute to unexplained fractures especially in young horses. In such cases a dietary history is important in the diagnosis. Blood calcium and phosphorus levels are usually normal, and the diagnosis is usually based on analysis of the diet and response to treatment with calcium supplementation.

Hypertrophic Osteopathy (Hypertrophic Pulmonary Osteoarthropathy)

Hypertrophic osteopathy is a progressive bilaterally symmetrical proliferation of subperiosteal bone and fibrous connective tissue on the appendicular and axial skeleton and facial bones.[119] It is a relatively rare disease in the horse. The pathogenesis of hypertrophic osteopathy is still unclear at present. Classically the disease is associated with a space-occupying pulmonary lesion such as a neoplasm or chronic suppurative process such as a large abscess, tuberculosis, or a fractured rib with pleural adhesions.[67] The disease rarely occurs in horses with such thoracic lesions, but has been associated with a granular cell myoblastoma.[32] The term hypertrophic osteopathy is preferred because the disease has also been associated with intra-abdominal disorders without pulmonary involvement. Hypertrophic osteopathy has been reported in a mare with a dysgerminoma (a neoplasm of ovarian primordial germ cells) that had abdominal metastases but was free of thoracic lesions.[67]

The two most common mechanisms for the development of the disease are classified as neurogenic and humoral. The more popular neurogenic theory is based on the fact that an apparent stimulation of the vagus nerve produces an alteration of the vasculature and periosteum of bones by way of an unknown efferent pathway. Support for this theory is based on the fact that in dogs and man hypertrophic osteopathy lesions may regress following vagotomy. A humoral mechanism may also exist, since hypertrophic osteopathy has been shown to occur in people when urinary excretion of estrogen is increased. High levels of circulating estrogen have been reported in a mare with hypertrophic osteopathy, although the exact relationship between estrogen levels and hypertrophic osteopathy is purely speculative.[67]

The clinical signs of hypertrophic osteopathy are related to periosteal hyperostoses. There is symmetric enlargement of the long bones of the limb with all bones in the limb affected. There is pain and edema of soft tissues, and the horse may have a stiff gait and be reluctant to move. The joint surfaces are rarely involved; however, there may be decreased motion in affected joints as well as pain on manipulation. There may be signs referable to pulmonary abnormalities such as coughing and nasal discharge.

Radiographically, there is a generalized increase in soft tissue swelling and evidence of periostitis. Irregular new bone growth occurs, especially at the proximal and distal ends of the long bones (Figure 7.51).[119] The differential diagnosis should include fluorosis, but the gross appearance of the bones, absence of dental lesions,

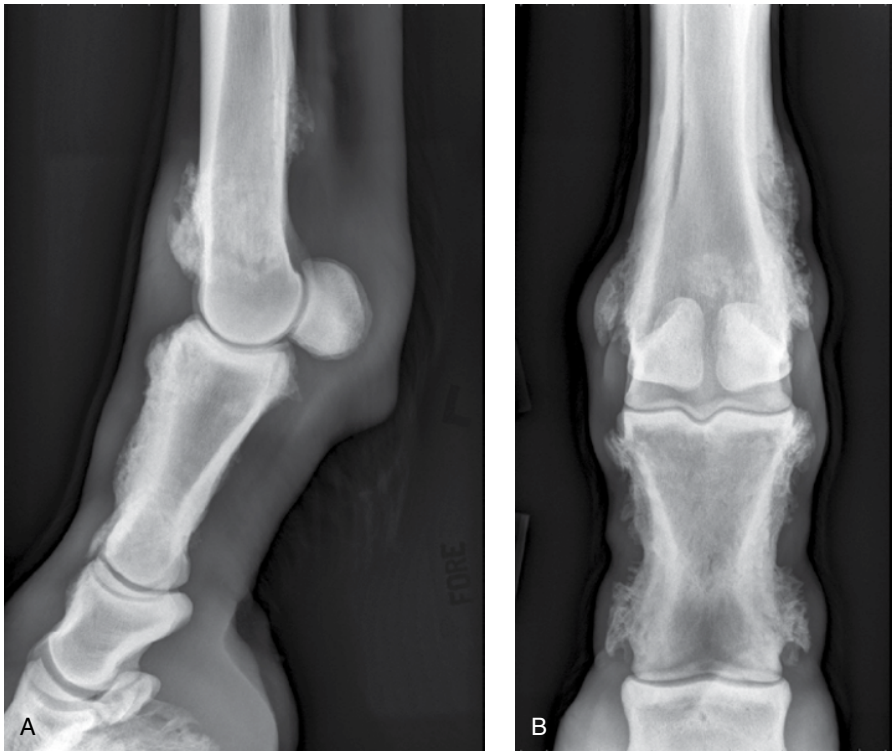

Figure 7.51. Lateral (A) and dorsopalmar (B) radiographs of the left front fetlock of a horse with hypertrophic osteopathy showing irregular new bone growth. A definitive cause was never determined.

VetBooks.ir

and blood and urine fluorine levels can usually eliminate fluorosis as the cause. Lateral radiographs of the chest or abdomen may help locate the causative lesion.

Effects of Medications on Bone

Recent research and development have demonstrated the effects of various medications on bone metabolism and bone healing. The two most investigated medication groups recently have been nonsteroidal anti-inflammatories and bisphosphonates.

Nonsteroidal anti-inflammatory medications (NSAIDs) are commonly used in horses to manage inflammation and the pain from a variety of sources. They are also used commonly to manage pain post-fracture and fracture repair. However, there has been work to show that NSAIDs can have a negative effect on bone healing, especially the "osteo-immunologic" cascade that is responsible for appropriate bone remodeling.[64] By reducing the inflammatory component of bone healing, a key signaling component is compromised, thus delaying bone healing. This has been demonstrated in several experimental models, including one study in the horse. Specifically, mineral apposition rate was reduced in horses administered phenylbutazone.[95] However, severe inflammation can impede bone and soft tissue healing, requiring significant anti-inflammatory therapy to overcome. The threshold at which NSAIDs should be used has not been determined.

Bisphosphonate therapy emerged on the equine market several years ago as a means of treating lytic lesions in the bones of horses.[50] Bisphosphonates act to inhibit osteoclast production and function. Tiludronate was initially marketed for equine use and shown in small clinical studies to be effective in managing pain in horses with caudal heel pain, bone spavin, and back pain.[17,20,33,74] The Freedom of Information report for approval of tiludronate in the United States shows that it had a positive effect on improving lameness by one grade in horses diagnosed with caudal heel pain.[120,121] Clodronate later emerged on the market, and it too showed ability to improve lameness in horses with caudal heel pain. However, the exact mechanism by which bisphosphonates work in horses is unknown. It is likely that they possess significant anti-inflammatory properties by which the action occurs, and the anti-osteoclastic effect has minimal clinical impact. Regardless of the therapeutic effects, there is concern about potential negative effects on young horses and the normal bone remodeling cascade that is necessary for physical adaptation to training. The AAEP has produced a white paper concerning the suggested use of bisphosphonates in horses, and the FDA has regulated that they should only be used in horses older than 4 years of age.

TENDON AND LIGAMENT INJURIES AND DISEASE

Laurie R. Goodrich

VetBooks.ir

ANATOMY

Tendons and ligaments are complex structures that exist in a hierarchical structure of subunits (Figure 7.52). Grossly, tendons are made up of many fascicles, which, during further macroscopic and microscopic examination, have decreasingly sized subunits, then fibers, and finally fibrils.

The anatomic structures of note are the paratenon, epitenon, endotenon, tendon fascicles, and tendon fiber/fibrils. Paratenon refers to the loose connective tissue and vessels that surround tendons. Epitenon is outside of tendon fascicles and is continuous with the endotenon. Endotenon contains vascular and neural structures and separate cell populations. Furthermore, the endotenon may be a source for pluripotential cells. Tendon fascicles are the bundles of fibrocytes and tenocytes that are surrounded by endotenon. Tendon fibers/fibrils are made of long bundles of collagen filaments that are predominately type I collagen and have elastin and glycosaminoglycan in the extracellular matrix. Larger fibrils are stronger than smaller fibrils.[32]

Collagen fibrils have many triple helical collagen molecules that are arranged such that a characteristic banding pattern is seen on electron microscopy. Collagen molecules are secreted extracellularly through the pores of the tenocytes. Cross-linking of these molecules results in fibril formation, and these fibrils fuse as horses age, leading to larger collagen fibrils.[17,21,32]

Under a light microscope, collagen fibers have a characteristic wavy pattern that is referred to as crimp (Figure 7.53). Crimp imparts elasticity to the tendon. A decrease in crimp occurs with aging along with a greater reduction in the central fibers.[27,32,43] When the tendon is stretched, the central fibers straighten primarily, and therefore a greater load is placed on these fibers relative to peripheral fibers. This may explain the more common occurrence of tendon lesions observed centrally (core lesions). Peripheral lesions are less clearly explained.

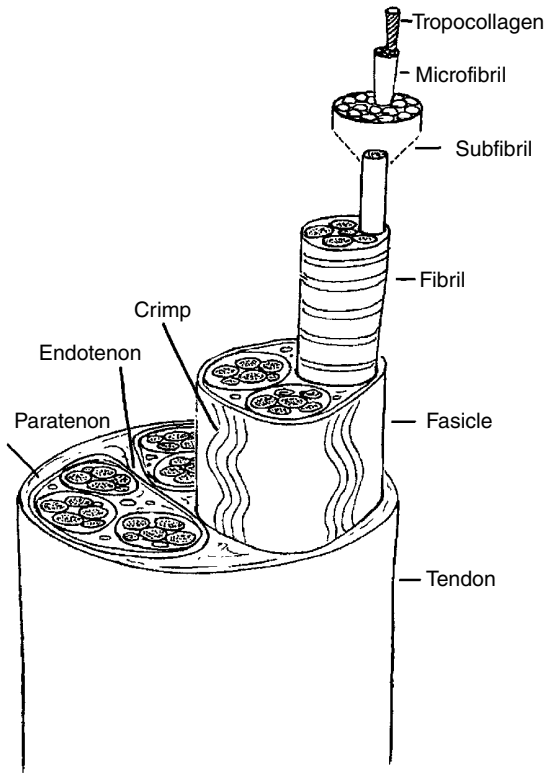

Figure 7.52. A schematic representation of the tendon hierarchy. The level of tendon fascicles can be viewed grossly, fibers may be seen microscopically, and individual collagen fibrils (tropocollagen) may be viewed via electron microscopy. *Source*: Modified from Davis and Smith.[12] Reproduced with permission of Elsevier.

Cellular Components

Tenocytes are the primary cell types found within equine tendon; they are responsible for the formation and maintenance of tendon tissue.[32] Three types are described (Figure 7.54). Type I cells have thin, spindle-shaped nuclei, type II cells have rounded or oblong nuclei, and type III cells appear as cartilage-like cells with round nuclei and visible nucleoli.[32] Proportions vary with age of the horse, site, and whether a ligament or tendon. Type I cells are more frequently found in older horses, type II cells can be found in higher numbers in young horses and in ligaments, and type III cells are found in areas sustaining higher compressive loads.[32] It is logical to assume that type II and III cells are metabolically active and maintain tendon extracellular matrix; however, type I cells most likely do this to some extent as well.

Cellular numbers vary depending on age and location within the tendon. As maturity is reached, the numbers remain constant; however, areas of tendon become acellular and have changes consistent with chondroid metaplasia such as the center of the superficial digital flexor tendon (SDFT) or the deep digital flexor tendon (DDFT) in the metacarpophalangeal region.[32] These areas are often surrounded by type II cells. Other cells found in tendon include synovial-like cells of the epitenon within the tendon sheaths and fibroblasts of the paratenon, epitenon, and endotenon. These probably have an integral role in tendon maintenance due to certain growth factors such as transforming growth factor-β (TGF-β) found in these areas.[8,18]

Tenocyte regulation has not been fully elucidated, but most likely it relies on mechanical and cytokine stimulation. Tenocytes have been shown to respond

quickly to mechanical stimuli in cell culture.[2] However, tenocytes in culture also require growth factors to respond to mechanical load.[17] Recent research has discovered cellular communication through cytoplasmic extensions of tenocytes, which most likely result in a coordinated upregulation in response to mechanical stimuli.[25,32]

The growth factors most noted to have anabolic effects on tendons include TGF-β and insulin-like growth factor-1 (IGF-1).[7,9] The concentration of these growth factors seems to be highest early in age and decreases with maturity. Furthermore, it is believed they are deficient in healing tendon. Further research will determine the important growth factors that are essential to tendon health and healing.

Molecular Composition

Tendon and ligaments are highly hydrated and have a water content of approximately 65% (wet weight), which makes up the majority of the extracellular matrix. The remaining content consists of collagen (30% wet weight) and noncollagenous glycoproteins (5% wet weight). Type I collagen is the predominant collagen in tendon (greater than 95%), and the remaining is type III, which is present in endotenon and increases with age. Type II collagen, the main collagen found in cartilage, can only be found at tendon insertions and areas where tendon changes direction and takes on a fibrocartilage-like character.[6] Collagen is synthesized outside of the cell as procollagen molecules. As the α-helical chains are produced and cleaved by procollagenases, they are cross-linked to form a collagen fibril.[12]

Other noncollagenous glycoproteins include cartilage oligomeric matrix protein (COMP), proteoglycans and elastin, fibronectin, and thrombospondin.[32,46] COMP has recently been studied intensely due to its perceived importance in organization of the collagen fibril framework during tendon formation and growth.[12] Recent data have shown that COMP accelerated collagen fibril formation *in vitro*.[37] As collagen molecules form a fibril, COMP does not remain bound and is displaced from the fibril. As such, levels of COMP increase during

VetBooks.ir

growth, peak about 2 years of age in flexor tendons at the metacarpal level, and decrease once growth ceases and the animals age.[35] A correlation exists between tendon ultimate tensile strength and the level of COMP at maturity.[34]

Other noncollagenous proteins such as the small proteoglycans (decorin, fibromodulin, lumican) can be found in the regions of tension; conversely, large proteoglycans (aggrecan and versican) are found in regions of compression where the tendon changes direction over a bony prominence (i.e. the DDFT at the level of the metacarpophalangeal joint).[12,13]

Collagen fibrils are bundled together into fibers that are separated by cellular cytoplasmic extensions of tenocytes (Figure 7.55).[25] Little is known about these cells; they may have different stages of activation. Various types of tenocytes have been described above; however, it is unknown how these cells function during growth, maturity, and aging.

Associated Structures

Blood Supply

Nutrients are supplied to the tendons and ligaments through diffusion and perfusion. Diffusion primarily occurs where a sheath encloses the structure with synovial fluid, playing an important role.[32] When blood is delivered via perfusion, it originates from three separate sources, including the musculotendinous attachments proximally, the osseous insertion distally, and the intratendinous and extratendinous vessels.[24] The extratendinous blood supply comes from vessels within the paratenon (extrasynovially) or mesotenon (intrasynovially) attachments. An example of intrasynovial mesotenon is when vessels lie at the vinculum between the fetlock annular ligament and the SDFT.

Connective Tissue

Connective tissues associated with tendons include sheaths and retinaculi. The tendon sheath is comparable to the joint capsule with an outer fibrous sheath and an inner synovial membrane.[24] Sheaths of tendons are folded around the tendinous structures, most commonly in areas in which the tendon passes over joint structures and bathes the tendon in synovial fluid. Annular ligaments, or retinacula, are tenacious fibrous bands that maintain tendons in the correct position (Figure 7.56).

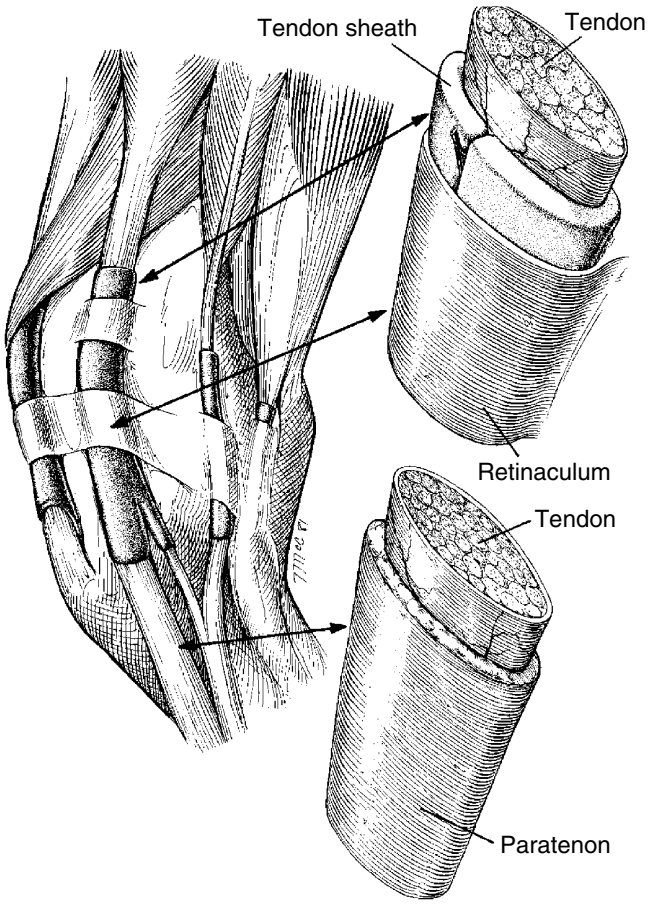

Figure 7.56. Diagram of tendons and their relationship to the retinaculum, endotenon, and tendon sheaths.

Bursae are structures very similar to tendon sheaths except that they are located between tendinous structures and bone. Similar to tendinous bursae, they have a synovial membrane and rely on synovial fluid to provide nearly frictionless movement between the tendon and the bone. Bursae that are commonly dealt with in lameness primarily include the navicular bursa, calcaneal bursa, bicipital bursa, and the olecranon bursa.

FUNCTIONS OF TENDONS AND LIGAMENTS

The elaborate anatomical architecture of tendons and ligaments is designed to allow tendons to passively transfer force generated by muscle to bony attachments on the opposite side of a joint, or joints, to provide movement.[32] Conversely, ligaments resist distraction of two bony attachments such as the collateral ligaments and suspensory ligaments.[32] Because the tendon and ligaments are on the palmar aspect of the equine distal limb, they receive significant weight-bearing loads and

VetBooks.ir

therefore provide support to the metacarpophalangeal and metatarsophalangeal joints during weight-bearing and exercise and act as force transmitters during rapid and unexpected movement.[24]

Tendons should also be considered as elastic structures that store energy for efficient locomotion.[1,32] Structures such as the SDFT provide shock absorption through the elasticity of the tendon combined with the attachment of the musculotendinous portion to the caudal aspect of the radius by the accessory or superior check ligament. The undulating gait of a horse at speed has been compared to the motion of a pogo stick with the tendons providing the elasticity of the bounce.[45] The unique structural arrangement within tendons and ligaments allows the horse to exercise at high speeds while minimizing energy expenditure.[32]

BIOMECHANICAL PROPERTIES

Biomechanical characteristics of tendons are usually described by stress–strain curves. These curves reveal the force per unit area (stress) plotted against the percentage of elongation (strain) and can be used to calculate elastic modulus (Figure 7.57). The four areas that are important to a stress–strain curve of a tendon are:

1. The toe region, where stretch is nonlinear. This represents the area where the undulating pattern of collagen fibrils are eliminated; this is also the elastic phase.
2. Linear deformation, or midsection, where the elastic stiffness of the tendon is represented.
3. Yield region, in which irreversible lengthening of the tendon occurs and the plastic phase begins.
4. Rupture, in which the collagen cross-links or fibrils sequentially rupture.

Initially, the tendon is highly compliant, but upon further extension, stiffness increases and viscoelastic (and permanent) changes occur.[24,42] It has been suggested that the second phase of the stress–strain curve for a tendon causes residual damage.[41] When the strain level is maintained between 3% and 5%, the normal linear stress–strain relationship is maintained; this is the typical strain that a tendon undergoes at a walk and trot. However, as strains reach 5% and 6%, the tendon is more viscoelastic, which results in permanent changes.[31] When the tendon reaches 10%–12% strain (ultimate tensile strain), permanent catastrophic changes such as rupture result. That said, maximum strains in Thoroughbreds at a gallop can reach 16%.[19,24] These are much greater than the strains most other species sustain at higher speeds and quite possibly explain why racing Thoroughbreds sustain a much greater incidence of disease affecting the SDFT.

The SDFT sustains loads of up to 1 metric ton at maximum weight-bearing.[32] Considering that the maximal cross section is approximately 1 cm^2 in cross-sectional area, it is little surprise that mid-metacarpal tendon injury is so prevalent. Variability in ultimate tensile force exists within any population of horses, however, with up to a twofold difference reported between weak and strong tendons.[46]

The modulus of elasticity/stiffness is represented by the force required to extend the tendon by a unit length. The stronger the tendon, the stiffer it is.[32] Hysteresis refers to the phase between loading and unloading a tendon and importantly results in loss of energy. It is estimated that approximately 5%[31] hysteresis occurs in equine tendon, increasing the temperature within the tendon core when repeated loads are applied to the tendon during exercise and possibly causing flexor tendinitis (Figure 7.58).[44]

TYPES OF TENDON AND LIGAMENT INJURIES

Three types of injury may occur in tendons and ligaments: excessive strain, physical tearing, and percutaneous injury. Overstrain may result from overwhelming the resistive strength in an acute manner, and it is believed to be the most common reason for ligament and tendon injuries in the horse.[32] Strain-induced injuries are believed to occur after a phase of molecular degeneration or inflammation that is not clinically

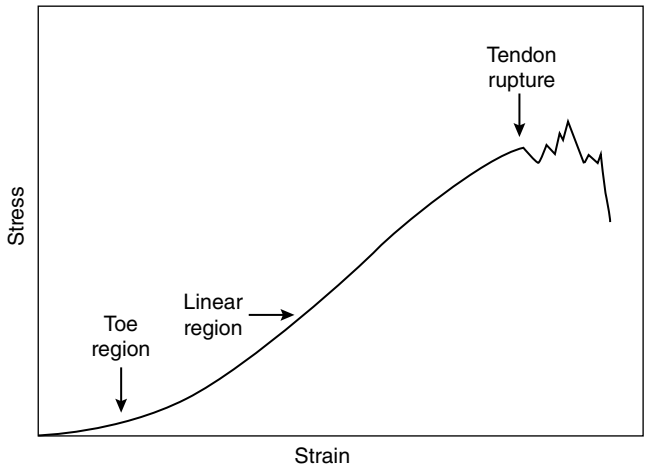

Figure 7.57. The stress strain curve for tendons. *Source*: From Goodship et al.[19] Reproduced with permission of Elsevier.

VetBooks.ir

evident nor produces any reparative responses, but instead progressively weakens the structure.[32] Detection of asymptomatic lesions in postmortem studies of normal horses is consistent with this observation.[40] Furthermore, many strain-induced tendinopathies are bilateral.[14] Large studies analyzing epidemiologic data in both horses and humans have shown strong correlations between age and injury rate.[22] Experimental studies and postmortem analyses of normal tendons have indicated that increasing age and exercise may induce tendon matrix degeneration instead of adaptation in the adult horse.[12,33]

Tendinopathies often begin with degeneration. Minor changes in the structural integrity predispose an already high-risk structure to injury. When the structural integrity is overwhelmed, irreversible damage ensues.[12] Palmar structures, especially at the heel, sustain load increases during heel strike, quickly placing the SDFT and suspensory ligament at risk.[19] Conversely, load of the DDFT rises during stance.

Physical disruption occurs within the tendon matrix when structural strength is overcome. Various structural breakdowns may occur, including fibrillar stretching with breakage of cross-links, fibrillar rupture, or, in severe cases, separation of tendon tissue.[12] Once this occurs, the damage signals repair processes that are common throughout the body such as inflammation followed by repair mechanisms (see phases of healing).

The risk of strain-induced injury is increased by factors such as the horse's speed, track surface (the harder the track, the higher the risk of injury), the horse's weight, fatigue level, and shoeing. Increased heel elevation has been demonstrated to be protective for the DDFT, but it increases the extension of the MCP joint.[3] Although low heels have been viewed as protective of SDFT tendinitis, epidemiologic studies have correlated an increased risk of tendon and ligament injuries with a low heel and long toe conformation.[12]

Tearing of the tendon also occurs, although with much less frequency than tendon degeneration. The most common site is the DDFT of the forelimb and occasionally the manica flexoria of the hindlimb. The mechanism of injury is not clear; however, it has been hypothesized that hyperextension of the fetlock canal combined with compression of the DDFT as it passes over the palmar aspect of the joint may predispose the structure to injury.[12] The hindlimb manica tears may be a result of ongoing tenosynovitis that frequently occurs in the tendon sheath of the hindlimb combined with hyperextension in that region.

The third common mechanism for tendon and ligament injury is percutaneous trauma. The distal limbs have minimal soft tissue coverage and commonly sustain contusion. Injuries resulting from wire, kicks, blunt trauma, and overreaching contribute to most of the percutaneous injuries seen. The most serious include those to the palmar/plantar region of the limb and tendon lacerations that are from wire. Common locations of tendon lacerations are the mid-cannon area of the hindlimb and the pastern region (including the tendon sheath) of both the front limb and hindlimb. These injuries often result in moderate to severe adhesion formation and a poor return to athleticism.

EFFECT OF AGING AND EXERCISE ON TENDON INJURY

Recently, a number of controlled studies in young and adult horses have elucidated the effect of exercise on developing and mature tendons.[5,13,23] Subjects used in these studies had no evidence of previous tendinitis nor any evidence of tendinitis induced by the exercise protocols.

Histological analysis revealed that local differences occurred in collagen fiber diameter of older but not younger exercised horses.[29] In adult tendon, a reduction in crimp occurred with aging and exercise. Exercise also induced a greater number of smaller fibrils within the central region of the SDFT. This change did not correlate with new collagen formation, indicating that an adaptive response occurred rather than an elevation in collagen.

Molecular composition changes also occurred with exercise. A reduction in GAG content and loss of COMP occurred in the center of the tendon with long-term exercise.[4] This is in contrast to an increase in GAG and type III collagen found in the SDFT of exercising horses whose tendons were collected postmortem. Because damage to these tendons was thought to result from subclinical tendon degeneration, these molecular changes most likely reflect a response to injury (or a reparative response) rather than a degenerative change associated with age and/or exercise.

Similar to cartilage, a lack of load to tendon results in a deficit of COMP levels within the tendon. However, once adequate COMP has accumulated within tendons, loading does not appear to affect the COMP levels.[32] Clinically, this implies that a deficit of exercise in the developing tendon may likely result in a tendon prone to injury due to a poorer quality of matrix since COMP levels are directly correlated to tendon strength. In contrast, too much exercise may also result in tendon injury if the strain levels of the tendon are exceeded.[5]

Exercise studies suggest that as tendon ages, degenerative changes associated with exercise accelerate. Cellular activity decreases and most likely collagen turnover slows. Growth factors such as TGF-β also decrease, which may lead to a reduced ability of the tendon to undergo a reparative response. Furthermore, less adaptive changes may occur following maturity, as evidenced by epidemiological data in horses and humans that draw a strong correlation between age and exercise and the incidence of tendon injury.[33] A recent study proved that as tendons age, there is an increase in stiffness in the interfascicular matrix that may result in tendon fascicles being loaded at an earlier point in the stress–strain curve, which leads to increased risk of damage.[40] Additionally, there is significantly less sliding at the fascicular interface in aged tendons.[40] Conversely, young growing tendon appears to be much more adaptive and responsive to loading and exercise, especially during the early stages of growth.

Among the unknown factors are the level and amount of work necessary to initiate the response. The natural exercise intensity of foals at play may be ideal to allow strain rates that boost tendon matrix production. Figure 7.59 is a hypothesized schematic representation of adaptive responses to injury in mature and immature

VetBooks.ir

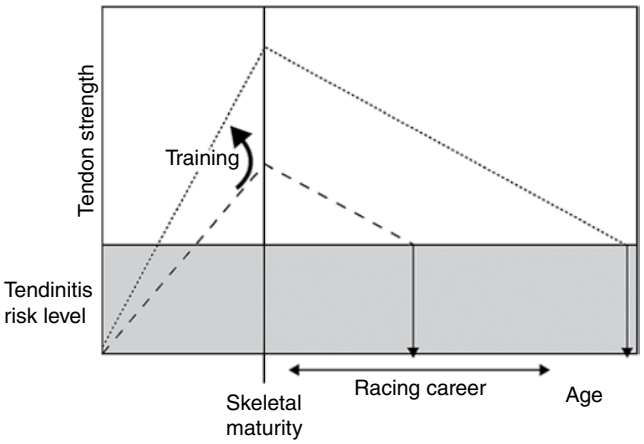

Figure 7.60. A diagram of an approach to tendinitis prevention. The dotted line represents a horse with strong tendons, in contrast to the dashed line, which represents a horse that has poor-quality tendons at skeletal maturity (approximately 2 years old). The horse with poor-quality tendons sustains tendinitis during its racing career due to cumulative fatigue damage to the tendon, whereas the horse with strong tendons, although sustaining the same degeneration, begins at a stronger point and does not suffer from tendinitis. Introduction of exercise throughout development improves tendon quality (arrow), potentially decreasing the incidence of tendinitis. *Source*: From Smith.[32] Reproduced with permission of Elsevier.

tendon. Figure 7.60 illustrates a strategy for preventing tendinitis in the horse, focusing on tendinitis risk before and after skeletal maturity.

MECHANISMS OF TENDON DEGENERATION

Mechanisms of tendon degeneration may have several etiologies including mechanical, physical, vascular, and inflammatory. Mechanical influences such as overextension or direct low-grade repetitive forces cause fatigue and microdamage, leading to degeneration. This also predisposes the tendon to clinical tendinitis when an acute supramaximal load is applied.

Hyperthermia during exercise is a physical influence that may predispose tendon to injury. Studies have determined that temperatures up to 45 °C occur secondary to galloping.[44] These temperatures are high enough to damage most other tissue types; however, *in vitro* experiments have revealed that tenocytes may resist these increases.[28] Nevertheless, the hyperemia that occurs in tendon at high speeds may damage the tenocytes or even the extracellular matrix.

Vascular disturbances are also hypothesized to contribute to tendon damage. When tendon is maximally loaded, blood flow is limited or abolished due to the compressive forces generated.[32] This may lead to a relative hypoxic state of the tendon, predisposing the tissue to degeneration. Although certain areas of tendon have poor perfusion, there is histologic evidence of an adaptive state to ischemia because fewer cells exist in these areas (i.e. the dorsal surface of the DDFT in the area of the fetlock) and matrix components in ischemic areas have compression-resistant components. In addition, these areas may receive nutrition from synovial fluid components.

Despite a reduction in blood flow to certain areas of tendon such as the DDFT in the area of the fetlock, these regions seem to be resistant to degeneration except in the most severe cases of tendinitis. Furthermore, studies have shown that mechanically reducing oxidative metabolism does not lead to abnormal cell proliferation.[4] Therefore, tenocytes, and tendons and ligaments in general, may be resistant to hypoxia compared with other tissues in the body. Although resistance may exist, however, generation of toxic free radicals predisposes the tendon to degeneration. This mechanism of injury may occur as a result of reperfusion injury when perfusion is restored.

Finally, mechanical, vascular, and hyperthermic environments may all lead to inflammation and release of proteolytic enzymes such as collagenase or aggrecanase that promote tendon degeneration. While inflammation and where it fits into tendon degeneration is yet to be defined in tendinopathy, most of the literature suggests that fibrosis of tendons results from persistent inflammation and lack of tendon healing.[10] Elevations in proteolytic enzymes result in a slowed matrix synthesis and an elevation in degradation, whereby overall degradation is high.[11,15,30]

In summary, tendon degeneration results from many factors that contribute to matrix and cellular abnormalities. Ultimately, the resident cell population cannot repair microdamage that is most likely due to deficient or absent growth factor stimuli (such as TGF-β) and cellular senescence within the tendon.[17] As loading continues and strain increases, failure of the fibrils occurs and results in tendon damage.

RESPONSE OF TENDONS AND LIGAMENTS TO INJURY: PHASES OF HEALING

When tendons and ligaments are damaged, the process of repair follows three stages of healing: the acute inflammatory phase, the subacute reparative phase, and

VetBooks.ir

the chronic remodeling phase. A subclinical phase of degeneration also exists; however, this phase is difficult to detect by clinical or ultrasonographic exam due to the minimal inflammatory reaction.

The initial inflammatory phase begins with an acute and substantial inflammatory response. The degree of inflammation depends on the severity of lesion and anti-inflammatory drugs that may be administered. This phase usually lasts 1–2 weeks and is characterized by intratendinous hemorrhage and edema, an increase in blood supply, leukocytes (initially neutrophils and then macrophages and monocytes), and proteolytic enzymes if unabated. Proteolytic enzyme release removes necrotic collagen; however, if the enzymes are not reduced with NSAID administration, their presence will result in expansion of the lesion within the inflammatory stage.

The subacute reparative phase peaks approximately 3 weeks following the initial injury.[32] This phase overlaps with the inflammatory phase and is marked by angiogenesis and the infiltration of fibroblasts in the damaged tissue. Fibroblasts originate from tendon, endotenon, and paratenon and are also delivered from the vascular origin.[7] Scar tissue is formed from the fibroblasts, which are characterized by randomly arranged collagen that is initially type III. Similar to cartilage repair, the resulting scar tissue is weaker than the original tendon tissue, and therefore predisposed to reinjury at the original site of injury. When reinjury occurs, the inflammatory and reparative phases of healing are perpetuated, furthering the damage within the tendon.[32]

The poor healing response of tendon in areas of poor blood supply and paratenon may be explained by a lack of migration of fibroblasts. Adhesions are formed following tendon injury, and although detrimental, they allow healing factors to contribute to injured tissue. Therefore, although adhesions restrict movement of tendon, they allow tendon to form reparative tissue.[32]

The chronic remodeling phase consists of a slow conversion of type III collagen to type I collagen. This process occurs over several months, and the original tendon strength is never restored. Loading (exercise) that ensues in a controlled manner enhances conversion of type III to type I collagen. It improves the alignment of the collagen fibrils in the direction of force and results in better mechanical tendon strength.

Controlled exercise programs are integral to every successful tendon rehabilitation program. It is important to use ultrasound therapy and modify the exercise program based upon the quality of repair. Table 7.1 illustrates a standard rehabilitation program with ultrasound reexamination at specified times.

Reinjury is common following repair of tendons and ligaments; it has been reported to occur in 8%–43% of racehorses.[14] Furthermore, the contralateral tendon or ligament also may become injured.[14] Although the strength of the remodeled tendon is improved 15–18 months following injury, the resulting elasticity is severely weakened, leading to elevated strains in the undamaged tendon. It is this tissue that often becomes damaged when reinjury occurs. Furthermore, if the SDFT is damaged and lengthened through the damage, the suspensory ligament may sustain microdamage and eventual injury due to increased strains.[22]

Table 7.1. A standard exercise program recommended following tendon injury.

Exercise level	Week	Duration and nature of exercise
0	0–2	Box rest
1	3	10-min walking daily
1	4	15-min walking daily
1	5	20-min walking daily
1	6	25-min walking daily
1	7	30-min walking daily
1	8	35-min walking daily
1	9	40-min walking daily
1	10–12	45-min walking daily
Week 12: Repeat ultrasound examination		
2	13–16	40-min walking and 5-min trotting daily
2	17–20	35-min walking and 10-min trotting daily
2	21–24	30-min walking and 15-min trotting daily
Week 24: Repeat ultrasound examination		
3	25–28	25-min walking and 20-min trotting daily
3	29–32	20-min walking and 25-min trotting daily
Week 32: Repeat ultrasound examination		
4	33–40	45-min exercise daily, gradually increasing in amount
4	41–48	45-min exercise daily with fast work 3 times a week
Week 48: Repeat ultrasound examination		
5	48+	Return to full competition/race training

This protocol can be modified based upon ultrasound recheck examinations.
Source: Davis and Smith.[12] Reproduced with permission of Elsevier.

The basic goals of treatment programs are to initially minimize the acute inflammatory phase, thereby decreasing the ongoing damage of tendinous inflammation and edema. Next, the goals are to implement therapies that improve collagen type I and extracellular matrix production, thereby strengthening the tendon so that the structure can withstand the mechanical forces that it encountered before the initial injury. Finally, the adhesions that may form in the healing phases significantly reduce athletic function due to pain and lameness. Therefore, minimizing inflammation, enhancing regeneration, and controlling exercise optimize the chances of successful healing of tendons. For more detail on intralesional therapies, see Chapter 8.

VetBooks.ir

MONITORING TENDON INJURY

Ultrasound examination remains the gold standard for monitoring tendinopathies. Clinical examination, while important, does not detect subtle changes and provides a poor objective assessment. Tendons and ligaments should be evaluated initially at the time of injury and then approximately 1 week following the injury due the frequent occurrence of expansion of the lesion in the first week. The prognosis for return to athleticism is determined by the appearance in the initial week.

The ultrasound exam is performed after clipping the hair and washing the limb to obtain the highest quality image. Transverse and linear images should be obtained and images should be recorded in a methodical fashion so that the images are accurately recorded. For example, during the examination, the limbs are divided into seven subunits, or, alternatively, the images are recorded as distance from the accessory carpal bones. Although one limb is almost always affected more severely than the others, ultrasound examinations should be done bilaterally due to the common occurrence of bilateral disease, especially in strain-induced tendon injury.

Ultrasound changes frequently associated with acute tendinopathy include enlargement, hypoechogenicity, alterations in tendon striated pattern viewed in the longitudinal images, and alterations in shape and margins (Figure 7.61).[12] Chronic tendinopathies are associated with enlargements or changes in echogenicity and irregularities in striations observed on the longitudinal view.

VetBooks.ir

A more recent diagnostic tool called sonoelastography is currently being investigated for diagnostic use for tendonopathy.[38,39] This technology can assess the inner stiffness of tissues and may be able to distinguish between different phases (acute, subacute, and chronic) of healing with much more accuracy than traditional ultrasound. If further investigation confirms initial promising data, this monitoring technique will be a mainstay in monitoring tendon response to rehabilitation and prognostic outcomes.

BIOMARKERS FOR TENDON DISEASE

The field of biomarkers is of keen interest to many clinicians and researchers. Accurate detection of subclinical disease contributes to improved prevention of a common career-ending disease. Furthermore, early detection of disease enables more tailored rehabilitation programs and altered training regimens. Ultrasound remains the gold standard of detection,[16] permitting a more accurate reflection of cellular disease and sensitivity to subtle changes in the tissue state. Biomarkers that detect the stage of disease may also predict optimal treatment and rehabilitation protocols and evaluate their efficacy.

Markers that have been studied intensively include collagen synthesis (carboxy-terminal propeptide of type I collagen or PICP) and degradation (cross-linked carboxy-terminal telopeptide of type I collagen or ICTP) after tendon injury.[12,20] Significant elevations in PICP concentrations have been associated with tendinitis, whereas ICTP has been unchanged in control groups. These changes reflect the ability of serum concentrations of PICP to reveal disease of tendons and indicate that these markers are not necessary bone specific.

COMP has also been intensively studied in tendon disease.[34] In one study, synovial fluid levels within tendon sheaths were significantly higher when tendons were damaged or sheaths were septic. However, serum levels were unaffected due to naturally high levels of COMP in blood. Although COMP appears to be a good marker in laboratory analysis of disease, it may not be an accurate marker for specific tendon disease.

COMMON CLINICAL CONDITIONS OF TENDONS AND LIGAMENTS

The most common tendon affected in tendinopathies is the SDFT. Although the lesion may be focal or generalized, it is usually centrally located in the tendon, just below the mid-metacarpal region of the limb. It can be focal or it may extend throughout the length of the tendon, giving rise to a palmar swelling of the metacarpal region (bowed tendon) (Figures 7.62 and 4.164). The section of the SDFT enclosed within the tendon sheath is affected much less often.

Desmitis of the accessory ligament of the DDFT can occur in association with superficial flexor tendinitis. Ponies have been observed to have a higher incidence of desmitis of the accessory ligament while rarely experiencing superficial flexor tendinitis.[12] Lameness is usually much less severe than with superficial flexor tendinitis,

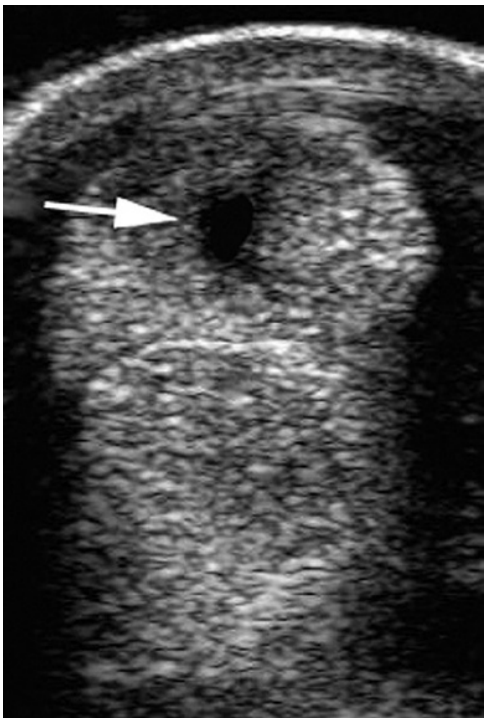

Figure 7.62. Ultrasound image of a core lesion in an SDFT. The arrow is pointing to the core lesion within the SDFT. *Source*: Courtesy of Dr. Natasha Werpy.

and swelling is often restricted to the proximal half of the metacarpus, immediately dorsal to the SDFT.

The suspensory ligament may sustain a desmitis along any section. Proximal suspensory desmitis (in both the front limb and hindlimb) is often restricted to that region, whereas midbody or branch lesions may occur concurrently or extend into each area. Branch lesions also may be found within the MCP joint and result in synovial effusion and lameness requiring arthroscopic debridement.[26] Synovial fluid may decrease the healing of these lesions as well.[12] With severe suspensory desmitis, the limb may have a characteristic dropped fetlock either standing or at the walk due to decreased support of the fetlock.

The DDFT is more frequently associated with tendinitis within the digital tendon sheath, especially of the hindlimb (Figure 7.63).[36,42,47] These lesions may be a result of single excessive load cycles.[12] Two manifestations are typically observed with one lesion found within the substance of the tendon and the other found more in the periphery (medial and lateral borders) of the tendon, usually in the region of the MCP/MTP joint.[47] Invariably, these lesions result in synovial effusion of the digital sheath, with peripheral lesions being more difficult to detect with ultrasound.

Other tendon and ligaments may sustain strain-induced injury, although the frequency of strain to the palmar soft tissue structures of the metacarpus is much more common. Ligament injuries are much more common when the joint they support (and span) is inappropriately overloaded. When this occurs, desmitis and more seriously subluxation or luxation can result (Figure 7.64). Finally, when significant tendon lacerations occur as the

result of trauma, characteristic stances of the limb can often help the clinician determine which structure(s) has(have) been affected (Figures 12.15 and 12.16). For more information on tendon lacerations, refer to Chapter 12.

MUSCLE INJURIES AND DISEASE

Stephanie J. Valberg

VetBooks.ir

CLASSIFICATION OF MUSCLE DISORDERS

A muscle disorder is usually suspected because of altered muscle tone, weakness and/or exercise intolerance, muscle atrophy, muscle pain or swelling, or a gait abnormality not attributed to skeletal/tendon or ligamentous structures. Horses with trauma or atrophy of individual muscle groups may show an asymmetric lameness. Those with generalized muscle soreness or myopathies affecting energy metabolism may show evidence of a mildly asymmetric gait, shifting lameness, poor performance under saddle, progressive stiffness, or inability to engage the hindquarters. Myopathies and skeletal/ligamentous causes of lameness often occur concurrently.

DIAGNOSIS OF SPECIFIC MUSCLE DISORDERS

Many times a complete examination of the musculoskeletal and neurologic systems is required to diagnose a myopathy. Myopathies can change the horse's movement to a point that lameness develops, and lameness can change muscle function to the point that soreness develops. Both possibilities should be considered. In addition, neurologic causes of muscle weakness, atrophy, and gait changes should also be fully evaluated. The topics below are key components of the examination of skeletal muscle.

History

A history of stiffness, muscle cramping, pain, muscle fasciculations, exercise intolerance, undiagnosed lameness, weakness, or muscle atrophy may all indicate a muscle disorder. Further characterization requires a detailed account of the horse's performance level, exercise schedule, previous lameness, diet, vaccination history, signs of respiratory disease, duration, severity and frequency of muscle problem, any factors that initiate the muscle problem, and all medications with which the horse is being treated.

Physical Examination

A detailed evaluation of the muscular system includes inspection of the horse for symmetry of muscle mass while standing with forelimbs and hindlimbs exactly square. Any evidence of fine tremors or fasciculations should be noted before palpating the animal. Horses originating in the Southwestern United States that have muscle pain and fasciculations should have their ears examined with an otoscope for ear ticks (*Otobius megnini*).[44]

The entire muscle mass of the horse should be palpated for heat, pain, swelling, or atrophy, comparing contralateral muscle groups. Firm, deep palpation of the lumbar, gluteal, and semimembranosus and semitendinosus muscles may reveal pain, cramps, or fibrosis. The triceps, pectoral, gluteal, and semitendinosus muscles should be tapped with a fist or percussion hammer and observed for a prolonged contracture suggestive of myotonia. Running a blunt instrument such as a needle cap or a pen over the lumbar and gluteal muscles should illicit extension followed by flexion in healthy horses. Guarding against movement may reflect abnormalities in the pelvic or thoracolumbar muscles or pain associated with the thoracolumbar spine or sacroiliac joints.

The horse should be observed at a walk or trot for any gait abnormalities and flexion tests performed for lameness. In some cases it may be helpful to observe the horse under saddle and have the owner demonstrate the exact nature of the gait abnormality or performance problem.

Ancillary Diagnostic Tests

Muscle Enzymes

The best assessment of the extent of acute muscle damage is attained by measuring serum CK activity. CK, a relatively low molecular weight protein (80,000 Da), is liberated into the extracellular fluid within hours of muscle damage, or increased cell membrane permeability, and usually peaks at 4–6 hours after muscle injury.[10] A three- to fivefold increase in serum CK from normal values is believed to represent necrosis of approximately 20 g of muscle tissue.[78] Limited elevations in CK (less than 1,000 U/L high range of normal value = 380 U/L) may accompany training or transport. Extreme fatiguing exercise (e.g. endurance rides or the cross-country phase of a 3-day event) may result in CK activities being increased to more than 1,000 U/L, but usually less than 4,000 U/L.[80] Under these circumstances, serum CK activities rapidly return to baseline (i.e. less than 350 IU/L in 24–48 hours). Recumbent animals also may have slightly elevated CK activities that are usually less than 3,000 U/L. In contrast, more substantial elevations (from several thousand to hundreds of thousands of U/L) in the activity of this enzyme may occur with rhabdomyolysis.

Serum AST is a higher molecular weight protein that has high activity in skeletal and cardiac muscle as well as in liver, red blood cells, and other tissues. Elevations in AST are not specific for myonecrosis, and increases could be the result of hemolysis, muscle, liver, or other organ damage. AST activity rises more slowly in response to myonecrosis than does CK, often peaking between 12 and 24 hours after the insult. In addition, AST is cleared slowly by the reticuloendothelial system and may persist for 2–3 weeks after rhabdomyolysis.[39,67]

By comparing serial activities of CK and AST, information concerning the progression of myonecrosis or muscle cell membrane permeability may be derived. Elevations in both CK and AST reflect relatively recent

VetBooks.ir

or active myonecrosis; persistently elevated serum CK indicates that myonecrosis is likely to be continuing. Elevated AST activity accompanied by decreasing or normal CK activity indicates that myonecrosis has ceased. The degree of elevation of CK and AST does not necessarily reflect the severity of clinical signs.

Elevations in plasma/serum myoglobin concentrations indicate acute muscle damage because this small protein leaks into plasma immediately after muscle damage and is rapidly cleared in the urine by the kidney.[30]

Exercise Response Test

Diagnosing chronic exertional rhabdomyolysis may be difficult in horses that have normal serum AST and CK when examined between episodes. In such cases, an exercise challenge can be helpful in detecting subclinical exertional rhabdomyolysis. In addition, quantifying the extent of rhabdomyolysis during mild exercise is helpful in deciding how rapidly to put a horse back into training. Blood samples should be taken before exercise and about 4–6 hours after exercise to evaluate peak changes in CK. Serum CK activity measured immediately post-exercise does not reflect the amount of damage occurring during the exercise test. Small fluctuations in serum CK activity may occur with exercise due to enhanced muscle membrane permeability, particularly if exercise is prolonged or strenuous and the horse is untrained.[27,57]

A submaximal exercise test is often valuable for detecting rhabdomyolysis because it provides more consistent evidence of subclinical rhabdomyolysis than maximal exercise tests.[67] Fifteen minutes of trotting is often sufficient to produce subclinical muscle damage in horses prone to chronic exertional myopathies.[36] If signs of stiffness develop before this, exercise should be concluded. A normal response is less than a three- to four-fold increase from basal CK. In the author's experience, horses with type 1 polysaccharide storage myopathy (PSSM1) and active recurrent exertional rhabdomyolysis (RER) are more likely to have a positive exercise response than horses with type 2 polysaccharide storage myopathy (PSSM2) or well-managed PSSM1.[38]

Ultrasonography

Physical disruption of muscle fibers and fibrosis can be detected by diagnostic ultrasonography. The typical striated echogenic pattern of skeletal muscle varies according to the muscle group, and careful comparisons must be made between similar sites in contralateral limbs, in both transverse and longitudinal images. The appearance of muscle is also sensitive to how the horse stands and whether the muscle is under tension, so it is important that the horse stand squarely and bear weight evenly. Muscle fascia appears as well defined, relatively echodense bands. Care must be taken in identifying large vessels and artifacts created by them.[58]

Relatively hypoechoic areas within muscle that lack the normal muscle fiber striation indicate acute injury. The jagged edge of the margin of the torn muscle may be increased in echogenicity. Tears in the muscle fascia may be identified. A loculated hematoma may fill the injured area and slowly be replaced by hypoechoic granulation tissue. As muscle fibers regenerate, there is a progressive increase in echogenicity. Relatively hyperechoic regions may develop due to fibrous scarring. Hyperechoic regions causing shadowing artifacts reflect mineralization.[70]

Electromyography (EMG)

Electromyography (EMG) is particularly useful for evaluating muscle atrophy, muscle fasciculations, and myotonia. Normal muscle shows a brief burst of electrical activity when the EMG needle is inserted and then quiescence unless motor units are recruited (motor unit action potentials) or the needle is very close to a motor end plate (miniature end plate potentials). Spontaneous electrical activity, fibrillation potentials, and positive sharp waves are seen in horses with denervation and myotonic discharges, or complex repetitive discharges are seen in horses with muscle conduction system abnormalities (e.g. myotonia, hyperkalemic periodic paralysis [HYPP]).[80]

Muscle Biopsy

A number of specific equine myopathies have been identified through the routine examination of muscle biopsies from horses with evidence of muscle dysfunction. Muscle fiber sizes, shapes, and fiber type distribution, mitochondrial distribution, polysaccharide staining pattern, neuromuscular junctions, nerve branches, connective tissue, and blood vessels can be fully evaluated in frozen sections using a battery of tinctorial and histochemical stains.

Inflammation, muscle fiber necrosis, cellular infiltrates, and proliferation of connective tissue are evident in formalin and frozen sections. However, there are many pathologic alterations that cannot be detected in formalin-fixed tissue but can readily be seen in histochemical stains of fresh-frozen biopsy samples.[14] These include identification of muscle fiber types to differentiate between neurogenic and myogenic atrophy, characterization of vacuolar storage material, characterization of inclusion bodies, and mitochondrial density. In addition, frozen samples may be used for biochemical analysis of substrate concentrations and enzyme activities as well as DNA isolation.

Muscle biopsies are preferably collected from abnormal/diseased muscle. A 6-mm outer diameter percutaneous needle biopsy technique can be used to obtain small muscle samples through a 1.5-cm skin incision using a local anesthetic subcutaneously. If this technique is used, enough muscle should be obtained to form a 1.5-cm^2 sample at a minimum. These samples do not tolerate shipment to an outside laboratory well. The optimum biopsy for shipment of histopathologic tissues to a laboratory is collected using surgical or open techniques, performed under local anesthesia (Figure 7.65).

Semimembranosus samples are often selected for open biopsy in cases of exertional rhabdomyolysis. Care must be exercised to infiltrate only the subcutaneous tissues, not the muscle, with local anesthetic agent. The objective is to obtain approximately a 2-cm cube of tissue without crush artifact; hence, a suitably long skin incision is required. Subsequently, two parallel incisions 2 cm apart should be made longitudinal to the muscle fibers with a scalpel. The muscle should only be handled in one corner

VetBooks.ir

Figure 7.65. Muscle biopsy of the semimembranosus muscle. Note that the sample is gently handled at one end without crushing the tissue. Samples can be wrapped in saline-moistened gauze and shipped in a hard container on ice packs for frozen sections.

using forceps, and care should be taken not to crush the tissue. The muscle sample is then excised by transverse incisions 2 cm apart, and the tissue fixed appropriately.

Routine histopathologic samples can be placed in formalin. Fresh specimens are best shipped overnight in gauze slightly moistened with saline in a plastic jar on ice packs to specialized laboratories where they are frozen in isopentane (methylbutane) that is suspended in liquid nitrogen to minimize freeze artifact. Samples that potentially may be used for biochemical analysis should be immediately frozen in liquid nitrogen.

Genetic Testing

DNA tests are available for the diagnosis of PSSM1, malignant hyperthermia (MH), HYPP, and immune-mediated myositis. Some laboratories prefer submission of a minimum of 20 mane or tail hairs pulled out with roots intact. Others analyze whole blood submitted in EDTA tubes.

MUSCLE SORENESS

Overuse and Muscle Strain

It is often difficult to assess the presence of muscle pain in horses because it is a subjective assessment and often coexists with a more easily recognized lameness. Frequently the lameness is treated without managing muscle soreness. In human athletes muscle stiffness and soreness are more easily recognized causes of decreased performance. In humans, muscle pain and stiffness are reported 24–48 hours after unaccustomed use of certain muscles; this is referred to as delayed-onset muscular soreness (DOMS). Pain resolves spontaneously, assuming the muscles are not overworked again; however, continued overstress may result in ultrastructural damage to myofilaments and eventually histological evidence of myofiber necrosis. Gradual training involving the activity that provoked the original DOMS decreases the amount of soreness associated with that condition over time. The muscles most prone to strain in horses appear to be the back muscles (Standardbreds, dressage and jumping horses), semimembranosus/tendinosus muscles (reining, roping, cutting horses), and pectoral muscles (event horses after cross-country jumping). Poor racing performance or poor jumping techniques and the horse twisting itself over jumps are common complaints in horses with sore backs.[70]

Muscle Trauma

When muscle has been strained to the point of tearing through entire muscle fascicles, hemorrhage and inflammation can result in acute muscular pain and recognizable swelling in superficial muscles. The most common sites of injury in the forelimb include biceps brachii, brachiocephalicus, pectorals, and the musculotendinous junction of the superficial digital flexor. In the hindlimb, semimembranosus and semitendinosus, adductor, gluteal, and gastrocnemius muscle injuries are common (Figure 7.66).[70] Whereas acute trauma is associated with swelling or herniation of a muscle belly through the overlying fascia, chronic injury may be associated with loss of muscle bulk, fibrosis, mineralization, or rarely ossification (Figure 7.67).

Diagnosis

An acute muscle tear may produce a palpable defect, but this becomes filled with edema, hemorrhage, and eventually granulation tissue. Localization of deeper muscle injury is more challenging, because the clinical signs are more subtle.

Pain and limitations in movement should be evaluated in a full range of passive movement of the neck, limbs, and thoracolumbar region. The horse should be observed for gait abnormalities at both the walk and the trot. However, overt lameness may not be present if pain only occurs when the muscle contracts strongly or is stretched maximally. Serum muscle enzyme concentrations are usually in the normal range for focal muscle trauma.

Treatment

After most insults, muscle will regenerate over time unless muscle architecture is so severely disrupted that fibrosis results. The choice of treatment depends upon the type of muscle injury and the stage of injury and repair. The goal is to relieve muscle spasm, decrease inflammation, restore circulation, minimize scarring,

VetBooks.ir

Figure 7.66. (A) Acute swelling of the right adductor muscles (arrow) in a mare that slipped in a muddy paddock. (B) The same muscle 2 weeks later after cold therapy and treatment with a nonsteroidal anti-inflammatory.

Figure 7.67. Severe atrophy, fibrosis, and contracture of the left hamstring region in a horse with previous trauma to the area. *Source*: Courtesy of Dr. Gary Baxter.

and maintain range of motion. Treatment modalities include cold therapy, therapeutic ultrasound or laser therapy, transcutaneous electrical stimulation, massage, passive stretching combined with box rest, and a graduated, controlled exercise program. Relief of acute muscle spasm may require chiropractic manipulation. The extent of rest depends upon the degree of tearing and hemorrhage. Once initiated, the exercise program must be carefully moderated according to the site of the injury to avoid overstress in the early stages of repair but encourage a progressive increase in strength. Aqua treadmills can provide an excellent controlled means of building muscle strength.

Muscle Ischemia

Muscle ischemia is extremely painful and occurs with acute trauma, vascular occlusion, and the crush/compartment syndrome. Vascular occlusion may be a sequela to infarctive purpura hemorrhagica, disseminated intravascular coagulation, and iliac thrombosis.

Compartmental syndrome develops when high pressure within a closed fascial space reduces capillary blood perfusion below a level necessary for muscle tissue viability. Trauma to the caudolateral compartment of the antebrachium can cause ischemia of the enclosed lateral digital extensor, ulnaris lateralis, superficial and deep digital flexor, and flexor carpi ulnaris muscles, as well as the median artery, vein, and nerve (Figure 7.68).[63] Lameness is acute and severe in onset, with reluctance to bear weight on the limb associated with firm swelling on the caudolateral aspect of the antebrachium. Treatment of compartment syndrome is by fasciotomy. In one case, incising the superficial fascia over the ulnaris lateralis resulted in immediate separation of the fascia by 3–4 cm and rapid relief of clinical signs.[63]

In recumbent or anesthetized horses, the triceps muscle, gluteal muscles, longissimus dorsi, or extensors of the hindlimb may become ischemic because of compression, prolonged hypoperfusion, and subsequent reperfusion and edema. Hypotension during surgery in which mean arterial blood pressure is less than 60 mm Hg contributes to the development of this syndrome. Clinical signs are usually evident as soon as the horse tries to stand, but may be delayed for up to 2 hours. In severe cases the horse is unable to stand.

Triceps myopathy is often characterized by a dropped elbow stance typical of radial nerve paralysis. Involvement of the gluteal muscles may result in unwillingness to bear

VetBooks.ir

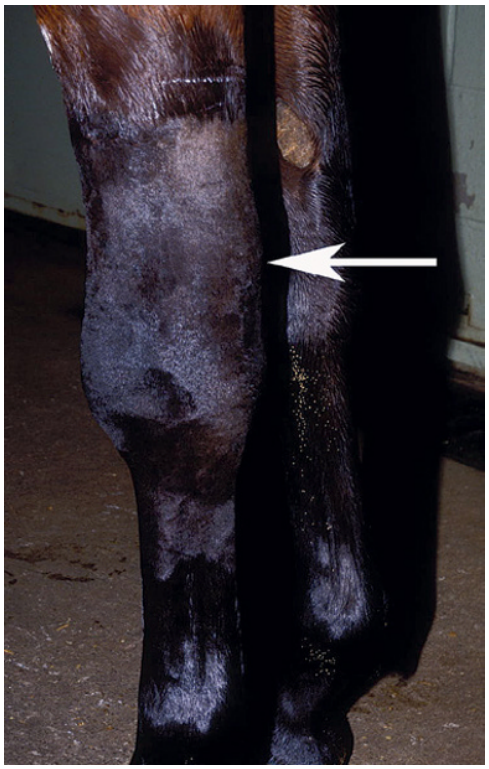

Figure 7.68. Trauma and associated swelling to the caudolateral antebrachium (arrow) that can cause ischemia of the enclosed structures, leading to signs suggestive of compartment syndrome. *Source*: Courtesy of Dr. Gary Baxter.

weight on the hindlimbs. Horses may appear distressed, with profuse sweating, tachycardia, and tachypnea. The degree of distress depends on the severity of the muscle damage. Affected muscles may feel very hard. There may be localized swelling. Neuropathy also may develop in the compressed muscles, resulting in temporary radial or peroneal nerve damage. Serum CK levels greater than 2,000 IU/L often occur within 4 hours after anesthesia as blood flow returns to the affected muscles.

Treatment of postanesthetic myopathy or neuropathy in horses is similar to that described in the section on acute exertional rhabdomyolysis. Bandaging and splinting of limbs with neuropraxia may help the horse stand and ambulate more easily, thus relieving much of the animal's anxiety. Horses that can stand on three legs have a good prognosis for recovery from myopathies or neuropathies and generally respond to treatment within 72 hours. Horses that are affected bilaterally and unable to stand have a very poor prognosis.

Muscle Abscesses

Staphylococcus aureus, *Streptococcus equi*, and *Corynebacterium pseudotuberculosis* are common causes of skeletal muscle abscessation. Abscesses develop following penetrating injuries or local or hematogenous spread of infection. Ultrasonography and culture of aspirated fluid are the best means of diagnosis in superficial sites. Deeper abscesses may be diagnosed using fibrinogen, nucleated white blood cell count, and the synergistic hemolysin inhibition test for abscesses due to *C. pseudotuberculosis*.

Clostridial Myositis

Clostridial myositis most commonly occurs following penetrating wounds, parturition injuries, castration, and especially intramuscular injections.[56] Spores of *Clostridia* species involved are found in soil and feces and may lie dormant in skeletal muscles. When tissue is traumatized by injection or injury (low oxidative potential and alkaline pH), organisms proliferate, elaborate exotoxins, and cause extensive necrosis of muscle and surrounding tissue. Death can occur quickly from toxemia with *C. sordelli*, *C. sporogenes*, and *C. chauvoei*. Cases of *C. perfringens* have a lower mortality rate and initially present with swelling and crepitus in an area in muscle, as well as moderate systemic signs of toxemia. Ultrasound is useful in identifying air bubbles in muscle exudate, and clostridial species can be identified in aspirates by fluorescent antibody staining and anaerobic bacterial culture. Antibiotic therapy, wound fenestration, aggressive surgical debridement over the entire affected area, and supportive care are the hallmarks of successful treatment.[56] High doses of intravenous potassium penicillin are recommended every 2–4 hours until the horse is stable (1–5 days) combined with or followed by oral metronidazole. Supportive fluid therapy and anti-inflammatory agents for control of pain and swelling are recommended. Extensive skin sloughing over the affected area is common in surviving horses.

Muscle Cramping

Muscle cramping is a painful condition that arises from hyperactivity of motor units caused by repetitive firing of the peripheral and/or central nervous system. The origin of the cramp in most cases is believed to be the intramuscular portion of the motor nerve. Most muscle cramps are also accompanied by fasciculations in the same muscle and normal serum CK activity. In contrast, muscle contractures, such as those seen in exertional rhabdomyolysis, are painful muscle spasms that represent a state of muscle contracture unaccompanied by depolarization of the muscle membrane. Muscle cramps can be induced by forceful contraction of a shortened muscle, changes in the electrolyte composition of extracellular fluid, and ear tick infestations in horses. Muscles may also develop intensely painful spasms, particularly following trauma to the caudal thoracic and lumbar regions. Manipulation to release muscle spasm can produce relief of pain and rapid restoration of normal performance.

Electrolyte Disturbances

Muscle cramping in endurance horses is most frequent in hot, humid weather when horses develop remarkable deficits in sodium, potassium, chloride magnesium, and calcium due to extensive sweating. Synchronous diaphragmatic flutter may be seen in association with cramping.[12] Mild muscle cramping is self-limiting, and the signs abate with rest or light exercise. Exhausted

VetBooks.ir

horses with metabolic derangements, however, require immediate treatment, including plasma volume expansion with oral or intravenous isotonic polyionic fluids and cooling (using water and fans).[11] Because most horses with this condition are alkalotic, administration of solutions containing sodium bicarbonate is contraindicated. Daily direct addition of 2 oz. of sodium chloride and 1 oz. of potassium chloride to the feed is recommended for horses with recurrent cramping in addition to electrolyte supplementation before and after endurance rides.

Muscle AtrophyDenervation Atrophy

Neurogenic atrophy results in fairly rapid atrophy of both slow- and fast-twitch muscle fibers because the normal low-level tonic neural stimulus that is necessary to maintain muscle fiber mass is absent. Complete denervation of a muscle results in more than a loss of 50% of muscle mass within 2–3 weeks. Denervation can be focal (e.g. suprascapular nerve damage causes supraspinatus/infraspinatus atrophy) or generalized with slower progression (e.g. equine motor neuron disease).

Focal denervation atrophy may occur due to nerve trauma (Figure 7.69) or focal ventral spinal cord infection from equine protozoal myelitis. If the injury is mild, then most nerves can regenerate (at about 4 mm/day) and the original continuity to the muscle can be reestablished. However, if the nerve injury is severe (e.g. transection), regrowth of the nerve to the muscle is delayed and may never occur. Furthermore, if concurrent muscle atrophy is severe, even if a functional connection is made, there may only be a limited number of fibers available for renervation. Generalized denervation atrophy occurs with diseases such as equine motor neuron disease and peripheral neuropathies.

Figure 7.69. Focal denervation atrophy of the gluteal musculature (arrow) that was attributed to nerve root trauma. *Source*: Courtesy of Dr. Gary Baxter.

Myogenic Atrophy

Muscle atrophy can be myogenic in origin, resulting from hypovitaminosis E, severe rhabdomyolysis, immune-mediated myositis, disuse, malnutrition, cachexia, and corticosteroid excess. Disuse, malnutrition, cachexia, and corticosteroid excess are characterized by slow onset of atrophy over months of exclusively type 2 fast-twitch muscle fibers and normal serum CK. Horses with rhabdomyolysis and marked elevations in serum CK activity can have a moderate onset of atrophy over a few weeks. Vitamin E deficiency causes gradual loss of muscle mass.[6,16] In contrast, immune-mediated myositis shows rapid loss of 30% of muscle mass over the topline within 48 hours. This disorder has lymphocytic infiltrates in biopsies of the atrophied muscle associated with elevated serum CK activity.[18,37]

EXERTIONAL RHABDOMYOLYSIS

Exertional rhabdomyolysis (ER) occurs in about 3% of exercising horses[13] and in a wide variety of breeds, including draft breeds, Warmbloods, Thoroughbreds, Standardbreds, Arabians, Morgans, Quarter horses, Appaloosas, American Paint horses, and many more. Terms such as tying-up, set fast, azoturia, and Monday morning disease have been used to describe this syndrome.

Classically, horses lose impulsion and develop a stiff, stilted gait, particularly involving the hindquarters. There is excessive sweating and a high respiratory rate due to pain. Horses may be unable to walk forward after resting due to firm, painful muscle contractures involving the back and hindquarters. Gluteal, biceps femoris, semitendinosus, and semimembranosus muscles are usually symmetrically affected with less frequent involvement of the forelimbs. Severe cases of rhabdomyolysis show signs of colic, become recumbent, and develop occult myoglobinuria. Attempts to move more severely affected animals may result in extreme pain, obvious anxiety, and exacerbation of the condition. Diagnosis of rhabdomyolysis is usually obvious based on the clinical signs, but measurement of serum muscle enzyme activities provides an assessment of the severity of muscle damage and confirms the diagnosis. The degree of elevation of muscle enzyme activity does not necessarily reflect the severity of clinical signs.

Treatment of Acute Rhabdomyolysis

If the attack occurs during exercise some distance from where the horse is normally stabled, the horse should not be made to walk home. If an attack occurs at a competition, the horse should be treated there and should not be transported home over a long distance for at least 24–48 hours.

The objectives of treatment are to relieve anxiety and muscle pain, as well as correct fluid and acid–base deficits (Table 7.2). Acepromazine is helpful in relieving anxiety and may increase muscle blood flow but should not be given to dehydrated horses due to hypotensive effects that produce recumbency. Alternatively, xylazine may provide short-term relief or in very painful horses, and detomidine combined with butorphanol provides

VetBooks.ir

Table 7.2. Potential medications that can be used to treat acute rhabdomyolysis in the horse.

Category	Drug	Dose	Comment
Tranquilizer	Acepromazine	0.04–0.07 mg/kg IV	May be hypotensive; use caution if dehydrated
	Xylazine	0.4–0.8 mg/kg IV	
	Detomidine	0.02–0.04 mcg/kg IV	
	Butorphanol	0.01–0.04 mg/kg IV	Use with xylazine/detomidine
Anti-inflammatory	Phenylbutazone	2.2–4.4 mg/kg IV or oral	Use caution if dehydrated
	Flunixin meglumine	1.1 mg/kg IV or oral	Use caution if dehydrated
	Ketoprofen	2.2 mg/kg IV	Use caution if dehydrated
	DMSO	1–2 mg/kg IV or oral	Use as a solution diluted to less than 20%
Pain control: CRI	Lidocaine	1.3 mg/kg IV followed by 0.05 mg/kg/min IV	
	Detomidine	0.22 mcg/kg IV followed by 0.1 mcg/kg/min IV	
	Butorphanol	13 mcg/kg/h	
Muscle relaxant	Methocarbamol	5–22 mg/kg IV slowly	
	Dantrolene	2–4 mg/kg oral QID	

excellent sedation and analgesia. NSAIDs such as ketoprofen, phenylbutazone, or flunixin meglumine provide additional pain relief. Analgesic treatment is continued to effect, but most horses are relatively pain free within 18–24 hours. For horses with extreme pain and distress, a constant rate infusion of detomidine, lidocaine, or butorphanol can make the difference between adequate time for recovery and euthanasia.

Intravenous or intragastric dimethyl sulfoxide can be used as an antioxidant, anti-inflammatory, and osmotic diuretic in severely affected horses. Muscle relaxants such as methocarbamol seem to produce variable results, possibly depending on the dosage used. Dantrolene sodium in severely affected horses may decrease muscle contractures and possibly prevent further activation of muscle necrosis. This can be repeated in 4–6 hours.

Severe rhabdomyolysis can lead to renal compromise due to the ischemic and the combined nephrotoxic effects of myoglobinuria, dehydration, and NSAIDs. The first priority in horses with hemoconcentration, or myoglobinuria, is to reestablish fluid balance and induce diuresis. In mild cases, administration of fluids via a nasogastric tube may be adequate, but generally fluids are better given intravenously. Balanced polyionic electrolyte solutions are best. If severe rhabdomyolysis is present, then isotonic saline or 2.5% dextrose in 0.45% saline may be necessary because horses often have hyponatremia, hypochloremia, and hyperkalemia.[34] If hypocalcaemia is present, then supplementing intravenous fluids with 100–200 mL of 24% calcium borogluconate is recommended, but serum calcium should not exceed a low normal range. Affected animals are usually alkalotic, making bicarbonate therapy inappropriate.

Etiology of Exertional Rhabdomyolysis

Some horses develop exertional muscle damage as a result of extrinsic nutritional or environmental factors. These sporadic cases of ER are usually amenable to treatment once the extrinsic cause of muscle damage is identified. Some horses, however, develop chronic ER, and many of these cases are due to an intrinsic and inherited dysfunction of muscle metabolism or muscle contraction.

Sporadic Exertional Rhabdomyolysis

The most common extrinsic cause of sporadic ER is exercise that exceeds the horse's underlying state of training. Horses that are advanced too quickly in their training, those that are only ridden sporadically while being continually fed full rations, and horses performing strenuous exercise such as racing or endurance riding without sufficient conditioning commonly develop rhabdomyolysis. In addition, rhabdomyolysis may be more common in horses exercising during an outbreak of respiratory disease. Both equine herpesvirus 1 and equine influenza virus have been implicated as causative agents.[23,26]

Dietary Imbalance

Horses consuming a high-grain diet appear to be more likely to develop ER than horses fed a low-grain or fat-supplemented diet.[42,43] The grain itself may not be responsible for rhabdomyolysis; however, high starch intake may trigger rhabdomyolysis in horses with particular myopathies such as RER and PSSM.

Electrolyte depletion in horses can occur due to dietary deficiency and losses in sweat with strenuous

VetBooks.ir

exercise. Sodium, potassium, magnesium, and calcium play key roles in muscle fiber contractility. With severe acute electrolyte depletion such as that found following endurance exercise, serum electrolytes may be below normal ranges.[11] With chronic dietary depletion, however, serum concentrations may not reflect total body electrolyte imbalances.

Work by Harris et al. established renal fractional excretions as a technique to evaluate electrolyte concentrations in horses with chronic ER.[28] Blood and urine samples are obtained concurrently, and creatinine and electrolyte concentrations measured in both. Serum creatinine/urine creatinine multiplied by the reciprocal for urine and serum electrolyte concentrations ×100 provides the fractional excretion of a particular electrolyte. It can be difficult, however, to obtain consistently representative renal fractional excretions of electrolytes in horses.[53] Hypokalemia has also been suggested to play a role in chronic ER, although it is not a common finding in horses consuming adequate quantities of forage.[4] Supplementation with good quality forage or 30 g of KCl/day (light salt) is recommended for horses with low renal fraction excretion of potassium.

Vitamin E and Selenium

Another postulated cause of sporadic ER is the increased generation of free radicals from oxidative metabolism associated with exercise. It has not been shown whether horses that experience repeated episodes of ER may generate more free radicals than normal horses. Primary selenium deficiency has rarely been demonstrated as a cause of ER.[60] In fact, many racehorses with chronic ER have higher concentrations of selenium and vitamin E due to zealous dietary supplementation by the owner. Adequate values for blood selenium are greater than 0.07 mcg/mL.

Horses with low serum vitamin E may present with muscle soreness, muscle fasciculations, muscle weakness, and loss of muscle mass. In early stages this may be due to a reversible myopathic process.[6] After years of deficiency, oxidative damage to motor nerves can result in generalized denervation typical of equine motor neuron disease.[16] Adequate values for serum vitamin E are above 2.0 mcg/mL.

Chronic Exertional Rhabdomyolysis

Horses that have repeated episodes of ER from a young age, from the time of purchase, or when they are put back into training after a long period of rest may have an underlying intrinsic abnormality of muscle function. Many of the horses with intrinsic muscle defects have repeated episodes of rhabdomyolysis with minimal exercise, even when the dietary and training recommendations for sporadic ER are followed. Five specific intrinsic causes of ER have been identified to date: MH, RER, PSSM1, PSSM2, and myofibrillar myopathy (MFM). It is likely that there are other specific causes that have yet to be identified (idiopathic chronic ER).

In all of these intrinsic forms of chronic ER, it appears that there are specific environmental stimuli that are necessary to trigger muscle necrosis in genetically susceptible animals. Horses cannot be cured of their susceptibility to this condition, but if the specific disease is identified, changes in management can be implemented to minimize episodes of rhabdomyolysis.

Malignant Hyperthermia

Prevalence

A genetic form of MH due to an autosomal dominant mutation in the skeletal muscle ryanodine receptor (*RYR1*) has been identified in 1% or fewer of American Quarter horses.[2]

Clinical Signs

Horses with MH may develop classic signs under general anesthesia of excessive body temperature, rigor, metabolic acidosis, and death.[1] In addition, affected horses may show signs of ER and high body temperatures. Some MH-affected horses have died suddenly after an episode of ER. The MH defect can coexist with the *GYS1* mutation for PSSM1.[45] The combination of these two mutations makes signs of ER more severe and increases recurrence of high serum CK, and horses do not respond as well to changes in diet and exercise.

Diagnosis

Genetic testing is recommended in Quarter horses and Paint horses with difficult to manage forms of PSSM or a family history of post-anesthetic complications.

Recurrent Exertional Rhabdomyolysis

Prevalence

About 5%–10% of Thoroughbred racehorses develop ER during a racing season, and 75% of these horses have more than four episodes in 4 months.[41] Approximately 6% of National Hunt horses[68] 13% of polo horses[54] and 6% of Standardbred horses[32] develop ER. Horses with a nervous disposition, especially fillies, are highly predisposed. Research suggests that a subset of Thoroughbred horses with chronic ER have a specific form of ER, denoted as RER.[35,72] RER appears to be an inherited, intermittent, stress-induced defect in the regulation of muscle contraction; however, a specific genetic cause of RER has not been established despite considerable research.[35] Recurrent episodes of rhabdomyolysis in Standardbreds and Arabian horses may be due to a similar abnormality, but this has not been confirmed.[32]

Clinical Signs

Horses with RER have intermittent elevations in serum CK activity.[55] Episodes of muscle stiffness, sweating, and firm muscle contractures often occur in horses once they become fit and are frequently associated with excitement at the time of exercise. In Thoroughbreds, rhabdomyolysis occurs most frequently during training when horses are held to a slow gallop.[41] In Standardbreds, rhabdomyolysis often occurs 15–30 minutes into jogging.[67] Obvious clinical signs are rare after racing. A history of poor performance and elevated serum AST and CK may be the only presenting complaints in some

VetBooks.ir

horses. Older Thoroughbreds used as riding horses may have very intermittent episodes of rhabdomyolysis associated with lay-up of fit horses. Event horses often develop clinical signs after the steeplechase phase of a 3-day event, or in the "10-minute box," or less commonly during the cross-country phase. Muscle stiffness and reluctance to collect may be present on a continual basis between episodes in some of these older horses. Arabian horses often develop clinical signs with little exertion, frequently in association with excitement.

Etiology

RER is characterized by abnormal sensitivity of intact muscle bundles to contractures induced by the addition of caffeine or halothane to a muscle bath.[8,35] Elevated myoplasmic calcium concentration has been reported in muscle of horses with acute ER and, in the face of caffeine, in myoblasts derived from Thoroughbreds with RER.[36,40]

There are physiological similarities between the contracture results of RER and contracture tests for MH; however, biochemical studies of isolated muscle cell membranes[79] and linkage analysis[17] do not support an identical biochemical basis for MH and RER. The increased halothane sensitivity of the muscles in RER horses may explain why many Thoroughbreds with RER develop rhabdomyolysis under halothane anesthesia.

Factors that trigger rhabdomyolysis in susceptible horses include gender, temperament, excitement, stress, dietary starch, exercise duration/intensity, season, and lameness.[66] Females are most commonly afflicted with RER (67% female to 33% male), particularly those that are 2 years of age and in race training.[41,50] Nervous horses are five times more likely to develop RER, and horses with lameness are four times more likely to develop rhabdomyolysis. Susceptible horses receiving more than 5 kg of concentrate feed (oats, corn, molasses mix) are more likely to develop rhabdomyolysis than those receiving 2.5 kg of concentrate feed/day.[43] Dietary effects of high carbohydrates in RER may in part be related to the psychogenic effects of grain on excitability. Glycogen storage does not increase substantially in horses with RER.[72] Inclement weather has been cited as a trigger of ER, and rhabdomyolysis is reported more commonly in the autumn and winter in the United Kingdom.[29]

A contribution of reproductive hormones to triggering ER has been postulated because the incidence of RER appears to be highest in mares. Many owners report that episodes of rhabdomyolysis occur most commonly during estrus, but in one study of racehorses, no direct correlation was shown between progesterone fluctuations and serum CK activity.[22] It is likely that the estrus cycle is one of many factors that combine to trigger ER in susceptible horses. Many racetrack practitioners report that the incidence of ER declines when susceptible mares are treated with testosterone. Hypothyroidism and lactic acidosis have also been suggested as a cause of ER but never substantiated.

Diagnosis

Acute cases of ER are readily diagnosed by serum muscle enzymes. Identification of RER in a horse that presents with a history of poor performance unrelated to signs typical of tying-up may be facilitated by a submaximal exercise test with pre- and 4-hour post-serum CK activity assessed. This test is useful for horses with concurrent problems but is not adequate to screen for RER in asymptomatic horses.

Muscle biopsies from horses with RER that are in training have increased numbers of centrally located nuclei in mature muscle fibers. They may have evidence of varying stages of muscle degeneration and regeneration, and they have normal to slightly increased subsarcolemmal muscle glycogen staining.[72] Histopathologic changes are often lacking in horses that have been laid up for a period of time prior to biopsy.

Polysaccharide Storage Myopathy (PSSM)

Prevalence

Recent research has shown that there are at least two forms of glycogen storage disorders in horses. PSSM1 is due to an autosomal dominant gain of function mutation in the glycogen synthase gene (*GYS1*).[49] This mutation is found in at least 20 different breeds of horses in Europe and North America, including Quarter horses; American Paint horses; Appaloosa horses; draft horse breeds including American Cream, Belgian, Percheron, Gypsy Vanner, Cob Normand, Trekpaard, Haflinger, Morgan, Mustang, and Rocky Mountain horse; Tennessee Walking Horse breeds; mixed breed horse; Cobs; Hanoverians; Rhinelanders; and Warmblood horses of unspecified type.[5,48,61] The prevalence of PSSM due to the *GYS1* mutation ranges from 8% in Quarter horses and Paints to 36% in Belgian draft horses, with no reported cases in the Thoroughbreds, Standardbreds, and Arabians tested.

PSSM2 is the term designated for those horses lacking the *GYS1* mutation that have with the histopathologic characteristic of abnormal-appearing amylase-sensitive or amylase-resistant polysaccharide in muscle biopsies of horses.[46] Importantly, the term PSSM2 does not indicate a specific etiology since no specific genetic mutations or biochemical aberrations have been described in these horses as of yet. The assessment of amylase-sensitive aggregates of glycogen is subjective and impacted by tissue handling, leaving considerable room for false-positive diagnoses and overlap with a diagnosis of RER. PSSM2 appears to account for about 25% of PSSM cases in Quarter horse-related breeds and 80% of PSSM cases in many Warmblood breeds.[46,47] In the United Kingdom approximately 35% of PSSM cases diagnosed by muscle biopsy would be classified as PSSM2.[62] The acronyms EPSM and EPSSM have also been used for polysaccharide storage myopathy (PSSM), although they do not indicate a specific genotype.[76,77]

Clinical Signs

PSSM1

Horses with PSSM1 often have a calm and sedate demeanor.[71] Clinical signs of muscle stiffness, reluctance to exercise, exercise intolerance, or overt muscle contractures and reluctance to move usually are apparent at the commencement of training.[20] Most horses have numerous episodes of ER or a consistent history of poor

VetBooks.ir

performance; however, some mildly affected horses are asymptomatic or have only one or two episodes of ER per year. In Quarter horses, PSSM1 has the highest frequency in halter horses, followed by pleasure horses and working cow horses.[64] It is uncommon in racing Quarter horses. Serum CK activities are often elevated in untreated Quarter horses, even when horses are rested, and while clinical signs are active, CK will usually increase by 1,000 U/L or more 4 hours after 15 minutes of exercise at a trot.[72] Muscle atrophy, renal failure, and severe colic-like pain are less common presenting complaints.

Draft horses with PSSM1 may be asymptomatic if not in work but may also show signs of a generalized decrease in muscle mass and weakness in the hindlimbs with difficulty rising.[74] ER can be a debilitating feature of PSSM1 in draft breeds. Although shivers was suggested to be a sign of PSSM, recent studies show there is no causal relationship.[21] Draft horses with PSSM1 often have only a mild elevation in serum CK and AST. A small percentage of Warmbloods are afflicted with PSSM1 and have an increased incidence of episodes of ER.[33]

PSSM2

In Quarter Horses and light breeds, chronic ER is the predominant clinical sign of PSSM2.[47] Elevations in CK and AST are common. One of the most common presenting complaints in Warmbloods with PSSM2 is a gait abnormality characterized by lack of impulsion and shifting undiagnosed lameness.[34] By 10 years of age, Warmblood horses with PSSM2 show signs of sore muscles, poor performance, reluctance to go forward under saddle, reluctance to collect, and in some cases slow onset of topline atrophy, particularly if taken out of work.[38] ER occurs infrequently in Warmbloods with PSSM2, and post-exercise increase in serum CK activity is absent to infrequent in Warmbloods.[38]

Diagnosis

PSSM1

PSSM1 is most readily diagnosed by genetic testing for the *GYS1* mutation performed on whole blood or hair root samples.[49] The distinctive features of PSSM1 in muscle biopsy samples are numerous subsarcolemmal vacuoles and dense, crystalline periodic acid-Schiff (PAS)-positive, amylase-resistant inclusions in fast-twitch fibers.[71] A false-negative diagnosis of PSSM1 by muscle biopsy may occur if biopsy samples are small or if horses are less than 1 year of age.[15]

PSSM2 must still be diagnosed by muscle biopsy at present.[66] Muscle biopsies from horses with PSSM2 have increased PAS staining for glycogen and aggregates of granular PAS-positive polysaccharide in the cytoplasm or under the sarcolemma. The PAS-positive polysaccharide in PSSM2 is frequently but not always amylase sensitive. False-positive diagnosis is possible for PSSM2 in highly trained horses that normally have higher muscle glycogen concentrations or in formalin-fixed sections, which show a greater deposition of subsarcolemmal glycogen in healthy horses. Other features that may be present with both forms of PSSM include muscle necrosis and macrophage infiltration of myofibers, regenerative fibers, and atrophied type 2 fibers.

Etiology

Muscle glycogen concentrations in horses with PSSM1 are 1.5–4 times normal.[71] Increased muscle glycogen concentrations in PSSM1 appear to be due to increased and unregulated glycogen synthase activity as a result of a gain-of-function mutation in the glycogen synthase 1 gene (*GYS1*). Horses with PSSM show increased glycogen synthase activity both in the basal state and when stimulated by glucose-6-phosphate.[49] Elevated insulin in the bloodstream can further enhance glycogen synthase activity. Abnormal amylase-resistant polysaccharide appears to result from production of a polysaccharide with a higher ratio of straight glucose chains, which are created by glycogen synthase, relative to branched chains, which are created by the less active glycogen branching enzyme. Rhabdomyolysis in PSSM1 appears to result from a deficiency of energy within individual contracting muscle fibers.[3] The genetic defect combined with a high-starch diet appears to produce substrate-limited muscle oxidative metabolism by both impairing production of acetyl-CoA from glycogen and preventing lipolysis and delivery of free fatty acids to skeletal muscle mediated by insulin release.[73] Clinical signs of muscle pain in horses with the *GYS1* mutation may be exacerbated by enhanced individual insulin sensitivity as well as by meals that produce elevated blood glucose and insulin levels.[59] The etiology of PSSM2 is not known at present.

Myofibrillar Myopathy (MFM)

Diagnosis

MFM is a recently identified disorder in horses presenting with exercise intolerance or intermittent ER that is defined by specific histopathology.[65,69] First and foremost MFM horses have cytoplasmic aggregates of the cytoskeletal protein desmin in scattered muscle fibers. Desmin functions to align sarcomeres at the Z-disc and tether them to the cell membrane. Other ultrastructural derangements evident in electron microscopy include disrupted myofibrillar alignment, ectopic accumulation of cytoskeletal proteins, and Z-disc degeneration. In some cases, MFM is also characterized by cytoplasmic aggregates of glycogen similar to PSSM2. This is likely because pools of glycogen form within disrupted myofibrils. MFM may represent a more extreme subset of PSSM2. Muscle glycogen concentrations in horses with MFM are similar to controls.

Warmbloods

Warmblood horses diagnosed with MFM have an insidious onset of exercise intolerance notable by 6–8 years of age characterized by a lack of stamina, unwillingness to go forward, inability to collect, abnormal canter transitions, and inability to sustain a normal canter.[65] Unresolved hindlimb lameness, stiffness, muscle pain, and, rarely, an episode of ER are reported. Serum CK and AST activities are usually within normal limits unless samples are taken in conjunction with ER.

Arabians

Arabian endurance horses diagnosed with MFM usually have a history of intermittent elevations in serum

VetBooks.ir

CK activity after endurance rides (>10,000 U/L) or during exercise that follows a week or more of rest.[69] Horses do not necessarily always show the same degree of pain, sweating, and reluctance to move as is frequently seen in other forms of acute ER. Myoglobinuria can be observed in horses with only mild muscle stiffness. Between episodes, the heart rate, lactate, and CK and AST responses to exercise are normal.

Management of Chronic Forms of Exertional Rhabdomyolysis

Expectations

Most horses with chronic forms of ER always have an underlying predilection for muscle soreness. However, with proper management, most cases can have successful competitive careers. A few RER horses are extremely difficult to manage and may be retired from racing. Most PSSM1 horses can be successful pleasure and trail horses but usually do not achieve success in upper-level dressage or fast-paced activities such as barrel racing. ER can be well managed in Quarter Horses and Arabians with PSSM2. Warmbloods with PSSM2 will improve with diet and exercise recommendations, but they may not attain a higher level of performance in dressage.

Following clinical episodes, more than 80% of PSSM1 and PSSM2 horses show notable improvement with adherence to both the diet and exercise recommendations provided below.[20,31] There is, however, a wide range in the severity of clinical signs shown by horses with PSSM1; horses with severe or recurrent clinical signs require more stringent adherence to diet and exercise recommendations to regain muscle function. PSSM1 horses that also have the mutation for MH do not respond as well to diet and exercise recommendations and may continue to develop ER with the possibility of a fatal episode.[45]

Rest

Stall rest appears to be counterproductive and predisposes RER and PSSM horses to further episodes of rhabdomyolysis. Providing daily turnout with compatible companions can be very beneficial. It decreases anxiety in RER horses and enhances energy metabolism in PSSM horses. PSSM1 horses that are confined for days following an episode of rhabdomyolysis often have persistently elevated serum CK activity. In contrast, PSSM1 horses kept on pasture with little grain supplementation often show few clinical signs of rhabdomyolysis and have normal serum CK activity.

Environment

If excitement is a triggering factor for RER, stressful environmental elements should be minimized. Many horses respond to a regular routine including feeding prior to other horses and training before other horses, especially if the horse becomes impatient while waiting. Other ways to decrease excitement include housing in an area of the barn where horses are not always walking past and next to calm companionable horses. The use of hot walkers, exercise machines, and swimming pools should be evaluated on an individual basis, because some horses develop rhabdomyolysis when using this type of equipment. Horses that develop rhabdomyolysis at specific events, such as horse shows, must be reconditioned to decrease the stress level associated with such events.

Most PSSM horses are calm and not easily stressed. They do best when turned out on large pastures without lush grass where they move about on a daily basis. Grazing muzzles may be of benefit to PSSM horses for periods when grass is particularly lush.

Exercise

Regular daily exercise is important for managing all forms of ER. Thoroughbreds and Standardbreds with RER should avoid days off exercise. This prevents the elevations in serum CK activity that occur after a day of rest.[55] Following chronic episodes of ER in Thoroughbreds and Standardbreds, mild, calm, low intensity daily exercise (less than 15 minutes) or preferably extensive daily turnout is recommended until serum CK is less than 1,500 U/L. Thoroughbred racehorses often develop rhabdomyolysis when riders fight to keep horses at a slower speed (gallop exercise); therefore, this should be avoided.[41] Standardbreds often develop ER after 15–30 minutes of submaximal jogging, and therefore interval training and reduction of jog miles to no more than 15 minutes per session is recommended.[74] For riding horses with RER, a prolonged warm-up with adequate stretching is recommended. Rest periods that allow horses to relax and stretch their muscles between 2- and 5-minute periods of collection under saddle may be of benefit. Event horses may require training that incorporates calm exposure to speed work to prevent rhabdomyolysis, as well as interval training at the speeds achieved during competitions.

Important principles to follow when starting exercise programs in PSSM horses include:

1. Providing adequate time for adaptation to a new diet prior to commencing exercise
2. Recognizing that the duration of exercise is more important than restricting the intensity of exercise
3. Ensuring the exercise is gradually introduced and consistently performed
4. Minimizing any days without some form of exercise

If horses have experienced an episode of ER recently, 2 weeks of turnout and diet change are often beneficial prior to recommencing exercise. Exercise should be very relaxed, and the horse should achieve a long, low frame without collection. For many horses this is most readily achieved in a round pen or on a lunge line. Successive daily addition of 2-minute intervals of walk and trot beginning with only 4 minutes of exercise and working up to 30 minutes after 3 weeks is recommended. Advancing the horse too quickly often results in poor adaptation or an episode of ER and repeated frustration for the owner. Warmblood horses with PSSM may benefit from long, low lunging prior to exercise under saddle.

Work under saddle after 3 weeks of ground work should be a gradually accelerating program that adds 2-minute intervals of collection or canter to the initial relaxed warm-up period at a walk and trot. Unless a

VetBooks.ir

horse shows an episode of overt ER during the initial first 4 weeks of exercise, reevaluating serum CK activity is not helpful for the first month. This is because it is very common to have subclinical elevations in CK activity when exercise is reintroduced in PSSM horses, and a return to normal levels often requires 4–6 weeks of gradual exercise.[59] Keeping horses with PSSM fit seems to be the best prevention against further episodes of ER. This gradual approach aims to enhance the oxidative capacity of skeletal muscle, which in most Quarter horses is very low but can be increased with daily exercise. The objective of enhancing oxidative metabolism is to facilitate the metabolism of fat and blood-borne fatty acids as energy substrates.

Dietary Management

A nutritionally balanced diet with appropriate caloric intake and adequate vitamins and minerals is the core element of treating all forms of ER. Dietary recommendations are summarized in Table 7.3. Diets with a restricted amount of starch and sugar and supplemental calories supplied with fat are the basis for dietary management. In general, grass hay is preferable to alfalfa hay. For RER Thoroughbreds and Standardbreds, the challenge is supplying an adequate amount of calories in a highly palatable feed to meet daily energy demands. Controlled experimental studies using Thoroughbreds with RER show that serum CK activity is significantly lower when horses are fed a specially formulated high-fat, low-starch feed rather than an isocaloric amount of high-starch grain.[42,55] Given the close relationship between nervousness and RER, assuaging anxiety and excitability by reducing dietary starch and increasing dietary fat may decrease susceptibility by making these horses calmer prior to exercise. Some racehorse trainers prefer to supplement with a titrated amount of grain 3 days prior to a race if horses are on a low-starch, high-fat feed to increase the horse's energy during the race.

For PSSM1 horses, the challenge can be to provide adequate fat for energy metabolism while preventing excessive weight gain. If horses are overweight, reducing caloric intake by using a grazing muzzle, restricting hay to 1.5% of body weight, and providing a vitamin/mineral ration balancer is recommended. The NSC content of hay should be <12% to avoid insulin release.[9] Adding excessive calories in the form of fat to an obese horse is inadvisable. Until horses are a normal weight, fat metabolism can be enhanced by riding horses after a 5- to 8-hour fast as a means to elevate plasma-free fatty acids.

Once a horse has achieved the desired body weight, feeds low in starch and sugar combined with dietary fat can be introduced. The starch and sugar content of the diet of PSSM1 horses must be managed more stringently than for RER horses (Table 7.3). Owners report that this type of diet improves clinical signs of muscle pain, stiffness, and exercise tolerance in draft horses, Warmbloods, Quarter horses, and other breeds with PSSM1 when combined with the recommended exercise program.[20,31,75] The addition of fat alone is not beneficial, and an exercise program must be instituted for PSSM1 horses to show clinical improvement. In the author's experience, there is a great deal of variation in individual needs for fat supplementation, and this should be balanced with the horse's weight.

Warmbloods with PSSM2 or MFM are fed similar NSC to PSSM1; however, there is less evidence that very low NSC or high-fat diets are the most effective means to manage these disorders. For MFM horses and horses with topline muscle atrophy, amino acid supplements can be used to enhance muscle mass.[25,65] There are an increasing number of whey-based amino acid supplements on the market for horses.

A number of well-balanced low-starch, high-fat commercial diets are suitable for horses with RER and

Table 7.3. Feeding recommendations for an average sized 1,000-lb horse with exertional rhabdomyolysis due to recurrent exertional rhabdomyolysis (RER) or polysaccharide storage myopathy (PSSM).

	RER			PSSM		
Exercise intensity	Light	Moderate	Intense	Light	Moderate	Intense
Caloric intake (megacalories/d)	20	25	33	18	23	30
Percentage of daily digestible energy as NSC	15–20	15–20	15–20	Less than 10	Less than 10	Less than 10
Percentage of daily digestible energy as fat	15	15–20	20–25	20	15–20	15–20
Selenium mg/d	2.2	2.8	3.1	2.2	2.8	3.1
Vitamin E[a] units	1,000	2,000	4,000	1,000	2,000	4,000
Daily amount (lbs) of 12% NSC, 10% fat concentrate[b]	5	7	10	4	6	8
Grass hay (lbs) with less than 12% NSC by weight	15–20	15–20	15–20	15–20	15–20	15–20
Sodium chloride (g)	34	34	41	34	34	41

[a] Natural vitamin is preferable to synthetic vitamin E due to better absorption.
[b] Concentrate such as Re-Leve made by Kentucky Equine Research for horses with exertional myopathies.

VetBooks.ir

PSSM; however, the amount of starch and sugar can vary widely, as can the type of fat. Not all of these feeds are equally effective. At present, the NSC content of equine feed products is not listed on the feed tag, and consultation with the feed manufacturer is necessary to obtain this information. Nutritional support is available through most feed manufacturers in designing an appropriate diet. There are published peer-reviewed studies to show the beneficial effect of one commercial diet on both RER and PSSM.[55,59]

Supplements

Horses require daily dietary supplementation with sodium and chloride either in the form of loose salt (30–50 g/day) or a salt block. Additional electrolyte supplementation is indicated in hot, humid conditions. Some studies suggest that electrolyte imbalances, as reflected by low urinary fraction excretion of sodium or high dietary excretion of phosphorus, may contribute to ER, although others have not found a consistent abnormality.[28,29]

A number of supplements are purported to decrease lactic acid buildup in skeletal muscle of ER horses. These include sodium bicarbonate, B vitamins, branched-chain amino acids, and dimethylglycine. Because lactic acidosis is no longer implicated as a cause for ER, it is difficult to find a rationale for their use.

Medications

Low doses of acepromazine prior to exercise have been used in RER horses prone to excitement. A dose of 7 mg IV 20 minutes before exercise is reported to make horses more relaxed and manageable.[24] Reserpine and fluphenazine, which have a longer duration of effect, are also used for this purpose. Horses given fluphenazine may occasionally exhibit bizarre behavior. Use of tranquilizers may only be necessary when horses are in their initial phase of training and accommodation to a new environment because they obviously cannot compete on these medications.

Dantrolene sodium acts to decrease release of calcium from the calcium release channel in skeletal muscle and is used to treat MH. Dantrolene given to horses with RER 90 minutes before exercise prevented abnormal elevations in CK following exercise.[52] A dose of 800 mg of dantrolene was given to Thoroughbred horses in the United Kingdom 1 hour prior to exercise and resulted in significantly lower post-exercise CK activity than a placebo.[19] It must be given 60–90 minutes prior to exercise and horses do not need to be fasted.[51]

Phenytoin (1.4–2.7 mg/kg PO BID) acts on a number of ion channels within muscle and nerves, including sodium and calcium channels. Therapeutic levels vary, so oral doses are adjusted by monitoring serum levels to achieve 8 µg/mL and not to exceed 12 µg/mL.[7] Drowsiness and ataxia are evidence that the dose of phenytoin is too high and the dose should be decreased by half. Initial dosages start at 6–8 mg/kg orally twice a day for 3–5 days. If the horse still experiences rhabdomyolysis but is not drowsy, the dose can be increased by 1 mg/kg increments every 3–4 days.

Intramuscular injections of vitamin E and selenium are used in an attempt to prevent RER. Ensuring adequate oral intake may prevent the muscle soreness associated with IM injections.

Some mares appear to exhibit signs of ER during estrus, and it may well be beneficial in these horses to suppress estrus behavior using progesterone injections. Testosterone and anabolic steroids are used at racetracks to prevent signs of RER, but the efficacy has not been evaluated.

Adjunct Therapies

Massage, myofascial release, mesotherapy, stretching, and hot/cold therapy performed by experienced therapists may be of benefit in individual cases of ER.

CHAPTER

Principles of Therapy for Lameness

SYSTEMIC/PARENTERAL

Drew W. Koch and Laurie R. Goodrich

Systemic administration of medications to treat musculoskeletal diseases in the horse mainly encompasses intravenous nonsteroidal anti-inflammatory drugs (NSAIDs), intramuscular (IM) polysulfated glycosaminoglycans (PSGAGs), and intravenous (IV) hyaluronan (HA). Less commonly used systemic medications include IV bisphosphonates, and a few other miscellaneous medications covered below. Excluding NSAIDs, there has been controversy regarding the use of the following medications in the horse and whether they reach high enough therapeutic levels at the intended area to be effective. Many (or most) of the drugs or nutraceuticals have been intended for systemic administration in humans, and levels high enough to be efficacious in the horse are often in question.

PARENTERAL NSAIDS

The most commonly used IV NSAIDs are phenylbutazone and flunixin meglumine. Recommended dosages are between 2.2 mg/kg q12 hours or 4.4 mg/kg q24 hours (phenylbutazone) and 1.1 mg/kg q24 hours to q12 hours (flunixin meglumine). Ketoprofen, carprofen, and firocoxib are less commonly used intravenously with ketoprofen and firocoxib now labeled for use in the United States (Ketofen® sterile solution, Zoetis, Parsippany, NJ; Equioxx, Merial, Inc., Duluth, GA). The NSAIDs mentioned above are most commonly used orally; however, in the acute case of inflammation when pain and swelling have not yet been addressed, the IV route of delivery is more effective and yields the desired pharmacologic effect faster.

Repetitive IV injections are not recommended due to increased likelihood in developing vasculitis. Oral formulations are recommended when a venous catheter is not in place and when repetitive dosing is necessary. For more information on specific NSAIDs, mechanism of action, dosages, and indications, see the section on oral/nutritional therapy later in this chapter.

POLYSULFATED GLYCOSAMINOGLYCANS (PSGAGS) AND PENTOSAN POLYSULFATE (PPS)

PSGAGs are a mixture of low molecular weight (approximately 6–10,000 Da) glycosaminoglycans (GAGs) that are very similar in structure to chondroitin sulfate, the major GAG in normal cartilage.[10] PSGAG administration has been associated with reducing the severity of clinical signs on both human and equine patients with OA.[35,58] Beneficial clinical effects are, at least in part, attributable to anti-inflammatory effects consisting of the inhibition of prostaglandin E_2 (PGE_2), cytokine release, and stimulatory effects on cartilage matrix components.[68] Modes of administration include IM and intra-articular (IA) routes. Elevated risks have been identified with IA administration; therefore, many practitioners still prefer to administer PSGAGs intramuscularly.[10,18] The efficacy of IM administration may be lower compared with direct injection into the joint;

VetBooks.ir

anecdotally, if a favorable response to IM administration occurs, it is rapid.

The PSGAG Adequan® (Luitpold Pharmaceuticals, Inc., Shirley, NY) is produced from the bovine trachea and lung and is in a class of drugs that exhibits chondroprotective properties in cartilage. Pentosan polysulfate (PPS; in a sodium or calcium derivative), within a similar class of medications, is produced from a plant source and is not licensed in the United States, but widely used in Europe and Australia.[49] In the United States, compounded versions can be obtained for use in horses. This section focuses on the use of IM PSGAG and PPS. Please refer to the chapter on IA therapy for IA use of PSGAG.

While there has been convincing evidence of the beneficial effects on cartilage, the exact mechanism of action remains unknown. It has been theorized that PSGAGs form stable complexes with fibronectin and collagen fibers and are deposited in cartilage.[3] Studies have shown that PSGAGs inhibit a plethora of degradative enzymes that contribute to the osteoarthritic (OA) process[32] and an anti-inflammatory role based on the inhibitory effects on leukocyte migration and interleukin levels.[20,39] A biosynthetic role has also been documented in terms of its stimulation of HA and collagen synthesis.[53,70]

Adequan® was originally intended for IA use; however, alterations in the complement pathway that potentiated sub-infective doses of *Staphylococcus aureus* resulted in IM administration becoming a more popular mode of administration.[34] There is less clinical data for IM use of the drug, although anecdotal reports of efficacy abound.[43] Reports in the literature reveal that IM administration of a single 500-mg dose of Adequan® in horses resulted in therapeutic levels of the drug in antebrachiocarpal, metacarpophalangeal, tibiotarsal, and distal interphalangeal joints within 2 hours of injection.[36] This was similar to a previous report examining radiolabeled IM PSGAG administration that led to measurable levels within the joints of interest for up to 96 hours; concentration also peaked at 2 hours after administration.[8] When efficacy of Adequan®, administered IM every 4 days for seven treatments, was evaluated in a full thickness cartilage defect model in ponies, no significant cartilage healing was noted.[69] Furthermore, Fubini et al. reported an inability of IM Adequan® to have a protective effect on methylprednisolone-injected joints in ponies.[26] When PSGAG (also IM every 4 days for 28 days) was used as a positive control in a carpal chip model evaluating the benefits of extracorporeal shockwave therapy (ESWT) after 70 days, PSGAG did not improve lameness scores nor produce any disease-modifying effects when synovial fluid and cartilage were evaluated.[24]

When PPS was first studied in animal models, a multimodal effect on proteoglycan preservation and production and inhibition of enzymes responsible for cartilage degradation were found.[27,29,31,51] *In vitro* studies using equine chondrocyte monolayers and articular cartilage explants indicate that both PSGAG and PPS stimulated proteoglycan production in cell monolayers; however, no difference in production was seen with cartilage explants.[21] This may suggest that common formulations might not be able to penetrate the extracellular matrix, bind chondrocytes, and stimulate proteoglycan production in the live animal.[21] While these aforementioned studies have shown inhibition of proinflammatory and degradative enzymes involved in progression of OA, other studies have not measured any significant difference.[11] When examined in the cartilage chip model,[50] significant improvement in cartilage fibrillation scores was noted in the PPS treatment group, which may indicate its benefit is likely through its disease-modifying effects.

Clinical Indications

Despite lack of scientific data to support IM administration of Adequan®, some clinicians believe that it has a beneficial effect on certain horses. In a survey of over 400 equine practitioners, IM Adequan® was one of the most commonly administered medications (not in the steroid category) in horses and was administered as a prophylactic therapy for OA.[18] The current dosing recommendations are 500 mg IM every 3–5 days for 5–7 treatments.

Data is currently lacking in the benefit of IM PSGAG administration. At this time, most veterinarians that recommend IM Adequan® do so for preventive therapy. IA use has shown greater benefit and is covered in the section regarding IA therapy. PPS has consistently shown greater benefit than Adequan® when administered IM, with current recommendations to administer 3 mg/kg IM once a week for 4 weeks.[49]

HYALURONAN

Hyaluronan (or hyaluronic acid, HA) is a large unbranched non-sulfated GAG composed of repeating units of D-glucuronic acid and *N*-acetyl glucosamine. It is an integral component of synovial fluid and articular cartilage.[23] HA actions in the synovial joint include increasing viscosity of synovial fluid, lubricating unloaded joints, restoring the rheologic properties of synovial fluid, and most importantly, inhibiting inflammation.[32,55] Many of these effects appear to depend on molecular size of the HA molecule administered, with molecular weights of $0.5–1 \times 10^6$ Da having the greatest ability of decreasing inflammation.[30]

IV administration of HA is noninvasive and a route that can be used to treat multiple joints. The benefits are most likely due to the effects in the synovial membrane because plasma half-life is less than an hour and is no longer detectable after 3 hours.[44,57] The effects of IV administration may be due to the fact that the synovial membrane is highly vascularized, which may allow greater exposure to synoviocytes than IA administration. The anti-inflammatory effects may also be due to the binding characteristics of HA to CD44 receptors present on several cell types within the synovial membrane, causing an inhibition of the expression of various cytokines.[66]

The only study to evaluate IV administration of HA in the horse used an osteochondral chip model of OA.[40] Horses treated with IV HA had reduced lameness, better synovial membrane scores, significantly lower total protein concentrations, and most importantly reduced prostaglandins in joints compared with horses receiving saline. Interestingly, HA did not have any effects on GAG content, synthetic rate, or morphologic scoring in articular cartilage, which lends credence to the theory that HA has mainly anti-inflammatory effects in joints.

VetBooks.ir

Intrasynovial injections are likely the most efficacious route of administration; however, the desire to treat multiple joints simultaneously has driven clinicians to use IV and oral preparations. Indications for IV HA are similar to those for IM PSGAGS in that IV HA reduces inflammation in one or multiple joints or prevents an inflammatory process in sport horses that are in heavy use. Although IA administration is the most effective way to deliver this drug to the joints, IA and IV administration are often concurrent. IV HA's effect is most likely through its anti-inflammatory nature and not through disease-modifying effects against the progression of OA.

In a recent review of the use of HA in all facets of clinical and benchtop research,[6] mention of the possibility of IV therapy was not made. At this time, IV use has only been evaluated in dogs and horses, and no human IV formulations exist. At this time, very little evidence-based medicine has been used to evaluate IV HA other than those listed previously. Likely, HA does have some beneficial anti-inflammatory effect, and anecdotal efficacy has been noted in our practice experience. At this time, IV HA appears to be safe, but whether true benefit is noted with its use remains to be shown.

Currently, the only labeled IV HA product on the market for equine is Legend® (Merial Inc., Duluth, GA). Current recommendations by the manufacturer include 40 mg intravenously weekly for three treatments. Another product, Polyglycan® (Bimeda, Inc., Oakbrook Terrace, IL), is licensed as a medical device and labeled for intrasynovial injection; however, it has been used off-label for IV and IM injection.[18] Although it has been used off-label, when a recent study examined its IV use, significant osteophytosis was identified on radiography in the treatment group compared with the control group in the equine osteochondral carpal chip fragment model.[25]

BISPHOSPHONATES

Bisphosphonates have been used for decades to inhibit loss of bone mass in human patients with osteoporosis associated with age or steroid administration and for rheumatoid arthritis.[12] Bisphosphonates inhibit osteoclast-mediated bone resorption,[12] a property that may play a role in conditions such as OA and navicular bone edema/sclerosis. Three studies in horses report the effects of the bisphosphonate tiludronate in clinical diseases such as navicular disease, vertebral pain related to OA of the thoracolumbar column, bone spavin, and bone loss due to cast immobilization.[13–15] All three studies reported reduced lameness, back soreness, and loss of bone with IV administration of the drug.

A second FDA-approved bisphosphonate licensed for treatment of navicular syndrome in horses, clodronate (Osphos®, Dechra Veterinary Products, Overland Park, KS), has emerged onto the market in recent years. With a similar mechanism of action to tiludronate, clodronate has also been hypothesized to be analgesic through inhibition of glutamate transport.[63]

A recent multicenter, double-blind, placebo-controlled clinical trial using clodronate showed that in horses with navicular syndrome confirmed with diagnostic analgesia and radiography, 75% saw at least one grade improvement in lameness at day 56 compared with 3% in the placebo group.[22] At day 180, 65% were still considered to have an improvement in their lameness. Clodronate has also been reported to successfully treat an acute, non-weight-bearing lameness in a horse that was diagnosed with coffin joint effusion and bone marrow edema of the second phalanx.[38] Clodronate was administered IM daily for 10 days at each recheck, and the horse's lameness improved.

More widespread use of bisphosphonates in horses has created concerns regarding their use in growing animals and in horses that have undergone therapy prior to sustaining a fracture. In one study examining healing and functional outcome in distal radial fractures in postmenopausal women undergoing bisphosphonate therapy, no significant difference was noted in healing or functional outcome between the treated and control group.[64] Other work in rabbit, dog, and sheep models, however, have mostly shown no effect of bisphosphonate therapy on fracture healing or that callus size and strength could be improved at initial stages of healing.[2,5,33,54] However, two studies noted long-term, high-dose therapy could delay healing but have no effect on mechanical integrity[46] or slow long-term callus remodeling.[48] These models all used varying bisphosphonates – incandronate, zoledronic acid, alendronate, ibandronate, and pamidronate – all of which are not currently licensed in equine medicine.

Due to the lack of available data, off-label use or use of bisphosphonates in young, growing horses cannot be recommended at this time. Further studies regarding long-term effect on bone density, ability of bone to heal after administration, and duration of action after administration are still needed.

Current recommendations for Osphos® administration are 1.8 mg/kg by IM injection with a maximum dose of 900 mg per horse (e.g. 900 mg dose standard for a 500-kg animal); recommendations to divide the dose between three sites are also given (Osphos®).[a] In a study of 146 horses, 10 horses developed mild signs of colic within the first 2 hours of treatment, but all resolved with minimal treatment.[22] For this reason, premedication with an NSAID is not recommended and, in our experience, rarely required. Due to renal excretion,[56] baseline creatinine values are recommended prior to starting a course of bisphosphonates. Concurrent administration with other nephrotoxic medications should also be avoided.

TETRACYCLINES

The anti-inflammatory effect of tetracyclines, independent of their antimicrobial role, has been well documented for multiple disease processes.[4,41,52,71] When more recently evaluated in a rodent model of acute inflammation, both minocycline and doxycycline were found to be effective through inhibition of TNF-α and nitric oxide.[45] Furthermore, and more relevant to equine practitioners, their use as disease-modifying osteoarthritic drug (DMOAD) has also been established.[7,60,65,72]

When these studies were translated to *in vitro* work with equine synoviocytes, doxycycline was noted to be chondroprotective through inhibition of specific matrix metalloproteinases (MMPs) that are known to cause

VetBooks.ir

progression of OA; their effect was also measured at a dose lower than what's required to inhibit bacterial growth.[19] Follow-up work from the same group reported that orally administered doxycycline was able to penetrate and accumulate within the synovial fluid,[62] and when administered to horses orally at 5 mg/kg every 24 hours for four doses, synovial fluid obtained from treated horses had significantly reduced MMP-13 expression.[47] At that time, the authors supported the use of doxycycline as a disease-modifying drug for OA.[47]

ESTROGEN

Estrogen therapy has been used to treat intermittent upward fixation of the patella in horses.[17] It has been hypothesized that estrogen affects muscle cell metabolism and muscle tone leading to the anecdotal benefit sometimes reported. However, no studies currently exist examining whether this therapy is beneficial as a medical treatment. Recommended therapy is 1 mg of estradiol cypionate IM for every 45 kg of body weight (i.e. 11 mg/500 kg) once weekly for 3–5 weeks.[17] Concurrent anti-inflammatories along with exercise to strengthen the quadriceps muscles are usually recommended as well.

METHOCARBAMOL (ROBAXIN)

Methocarbamol, marketed under the trade name Robaxin in the United States and Canada, is a centrally acting muscle relaxant commonly prescribed for various inflammatory and traumatic muscle disorders and to treat muscular spasms in the horse.[42] Methocarbamol produces variable results, but it seems to be most beneficial in horses that are prone to rhabdomyolysis or back soreness secondary to musculoskeletal disease of the axial skeleton or hind limbs. At our hospital, methocarbamol is commonly prescribed in conjunction with gabapentin in horses with suspected axial skeleton disease with associated secondary epaxial muscle sensitivity. Horses are treated for 4–8 weeks, while IA therapy (articular process joints, sacroiliac joint, etc.) is allowed time to improve the horse's comfort. Previous publications have reported a dose range of 4.4–55 mg/kg.[42] While an IV formulation can be obtained, oral tablets are now available for use in veterinary medicine.

GABAPENTIN

Gabapentin, an analog of γ-aminobutyric acid (GABA), has been shown to have analgesic effects through modulation of voltage-gated calcium ion channels.[28] It is used as an antiepileptic medication and for the treatment of neuropathic and chronic pain in humans.[67] Very little data exists to support its analgesic properties in animals,[1,9,61] although small numbers of case reports have found it beneficial as one component of multimodal analgesia for head shaking in temporohyoid osteoarthropathy (THO) and for chronic pain in cases of laminitis.[16,59]

At our hospital, gabapentin is most commonly prescribed in conjunction with methocarbamol to combat chronic back soreness secondary to pain associated with the axial skeleton or as a component of multimodal analgesia for musculoskeletal pain refractory to NSAID and opiate treatment. Dosages range from 5 to 20 mg/kg PO two to three times daily with dosages being titrated to effect.[37]

TOPICAL/LOCAL

Drew W. Koch and Laurie R. Goodrich

VetBooks.ir

Topical and local therapies are commonly used to treat equine musculoskeletal diseases, both acutely when inflammation is most pronounced and chronically when ongoing inflammation results in soreness and/or lameness. Although NSAIDs are commonly used orally to control musculoskeletal inflammation and intravenously in the acute stages of inflammation, clinicians often look for local modes of therapy to control associated edema and release of inflammatory mediators. The need for systemic NSAID therapy can be reduced and associated edema and tissue damage minimized with effective use of topical therapy.

TOPICAL NSAIDS

A topical formulation of diclofenac liposomal cream (DLC; Surpass®, Boehringer Ingelheim Vetmedica, Inc., St. Joseph, MO) is now approved for treatment of horses with OA.[19] The drug comes as a cream that is applied locally to areas of inflammation. Studies in horses revealed that when the drug was incorporated into liposomes, it readily penetrates skin and significantly attenuated carrageenan-induced local production of prostaglandin E_2 (PGE).[8] Furthermore, minimal concentrations of diclofenac were detectable in plasma. In a study of 24 horses that had induced OA in the middle carpal joint, application of 7.3 g of DLC twice daily (label dose) to the skin had significant improvement in lameness, significantly less carpal bone sclerosis, and overall gross cartilage erosion compared with control.[19] A study reporting the serum and urinary concentrations at 1, 2, and 4 times the recommended dose applied over 10 days revealed slow absorption and elimination of the cream. This study is a useful resource to determine withdrawal times in order to prevent an inadvertent positive drug test.[3]

In the United States, diclofenac-based topical ointments are the only labeled products for topical use in people. In the European Union, ibuprofen creams and gels, ketoprofen gel, felbinac gel and cutaneous foam, and piroxicam gel are labeled for use. One review concluded that diclofenac and ketoprofen gel displayed the most meaningful analgesia in mild to moderate cases of hand and knee OA, had few systemic adverse effects, and had modest efficacy in chronic pain.[2] However, efficacy does appear to be limited in patients with more than one joint affected by OA.[2] Currently, diclofenac is the only NSAID labeled for topical use in horses and has modest data to substantiate its use in decreasing pain associated with synovitis in horses. No studies evaluating its use in chronic OA in horses have been documented.

Clinical Use

Surpass® is used commonly in clinical practice. It can be used under a bandage, and there are currently no reported adverse effects. Although the dose is 7.3 g BID, some clinicians use this drug once daily or every other day for less acute inflammation. It is used for OA, tendinitis, and various musculoskeletal inflammatory conditions. Concurrent use of this product with systemic NSAIDs is common and seems to be very effective for a variety of inflammatory conditions.

TOPICAL FIRST AID (COLD THERAPY AND BANDAGING)

With acute inflammation associated with tendon injury or joint trauma (capsulitis, synovitis), initial cold therapy using ice boots, cold water hosing/hydrotherapy, or medical devices that provide cold therapy and compression (Game Ready®, Alameda, CA) are useful therapies. Cold compression in the early stages of inflammation retards the inflammatory processes of exudation and diapedesis and reduces local circulation, tissue swelling, and pain.[23,33] The application of cold therapy as a primary treatment for most acute joint or tendon injuries is commonly practiced and is extremely beneficial. Following an initial cooling out phase, usually 48–72 hours, warm hydrotherapy is often used to relieve pain and tension in tissues and stimulate the vasodilatory effect to aid with fluid resorption and the stimulation of phagocytic cells.[33] These effects aid in increased local circulation, encourage muscle relaxation, and improve the metabolic rate of reparative cells and enzyme systems.[23]

Bandaging and pressure wraps are also commonly used to decrease edema formation and generalized swelling that results from inflammatory mediators released from the torn tendon or joint capsule. Further benefits may include stimulation of mechanoreceptors that aid in reduction of pain sensation.[33] Recent work has compared a standard cotton compression or light adhesive tape bandage at multiple sites and the effect of walking on pressure maintenance.[9] Cotton compression bandages applied to the limb below the carpus maintained their pressure, while those applied directly over the carpus and tarsus quickly lost pressure after walking a short distance. Light elastic bandages over the carpus, however, maintained their pressure after walking. Double-layer cotton compression bandages nor the addition of the "inner sanctum" to a standard cotton compression bandage at the distal limb did not improve bandage pressures any further. The authors concluded that modifications to the standard cotton compression bandage were of no additional benefit, while light elastic bandages over the carpus were resistant to pressure changes with ambulation and may be adequate for edema reduction.[9]

A survey of equine veterinary groups revealed that multiple modalities are used across both North America and Europe to combat injury and performance issues

VetBooks.ir

associated with musculoskeletal injury.[44] Controlled hand walking, therapeutic shoeing, ice, compression bandaging, platelet-rich plasma (PRP), therapeutic exercises, interleukin-1 receptor antagonist protein (IRAP), stretching, and cold water therapy were used by over 80% of respondents; to a lesser degree, heat, acupuncture, and massage were also used.[44] Use of these modalities is dictated by ease of use, whether specific personnel are required for their application (e.g. a licensed veterinarian) and time commitment. While evidence-based medicine for their benefit is lacking for many of these modalities, anecdotal beneficial effects have kept many of them within the armamentarium of both equine veterinarians and horse owners alike.

DIMETHYL SULFOXIDE

The chemical solvent dimethyl sulfoxide (DMSO) has been used alone or mixed with corticosteroids to treat soft tissue swelling and inflammation resulting from acute trauma.[33] Its main benefit is considered to be reduction of edema;[45] however, some work has suggested analgesia through blockade of C-fiber transmission and/or blocking sensory neurons.[16,41] Additionally, DMSO has been shown to possess superoxide dismutase activity and inactivate superoxide radicals. Further, the drug enhances penetration of percutaneous steroid when mixed with DMSO, and when cortisone was dissolved in DMSO, the dilution of cortisone necessary to stabilize lysosomes was reduced from one-tenth to one-thousandth.[45] If applied under a bandage, it should be used with caution due to its predilection in causing skin irritation.

The pharmacokinetics of DMSO in the horse has been established.[38] However, studies investigating the anti-inflammatory or analgesic effect in horses or companion animals are still lacking. Continued use in the horse without objective data of its efficacy is likely.

EXTRACORPOREAL SHOCKWAVE THERAPY

Extracorporeal shockwave therapy (ESWT) is used by veterinarians to treat many different musculoskeletal conditions in horses. Extracorporeal shock waves are acoustic waves generated outside the body, characterized by transient high peak pressures, followed by negative pressure, and then return to zero pressure. Pressures reached by current equipment range from 10 to 100 MPa with a rapid rise time of 30–120 ns and a short pulse duration (5 μs). Other variables include energy level, pulse frequency, and depth of penetration. Originally designed to treat bladder and ureteral stones (lithotripsy), it has also been used to treat horses with suspensory ligament desmitis, OA of the low-motion joints of the tarsus and dorsal metacarpal disease.[29,32]

The exact mechanism of action that ESWT has on specific tissues has yet to be determined. Through its ability to cause cavitation, or the rupture of gas bubbles within the tissues, it is postulated that it has effects on the tissues that are influenced by pressure, energy flow, and pulse frequency of the machine generating the waves.[32] Work in laboratory animals has demonstrated various dose-dependent effects, including microfracture of the cortical bone, medullary hemorrhage, subperiosteal hemorrhage, and stimulation of osteogenesis. Work in tendons has also demonstrated various dose-dependent effects from hematoma formation and tendon cell damage to increased glycosaminoglycan and protein syntheses.[7,31] Analgesic properties attributed to ESWT have also long been recognized, and concerns over its use at racetracks have stimulated debate due to its abilities to reduce or eliminate pain from an injury that may become catastrophic if the horse continues to race. Two studies have been performed in the equine that have detected decreases in nerve conduction properties.[6,32] One of those studies reported observations of significant disruption of the myelin sheath with no evidence of damage to Schwann cell bodies or axons following treatment with non-focused ESWT.[6] Further, bone effects have also been documented in the horse in which both focused and radial shockwaves resulted in an increase of microcracks on the dorsal surface of the third metacarpus and metatarsus.[11]

Several musculoskeletal conditions in horses have been treated with ESWT including the bucked shin complex, tibial stress fractures, proximal sesamoid bone fractures, incomplete proximal phalangeal fractures, subchondral bone pain, insertional desmopathies (most notably proximal ligament suspensory desmitis), impinging dorsal spinous processes, OA of the distal hock joints, navicular disease, and superficial digital flexor tendonitis.[31] Clinical trials have been inconclusive in the horse because the type of machine used varied as well as the energy levels, pulse frequency, depth of penetration, and number of treatments.

One of the most common clinical entities in which shockwave therapy has been utilized is proximal suspensory ligament desmitis. Data from clinical trials in both Germany and the United States revealed a 70%–80% success rate of return to work 6 months following focused or radial shockwave therapy.[31] Other work, however, reported return to work at 6 months to be more in the range of 55%–60%, and follow-up at 1 year showed much worse prognosis, especially for hind limbs.[28] Another popular use of shockwave therapy is in the treatment of navicular syndrome. In a clinical model of induced OA in the middle carpal joint of horses, no disease modification was seen with ESWT. Significant improvement in analgesia was observed in horses.[18] Most likely, this effect is due to the nerve sheath alterations observed in other studies.[6]

Use of ESWT will most likely continue in equine practice due to anecdotal evidence of its use in proximal suspensory ligament desmopathy and improvement in lameness scores in horses with induced OA. To this day, large clinical trials are still lacking. With the advent of a specialty college focused in rehabilitation medicine, controlled studies to validate the appropriate use and ideal settings, units, and specific diseases that will benefit from this treatment modality are much more likely to occur.

REGIONAL PERFUSION

Intravenous regional limb perfusions (IVRLPs) of the equine limb have become a standard of equine veterinary medicine over the last decade, with a multitude of

VetBooks.ir

publications within the veterinary literature investigating the ideal medication, concentration, and method of application for their use in a variety of disease processes. Nomenclature from early work in both human and veterinary medicine, however, made specific route of medication delivery difficult to ascertain. Those first to perform "regional limb perfusions" did so through direct antibiotic delivery within the medullary cavity in an effort to allow retrograde flow into the venous system to perfuse the limb (see below). In many instances, these were often referred to as intravenous therapy. However, today, most regional limb perfusions (RLPs) traditionally use a peripheral vein – and at times an artery – for application of intravascular therapy, while intramedullary application is seldom utilized.

Our understanding of IVRLPs has grown dramatically over the last several years. Current recommendations for antibiotic administration vary from tourniquet times of 10–30 minutes[24] and perfusate volume of 10–60 mL[22] and typically include an aminoglycoside – and more specifically amikacin – as the class of antibiotic administered due to their concentration-dependent and post-antibiotic effects.[10,21,22,24,30,35,40] Many other classes of antibiotics have been explored[12,26,36] but are likely poor candidates due to insufficient time above minimum inhibitory concentration (MIC) to cause beneficial effects.[35] RLPs have also been used in horses to provide distal limb contrast for MRI,[1] for mesenchymal stem cell therapy,[39,42] and for anti-inflammatory and antifungal treatment with DMSO and amphotericin B to combat pythiosis.[13,14] When multiple antibiotics have been used in combination or antibiotics with a local anesthetic, a reduction in antibacterial efficacy has not been measured.[10,12]

THERAPEUTIC ULTRASOUND, LASERS, AND ELECTROMAGNETICS

The use of therapeutic ultrasound, lasers, and electromagnetics is common in the horse industry. Horse owners that have done extensive investigation on the Internet where anecdotal reports abound will frequently request equine clinicians input on this therapy. Therapeutic ultrasounds emit unfocused sound waves that may have the potential to penetrate underlying tissues. The exact mechanism of action is unknown, but purportedly, thermal energy is produced as the sound energy contacts the tissues. *In vitro* studies have reported alterations in blood flow, angiogenesis, collagen and protein synthesis, and osteogenesis. Clinical trials have shown conflicting results in treating tendon injuries. Therapeutic ultrasound did not improve muscle regeneration in injured tissue nor alleviate chronic heel pain in people.[5,15] One trial in horses reported improved healing characteristics 4 and 6 weeks following tendon injury.[34] Until more clinical trials become available, use of this treatment will remain empirical.

Therapeutic laser therapy is based on light that is emitted from the instrument, which is a focused beam of photon energy. The power output of lasers used in physical therapy is in the milliwatt range (low). Mechanisms of action of therapeutic lasers are thought to include alterations in mitochondrial enzymes, cytochromes within the electron transport chain, and cellular calcium channels.[5] Cellular alterations may trigger mitosis and cellular proliferation, which may have biomodulatory effects on circulation and analgesia. Classification of lasers is defined by wattage output. Most used in clinical practice fall into the class IIIb criteria, which are those that emit power of 5–500 mW.[27] When used in a therapeutic setting, these lasers are commonly referred to as low-level laser therapy (LLLT) or cold lasers because their use does not generate noticeable heat to the patient. Class IV lasers are of greater wattage and have started to find their place on the human and veterinary market for treating injuries deeper within the body due to their higher output.[27]

A previous study examining its use of LLLT in the treatment of wounds in the horse showed no benefit.[37] The only benefit that has been shown in the horse is through the application of LLLT in the treatment of periodontal defects. Furthermore, when LLLT was used for treatment of surgically created wounds in dogs, no improvement in subjective healing nor wound size was observed compared with control groups.[20]

Magnetic and electromagnetic therapy remains a controversial subject. A large amount of anecdotal information is available, especially by equipment manufacturers. Ironically, this information is highly available to lay horseman, despite a lack of technical information, understanding, and directions for use. In general, an electromagnetic field is created by passing an electric current through a coil of insulated wire. When piezoelectrical properties of bone where discovered, evidence became available, which supported the use of electromagnetic fields on bone healing.[5] Limited studies are available in horses. Some benefit in fracture healing was observed after 2 hours of daily therapy.[4] Conversely, pulsed electromagnetic field therapy delayed tendon healing in experimentally created defects in the superficial digital flexor tendon (SDFT) in horses.[43] In a rabbit study, however, beneficial effects were demonstrated in tendon healing.[17] Since the last edition of this book, more recent work in human medicine has shown an added benefit when electromagnetic therapy was used in combination with shockwave therapy in rotator cuff tendinopathy.[25] However, no further elucidation on mechanism of action has been published, nor any further evidence-based studies performed in equine medicine. As with therapeutic ultrasound and therapeutic laser therapy, magnetic therapy applications will most likely continue to be touted by the lay horseman until clinical trials are available to prove or disprove efficacy.

COUNTERIRRITATION

Topical blistering and pin firing have long been part of veterinary medicine, but fortunately, they are rarely practiced today due to the lack of clinical data as well as their inhumane ramifications. They are mentioned in this section only to acknowledge their common usage in the past. Topical blisters historically were made of iodine or mercuric iodide and were mainly used on splints, sore shins, or curbs. More severe blistering agents were made from cantharides or croton oil. The technique involved application to the skin and light exercise.

VetBooks.ir

Firing most typically involves the use of a pinpoint hot iron applied to the skin over the affected structure. Most commonly, firing is used for bucked shins and plantar ligament desmitis (curb) when the condition has not responded favorably to other forms of treatment. The expectations that counterirritation may result in an improved fiber pattern with crimp and collagen within tendons are curious at best. Beyond enforced rest and low-grade exercise, the benefits of the treatment on underlying structures are most likely minimal or nonexistent. Occasionally, the technique continues to be used, but with the retirement of veterinarians who commonly utilized this method, it is seldom practiced. At this juncture in veterinary medicine, when a greater push for evidence-based medicine is becoming standard, counterirritation has little evidence to support its use, is antiquated, and can no longer be recommended.

INTRASYNOVIAL

Lauren E. Smanik and Laurie R. Goodrich

VetBooks.ir

Intrasynovial therapies are used to diminish the inflammatory response in synovium, cartilage, tendon (or tendon sheath), or meniscus. An effective therapy should halt progression of degradation of these structures and restore the normal intrasynovial environment, which should alleviate pain. Equine practitioners currently have several options available to treat intrasynovial inflammation. Intrasynovial therapies, specifically corticosteroids, are used frequently in horses to minimize or control pain associated with synovitis and osteoarthritis (OA).[20] New therapies are also beginning to be used intrasynovially as potential disease-modifying agents of osteoarthritis (DMOAD); their reputed properties are prevention, retardation, or reversal of morphologic cartilaginous lesions of OA. While claims of these properties exist, evidence-based clinical studies about their true abilities to reverse OA are still in their infancy. The intrasynovial therapies covered in this section are the most commonly used treatments currently available for equine practitioners.

CORTICOSTEROIDS

Corticosteroids (CS) are the most potent anti-inflammatory drugs available that decrease the catabolic effects of joint disease. Historically, their use has been highly controversial due to the negative effects associated with overuse and high dosages utilized in the past.[78] Current clinical studies suggest judicious use of CS may be extremely beneficial and can result in long-lasting pain relief and control of inflammation.[36,66]

Mechanism of Action

CS have powerful inhibitory effects on inflammation through stabilization of cellular lysosomal membranes, reduction of vascular permeability and leukocyte adherence to vessel walls (margination), inhibition of platelet aggregation, and leukocyte diapedesis. Furthermore, they inhibit prostanoids and nitric oxide, mediators integral to the progression of osteoarthritic lesions.[9,56] CS are considered to be disease modifying through their actions on the abrogation of important mediators of inflammation, interleukin-1 (IL-1), and tumor necrosis factor-α (TNF-α). Degradative enzymes such as matrix metalloproteinases (MMPs) and other related proteinases are also decreased through the actions of CSs which alters the progression of an inflamed joint toward osteoarthritic conditions.[27,60]

Detrimental Effects and Concerns Regarding Intra-Articular Corticosteroids

The literature is replete with reports describing the deleterious effects of CS on cartilage. They include decreased chondrocyte size, loss of glycosaminoglycans (GAGs) and decreased GAG synthesis, inhibition of proteoglycan synthesis, chondrocyte necrosis, and hypocellularity.[14,25,61,103] Particularly at high concentrations, CS inhibit production of important components of cartilage such as proteoglycans, collagen, and hyaluronic acid, and furthermore result in chondrocyte necrosis.[25,111] It is believed the high concentration and extended exposure used in earlier studies resulted in the detrimental effects of CS on cartilage. As more realistic clinical models have emerged, such detrimental effects are less noted, and more cartilage-sparing effects have been observed with use of low-dose CS.[66,89] The emerging stand by many clinicians seems to be that intra-articular (IA) steroids can be extremely beneficial when used judiciously. This has been supported in the human literature as well, which has shown that CS have a time- and dose-dependent effect on articular cartilage, with beneficial effects occurring at low doses (<2–3 mg/dose or 8–12 mg/cumulative total dose) and durations and detrimental effects at high doses (>3 mg/dose or 18–24 mg/cumulative total dose) and durations.[117]

Postinjection flare associated with CS use in the horse is rare and usually self-limiting but associated with some discomfort, necessitating nonsteroidal anti-inflammatory drug (NSAID) therapy. The inflammation is believed to be caused by the microcrystalline characteristics of CS preparations, as well as the dose and particular ester that is injected; however, the incidence of postinjection flare has decreased with the advent of branched-chain esters.[113] More concerning is the potential for infection following CS injections, and a reaction to medication should be treated as a septic process until proven otherwise. While the incidence is low, 1 case per 1,279 joints injected in one study,[106] the occurrence of infection can be devastating and expensive to treat; therefore, strict adherence to aseptic technique is mandatory, and the combination with an antimicrobial is commonly practiced.

It is important for practitioners to be aware that CS injections associated with sepsis may take up to 10 days to become apparent due to their powerful anti-inflammatory properties. When faced with determining between a CS flare and joint sepsis, a synovial aspirate should be performed to determine a leukocyte count and differential consistent with bacterial infection. Clinicians should bear in mind that CS can falsely lower white blood cell count post-CS injection.

Laminitis has been associated with CS administration, and although rare, its occurrence subsequent to IA steroids can be devastating. In a study in which 205 horses were injected with triamcinolone at a dosage between 10 and 80 mg/treatment, only 2 of 205 horses developed laminitis, and 1 of those cases was considered unrelated to the treatment because the laminitic event occurred several months following the treatment. This study reveals the low incidence of this complication,[80]

VetBooks.ir

with earlier studies and anecdotal reports suggesting a total cumulative dose of less than 18–20 mg triamcinolone acetonide (TA) to be safe.[13,50]

Finally, there has been concern regarding the use of CS in Thoroughbred racehorses due to a positive correlation between local corticosteroid injections (LCIs) and subsequent musculoskeletal injury rates, most likely due to progression of the condition that prompted treatment.[118] A retrospective cohort study comparing the rate of musculoskeletal injury among Thoroughbred racehorses after receiving LCI to those not being treated with LCI reported a 3.3–4.6 times greater incidence rate of musculoskeletal injury in treated versus untreated horses; however, due to study design, a direct assessment of the independent effect of LCI could not be performed.[118] The risk of musculoskeletal injury in that study also appeared to rise with subsequent treatments, with the carpus and fetlock joints being at the highest risk of injury post-medication.[105,118]

Another study investigating the association between intrasynovial medication and fracture risk in racehorses reported serious musculoskeletal injuries in 3% (44/1,488) of horses following intrasynovial medication, with ≥3 previous intrasynovial medication sessions resulting in an increased hazard of sustaining a fracture within 56 days of treatment.[105]

While additional research regarding the relationship between intrasynovial use of CS and the risk of subsequent musculoskeletal injury is still warranted, the greater hazard of injury identified in the current literature is more likely dependent upon identifying horses at risk for musculoskeletal injury rather than a direct adverse effect of the CS.[118] Therefore, a thorough examination, including diagnostic imaging, should be performed to determine whether to treat a problem with LCI and continue to train and race the horse.

Clinical Choices

Despite decades of CS use to treat IA inflammation in the horse, the choice of formulation, dose, and frequency of administration remains somewhat empiric. Currently, the most commonly used formulations are TA, methylprednisolone acetate (MPA), and betamethasone acetate (BA).[30] Less commonly used CS include isoflupredone acetate and flumethasone. In a survey of more than 400 equine practitioners, TA was found to be more commonly used in high-motion joints and MPA in low-motion joints.[30]

Clinicians currently use lower dosages of CS than in the past because they seem to result in similar inhibition of inflammation with fewer detrimental effects on cartilage metabolism. Doses vary depending on the volume of synovial fluid in the joint, severity of inflammation, and the number of other joints requiring treatment. The formulations in Table 8.1 represent currently used CS and the associated dosages most commonly administered.

Triamcinolone Acetonide

Both *in vitro* and *in vivo* studies have demonstrated that low doses of TA can inhibit degradative metalloproteinases with minimal negative effects on extracellular matrix of cartilage.[42,97] Studies suggest that a dose of 6–12 mg/joint should be adequate for anti-inflammatory effects, with one study demonstrating that 12 mg of TA administered twice, 2 weeks apart, minimized the development of OA secondary to osteochondral chip fractures.[42] These effects were also noted in the contralateral joint, and subchondral bone remodeling or fragility was not detected.[66] Another study provided further evidence for the anti-inflammatory effects of IA TA (9 mg dose) with significant changes in inflammatory gene expression; however, downregulation of collagen gene expression was also observed and warrants the careful use of TA in horses.[70]

In contrast, 12 mg of TA administered at 3, 5, and 7 weeks into normal joints significantly altered cartilage metabolism both in injected and remote joints.[22] Although the joints in this study were not inflamed, it emphasizes that TA may change regulatory processes important in cartilage metabolism both in the injected joint and remote joints. The remote effects of TA have not been observed with other CS.

Additionally, an intrasynovial structure may be injected with a CS and anesthetic as a combination of treatment and diagnostic aid. Recently, a study found that the combination of TA and mepivacaine does not alter the potency or duration of TA's action.[67]

Methylprednisolone Acetate

MPA has been studied extensively both *in vitro* and *in vivo*. Various beneficial and detrimental effects have been noted in cartilage, subchondral bone, and synovium.[21,29,97] Beneficial effects of MPA include reduction in the transcription of harmful molecules such as

Table 8.1. Commonly used intra-articular corticosteroids.

Corticosteroid	Trade name	Manufacturer	Drug conc. (mg/mL)	Dose (mg)	Duration of action
Triamcinolone acetonide	Kenalog-10 Vetalog	Bristol-Myers Squibb Boehringer Ingelheim	10 6	6–18	Medium
Methylprednisolone acetate	Depo-Medrol	Zoetis US	40 or 20	40–100	Long
Betamethasone acetate/ sodium phosphate	Celestone Soluspan BetaVet	Merck Inc. Luitpold Pharmaceuticals	6	3–18	Medium to long

VetBooks.ir

IL-1β, TNFα, MMPs, and others that directly cause matrix degeneration. Harmful effects include chondrocyte necrosis, inhibition of proteoglycans, and procollagen synthesis.[77,112] The dose of MPA seems to predict the fine balance between inhibition of inflammation with overall beneficial effects of the joint or destruction of matrix and disruption of normal cartilage metabolism. Studies regarding what level of MPA inhibits the destructive cascade of inflammation while preserving the normal joint environment are still ongoing.

Studies suggest that more physiological doses of between 10 and 40 mg/joint inhibit inflammation and preserve normal joint environment.[29,84,111] Furthermore, it has been suggested that the propensity for matrix changes tends to occur immediately following injection (softening), with inhibition of biosynthesis and evidence of matrix damage seen after intense exercise (running) within 6 days' post-MPA; therefore, it is recommended that horses be prohibited from applying excessive loads (exercising at more than a trot) for 6 days after injection with MPA.[29]

In contrast, a study performed in equine middle carpal joints found that microhardness of subchondral bone did not change with repeated injections of MPA and treadmill exercise; however, this study was done in normal joints.[85] One study in horses that had osteochondral fragments induced in the middle carpal joints, had MPA injected at 100 mg, and underwent exercise on a treadmill not only revealed lower prostaglandin E_2 (PGE_2) levels but also exhibited articular cartilage erosion and morphologic lesions associated with IA MPA.[43] In a survey of more than 400 practitioners regarding the use of CS, 75% revealed that they use MPA in low-motion joints, 36% use a dose of 20–40 mg, and 44% used 40–80 mg/joint injection.[30]

Betamethasone

Similar to MPA, betamethasone (BA) is considered an intermediate-to-long acting glucocorticoid, with intrasynovial levels falling below the level of detection between 14 and 21 days after a single IA injection (9 mg).[69] One clinical study that utilized the osteochondral chip model in the middle carpal joint with 15.9 mg of BA administered to the joint at 2-week intervals followed by treadmill exercise revealed no statistically significant differences between treated and control joints at 56 days, but there were trends toward decreased GAG staining in treated joints.[36] Despite these findings, *in vitro* work still indicates potential detrimental effects as measured by suppressed proteoglycan synthesis at medium to low physiological doses.[41] Collectively, the scientific literature on BA demonstrates time- and dose-dependent deleterious effects on articular cartilage and chondrocytes, with chondrotoxicity, loss of cartilage proteins, and progressive gross damage observed at higher doses.[117]

HYALURONAN

HA, or hyaluronan, is a large, unbranched, non-sulfated GAG composed of repeating units of D-glucuronic acid and *N*-acetyl glucosamine and is secreted by the type B synoviocytes of the synovial membrane.[63,95] HA serves various important functions in the joint, such as viscoelasticity to the joint fluid and boundary lubrication of the IA soft tissue. HA may also influence the composition of synovial fluid through steric hindrance of active plasma components and leukocytes from the joint cavity.[63] Furthermore, HA appears to modulate the chemotactic response within the synovial membrane by reducing cell migration and decreasing rates of diffusion and flow of solutes.[62]

HA is locally synthesized by chondrocytes and is the backbone of the proteoglycan aggregate in the extracellular matrix. The compressive stiffness in articular cartilage depends on the integrity of the matrix proteoglycans.[52]

Mechanism of Action

Although the exact mechanism of action is unclear, studies suggest that exogenously administered HA supplements replace the actions of depleted or depolymerized endogenous HA in the synovial fluid, which restores viscoelasticity, steric hindrance, and lubrication of the articular soft tissues. *In vitro* studies suggest additional effects, including the ability to inhibit macrophage chemotaxis, reduce lymphocytic ability to proliferate and migrate, reduce the formation and release of prostaglandins from macrophages during phagocytosis, and scavenge oxygen-derived free radicals and degradative enzymes.[10,37,52,92] Equine synovial fluid exhibits poor lubrication properties within the acute postinjury phase, with diminished concentration and molecular weight of HA suggested as the cause.[5] HA also possesses direct analgesic properties that seem to be partially attributable to reductions in the sensitivity of articular nerve endings.[20,54] Furthermore, it is suspected that exogenous injection of HA into osteoarthritic joints increases synthesis of high molecular weight HA by the synoviocytes.[63]

Many clinical studies in horses have supported HA administration in joint disease.[6,7,46,76,98,99] While the criteria for treatment success vary, the overall clinical impression is favorable. Inherent to clinical trials, duration of posttreatment observation periods is varied and short in some studies. Nevertheless, parallel clinical trials in people also indicate symptomatic efficacy measured by improvement in pain, activity level, and function, especially following use of high molecular weight products.[2]

Molecular Weight and Efficacy

The controversy continues regarding efficacy and molecular weight of high versus low molecular weight HA. Proponents of the viscosupplementation theory believe higher molecular weight products are more effective,[90] while others minimize this importance of size and suggest the activity of HA is mediated pharmacologically rather than physically.[8] A study evaluating the effects of joint injury on the boundary lubrication properties of synovial fluid found that relative to normal equine synovial fluid, there was diminished concentration and molecular weight of HA in equine synovial fluid from joints with acute injury.[5] This same study also showed restoration of the boundary lubrication function of the synovial fluid following *in vitro* supplementation with

VetBooks.ir

[b] Marketed for IV and IA use.

high molecular weight HA. There was no significant difference in HA molecular weight between synovial fluid from normal joints and those with chronic injury. Table 8.2 lists commonly used HA products, their molecular weights, and current recommended dosages.

HA can be expensive for owners, and therefore, use in joints with advanced disease may yield less satisfying results compared with joints with incipient disease. This is consistent with human medicine, where people with less severe joint disease demonstrate greater improvement to IA HA compared with those with more advanced radiographic changes.[114]

CORTICOSTEROID AND HA COMBINATIONS

The combination of HA and steroids to treat inflammation intrasynovially is commonplace.[15,26,74] Synergistic effects have been reported in human patients, and similar effects have been seen *in vitro* in horses.[75,119] Many clinicians believe that the combination allows a smaller dose of CS to be administered with the HA, although further clinical studies are needed to determine efficacy of combinations. The combination of HA and CS is also thought to provide a longer clinical effect than either injection alone, especially in high-motion joints.

A recent open-label multicenter clinical trial involving 80 horses with clinical joint disease found that the IA combination of 12-mg TA and 20-mg HA was associated with a lower short-term success rate (64.1%) compared with 12-mg TA alone (87.8%).[55] In this study, short-term success was defined as greater than or equal to a 2-grade reduction in lameness (0–5 scale) 3 weeks after injection. Furthermore, this reduction in short-term success rate for the combination treatment group was associated with advanced age (≥13 years). This same study revealed no significant difference in medium-term outcome (3 months' posttreatment), with approximately 50% of horses returning to their previous level of exercise regardless of treatment group. The reason for the difference in the observed outcome is unknown.[55] One speculation includes the presence of unknown drug interactions; however, further evaluation of the combination of HA and TA is warranted. At this time there is minimal clinical evidence to support combining HA and TA in horses.

IA POLYSULFATED GLYCOSAMINOGLYCANS

Polysulfated glycosaminoglycans (PSGAGs) principally comprise chondroitin sulfate, a GAG found in the aggregating proteoglycan of cartilage. It is a semisynthetic preparation from bovine trachea and is reported to have chondroprotective and anti-inflammatory properties as well as the ability to induce articular cartilage matrix synthesis and minimize matrix degradation.[110]

Mechanism of Action

The exact mechanism of action remains unclear. The drug most commonly is administered intramuscularly as IA administration was initially associated with joint infections due to a reduction in complement activity in the joint. IA administration is now most commonly combined with 125–250 mg of amikacin to deter any infection, and this practice appears to be effective.

Many *in vitro* studies mimic the IA administration of PSGAGs because it is unlikely that concentrations injected intramuscularly can translate to similarly elevated concentrations in the joint fluid. *In vitro* studies and *in vivo* IA administration have revealed a significant ability of the drug to decrease lameness, modify OA through reducing bone remodeling, promote synthesis of endogenous HA, and inhibit mediators of inflammation, specifically PGE_2 production. Additionally, it has been found to reduce the levels of MMPs that rise in response to production of IL-1β.[20,49,52] Most recently, IA PSGAGs were compared with HA in an osteochondral chip fragment model. While HA significantly reduced fibrillation of the cartilage, PSGAGs were demonstrated to reduce joint effusion and reduce synovial membrane

VetBooks.ir

vascularity and subintimal fibrosis compared with control horses when the drug was administered weekly for 3 weeks.[46] However, neither PSGAGs nor HA had a beneficial effect on lameness. It was concluded that in the osteochondral fragment model, both drugs had beneficial disease-modifying effects. Furthermore, in a study that compared PSGAGs with IA CS (MPA 40 mg), a regimen of weekly IA PSGAGs for three treatments gave significantly improved results (67%) compared with one treatment of CS (46%) in terms of returning horses to performance.[73] It has also been suggested that, using the osteochondral fragment model, the IA combination of TA (5 mg) and PSGAG (250 mg) is less effective than IA PSGAG used alone when administered at weekly intervals for five treatments.[48]

Clinical Considerations

PSGAG is most likely more efficacious if administered IA; however, due to the drug's ability to potentiate sub-infective doses of contaminant bacteria, this route of administration should be accompanied with amikacin in order to obviate this risk.[57,58] Currently, the approved frequency of IA administration is three to five injections (250 mg each) at weekly intervals.[1,93] It may be most efficacious in joints with known or suspected articular cartilage pathology.[1]

POLYGLYCAN®

Polyglycan®, which is not yet licensed for use as an IA medication, is a patented formulation composed of HA, chondroitin sulfate, and *N*-acetyl-D-glucosamine and has been used clinically in horses IA for viscosupplementation. This product is currently used extensively in equine practice; however, only one randomized blinded placebo-controlled study has been performed to assess its efficacy. Using the OA osteochondral fragment model of the middle carpal joints, horses that received Polyglycan® IA (5 mL) at days 0, 7, 14, and 28 showed significant improvements in lameness, bony proliferation, and degree of full thickness articular cartilage erosions observed grossly.[47] Treatment with Polyglycan® resulted in a mild transient reduction in lameness throughout the study, with the greatest improvement (30% reduction) noted on day 42. When compared with the use of HA alone in one *in vitro* study, cells treated with HA had significantly better morphology scores; however, Polyglycan® resulted in superior suppression of lipopolysaccharides (LPS)-induced production of proinflammatory cytokines, providing further support for its protective potential.[68]

AUTOLOGOUS CONDITIONED SERUM

Autologous conditioned serum (ACS, also called interleukin receptor antagonist protein, IRAP) has been used extensively in practice to treat intrasynovial inflammation, especially in cases that are refractory to IA CS. Although clinical impressions have been favorable, this method of treatment is not widely used due to cost. IRAP, a substance that inhibits IL-1 activity, decreases the progression of joint disease and is believed to be present in high amounts in ACS.[45] Specifically, it has been reported that production of IL-4, IL-10, IRAP, and other growth factors is stimulated through incubation of whole blood with medical-grade glass beads exposed to chromium sulfate.[82]

A study in which ACS was injected into the middle carpal joints on day 14, 21, 28, and 35 following induction of OA through a chip fragment model revealed significant clinical improvement in lameness and reduced gross cartilage fibrillation and synovial membrane pathology.[45] This same study detected elevated levels of IRAP in the synovial fluid of the horses injected with ACS at 70 days' post-OA induction.[45] Clinical trials in humans with OA have indicated that people injected with ACS experienced greater reduction in clinical signs and improved quality of life compared with people whose joints were injected with HA.[11,116] Significant pain reduction has also been seen following treatment of patients with varying degrees of hip OA with ACS alone, with no increase in beneficial effects seen when ACS was combined with cortisone or cortisone + recombinant IRAP (rIRAP).[12] Use of this medication requires incubation of equine serum with beads coated with chromium sulfate to obtain the ACS solution. The ACS is usually administered IA weekly for three to four treatments, depending on the quantity of ACS obtained. Treatment with ACS prior to injection of other biologic agents is increasing in practice, although further clinical trials are necessary to evaluate the benefits and effectiveness of this technique.

PLATELET-RICH PLASMA

Platelet-rich plasma (PRP) is an increasingly popular intralesional therapy used in equine practice to enhance the regeneration of injured tissues with poor healing capabilities (i.e. limited blood supply). However, IA use of PRP has recently emerged as a potential treatment of OA both in humans and horses.[19,33,34,39,71,83,94,101] PRP is a platelet-concentrated, autologous blood product created through various centrifugation processes that delivers increased platelet-derived growth factors (PDGF) to the site of injury.[40,107] Various cytokines detected in PRP that can potentially promote healing include transforming growth factor-β (TGF-β), PDGF, insulin-like growth factor (IGF-I, IGF-II), fibroblast growth factor (FGF), epidermal growth factor, vascular endothelial growth factor (VEGF), and endothelial cell growth factor.[40] *In vitro*, PRP has been shown to induce chondrogenesis by stimulating proliferation of chondrocytes and extracellular matrix synthesis of proteoglycans and type II collagen,[3] to induce chondroprotection by increasing the production and secretion of HA from synoviocytes,[4] and to inhibit inflammatory processes in chondrocytes.[19]

Due to the limited number of *in vivo* studies, IA PRP is not yet a standard treatment for OA but has shown potential as a therapeutic option in refractory cases. In both horses and humans, IA PRP appears to incite an acute, short-term inflammatory response within the injected joint;[83,94,104,107] however, studies evaluating its use in healthy equine joints have found IA PRP to be safe without long-term detrimental effects.[83,101,107] One clinical study evaluated PRP for the treatment of refractory

VetBooks.ir

OA in endurance horses and reported that 80% of horses were able to return to regular work following treatment.[91] While largely positive, variable results have also been reported in the human literature.[33–35,40,71,94,96]

AUTOLOGOUS PROTEIN SOLUTION

Autologous protein solution (APS, Pro-Stride®) is a newly developed, modified blood product generated from a dual-device system that concentrates plasma and WBC proteins and enriches platelet growth factors. APS is meant to achieve the goals of both ACS (IRAP) and PRP through a two-step centrifugation process.[17] This process separates a small volume of plasma concentrated with platelets and WBCs, which is then filtered through polyacrylamide beads to desiccate and further concentrate growth factors and plasma proteins.[17] Additionally, APS can be drawn, processed, and injected stall side without the need for incubation or processing.

A prospective, randomized, placebo-controlled clinical trial that evaluated the efficacy of a single IA injection of APS in horses with OA in various high-motion joints found that treated horses had significant improvements in lameness grade, asymmetry indices of vertical peak force, and range of joint motion by 14 days' post-treatment.[17] In this group of horses, APS had a greater likelihood of a therapeutic response in horses with a lameness score <4, <10% vertical force asymmetry, or absence of marked osteophyte formation, subchondral sclerosis, or joint space narrowing.

Current research on APS in horses has been limited; however, the benefits described in the previous study have been validated in both canines and humans. In a study of 21 dogs with OA of the stifle or elbow, a single injection of APS resulted in reduced pain and lameness scores and increased weight-bearing associated with the OA-affected joint at 12 weeks' postinjection.[115] A study involving 41 human patients that received a single injection of APS for knee OA showed significant clinical improvement in pain scores as well as reduction in bone marrow lesion size on MRI and osteophyte formation 6–12 months after injection.[72]

BONE MARROW- OR FAT-DERIVED MESENCHYMAL STEM CELL THERAPY

The use of bone marrow-derived mesenchymal stem cells (BMSCs) or fat-derived mesenchymal stem cells (MSCs) has grown in popularity in equine practice in the last decade. It is believed that these cells possess anti-inflammatory properties and may also contribute to healing of musculoskeletal tissues by becoming incorporated into the repair tissue.[87] A recent retrospective study of 40 horses that received IA injection of BMSCs that had been expanded to approximately 10–20 million cells revealed a return to athleticism in 72% of all horses with IA injuries, ranging from mild to severe.[31] IA administration of BMSCs postoperatively for stifle lesions has also been reported in horses, with improved ability to return to work (75%).[32] Although more is known regarding the efficacy of MSCs in tendon injuries compared with synovial disease, early results suggest that these cells may also have a place in intrasynovial therapies.

The concomitant use of CS and MSCs has been shown to have a detrimental effect on cell viability, with both MPA and TA resulting in the rapid death of significant numbers of MSCs, and should not be performed.[28] Similar effects have been shown when combining cultured BMSCs with therapeutic concentrations of aminoglycoside antimicrobials (150-mg gentamicin or 250-mg amikacin), resulting in >95% cell death within 2 hours of incubation.[18] Based on these findings, the co-injection of BMSCs and aminoglycoside antimicrobials is not recommended. The same study reported minimal effects of HA (22-mg total dose) on the viability and proliferation of cultured BMSCs, with a trend noted for mild stimulation and enhanced secretion of immunomodulatory mediators.[18]

Concentrated bone marrow aspirate concentrate (BMAC) is another autologous source of MSCs being investigated for the treatment of OA and regeneration of cartilage in osteochondral defects. While the overall concentration of MSCs in BMAC is limited, BMAC also serves as a source of growth factors important for the induction of chondrogenesis.[64,100,102] BMAC has been shown to improve cartilage healing in horses following microfracture repair of cartilage defects. Horse treated with BMAC had improved structure, matrix composition, and integration of the cartilage repair tissue into the surrounding normal cartilage.[38] Overall, similar positive results have also been published in the human literature for treating OA in the knee.[23] Although further work is needed, current evidence suggests that BMAC has the potential to be an effective, minimally invasive option to help repair cartilage defects and treat OA in the horse.

POLYACRYLAMIDE HYDROGEL

Polyacrylamide hydrogel (PAAG) is a nontoxic, nonimmunogenic, nondegradable, and biocompatible polymer gel consisting of 2.5% cross-linked polyacrylamide with a long-lasting viscous effect shown to support cellular growth and augment tissues.[109] This product has historically been used as a bulking agent to enhance soft tissue integrity in human medicine.[16,86,88] Just recently approved for use by veterinarians in the United States, PAAG has been a newly investigated therapeutic option for treating OA in horses.

An international multicenter study that evaluated the efficacy of IA PAAG in horses with OA showed that PAAG significantly alleviated lameness and joint effusion, with 59% of horses sound 1 month after treatment.[109] Improvement in the number of non-lame horses and reduction in joint effusion were observed over time, with 82.5% of horses sound after 24 months. Furthermore, the effect of treatment increased over time with no significant side effects observed in treated joints. A comparative prospective study by the same author also demonstrated that horses with OA treated with PAAG had significantly improved clinical signs when compared with horses treated with TA combined with sodium HA.[108] A preliminary field trial that evaluated the efficacy of a 4% PAAG in osteoarthritic horses

VetBooks.ir

showed decreased lameness with no adverse effects within the first 3 weeks of treatment, and this effect was sustained until the 90-day follow-up evaluation.[79] Limited information can be taken from this study as follow-up was not continued beyond 90 days and there was no control group for comparison.

Incorporation of PAAG into the synovium after injection into normal and osteoarthritic joints has also been demonstrated in horses, with evidence of integration, proliferation, and invasion of synovial cells into the gel by day 14.[24] This was followed by the formation of a vascular, sub-synovial connective tissue layer by day 30 that was covered by a synovial lining. This histological appearance persisted up to 2 years postinjection in equine joints. Further clinical studies to explore potential effects on synovial inflammation and pain are warranted.

MISCELLANEOUS

Other modes of therapy that control intrasynovial inflammation are currently being investigated. Gene therapy modalities engineered to overproduce beneficial cytokines such as IGF-I and IRAP are still being developed.[44,53] Clinical trials will clarify the utility of these therapies.

Atropine is an anticholinergic drug that is occasionally used intrasynovially to reduce joint effusion. Its efficacy in a mouse model was proven by reducing induced joint effusion.[81] It has been used with some success in the horse; however, its use for reduction of joint effusion remains empirical. It is primarily used to reduce effusion in synovial cavities (mostly joints and tendon sheaths) that have not responded to other forms of therapy. The dose used is 7-mg IA, and if used for treatment of hygroma, it should be combined with bandaging.[65] Horses should also be observed for colic following IA injection.

INTRASYNOVIAL THERAPY: PRACTICAL CONSIDERATIONS

Intrasynovial therapies are an integral part of the treatment of lameness in horses. Of course, success of the therapy depends on the correct synovial structure being medicated, and that decision should be based on an accurate lameness examination and appropriate imaging. Furthermore, success of diminishing lameness also depends on the severity of the disease in the synovial structure being medicated and the efficacy of the medication being injected. For example, a recent study found a direct correlation between the success of intrabursal injections and the severity of the disease seen on MRI, with less severe disease having greater long-term success in treatment.[15] There are no accurate reports of how long a horse should be rested following CS injections; however, common practice is to combine the intrasynovial injection with at least 4–5 days of rest because the mechanical integrity of the cartilage has been shown to be compromised for several days following injection.[29] It is recommended that horses be returned to exercise slowly, over 1–2 weeks.

Finally, as previously mentioned, sepsis may be a complication with any intrasynovial medication, and it is paramount for the clinician to be aware of any worsening of lameness following medication of a synovial structure. A survey of 241 equine veterinarians revealed an incidence of 2.1 septic joints per 10,000 IA injections, with significantly lower infection rates when veterinarians prepared their own injection sites and had <20 years of practice experience.[51] Strict adherence to aseptic technique should also be practiced. Clipping the hair is not mandatory,[59] and a survey of veterinarians actually suggested that synovial infection rates were significantly higher for veterinarians that routinely removed the hair at the injection site.[51] Nevertheless, clipping the area of injection is still recommended by the author if winter hair growth precludes the ability to adequately prepare the skin site – due to the devastating consequences of synovial infection.

INTRALESIONAL

Sara K.T. Steward and Laurie R. Goodrich

VetBooks.ir

INTRODUCTION

Therapies that are injected intralesionally are usually directed at healing tendon or ligament. They are most often intended to augment the healing processes locally by providing the necessary components of healing to the tissue being treated. Alternatively, they may act locally to either reduce inflammation and/or signal the cellular and molecular components of the injured and surrounding tissue to begin the reparative processes. During repair of these tissues, injured elastic fibers are replaced with modified fibrous scar tissue, resulting in repair that is suboptimal. The quality of repair varies greatly depending on the severity of lesion, the inherent healing properties of the individual, the rehabilitation program, and the local environment of the lesion. Some injuries may repair and resolve with enough mature collagen so that they return to normal size, with sufficient remodeling that results in parallel alignment of the fibers within the tissue. Other injuries form a scar, with a resulting increase in size of the tendon/ligament, poor or random fibrous tissue alignment, and peritendinous/ligament fibrosis.

Intralesional approaches are directed at maximizing the chances for a more physiologically functioning tendon. Along with intralesional therapies, rehabilitation and constant ultrasonographic monitoring must accompany any treatment. Treatments usually reduce the acute inflammatory response and hemorrhage in the acute phase and improve fiber alignment during the reparative phase. Ultimately, the goal is to maximize the chances for a tendon or ligament to repair with adequate strength and elasticity for a return to a similar level of performance with minimal risk for reinjury.

HYALURONAN AND POLYSULFATED GLYCOSAMINOGLYCANS

Hyaluronan (HA) has been investigated for tendon injuries and adhesion prevention throughout the last three decades. Its use is predicated on its abilities to decrease inflammation and to prevent adhesion formation through its mechanical characteristics.[27] Further, it was believed to stabilize the fibrin clot early in wound healing, enhance the migration and replication of fibroblasts in the wound,[15] and improve fiber and biochemical characteristics of tendons.[46] The use of polysulfated glycosaminoglycans (PSGAG) intralesionally is based on the known abilities of this drug to inhibit many of the enzymes associated with connective tissue degradation. *In vitro* studies have shown that PSGAG are capable of inhibiting lysosomal elastase, cathepsins G and B, lysosomal hydrolases, keratin sulfate glycoanhydrolase, serine proteases, neutral metalloproteinases, beta-glucuronidase, alpha-glucosidase, beta-*N*-acetylglucosaminidase, and hyaluronidase.[2,6,31]

Recent clinical studies have reported no difference in outcome or reinjury rate in performance horses (race, national hunt, dressage, and jumper horses) when horses were injected with intralesional HA, PSGAG, or conservative management.[12,28,29] While intrasynovial and systemic administration of both HA and PSGAGs is still used clinically, the intralesional administration previously investigated is no longer the treatment of choice for intralesional tendon injury.

AUTOLOGOUS CELL THERAPIES: MESENCHYMAL STEM CELL THERAPY, AUTOLOGOUS BONE MARROW ASPIRATE, TENDON-DERIVED PROGENITOR CELLS

The use of mesenchymal stem cell (MSC) therapy in veterinary orthopedics has been described including treatment of subchondral bone cysts, bone fracture repair, and cartilage repair.[26,32] However by far the most frequent use of MSCs has been in the treatment of overstrain-induced injuries of tendons in horses.[35] Although the mechanism of action in how these cells influence their "trophic" activity is still under intense investigation, many models of animal studies suggest that MSCs secrete bioactive molecules that (1) inhibit apoptosis and limit the field of damage or injury, (2) inhibit fibrosis or scarring at sites of injury, (3) stimulate angiogenesis and bring in a new blood supply, and (4) stimulate the mitosis of tissue-specific and tissue-intrinsic progenitor cells.[7] Historically, in untreated racehorses, the reinjury rate in tendons sustaining superficial digital flexor (SDF) tendonitis is approximately 56%.[12] Due to the scar tissue formation, the primary need to restore functionality to tendons has encouraged the development of regenerative strategies. Regenerative therapies require an exogenous cell source. Tendons and ligaments do not have a lack of cellular inflammation following injury however; cells actually involved in the synthesis of new tissues are mostly locally derived. Transplantation of MSCs into various injured skeletal tissues has been shown to promote healing, and the use of autologous cells has a benefit since they do not incite an immune response from the host.[8,14,22] Current theories on how transplanted MSCs act in tendon when injected intrathecally are that they either differentiate into cells capable of synthesizing tendon matrix or they secrete important factors that induce adjacent cells to synthesize tendon matrix.[35]

Currently, two techniques exist for MSC transplantation using intrathecal injections. One has used non-adipocyte-cell mixture from fat, and the second has used cultured bone marrow aspirate. The current widely used fat-derived stem cells do not involve a culture step and therefore have the advantage of cheaper cost and speed of preparation (cells are returned to the practitioner with 48 hours). However, the cell mixture is believed to

VetBooks.ir

be heterogeneous with regard to cell type. A small controlled study using adipose-derived cells in a collagenase model of tendon injury reported some benefit in terms of crimp pattern.[33] Another study reported a return to athleticism in 14 out of 16 horses with SDF tendonitis with no comment on reinjury rate.[9] Up until now, no head-to-head comparison studies of adipose-derived to bone marrow-derived MSCs have been performed in clinical cases of naturally occurring disease.

The culture-expanded bone marrow-derived MSC therapy involves aspirating bone marrow from the sternum or tuber coxae, transferring to a laboratory for culture and expansion, and then implanting the cell population (approximately $10–50 \times 10^6$) under ultrasound guidance.[20] Continued investigation of tissue uptake of these cells has shown retention of the stem cells within the lesion for up to 9 weeks when injected intralesionally.[18] This technique has been widely used in the United States, the United Kingdom, Europe, and Australia.

Currently, long-term follow-up is encouraging. In a 2008 study, over 168 racehorses undergoing this regimen were shown to have an 18% reinjury rate.[41] This is in contrast to a 56% reinjury rate for horses receiving no intralesional therapy. Two smaller-scale studies one in research horses[39] and one in 11 racehorses[34] also reported improved tendon repair. In a more recent study by Godwin et al., 141 racehorses with overstrain injuries of the SDFT were treated intralesionally with bone marrow-derived MSC and followed with repeat ultrasonography. A re-injury rate of 27.4% was reported for this population after a 2-year period.[19] No adverse effects were reported in these studies other than ultrasonographic evidence of needle tracks.

The efficacy of administering stem cells via regional limb perfusion (RLP) has also been evaluated via technetium-99m-labeled cells, which has shown a homing effect to the region of injury.[10] Additionally, the efficacy of intra-arterial administration of MSCs has recently been investigated. Technetium-labeled MSCs injected into the median artery via ultrasound guidance were shown to perfuse into the entire distal limb via scintigraphic imaging.[13] Longer-term evaluation of tissue uptake when administered via RLP or intra-arterially has yet to be investigated.

In addition to autologous stem cell usage, in which a sample is harvested from the patient, cultured, and reinjected intralesionally, investigation of the safety of allogenic stem cell use has been reported. In a retrospective study of 164 horses receiving bone marrow-derived stem cells from a single donor, 10/230 injection sites were reported to have adverse reactions which is not dissimilar to allogeneic administration.[43] Adverse reactions were defined as pain, swelling, heat, or lameness associated with the injection site. Seven of these reactions were in soft tissue injections.[43]

Tendon-derived progenitor cells (TDPC) have also been investigated in recent years as an alternative to bone marrow or stem cell therapies. Cells are harvested from a donor tendon site, such as the lateral digital extensor tendon, and then cultured for intralesional injection. In a recent study model using collagenase-induced tendon lesions, improved tensile strength and fiber alignment were shown in the TDPC-treated groups as compared with the saline-treated controls.[11] Studies now need to be performed comparing the efficacy of TDPC with bone marrow-derived and adipose-derived MSCs.

BLOOD-DERIVED BIOLOGICS: PLATELET-RICH PLASMA, AUTOLOGOUS CONDITIONED SERUM, AUTOLOGOUS PROTEIN SOLUTION, AND BONE MARROW ASPIRATE

Platelet-rich plasma (PRP) has been used for treatment of soft tissue injuries and bone healing and has been investigated for regeneration of bone, cartilage, tendon, and ligament. The reason behind the use of PRP comes from the knowledge that growth factors are released from platelet α-granules including platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β), fibroblastic growth factor (FGF), vascular endothelial growth factor (VEGF), insulin-like growth factor-I (IGF-I), and epidermal growth factor (EGF). Many animal models have demonstrated positive effects of these growth factors, both alone and in concert with each, in enhancing cellular migration and proliferation, angiogenesis and matrix deposition in tendon and wound healing and repair.[1,3,38]

Current studies report beneficial effects of PRP on equine ligament and tendon both *in vitro* and *in vivo*.[30,42,44] *In vitro* studies support the belief that PRP supplies high levels of growth factors and the presence of these growth factors results in higher type I collagen and cartilage oligomeric matrix protein (COMP) and reduced levels of inflammatory mediators such as matrix metalloproteinases (MMP) 3 and 13. A recent *in vivo* study reported improved repair of the SDFT when core lesions were induced mechanically.[5] When lesions that were injected with PRP were compared with lesions injected with saline, tendons had better mechanical characteristics as well as higher collagen, glycosaminoglycan, and cellularity. These findings correlate with the *in vitro* effects reported. A more recent randomized controlled study was performed using intralesional injection of either PRP or saline in 20 horses with naturally occurring tendinopathies. At 12-month follow-up, 80% of the PRP-treated horses had reached their previous or a higher level of performance as compared with 50% in the control. However, after 24 months only 60% of the treated horses and 40% of the control were still used at this level.[17] Additionally, in a retrospective review of 127 National Hunt racehorses, intralesional PRP was not superior to other treatments in the studied population, which included controlled exercise and bar firing.[45]

PRP is also commonly used in conjunction with extracorporeal shockwave therapy (ESWT) (see section on topical/local). An *in vitro* study showed that concentrations of TGF-β_1 and PDGF-ββ were significantly increased when PRP was exposed to ESWT; however this model has not been validated *in vivo*.[40]

Autologous conditioned serum (ACS) has become popular for its anecdotal anti-inflammatory effects and rapid improvement in lameness. ACS is similar to PRP in its rapid processing and ease of acquisition. Whole blood is processed via exposure to glass beads, which stimulates

VetBooks.ir

the expression of anti-inflammatory cytokines, including IL-1Ra and IL-10.[24] In a recent randomized controlled study,[16] naturally occurring tendinopathies of the forelimb SDFT were treated with either ACS or saline.[16] In ACS-treated limbs, lameness and swelling were significantly decreased, while ultrasonography revealed a decrease in size and increased echogenicity in the treated groups following a single intralesional injection. Recurrence of tendon injury was not reported in any of the horses in this study up to 2–4 years' post-diagnosis. Five of eight ACS-treated horses returned to previous levels of work, while four of five control horses also returned to previous work.

A newer class of biologics, autologous protein solution (APS), contains high concentrations of growth factors and anti-inflammatory cytokines, such as IL-1 receptor antagonist, IL-10, IGF-1, and TGF-β, and has had promising results intra-articularly.[4] APS has a similar processing time and centrifugation style to PRP. APS is distinct in that a second centrifugation step further concentrates the cell solution in the presence of polyacrylamide beads resulting in a solution with higher concentrations of interleukin-1 receptor antagonist proteins than PRP.[23] To date, APS has not been investigated intralesionally.

Autologous bone marrow aspirate (ABMA) has been used in recent years as an inexpensive and fast intralesional treatment modality, by which stem cells and growth factors may be administered into a lesion without conditioning or culture. In a recent study of racehorses with SDFT injuries treated with intralesional ABMA at the time of desmotomy of the distal accessory ligament of the SDFT (DAL-SDFT), Thoroughbreds showed an 82% return to racing with 59% starting five or more times. Of Standardbreds with similar lesions and treatment, 76% had one or more starts, and 62% had five or more starts.[37] The success rates of horses treated with ABMA are improved over previously reported rates of Thoroughbreds undergoing DAL-SDFT alone (72% return to racing and 48% with five or more starts).[25]

CORTICOSTEROIDS

Perilesional corticosteroids are occasionally used acutely to treat tendonitis/desmitis. However they are considered contraindicated, especially for long-term usage, because they may delay collagen formation.[36] However, some clinicians use a single perilesional dose of triamcinolone (6–9 mg) or methylprednisolone acetate (40 mg) perilesionally in horses with peripheral tendon lesions or suspensory ligament desmitis. Results using this therapy vary and should probably be reserved for tendon or ligaments in which minimal or no structural damage is seen ultrasonographically. Furthermore, dexamethasone acetate has been shown to differentiate tendinous stem cells into fatty tissues, cartilage-like tissues, and bony tissues, which may put tendinous structures at risk of rupture.[47] Anecdotally in the horse, dexamethasone acetate has been associated with dystrophic mineralization that has been noted following injection of this corticosteroid into soft tissues.

Numerous other uses have been described for local injection of corticosteroids in areas of inflammation, such as over splint bones, muscle/back soreness, and various soft tissue inflammatory conditions or trauma. The choice and amount of steroid seem to be empirical and clinician dependent; however, this does not seem to greatly impact the efficacy of the injections.

MISCELLANEOUS

Sarapin is occasionally utilized as an intralesional treatment for lesions associated with chronic nerve pain. Sarapin is an extract derived from the pitcher plant and is believed to have a numbing effect in chronic pain. The only study performed in the horse however could not detect analgesic effects of sarapin in a model of acute pain using heat.[21] Nonetheless, this therapy is commonly utilized to treat various forms of desmitis and muscle soreness with a widely believed suspicion that a temporary analgesic effect is produced. Sarapin is often combined with other medications such as corticosteroids and is used primarily to treat lameness conditions of the axial skeleton such as back and sacroiliac problems.

ORAL/NUTRITIONAL

Nicolas S. Ernst and Troy N. Trumble

VetBooks.ir

Lameness is one of the most prevalent diseases, which affects the equine industry. It is considered the most common and important performance-limiting problem in horses. This section discusses oral formulations used to treat the causes of lameness. Specifically, it focuses on oral formulations of nonsteroidal anti-inflammatory drugs (NSAIDs) and the most common compounds used in equine nutraceuticals.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs are a large group of drugs with differing degrees of analgesic, anti-inflammatory, and antipyretic properties (Table 8.3). In a survey of horse owners and trainers, 96% of respondents stated that they use NSAIDs, and 82% said they administer them without consulting a veterinarian.[101] However, NSAIDs are also heavily prescribed by veterinarians as demonstrated in an observational study of multiple practices in multiple countries where clinicians prescribed NSAIDs in the United States (42.4%) more than those in Canada (34.2%), or in the United Kingdom (28.6%).[39] Oral formulations come in many varieties such as pills, paste, granules, and powder, allowing the consumer to choose which formulation is best for each individual. Some of these medications can also be administered systemically via intramuscular or intravenous injection (Table 8.3). In general, NSAIDs act by inhibiting cyclooxygenase (COX) enzymes that convert arachidonic acid into prostaglandins and thromboxanes. There are two well-known isoenzymes of the COX enzymes, COX-1 and COX-2.[162] In general, COX-1 is considered the housekeeping isoenzyme responsible for producing prostaglandins involved in normal physiological functions such as gastric and renal function and hemostasis.[100] The COX-2 isoenzyme is considered to be an important inducible mediator of inflammation in several organs and is primarily responsible for the inflammatory pathway.[100] However, the concept that COX-2 is purely involved in inflammation has changed since the COX-2 isoenzyme has been found to be constitutively formed in the brain, spinal cord, kidney, uterus, and some other regions.[134] In fact, one study demonstrated that in volume-depleted horses a COX-2 preferential agent (meloxicam) had similar adverse renal effects as the nonselective NSAID, phenylbutazone (PBZ).[117]

The variation in efficacy and toxicity of the different NSAIDs is closely related to inhibition of the different COX isoenzymes (Table 8.3). Some are more potent inhibitors of COX-1 than COX-2, some equally inhibit both, and others inhibit COX-2 more than COX-1.[100] In general, the anti-inflammatory and analgesic properties of NSAIDs are believed to be mainly due to inhibition of the inducible COX-2, whereas the adverse effects seem to be caused by inhibition of the constitutive COX-1.[96] This has led to the development of NSAIDs with a selective inhibition of COX-2. In humans, COX-2-selective inhibitors demonstrated adverse cardiovascular and thromboembolic effects, but horses do not appear to be predisposed to these adverse effects.[165] It is also important to note that COX-2 selectivity is only achieved when administered at correct dosing; overdosing can lead to similar adverse effects of nonselective NSAIDs.[165]

Recommendations for NSAID usage should be formulated in attempt to minimize adverse effects when it is determined that an oral NSAID may be a beneficial

Table 8.3. Commonly used NSAIDs and their modes of action, formulations, and doses for equine musculoskeletal disorders.

Name of NSAID	Primary inhibitory action	Available formulations	Recommended dose
Phenylbutazone	Cox-1 and -2	Powder, tablets, paste, and injectable solution	2.2–4.4 mg/kg SID or BID
Flunixin meglumine	Cox-1 and -2	Paste, granules, and injectable solution	1.1 mg/kg SID
Acetylsalicylic acid	Cox-1 > Cox-2	Gel, powder, granules, paste, and tablets	25–35 mg/kg SID or BID
Meclofenamic acid	Cox-1 and -2	Granules	2.2 mg/kg SID for 5–7 days
Naproxen	Cox-1 and -2	Granules, tablets, and suspension	10 mg/kg SID or BID
Firocoxib	Cox-2	Paste, injectable solution, and tablet	0.1 mg/kg SID, 0.09 mg/kg SID IV
Carprofen	Cox-2 > Cox-1	Tablets and injectable solution	0.7 mg/kg SID
Vedaprofen	Cox-2 > Cox-1	Gel and injectable solution	2 mg/kg loading dose followed by 1 mg/kg q12 h
Meloxicam	Cox-2 > Cox-1	Suspension, injectable solution, oral solution, and tablets	0.6 mg/kg SID

VetBooks.ir

treatment option. In general, oral NSAIDs should be used at the lowest effective dose and frequency as possible, for the shortest period of time. Special consideration should be used when treating susceptible breeds (ponies), foals, and systemically ill, dehydrated, or old horses. NSAIDs are commonly used in performance horses for recovery of minor injuries. However, most sport horse disciplines have rules about using NSAIDs before or during competitions. See each individual governing body for guidelines regarding appropriate therapeutic use of NSAIDs for that discipline.

Phenylbutazone (Butazolidin®, Butatron™, Bizolin®, Phenylbute™, Phenylzone®, Equiphen®, Butequine®, Superiorbute®, and Equizone 100™)

PBZ is an acidic, lipophilic NSAID that is classified as an enolic acid and is metabolized in the liver and excreted in the urine. Following oral administration, PBZ is well absorbed in the stomach and small intestine.[94] The plasma half-life after oral administration has been reported to be between 6.2 and 6.7 hours.[75] However, absorption can be influenced by the drug's formulation and the route of administration.[4,75] For example, the paste formulation offers a greater rate and extent of absorption than tablet or powder formulations, and peak plasma concentrations and onset of action can be delayed by administration close to feeding.

Oral PBZ is an inexpensive NSAID that has potent pain relief, antipyretic, and anti-inflammatory properties. It provides pronounced analgesia and reduction in inflammation in many common lameness problems, including naturally occurring chronic osteoarthritis (OA).[36] It is often administered prior to surgery to minimize pain and inflammation associated with orthopedic surgical procedures. However, studies have demonstrated that oral PBZ may have negative effects on cartilage and bone metabolism. A study in healthy horses receiving oral PBZ reported a decrease in bone activity (decrease in mineral apposition rate and a reduction in the magnitude of healing) compared with horses not receiving PBZ.[124] In another study, PBZ administered (4.4 mg/kg) orally twice daily for 14 days to healthy horses resulted in significant decreases in proteoglycan synthesis by suppressing chondrocyte metabolism in articular cartilage explants.[8] Recovery of chondrocyte metabolism took 2 weeks to normalize after cessation of treatment. In contrast, no significant adverse effects were identified using systemic cartilage and bone biomarkers when PBZ (4.4 mg/kg) was administered orally twice daily for 3 days followed by a lower dose (2.2 mg/kg) for 7 days in healthy horses.[48]

Oral PBZ has been widely studied for its toxic effects on horses. It is considered relatively nontoxic at repeated doses of 2.2 mg/kg twice a day or less.[137] Clinical signs reported with PBZ toxicity in horses are anorexia, depression, loss of weight, abdominal edema, hypoproteinemia, leukopenia, anemia, and death within 4–7 days.[132] The gastrointestinal (GI) tract is the most commonly affected area following oral administration, causing ulcers (oral, esophageal, gastric, cecal, and right dorsal colon) and a protein-losing enteropathy.[132] Renal papillary necrosis has also been described and may be due to the inhibition of prostaglandins that maintain renal blood flow and/or direct toxic effect of the drug or its metabolites.[84,117] Because of this narrow margin of safety and adverse effects, special considerations or alternative therapies should be considered when horses require long-term administration. Often in severely affected orthopedic cases, horses can be safely maintained on 2.2 mg/kg/day of PBZ for months when gastroprotectants are used concurrently.

Combination of oral PBZ with other NSAIDs may enhance the analgesic properties of these drugs in performance horses.[74,120] Some studies have shown a better clinical improvement in lameness when a combination of drugs is used than when PBZ is used alone,[74,120] whereas others have not.[47] Caution should be used when combining NSAIDs to minimize the potential toxic effects.

Flunixin Meglumine (Banamine®)

Flunixin meglumine is a derivative of nicotinic acid that exhibits analgesic, anti-inflammatory, and antipyretic activity. After oral administration the drug is rapidly absorbed with a peak in plasma levels within 30 minutes, and the plasma half-life is approximately 1.6 hours.[20] This rapid absorption may be important in minimizing potential ulcerogenicity.[20] The onset of action after oral administration occurs after 2 hours, with the greatest effect between 2 and 16 hours; some activity may persist for up to 30 hours.[62] Similar to PBZ, recent feeding delays absorption.[157] Oral administration of flunixin is relatively safe. In one study, three times the recommended dose given orally for 15 days failed to induce toxic effects.[62] However, oral administration of flunixin at 1.1 mg/kg/day for 30 days in foals resulted in oral and gastric ulceration.[140] In addition, high doses for long periods can cause GI intolerance, hypoproteinemia, and hematological abnormalities.

Oral flunixin meglumine can be used to treat musculoskeletal disorders in horses,[62] but because of its cost compared with PBZ, oral formulations are used infrequently. In general, oral flunixin has been used mostly to treat musculoskeletal injuries associated with soft tissue structures such as muscle and tendons. However, there are no studies indicating that it is better or worse than other NSAIDs at controlling pain and inflammation associated with the musculoskeletal system. When flunixin is combined with other NSAIDs, some studies have shown enhanced analgesic properties of these drugs in performance horses compared with when used alone,[74,120] whereas others have not.[47]

Acetylsalicylic Acid (Aspirin)

Aspirin is a weak acid that reduces platelet aggregation and has analgesic, anti-inflammatory, and antipyretic properties. It is only available in oral forms and has a limited clinical use in the horse. It is best absorbed in the acidic environment of the upper GI tract. In ponies, oral administration of salicylate demonstrated rapid absorption with a peak in plasma levels within an hour, with the highest concentrations of drug attained in the liver, heart, lungs, renal cortex, and plasma.[31] Aspirin affects platelet function at low dose rates, reducing clotting times and thrombus formation.[16] Aspirin has been reported to decrease platelet numbers

VetBooks.ir

and prolong bleeding time in horses with doses between 12 and 24 mg/kg.[16,70,141] These effects can occur after a single dose and can last as long as 48 hours.[16,70] Therefore, caution should be used and close monitoring performed when using this drug on horses before surgery or with bleeding tendencies or anemia. Due to its effect on platelets, aspirin has been historically used for the treatment of navicular syndrome and chronic laminitis.[97] However, its therapeutic benefits for these diseases are not well defined.

Meclofenamic Acid (Arquel)

Meclofenamic acid (MA) is another oral nonselective NSAID used to treat lameness and chronic musculoskeletal conditions such as navicular disease, OA, and laminitis in horses.[25] Compared with other NSAIDs, MA has a slow onset of action of 36–96 hours for full effect.[25] It is not clear whether feeding time dramatically affects absorption because one study demonstrated that fasted and nonfasted ponies had similar oral absorption,[131] whereas another study demonstrated that plasma levels could be delayed by feeding.[136] The reported bioavailability after oral administration varies between 56% and 90%.[68,131] MA may prove to be useful for OA because high levels can be found in synovial fluid and articular cartilage.[25] High doses produced clinical signs of toxicity similar to those of PBZ (at a dose 13–18 mg/kg).[84,138]

Naproxen (Equiproxen, Naprosyn)

Naproxen is a nonselective NSAID with analgesic and antipyretic properties that has been used primarily to treat myositis and soft tissue problems.[27,138] In a study using an equine myositis model, oral naproxen was reported to be superior to oral PBZ, with faster relief of inflammatory swelling and associated lameness.[69] After oral administration the bioavailability of the drug is approximately 50% with peak plasma levels reached at 3–4 hours; the plasma half-life is approximately 4 hours.[138] Naproxen has a wide margin of safety. Oral administration of four times the recommended dose for 42 days did not cause signs of toxicity.[138] In another study, administration of the recommended dose of naproxen for 14 days, followed by twice the dose for another 7 days, did not alter plasma protein concentrations.[133] Even though this drug has been marketed for soft tissue conditions, successful usage in the human field for treating joint pain may suggest that it can be used to treat inflammatory swelling and associated lameness.[69,97]

Firocoxib (Equioxx®)

Firocoxib is a COX-2-selective NSAID that has been approved by the FDA for controlling pain and inflammation associated with OA in horses. The bioavailability after oral administration in horses is 79%, with a time to peak concentration of 3.9 hours and elimination half-life of 30 hours.[60,80,81,85] It is metabolized in the liver and excreted in the urine.[85] It is well distributed in the body, including synovial fluid, liver, fat, kidney, and muscle.

Firocoxib is available in two oral formulations (paste and tablets). When a single dose of 57 mg was administered to 6 horses, the paste revealed a better bioavailability, higher C_{max}, shorter T_{max}, greater area under the concentration curve (AUC), and greater inhibition of prostaglandin E_2 (PGE_2) when compared with the tablets.[60] The efficacy of different doses of firocoxib in horses with chronic lameness was assessed using objective assessment with a force plate, showing that a dose of 0.1 mg/kg orally once a day was found to be most effective in reducing chronic lameness in horses.[3] When administering this oral dose (0.1 mg/kg SID) over multiple days, it has been shown that it can take up to 7 days to reach steady state.[85] However, if a loading dose (0.3 mg/kg) is administered 24 hours before starting a multidose regimen at 0.1 mg/kg, the steady-state concentration of the drug can be achieved after the first day of treatment.[26]

In a study of horses with chronic OA and navicular syndrome,[36] no significant differences in clinical improvement were found between horses treated for 14 days with firocoxib compared with PBZ treatment. However, a greater proportion of horses treated with firocoxib had improvement in scores for pain on manipulation or palpation, joint circumference, and range of motion compared with PBZ. In another study of a large number and cross section of horses with musculoskeletal pain or lameness associated with OA, firocoxib paste significantly improved lameness scores, comfort, and mobility in horses with the most change occurring within the first 7 days of treatment.[112]

Compared with other nonselective NSAIDs, firocoxib is relatively safe. No clinical and biochemical signs of NSAID toxicity were reported when using the recommended dose (0.1 mg/kg).[43] A pharmacokinetic and safety study was performed in neonatal foals, where 36-hour-old neonates received 0.1 mg/kg orally SID for 9 days; it showed that firocoxib was rapidly absorbed with no reportable adverse effects.[63] In a postoperative *ex vivo* study, firocoxib action on COX-2 was similar to flunixin meglumine in that they both prevented its increase 24 hours after surgery; the firocoxib group demonstrated a sparing effect of COX-1 activity with greater activity than flunixin.[38] However, it has been reported that an oral dose of 0.1 mg/kg SID for 10 days can still develop gastric ulceration, but the severity of the ulceration being less severe than with PBZ administration (4.4 mg/kg PO SID).[121] In addition, co-administration with another NSAID can eliminate the benefit of the COX selectivity; adverse renal issues were present when oral firocoxib (0.1 mg/kg SID) was combined with oral PBZ (2.2 mg/kg SID) for 10 days.[79] For this reason, some equine governing bodies are no longer permitting the combination use of firocoxib with other NSAIDs.[165]

The main downfall to firocoxib is that it is more expensive than PBZ. Therefore, the economic feasibility must be discussed with the client. This can often lead to off-label use of the chewable canine tablets by owners due to the substantial difference in cost between the formulations for the different species. Because of this, one study examined the effect of 57 mg of the canine tablet or the equine paste administered orally to horses for 7 days.[5] The collected blood was challenged with lipopolysaccharides (LPS) to induce PGE_2. There was no difference between formulations in reducing PGE_2 production or in plasma firocoxib concentrations. Therefore, they conclude that tablets may be viable option if extra-label use can be justified,[5] but it is important to note that one cannot legally prescribe the

VetBooks.ir

formulation labeled for one species to another (in other words, the canine formulation cannot be legally prescribed for horses just because it is cheaper).[165]

Carprofen (Zenecarp, Rimadyl®)

Carprofen is a propionic acid NSAID approved in Europe for oral use in horses. Its mechanism of action in horses is still unclear; however, it is described as being a more effective analgesic than anti-inflammatory agent.[99] Carprofen in horses was well tolerated when given at twice the oral dose for 14 consecutive days.[99] The benefit of using this NSAID in horses compared with other available NSAIDs requires further investigation.

Vedaprofen (Quadrisol®)

Vedaprofen is an arylpropionic acid NSAID with anti-inflammatory, antipyretic, and analgesic properties. Vedaprofen is approved in Europe for oral use in horses. It is recommended for musculoskeletal disorders and soft tissue lesions. Side effects of this drug are those associated with the use of NSAIDs in general. The main toxic effect is ulcer formation in the GI tract, making it contraindicated for use in foals under 6 months of age.[146] Use of this NSAID in horses compared with other available NSAIDs requires further investigation.

Meloxicam (Metacam®)

Meloxicam is a relative COX-2-selective NSAID intended for the treatment of inflammatory orthopedic problems, including chronic musculoskeletal and soft tissue disorders.[10,105] It is available for horses in Europe. Meloxicam was shown to be more effective than PBZ in decreasing pain in an LPS synovitis model.[143] It was also shown to be effective in controlling swelling and lameness postoperatively after partial resections of fractured splint bones compared with placebo controls.[154]

Side effects seen with this drug are those routinely associated with the use of NSAIDs. Oral doses of 0.6 mg/kg were well tolerated when administered daily for 2 weeks[151] and 6 weeks,[109] but 1.8 and 3 mg/kg demonstrated decreased protein and albumin concentrations, GI and renal damage, or bone marrow dyscrasia.[109] Oral administration of three different doses (0.6, 1.8, and 3 mg/kg q24) for 14 days demonstrated less compromise to the gastric mucosa than oral administration of decreasing doses of PBZ over the same time frame; however, there was no difference in ulceration between the NSAIDs.[30] Oral doses of 0.6 mg/kg for 3 weeks were well tolerated in 6-week-old foals, and interestingly, foals demonstrated no adverse effects after 1.8 mg/kg was administered BID for 7 days.[116] Caution should be used and close monitoring performed when using this drug on horses treated concurrently with another NSAID, corticosteroid, or nephrotoxic medication.[148]

NUTRACEUTICALS

The nutraceutical term has undergone many different definitions over time but is basically any substance that is a food, or part of a food, that can be administered orally to provide or stimulate production of raw materials or biochemical pathways required for normal bodily functions. Although these substances are neither nutrients nor pharmaceuticals, they are generally used in an attempt to lower the dose of other drugs that are more problematic and provide medical benefits that prevent or treat disease. Included in this broad category of products are nutrients, dietary supplements, functional foods, and phytochemicals (including herbs).

The FDA does not recognize nutraceuticals as foods or drugs. However, based on the definition of nutraceuticals, the FDA perceives veterinary nutraceuticals as unapproved drugs even though they are not labeled or marketed as drugs. The FDA does not regulate these products unless they become unsafe or are associated with labels that claim a drug use. The Center for Veterinary Medicine (CVM) has allowed products to be marketed as nutraceuticals provided that they do not claim to treat, cure, or mitigate disease. Ultimately, there is no requirement to prove safety or efficacy of a nutraceutical for its intended use.[12]

The Dietary Supplement Health and Education Act (DSHEA) allows manufacturers to make claims with regard to health, structure or function, and nutrient content of a nutraceutical and requires that the manufacturer ensure that its product is safe before marketing.[142] In general, the manufacturer must identify each dietary ingredient contained in the product and adhere to state licensing requirements.[98] However, neither the DSHEA nor FDA have set up a system to monitor manufacturers. There is no requirement for manufacturers to guarantee high quality and batch-to-batch consistency, and product safety is completely up to each individual manufacturer.[142] In 2001, the National Animal Supplement Council (NASC), a nonprofit trade organization, was founded by animal supplement industry stakeholders to try to improve and standardize the industry.[145] As part of this goal, the NASC developed the concept of a "Quality Seal Program." The idea was that the presence of the seal on a product indicates to the consumer that the company is reputable and has undergone some form of quality control. To have a seal placed on their product, the company must demonstrate compliance in four main areas to NASC investigators: a quality control manual that demonstrates standard operating procedures that are in place, an adverse event reporting system to evaluate the ingredients within each product, proper labeling guidelines, and inclusion of any warning and caution statements recommended by the FDA's CVM for particular ingredients. A list of NASC companies that completed the quality audit can be found at www.nasc.cc/members/.

Nutraceuticals are often used by many owners or trainers independent of their veterinarians. Products have become widely available in many formulations including capsules, tablets, and powder, and they are incorporated within packaged feed. When using or recommending these products, documentation validating the contents, purity, and quality control procedures should be requested from the manufacturer to examine and understand the quality, efficacy, tolerance, and safety of each individual nutraceutical.[142,159]

Several of the products in the equine market have considerable variability in purity, formulation, and

VetBooks.ir

consistency between batches. Although these products are marketed with "guaranteed analysis," only a small number have consistently met the label claims.[1, 86,87,118,144] In fact, truth-in-labeling problems have been documented, in which ingredients listed on the package were not present at the claimed concentration or purity. The products that have the most inconsistency in concentrations compared with the label claims tend to be those that state that they are a "complex," "formula," or "blend" of ingredients with no weight of each component listed.[144] In general, products should be avoided if they do not have information on the quality, make exaggerated claims, or rely on testimonials.[142] The presence of lot numbers and expiration dates generally offers some evidence of accuracy in labeling, but does not guarantee it.[12]

Many manufacturers with similar products attempt to compete in the market with claims based on research conducted by another company, even though there is no proof of comparable efficacy. Efficacy of these products in the horse is hard to prove, even for those products in which research was conducted; a systematic review of five studies using nutraceuticals for treating OA in horses stated that the strength of evidence of efficacy to improve pain or gait abnormalities was poor.[152] Because these products are oral, it is also important to ensure that there is adequate evidence of absorption in the species of interest, or else the product is essentially useless.[142] As with many medications, each particular individual may respond in an adverse fashion to various ingredients within the product. This could be a reaction to the main ingredients, contaminants, or inert ingredients that are added to help disperse or dilute the product.[12] Unfortunately, to date, little to no information exists about these products, which is important to consider when discussing safety of the product with a horse owner or trainer. Most of the information is anecdotal and is based on the lack of any major adverse reactions after treatment.[142]

One should not, and cannot, assume that these products will not cause harm. Just because there is a lack of published adverse reactions to a nutraceutical does not mean that one should extrapolate that the product is safe. In fact, most manufacturers will not spend the money to prove safety, so the lack of side effects does not mean that a product is safe.[142] Unfortunately, even when safety data is present on a particular product, the variability in concentrations of the ingredients within and between batches can make this data inaccurate. It is also worth noting that these products have only been around for a few decades, so there is limited data regarding the effects of long-term administration.

The remainder of this section discusses the known scientific effects of the most common compounds contained in equine nutraceuticals that are currently available.

Glucosamine

Glucosamine (GLN) is an aminosaccharide essential for normal growth and repair of articular cartilage.[115,139] GLN compounds have been used as nutraceuticals in horses due to their possible role in stimulating chondrocyte metabolism and reducing inflammation in the articular cartilage.

Exogenous GLN can be produced synthetically or derived from marine exoskeletons or beef carcasses. There are three commercially available forms of exogenous GLN: hydrochloride (HCl), sulfate, and *N*-acetyl-D-glucosamine. Several reports have demonstrated differences among the available GLN forms. For instance, *in vitro* studies have demonstrated that GLN HCl and GLN sulfate appear to inhibit cartilage degeneration more consistently than *N*-acteyl-D-glucosamine.[45,46,129] The GLN sulfate form has been postulated to be more efficacious because serum and/or synovial fluid concentrations of sulfate increase after GLN sulfate administration.[59,65,102,130]

Oral bioavailability of GLN HCl in the horse has been reported to range from 2.5% to 6.1%, which has been attributed to a large volume of distribution, poor absorption from the GI tract, and extensive tissue uptake.[37,82] Radiolabeling studies have shown that there is good distribution of GLN to articular cartilage with levels exceeding those in the plasma.[128] However, GLN delivery to the articular cartilage does not necessarily mean that it becomes incorporated into articular cartilage. In fact, after oral dosing in the horse, it has been shown that synovial fluid levels of GLN are less than 10% of those in the serum at the same time.[82] This indicates that GLN does not diffuse readily into the synovial fluid from the plasma, suggesting that the effects of GLN may lie in its effect on nonarticular tissues.[82] The presence of synovial inflammation induced by LPS in carpal joints led to significantly higher synovial GLN concentrations compared with levels attained in healthy joints following oral administration of GLN HCl,[103] as well as the potential to mitigate production of inflammatory mediators and elicit reparative processes to articular cartilage.[83]

Exogenous GLN has been shown *in vitro* to have no detrimental effects on normal articular cartilage explants[32] or on chondrocyte metabolism after long-term exposure.[67] Many *in vitro* studies have generally found that GLN induces the production of new cartilage while protecting cartilage that is already present.[6,32–34,71] GLN stimulates synthesis of proteoglycans (PG) and collagen while inhibiting PG degradation. This may occur partly via downregulation of matrix metalloproteinases (MMP) and aggrecanases.[110,128] The anti-inflammatory effects are likely prostaglandin-independent and may be due to enhanced production of HA by synoviocytes.[44,66,82,115,131] In addition, GLN may protect against some of the negative effects of steroids on cartilage, as demonstrated in an *in vitro* equine chondrocyte pellet model in which GLN had a protective effect against the inhibition of proteoglycan production caused by methylprednisolone.[14]

Few equine *in vivo* studies have used only GLN. Oral administration of GLN in young horses in training showed no significant treatment effect on serum biomarker concentrations of bone and cartilage metabolism.[17,44] High levels of GLN used for *in vitro* experiments that were effective have never been achieved in experimental models in humans and animals.[153] Therefore, extrapolating the results from *in vitro* studies to the *in vivo* setting must be done with caution. The most consistent information that can be extrapolated from human studies is that it appears to take 4–8 weeks before GLN begins to act and that GLN would likely give the best results when used preventatively – when minor lesions are present prior to the advancement of the disease process.[108]

VetBooks.ir

The quality of products that contain GLN has been questioned. One study compared the measured amount of GLN in commercially available equine oral supplements to levels listed on each product's label.[110] The study concluded that of the 23 products considered, 9 (39.1%) contained less GLN than claimed by the manufacturer and 4 (17.4%) contained less than 30% of the listed amount. In another study examining five GLN equine products, the actual composition of GLN varied between 63.6% and 112.2% of the label claim.[118] A large variation in the average recommended daily maintenance dose of GLN was also found in the product labels, ranging from 1,800 to 12,000 mg GLN orally per day for an average sized mature horse. This variability should be considered when evaluating the efficacy of these products.[111]

Chondroitin Sulfate

Chondroitin sulfate (CS) is a long-chain polysaccharide that is a normal constituent of aggrecan, and it constitutes about 80% of all glycosaminoglycans in articular cartilage. Within the cartilage it plays an important role in creating osmotic pressure due to its polyanionic charge. CS is often derived from shark and bovine cartilage, and it is rather expensive to synthesize and extract. The species or tissue of origin of CS can determine differences in the concentrations, pharmacokinetics profile, molecular composition and weight, metabolic fate, and therapeutic results.[76,163] Therefore, it cannot be assumed that all formulations of CS have the same clinical effect.

CS is orally absorbed in horses; however, the molecular weight and source can have a direct influence on its permeability across the GI tract and its bioavailability.[37, 40] Studies in other species have shown that the GI mucosa contains a variety of glycosaminoglycan (GAG)-degrading enzymes, suggesting that CS is not absorbed as an intact molecule due to a potential enzymatic degradation.[88,89] It has been proposed that the liver can further modify the final CS molecule prior to reaching circulation.[54,88,89] Reports using radiolabeled CS have demonstrated that it achieves high concentrations in plasma, articular cartilage, and synovial fluid.[24]

Exogenous CS has been shown *in vitro* to have no detrimental effects on normal articular cartilage explants[32] and to increase the synthesis, or decrease the turnover, of proteoglycans/GAGs. *In vitro* studies have also demonstrated a profound anti-inflammatory effect on several tissues involved with joint metabolism. This may be due in part to exogenous CS-stimulating HA synthesis in synoviocytes along with improved composition (viscosity) of HA.[23,119,125] In addition, anti-inflammatory effects may stem from a downregulation of PGE_2 as well as from NO production.[19,113] CS has also been shown to inhibit MMP and aggrecanase expression/activity in a dose-dependent manner.[113,125,135]

In a synovitis model in horses, CS was found to be markedly less effective than polysulfated glycosaminoglycans (PSGAG) administered intramuscularly (Adequan®, Luitpold Pharmaceuticals, Inc., Shirley, NY) for relief of lameness, stride length, and carpal flexion.[160] In another study using the same model, there was evidence that CS had therapeutic value irrespective of the route of administration (oral or intramuscularly) by improving joint function and reducing lameness scores.[35] However, the time of onset of clinical improvement was slower with oral administration of CS. In a human study, response to treatment with oral CS appeared later (at 60 days) was greater at the end of the 3 months' treatment and lasted up to 3 months after the treatment,[104] suggesting that response not only may take time but also may last beyond the last administration. In a study examining five CS equine products, the actual composition of CS ranged from 22.5% to 155.7% of the label claim.[118]

Glucosamine and Chondroitin Sulfate

Many equine nutraceuticals contain a combination of GLN and CS. Synergistic effects have been suggested in a rabbit instability model in which the combination was more efficacious in delaying cartilage lesions than with either agent alone.[91] It has also been shown that the combination improves collagen synthesis in tenocytes and ligament cells, and it may be important for use in accessory joint structures.[90]

In vitro studies demonstrated no detrimental effects of GLN-CS on cartilage metabolism.[32] *In vitro* studies have also suggested that the combination inhibits proteolytic activity, potentially via retardation of the molecular and biochemical events associated with proinflammatory cytokines, including decreased PGE_2 and NO levels while also preventing GAG degradation.[19,32,113] These studies suggest that the GLN would be best for potentially inhibiting OA progression, whereas CS may be best for controlling symptomatic action of OA.

Oral administration of GLN-CS at doses greater than those recommended in horses is associated with a good safety profile, with no alterations in hematological or clotting profiles.[78] In an induced synovitis model in horses, a GLN-CS product showed no clinical detectable benefits.[158] However, there was a significant treatment effect in other synovitis studies, with one showing an anti-inflammatory effect (lower PGE_2 than controls).[35,150] In studies of clinical cases treated with this compound, the results are mixed but with more showing a generally favorable response. When an oral mixed supplement (GLN, CS, and methylsulfonylmethane [MSM]) was administered to veteran horses for 3 months, there was no evidence of any substantial improvement of locomotor performance in geriatric horses.[58] In other clinical studies, horses showed improved lameness, flexion, and stride length, while navicular horses showed significant improvement in soundness compared with placebo controls.[2,55,56] GLN-CS was also evaluated in horses with tarsal OA using gait analysis, demonstrating significant improvement in the left-to-right symmetry of peak vertical ground reaction forces and impulses, as well as tarsal range of motion and joint energy generation during stance.[21]

Hyaluronic Acid

Hyaluronic acid (HA) is a natural component of articular cartilage synthesized by synoviocytes, fibroblasts, and chondrocytes. It is responsible for the viscoelastic and lubricating properties of synovial fluid and plays an important physiologic role in nutrition of the articular cartilage.[64] Many oral formulations of HA have become available for horses. There are several anecdotal reports about the use of these products in horses, but scientific

VetBooks.ir

evidence of oral absorption, bioavailability, distribution, and controlled evaluation of the efficacy of oral HA products in the horse is lacking. One controlled double-blinded study using yearling Thoroughbreds that had arthroscopic surgery to remove osteochondritis dissecans (OCD) lesions from the tarsus demonstrated that the mean effusion score for the treated horses (100 mg orally once daily) was significantly lower than for the placebo group.[11]

Methylsulfonylmethane

MSM is a normal oxidative metabolite product of industrial-grade dimethyl sulfoxide (DMSO) that is an odorless and tasteless organic form of sulfur. It is naturally found in small amounts in fruit, alfalfa, and corn and is very soluble in water.[122,147] It can be found as a product by itself or in combination with GLN and/or CS.[58] It has been used as a nutraceutical because of its analgesic, anti-inflammatory, and antioxidant properties.[77,114,149] There is little known about the pharmacokinetics of MSM. Similar to DMSO, MSM has been suggested for the management of musculoskeletal pain as well as OA. It has been suggested that MSM may relieve muscle discomfort by decreasing the nerve impulses via cholinesterase inhibition and subsequently reducing muscle spasm.[42]

Very little is known about oral administration of MSM safety and toxicity. In a study in rats, MSM given for more than 90 days did not cause any adverse effects nor increase mortality.[61] Few studies have been published to support the use of MSM for managing OA in horses. Horses receiving oral MSM and vitamins demonstrated that MSM could exert some protective effect on oxidative and inflammatory exercise-induced injury related to jumping.[95] In another uncontrolled, non-peer-reviewed study, MSM was associated with improved performance in Standardbred racehorses in training.[123]

Avocado and Soybean Unsaponifiable Extracts

The unsaponifiable portions of avocado and soybean oils are extracted via hydrolysis to make up fractions of one-third avocado oil and two-thirds soybean oil. It appears that this mixture has synergistic properties; however, the active ingredient is still unknown.[93] *In vitro* studies have suggested that avocado and soybean unsaponifiable (ASU) extracts may have a positive effect on both the inflammatory cascade and structural components of the cartilage matrix. Studies have demonstrated that the extracts reduce MMPs, cytokines, nitric oxide, and PGE_2 while increasing growth factors and aggrecan production.[13,57,153] One controlled study that used horses with induced OA in the middle carpal joint failed to demonstrate any significant clinical effects.[72] However, the study demonstrated that ASU displays disease-modifying capabilities because of a significant decrease in intimal hyperplasia and histologic cartilage disease score along with an increase in articular cartilage GAG synthesis in joints with OA.

ASU has been combined with GLN-CS in some products, which may help to decrease some of the symptomatic signs. When combined with α-lipoic acid, an *in vitro* study demonstrated that ASU was better able to inhibit PGE_2 production from chondrocytes than either administered alone.[49]

Fatty Acids

Polyunsaturated fatty acids (PUFAs) are essential fatty acids that are found in fish and plants. Essential fatty acids are components of cell membranes, involved in lipid transport, and serve as precursors to the eicosanoid hormone family, which regulates inflammatory processes.[51] The two principle essential fatty acids are linoleic acid and α-linolenic acid. In the body they are desaturated and elongated to produce analogs of arachidonic acid (*N*-6 fatty acid) called eicosapentaenoic acid (EPA omega-3 fatty acids) and docosahexaenoic acid (DHA omega-3 fatty acids).

In horses, it was reported that the source of essential fatty acids affects the concentration of EPA and DHA in serum.[110] When horses received fish oil in the diet, there was an increase in the concentration of EPA and DHA in their serum, compared with horses that received corn oil. The anti-inflammatory effects of fatty acids have been attributed to stabilization of cell membranes, inhibition of the formation of inflammatory mediators, and protection against oxidation.[15,29,52] Studies have demonstrated that *n*–3 fatty acid supplementation can reduce or inhibit the inflammatory and matrix-degradative response elicited by chondrocytes during OA progression.[28,29] An *in vitro* study using an LPS challenge model in equine synovial explants demonstrated that pretreatment with α-linolenic acid significantly decreased PGE_2 production induced by LPS, reducing the inflammatory response.[107] An *in vivo* study of horses examined the effects of *n*–3 long-chain PUFA (LCPUFA) effects on LPS synovitis after 3 months of supplementation. Aggrecanase 1 concentrations were lower than controls, but there was no effect on PGE_2 or MMP activity in the synovial fluid compared with controls.[126] The clinical usefulness in the treatment of joint disease is still not entirely clear due to the uncertainty of which components of the oils might be effective.

Cetyl myristoleate (CM) is another fatty acid that is used in equine nutraceuticals. It is an ester, omega-5 fatty acid that may act by inhibiting the 5-lipooxygenase pathway,[66] which is responsible for the metabolism of leukotrienes (potent inflammatory mediators from the arachidonic acid cascade). One equine product demonstrated lower lameness scores compared with placebo horses in a double-blinded OA clinical trial.[73] However, there are no published reports on safety, absorption, and metabolism of CM in horses.

Collagen Hydrolysate

Collagen hydrolysate (CH) is a food ingredient that has been used in humans to improve joint comfort and function.[106] CH is derived from bovine or porcine skin and bones. Orally administered CH has been shown to be absorbed intestinally and to accumulate in cartilage.[164] In contrast with other nutraceuticals, no direct analgesic and anti-inflammatory effects have been found after using CH.[9] The theory behind CH is that it provides amino acids specific to the collagen network, playing an important role in the structure and function of cartilage by directly stimulating chondrocytes to synthesize collagenous matrix. Several studies in humans have indicated that the use of CH in people with OA is safe and provides improvement in some measures of joint

VetBooks.ir

pain and function.[7,9] A study using an experimental synovitis model in horses demonstrated anti-inflammatory properties (lower PGE_2 compared with controls) of collagen hydrolysate.[150] There are no published reports on the safety, absorption, metabolism, or clinical use of CH in the horse.

Another collagen product that has been used as a nutraceutical is glycosylated undenatured type-II collagen. A study using this product in horses diagnosed with moderate OA revealed a significant reduction in arthritic pain. This product was determined to be twice as effective compared with a glucosamine plus chondroitin formulation used in the same study. Results and conclusions of this study have to be considered with caution because the improvement was based on the response to flexion.[53]

Resveratrol

Resveratrol is a non-flavonoid, polyphenolic compound found in some fruits (such as grapes) and plants. It has been shown to decrease interleukin-1 synthesis via inhibition of nuclear factor-κB, downregulating COX-2 pathways, and scavenging of reactive oxygen species.[156] Cartilage does not have any blood vessels incorporated within it, and as such chondrocyte activity can be quite susceptible to low oxygen and pH levels. These levels can be further reduced in the face of OA due to mechanical stress, inflammatory mediators, and enzymatic activity causing chondrocytes to produce reactive oxygen species.[22] Resveratrol has been shown in experimental models of OA to protect cartilage due to balancing the oxidation–reduction (redox) reactions.[41,155] In an equine *in vitro* study, resveratrol partially restored mitochondrial membrane potential and reactive oxygen species levels resulting in prevention of GAG release and cell death of cultured chondrocytes.[22] Promise has been shown for use in lameness. Watts et al. performed a randomized, blinded, placebo-controlled clinical trial, where resveratrol was given to horses for 4 months after having their distal tarsal joints injected with corticosteroids.[156] A significantly greater percentage of riders reported that their horse's performance was better in the resveratrol group at 2 (95% versus 70%) and 4 (86% versus 50%) months compared with placebo. This was backed up by an objective inertial lameness exam, but not subjective lameness exam at 4 months.[156]

Vitamins, Minerals, Trace Elements, and Herbs

Many equine nutraceuticals contain vitamins, minerals, trace elements, and herbal ingredients in an attempt to supply elements that are necessary for the maintenance of normal cartilage metabolism as well as provide protection against reactive oxygen species.[142]

Vitamin C has been shown to stimulate collagen and aggrecan synthesis.[127] In addition, vitamin C is a free-radical scavenger that potentially provides anti-arthritic effects by protecting chondrocytes from damage by prooxidants.[92] α-Tocopherol (vitamin E) may have anti-inflammatory effects in the joint, in part by protecting chondrocytes from damage by reactive oxygen species.[92] In addition, vitamin E can enhance chondrocyte growth and increase the synthesis of proteoglycan.[50] Beta-carotene (provitamin A), selenium, zinc, manganese, niacinamide, and bioflavonoids all have potential antioxidant effects.[92] Many plants, parts of plants, or plant-derived substances have anecdotally been suggested to have antioxidant and/or anti-inflammatory properties,[161] with one *in vitro* study demonstrating that a polyherbal formulation was a significant source of antioxidants.[18] Some pharmaceuticals have "natural" plants as one or more of their components. Although some of these may have clinical merit, there are numerous products available, and none have been proven effective in the horse.[161]

THERAPEUTIC TRIMMING AND SHOEING

Andrew H. Parks

INTRODUCTION

The terms "corrective shoeing" and "therapeutic shoeing" are frequently used interchangeably, and to make the differentiation yet more confusing, they mean different things to different people. Literally, corrective implies changing a situation to prevent something harmful, whereas therapeutic suggests a measure designed to heal a pathological process. For the purposes of this discussion, they will be considered synonymous, and the term therapeutic shoeing will be used.

Most horses requiring therapeutic shoeing present with either lameness, including poor performance, or undesirable foot/distal limb conformation/balance as the primary problem.

Ideally, therapeutic shoeing would follow a logical sequence of thought. A thorough understanding of foot function would determine one of two things: How foot conformation or imbalance has predisposed to or caused a disease process to occur in the foot, and/or how a disease process in the foot has altered foot function. From this it should be possible to deduce what principles need to be employed to counteract the causes or effects of the problem and devise a practical strategy to implement those principles.

There are obvious limitations at all these steps. While sometimes a diagnosis can be definitive, there are other occasions when the most specific diagnosis a clinician can make is heel pain. Although significantly improved over the last 10–20 years, our understanding of foot function is still quite incomplete, and therefore, the clinician must often pick the most rational explanation.

Most disease processes of the distal limb are traumatic in origin; more specifically, they are the result of repetitive stress resulting from normal athletic activity. The stresses on the distal limb vary with the phase of the stride.[26] The impact phase of the stride is separated into two overlapping collisions. The primary collision occurs as the foot contacts the ground and is associated with high accelerations but low mass. The secondary impact phase of the stride occurs as the mass of the body collides with the foot that is then firmly planted on the ground, but by this phase of the stride, the shockwaves are diminishing. During the support phase of the stride, the accelerations have ceased, but the overall load increases to a maximum at approximately mid-stride, after which the load diminishes.[26] The breakover phase of the stride is also associated with accelerations as the foot rotates. The distal limb has sophisticated mechanisms to dampen shockwaves and spread out the duration of loading and unloading, but extreme exercise, or changes to the foot or ground surface that enhance the accelerations within the distal limb or shorten the duration of loading, increase the likelihood of injury. Both shockwaves and large loads associated with weight-bearing are potentially injurious. In addition, attaching steel shoes with nails is known to increase the magnitude and frequency of impact shockwaves.[3,8] Therefore, once the principle abnormality is determined, the goals of therapeutic shoeing are almost always designed to strategically address the way structures in the distal limb are stressed to prevent, palliate, or heal injury to the structures that are at risk or diseased. Consequently, it is important to consider the way the structures of the distal limb are stressed during weight-bearing and locomotion.

The hoof capsule normally endures stress under tension or compression, depending on circumstances. These stresses may be longitudinal, radial, or circumferential and likely a complex combination of these. Ligaments and tendons are built primarily to resist tensile forces, cartilage best resists compression, and bones can withstand compression, tension, bending, or torsion to different degrees. The stresses associated with bending and torsional forces are much more dangerous to the bones of the distal limb than are those of compression, in which the bones are primarily loaded. Therefore, injury prevention is aimed at normalizing the stresses in the distal limb, and treatment is designed to protect a structure from stress as it heals.

The definition of ideal conformation is elusive. However, deviation from an optimal conformation is likely to lower the threshold at which injury related to the stresses of locomotion and weight-bearing is likely to occur. The hoof capsule, as part of the integument, differs from the musculoskeletal structures of the distal limb because it constantly grows and wears away and because it has remarkable viscoelastic properties. In response to prolonged application of abnormal stresses, the hoof capsule becomes distorted, and prolonged altered load bearing changes both wear and growth patterns.

EXAMINATION OF THE LIMB FOR THERAPEUTIC SHOEING

Examination of the horse and its limbs should identify both predisposing factors and disease. When the disease process is identified, a specific strategy may be formulated that includes a combination of therapeutic shoeing, medication, and/or surgery. Frequently, the clinician is expected to develop a strategy to treat a lameness originating from the digit that cannot be ascribed to a particular structure or process, compensate for a conformational abnormality, correct an apparent imbalance in the foot, or a combination of the above. This necessitates careful examination of the morphology of the foot, the relationship between the foot and the rest of the limb, and the way the foot interacts with the ground. Radiography is a useful adjunct to assess the relationship between the phalanges and the relationship between the phalanges and the hoof capsule.

Examination of the hoof capsule morphology indicates where the wall is unduly stressed, though care must be taken not to overemphasize any one characteristic,

VetBooks.ir

but rather correlate all findings. The hoof capsule should be examined from all sides with the foot on the ground, and from the solar perspective with the foot off the ground. With the foot on the ground, the following findings suggest too much stress in the wall in one portion of the foot: compression of growth ring (Figure 8.1), flares at the quarter or toe, underrunning of the heels, and proximal and/or abaxial displacement of the coronary band. With the foot held up, the ground surface should be examined for approximate mediolateral symmetry, including position of the heels and irregularities in the outline of the capsule. Additionally, the ground surface should be evaluated for appropriate width in relation to length and position of the widest point of the foot in relation to the center of the ground surface (see Chapter 11).

The phases of the stride are best observed at a walk. The most common pattern of landing at a walk or trot is either lateral heel/quarter first or flat, i.e. both sides simultaneously. Toe-first landing and medial-first landing are both suggestive of an abnormality in gait when a horse is moving in a straight line and should also prompt investigation.

Lateromedial and dorsopalmar radiographs are required to assess conformation and balance of the distal limb. For these purposes, the center of the X-ray beam should be centered approximately 1.5 cm above the ground surface of the foot. For the lateromedial radiographs, the X-ray beam should be centered midway between the toe and heels, and for the dorsopalmar radiographs, the beam should be centered in the middle of the foot. In a foot with good conformation and balance, the dorsal wall is approximately parallel to the dorsal surface of the distal phalanx, the sole depth is appropriate for the size of horse (variable from 10 to 16 mm though optimally greater than 15),[11,16,19] the center of rotation of the distal interphalangeal joint is slightly palmar to the center of the weight-bearing surface of the foot, and the average angle that the solar margin of the distal phalanx makes with the ground is 6°.[9,22]

Dorsopalmar radiographs must be taken with the metacarpus vertical and aligned with the median plane of the foot, which may not be the same as the median plane of the more proximal limb or the trunk. Both feet should be weight-bearing because elevating the contralateral limb induces collateromotion and rotation within the digit.[7] There should be no forced rotation in the limb. The most important observations are the angle of the articular surface of the distal phalanx to the ground and the symmetry of the articulations. The height of the coronet should be correlated with the position of the distal phalanx and any flares identified.

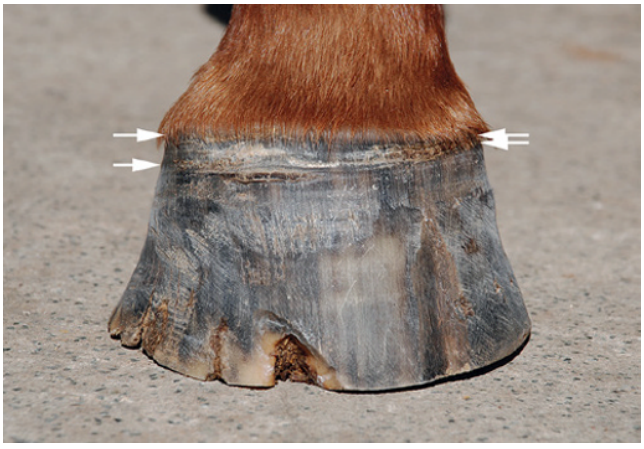

Figure 8.1. Photograph of a horse with growth rings that diverge markedly from medial to lateral (arrows). This horse has medial distal displacement of the distal phalanx.

THE TRIM

The foundation for any corrective shoeing is the trim. If the trim is not appropriate, whatever shoe is used will be less than optimal. The ideal shape of the foot and basic technique of trimming is well described in Chapter 11. In short, there are just three basic variables that can be altered: depth of sole, angle of the dorsal wall, and mediolateral symmetry. The length of the wall at the toe is predicated on the depth of the sole; the wall is either level or slightly longer than the adjacent sole. The length of the heels is then predicated on the length of toe and the angle of the foot-pastern axis. Distortions in the hoof capsule may necessitate additional measures. Likewise, application of techniques described below may require variation from the basic pattern.

SHOEING

There are only so many basic principles that can be implemented to improve the function of the equine foot, and these include increasing shock absorption, moving the center of pressure, easing movement about the distal joints in the limb, altering the distribution of force, changing traction on the ground surface of the shoe, and altering the motion of the limb during the flight phase of the stride (Table 8.4). However, there is a wide range of tools that can be applied to achieve these principles, and the combinations thereof are almost infinite. Some of these modifications to the shoe are covered in Chapter 11. Unfortunately, all too often the focus is on the method rather than underlying principles.

Shock Absorption

High-frequency, high-energy shockwaves are generated during the impact phase of the stride and to a lesser extent during the breakover phase. They occur in all planes, and the magnitude and frequency of these waves are affected by the structure of the distal limb, the presence of shoes and pads, and the nature of the ground surface.[2,3,18,21] Numerous manipulations of the foot influence – potentially influence – the magnitude of shockwaves, including the application of a shoe, the method of shoe attachment, the material of the shoe, pads interposed between the shoe and hoof, traction devices on the shoe, and the surface of the ground.

Usually, it appears that most interventions that involve shoeing increase the shockwaves associated with impact. Therefore, the natural damping mechanisms within the digit almost always function better in a healthy horse if it is barefooted. However, conditions of the working environment frequently necessitate shoeing. Most research has compared attachment of a

VetBooks.ir

Table 8.4. Principles for therapeutic trimming and shoeing.

Modification	Goal of modification	Examples of how to achieve goal
Move the center of pressure	Move the ground reaction force in relation to the center of the foot/center of rotation of the distal interphalangeal joint to move the load of weight-bearing from one side of the foot to the other	Wedges, extensions; alter width of web unevenly, either medial vs. lateral or dorsal vs. palmar
Shock absorption	Dampen vibrations associated with deceleration and acceleration	Aluminum shoes instead of steel, synthetic polymer shoes, viscoelastic pads
Ease movement about the distal interphalangeal joint	Shorten arm of extensor moment about the distal interphalangeal joint at breakover	Roll the toe, rocker the toe, square the toe, set the shoe back
Change distribution of force	Increase ground contact of part or all of sole, bars, and frog to reduce load on wall	Heart-bar shoes, custom pad (e.g. heart-bar pad), pour-in pads
Motion of limb during flight	Prevent interference or improve esthetics of gait	Forging: Speed up breakover of forelimb and retard breakover of hind limb Brushing in hind limbs: Widen gait by squaring toe, adding traction or trailer to lateral branch, ± lowering medial wall
Traction	Increase traction to reduce slippage; decrease traction to reduce horizontal deceleration	High traction shoes: rim shoes, calks, and grabs Low traction shoes: sliding plates, half-rounds, flat shoes

steel shoe with nails to the barefoot condition and the horse exercised on a firm, flat surface. Under these circumstances, the steel shoe reduces the natural damping mechanisms and reduces – but does not abolish – foot expansion.[6,8] Research also shows that aluminum and synthetic shoes may impede the natural damping mechanisms less than steel.[1,3]

The effect of rim pads inserted between the shoe and ground surface of the foot vary, depending on the material they are made from. Rigid pads and those that become compressed with use are unlikely to be of much benefit, but pads that undergo viscoelastic compression and relaxation with the phases of the stride may offer significant benefit. Unfortunately, there is virtually no information about commercially available pads to know which are likely to provide the greatest benefit. Similarly, there is a wide range of synthetic shoes available, some of which dampen impact vibrations, whereas others do not show a detectable improvement.[1,3]

The nature of the ground surface is also important in the interaction between the shoe and the ground in both damping impact shockwaves and loading and unloading the osseous and tendinous structures of the limb.[21,26] Usually, the surface is dictated by the nature of the work. Numerous devices such as calks, toe grabs, and modifications to the shoe profile (such as rims) are used to increase traction. Wide-web flat shoes or half-round shoes may decrease traction. Too much traction increases the horizontal impact vibrations, and too little predisposes to slipping and potential ligamentous injury. There are few data to assist a clinician in the choice of these devices to optimize traction, except to implicate the use of toe grabs in causing musculoskeletal injuries in racehorses.[14] Therefore, their application is largely based on individual experience. It is wise to err on the side of caution and use creases or low rims if possible, and if calks or grabs are needed, to use the lowest, broadest devices applicable.

Weight-Bearing and the Center of Pressure

The center of pressure determines the relative load bearing by the medial and lateral and dorsal and palmar halves of the foot, which in turn determines the loads and subsequent compressive and tensile stresses on the different structures of the foot. At rest, the center of pressure is at or near the center of the ground surface of the foot. The center of pressure changes during the course of the stride; it can be most simply described as moving rapidly from the point of contact to the point at or near the middle of the ground surface of the foot for the majority of the stride, until breakover, when it moves toward the toe.

The center of pressure can be moved in numerous ways. The simplest that works on all surfaces is to increase the relative length of one side of the foot to the other, which moves the center of pressure to the elevated side.[28] Increasing the length of the heel or toe moves the center of pressure toward or away from the center of rotation of the distal interphalangeal joint (Figure 8.2). In doing so, it shortens or lengthens the arm of the extensor moment about the distal interphalangeal joint.

Other manipulations to move the center of pressure without altering the relative lengths of one side of the foot are based on increasing or decreasing the resistance of the foot to descend into the surface of a yielding substrate. Extension of the shoe outside of the normal perimeter of the foot increases the length of the lever arm on that side. This increases the leverage that the substrate can exert about the center of rotation; for example, an egg-bar shoe moves the center of pressure away from the toe.[20] A similar effect can be achieved by altering the width of the shoe at any point about the perimeter in relation to the rest of the shoe. A decrease in the width of the web increases the descent of the shoe into a yielding substrate at that point; an increase in web width decreases it. Moving the center of pressure in this

VetBooks.ir

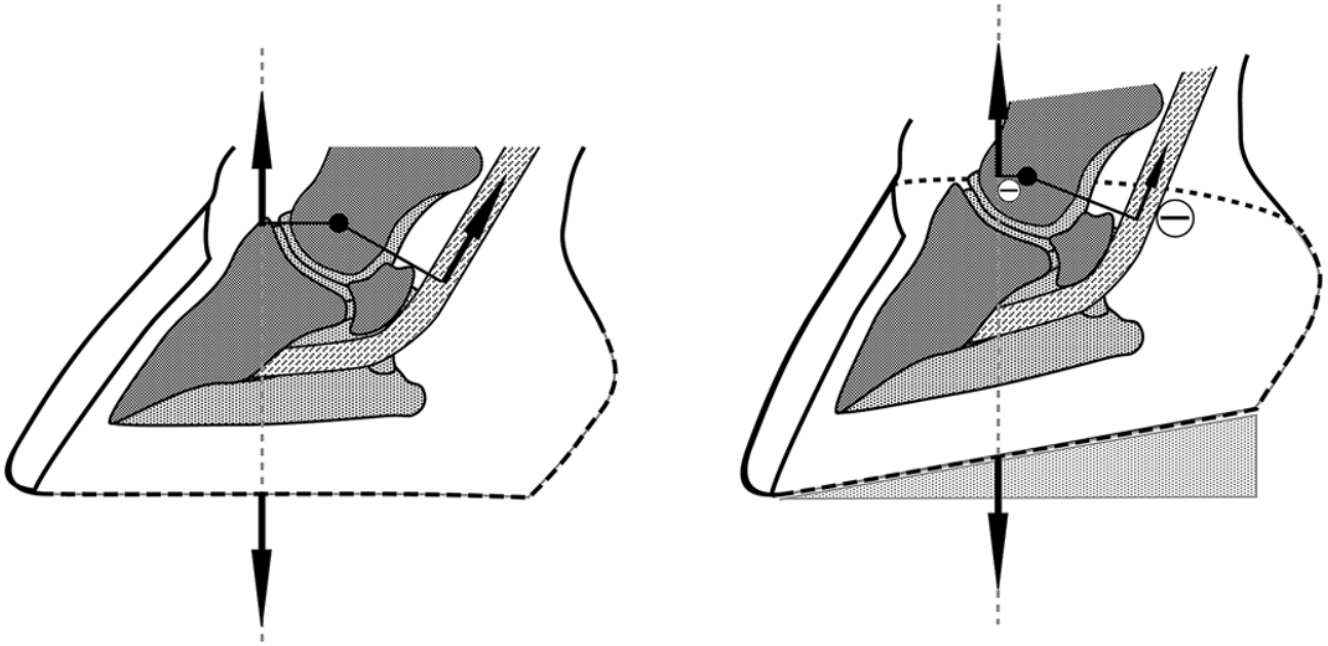

Figure 8.2. Schematic illustration demonstrating effect of heel wedge on moments about the distal interphalangeal joint. Elevating the heel shortens the moment arm of the extensor moment. As the flexor moment arm remains approximately the same, the force in the deep digital flexor tendon is decreased. The center of pressure remains approximately in the center of the foot. (Vectors represented by arrows are for illustrative purposes and do not represent real values.)

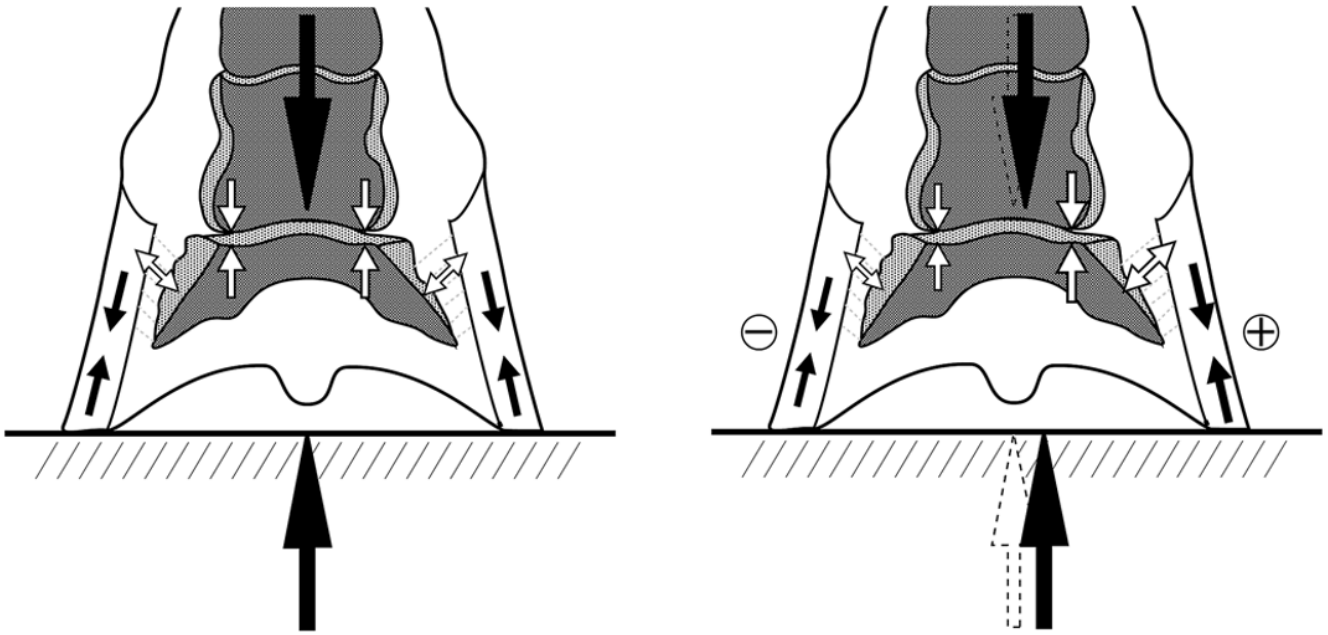

Figure 8.3. Schematic illustration demonstrating the effects of moving the center of pressure in the frontal plane on the structures in the foot. As more weight is borne by one side of the foot, the bones and joints become more compressed, the tension in the collateral ligament is reduced, and the tension in the lamellae is increased. These changes are reversed in the opposite side of the foot. (Vectors represented by arrows are for illustrative purposes and do not represent real values.)

manner to one side of the foot decreases the stress in the ipsilateral collateral ligament and the contralateral lamellae and articular surfaces (Figure 8.3). Moving the center of pressure toward the heels with a wedge or any shoe that functions as a wedge reduces tensile stress in the deep digital flexor tendon, compressive stress on the navicular bone, and is thought to decrease the tensile stress in the dorsal lamellae (Figure 8.4).

Each of these manipulations has a concurrent side effect. The manner in which horses place their foot on the ground suggests that proprioceptive feedback, rather than the ground surface of the hoof, controls the position

VetBooks.ir

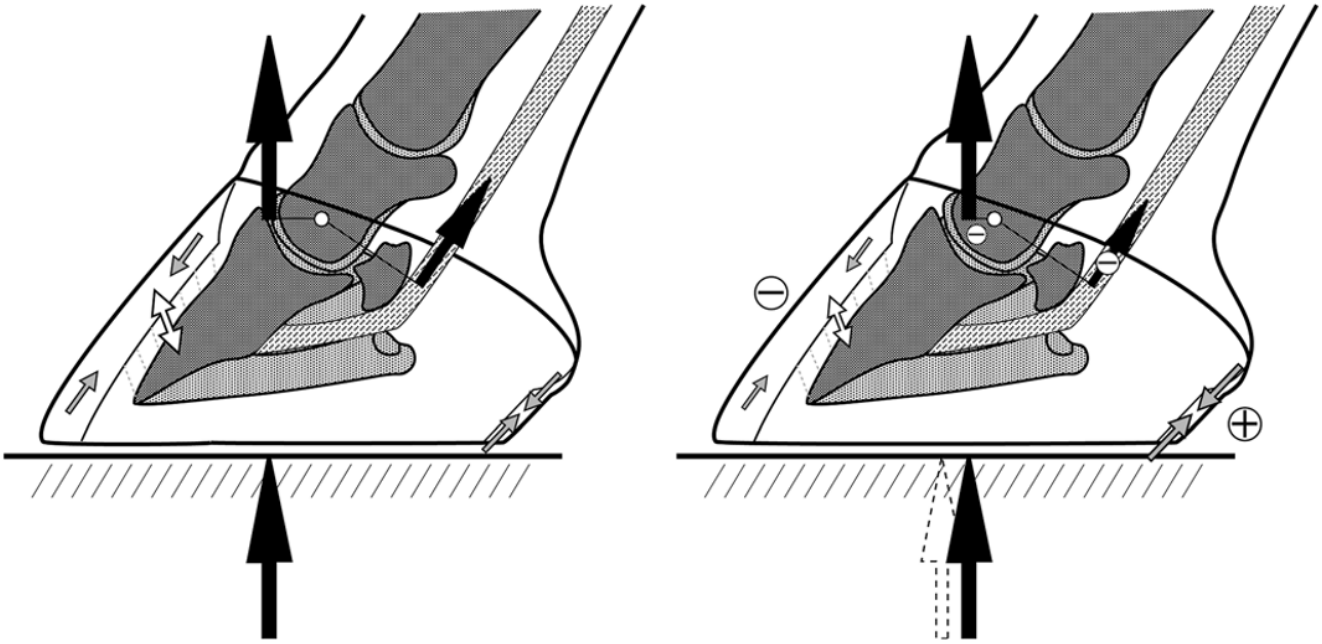

Figure 8.4. Schematic illustration demonstrating the effect of moving the center of pressure in a palmar direction. The arm of the extensor moment becomes shorter, and because the arm of the flexor moment remains approximately the same, the force in the deep digital flexor tendon is decreased. (Vectors represented by arrows are for illustrative purposes and do not represent real values.)

of the distal phalanx.[5] Therefore, extending the effective border of the hoof distally at any point around its circumference increases the tendency that the foot will land on the lengthened wall first. Extensions on the medial side of the foot of a horse should be used with caution because of the risk of interference. Similarly, toe extensions should be used with caution because they increase the propensity of a horse to trip. Lateral extensions may be used without such obvious side effects but are likely to alter flight of the foot as the limb is protracted due to increased air resistance, the magnitude, and significance of which have not been determined. Changing the width of the web of one branch of the shoe causes the foot to become asymmetrically weighted, changing the inertia that must be overcome as the foot accelerates away from the ground at breakover and decelerates at impact. The significance of this effect has not been investigated.

Ease of Movement

Clinicians have long thought that making the breakover point more palmar improves the function of the foot and relieves mild lameness, particularly that associated with palmar heel pain. However, several studies have examined the effect of changing breakover in this manner and have been unable to demonstrate a decrease in the duration of the breakover or a change in the flight of the foot,[10,17] though it may cause the foot to breakover slightly earlier. Additionally, it does not change the peak moment about the distal interphalangeal joint or the peak force on the navicular bone, even though it decreases the length of the moment arm of the ground reaction force about that the distal interphalangeal joint at breakover (Figure 8.5).[10]

The most likely explanation for the improvement seen by clinicians is that the foot breaks over (unrolls) more smoothly, thereby decreasing the abruptness in changes in stress in the underlying tissues.[13] To a lesser extent the medial and lateral abaxial branches of the shoe can be beveled to improve the ease of motion as a horse is turning. While this has not been explicitly studied, it is known that a turning horse loads the side of the hoof on the inside of the turn.[25] Therefore, it is rational to anticipate that rolling or beveling the abaxial margins of the shoe smoothes out the changes in stress in the underlying tissues on the ipsilateral side of the foot.

Distribution of Force

The main rationale for distributing part of the load of weight-bearing over more of the sole and frog is to reduce load bearing by the lamellae and wall, which assumes that most of the load is normally born by the wall. This is frequently done by recruiting the entire ground surface in horses with laminitis. In those with underrun heels, reducing weight-bearing by the heels is attempted by increasing weight-bearing by the frog, bars, and angles of the sole.

However successful these manipulations appear clinically, the mechanical effectiveness of this manipulation is uncertain because the role of the sole and wall in weight-bearing is poorly understood. It has been clearly demonstrated that when a horse that has been at pasture barefoot stands on a firm surface, it bears weight in a "4-point" pattern[15], that is, on its heels and at the toe-quarter junctions. If the same horse is housed on concrete, the wear of the ground surface of its foot causes it to bear weight around more of the perimeter of its foot and frog. If the same horse is made to stand on sand, the weight is distributed over a much greater area, which is no longer distributed around the periphery of the foot but over the sole in a band running from quarter to

VetBooks.ir

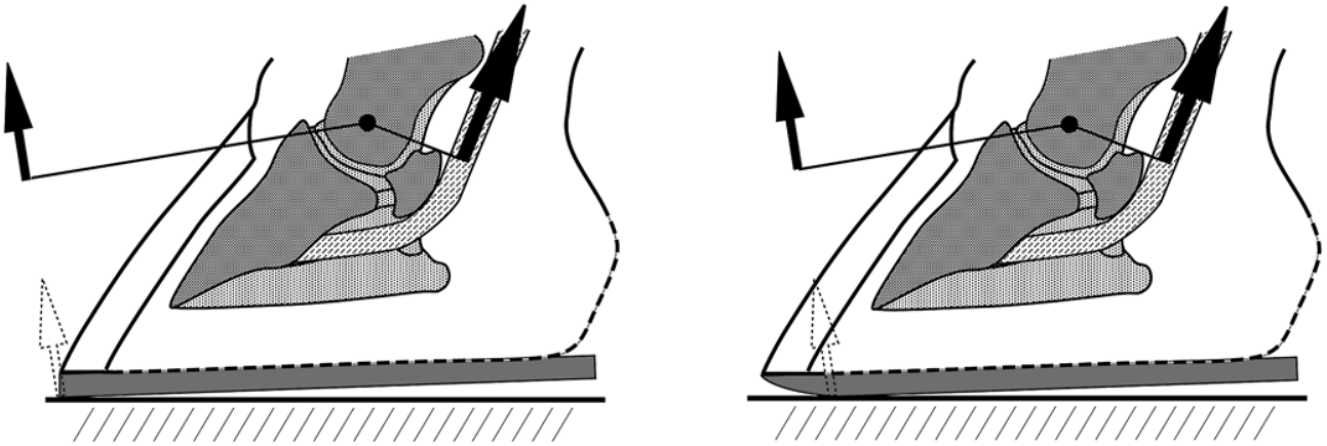

Figure 8.5. Schematic illustration demonstrating the effect of moving the point of breakover in a palmar direction. At the moment the heel leaves the ground, the arm of the extensor moment is shorter in shoes with rolled toes compared with shoes without rolled toes. (Vectors represented by arrows are for illustrative purposes and do not represent real values.)

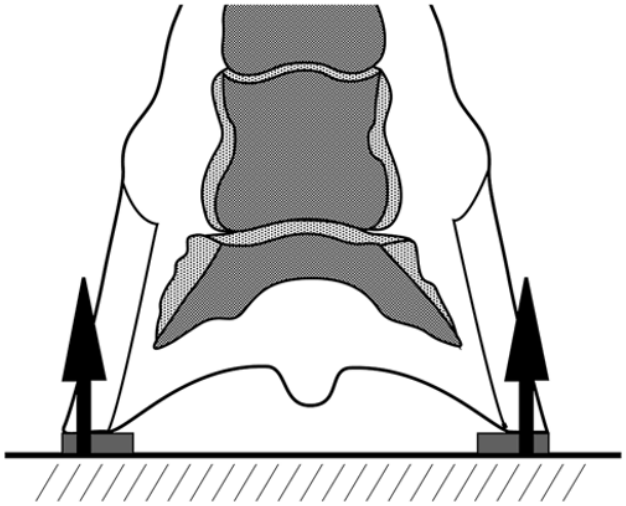
quarter.[15] It has also been demonstrated that filling the space between the sole and the branches of the shoe with polyurethane (a pour-in pad) distributes the forces associated with weight-bearing broadly across the bottom of the foot when standing on sand though not when standing on a firm rubber surface.[12]

What is much less clear is how the weight is transmitted from the hoof capsule to the distal phalanx. Intuitively, it would seem that when a horse is bearing weight on a flat, firm surface and only the wall is in contact with the ground, all of the load is transferred through the wall to the distal phalanx through the lamellae and that the sole has little role in weight-bearing.

What then is the manner of load transmission when the horse is standing on a deformable surface such as sand or turf? Intuition might suggest that now weight is directly transmitted from the sole to the distal phalanx. However, evidence from finite element analysis suggests that this is not the case.[24] Rather, evidence suggests that the load is transmitted from the sole to the wall and presumably then to the lamellae. This model also suggests that expansion of the foot is caused by the wall at the quarters spreading, which causes the sole to spread and flatten. In doing so, the sole descends more than the distal phalanx. The implication behind the latter observation is that completely filling the space between the branches of the shoe, as with pour-in pads, may decrease the sole from descending, limiting expansion of the wall, and hence decreasing one of the hoof's mechanisms for dissipating shockwaves.

The distribution of force on the ground surface of the foot can be changed by increasing the area of contact with the ground during the stride, so that the force on the ground surface of the foot is more broadly distributed (Figure 8.6) or vice versa. This may be achieved by increasing the ground surface area of the web of the shoe so that it has greater contact with the ground and the foot. Alternatively, a variety of materials, such as polyurethane or silicone putty, may be placed inside the contour of the shoe to either partially or completely fill the space between the branches of the shoe, the ground surface of the foot, and the ground. A similar result may be achieved by using a heel plate in conjunction with a composite (Figure 8.7). A symmetrical increase in distribution of load about the center of pressure across the ground surface of the foot is unlikely to alter the center of pressure, but any asymmetrical redistribution of load bearing is likely to cause the center of pressure to shift. Additionally, there is a risk that making the ground surface of the foot completely flat reduces traction excessively, depending on the surface, and hence predisposing to ligamentous injuries related to slippage.



Clinical experience indicates that the lameness of some horses can be dramatically improved by distribution of weight across the sole, while in others it is made worse, and in yet others it seems to make little difference. The failures only serve to emphasize that our knowledge is insufficient to accurately apply scientific principles to the use of redistributing weight-bearing across the ground surface in a predicable manner. That said, the successes encourage further exploration to determine when and why it is successful.

Motion of Limb During Flight

The flight phase is the least investigated of the phases of the stride with respect to the effects of shoeing. Therefore, most modifications to change it are based on reasoned arguments, with all their flaws, and experience. The way the foot lands influences the position of the foot during the stance phase, and the position of the foot during the stance phase influences the way the foot leaves the ground. Thus, the patterns of the stance and flight phases are at least in part intertwined. Redirection of the path of flight of the foot not only is primarily directed at preventing interference injuries but also might be directed at improving the appearance of flight path for esthetic reasons. Any manipulation of the foot to change to flight path that causes the structures to move outside of their normal plane of motion or increases their range of motion potentially predisposes these structures to injury.

Interference between two limbs is a potential cause of injury. It may occur between two forelimbs, two hind limbs, and two ipsilateral limbs and in pacers between diagonal limbs. Interference is more common in shod

horses, and it is thought that conformation, imbalance, and fatigue are the main precipitating factors.

Given the likely etiology of interference, the best starting point is to ensure the foot is balanced and use the lightest, appropriately sized shoe compatible with the level of work. Although the general strategy to avoid interference that occurs between ipsilateral limbs is to speed up breakover of the forelimb and slow down breakover of the hind limb, this practice is not well supported by scientific evidence. Changing the point of breakover on a forelimb has limited impact on the kinematics of breakover. Furthermore, while lengthening the toe and therefore moving the point of breakover dorsally in the hind limb does prolong breakover, the limb compensates during protraction to impact the ground at the same time as it would with a shorter toe.[4,17]

The general principle in treating interference between contralateral limbs is to widen the gait. This is generally achieved by a combination of squaring the toe, increasing traction laterally, and using a lateral trailer on the hind foot, with or without lowering the medial side of the foot. Again, evidence to substantiate these modifications of the shoe to achieve these goals is lacking, but they are long-standing traditional approaches. When these approaches do not work and interference persists, then the limb that is interfered with is protected with boots, and the shoe on the interfering limb may be safed.

PROTECTION AND SUPPORT

Protection and support are goals of therapeutic shoeing, and they deserve separate consideration since there is some overlap in their implementation. The term protection in relation to shoeing is usually used to indicate reduction or prevention of pressure on part of the ground surface of the foot. Therefore, protection is usually provided by eliminating pressure in a given area by redistributing the force associated with weight-bearing on the distal surface of the foot or placing a shielding device superficial to the area. This may involve using a wider web shoe, a strategically placed bar, or a treatment plate across the entire ground surface of the foot.

The use of the term support is more ambiguous. Support can be used in relation to maintaining an anatomical relationship; for example, after the deep digital flexor tendon has been severed, a heel extension may be used to maintain the foot flat on the ground. Alternatively, a structure can be considered supported when the stress in it is reduced; for example, in the case of a strained deep digital flexor tendon, elevating or extending the heels decreases the stress in the tendon. In these examples, one action meets both definitions of support; however, this is not always the case. It is common to hear that a modification to the shoe supports the heels, usually by extending or elevating them. In reality, extending or elevating the heels maintains the alignment of the foot-pastern axis and supports the deep digital flexor tendon but increases the load on the heels, thereby increasing the likelihood that they will deform and decrease their growth. Most actions that provide support involve movement of the center of pressure.

VetBooks.ir

CLINICAL APPLICATIONS OF PRINCIPLES

The specific diseases of the equine digit are covered in detail elsewhere in the text, but it is useful to briefly examine how the above principles might be applied to several common conditions. Because navicular syndrome is generally considered to be progressive, prolonged rest for a working horse is not usually an option. Therefore, therapeutic measures are primarily directed at palliation, and therapeutic shoeing is pivotal.

Moving the point of breakover in a palmar direction by aggressively rolling the toe smoothes out breakover. Increasing the ground contact in the palmar half of the foot, such as with a straight bar, heel plate (Figure 8.7), or egg-bar shoe, decreases the descent of the heel into a yielding substrate and thereby acts as a mild wedge. Therefore, these maneuvers move the center of pressure in a palmar direction to decrease the tension in the deep digital flexor tendon at rest and in the support phase of the stride.

To move the center of pressure in a palmar direction more aggressively, the heels may be raised by one of several means including a graduated shoe or a wedge pad. The compromise made in moving the center of pressure in a palmar direction is that the palmar hoof capsule will bear more load and will be more likely to become deformed. Therefore, the center of pressure should be moved as little as possible to produce the desired result.

There are several shoe designs in which the palmar half of the shoe is flat, but the design of the shoe incorporates a breakover point at or just dorsal to the midpoint of the foot, for example, the Tennessee navicular shoe (Figure 8.8). Presumably, this shoe acts as a flat shoe for the landing and support phases of the stride but as a wedge during breakover. It appears to mitigate some of the disadvantages of heel elevation.

Finally, impact vibrations can be potentially dampened by switching from a steel shoe to an aluminum or synthetic shoe, or by incorporating a viscoelastic pad.

Strains and rupture of the deep digital flexor tendon share features with navicular disease in that they are likely caused by repetitive excessive strain; therefore, similar measures should benefit both. However, the goal of treatment of a deep digital flexor tendon injury is to promote repair. The horse is rested, and reducing tension on the tendon at rest or in the support phase of the stride becomes the primary goal of shoeing. Consequently, the center of pressure is moved in a palmar direction more aggressively, usually by extending the shoe in a palmar direction and by elevating the heels, often using a custom forged patten shoe (Figure 8.9). Prolonged used of this type of shoe causes marked distortion of the hoof capsule by decreasing heel growth, causing the heels to underrun and contract, increasing growth at the toe, and causing the dorsal wall to assume a marked convex shape. Therefore, the degree of elevation must be reduced as rapidly as is compatible with healing of the tendon.

Laminitis is a complex disease that has many clinical manifestations. The goals of shoeing are to minimize additional injury and control pain in the early chronic stages of the disease and in later stages of the disease to encourage realignment of the hoof wall with the distal phalanx and normal hoof wall growth. Because the lamellae are stressed under tension, which contributes to the pain, the center of pressure should be moved to the opposite side of the foot. In a horse with rotation, this is commonly accomplished with heel extension or elevation to decrease stress in the dorsal lamellae (see Chapter 4). Additionally, because it is preferable to reduce weight on all the lamellae as much as possible, part of or the entire ground surface of the foot between the branches of the shoe may be recruited to bear weight (this is apparently used to good effect when standing an acutely laminitic horse on sand). However, caution must be taken to ensure that the shoe or packing material/pad does not put pressure on the sole where the solar margin of the distal phalanx has displaced distally. If the horse has sunk unilaterally, then the center of pressure should be moved to the contralateral side of the foot. This has been attempted by setting a shoe, either metal or wood, wide to act as an extension on the contralateral side of the foot. In horses that have complete loss of lamellar integrity and have distal displacement of the distal phalanx, there is little advantage to moving the center of pressure. In addition, spreading the load across the sole

Figure 8.9. Patten shoe used to elevate and extend the heels in horses with severe deep digital flexor tendon injury.

VetBooks.ir

is problematic because in unloading the wall it loads the sole where the distal phalanx has displaced. Generally, once the distal phalanx has become more stable and the sole thickened, horses with distal displacement can be shod. Then a seated out wide-web shoe is used to protect the sole adjacent to the wall, and a composite such as silicone putty is used to recruit weight-bearing by the sole, bars, and frog. While this outline suggests logical approaches to protect the affected lamellae as they heal, more documented experience is needed.

Pedal osteitis is a syndrome associated with a flattened sole, bruising of the solar dermis, and osteopenia of the solar margin of the distal phalanx. Therefore, the principal goal of treatment is to protect the affected areas by limiting their contact with the ground. Wide-web shoes that have been seated out protect that area immediately adjacent to the wall, the principally affected area, and therefore are the most common shoe modification used. Pads that elevate the ground surface of the foot may also decrease the likelihood of ground contact. However, pads that cover the ground surface of the foot are of mixed benefit because while they may dissipate the energy of contact, they may actually increase the likelihood of contact; this particularly applies to pads of the pour-in variety. Therefore, the use of a pad must be decided on a case-by-case basis and careful choice of material.

Osteoarthritis of the interphalangeal joints is progressive, and pain can be exacerbated by concussion and extreme motion within the joint. Therefore, the goals of treatment should be to decrease concussion associated with impact and loading and decrease the abruptness in changes of stress associated with locomotion. This can be accomplished by using aluminum or synthetic polymer shoes instead of steel shoes, using viscoelastic rim pads, and ensuring that the shoe has limited traction to decrease the jarring associated with deceleration. Moving the breakover in a palmar direction and beveling the abaxial margins of the shoe minimize strain on the joint capsule and collateral ligaments. These may be achieved with a roller motion shoe (Figure 8.10), but other shoes, such as half-round shoes, can be modified to provide similar all-around benefits.

Ideal distal limb conformation is poorly defined and depends on the nature of athletic activity a horse performs. Nevertheless, some generalizations can be made about the various forms it takes. Most are related to mediolateral angulation within limb, rotation within the limb, and changes in relative length and angle of the pastern. If one of these is present, without clinical lameness, hoof wall distortion, or changes in foot flight, it is usually unadvisable to perform anything other than routine trimming and shoeing because almost all measures will have an unintended consequence. For example, it has been proposed that if the foot is lateral to the median plane of the metacarpus, a medial extension should be placed on the foot to bring the center of pressure under the metacarpus. The potential benefit is that the metacarpophalangeal joint is more evenly loaded.[27] Unfortunately, this also loads the medial structures of the foot that are under compression and the lateral structures that are under tension. At a minimum, the compression of the medial hoof capsule causes decreased hoof wall growth and flaring of the capsule at the quarters.

Similarly, it has been proposed that when the foot is further dorsal in relation to the metacarpus than "normal," the shoe is extended farther in a palmar direction to bring the center of pressure closer to the axis of the metacarpus to decrease the strain on the tendons.[23] However, the tendon that receives the greatest benefit is the deep digital flexor tendon, whereas the tendons most affected by the length/low angle of the pastern are the superficial flexor tendon and the suspensory apparatus. This strategy also places greater load on the heels, increasing the likelihood that they will deform. Nevertheless, it can be envisaged that there are occasions when these compromises are necessary. Indeed, in foals, both strategies are used. Abaxial extensions are used to treat angular and rotational deformities and palmar extensions to treat flexor tendon laxity. In part, these techniques are successful in foals because they are only needed temporarily and the growth plates have not fused.

In brief, the treatment of imbalance restores the shape of the hoof capsule, its relationship to the skeletal structures of the limb, and the pattern of landing. Because imbalance takes so many forms, there is no universal recipe, but there are some general guidelines. Imbalance of the hoof capsule is best treated by trimming rather than shoeing if possible. Imbalance may be a more general problem, i.e. when it affects the symmetry of the whole foot, either medial versus lateral or dorsal versus palmar. Alternatively, it may be a local phenomenon, such as occurs when there is proximal displacement of the coronary band immediately proximal to the ground surface of the heel buttress associated with a quarter crack.

The trimming is best guided by examining the hoof capsule for evidence of areas with increased stress, such as flares and compression of growth rings (Figure 8.1). If possible, the length of the wall should be trimmed in these areas. If there is not enough wall below the preferred plane of the sole to trim to correct it – for example, when the wall has moved proximally in relation to the distal phalanx or correction of a local imbalance leaves an uneven ground surface – then it is best to leave the hoof unshod. This encourages migration of the wall into a more normal position.

Figure 8.10. ACR Rolling Sport Shoe, a form of a roller motion shoe.

VetBooks.ir

Graduated shoes, pads, and attachment of shoes with composites can also be used to correct imbalance. However, placement of a shoe may also limit or prevent movement of the hoof capsule that contributes to restoring the desired shape of the foot. There are occasions when indicators of imbalance suggest conflicting actions; then it is advisable to go with the preponderance of the evidence and be prepared to use trial and error.

SUMMARY

The science of farriery is far from fully developed. It is important that clinicians understand the limited amount of experimental evidence that is available to support different trimming and shoeing techniques. For experiments to have value, they must be performed under very specific constraints. Extrapolation beyond these constraints increases the variability of expected results, and therefore, an apparently rational approach is not always successful. Consequently, a willingness to use trial and error greatly increases a clinician's chances of success; it also builds the clinician's body of knowledge. It is natural for any veterinarian or farrier to prefer a given technique based on experience because practice improves success, and it is difficult, if not impossible, to be adept at all techniques available. The goal should always be to find the simplest solution that meets the objectives. Finally, it is important to remember that whenever a change is made to a shoe, there is an unintended, though potentially anticipated, consequence.

ACUPUNCTURE TREATMENT OF LIMB LAMENESS AND BACK PAIN

Kevin K. Haussler

INTRODUCTION

Acupuncture is the stimulation of specific anatomical landmarks with the goal of providing pain relief or normalizing physiologic function. The exact location of equine acupuncture points has been debated, and clear consensus on anatomic locations and naming systems is lacking.[14] Numerous studies have proposed unique anatomical or physical characteristics of acupuncture points, such as sites of palpable indentation or tenderness, decreased electrical resistance, increased free nerve endings, motor points, or neurovascular bundles. A Western perspective of acupuncture points is that most sites correspond to underlying nerves that produce specific local, autonomic, and central neurophysiologic effects.[19] Acupuncture has many reported effects via neurophysiologic, humoral, and bioelectric mechanisms. Needle insertion into the skin produces local tissue effects and afferent sensory stimulation of central neural pathways.

The most commonly reported mechanisms of action for acupuncture-induced analgesia include stimulation of endogenous opioids and peripheral electrical stimulation of large sensory afferent nerves that modulate nociceptive input in the dorsal horn of the spinal cord (i.e. gate control theory of pain) via release of neurotransmitters and neuromodulators.[18,25] However, there is no consistent relationship between the level of analgesia and plasma or cerebrospinal fluid concentrations of β-endorphins or cortisol. Neurologic connections between acupuncture points on the trunk and sympathetic pathways in the thoracolumbar spinal cord also provide possibilities of influencing internal organ function by stimulating paraspinal acupuncture points.[14] Recent neuroimaging studies using functional MRI to measure brain activity have revealed that acupuncture stimulation modulates the human central nervous system, including cerebral limbic/paralimbic and somatosensory cortex.[27]

De qi is a characteristic needling sensation as perceived by the patient and the sensation of needle grasp as perceived by the acupuncturist. During needle grasp, the acupuncturist feels pulling and increased resistance to further movement of the inserted needle, which is considered to be due to mechanical coupling between the needle and connective tissue.[6] A large number of acupuncture points have been reported to occur along intermuscular or intramuscular connective tissue planes. Evaluation of connective tissue responses to acupuncture stimulation has revealed quantitative differences between acupuncture and nonacupuncture points, which may provide a valid anatomical and physiological explanation for acupuncture meridians. Mechanical coupling between the acupuncture needle and connective tissue produces mechanical, neurologic, and chemical extracellular signaling, which may explain some of the local and remote and long-term effects of acupuncture.[7] This may provide one explanation why inserting a needle anywhere in the body can produce measurable physiological responses.[13] Further research is needed to fully explain the physiologic effects of acupuncture.

TECHNIQUES OF STIMULATION

Numerous forms of stimulation have been applied to acupuncture points. Different pain-controlling mechanism can be evoked by changing the type or intensity of acupuncture stimulation.[19] The most common methods of acupuncture stimulation include the insertion of solid needles (i.e. dry needling), electroacupuncture, and aquapuncture. Dry needle acupuncture uses disposable, 25- to 34-gauge, filiform, solid needles of varying lengths. Dry needle insertion causes immediate changes in neural or segmental interactions and local inflammatory responses.[19] Prolonged stimulation can induce humoral responses and activation of the opiate system, which creates generalized analgesia.

Electroacupuncture is the application of electrical stimulation to inserted needles, with the goal of providing more intense or focused neurologic stimulation and muscle relaxation (Figure 8.11). Electroacupuncture and dry needle acupuncture both provide cutaneous analgesia in horses, compared with controls.[18] However, electroacupuncture is more effective than needle acupuncture for activating the release of β-endorphins into the cerebrospinal fluid. Electroacupuncture produces effects according to the polarity, frequency, intensity, and duration of electrical stimulation, as well as the number and pairing of needles stimulated.[25] Low-frequency

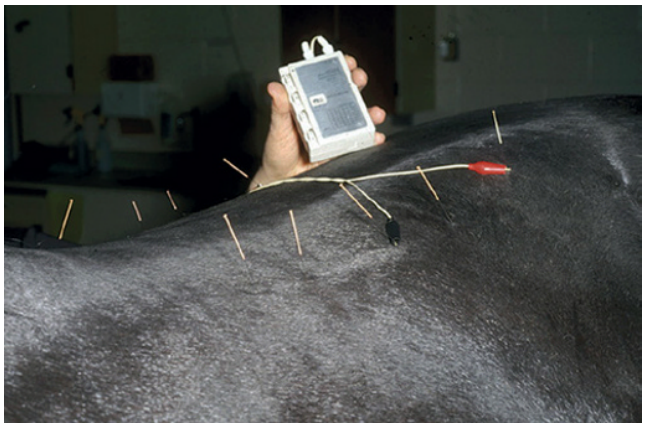

Figure 8.11. Electroacupuncture of the longissimus muscle near the thoracolumbar junction in a horse with back pain and muscle hypertonicity. *Source*: Courtesy of Dr. Gary Baxter.

VetBooks.ir

(less than 20 Hz), high-amplitude stimulation causes visible muscle contractions and produces generalized analgesia with slow, prolonged, and cumulative effects that are mediated by endorphins.[19] High-frequency (80–100 Hz), low-amplitude stimulation activates low-threshold skin and muscle receptors and produces non-opiate-derived analgesia that has a rapid onset and decline, is localized segmentally, and is not cumulative.

In a randomized control trial, four different electroacupuncture protocols were evaluated for antinociceptive effects on thermal stimulation of the pastern region.[25] Local acupuncture points and high-frequency (80–120 Hz) stimulation were more effective in blocking limb pain than the use of distant acupuncture points and low-frequency (20 Hz) stimulation.

Aquapuncture uses a 20- to 25-gauge, hypodermic needle to mechanically stimulate acupuncture points, followed by injection of various solutions in an effort to produce longer-lasting or combined pharmacological effects. Some of the more commonly injected substances include saline, vitamin B_{12}, and 2% iodine in peanut oil. Other substances include corticosteroids, Sarapin, Traumeel (a homeopathic remedy), vitamin B_1, 25% magnesium sulfate, 2% procaine, and 15% dextrose.[23] Injected volumes at each site vary from 0.5 to 5 mL (and up to 30 mL)/site, depending on the injected substance and desired response. Some practitioners believe that treatment effects last longer with injected substances, compared with dry needling. Other practitioners prefer dry needling with solid acupuncture needles due to the increased risk of breaking off hypodermic needles under the skin due to skin or fascial movement.

Additional forms of acupuncture stimulation include acupressure (i.e. digital pressure), implantation of gold beads or surgical staples for long-term stimulation, and laser stimulation, which uses low-level laser generation to stimulate superficial acupuncture points. Laser acupuncture provides the benefit of having no physical puncturing of the skin, but the initial cost of equipment is expensive. Anecdotal evidence experienced by the author suggests that low-level laser stimulation is effective for producing a temporary reduction in acute or severe back pain when affected horses do not tolerate acupuncture needle placement or forms of manual therapy. Dry needling, laser stimulation, and injection of saline into acupuncture points appear to be equally effective for treating horses with chronic back pain.[8]

GENERAL INDICATIONS FOR TREATMENT

Acupuncture case selection is often based on thorough physical examination and elimination of conditions that are judged to respond more effectively to conventional therapies.[11] Because of the lack of proven effective medical or surgical approaches for the treatment of chronic back pain in horses, acupuncture is often considered as a first treatment of choice.[11] If clinical signs of back pain persist after a few acupuncture treatments, then additional diagnostics and re-examination are indicated in an attempt to better localize and identify the source of pain and to prescribe a targeted treatment or a combination of therapies. Acupuncture is generally not sufficient by itself to manage overt lameness, unless the lameness is judged to be caused by muscle hypertonicity.[9] Acupuncture may be used in cases that have an incomplete or lack of response to traditional medical and surgical approaches or compensatory lameness associated with primary joint or limb pain.[11] The use of acupuncture or the combination of acupuncture with conventional care is believed to produce beneficial and lasting effects and provides an opportunity to expand a veterinarian's diagnostic and therapeutic armamentarium. Acupuncture combined with diagnostic joint blocks and intra-articular therapy is thought to provide a more comprehensive diagnostic and treatment approach to chronic lameness.[9,10]

Contraindications for acupuncture include acute injuries, fractures, severe cardiac disease, extremely nervous or exhausted patients, acute infections, and neoplasia. Patients with organic disease or overt musculoskeletal pathology need a complete diagnostic workup and consideration of appropriate Western treatments with documented efficacy and safety for the condition of interest.

LAMENESS

Acupuncture is reportedly useful for treating myofascial pain, osteoarthritis, stifle or hock pain, tendinitis, laminitis, and navicular disease, but there is a lack of controlled studies to validate efficacy.[21] Most evidence is in the form of clinical experience, case reports, and case series.[17] Numerous equine acupuncture case series on lameness are reported in the Chinese literature; however, poor scientific quality and lack of controls make the evidence difficult to interpret.[22] A review of several case series on nonspecific shoulder lameness, fetlock injuries, and laminitis report overall success rates ranging from 87% to 94% after 1–5 treatments, applied every 1–4 weeks.[22] However, the lack of details about case selection, diagnostic findings, objective outcome parameters, and nonuniform point selection and type of stimulation reduces the strength of the studies. A large number of horses across several disciplines were used to investigate the reported usefulness of acupuncture in the diagnosis of stifle disease in athletic horses.[12]

Only a few randomized, controlled trials have evaluated the effectiveness of acupuncture for limb pain or lameness. Cutaneous nociceptive thresholds to mechanical and heat stimuli during control and electroacupuncture trials in 23 horses showed significant cutaneous analgesia within 5 areas of the trunk, but not in the head or limbs.[1] Electroacupuncture has demonstrated variable effectiveness for reducing pain associated with either experimentally induced or naturally occurring lameness.[20,25] In a randomized controlled trial, electroacupuncture was used to treat horses with chronic laminitis ($n = 10$) and navicular disease ($n = 10$).[20] The degree of lameness was assessed by changes in subjective lameness scores, stride lengths, and ground reaction forces. Although 7 out of 10 horses with chronic laminitis improved clinically during the trial, there were no statistically significant differences between treatment and control groups. Six out of 10 horses with navicular disease improved, but there were no significant differences between treatment and control groups. Reasons for failing to demonstrate efficacy of acupuncture treatment

VetBooks.ir

include small sample size and inappropriate point selection, frequency, or intensity of stimulation. An additional randomized, blinded study using dry needle and electroacupuncture to treat palmar heel pain reported no significant differences between treatment and control groups with regard to lameness grade or hoof compression thresholds.[15] The authors reported limitations of a small sample size and the need for MR imaging to improve diagnostics for inclusion criteria. A case series of 12 horses with chronic laminitis showed positive results to two acupuncture treatments 1 week apart, based on inertial sensor-based lameness evaluation and subjective lameness scores.[3] Another prospective, single-blinded, crossover study to evaluate the effects of acupuncture treatment on gait parameters demonstrated that objectively assessed pelvic limb parameters could detect changes in gait that might be difficult to appreciate by visual assessment.[2] Overall, treated horses moved in a more symmetrical manner, which suggested a lesser degree of discomfort.

Electroacupuncture has also been evaluated in an experimentally induced lameness model using an instrumented shoe to apply transient localized sole pressure.[24] Electroacupuncture was able to partially reduce lameness scores, compared with bupivacaine or saline controls. Inconsistent changes in stride kinematics were noted, but there was no change in overall stride lengths. In another study using instrumented shoes to induce lameness in 6 horses, there was inconsistent evidence to suggest that pain, as measured by increased heart rates, was reduced after needle puncture to induce bleeding (hemoacupuncture) around the coronary band and dry needle placement between the heel bulbs.[4] For empirical treatment of laminitis, acupuncture points around the coronary band (*Ting* points) reportedly reduce local pain, and proximal thoracic limb points are used to address the sustained laminitic posture and subsequent muscle hypertonicity and pain associated with chronic laminitis (Figure 8.12).

CHRONIC BACK PAIN

The majority of the equine acupuncture literature addressing musculoskeletal issues is focused on treatment of chronic back pain (Figure 8.13). In one review of acupuncture treatment for back pain, 11 different types of acupuncture stimulation have been described; however, some methods are quite unconventional and not used in Western acupuncture.[23] In acupuncture case series for treating back pain, success rates range from 66% to 100%; however, many studies have small sample sizes, and all studies lack objective outcome parameters.[22,23] In a case series of 200 horses treated with acupuncture, 73% had primary back problems or back problems combined with pelvic limb lameness.[11] Of the horses that received treatment for primary back pain, 58% (84 of 146) received acupuncture treatment alone. Another case series of 25 horses with back pain and poor performance reported that all horses returned to their previous level of competition following a combination of acupuncture treatment, changing saddle pads, and addressing poor saddle fit.[5] In a large case series (n = 350) reported over several successive studies, horses presenting with a chief compliant of poor performance, presumably due to primary back pain, were treated with different forms of acupuncture stimulation, and pain alleviation varied from 53% to 87%.[8] Out of the 350 horses, 75% were able to perform at an acceptable level after acupuncture treatment. Unfortunately, there were no control groups in these studies, so the natural course of back pain resolution or true effectiveness of acupuncture treatment could not be determined.[8]

In a randomized controlled study, both dry needle acupuncture and electroacupuncture of the trunk significantly increased cutaneous analgesia measured by thermal stimulation, compared with sham needle placement.[18] Another randomized, controlled study reported that electroacupuncture produced significant decreases in thoracolumbar pain scores after three treatments, which remained reduced 14 days after the last treatment, compared with oral phenylbutazone and control (i.e. oral

VetBooks.ir

saline) groups.[26] A third randomized, double-blind, controlled trial evaluated the effectiveness of electroacupuncture on chronic back pain using pressure algometry to assess mechanical nociceptive thresholds.[16] A series of electroacupuncture treatments over 15 days combined with rest was significantly more effective for increasing mechanical nociceptive thresholds (i.e. reducing pain) than sham electroacupuncture and rest.

ADVERSE EFFECTS

Adverse effects associated with acupuncture use in horses are largely unreported. Bleeding at the site of needle insertion is common and may actually be used as a treatment technique (i.e. hemoacupuncture) for certain conditions. In one equine study, approximately 20% of horses experience increased signs of back pain the day after saline aquapuncture treatment, which was alleviated by prescribed exercise.[8] Bent or retained needles are most commonly due to the use of excessive force to insert needles through thick skin, muscle spasms, or patient movement. Close patient monitoring is indicated, and repeat acupuncture treatment sessions may need to be revised by changing point selection or the method or intensity of stimulation. Equine acupuncture is considered a safe treatment modality for practitioners experienced in addressing pain associated with lameness or back problems.

MANUAL THERAPY TECHNIQUES

Kevin K. Haussler

INTRODUCTION

Manual therapy is the application of the hands to the body with a therapeutic intent.[11] Chiropractic, osteopathy, physical, massage, and touch therapies are all considered forms of manual therapy techniques that have been developed for treatment of musculoskeletal disorders in humans and transferred for use in horses. Each technique has unique origins and different proposed biomechanical or physiological effects; however, all forms of manual therapy are characterized by applying variable gradations of manual force and degrees of soft tissue or articular displacement. The goal of all manual therapies is to influence reparative or healing processes within the neuromusculoskeletal system.

Therapeutic effects may be generalized to the entire body by inducing relaxation or altering behavior, regional effects may include alterations in pain perception or neuromuscular control, or effects may be localized to specific tissues and cellular responses.[15] The challenge is in selecting the most appropriate and effective form of manual therapy to produce the desired physiological effect within an individual patient, such as increasing joint range of motion, reducing pain, or promoting general body relaxation. Anecdotally, all forms of manual therapy have reported levels of effectiveness in humans and horses. Unfortunately, most claims are not supported by high levels of evidence such as randomized controlled trials or systematic reviews of the literature.

THERAPEUTIC TOUCH

The physical act of touching someone can induce physiologic responses and is often considered therapeutic.[5] In horses, touch therapies have been primarily developed and promoted by Linda Tellington-Jones in a collection of techniques named the Tellington Touch Equine Awareness Method (TTEAM) or Tellington TTouch.[25] Anecdotally, therapeutic touch is thought to improve behavior, performance, and well-being of horses and enhance the relationship between horse and rider, but no controlled studies support these claims. Similar touch therapy techniques have been used in foals at birth to assess the effects of touch or imprint training on behavioral reactions during selected handling procedures.[23] Conditioned foals are reported to be significantly less resistant to touching the front and hind limbs and picking up the hind feet at 3 months of age. More controlled studies are needed to determine the effectiveness of touch theories in managing behavioral or musculoskeletal issues in horses.

MASSAGE THERAPY

Massage therapy is the manipulation of the skin and underlying soft tissues either manually (e.g. by rubbing, kneading, or tapping) or with an instrument or machine (e.g. mechanical vibration). Massage techniques include many named methods such as Swedish massage, sports massage, trigger point therapy, cross-fiber friction massage, lymphatic drainage, and acupressure. Clinically, massage and soft tissue mobilization are thought to increase blood flow, promote relaxation, relax muscles, increase tissue extensibility, reduce pain, and speed return to normal function.[2] In horses, massage therapy has been shown to be effective at reducing stress-related behavior and pain thresholds within the thoracolumbar spine.[16,24] A noncontrolled, clinical trial using 8 horses measured increased stride lengths at the walk and trot compared pre- and postmassage, but changes were not significant due to a small sample size.[28] More high-quality, scientific evidence is needed to support the use of massage therapy in horses.[20]

PASSIVE STRETCHING EXERCISES

Passive stretching consists of applying forces to a limb or body segment to lengthen muscles or connective tissues beyond their normal resting lengths, with the intent of increasing joint range of motion and flexibility (Figure 8.14).[1] The amplitude of motion and length of time that an individual stretch is held is gradually increased over time, according to patient tolerance and ability. Stretching exercises are thought to increase joint range of motion, enhance flexibility, improve coordination and motor control, increase blood flow to muscles, and help to prevent injuries. In horses, passive stretching

Figure 8.14. Passive thoracic limb protraction stretch. The thoracic limb is fully extended and held at the end range of motion to promote elongation of soft tissues and increase joint range of motion.

VetBooks.ir

of the limbs and axial skeleton have anecdotal effects of increasing stride length and joint range of motion and improving overall comfort.[7] In a noncontrolled study, passive thoracic limb stretching lowered wither height due to possible relaxation of the fibromuscular thoracic girdle.[8] However, a randomized controlled trial in riding school horses evaluating the effect of two different 8-week passive stretching programs reported no significant changes in stride length at the trot but did measure decreased joint range of motion within the shoulder, stifle, and hock articulations, instead of the expected increased joint range of motion.[21] The authors concluded that daily stretching may be too intensive in normal horses and may actually cause negative biomechanical effects.

MOBILIZATION

Mobilization is manually induced movement of articulations or soft tissues for therapeutic purposes. Soft tissue mobilization focuses on restoring movement to the skin, connective tissue, ligaments, tendons, and muscles with the goal of modulating pain, reducing inflammation, improving tissue repair, increasing extensibility, and improving function.[2] Joint mobilization is characterized as nonimpulsive, repetitive joint movements induced within the passive range of joint motion with the goals of restoring normal and symmetric joint range of motion, stretching connective tissues, and restoring normal joint end feel.[22] Manipulation is a manual procedure that involves a directed impulse that moves a joint or vertebral segment beyond its physiological range of motion, but does not exceed the anatomical limit of the articulation. Therefore, the primary biomechanical difference between joint mobilization and manipulation is the presence of a high-speed thrust or impulse. Spinal manipulation involves the application of controlled impulses to articular structures within the axial skeleton with the intent of reducing pain and muscle hypertonicity and increasing joint range of motion (Figure 8.15).

Manual techniques used by physical therapists consist primarily of soft tissue and joint mobilization to assess the quality and quantity of joint range of motion and as a primary means of treating musculoskeletal disorders. Subjective assessment of the ease of joint motion, joint stability, and joint end feel provide insights into the biomechanical and neurologic features of an articulation. Few formal studies support the use of limb or spinal mobilization techniques in horses.[14] Most mobilization studies in horses involve a period of induced joint immobilization by a fixture or cast followed by allowing the horse to spontaneously weight bear and ambulate on the affected limb, without evaluation of specific soft tissue or joint mobilization techniques.[10]

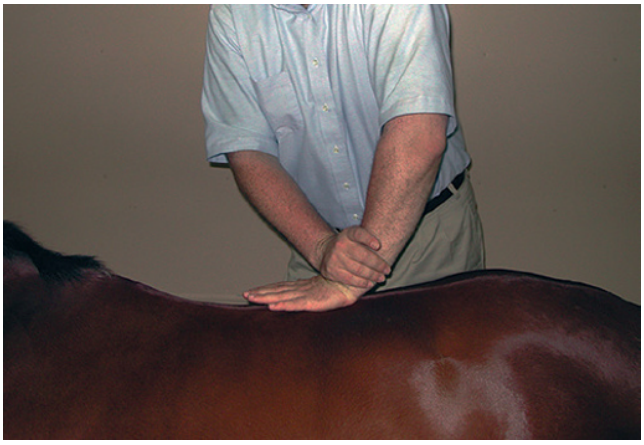

Figure 8.15. Thoracolumbar spinal extension mobilization. A gentle rhythmic force is applied over the dorsal spinous processes of the thoracolumbar junction in an effort to assess regional spinal flexibility and local pain or muscle hypertonicity.

JOINT MOBILIZATION AND MANIPULATION

The chiropractic and osteopathic professions have many overlapping philosophies, techniques, and potential mechanisms of action related to joint mobilization and manipulation. Manual osteopathic techniques use a combination of mobilization and manipulation methods to address impaired or altered function of the musculoskeletal system (i.e. somatic dysfunction).[3] From an osteopathic perspective, somatic dysfunction relates to impaired or altered function of skeletal, articular, myofascial, and related vascular, lymphatic, and neural elements.[17,19] Human osteopathic techniques also include highly controversial methods associated with mobilizing cranial bones and abdominal viscera, which have questionable application to horses.[26] Equine osteopathic evaluation and treatment procedures have been described in textbooks and case reports, but no formal hypothesis-driven research exists.[18,26] A case series of 51 horses with chronic lameness or gait abnormalities that were poorly localized were treated with osteopathic techniques under sedation and had reported positive results in the majority of case from 6 to 12 months after treatment.[4].

Chiropractic treatment is characterized primarily as the application of high-velocity, low-amplitude (HVLA) thrusts to induce therapeutic effects within articular structures, muscle function, and neurological reflexes. From a chiropractic perspective, the basic elements of joint or spinal dysfunction include altered articular neurophysiology, biochemical alterations, pathological changes within the joint capsule, and articular degeneration. Recent equine chiropractic research has focused on assessing the clinical effects of spinal manipulation on pain relief, improving flexibility, reducing muscle hypertonicity, and restoring spinal motion symmetry. Obvious criticism has been directed at the physical ability to even induce movement in the horse's back. Pilot work has demonstrated that manually applied forces associated with chiropractic techniques are able to produce substantial segmental spinal motion within the thoracolumbar region of horses.[13]

Two randomized controlled clinical trials using pressure algometry to assess mechanical nociceptive thresholds (MNTs) in the thoracolumbar region of horses have demonstrated that both manual and instrument-assisted spinal manipulation can reduce spinal nociception (or increase MNT values).[12,24] Additional studies have assessed the effects of equine chiropractic techniques on increasing passive spinal mobility (i.e. flexibility) and

Manipulation	Mechanical: articular and soft tissues Neurophysiological: Pain Mechanoreceptive stimulation	Restricted joint motion Joint motion asymmetry Muscle hypertonicity Pain

reducing longissimus muscle tone.[14,27] The effect of manipulation on asymmetrical spinal movement patterns in horses with documented back pain suggest that chiropractic treatment elicits minor but significant changes in thoracolumbar and pelvic kinematics and that some of these changes are likely to be beneficial.[6,9]

Manual therapy is believed to produce physiological effects within local tissues, on sensory and motor components of the nervous system, and at a psychological or behavioral level.[15] It is likely that specific manual therapy techniques are inherently more effective than others in addressing each of these local, regional, or systemic components (Table 8.5). The question is choosing the most appropriate form of manual therapy or combination of techniques that will be efficacious for an individual patient with specific musculoskeletal disabilities.

CONTRAINDICATIONS

Contraindications for mobilization and manipulation are often based on clinical judgment and are related to the technique applied and skill or experience of the practitioner.[22] Few absolute contraindications exist for touch therapies, massage, and joint mobilization, if the techniques are applied appropriately. Manual therapy is generally contraindicated in the presence of fractures, acute inflammatory or infectious joint disease, osteomyelitis, joint ankylosis, bleeding disorders, progressive neurological signs, and primary or metastatic tumors.[22] Acute episodes of osteoarthritis, impinged dorsal spinous processes, and severe articular instability, such as joint subluxation or luxation, are also often contraindications for manipulation. All horses with neurologic diseases should be evaluated fully to assess the potential risks or benefits of joint mobilization or manipulation. Serious diseases requiring immediate medical or surgical care must be ruled out and treated by conventional veterinary medicine before any routine manual therapy is initiated.

REHABILITATION/PHYSICAL THERAPY

Melissa King, Katherine Ellis, and Narelle C. Stubbs

VetBooks.ir

INTRODUCTION

Rehabilitation and physical therapy (PT) play an important role in performance enhancement, injury prevention, and restoration of full function during recovery from injury. The principles of rehabilitation and PT are based on a combination of evidence-based medicine, clinical reports, and comparative human sports sciences. Veterinary medicine continues to follow the principles of human sports medicine and rehabilitation to encompass many professional fields, including PT. Rehabilitation encompasses broad-based concepts with a focus on tissue healing, biomechanics, and neuromotor control. These concepts relate to morphology, conformation, training, environmental conditions, type of competition, age, performance limitations, exercise effects on the neuromuscular and skeletal systems, and interaction between horse and rider. The sciences underlying rehabilitation/PT include biomechanics, motor control, and exercise physiology.[11,28,76,127]

The word rehabilitation comes from the Latin "rehabilitare," meaning to make fit again. Rehabilitation/PT techniques are individually tailored to each patient rather than prescriptive for a given lesion or pathoanatomical diagnosis and consider the whole horse, short- and long-term goals, discipline, and overall prognoses. Each individual patient protocol is designed to complement medical management and facilitate the process of recovery by promoting tissue healing, assisting the normal physiological processes, and restoring the patient to its former capacity following an illness or injury. This includes manual therapies, electrotherapy, functional retraining, proprioceptive exercises, application of various modalities, and therapeutic exercise-based treatments, along with education and ongoing owner-managed procedures. These are the founding principles of the physiotherapy or PT profession as described by the World Confederation for Physical Therapy (WCPT).[196] PT in all species is concerned with identifying and maximizing quality of movement potential within the spheres of promotion, prevention, treatment/intervention, rehabilitation, and more recently sports medicine and performance enhancement.

Rehabilitation in veterinary medicine involves the veterinarian as the primary pathoanatomical diagnostician, a thorough objective functional assessment of the patient, and consultation with other health professionals.[127] Using knowledge and skills unique to these professions, the movement potential of the patient is assessed, with all information and confounding factors incorporated to establish an accurate functional diagnosis, problem list, management plan, and goals. Clinically, it is imperative that during the rehabilitation process, valid and reliable objective measures are taken to determine accurate outcome measures. It is the author's opinion and one that is advocated in all modern sports medicine literature that rehabilitation should begin as soon as possible after the injury occurs, alongside therapeutic pharmacological measures such as anti-inflammatory and other pain-modulating agents.[55] This might also begin before or immediately after surgery; therefore, the rehabilitative process is managed by a multidisciplinary team.

There is still a great need for further research on the effects of PT in horses to complement the considerable research in pathology and the high prevalence of injuries in athletic horses.[50,179,206] Although peer-reviewed research is limited in equine rehabilitation,[29,31,72,106,107,161,193,204,211] many animal models have been used for human rehabilitation research, with many findings able to be related to current concepts in equine rehabilitation. The *Animal Physiotherapy: Assessment,* Treatment *and Rehabilitation of Animals* textbook laid the foundations of animal physiotherapy; it is a good reference with respect to evidence-based rehabilitation.[128] The profile of rehabilitation and performance enhancement has been heightened by the official use of PT and other allied health professionals during international level equestrian competitions, highlighting how equestrian sports are rapidly catching up to other international competitive sports.

Readers are directed toward the many evidence-based human therapeutic texts to extend the scope of evidence-based techniques that may be enlisted to rehabilitate joint and soft tissue disorders and lesions. These include manual therapies, soft tissue mobilization/massage,[18] myofascial pain and dysfunction,[179] electrotherapy and physical agents,[131,209] and integrative therapeutic approaches relating to mechanical passive constraints of locomotion and neuromotor control, including facilitation and strengthening techniques.[116,126,135]

It is beyond the scope of this section to cover all aspects of equine rehabilitation. The aim is to present some fundamental evidence-based concepts of PT/rehabilitation focusing on manual therapies, electrotherapy, therapeutic and proprioceptive exercise-based treatments, and commonly applied modalities.

CLINICAL AND CLIENT DEMAND FOR REHABILITATION/PT

The clinical need for rehabilitation interventions is verified by the amount of waste and loss of performance in equine sports due to musculoskeletal injuries.[14,50,146,200] Statistics indicate that diseases of the musculoskeletal system are the predominant cause of loss of use and death in sport horses.[26,45,74,147,206] For example, it is well established that flexor tendon and suspensory ligament injuries are the most frequently reported soft tissue injuries in sport horses, resulting from chronic repetitive overuse injuries.[32,92,125,133,162,165,167] Similarly, in a population of western performance horses, soft tissue injuries of the forelimbs (deep digital flexor tendinopathy within

VetBooks.ir

the foot) and hind limb proximal metatarsal desmopathy were most notably the highest identified sources of lameness.[96] Furthermore, conservative management of hind limb suspensory desmopathy carries a poor prognosis with only 14% of horses returning to work for at least 1 year.[44] However, recent retrospective studies are demonstrating that professional rehabilitation alongside other employed therapeutics improved results, with 56% of horses suffering from hind limb proximal suspensory disease returning to their previous level of work.[97]

Back pain is considered one of the most common and least understood clinical problems in horses. It is a common cause of decreased performance, behavioral issues, and loss of work in equine athletes. Equine back pain can be of primary origin or can be secondary to referred pain from the appendicular skeleton.[77] The prevalence of back problems has been reported in 27%–100% of the ridden horse population.[118] It has been reported that 32% of horses with lameness also have concurrent back pain.[112] Biomechanical studies demonstrating three-dimensional motion of the thoracolumbar and pelvic regions have provided valuable information into the adaptive and maladaptive compensatory movement patterns associated with fore and hind limb lameness and back pain.[8] With our increased understanding of the underlying mechanisms causing various types of back pain comes a dire need to develop multimodal therapeutic and rehabilitative protocols.

Common treatments of back pain in horses include local injection with corticosteroids, systemic anti-inflammatories, extracorporeal shockwave therapy, and acupuncture.[164] Unfortunately, these traditional therapeutic pursuits often result in recurrent pain, associations with concurrent lameness and behavioral issues.[21,37] In people with low back pain, the early institution of therapeutic modalities targeting pain, muscle spasms, and restricted range of motion leads to significant improvements in function and substantial reductions in pain.[25,103,203] In addition, institution of core stability exercises results in reduced back pain and longer remission of low back pain.[2,102,218] In horses, improving core fitness results in improved lameness.[164] However, before a core fitness program can be instituted effectively, a reduction in the horse's pain must occur. Whether human or equine, the specific rehabilitation goals to augment spinal and pelvic dysfunction include decreasing pain, improving flexibility, and restoring neuromotor control and function. Treatment of back pain can be extremely challenging and often requires a multimodal approach including targeted rehabilitation protocols designed to maximize back pain treatment efficacy.

MANUAL THERAPY

Manual therapy techniques are suitable for many conditions following a veterinary pathoanatomical diagnosis, when possible. These techniques encompass the application of very specific passive and/or active assisted movements by the therapist to the horse to manage and/or alter pain and dysfunction of the articular, neural, and muscle systems. Manual therapy techniques are based on a wide range of methods and theories related to the intervertebral and peripheral joint complexes, myofascial, and the neuromuscular system.

Passive accessory and physiological joint mobilization techniques are specific to PT and osteopathy and have been clinically reported to be successfully adapted to treat the horse. Some technique examples used in human manual therapy include Maitland, Mulligan, Kaltenborn, McKenzie, and muscle energy techniques. Numerous myofascial and neuromuscular mobilization techniques also can be used, some of which include massage (friction, effleurage, petrissage, tapôtement, vibrations, and shaking), trigger point therapy, direct and indirect myofascial release, positional release, reflex inhibition techniques, craniosacral therapy, adverse neural tension techniques, and stretching.

To effectively establish a treatment protocol and apply these techniques, an accurate functional assessment of the musculoskeletal and neuromuscular systems is vital, identifying the primary and secondary condition(s) that may be responsible for and/or attributed to pain and loss of function. The assessment procedure, where applicable, includes a full static and dynamic examination, followed by palpatory evaluation including specific manual testing and provocation tests. Examination procedures determine the regions of altered range of motion, quality of movement, muscle function, and tissue irritability that may be related to pain, pathology, altered motor control, and/or dysfunction.[61,62,151]

Joint Mobilization

Degenerative joint disease or osteoarthritis is an example of a common dysfunction and cause of lameness and loss of performance in the horse in which manual therapy can be successfully applied, as is the case in humans. Many manual therapy techniques such as passive mobilizations can be applied to the articular system, including the vertebral column and peripheral joints, with complementary soft tissue techniques applied to the associated neuromuscular and fascial tissues in this condition. These repeated movement techniques have reported effects on the intra-articular, periarticular (joint capsule and ligament), and extra-articular structures (muscle, fascia, and neural tissue) and thus affect the passive and active constraints of the joint complex and primarily assist in pain modulation.[60,62,70,151]

There is a vast amount of scientific evidence in the human literature to support manual therapy techniques and the possible biomechanical and neurophysiological mechanisms behind the effects, with many studies using animal models.[10,90,183,184] The neurophysiological mechanisms that explain the pain-relieving effects are now supported by scientific evidence, both in the vertebral column and in peripheral joints. Evidence has shown that manual therapy produces an initial treatment-specific hypoalgesia and sympathetic excitatory effect locally in the treatment area beyond placebo or control conditions and then a nonopioid-mediated hypoalgesia systemically.[148,183,201,202,204,213]

Human clinical studies assessing passive range of motion exercises in patients following knee arthroplasty showed a significant improvement in range of motion that was still apparent after 1 year.[170,171] The improvement in range of motion can be supported from results in the rabbit models that demonstrate as healing occurs within the joint capsule collagen fibers align randomly.

VetBooks.ir

This random, cross-linking pattern causes increased fibrosis and thickening of the capsule. Passive range of motion exercises are proposed to work at a cellular level by decreasing the random alignment of the collagen fibers through stimulation of physiologic motion enhancing parallel fiber orientation.[52] Two very effective mobilization techniques often used to restore joint motion and reduce pain in the horse are described by Goff:[60] (1) passive physiological mobilizations, whereby the forces being directed reproduce passive physiological or coupled joint motion around the 3 axes of motion of the affected joint complex, as occurs with voluntary motion, and (2) passive accessory movements, in which the motion produced is a translation that accompanies rotations, which cannot be voluntarily performed by the horse. Figure 8.16 is an example of the application of a combination of these techniques applied to the carpus.

These techniques are highly applicable in mid and end of range of motion positions (as seen in Figure 8.16), which is commonly the practice in human PT, rather than treatment taking place only in the neutral standing posture. Clinically this is particularly effective in relation to intersegmental motion in the spine. The practitioner is able to use combined mobilization with movement techniques as described below, or with an assistant to maintain the desired postures. Direct dorsoventral and lateral passive accessory glides can then be performed manually over the dorsal spinous processes, ribs, vertebral bodies (cervical spine), and transverse processes (lumbar spine), in the end-of-range functional positions.

Soft Tissue Mobilization

The aim of many manual therapy techniques directed at the myofascia, tendons, and ligaments is to normalize tissue irritability, muscle tone, extensibility, length, contractility, strength, and coordination and ultimately improve motor control. Addressing these impairments in an attempt to regain function and optimize performance is a key feature of the rehabilitation process.

Muscular dysfunctions are often seen occurring secondarily to underlying bone pathology in horses with limb and/or back pain; however, dysfunction and/or atrophy may also be due to pathology of actual muscles such as a generalized muscle disorder, or muscle damage attributed to a poorly fitting saddle.[58,69,159,199] Valentine[200] investigated the pathological findings in equine muscle (excluding polysaccharide storage myopathy) in 229 equids. Sixty-five percent (n = 129) suffered muscle lesions, (13.1%, n = 30) generalized muscle atrophy, and (6.1%, n = 14) denervation atrophy. Clinical signs of myopathies have been shown to improve with dietary management along with a regulated exercise routine as part of rehabilitation.[86]

Figure 8.16. Manual therapy mobilization technique. A combination of passive physiological and passive accessory mobilization techniques is applied to the carpus to increase the available range of motion into flexion. The carpus is flexed, the radius is stabilized, and medial (A) and lateral motions (B) are applied to the end of range via the third metacarpus.

VetBooks.ir

Following soft tissue trauma or pathology, dynamic stretching regimes can be implemented to regain and maintain full range of motion during the healing process. As a preventative measure, this also applies to any horse that is on a restricted exercise regime or confined to the stable for other reasons to help avoid the detrimental effects of immobilization.[144] Passive stretching techniques are much more difficult in the horse because the horse is never entirely passive with respect to muscle tonicity, because it is usually standing during treatment. Therefore, the stretching procedure is dynamic and never completely passive, even when stretching limbs. However, an osteopathic technique that is reported in the clinical literature suggests that a form of gentle stretching ("positional release") in the treatment of chronic myofascial restrictions can be performed under sedation or anesthesia. This technique has been reported to have some success.[157] The technique is often used after all other avenues have been exhausted due to the anesthetic risk. Therefore, tissue mobilization with movement may be a more apt title for many forms of stretching techniques in the horse. These techniques are performed rhythmically or in a sustained manner depending on the desired response and effect on the tissues. Examples of these techniques are described below in the section on mobilization with movement exercises.

If there is a primary lesion of a soft tissue structure such as muscle, ligament, or tendon, stretches or active mobilizations with movement exercises in conjunction with other therapies may be appropriate to avoid excessive scar formation and disorientation of the fiber alignment in the subacute and chronic phases of healing. With respect to rehabilitation of distal tendon and ligament lesions, it has been widely reported in the human literature that dynamic motor control-based exercises, including eccentric loading exercises, accelerate healing and tensile strength, especially in relation to Achilles tendon lesions.[108] This type of rehabilitation strategy is beginning to be more commonly implemented where appropriate in horses. In these cases, the horse undergoes "active rest" and begins a walking program along with other forms of therapy, once the lesion is determined to be stabilized. It is the author's suggestion to also include unmounted exercises to increase the dynamic core muscle strength as described below.[190] Fibrotic myopathy is an example of a chronic condition in which repeated sustained positioning of a limb may be warranted in combination with other forms of therapy. In this case, the affected limb is manually moved to the available range of motion to stress the desired soft tissue structures.

Mobilization with Movement Techniques/Exercises

Indirect mobilization with movement techniques/exercises in conjunction with direct manual therapy techniques is also very effective clinically, especially in relation to functional motor control. Altered motor control (neuromuscular function) may be a result of the underlying lesion in the spine and/or peripheral joint disease, with pain and inflammation causing reflex inhibition of motor neurons, which in turn causes weakness and atrophy of associated muscles.[219] This is widely reported in the human literature, indicating that motor control is a vital component of the management of musculoskeletal conditions, especially related to spinal disorders and dysfunction.[75,102] McGowan et al.[128] reported that there is a relationship between muscle function and pathology via ultrasonography and necropsy analysis, whereby significant atrophy of the multifidus muscles was evident at the level and side of the thoracolumbar lesion in 22 racehorses. This has been widely reported in the human literature.[75] This is also an area of veterinary medicine in which rehabilitation/PT techniques may be of great use.

Many of these mobilization techniques/exercises use neuromuscular reflexive responses along with muscular facilitation and inhibition. They use similar theoretical principles to those used in human manual therapy, including muscle energy techniques to gain motion that is limited by restrictions of neuromuscular structures, as well as restore or normalize motor control. In people, the patient is asked to contract and relax specific muscles in a given range of motion, and often resistance is applied to the body part. These techniques promote muscle relaxation by activating the Golgi tendon reflex.[38] The techniques implement the principles of reciprocal inhibition and post-isometric relaxation. Reciprocal inhibition uses the body's antagonist-inhibition reflex to induce relaxation of a muscle.

A simplified example in people: If there is a loss of elbow flexion range of motion due to tricep muscle hypertonicity, the elbow is placed into end range of flexion, and biceps (agonist) are then contracted, which induces the triceps (antagonist) into relaxation. The joint is then moved farther into maximal flexion, and the technique is repeated, with incremental restoration of range of motion. Conversely, other techniques use the antagonist-inhibition reflex to incrementally restore range of motion, whereby a muscle is stretched immediately following its isometric contraction due to the neuromuscular apparatus becoming briefly refractory, or its inability to respond to further excitation.

It is the author's opinion that many of these applied techniques/exercises are very useful in the majority of rehabilitation cases to maintain and improve mobility, strength, and dynamic stability. This is especially true in those cases involving regions where the affected joint complexes are inaccessible due to the horse's morphology.

The horse alters its posture reflexively in response to digital pressure on various regions of the axial skeleton, both into dorsoventral flexion–extension and into coupled lateral bending/rotation and dorsoventral motion. For example, this can be seen when there is a reduction of dorsoventral motion into flexion and/or lateral bending of the cervicothoracic and thoracolumbar–lumbopelvic regions due to pain, muscle spasm, and/or joint pathology or dysfunction. The intention is not only to increase the joint mobility but also to activate and strengthen the muscles required to move the horse's body to the desired position.

A simple example of these exercises is seen in Figure 8.17, where the therapist applies a slow, constant pressure to the ventral midline and dorsal sacral region simultaneously, facilitating end of range of motion via a dorsoventral flexion response of the cervicothoracic and thoracolumbar spine and the pelvis. In this example, activation of the horse's core muscles, serratus ventralis and

VetBooks.ir

Figure 8.17. Manual therapy mobilization with movement technique. A combined rounding response into end-of-dorsoventral flexion range of motion of the thoracolumbar spine and pelvis. This is performed by manual finger pressure to the ventral midline with one hand and dorsally directly over the midline of the sacrum with the other hand. Depending on the size of the horse, this may need to be performed by two people.

hypaxial muscles (pectoral, abdominal, and iliopsoas complexes) produces the desired posture in combination with relaxation and lengthening of the opposing epaxial muscles. This posture is maintained for 3–5 seconds and repeated multiple times as reported by Stubbs and Clayton to incrementally restore range of motion and strengthen the core muscles.[190] Indirect techniques can also be used to mobilize other inaccessible regions such as the cervicothoracic junction, whereby a muscle reflex/response occurs on deep palpation (constant index and thumb pressure) of the distal third of the brachiocephalicus muscle, producing flexion in this region. The brachiocephalicus response is shown in Figure 8.18. This can also be coupled with ventral pressure to the sternum to mobilize the joint complexes into an increasing range of upper thoracic flexion.

Many combinations of mobilization, core strengthening, and stability/balancing exercises have been described in the literature.[60,144,190] These often use a food incentive or bait (such as a carrot) to encourage the horse to move into the desired posture. Baited exercises encourage the horse to move into end-of-range postures of the cervicothoracic and lumbopelvic regions, for example, into flexion with movement of the chin to chest, between carpi and fetlocks, or coupled lateral/rotation bending and flexion, with movement of the chin to girth, flank, and hock (Figure 8.19). The aim of these exercises is not only to mobilize both the axial and distal skeletons but also to facilitate core muscle activity (thoracic sling, hypaxial/epaxial, and pelvic musculature), improve neuromuscular control, and strengthen over time.[190] This is a key concept in human rehabilitation and sports medicine. Pursuant to the equine patient, several core strengthening exercises and their role in activating deep epaxial musculature to subsequently improve postural motor

Figure 8.18. Mobilization with movement technique. The brachiocephalic response results in flexion of the mid-lower cervical spine, including the cervicothoracic region. Gradual digital pressure is applied by the forefinger and thumb (pincer) to the distal third of the brachiocephalicus muscle. Pressure is maintained and gradually increased until the desired posture is attained, then held for 3–5 seconds.

The horse's functional end-of-range posture is attained by the horse's chin following the carrot toward its hock/fetlock. The position is held for 3–5 seconds to increase the activity of the core muscles of the thoracic sling, trunk, and pelvic sling, as seen in the photograph.

control and alter thoracolumbar kinematics have been investigated.[30,100] Both baited and passive exercises offer opportunities to facilitate stretching during dynamic phases and strengthening during static phases of the exercise. Institution of dynamic mobilization exercises over a 3-month time period has been shown to increase both size and symmetry of the multifidus muscle as assessed through longitudinal ultrasonographic evaluation.[191,192]

Multiple human studies have demonstrated that individuals with spinal pathology and back pain have reduced muscle CSA leading to loss of function and impairments in postural control and proprioceptive acuity. Human athletes that incorporate core, balance exercises into their rehabilitation programs are significantly less likely to suffer re-injury during a 12-month period following injury, compared with those individuals with similar injuries that did not emphasize core strength (7% re-injury rate in the balance training group versus 29% re-injury rate in the control group).[80] Strengthening and improving proprioception and balance control following injury remain a central focus of human physical therapy programs, and while standardized investigations have yet to focus on equine applications, there are several mechanisms through which neuromotor control can be recruited. Physical therapy aides such as balance pads (Figure 8.20), ground poles, tactile stimulators, and incorporation of surface changes offer clinicians passive means of engaging neuromotor control during activities of daily rehabilitation or training. Ground poles when arranged at various distances, heights, and configurations can encourage increase in lateral thoracolumbar excursion. Hill work and incorporating backing exercises into hill work can also be used to simultaneously improve muscular strength and challenge proprioceptive acuity.

PROPRIOCEPTIVE FACILITATION/NEUROMOTOR CONTROL TECHNIQUES

Recent human research has expanded our understanding of neuromuscular responses to joint pain.[194] Mechanoreceptors are characterized as sensory receptors within periarticular tissues that respond to changes in joint position and acceleration of movement, as well as playing an important role in regulating and maintaining neuromuscular control of joint stability. Pain, inflammation, and joint effusion associated with OA alter the normal sensory input from articular mechanoreceptors, which may result in decreased motor neuron excitability and reduced muscle activation.[93] A common outcome following experimentally induced knee effusion is the presence of significant quadriceps muscle inhibition.[81,82,89,143] A linear relationship exists between increased intra-articular pressure and the level of quadriceps inhibition.[81] Electromyography studies conducted on the quadriceps muscle of patients with knee osteoarthritis often indicate a decrease in muscle strength and altered muscle timing.[39] Typically there is a delay in the onset of quadriceps muscle activation, which results in the inability of the quadriceps to stabilize the joint and attenuate

VetBooks.ir

Figure 8.20. Horse standing with all four limbs on firm textured balance pads. Balance pads can be used during various stages of rehabilitation to engage the core and improve core strength and postural stability.

the loading forces properly during locomotion.[82] The increased joint instability further alters the distribution of weight-bearing forces across joint surfaces and increases the recruitment of adjacent muscles to aid in joint stability.[177] The resulting imbalances in paired agonist–antagonist muscle groups contribute to increased joint instability and altered limb biomechanics, which leads to progressive OA and chronic maladaptive compensatory mechanisms.[214]

Similar results would be expected in horses: the presence of pain may lead to loss of function, diminished neuromotor control, decreased joint range of motion, and muscle atrophy. The application of various proprioceptive techniques is frequently utilized to increase joint range of motion, reestablish appropriate neuromuscular firing patterns, and improve the strength of targeted muscles that function to move and stabilize the joints.[31] Sensory integration techniques during exercises involve stimulating the afferent proprioceptive/mechanoreceptive input that modulates and coordinates motor function. These techniques are potentially very effective due to the horse's heightened skin-mechanoreceptive system in conjunction with the underlying cutaneous trunci myofascial attachments to the skin. For example, the horse has the ability to feel the smallest tactile stimulus such as a fly and respond by altering its muscle activity (i.e. fasciculation of cutaneous trunci). Tactile stimulants (Figure 8.21) or cues can be applied to the skin over targeted regions, including the limbs or specific muscles,

Figure 8.21. Sensory integration technique. A lightweight (55-g) tactile stimulation device is placed around the coronary band of a horse and worn during exercise to increase the peak height of the swing phase of gait.

to alter mechanoreceptive/proprioception feedback and thus potentially alter motor control. The use of tactile stimulators applied around the equine hind limb pastern demonstrated a significantly higher hoof flight arc, with increased flexion of the fetlock, hock, and stifle joints.[31] The use of this proprioceptive technique supports the facilitation of enhanced afferent input to indirectly produce and modulate a targeted efferent response for the purpose of reestablishing motor control and improving joint range of motion.

A multitude of other proprioceptive techniques are utilized from resistive bands and kinesio tape, to ground

VetBooks.ir

poles and changes in ground surfaces. Resistance band training is successfully used in human physical therapy programs to improve core strength and stability.[101,122] Commonly referred to as a Theraband,[11] the two-piece equine elastic band system is thought to stimulate core abdominal muscles with the abdominal band and engage hind limb musculature with the hindquarter band. Its use in horses at a trot was recently investigated and found to reduce mediolateral and rotational movement throughout the thoracolumbar region.[152] Further studies investigating more long-term use and potential mechanistic pathways will help refine its use in the rehabilitation setting. Also pertinent to rehabilitation is the use of training lines. Pessoa training aids were demonstrated to increase both lumbosacral angles and thoracolumbar dorsoventral excursion when used in horses being lunged at a jog.[205] While further studies are needed to establish specific recommendations regarding use, initial biomechanical affects for targeted rehabilitation are encouraging.

Additional proprioceptive facilitation involves the use of elastic therapeutic tape. Elastic therapeutic tape is an adhesive product designed for use in treating sports injuries and a variety of other musculoskeletal disorders in humans. Manufacturers claim that elastic therapeutic tape supports injured muscles and joints and helps to relieve pain and edema by lifting the skin and allowing improved blood and lymph flow.[212] A review of the current human literature suggests that elastic therapeutic tape may have a small beneficial role in improving cutaneous proprioception, strength, and joint range of motion, but further studies are needed to confirm these findings.[212] Studies have shown effects on underlying muscle activity, but it is unclear whether these changes are beneficial or harmful in the management and prevention of specific human sports injuries. In the veterinary literature, Ramon et al.[201] reported that rigid mechanical athletic taping of the fetlock does not alter the kinematics of the forelimb during stance, but it does limit flexion of the fetlock during the swing phase.[183] However, there was a decrease in the peak vertical force, which may be due to an increased proprioceptive effect. The authors concluded that the reduced peak vertical forces may be helpful in preventing or reducing injury and potentially could be applied for tendinous or ligamentous rehabilitation in equine patients. These effects also may differ if using a nonmechanical but functional taping technique, as is commonly used in human athletes and has been widely researched. Theoretically, tape is stretched and placed along the length of a muscle that the practitioner wishes to facilitate. This is achieved through tension that increases the kinesthetic awareness across the fibers of the muscle where an inhibitory effect is desired. The horse can perform specific exercises with the tape attached, including individual sport-specific activities under saddle, which is an advantage with respect to alteration of neuromotor function over time. The author has successfully used taping techniques in the regions of the core dynamic stability musculature, specifically the biceps femoris and the abdominal complex (Figure 8.22). Equine taping certification courses have been initiated; however, the current level of evidence for use in treating musculoskeletal disorders is largely anecdotal, but promising results have been appreciated with preliminary investigations incorporating the use of pre- and post-application algometry pressure scores (King, unpublished data). Elastic therapeutic taping is used clinically most often to promote changes in motion and limb function.

These techniques may be combined with many forms of in-hand and ridden exercises that are widely described in the clinical literature.[60,63] The exercise protocol should be individually tailored by the therapist, with a skilled handler/trainer required to perform these exercises on a daily basis. The exercise protocol should follow the principles of conditioning,[27] with constant reassessment of the horse's motion to ensure that compensatory strategies are minimal and the desired effects evident. The program should be gradually increased with consideration given to exercise time, gaits, transitions, direction, surfaces, and gradients/slopes. The horse should be constantly monitored for excessive fatigue.

PHYSICAL MODALITIES

It is beyond the scope of this section to define and describe all forms of electromodalities and biophysical agents that alter and/or accelerate tissue healing and minimize the effects of disuse atrophy, immobilization, and denervation. The reader is advised to consult texts that are specifically aimed at evidence-based practices in the field of PT, electromodalities, and physical agents.[15,132,166,209]

Thermal Therapy

Thermal therapy consisting of cryotherapy, heat therapy, or a combination thereof (contrast therapy) remains a fundamental cornerstone of many physical therapy programs. Generally speaking, cryotherapy is indicated in acute injuries to reduce pain, swelling, and inflammation, while heat therapy is utilized in more chronic conditions to encourage soft tissue extensibility, decrease muscle spasming, and increase local blood flow.[11] Methods to apply thermal therapy have been widely developed for use in the equine distal limb, but the equine back and pelvic regions remain challenging due to limitations in anatomic depth of penetration and difficulty in secure application mechanisms.

Cryotherapy

Mechanism of Action

The therapeutic effects of cold therapy are generated through reducing tissue temperatures to 10–15 °C. (petrov03)[152] Tissue cooling produces peripheral vasoconstriction and decreased soft tissue perfusion, which can reduce edema formation and swelling at the site of tissue injury. Cold therapy also mitigates tissue metabolism and apoptosis, inhibits the effect of inflammatory mediators, and abates local enzymatic activity.[6] The application of cold also serves as a form of pain modulation by decreasing nerve conduction velocities in local sensory neurons and by activating descending inhibitory pathways.[182] Cold therapies can penetrate up to 1–4 cm in depth, which is dependent on local circulation and adipose tissue thickness.[19] Human studies have documented

VetBooks.ir

In this example of a taping technique of the abdominal complex, Kinesio Tape™ is applied to stretch from the transverse processes of the lumbar vertebrae, following the line of the transverse abdominus, internal oblique, and rectus abdominus muscles. The tape finishes on the ventral aspect of the sternum and pectoral muscle complex.

the analgesic benefits of cryotherapy with a 15–20 minute application providing pain relief for 1–2 hours.[65,172]

Evidence in Horses

Ice water immersion for 30 minutes reduced the superficial and subcutaneous tissues in the distal limb to within optimal therapeutic range compared with cold pack application.[100] Ice water immersion remains the superior form of cryotherapy for the horse; however application of a compression boot with continuous circulating coolant applied to the distal forelimb of horses for 1 hour significantly reduced the superficial digital flexor tendon (SDFT) core temperature to 10 °C.[150] Similarly, a dry sleeve perfused cuff with continuous circulating coolant that included the hoof and distal limb was as effective as ice water immersion in reducing hoof wall surface temperatures to <10 °C for over an 8-hour period.[51] In both humans and dogs, circulating cryotherapy and intermittent compression provide a significant reduction in pain, swelling, and lameness and an increase in joint range of motion after orthopedic surgery.[16,42] The recent results of tissue cooling being as effective with circulating cryotherapy units compared with ice water immersion enhances efficacy and safety in the clinical application of cryotherapy. Further *in vitro* research has demonstrated that the viability of tenocytes exposed to cold treatment (10 °C) for 1 hour did not significantly differ from those cells maintained at 37 °C.[51] Cryotherapy research in horses has focused primarily on applications within the distal limbs and on inflammatory responses associated with laminitis.[155] The exact effect of cryotherapy on various equine musculoskeletal injuries has not been fully elucidated. Additional studies are still needed to create evidence-based guidelines on the use of cryotherapy. These must address effective duration, frequency, temperature, and safety of application that will optimize outcomes after injury.

Heat Therapy

Mechanism of Action

The topical application of heat produces increases in local circulation, induces muscle relaxation (and therefore, reduction of muscle spasms and associated pain), and increases tissue extensibility.[73,132] Increased local blood flow mobilizes tissue metabolites and increases tissue oxygenation and the metabolic rate of cells and enzyme systems. In general, metabolic rate increases

VetBooks.ir

2–3 times for a tissue temperature increase of 10 °C.[161] Soft tissues may be stretched more effectively when they are warm. Heat decreases tissue viscosity and increases tissue elasticity. Low-load, prolonged stretching of tissues heated between 40 and 45 °C results in increased extensibility of tendons, joint capsules, and muscles.[73,132]

There are two forms of thermotherapy: superficial (heating tissues at a depth of 1 cm) and deep. Deep thermotherapy is the application of modalities that cause a rise in tissue temperatures beyond the level of the skin. Mechanisms to heat the deeper tissues include use of continuous wave therapeutic ultrasound and radiofrequency diathermy. Both modalities have been reported in nonequine species to therapeutically heat tissues and thus modulate pain at a depth of 3–5 cm. Methods of superficial heat application include heating blankets and packs, or other materials that can be heated in a microwave and affixed to the patient. Although clinical effectiveness for superficial heating has yet to be demonstrated, it is often recruited in both the training and rehabilitation settings prior to exercise as mounted heating lamps (solarium).

Therapeutic Ultrasound

Mechanism of Action

Therapeutic ultrasound converts mechanical energy into sound waves through the piezoelectric effect – passing an electric current through a crystal. The sonic waves produced are transmitted by propagation through molecular collision and vibration, which results in generation of heat if a continuous pulse wave is applied.[142,188] The thermal effects of therapeutic ultrasound are dependent on the amount of tissue heating that occurs. Increasing tissue temperature by 1 °C from baseline tissue temperatures will increase the regional tissue metabolic rate, a 2–4 °C rise in tissue temperature reduces pain and inflammation and increases blood flow, and a tissue elevation >3 °C is necessary to improve tissue elasticity.[36,78,114] Nonthermal effects also occur, which include induction of cavitation and acoustic microstreaming. These effects alter cell membrane structure and function, resulting in stimulation of tissue repair, fibrinolysis, collagen synthesis, tissue regeneration, and bone healing. Other nonthermal effects demonstrated *in vitro* include earlier resolution of inflammation, heightened fibroblast recruitment, accelerated angiogenesis, and increased tissue tensile strength.[24,188] Nonthermal effects occur during both application of a continuous and pulsed duty cycle application. Penetration and absorption of the ultrasound waves are dependent on the intensity applied and the frequency used. Use of 1 MHz results in absorption at a depth of 3–5 cm, while use of 3 MHz results in absorption at 1–2 cm. Low absorption of ultrasound waves occurs in tissues of high water content, such as fat, while high absorption occurs in tissues rich in protein, such as skeletal muscle.[188] Therapeutic ultrasound can also be used to delivery low molecular weight drugs transdermally, a process known as phonophoresis.[141,188]

Evidence in Humans

Therapeutic ultrasound has been shown to be effective at reducing pain (average reduction of 47%) and increasing functional scores in patients with knee osteoarthritis, when compared with placebo.[142] It has also been shown to increase the effectiveness of isokinetic exercise for functional improvement in knee osteoarthritis (range of motion, walking speed), particularly when a pulsed duty cycle was used.[84] However, therapeutic ultrasound showed no significant reduction in pain when used for conditions affecting the lower limb.[175] Thermal application of therapeutic ultrasound was shown to increase tissue temperature by 5 °C in the triceps at 3 MHz. This temperature increase, however, was short-lived, lasting 3.3 minutes.[41] Therapeutic ultrasound has been used with mixed success to stimulate bone growth and fracture healing in both animal models and human clinical trials. In humans, low-intensity pulsed therapeutic ultrasound has been approved by the FDA to treat acute and nonunion fractures. Low-intensity pulsed therapeutic ultrasound targeting fracture healing has established an optimal intensity of 30 mW/cm^2 at 1.5 MHz for 20 minutes in both human and nonhuman models. Success rates of low-intensity pulsed ultrasound for the treatment of human delayed unions and nonunions range from 67% to 90%.[94,207]

Evidence in Horses

A study performed in 2013 evaluated the ability of therapeutic ultrasound to heat the SDFT, DDFT, and epaxial musculature to therapeutic levels. The mean temperature rise was 3.5 °C in the SDFT and 2.5 °C in the DDFT after 10 minutes of application using 1.0 W/cm^2 at 3.3 MHz with a continuous wave. No significant increase in heat production occurred when the intensity was increased to 1.5 W/cm^2. Cooling of the SDFT and DDFT occurred at 2.5 and 1.5 minutes, respectively.[134] Similar results were found in a canine study, which showed that cooling of the caudal thigh muscle after therapeutic ultrasound occurred in less than 10 minutes.[120] Therefore, if stretching is to be performed following heating of the tissues, it should be performed immediately after application of therapeutic ultrasound.

A 20-minute treatment was applied to the epaxial musculature of horses using an intensity of 1.5 W/cm^2 at 3.3 MHz. Tissue temperature was measured at three different depths – significant differences in mean temperature rise were seen when comparing 1-cm versus 4-cm depths and 1-cm versus 8-cm depths. No difference was seen between 4-cm and 8-cm depths.[134] While therapeutic ultrasound was ineffective at heating the deeper epaxial muscle, the use of a frequency of 3.3 versus 1 MHz likely resulted in a lack of penetration of the ultrasound waves, as acknowledged by the authors. Therefore, further studies are needed to determine if therapeutic ultrasound can heat deeper tissues. Additionally, although a statistically significant difference was seen between 1-cm and 4-cm depths, the rise in tissue temperature at 1 cm was only 1.6°F, and therefore unlikely to be clinically significant.[134]

Radiofrequency Diathermy

Mechanism of Action

Microwave and shortwave radiofrequency radiation is used to heat tissues situated deep in the body while minimizing a rise in skin temperature. Microwave

VetBooks.ir

diathermy units operate at a frequency higher than that used for shortwave diathermy. Heating occurs by production of electromagnetic radiation that is absorbed in the tissues, creating vibrational energy that results in heat production. Tissues with high water content absorb microwaves strongly with muscle and joint effusion heated preferentially.[59] The tissue effects are determined by the degree of tissue heating that occurs, similar to that described for therapeutic ultrasound above.

Evidence in Humans

Radiofrequency diathermy has been shown to significantly improve shoulder pain, range of motion, and better performance in activities of daily living in people with frozen shoulder.[119] In addition, radiofrequency diathermy had a small but significant effect on pain and muscle performance in patients with knee osteoarthritis.[114] However, another study demonstrated no additional benefit of radiofrequency diathermy for knee osteoarthritis when isokinetic exercises were performed.[3] This modality must be used with caution, as negative effects, such as burns/scalding at the application site and teratogenic effects in pregnant animal species have been described. Radiofrequency diathermy is contraindicated in humans with metal implants (excessive heating can occur) and those with a cardiac pacemaker.[35]

Evidence in Horses

Currently, no studies are available in the horse.

Laser Therapy

Mechanism of Action

Light amplification by stimulated emission of radiation (laser) is created when energy from a power source excites a lasing medium. Energy is then released as photons. The laser medium typically creates light with one wavelength (monochromatic). Biostimulating lasers are those used in our rehabilitation patients and are categorized into classes 1–4.[79,166] Class 1 and 2 lasers have no adverse effects on eyes and skin (laser pointers, laser used for laser disc). Class 3 lasers are those used for low-level laser therapy (LLLT) that operate at a power level <500 mW and include mid-power lasers that are safe on the skin but carry a risk for eye injury (cold lasers used for therapeutic purposes).[17] Class 3 lasers are further subcategorized into Class 3a and 3b. Class 3a lasers consist of lasers from 1 to 5 mW in power and pose moderate ocular hazard. Class 3b lasers consist of lasers from 5 to 500 mW power output and pose greater ocular hazard than Class 3a.[181] Class 4 lasers are used for high-intensity laser therapy (HILT) and carry a risk to both eyes and skin (used for therapeutic purposes).[17,79] The effect that occurs in the tissue depends on the wavelength and power that is used, as well as the absorption potential of the tissue itself.[17]

Evidence in Humans and Laboratory Animals

Both LLLT and HILT have been shown to reduce musculoskeletal pain, increase range of motion, and reduce neuropathic pain.[1,48,186] Laser therapy has been shown to accelerate tissue healing by improving fibroblast function, enhancing local microcirculation and oxygen supply, aiding in the removal of waste products,[1] increasing neovascularization, and promoting angiogenesis.[33] In addition, laser therapy significantly reduces inflammation by decreasing the production of prostaglandins, TNF-alpha, IL-1beta, plasminogen activator, and cyclooxygenase.[124] Laser therapy has also been demonstrated to improve motor and sensory nerve conduction by enhancing myelin production,[123,195] as well as improving collagen fiber alignment within injured tendons.[87]

There is also evidence that laser therapy may improve muscle strength and recovery in human athletes. LLLT applied to people before an eccentric training session improved muscular strength gain and the hypertrophic muscle response.[13] LLLT performed in elderly women resulted in increased number of knee flexion–extension repetitions compared with those who received sham treatment.[197] In a study of university athletes with a variety of musculoskeletal injuries, those who received LLLT had a significantly shorter return-to-play duration than those who did not receive laser therapy.[54]

HILT may be more effective than LLLT for certain conditions. HILT is able to reach and stimulate large and/or deep structures that are difficult to reach with LLLT. In a study comparing HILT versus LLLT for patients with knee osteoarthritis, HILT was more effective than LLLT at reducing pain after 6 weeks of treatment.[104] HILT was also shown to significantly increase range of motion, decrease pain, and improve functional disability in patients with cervical and shoulder pain.[5,153] For patients with chronic low back pain, HILT combined with exercise was more effective at reducing pain and improving function than exercise and HILT alone.[4]

Evidence in Horses

Laser therapy in horses has not been as extensively researched. However, studies show that equine patient preparation is essential to having adequate laser energy penetration. Clipping and cleaning of the limb results in significantly greater energy penetration than in unclipped limbs.[43,168] In horses with unclipped hair, only white or cream-colored hair allowed laser energy to penetrate through equine skin. In horses with gray, brown, chestnut, and black hair, >99% of laser energy is blocked if unclipped. Better penetration occurs in all horses after clipping; however, energy penetration is still greatest in nonpigmented skin and is greater for medium-colored than dark-colored skin. While a longer wavelength is meant to result in greater energy penetration, skin color has been shown to have a greater effect. In horses with moderate/dark pigmented skin, laser energy penetration was greater at a wavelength of 980 nm compared with 800 nm. However, in horses with nonpigmented skin, energy penetration was greater at 800 nm than at 980 nm.[43] Therefore, adjusting laser setting based on skin pigmentation is critical if targeting deeper tissues.

One retrospective equine study is available showing the benefit of laser therapy in horses with tendinopathy/desmopathy. In a study of 150 sport horses with tendinopathy/desmopathy of the SDFT, deep digital flexor tendon (DDFT), and suspensory ligament (SL), lameness, and ultrasound scores were significantly improved

VetBooks.ir

after 2 weeks of HILT.[154] A single study of chronic back pain in horses that applied laser therapy (904 nm) over 9 acupuncture points weekly demonstrated that clinical signs of back pain were alleviated in 10 of 14 horses.[71]

In addition, laser therapy may enhance stem cell applications. In an *in vitro* study using equine mesenchymal stem cells combined with the addition of growth factors, LLLT influenced the differentiation of stem cells toward the tenogenic fate.[64] An additional *in vitro* study evaluated the safety of using HILT with stem cells. This study showed no negative effects of HILT on the stem cells *in vitro*, and stem cells showed increased expression of IL-10, which has anti-inflammatory action, and VEGF, which positively regulates angiogenesis.[145] However, caution should be taken in combining laser therapy with stem cells until *in vivo* studies have been performed.

Transcutaneous Electrical Nerve Stimulation

Mechanism of Action

Transcutaneous electrical nerve stimulation (TENS) uses electrical current applied via surface electrodes to preferentially stimulate peripheral nerves and is used primarily for pain modulation.[34,95] There are two proposed mechanisms for the antinociceptive effects of TENS:

1. Gate control theory: TENS stimulates large, myelinated A-beta fibers that are stimulated during movement. These fibers synapse within the spinal cord at the same location as small, unmyelinated C-fibers that transmit pain. Because the A-beta fibers are large and myelinated, their signal transmits faster than the signal from C-fibers, thereby blocking pain.
2. Opiate-mediated pain control: TENS stimulates release of endorphins and their precursors into the cerebrospinal fluid. Three applications of TENS have been described: (1) conventional TENS, which consists of application of high-frequency, low-intensity current; (2) acupuncture-like TENS, which consists of application of low-frequency, high-intensity current; and (3) intense TENS, which consists of application of a high-frequency, high-intensity current and is typically painful in its application.[95]

Evidence in Humans

TENS is commonly recommended for use in patients with chronic pain in addition to medication. Benefits have been reported in 60% of patients during the first few months of use. However, this effect is noted to diminish over time.[34] Conflicting results are present when evaluating the ability of TENS to diminish pain. In some studies, TENS has been shown to relieve chronic musculoskeletal pain compared with placebo. TENS has also been shown to alleviate procedural pain during dental procedures (minor tooth extractions, cavity preparations, intraoral injections) and to reduce postoperative pain, analgesic consumption, nausea/vomiting, and speed of recovery.[95] TENS was shown to be effective for reducing acute postoperative pain if electrodes were placed close to the incision and a strong, definite, subnoxious (maximal tolerable) sensation was achieved.[34] However, in a randomized study evaluating the use of TENS for chronic lower back pain, there was lack of support for its use even when patients were educated of how to correctly use the TENS unit.[56] In addition, conflicting results are present when evaluating pain modulation for rotator cuff tears, sciatica, and fibromyalgia.[34] Use of TENS is contraindicated for patients with cardiac conditions, pregnancy, and epilepsy.[34,95]

Evidence in Horses

While there is no evidence of the effectiveness of TENS use in horses, there may be some overlap in the mechanisms of action, clinical indications, and similar effects reported for electroacupuncture.[176] If used on the horse, it is recommended to clip the hair and apply a small amount of ultrasound gel to the application pads in order to maximize contact.

Neuromuscular Electrical Stimulation

Mechanism of Action

Neuromuscular electrical stimulation (NMES) uses a low-level electrical current that through stimulation of the alpha-motor neurons allows recruitment and muscle contraction after orthopedic or neurological injury. NMES therapy has been successfully used by human physiotherapists to increase muscle strength, maintain muscle mass during prolonged periods of immobilization, and control edema after injury. This therapy assists neuromuscular function by enhancing the force capacity, or the ability of the muscle to contract, as compared with a true strengthening of the muscle. It is unclear if the role of electrical stimulation in improving muscle function is actually related to increased muscle strength, improved voluntary contractions, restoring motor control, or possibly due to proprioceptive activation within injured or atrophied myofascial tissues.[140,174]

Evidence in Humans

The combination of electrical stimulation and exercise has been reported to be effective in alleviating pain and improving voluntary activation in human osteoarthritis patients, but in one study did not enhance muscle strength or functional performance. However, other studies showed significantly improved muscle strength and functional performance following NMES(langeard 17,son14,salazar18).[113,169,185] The use of NMES can also aid in the reduction of edema and swelling as the direct current drives the charged plasma protein ions within the interstitial spaces to move in the direction of the oppositely charged electrode, facilitating movement into the lymphatic channels.[20]

Evidence in Horses

The difficulty in applying this modality to the horse is the lack of standardized protocols and no validated treatment programs due to large variations in methodology that include treatment parameters, the frequency and duration of treatment, the disease stage and severity, and patient selection. One recent equine study used functional electrical stimulation in horses with induced

VetBooks.ir

injury to the recurrent laryngeal nerve and cricoarytenoid muscle. Horses that received electrical stimulation showed improved muscle strength and geometry and had an increased type I:II fiber proportion than controls.[23] NMES is typically conducted 3–5 times a week, inducing 8–15 contractions within a treatment session. The electrodes are placed in a bipolar fashion with the muscle at resting length or slightly lengthened at the time of electrode placement. The rest cycle should be 5–6 times as long as the contraction, typically in a 1:6 ratio. The hair coat may need to be clipped depending on length and should be cleaned of dirt and debris with water and coupling gel applied.

Pulsed Electromagnetic Field Therapy

Mechanism of Action

Pulsed electromagnetic field (PEMF) therapy is created when an electrical current is driven through a coiled wire that generates a magnetic field. This magnetic field creates small currents inside the tissue. PEMF utilizes a low-frequency and short-phase duration, which results in a current generated within the tissues without heat production.[83,166] PEMF is most commonly used to aide in bone healing. When bone deforms during weight-bearing, it becomes electrically polarized and generates a very low electrical current. This explains Wolff's law of functional adaptation within bone, in which this electrical signal regulates the osseous elements and maintains bone mass.[174] PEMF also generates a weak electric current in the tissue similar to those generated by bone in response to mechanical deformation, thus stimulating osteogenesis.[109,220] PEMF has also been shown to help reduce pain and inflammation, mainly through its stimulation of nitric oxide, which results in vasodilation and enhanced circulation.[180]

Evidence in Humans and Laboratory Animals

PEMF is approved by the FDA for treatment in humans with long-bone fracture nonunions and as an adjunct treatment following lumbar/cervical spine fusion surgery.[198] PEMF has been shown to accelerate fracture healing in both skeletally mature normal rats and in rats with induced osteoporosis.[9] PEMF significantly improved the success rate in people with delayed union long-bone fractures with 77.4% of the PEMF-treated fractures healing compared with 48.1% in the sham group at 4 months.[180] PEMF has shown to increase bone volume fraction, trabecular thickness, trabecular number, and suppress trabecular separation in a rat model of induced knee osteoarthritis. In this same study, PEMF was shown to promote WNT gene expression in the subchondral bone. Activation of WNT promotes osteoblast and osteocyte activity while indirectly suppressing bone resorption and osteoclast differentiation.[217] In a rat model of rotator cuff tearing and repair, PEMF improved early tendon healing and bone quality.[198] PEMF has also been shown to reduce pain in patients with low back pain;[49,187] however caution must be taken in interpreting these findings, as in some studies patients were not blinded to treatment or no control group was present.[88,173] One study showed PEMF was not effective in reducing pain, stiffness, or improving function in women with fibromyalgia.[136] However, more information on device settings for specific conditions is needed. One human study showed that a small change in the dose of PEMF energy applied had a significant effect on patient outcome.[187]

Evidence in Horses

Limited equine studies have been performed. One study from 1987 looked at the effect of PEMF for incorporation of cancellous bone grafts in ponies and found a small but statistically significant positive effect.[109] A more recent canine study showed significantly faster recovery of load bearing, significantly increased new-bone formation, and higher mechanical strength of healing in dogs treated with PEMF following mid-diaphyseal tibial osteotomy.[91] An equine study assessing tendon healing conducted in 1985 evaluated use of PEMF in surgically created defects in the SDFT. This study showed no significant differences in PEMF vs control limbs for tendon enlargement or peritendinous fibrous reaction. Interestingly, the PEMF-treated tendons showed delayed transformation of collagen from immature to mature fibers, increased vascularity, and more poorly organized and differentiated cells compared with controls. This study suggests that PEMF may actually delay tendon healing.[208] However, significantly more equine research is needed to determine the efficacy of PEMF for a variety of conditions. Given the wide variability in available device parameters,[57] specific information regarding device settings is necessary.

Underwater Treadmill

Mechanism of Action

Underwater treadmill (UWT) training has been utilized in humans and horses for rehabilitation of acute and chronic injuries.[99,106,107] Underwater treadmill training is used because of effects from multiple water characteristics, including buoyancy, hydrostatic pressure, viscosity, drag force, and temperature.[99,106] The effect of buoyancy decreases the vertical ground reaction force[137] and allows partial weight-bearing, which alleviates stress and pain on the lower extremity joints. It also allows patients to train to improve gait when they may be deficient in muscle strength, postural control, and motor coordination.[99] Hydrostatic pressure and water viscosity provide postural support to patients with impaired balance or motor control[99,178] while the drag force (resistance) of the water allows functional strength training.[130]

Underwater resistance has been shown to be 12 times greater than over ground resistance.[117] Water temperature can be utilized to provide one of two effects – warm water can help improve the level of comfort during training,[67] while use of cold water provides cryotherapy effects, including reduced pain and swelling.[105] Decreased pain has also been suggested to occur due to stimulation of sensory receptors by the water.[129]

Evidence in Humans

Underwater treadmill training has been shown to reduce body weight by 50% with the water level that is

VetBooks.ir

at the waist, 70%–75% with the water level at the chest, and 90% with the water level at the neck.[111] The effect of water depth has also been shown to affect stride length, stride cadence, and range of motion. Increased stride length and decreased stride cadence were seen with water at the level of the neck compared with water at the level of the waist and chest. An increase in ankle range of motion and a decrease in hip range of motion were seen as the water level was progressively increased.[99] Underwater treadmill training has also been shown to increase muscle strength[117,189] and improve balance.[115,189]

Evidence in Horses

Underwater treadmill training has been shown to have significant effects in horses with experimentally induced carpal osteoarthritis. In the horses undergoing UWT training compared with those walked on an overground treadmill, a significant decrease in synovial membrane inflammation was seen. In addition, the UWT group showed significant improvements in symmetric limb loading, muscle activation, and joint range of motion[107] indicating a benefit of UWT training in horses with carpal osteoarthritis. Underwater treadmill training was also shown to significantly improve postural sway characteristics compared with horses exercised on an overground treadmill with carpal osteoarthritis.[106] However, UWT training was shown to have no significant effect in adaptation of the superficial digital flexor (SDF) and gluteal muscles or muscle metabolic response compared with horses undergoing overground treadmill training.[53]

As in humans, water depth has also been shown to have a significant effect on joint range of motion as well as limb protraction/retraction. The greatest range of motion of the carpus has been shown to occur with the water at the level of the tarsus. The greatest range of motion of the tarsus occurs with the water at the level of the stifle, while the greatest range of motion of the metacarpo/tarsophalangeal joints occurs with the water at the level of the metatarsophalangeal joint and tarsus.[129] Overall forelimb range of motion has been shown to be the lowest with the water at the level of the stifle. While the greatest overall hind limb range of motion occurs at the level of the stifle. Walking in the UWT resulted in lower forelimb protraction with the water at the level of the tarsus and stifle compared with dry treadmill. Hind limb retraction was significantly greater in the UWT compared with dry treadmill, and retraction was greater with water at the tarsus and stifle compared with the fetlock in the UWT. A slower walking speed on the UWT resulted in decreased forelimb and increased hind limb protraction–retraction compared with a normal walking speed.[138] Increased overall flexion–extension of the back and lumbar flexion occurred as the water depth is increased to the level of the stifle. Horses showed increased cranial thoracic extension and increased thoracolumbar flexion in higher water depths.[139] Because of this, horses with back and sacroiliac joint pain should be monitored closely for worsening discomfort if undergoing UWT training at high water depths. In addition, UWT training should be used with caution in horses with respiratory and cardiovascular disease. The increased hydrostatic pressure has effects on lung volume, which can result in inadequate ventilation.[101] A higher water depth also results in increased VO_2, tidal volume, and heart rate.[149] Underwater treadmill training should also be avoided in horses with surgical incisions, open wounds, fever, myositis, and in animals that are fearful or panicky.[105]

Whole Body Vibration Therapy

Mechanism of Action

Whole body vibration (WBV) therapy is performed with the goal of improving muscle and core strength. In addition, vibration stimuli provide mechanical loading that is necessary to facilitate mechanotransduction in bone and thus osteogenesis. The transmission of mechanical oscillations initiates rapidly and repeating eccentric and concentric muscular action through activation of alpha-motor neurons.[12,22,163] These oscillations lead to physiological changes by stimulation of skin receptors, muscle spindle cells, and joint mechanoreceptors.[163]

Evidence in Humans and Laboratory Animals

WBV therapy has been shown to improve muscle strength,[12,47,98,156] as well as improve postural stability [40,66,160] and power.[46,98,216] WBV therapy has also been shown to improve bone strength in humans[47,66,160] and improve fracture healing in a sheep model.[121] Peripheral blood flow and tissue oxygenation in people have been shown to be positively influenced by WBV. The mechanical oscillations transferred from the vibration plate to elderly individuals have improved postural control and thus have reduced the risk of falling within the elderly population. Furthermore, there is modest evidence that supports the use of vibration therapy to reduce pain perception in osteoarthritic individuals. Lastly, there is an emerging profile for application of vibration therapy as an exercise modality for people. Vibration training for human athletes appears to have a rapid and energy sparring warm-up effect and has demonstrated increases in jump height and muscle power.[53,115,138,189] However, other studies demonstrate no change in bone density or microstructure after patients used a low-magnitude vibration plate for 6 months.[215] In addition, the timing of application of WBV therapy has been shown to be important. In one study, increased upper body power was seen 10 minutes after cessation of WBV therapy; however, decreased power was seen 1 minute after cessation of WBV therapy.[98] Therefore, exercising immediately after WBV therapy may be detrimental.

Additional detrimental effects of WBV therapy may be seen in patients with osteoarthritis. In a rat model of knee osteoarthritis, rats treated with WBV therapy showed accelerated cartilage degeneration and further functional deterioration than control.[158] Changes in machine parameters (i.e. frequency and oscillation type) have been shown to have significant effects;[7] therefore, exact parameters need to be determined for specific conditions. For example, both closed and open fracture repair models in rodents demonstrate that vertical vibration at a frequency of 45 Hz negatively impairs fracture healing, while vibration frequencies of 35 and 50 Hz enhance fracture healing. In contrast, horizontal oscillatory vibration therapy regardless of frequency demonstrates no positive or negative effects on fracture healing in rodent models.[110,210] A similar study found

VetBooks.ir

no significant difference between application of horizontal versus vertical vibration on jumping force.[12]

Evidence in Horses

A translational comparison within the human literature to the horse becomes very difficult as a number of different WBV platforms are commercially available. Anecdotally, WBV has been applied to horses with various claims of effectiveness. Acute hematologic and clinical effects of horses undergoing alternating horizontal and vertical vibration therapy have been recently described, noting no adverse effects following vibration sessions exposed to a frequency of 15–21 Hz.[22,68] Within the rehabilitative setting, there has been recent interest in the effects of prolonged vibration therapy on the cross-sectional area and symmetry of the multifidus muscle. A significant increase in multifidus muscle cross-sectional size and symmetry was found following 60 days of twice daily, 30 minute, 40 Hz vertical WBV sessions. Known for its role in spinal stabilization and postural muscle acuity, development of the multifidus muscle is thought to have potential as an osteoarthritis deterrent.[85] Only one study has been conducted in the horse evaluating the effects of vibration therapy on bone density in stalled patients. Twelve horses were confined to stalls for 60 days with half the group exercised daily on a mechanical walker, and the others underwent vertical WBV therapy at 50 Hz for 45 minutes, 5 days a week. Whole body vibration therapy in stalled horses maintained the same bone mineral content to that of horses that received daily light exercise and therefore should be considered for horses restricted to stall rest only.[85] However, to date no direct comparison studies on vibration direction, frequency, duration, or magnitude in the horse have been conducted.

CONCLUSION

Although there is currently relatively limited scientific evidence regarding rehabilitation strategies and PT in equine veterinary medicine, their use is rapidly expanding. Research and documented clinical experiences are still needed to complement the adaptation of the scientific-based principles presented in this section. Nevertheless, it is the author's opinion and clinical experience that rehabilitation/PT strategies can be successfully incorporated in conjunction with traditional veterinary medicine. A team approach with the necessary clinical reasoning skills is vital in choosing the appropriate rehabilitation strategy and PT technique and monitoring the patient's progress. Constant reassessment and, where possible, objective measures to validate the outcome of the interventions are indicated for successful treatment strategies involving PT and rehabilitative techniques.

CHAPTER

Occupational-Related Lameness Conditions

THE THOROUGHBRED RACEHORSE

Ryan Carpenter

The incidence and impact of lameness in Thoroughbred racehorses is significant. Essentially all horses participating in training and racing are vulnerable to injury associated with varying degrees of lameness. In one review, 37 of 40 juvenile horses became lame during training.[48] Failure to train due to lameness has a significantly detrimental economic impact. Monetary considerations, coupled with the recent increased public awareness focused on the welfare of horses in general, have resulted in a new era of philosophy in lameness management in the Thoroughbred racehorse. As a result, there is marked emphasis on injury prevention, early recognition of lameness, and early proactive intervention prior to the onset of serious lameness. It is important to be able to differentiate potentially life-threatening disorders from those that are transient or pose minimal threat to the horse's well-being while continuing to compete.

As with any sport, occupational-related injuries from racing and training are prevalent, and several etiologic factors have been incriminated in these types of injuries. Variables include genetics, racetrack surface, number of starts, age of the horse, preexisting pathology, conformation, and trauma. In the Thoroughbred racehorse, stress remodeling and stress fractures are the most common cause of lameness. Only occasionally, these injuries result from a single event that stresses the bone or tissue beyond its ultimate strength. More commonly these injuries are a result of repetitive overuse that results in cumulative fatigue failure of the bone or tissue. Therefore it is important to recognize when the balance may be tipped toward ultimate tissue failure. Balanced stress remodeling is critical in the longevity of the horse's athletic career. Ideally every stress-related lameness would be identified prior to tissue failure allowing an alteration in the horse's training program. Therefore, the focus of this discussion will be to identify the most common causes of lameness in the Thoroughbred racehorse, with an emphasis on how to manage each case with an appropriate plan to help minimize the number of days lost to training and to prevent the progression to a more serious injury or catastrophic failure.

RISK FACTORS FOR INJURY

Emphasis has been given to the identification of risk factors for development of musculoskeletal injury, especially those that are fatal.[11,15,38,43,44,57] As noted, the occurrence of lameness is extremely high. Fortunately, the incidence of catastrophic breakdown in racehorses is very low; approximately 1–2 catastrophic events occur per every 1,000 starts.[23] The 2016 Jockey Club reported a declining number of catastrophic events to the lowest level since 2009. The total number of catastrophic events in 2016 was 1.54 per every 1,000 starts. Dirt, synthetic, and turf surfaces accounted for 1.70, 1.14, and 1.09 catastrophic events, respectively.

Several postmortem studies have categorized injuries that result in destruction of the horse. These studies have elucidated not only training factors that appear to predispose racehorses to specific injuries but also apparent geographic differences. For example, the incidence of soft tissue injuries incurred during racing differs among various racetracks in the United States. One Australian study

of fatal injuries in Thoroughbred racehorses found that most were euthanized after a catastrophic injury to a forelimb; however, there was no statistically significant difference between forelimb affected.[6] Conversely, there was a predisposition for right forelimb injury in the United Kingdom.[44] In the United States, horses were more likely to sustain fracture of the left forelimb during racing and right forelimb during training.[29] Fractures of the proximal sesamoid bones were the most common injury in the United States, but Australian studies showed that fracture of the front or rear cannon bone was most common during racing, followed by accompanying fractures of the proximal sesamoid bones and proximal phalanx.[6,7]

Training and racing schedules have been scrutinized.[2,11–13,17–20,26] The risk of catastrophic injury and forced lay-up in fit California Thoroughbred racehorses was significantly increased following 2 months of high-speed exercise with distance accumulation.[17] Two-year-olds exceeding 0.76 furlongs/day, 3-year-olds exceeding 0.85 furlongs/day, and 4-year-olds exceeding 0.95 furlongs/day were at higher risk of sustaining injury than those working shorter distances. In another study, the racing injury rates were inversely proportional to the success of the individual trainer.[59] The incidence of tibial and pelvic stress fractures rises with increasing distances cantered during a 30-day training period but not over a 60-day period.[40,58]

Track conditions also correlate with injury.[10,46] Fracture rates in Japan increased as dirt tracks became muddier and decreased as turf surfaces became softer.[41] The differences between synthetic surfaces, dirt, and turf courses are still under investigation. One study showed a greater proportion of stress fractures detected on scintigraphic examinations from horses training on a synthetic surface (31.7%) compared with horses training on a dirt surface (23.0%) at an earlier point in time. Additionally, there were a greater proportion of pelvic and tibial stress fractures diagnosed in horses from a synthetic surface-trained group than from the dirt-trained group.[34]

Individual conformation has been recognized clinically to affect locomotion and long-term soundness.[36,37] Some traits have been shown to influence the onset of clinical abnormalities. For example, horses with offset knees have an increased incidence of stress-related disorders of the knees and an increased risk of fetlock problems.[36] Other flaws that likely predispose a horse to injury include back-in-the-knee conformation and carpal or fetlock varus deviations.

DIAGNOSIS OF LAMENESS

History and physical evaluation, economics, and personal experiences help determine the appropriate diagnostic steps for every horse. Knowledge of the exercise and racing schedule, including when fast work has taken place, intensity level of training, and past performance is important. It is also important to be aware of recent lay-up, convalescence, and previous surgery.

The physical evaluation is straightforward and basic, but it must be thorough. It is especially helpful if the veterinarian is familiar with the patient. The general health of the horse must be considered, including appetite, hair coat, general disposition, and the presence of any current medical conditions as well as treatment thereof. Recognition of previous lameness in the specific patient coupled with results from current diagnostic procedures may raise the level of suspicion for a recurrent injury.

Racetrack practitioners who are familiar with their patients have a number of advantages, including the ability to perform multiple examinations either in hand or on the racetrack in the horse's routine work environment. A disadvantage of known history is the potential for bias in diagnoses. Another disadvantage for the racetrack practitioner is obstacles in the working environment that may preclude a thorough locomotor examination. Special scheduling may be required to accomplish a complete examination. The behavior of a fit racehorse likewise limits the time allowed for the evaluation, in addition to presenting an inherent safety hazard. Many racehorses become rank and difficult to handle after only a few jogging sessions and may hide a subtle lameness due to excitement. Diagnosis of a new injury may be challenging if there are preexisting healed injuries that are not clinically active.

Lameness may be displayed in a broad spectrum of clinical signs, ranging from behavioral changes, reluctance to train, and poor performance to mild or overt gait alterations. It is common for horses to display changes in temperament, such as aggressive or passive behavior, prior to displaying actual lameness. Horses may become track sour or display changes during training such as lugging in or out or running off. Other manifestations include reduced appetite, poor hair coat, soft palate displacement, or tying up.

Lameness associated with pain is the manifestation of an avoidance response. The character of lameness is largely determined by the location or source of an injury, although it is difficult to differentiate exact foci of pain or specific disorders based on gait alone. Generalities of gait combined with the rest of the clinical picture often aid in lesion localization, but there are no absolutes based solely on gait.

Gait alterations associated with mechanical limitations may be challenging to distinguish from lameness associated with pain. An example of characteristic gait patterns is a delay in contact of the foot with the ground (drift) caused by a foot bruise or developing abscess in a front foot; a similar problem in a hindfoot produces a stringhalt appearance. Abduction of a limb prior to ground contact is often observed with a fracture of the lateral wing of the coffin bone, incomplete lateral condylar fracture, and fracture of the lateral aspect of the carpus. Changes in advancement of a limb and stride length occur with many lameness conditions and vary with location and severity. Horses with a humeral stress fracture, high suspensory desmitis, or other proximal limb injury do not advance the limb fully in the cranial phase of the stride. Tibial stress fractures often display a limited contact or support phase of the stride, which results in a jerking lift-off of the limb in addition to a limited cranial phase of the stride.

Diagnosis of lameness should be confirmed by isolating the source of lameness. Ancillary diagnostic anesthesia may be employed to localize the pain if necessary and feasible. Diagnostic nerve blocks may be difficult to perform for two reasons: the fractious behavior of some

VetBooks.ir

horses and potential regulatory hurdles if the horse is scheduled to compete. Caution is imperative in the racehorse if the possibility of anesthetizing a potential fracture exists. The results of local anesthesia are sometimes open to interpretation, due to the ineffectiveness of the block and the time frame required for anesthesia to develop.

For example, a horse with proximal suspensory desmitis will occasionally improve to diagnostic anesthesia of the middle carpal joint. Results may also be confused because excitement of the horse can obscure the lameness independent of the regional anesthesia.

Further ancillary diagnostic techniques include imaging modalities such as radiographs, ultrasound, nuclear scintigraphy, MRI, and computed tomography. It is routine for racetrack practitioners to be equipped with portable digital radiographic and ultrasonographic equipment.[5] Instant stall side diagnosis of fracture or other injury has become standard.

Nuclear scintigraphy has had a tremendous impact on understanding bone disease in the racehorse and the management of many of these conditions. Because it provides a reflection of the physiologic status of tissue, pathology may be detected and therefore addressed earlier than with plain radiography. For example, detection of stress-related bone injuries may be observed before catastrophic failure occurs.

COMMON CONDITIONS

An almost endless number of clinical problems resulting in lameness regularly confront the racetrack practitioner. Certain problems occur routinely and become standard and expected, while other conditions are uncommon and may be overlooked because of their relative infrequence. As more information is gained with advancement of studies, our knowledge base and future management of these conditions may be subject to change.

Foot

The foot of the racehorse is a common region affected by lameness. It is standard belief that the hoof of the North American Thoroughbred is inferior to that of the European Thoroughbred due to less mass. The front feet of the average racehorse undergo conformational changes as it progresses through its training and racing career. It is common to develop a long toe and an underslung heel with the axis of the foot becoming reoriented in a broken back fashion. Improper shoeing is often implicated; however, these changes are also the result of the mechanical forces on the foot associated with training. These conformational changes combined with the trauma to which the foot is subjected contribute to many lameness conditions in the foot.

The most frequent problem is bruising in the subsolar region, heels, or frog. Treatment for bruising is to rest and protect the region, remove the offending load responsible for the bruising, and prevent abscessation. Generally little training is missed as a result of a foot bruise because most are self-limiting problems; however, abscessation may occur if sepsis occurs. Abscessation is treated with plain hot water soaks and a softening hoof pack (Animalintex) until the horn is pliant enough to allow eruption of the abscess. Most resolve uneventfully and carry a good prognosis if managed with proper hygiene and rest.

Quarter cracks occur less commonly but often enough to be a particular nuisance. They almost always occur in horses that have shearing of the heels, thin walls, an unbalanced foot, and often underslung heels, and males seem to be more affected than females. The side with the crack is usually taller than the unaffected side. An integral component of management involves balancing the foot in addition to stabilizing the wall. Without balancing the foot, repair of the crack is futile and it will recur. A support shoe such as a Z-bar shoe or a three-quarter shoe with a Z bar is helpful at lessening the shearing forces of the involved wall while healing occurs. Direct repair of the crack by lacing and/or patching is often necessary to stabilize the hoof wall. The crack must be dry and free of sepsis, and if there is sensitive tissue involved, a drain must be placed beneath the crack. Many horses are able to continue training while undergoing treatment for quarter cracks, while others must be convalesced to allow hoof regrowth and conditioning. The farther palmar the crack is located on the foot, the more difficult it is to manage.

Six types of coffin bone fractures are described in the literature and occur in racehorses, but the most common are fractures of the lateral wing of the left forelimb and medial wing of the right forelimb (Figure 9.1).[27,49] These fractures may be recognized with nuclear scintigraphy prior to the appearance of radiographic changes, suggesting a stress-related bone injury as the underlying

Figure 9.1. Forty-five-degree dorsoproximal palmarodistal radiograph illustrating a wing fracture of the third phalanx.

VetBooks.ir

cause.[49] Fractures may not be apparent on radiographs until 7–10 days after they occur. Conventional management includes rest with a bar shoe with or without clips for 8–12 weeks. If lameness is still evident it is common to perform a palmar digital neurectomy; however, some racing jurisdictions do not allow the horse to race following this procedure. There is usually a good prognosis for return to racing, even though there is commonly evidence of osteoarthritis (OA) or a step defect once healing is complete. Unfortunately, horses with type III coffin bone fractures with significant displacement or fractures of the navicular bone have a poor prognosis to return to racing.

Pastern

Lameness associated with the pastern region is relatively uncommon, but fractures of the proximal phalanx (P1) occur frequently. The most commonly reported fracture configuration is parasagittal, extending distally from the sagittal groove of the proximal articular surface of the bone. As the fracture courses distally, it most commonly diverges laterally before either exiting the lateral cortex of the bone or spiraling into an oblique (dorsolateral/palmar/plantaromedial) plane approaching the distal epiphysis and proximal interphalangeal joint. Long (>30 mm) incomplete parasagittal fractures are the most frequent fracture configuration and commonly affect the forelimbs more than the hindlimbs.[53] Typically lameness is very apparent; however, soft tissue swelling is often minimal, and varying degrees of fetlock joint effusion may be present. Therefore, if a pastern fracture is suspected, radiographic evaluation is recommended prior to diagnostic anesthesia as it is possible to block a pastern fracture with palmar digital anesthesia. The fracture often extends more distally in the weeks' post-injury suggesting that these fractures are more extensive than initially appreciated at the time of injury.[53] Incomplete parasagittal fractures heal very well with internal fixation and have an excellent prognosis for return to athletic use. However, complete biarticular parasagittal fractures typically have a much lower prognosis. Although the parasagittal configuration is by far the most common fracture configuration seen, almost any fracture configuration can occasionally be seen.

Fetlock

The fetlock is the single most common region affected by lameness in the TB racehorse. The fetlock joints of both the forelimbs and hindlimbs are plagued with multiple problems that contribute to lameness, and they are the most commonly affected articular structure in the racehorse. One report indicates that up to 56% of the total days lost in training as 2-year-olds are attributed to fetlock pathology.[4] Most are associated with some form of cumulative stress-related disease, which may involve the bone, cartilage, or soft tissue.

Synovitis and capsulitis of 2-year-old training horses are common and often self-limiting, as long as training is reduced and the tissue is permitted to heal.[35] The predominant clinical sign is joint effusion with or without heat. Lameness is mild if present, but there is usually resentment to flexion of the joint. Radiographs are unremarkable, whereas ultrasonography confirms increased joint fluid and mild thickening or proliferation of the synovium. Treatment includes local therapy with ice, hydrotherapy, poultice, and bandaging. Joint injection with chondroprotective agents and corticosteroids or IRAP is common. Systemic nonsteroidal anti-inflammatory drugs (NSAIDs) are also frequently administered.

Common areas of cartilage and osteochondral trauma involve the dorsal rim of P1, usually medially or less commonly medially and laterally. This is believed to occur from the repetitive trauma and wear of the rim against the distal metacarpus and is the most common area for development of chip fractures in the fetlock.[54] Usually there are joint effusion, warmth, and varying degrees of pain on flexion, along with focally sensitive palpation on the area of the rim that is involved. Lameness is usually only transient if present at all, unless advanced changes have occurred in the joint. Often there is a reduction in performance rather than an overt lameness. The prognosis is good with arthroscopic removal of dorsal P1 chip fractures in racehorses as long as appropriate convalescence is allowed.[14] Recuperation time averages 2 months or longer. Reports indicate that there is no difference in prognosis with different sizes of fragments, but larger fragments usually induce more cartilage damage and wear on the distal metacarpus, especially if they are longstanding.

Dorsal frontal fractures of P1 occur relatively frequently. These fractures commonly affect the hindlimbs although these can occur in forelimbs. There is no specific gait characteristic associated with this injury, but affected horses are often described as having a proximal limb lameness. Frequently this injury is confused with tibial stress fractures. Diagnosis is often made with nuclear scintigraphy and confirmed by radiographs. Unless extreme displacement occurs, which is infrequent, the treatment is rest for 60–90 days. Extracorporeal shockwave therapy (ESWT) can help promote healing, although these fractures heal consistently without treatment. There is a good prognosis for return to racing.
